Abstract
It was observed that a bunch-length shrunk with acceleration in the Induction Synchrotron (IS) experiment, where a single proton-bunch injected from the 500 MeV Booster was accelerated to 6 GeV in the KEK-PS. A novel technique capable of quantitatively predicting the adiabatic phenomenon of bunch shortening has been developed, based on a hypothesis that the particle oscillation amplitude varies inversely proportional to the square root of its oscillation frequency. The experimental result and analytical prediction is in good agreement with each other.

INTRODUCTION
The induction acceleration experiment was carried out using the KEK 12 GeV proton synchrotron (12GeV-PS) in a series of experiments to demonstrate a proof of principle of the IS [1], the schematics of which is shown in Fig. 1. Details of the experiments have been described in the literatures [2,3,4].

A specific property of the functional separation of acceleration and confinement in the IS allows us to control the beam size through the entire period of acceleration. However, the accelerated beam bunch is subjected to adiabatic damping, as seen in the conventional RF synchrotron. It is quite important to know how the bunch size evolves through the entire acceleration in the IS and what factors dominantly determine the bunch size. A theoretical approach to predict the temporal evolution of the bunch size is developed. After the approach is carefully justified by comparing with computer simulations, the theoretical prediction is compared with the experimental results. Last we will discuss how this theoretical approach can provide a useful tool to estimate a temporal evolution of the bunch size associated with adiabatic changes in the external parameters, such as the barrier voltage amplitude and a time-interval between barrier voltages.

EXPERIMENTAL RESULTS
The bunch profile which was monitored by the wall current monitor, was recorded every 33 msec from the injection to the end of acceleration. Experimental results through the entire acceleration period are plotted for typical four shots in Fig. 3, where the bunch size is defined as a width measured at 5% of the peak height. From Fig. 3, we can clearly identify four regions: At the injection (I), the bunch width is 100 nsec but it quickly increases to ~ 400 nsec because of mismatching to the barrier bucket [3]. Tumbling of the bunch in the phase space and the succeeding filamentation are apparent there, leading to a long bunch width. In the remaining minimal field region (II) before acceleration, the bunch size is almost constant. This implies good matching with the barrier bucket shape throughout the region. The initial acceleration region (III) is characterized by serious beam loss as shown in Fig. 2. Quick shrinking of the beam size is caused by the beam loss in addition to damping associated with acceleration. The reason of beam loss is not fully understood, although it is speculated that the control of the trigger pulse density is not enough at this transient region. There is no beam loss in the constant acceleration region (IV). A steady state damping is clear. Near the end of acceleration region, the bunch width is almost constant. We will discuss more about this region hereafter.

THEORY
To develop the theory, we set a hypothesis that the phase oscillation evolves such that the instantaneous oscillation amplitude is inversely proportional to the square root of the phase oscillation frequency. This hypothesis is originated from an analogy of the WKB solution for a harmonic oscillator with slowly varying
The instantaneous amplitude of the phase, \( <\phi> \), is given by

\[
\phi = C A
\]

The motion in the barrier bucket is qualitatively divided into three regions: (I) focusing in the linear potential, (II) focusing in the parabolic potential, and (III) drift in the null voltage region. It is noted that the motion in region (I) and (II) is subject to adiabatic damping. In addition, it is emphasized that the exact solution throughout the region is known for the above short time period.

To analyze the temporal evolution of this oscillation amplitude associated with acceleration, we start from the canonical Eq. (1). From Eq. (1), we have the second-order differential equation with respect to \( \phi \)

\[
\frac{d^2\phi}{dt^2} - \frac{dA(t)}{dt}\frac{d\phi}{dt} + eV_{bb}(\phi)\frac{A(t)}{2\pi}=0,
\]

where the abbreviation \( A(t) = |\eta|\omega_0^2/\beta E_s \) is used. A temporal change in the phase of an individual particle is governed by Eq. (2).

The parameters in this equation include all information associated with acceleration, its solution can tell us what happens in the phase motion through the entire acceleration period. To eliminate the damping term, a new variable \( u(t) = \phi(t)/\sqrt{v(t)} \) is introduced. When \( v(t) = A(t)^2 \), Eq. (2) reduces to

\[
\frac{d^2u}{dt^2} + \left[ \frac{d^2A(t)}{2A(t)} - \frac{3}{4}\left(\frac{dA(t)}{2A(t)}\right)^2 \right] u(t) + B(t) = 0,
\]

where \( B(t) = eV_{bb}(\phi)A(t)^2/2\pi \). Since \( A(t) \) is a slowly varying function of time, its first-order and second-order time-derivatives are small. Accordingly, the second term in the left-hand side of Eq. (3) can be ignored in the further derivation. We arrive at a final form of the phase oscillation equation that must be substantially solved, \( d^2u/dt^2 = -B(t). \) The restoring force \( B(t) \) can be assumed to be constant during a single synchrotron oscillation period, \( T, \) which is much shorter than \( 1/(dA/dt)/A. \) In addition, the synchrotron oscillation is symmetric in the phase space, as depicted in Fig. 4b. If we obtain exact solutions in three regions of I, II, and III in Fig. 4a, the synchrotron frequency \( \Omega_s = 2\pi/T \) is written in an analytic form [5]. From the hypothesis, the instantaneous amplitude of the phase, \( <\phi> \), is written by

