Abstract
In the ILC Main Linac the dark current electrons, generated in SRF cavity can be accelerated to hundreds of MeV before being kicked out by quadrupoles and thus will originate electromagnetic cascade showers in the surrounding materials. Some of the shower secondaries can return back into vacuum and re-accelerated again. The preliminary results of simulation of the dark current generation in ILC cavity, its dynamics in linac are discussing in paper.

INTRODUCTION

High gradient superconducting may produce electrons emitted from the cavity surface that may be captured in accelerating regime. Since dark current particles have broad angular, space and phase distribution, particles will be lost somewhere in downstream cavities causing undesirable effects, like heat and RF loading of the cavity and production of avalanches of secondary electrons. This process may limit performance of the ILC cryomodule. It is important to simulate dark current and understand dynamic in the ILC linac. In this paper we present very preliminary results. The first part of study is simulation of the dark current production in one ILC cavity at gradient 30 MV/m. The second part is developing model of the ILC linac in MARS code which can simulate both propagation of the dark current in linac lattice and interaction of the particles with the surrounding media – walls of the cavity, helium and walls of titanium vessel. Interaction with media is not started yet and we are planning to do this in this year with the goal a) reproduce and cross-check results of dark current simulations done for XFEL project [1] and b) study dark current deposition for ILC main linac and bunch compressor.

PARTICLE TRACKING IN 9-CELL CAVITY

Since a task is to figure out how the dark current electrons are captured into acceleration and what this accelerated dark current beam looks like at the exit of cavity, 9-cell TESLA cavity has been replaced by a MWS model without HOM couplers, and a perfect field distribution was considered (see Fig.1). To calculate the particle trajectories a tracking code has been written in VBA for use in Microwave Studio environment. The tracking code uses smooth approximated fields and solid models created by MWS. The code solves the relativistic equations of particle motion in RF fields combined with uniform static magnetic field. Buneman-Boris method is used to solve the equations of motion.

In RF accelerating cavities electric field is variable in time and has highly non-uniform surface distribution. As a result field emission can not occur everywhere and at all times. As a function of time (or rf phase) the emitted current is approximately Gaussian, with rms width \( \sqrt{BE/6.5} \cdot 10^9 \phi^{1.5} \) [2]. For copper at surface field of 85-130 MV/m and enhancement factor of 30 it varies from 11° to 14°. For niobium a surface field of 60 MV/m is expected at accelerating gradient of 30 MV/m. Assuming working function for niobium 4.3 eV and \( \beta = 30 \) we have rms width of appropriate phases \( \approx 10° \). So, an interval of initial phases of 70°-110° should be considered, assuming \( E = E_0 \cdot \sin(\alpha \phi + \phi) \).

![Figure 1: MWS model of 9-cell TESLA cavity.](image)

The field emission takes place, naturally, on the surfaces with highest surface electric field. For TESLA type cavity maximum surface field is on the irises. The extensive particle tracking have been performed at accelerating gradient of 30 MV/m to define more precisely the emission sites and the interval of phases at which the emitted electrons are captured into acceleration. It turned out that the area of “successful” emission is rather small as it seen in Figure 2. The appropriate emission area is 2-4 mm wide ring on both sides of iris. The tracking also shown that the relevant interval of phases shrinks as well from 70°-110° to 88°-110°, because the electrons emitted at phases <88° just cannot go out from cell.

After the emission areas and appropriate for emission phases were found, the final tracking has been performed. The goal of tracking was to determine high field emission current parameters at the end of the cavity as a sum of emission currents from all irises. The particles were emitted one by one from high surface field area on each of 9 irises at fixed accelerating field phase of 95° and accelerating gradient of 30 MV/m. The cavity has axial...

symmetry and symmetry relatively to its center, so it is sufficient to consider emission in one plane (Y-plane) and from one side of irises (right side as shown in Figure 2). Then all particles from all irises that have been accelerated and reached the cavity’s exit are analyzed. Of course, the flight time for particles from different irises is different, but after 8-9 RF periods there is a steady ensemble of particles from all irises at any moment.

Figure 2: Electrons emitted from narrow area only can get through aperture and be accelerated. GUI of tracking code is also shown.

For each iris 60-80 particle trajectories were simulated to get reasonable density of particles at the cavity exit and saved in data files. Then an additional program written in Mathematica analyzed the data and saved the results for further use in MARS. The Figure 3 and 4 shows the plots of some data sets created by this program.

For different initial phases of emission in interval of 88-110° the beam parameters are very similar. But density of emitted current changes very rapidly according to the Fowler-Nordheim theory of field emission. As a result of that the normalized beam density at the exit of cavity changes significantly. The integral (sum of currents from all irises emitted in interval of 88-110°) current density over phase space is shown in Figure 5.

Figure 3: Kinetic energy of electrons vs. RF phase at the cavity exit. The points corresponding to different irises have different colors.

Figure 4: Transverse emittances at the cavity exit.

**DARK CURRENT PROPAGATING IN ILC LINAC**

For beam dynamics simulation of the dark current in a regular accelerating structure of the ILC the package MARS was used. The structure of the package is flexible and easily allows to include special user-developed sub-programs, which can accommodate needs for a specific task. MARS is dedicated and effective code for modeling of particle interaction with media, but not quite adequate for simulation of accelerating beam physics. That’s why along with developing of the special user programs, the tracking part of the MARS was upgraded to simulate beam propagation in cavities.

Figure 6: Simplified geometry of the 9-cell ILC cavity in MARS. Here only three cells are shown: input, middle (regular) and output.
For energy deposition simulation in MARS the cavity geometry was simplified, instead of elliptical shape the simple pill-box shape was used as shown in Figure 6. In the first step of simulation we replace niobium material in MARS with the artificial so-called “black hole” material, which guarantee that any particle touching this material will disappear without producing secondary particles. The real modeling of the secondary particle, generated in niobium, helium media and titanium vessel, is not done yet and will be a subject for further studies. Some of these secondary electrons may come back to the cavity and contribute to the dark current dynamics [1].

ILC quadrupoles are key element for cleaning dark current, they focus high energy main beam, but over-focus low-energy dark current particles. Each quadrupole is located in middle of cryomodule replacing one of cavity. ILC lattice used in simulation has 75°/60° phase advance per FODO cell with one quad per 3 cryomodules (9-8-9 cavities in each). For modeling behaviour of dark current in vicinity of quadrupoles we investigated building-up the dark current in preceding cavities. Figure 7 shows the trajectories of ~60 particles (out of 2469 generated in cavities), that reached focusing quad with the gradient G=2.34T/m corresponding low energy part of the main linac (15GeV).

As one can see the major part of particles will be lost after focusing quad at the walls of downstream cavities. Simulation shows that only ~25% of particles generated in cavity will reach next cavity and this portion dramatically falls down in next cavities, as shown in Figure 8.

Next three plots in Figure 9 show radial, angular and phase distributions of the particles generated in cavity #0 at the entrance of 17 downstream cavities. This information is using for generation of dark current distribution at the entrance of each quadrupole by summarizing all particles generated in each cavity in between of two quadrupoles (this is standard accelerating module for linac). It simplifies dark current simulations allowing track in cavities only particles that survived after preceding quadrupole and then add at the entrance of the next quadrupole a new particle ensemble generated in all cavities of this module.
