Abstract
We have performed a single-shot, time-resolved measurement of the output field of a SASE FEL using the frequency-resolved optical gating (FROG) technique. The measurement reveals the phase and the amplitude of the SASE output as functions of time and frequency, hence enables us to perform a full characterization of the SASE FEL output. We examined both the single-shot field evolution as well as the statistics over multiple shots on the phase and intensity evolution.

INTRODUCTION
In a SASE FEL, a favorable instability occurs due to the interaction of an electron beam and the electromagnetic wave it produces as the beam propagates down an undulator. Provided the interaction is strong enough, the radiation power grows exponentially with the undulator distance until it reaches saturation [1,2]. Due to the mirrorless operation, such single-pass, SASE FELs are proposed for the next generation of high-brightness, coherent X-ray sources [3,4]. Recent experiments have demonstrated saturation of such SASE FELs [5-7] and their capability of achieving shorter and tunable wavelengths by direct amplification [6] as well as by harmonic generation [7,8].

We report the first single-shot time-resolved characterization of SASE pulses using the frequency-resolved optical gating (FROG) technique [9]. The measurement revealed the phase and intensity evolution of the FEL and their statistics over multiple shots. In this paper we will concentrate on the phase evolution [10].

EXPERIMENT
The measurements were conducted at the low-energy undulator test line at the Advanced Photon Source [5,10]. Table 1 is a summary of the main parameters for the two experiments. Briefly, a high-brightness electron bunch generated from an rf photocathode gun is compressed through a magnetic chicane, accelerated to 217 MeV in energy, and sent into an undulator line. A full diagnostic system for the FEL output and the electron bunch are installed at each undulator, enabling us to verify the gain of the FEL [5,11]. A mirror at each station can direct the SASE light toward diagnostics located outside of the tunnel, where the FROG device resides.

Negative energy chirp of the electron bunch $\sigma_e/\sigma_r$ in data set A is determined by energy spread on a spectrometer using a modified linear zero-phasing technique. Here $\sigma_b$ is the relative correlated energy spread, and $\sigma_r$ is the rms bunch length. Exponential gain was verified by measuring the FEL output as a function of the distance along the undulators.

A single-shot FROG device using the second harmonic gating geometry [9] records single-shot spectrograms (see Fig. 1 for the device setup). In this configuration, the signal is $I_{\text{FROG}}(\omega, \tau) \propto \left| \int_{-\infty}^{\infty} E(t-\tau) E(t) \exp(-i\omega t) dt \right|^2$, where $E$ is the field of the optical pulse and contains both amplitude and phase information.

Example traces of the FROG measurement along with the retrieved pulse shape and phase in the time and frequency domains are given in Fig. 2.

In general, the traces measured by the FROG have large fluctuations. Figure 2 shows cases with single (a) and multiple (b) intensity spikes. The asymmetry in the frequency axis in the trace is an indication of overall energy chirp. While the phases for each spike are very complicated, there are clearly phase discontinuities at the edge of some spikes.

To interpret the observation in Fig. 2, we recall that the temporal characteristics of a SASE pulse, due to the noisy startup, are those of chaotic light. Under the one-dimensional, cold-beam approximation with the electron energy chirp considered, the electric field in the temporal characteristic of a SASE pulse, due to the noisy startup, are those of chaotic light. Under the one-dimensional, cold-beam approximation with the electron energy chirp considered, the electric field in the time and frequency domains are given in Fig. 2.

as the effect of the longitudinal wake field, if not intentionally imposed. The results in Fig. 3 unambiguously reveal the positive intrinsic SASE chirp. They also verify that the electron beam energy chirp directly maps into the FEL output, a key process for compressing and slicing the pulse from future X-ray FELs. Figure 3 also serves as an independent measurement of the electron bunch energy chirp.

The FROG traces also provide rich information on the statistics of the SASE output, especially the temporal information on these pulses. As the FROG traces provide the information in the frequency domain simultaneously, a correlation analysis between the time and the frequency domain is now possible. A more detailed analysis of the statistics is underway.

SUMMARY

In conclusion, we observed a positive intrinsic chirp in the SASE FEL spikes, and we confirmed that the energy chirp in the electron bunch does map to the SASE output. These observations have very important applications for future X-ray FEL sources in pulse engineering and manipulation.

The authors are grateful for help by O. Markarov and R. Dejus for performing the gain length measurement and processing the data. We also thank L. Teng for insightful discussions.
