Abstract
At the SPring-8 storage ring, we have recently developed two X-ray instruments for emittance diagnostics. The one for a bending magnet source is the X-ray pinhole camera which directly images the beam profile. A pinhole in the atmosphere is composed of combined narrow X-Y slits made of tungsten. A scintillator crystal is used to convert the X-ray beam image to a visible image. The spatial resolution is about 7 μm. It is operated for continuous emittance diagnostics and coupling correction of user operation of SPring-8. The other for an undulator source is the X-ray Fresnel diffractometry monitor. Monochromatic X-rays are cut out by a single slit, and the vertical beam size is deduced from the depth of the central dip in a double-lobed diffraction pattern. Resolving beam size less than 5 μm is feasible.

INTRODUCTION
Light source rings are competing to achieve lower emittance and emittance coupling ratio for higher brilliance. Serious and elaborate efforts are being paid for upgrade plans of existing synchrotron radiation (SR) rings or new plans of low emittance rings.
X-ray SR is the key diagnostics probe for non-destructive beam emittance [1]. Both direct imaging and interferometric techniques can resolve the micrometer-order transverse beam size. The beam emittance is obtained from the measured beam size with the knowledge of the betatron and dispersion functions and the beam energy spread.

At the SPring-8 storage ring, we have recently developed two X-ray instruments for emittance diagnostics. The one for a bending magnet source is the X-ray pinhole camera which directly images the beam profile. The spatial resolution is about 7 μm. It is operated for continuous emittance diagnostics and coupling correction of user operation of SPring-8. The other for an undulator source is the X-ray Fresnel diffractometry (XFD) monitor [2,3]. Monochromatic X-rays are cut out by a single slit, and the vertical beam size is deduced from the depth of the central dip in a double-lobed diffraction pattern. Resolving beam size less than 5 μm is feasible.

X-RAY PINHOLE CAMERA
The layout of the SPring-8 X-ray pinhole camera is shown in Fig. 1 and the specifications are summarized in Table 1.
The source point is in a dipole magnet (29B2), 1.0 mrad inside from the edge. The magnetic field and the critical photon energy of emitted X-rays is 0.5 T and 21.1 keV, respectively. The X-ray window is located at a distance of 6.2 m from the source point. The window material is aluminium alloy of 3 mm thickness. The window separates the ultra-high vacuum and the atmosphere, and the X-rays emitted in the source dipole magnet go out to the atmosphere.
The pinhole assembly in the atmosphere is located at a distance of 11.4 m from the source. It is composed of

Figure 2: Pinhole assembly.

Combined narrow X-Y slits made of tungsten (Fig. 2). The thickness of each slit is 3mm, and the aperture size of the pinhole is 20 μm x 20μm. The pinhole assembly is equipped with remote controllable gonio and rotary stages for adjustments of pitch and yaw of the pinhole. It is mounted on a manual XZ stage for alignment.

The X-ray image of the electron beam formed by the pinhole is converted to a visible image by a scintillator located at a distance 34.3 m from the source. The magnification factor of the pinhole is accordingly two. The visible image is measured by a CCD camera through a lens. The details of the scintillator and camera assembly are shown in Fig. 3. The scintillator is made of CdW₄O₄ with a thickness of 0.5mm. The lens is object-space telecentric with a magnification factor of two. The CCD camera (Basler AG, piA2400-17gm) has 2448 x 2050 square pixels of 3.45 μm size. It is connected to a remote computer through the Gig-E (Gigabit Ethernet) interface.

The total spatial resolution of the pinhole camera $\sigma_{XPC}$ is expressed as,

$$\sigma_{XPC} = \sqrt{\sigma_{\text{diff}}^2 + \sigma_{\text{CAM}}^2}$$

where $\sigma_{\text{diff}}$ stands for the contribution of diffraction of pinhole and $\sigma_{\text{CAM}}$ for that of the scintillator and camera assembly.

The pinhole resolution $\sigma_{\text{diff}}$ was evaluated according to numerical calculation of the point-spread function (PSF) based on wave optics by using diffraction formula. Examples of PSFs of the pinhole for monochromatic X-rays, pinhole diffraction patterns for a monochromatic point source, are shown in Figs. 4(a) and (b). The resolution $\sigma_{\text{diff}}$ was defined by width of a Gaussian curve fitted to the PSF. Fig. 5 (a) shows the monochromatic pinhole resolution as a function of the X-ray energy.

Figure 4: Examples of the point-spread functions (PSFs) of the pinhole for monochromatic X-rays (blue), and fitted Gaussian curves (red).
Spectral power absorbed by the scintillator was calculated by the calculation code SPECTRA [4], and found to peak at an X-ray energy of 42 keV as shown in Fig. 5(b). The resolution of the pinhole $\sigma_{\text{diff}}$ was evaluated to be 6.9 $\mu$m from the width of the monochromatic PSF at 42 keV.

