

EQUIVALENT CIRCUIT ANALYSIS OF THE RHIC INJECTION KICKER

H. Hahn* and A. Ratti†, Brookhaven National Laboratory, Upton, New York 11973

Abstract

The RHIC injection kicker is built as a travelling wave structure in order to assure the required 95 nsec risetime in the deflection strength. The kicker is constructed from 14 cells, each 7.5 cm long, with alternating ferrite and high-permittivity dielectric sections. The cell structure permits an analysis of the electrical properties of the kicker using lumped L , C , and R circuit elements. Their values are obtained directly from impedance measurements of the full-length kicker, the inductance and shunt capacitance values by measuring the input impedance at 1 MHz with the output shorted and open, respectively. A lossy series resonance circuit in each cell is found to reproduce the measured input impedance of the terminated kicker up to ~ 100 MHz. The validity of the equivalent circuit was confirmed by comparing the measured output current pulse shape time with that computed by the P-Spice program.

1 INTRODUCTION

The RHIC injection kicker was conceived as a transmission line magnet in order to achieve the required rise time of < 95 nsec[1]. The kicker is configured from ferrite and dielectric blocks as a “C” type magnet with its geometry shown in Fig. 1. The deflecting properties of the kicker are dominated by the magnetic field and thus by the geometry and properties of the ferrite blocks. The nickel-zinc ferrite (CMD-5005 by Ceramic Magnetics) has a high permeability and resistivity for use at frequencies up to ~ 100 MHz. Although in principle continuous at the side, the ferrite must be subdivided to limit eddy current effects. The capacity required to achieve the transmission line behavior is predominantly provided by the dielectric ceramic blocks, a sintered mixture of magnesium and calcium titanate (MCT-125 by Trans-Tech) with high dielectric constant, $\epsilon = 125$, to achieve the characteristic impedance of 25Ω . The contribution to the capacity from the ceramic beam tube is negligible, and for convenience sake, all kicker measurements were made without it.

The original kicker design was based on an equivalent circuit analysis of a low-pass filter with lumped L and C elements[2]. In a subsequent paper, the kicker was treated as a transmission line with uniform, albeit anisotropic properties in order to establish a better correlation of geometrical with electrical parameters[3]. In an attempt to estimate the current rise time from the low-pass band width, the kicker was treated as a cascaded chain of transmission

lines with different characteristic impedances and propagation velocities[4]. Although useful, the simple equivalent circuits presented so far are limited and do not allow a reliable prediction of the kicker performance resulting from engineering changes or from varied operational conditions, such as the mismatched 20Ω termination used in the Sextant Test. In this paper, an equivalent circuit for a generalized low-pass filter with lumped elements is presented, which was obtained from direct measurements of the kicker. The P-Spice program was then used to simulate the kicker performance and the comparison with experimental data showed fully satisfactory agreement[5].

2 EQUIVALENT CIRCUIT

The RHIC injection kicker is constructed as a low-pass filter with 14 cells, each 7.5 cm long, with alternating ferrite and high-permittivity dielectric sections, thereby approximating a transmission line magnet. The cell structure permits an analysis of the electrical properties of the kicker using an equivalent circuit with lumped L , C , and R elements. Their values are obtained directly from input impedance measurements of the full-size kicker in the frequency range up to ~ 100 MHz. Discussed here in detail is the production kicker #5, in which the MCT-125 dielectric blocks are used.

The inductance is obtained from the input impedance at 1 MHz with the output port shorted. The total inductance was measured to be $1.59 \mu\text{H}$, resulting in 106 nH for each of the 15 series inductors. At frequencies below the $\lambda/4$ resonance, 4.757 MHz, the input impedance of the shorted

kicker is given by $Z_{in} = Z_K \tan(\frac{1}{2}\pi f/f_{\lambda/4})$, from which follows the characteristic impedance of the kicker as $Z_K \approx 26 \Omega$.