\[
<\phi> = C\frac{A}{\sqrt{\Omega_s}}
\]
where $C$ is a constant coefficient determined from the initial condition. Introducing the instantaneous oscillation amplitude in time $<\tau> = -\phi/\omega_1$ and substituting the analytic form into Eq. (4), we obtain

$$
t(t) = C \left[ \frac{8\eta\Delta_t}{\pi\omega_1v\beta_{1s}E_1} \left\{ \sin \left[ \frac{\Delta_t}{2(\tau^2 - (U_1 + U_s))} \right] + \frac{\Delta_t}{2(\tau^2 - (U_1 + U_s))} \right\} \right].
$$

Equation (5) is a transcendental equation of $<\tau>$. Note that the equation includes information about the initial condition of an individual particle through the term of $C$, the barrier conditions of $V_{bb}$, $\Delta t_1$, and $\Delta t_2$, and the parameters of $\omega_0$, $\beta_{1s}$, $E_1$, and $\eta$ uniquely determined for a fixed accelerator. By solving Eq. (5), we can obtain the temporal evolution of the oscillation amplitude in time associated with the acceleration.

Here, we have to pay our attention on an important feature in the adiabatic damping of the synchrotron oscillation. If the barrier condition is maintained to be a constant, a particle, the oscillation amplitude of which has initially extended to the flat barrier region (I), will fall in the linear barrier region (II) as a result of the adiabatic damping. In this situation, Eq. (5) becomes invalid. Beyond the boundary between the linear and quadratic potentials, the analytical form for the synchrotron oscillation changes. The instantaneous oscillation amplitude in time must satisfy the following relationship,

$$
\langle \tau \rangle = C^2 \left[ \frac{8\eta\Delta_t}{\pi\omega_1v\beta_{1s}E_1} \right] \left[ \frac{\pi}{2} + \frac{\Delta_t}{\sqrt{2(\tau^2 - \Delta t)}} \right].
$$

where $C$ is determined from the boundary condition. Consequently, Eq. (5) and Eq. (6) gives the oscillation amplitude in the regions where $<\tau> > (\Delta t_1 + \Delta t_2)$ and $<\tau> < (\Delta t_1 + \Delta t_2)$, respectively. These two solutions should be connected at $<\tau> = (\Delta t_1 + \Delta t_2)$.

The present result has been obtained assuming the trapezoidal profile of the barrier voltage. It is straightforward to know the temporal evolution of the oscillation amplitude $<\tau>$ for more extreme profiles, such as a rectangular profile ($\Delta t_1 = 0$), a short profile ($\Delta t_2 = 0$), and a discrete profile ($\Delta t_1 = \Delta t_2 = 0$). For the rectangular profile,

$$
\langle \tau \rangle = C^2 \left[ \frac{8\eta}{\pi\omega_1v\beta_{1s}E_1} \right] \left[ \frac{\sqrt{2(\tau^2 - \Delta t)}}{\sqrt{2(\tau^2 - \Delta t)} + \frac{\Delta t}{\sqrt{2(\tau^2 - \Delta t)}}} \right].
$$

This form mostly suggests a particular feature of the adiabatic damping in the induction synchrotron, which can be distinguished from that in RF synchrotrons. A solution of Eq. (7) is always written in terms of $<\tau> = g(t; \Delta t_1 + \Delta t_2)$, where $g(t; \Delta t_2)$ is a slowly varying function of $t$ and is subjected to adiabatic damping and gradually becomes smaller. Since the isolated offset term of $\Delta t_2$ is controllable, the oscillation amplitude can be maintained in a well controlled manner throughout the acceleration, as expected.

### COMPARISON WITH EXPERIMENTAL RESULTS

Experimental results and analytical predictions can be compared only after loss at the beginning of acceleration, i.e., from 0.633 sec from injection as shown in Fig. 3. From this time onwards bunch shrinking can be attributed only to adiabatic damping. Assuming an initial bunch length of 190 nsec, which was taken from the experimental result at $t=0.633$ sec, the theoretical prediction is plotted in Fig. 5. We can see that both are in fairly good agreement.

### SUMMARY

A novel theory to estimate adiabatic damping phenomenon in the induction synchrotron has been presented. The theory is based on an analogy of the WKB solution for a harmonic oscillator, the parameters of which slowly vary in time. It has turned out that the theory can quantitatively explain the experimental results. In RF synchrotrons the bunch size infinitely shrinks beyond transition energy. We know that this is intrinsic feature in the RF synchrotrons. However, this is not the case in an induction synchrotron. The bunch-length in an induction synchrotron is mainly determined with the time duration between barrier voltages as expected. This fact has been proven mathematically.

The present research has been supported by a Grant-In-Aid for Creative Scientific Research (KAKENHI 15GS0217).