The resolution of the scintillator and camera assembly $\sigma_{\text{CAM}}$ was calibrated by the sharpness of the observed edge of a tungsten bar placed in front of the scintillator. Fig. 6(a) shows the tungsten bar and 6(b) an observed beam image with an edge cut by the bar. The profile of the observed edge and its derivative are shown in Figs. 7(a) and (b). The resolution $\sigma_{\text{CAM}}$ of the scintillator and camera assembly was evaluated as 2.2 $\mu$m on the beam coordinate (4.4 $\mu$m on the scintillator) from the width of a Gaussian curve fitted to the derivative in Fig. 7(b).

The total spatial resolution of the pinhole camera $\sigma_{\text{XPC}}$ given by Eq. (1) is accordingly 7.2 $\mu$m.

The scale of the camera pixel to the beam coordinate was calibrated by introducing vertical bump orbits (Fig. 8). The calibrated scale is 0.848 $\mu$m/pixel, which is consistent with the designed value of 0.863 $\mu$m/pixel within the manufacturer’s specified accuracy of the lens magnification factor.

The display for the X-ray pinhole camera in the SPring-8 control room is shown in Fig. 9. Live beam image view is available with the refreshing rate of approximately 15 frames per seconds.

Parameters of the beam profile, including the horizontal and vertical beam sizes $\sigma_x$ and $\sigma_y$ and the beam tilt angle $\theta$, are obtained periodically with a cycle time of 1s by fitting a two-dimensional Gaussian profile to the beam image. They are logged to the control system database.

The SPring-8 X-ray pinhole camera was installed in March 2014. After commissioning and calibration, it has been operating as a real time emittance diagnostics since September 2014. It is an indispensable diagnostics tool for both beam tuning and user operation of SPring-8.
X-RAY FRESNEL DIFFRACTOMETRY MONITOR (XFD)

X-ray Fresnel diffractometry monitor (XFD) is a diagnostic technique for light source rings to measure vertical beam size at ID (undulator) source point [2,3]. Schematics of XFD are illustrated in Fig. 10. It employs a single slit and a monochromator and an imaging device (X-ray camera). Diffraction patterns observed on the screen of the imaging device depend on a width $A$ of the slit. By adequately tuning the slit width, a double-lobed Fresnel diffraction pattern is available. The optimum slit width for the deepest median dip is expressed as:

$$A \approx \sqrt{7L \frac{LR}{L+R}}.$$

The depth of the median dip correlates with the light source size.

The setup for the initial XFD experiment at SPring-8 is shown in Fig. 11 [2,3]. The source is a planar undulator (ID05) with 51 magnetic periods of 76 mm long. The vertical beam size at the source point of ID05 smaller than 10 $\mu$m was successfully resolved [2,3].

In order to improve the performance of the XFD, we have recently replaced an X-ray imaging device and increased the observing photon energy. The new setup for X-ray imaging is shown in Fig. 12. The screen material is YAG(Ce) of 50 $\mu$m thick. The pixel size of the camera is 16 $\mu$m x 16 $\mu$m. Minimum available exposure time of the camera is 0.2 ms five times shorter than that of the previous camera of 1 ms. The shorter exposure time reduces the influence of the vibration of the cryogenically cooled monochromator crystals. The resolution of the X-ray imaging device was calibrated by the sharpness of the observed edge of a tantalum slit installed in front of the screen. The obtained resolution as converted to the source

![Sensitivity Curve](image1.png)

![Example of observed diffraction pattern](image2.png)

Figure 14: Example of observed diffraction pattern (red) and fitted model function (blue). The deduced source vertical beam size is 6.3 $\mu$m (rms).
point coordinate is 2.2 μm, which is three times better than the previous device. The sensitivity curve, peak-to-valley-ratio of the median dip of the double-lobed diffraction pattern as a function of vertical beam size, is shown in Fig. 13. Improvement of the sensitivity for small beam size below 5 μm is evident for the increased observing energy (16 keV). An example of diffraction pattern observed with the new imaging device at the increased X-ray energy (16 keV) is shown in Fig. 14. By fitting the theoretical model function [3] to data, vertical beam size (rms) of 6.3 μm was deduced.

CONCLUSION

The SPring-8 X-ray pinhole camera was installed in March 2014. It images a dipole magnet source with a spatial resolution (rms) of 7.2 μm. It has been operating since September 2014 as a real time emittance diagnostics indispensable for both beam tuning and user operation of SPring-8.

The XFD developed at SPring-8 is a diagnostic technique for light source rings to measure vertical beam size at ID (undulator) source point, feasible to resolve beam size smaller than 5 μm (rms). It requires only slit, monochromator, and imaging device (X-ray camera), and has potential universal availability to ID beamlines of the diffraction limited storage rings (DLSRs).