The capacitance is obtained from the input impedance at 1 MHz with the output port open. The total capacitance was 1.99 nF, resulting in ~ 140 pF for each of the 14 dielectric blocks. The measured input impedance of the kicker terminated with the nominal 25Ω is shown in Fig. 2. The pronounced resonance at 64 MHz can be represented by a lossy series resonance. This resonance is associated with eddy currents in the ferrite side blocks, as established by a series of measurements with side blocks of different lengths. The circuit elements, and in particular the damping resistors, were adjusted to render the strength of the resonances in the open and shorted condition.

Figure 2: Measured input impedance of kicker with matched output port termination and comparison with P-Spice computations.

Using the equivalent circuit shown in Fig. 3, the P-Spice computed input impedances for the output port terminated in the design 25Ω are compared with the measured results in Fig. 2. As seen, the agreement is quite satisfactory and establishes the confidence, that dependable predictions of the kicker performance can be made based on the equivalent circuit diagram. Of interest are, for example, the kicker response to a step function voltage, the operation

of the kicker with a 20Ω termination to reduce the voltage requirement, and the estimate of the longitudinal coupling impedance in the frequency range below 100 MHz for which the equivalent circuit is applicable[6].

Figure 3: Equivalent circuit of injection kicker. Only 3 of the 14 dielectric capacitors in a full-length kicker are shown.

3 TIME DOMAIN KICKER PERFORMANCE

Having established the equivalent circuit based on measurements in the frequency domain, it is now possible to predict the kicker performance in the time domain by means of P-Spice computations. Measurement of the performance of the kicker without beam is effectively limited to the current in the output load. The charging voltage on the Blumlein pulser can also be measured, but its value is not rigorously equal to the input voltage at the kicker.

The kicker load current in production unit #5 terminated into 25Ω is shown in Fig. 4 for a ~ 40 kV pulser voltage, which satisfies the nominal design requirement of 1.6 kA. The measured current is in good agreement with the P-Spice computation. Also shown is the computed “effective kicker current,” which renders the rise time of the deflecting force and, neglecting the 3 nsec ion transit time, is obtained by averaging the instantaneous current in the 15 series inductors. The computed rise time of the effective current is ≤ 100 nsec in full agreement with the Sextant Test beam measurements[7].

The pulse propagation time in the 1.12 m long kicker was directly measured by means of uncalibrated capacitive probes at the input and output ends. The two signals are shown in Fig. 5; by using a single trigger, the propagation time was directly measured to be ~ 50 nsec, in excellent agreement with the theoretical prediction based on a propagation velocity of $v/c = 0.07$. The measured value is also in agreement with the computed P-Spice predictions as seen in Fig. 5, where the the voltages at the input, at the first dielectric block and at the load are shown.

4 EQUIVALENT CIRCUIT ANALYSIS OF COUPLING IMPEDANCE

The analytical treatment of the kicker coupling impedance at low frequencies, i.e. below ~ 100 MHz, is instructive but limited and can be complemented with the use of equivalent circuits[6]. An appropriate model seems to be a multi-cell

Figure 4: Measured load current at 500 A/division and comparison with P-Spice computed curve. The computed “effective” current represents the average of currents in the 15 series inductors and is an estimate of the time-dependent kicker deflecting strength.

Figure 5: Measured voltage of pulse at input and output end of the kicker. The measured transit time of ~ 50 nsec is confirmed by the P-Spice computations.

section low-pass filter with lumped elements, shown in Fig. 6 for a half-size kicker model. Having established the equivalent circuit of the kicker alone, one can add the beam as a series of magnetically coupled inductors, the values of which are determined from impedance wire measurements $L_B = 18.9$ nH and $\kappa = 0.82$. The coupling impedance computed by the P-Spice program at low frequencies has been compared with the results from the “wire” measurements[6]. The agreement is reasonable considering the possible errors in measurement and the limitations of the model.
