Abstract

The injector for the second axis of the dual-axis Radiographic Hydrotest Facility (DARHT) is being designed and manufactured in LBNL. The injector consists of a single gap diode, extracting at 2 microseconds, 2kA (can be extended to 4kA), up to 3.5MV electrons from a dispenser cathode. The diode is powered through a high voltage insulating column by a Marx generator. We shall present an overview of the 3.5MV diode diagnostics, including: the A-K gap voltage measurement using a capacitive voltage divider (dE/dt) probe, cathode (source) current using 12 low inductance stainless steel foil current viewing resistors (CVRs) located on the cathode base plate, and anode dark current collected on the anode shroud using CVRs. A rise in the dark current, can indicate a buildup of an A-K breakdown, and is used to trigger the injector crowbar switch, thus limiting breakdown damage.

Beam spillage, generating X-rays around the anode tube and shroud, is monitored using solid state PIN diodes positioned around the anode tube.

2 INJECTOR DIODE DIAGNOSTICS

2.1 A-K gap voltage measurement

The A-K gap voltage, up to 3.5 MV, measurement is performed using a capacitive divider, dV/dt monitor. The monitor which consists of a 7.5 inch diameter charge collecting plate is positioned on the vacuum tank wall facing the diode dome. The plate output voltage $V_s$ can be estimated using:

$$V_s = C_c Z_o dV/dt = 0.13\text{pF} \times 50\Omega \times \frac{3.2\text{MV}}{0.4\mu\text{s}} = 52\text{V}$$

where $C_c$ is the coupling capacitance (Dome to plate), $Z_o$ cable impedance and $dt$ is the $V_d$ rise time. $V_s$ is integrated into $V_{A-K}$ at the scope input. The $V_s$ response (frequency band width) is determined by $Z_o C_s$ time constant $T_s$, where $C_s$ is the monitor plate stray capacitance $< 15\text{pF}$ leading to $T_s < 0.75\text{ns}$, i.e., B.W $< 250\text{MHz}$.

Fig. 1 Shows the DARHT Marx injector 3.2MV output pulse. This wave form was measured at the Marx exit (dome), using a capacitive divider with a similar design facing the Marx dome.

2.2 Cathode current measurement

The cathode (source) electron current $I_c$ of 2kA flow is symmetrically distributed through 12 parallel current viewing resistors (CVRs). Each100m$\Omega$, resistor consists of a 304 (non magnetic) stainless steel 2mil foil strip. The strip is folded around a 5mil insulating Keptan foil. The resistor is “sandwiched” between the source flange and the water cooled cathode support plate, Fig. 1. The CVR response time is determined mainly by CVR skin effect resistance and inductance. For the 2mil CVR foil and a B.W. of 250 MHz, the calculated skin depth is 16 mils $>>$ 2 mils foil. The calculated CVR inductance is 0.057 nH.
leading to a L/R time constant of about 0.5 ns, i.e., 
B.W. > 300MHz.

Four output current signals $V_s$ (about 15V at $I_c$ of 2KA) across 4 CVRs are measured and displayed. The current signals (through vacuum coaxial cable along the diode dome and the high voltage insulting column) are digitized and stored using 4 fast digitizers in the Marx dome. During injector operation the cathode, the Marx dome, and column go to 3.2MV. The current signals from the digitizers are converted into optical signals and transferred through fiber optics lines to ground potential to be displayed in the control room.

Fig. 2 shows the cathode (source) current measured on the LBNL Relativistic Klystron Test Accelerator (RTA). The RTA cathode current monitor uses a design similar to the above. Furthermore, the monitor was successfully tested using fast (2ns rise time) pulses. The 12 CVRs cathode assembly was tested and calibrated showing a less than 2% spread in the measured output (current).

### 2.3 Anode dark current ($I_d$) measurement

A rise in anode dark current $I_d$ can lead to a non symmetric magnetic field offsetting the beam into the accelerator wall. Furthermore, it can be an indication of the buildup of an A-K voltage breakdown.

The dark current is collected in an open ended anode shroud (Fig. 1). The other end of the shroud is connected to the accelerator structure (ground) through a 1.1 $\Omega$ dark current viewing resistor (DCVR). The DCVR consists of 24x27 $\Omega$ resistors connected in parallel around the shroud end. Each resistor is bypassed by a 300V MOV to limit energy in the DCVR during an A-K breakdown. The accelerator return current flows through the accelerator structure (inner shroud Fig. 1).

$I_d$ of about 100A is used as a threshold indicator to a buildup of an A-K breakdown, or, a beam offset. Injector circuits simulations anticipate the dissipation of high damaging energy (kJs) in the diode electrodes. To limit the damage, $I_d$ above 100A is used to turn on the Marx crow bar, thus limiting pulse duration, i.e., damaging energy. This fast gating system can be used in other cases of beam spillage (bumping) into the accelerator tube walls.

Within the physics design of the monitor, we checked the following physics issues:

- **Displacement current ($I_d$)** During the injector A-K pulse rise, within 0.4ms to a VA-K of 3.2MV, $I_d$ of about 75A will flow into the anode shroud through the A-K stray capacitance.

- **Induced voltage** The magnetic field generated by the accelerator return current along the inner shroud and the induced current around the anode shroud leads to an induced voltage of $V_{ind} < 2kV$. $V_{ind}$ appears across the 1cm gap formed between the anode shroud and accelerator tube. $V_{ind}$ is well below the breakdown voltage for this gap.

The measurements results are summarized in Table 1:

<table>
<thead>
<tr>
<th>$f$, MHz</th>
<th>$Q$</th>
<th>damping ferrites</th>
</tr>
</thead>
<tbody>
<tr>
<td>540</td>
<td>54</td>
<td>No</td>
</tr>
<tr>
<td>&lt; 5</td>
<td>Yes</td>
<td></td>
</tr>
<tr>
<td>330</td>
<td>15</td>
<td>No</td>
</tr>
<tr>
<td>317</td>
<td>8</td>
<td>Yes</td>
</tr>
</tbody>
</table>

A high Q (~50) dipole mode at about 540MHz, was considered too close the accelerator cut off frequency. Introducing damping ferrite tiles in the cavity around the inner shroud led to a reduction in the 540 MHz dipole Q to <5, which is acceptable.

### 2.4 Anode beam spillage

Beam spillage on anode and accelerator tube is measured by monitoring the spillage generated X rays. Four fast X ray detectors were placed around the beam tube near the anode beam entrance to the accelerator. The detectors consists of fast PIN silicon diodes. The diodes are backward biased 1kV. One cable is used for applying the bias and extracting the X-ray signal. The spillage signal is separated in a “coupling box” outside the accelerator and shipped to the control room.

The X ray detector was tested on the LBNL RTA. The detector was positioned outside of the accelerator tube at a distance from the cathode near a diagnostic cross. The accelerator was tuned to allow some spillage during the beam rise and fall times. Fig. 3a shows the accelerator cathode current, Fig. 3b shows the beam current at the accelerator end and Fig. 3c shows the X-ray monitor output showing beam spillage as expected during the beam rise and fall times.
