PVMANAGER: A JAVA LIBRARY FOR REAL-TIME DATA PROCESSING
G. Carcassi, K. Shroff NSLSII, Upton, NY 11973, USA

ABSTRACT
Increasingly becoming the standard connection layer in Control System Studio, pvmanager is a Java library that allows creating well behaved applications that process real-time data, such as the one coming from a control system. It takes care of the caching, queuing, rate decoupling and throttling, connection sharing, data aggregation and all the other details needed to make an application robust. Its fluent API allows to specify the detail for each pipeline declaratively in a compact way.

INTRODUCTION
A common problem encountered by client applications for control systems is the decoupling of the events from the controls network and the UI thread. The need to aggregate the events in time (for rapidly changing pv/pvs) and for groups of pvs was necessary to address various performance issues in CS-Studio and to support multi-channel applications.

The goal of pvManager is to make writing clients for real-time data more straightforward, by providing all the pieces that such a client require, such as data rate decoupling, via either queuing or caching, data aggregation/manipulation and notification dispatch on the appropriate final thread.

ARCHITECTURE
The initial intent of pvManager was just to address the recurring issues of writing a well behaved client of a soft real-time system. The aim has now grown to provide a full end-to-end framework for gathering data from different sources, both publish/subscribe and command/response, aggregating it and performing computation on background threads.

The framework now consist of multiple modules:
• type: provides the definition in terms of Java interfaces of a standardized set of data. One is not limited to the use of these types (the basic type in pvManager is Object) but standardization on them allows to unlock all the functionality already implemented
• datasources: provides support for accessing data from publish/subscribe systems
• services: provides support for accessing data from publish/subscribe systems
• formula: provides a pluggable Domain Specific Language for aggregation and computation

The core of pvManager allows combining all these elements and creating readers or writers that are thread-safe with a managed rate of notification.

CS-Studio can now leverage all these elements, but, since they are well separated, they can be tested without the UI environment (unit tests much easier to write) and can be used in other environments (such as plain Swing applications, command line, web servers, and so on).

The framework integrates the above components as well as others, such as caching, queuing, network configuration, connection sharing, data aggregation and all the other details needed to make an application robust.

PVReader<> pv = pvManager.read(expression)
.removeEventListener(new PVChangeListener<>(event)

public void pvChanged(PVReaderEvent event)

})
.notifyOn(executor)
.timeout(timeDuration)
.maxRate(timeDuration);

DATASOURCES
Datasources are the abstract definition for publish/subscribe data, which is the typical mode for real-time systems, such as EPICS. Datasources work on channel, and are able to subscribe readers or writers to each channel. Current implementations include support for simulated signals, an in memory scratch space, filesystem, Channel Access (v3) and PVAccess (v4).

The system can be easily extended with other types. All one needs to do is implement a few abstract methods, and connect the callback of the desired system to the methods that trigger processing of connection and message notifications. Datasource automatically provide support for multiplexing (multiple readers on the same channel). The rate decoupling (limit the rate from the datasource to the UI subsystem) and rate throttling (decrease the rate if the UI can’t keep up) that are needed for a well behaved client, are also automatically supported.

SERVICES
Command/response is another typical source of data. Examples of command/response include web services (REST or SOAP), CORBA services and databases. The abstraction for a service within the framework is an asynchronous call that takes a key/value map of argument, and returns a key/value map of results. This allows to generically handle very different types of data and services. The value, if possible, should map to VTypes so that one can reuse many of the functionality and clients built on top of those.

The framework also includes a ServiceRegistry, which works as a locator for the services. A typical use case in CS-Studio is that some plug-ins would register their service implementation to the registry, while UI elements would use the registry to fetch the service implementation given a name provided by the user.

FORMULA
PvManager provides a Domain Specific Language for data computation. This is automatically done on background threads, making it easy to leave the UI thread free. FormulaFunctions can be dynamically added in a formula registry, in much the same way that services are added. They are automatically picked up by the parser.

The language supports overriding, and the match to the correct signature is done at runtime. This also supports the case in which types within the expression are changing dynamically. Support for standard mathematical operation has already been added, as well as aggregation such as scalars into array and arrays into tables, and other utility functions (pick the highest alarm, “pointer-like” function that given a string returns the value of the channel with that name).

CONCLUSION
PvManager has grown into a full framework to gather data in real time, aggregate it and perform computation. All this while taking care of the issues that such a complicated multi-threaded system would entail.
