

ICALEPCS 2015

International Conference on Accelerator
& Large Experimental Physics
Control Systems

17-23 OCTOBER 2015 MELBOURNE AUSTRALIA

ICALEPCS 2015, hosted by the Australian Synchrotron, will bring together control systems specialists from the world's large experimental physics facilities in the vibrant city of Melbourne, Australia.

The technical program will include the latest on:

- Project Status Reports
- Systems Engineering and Project Management
- Integrating Complex or Diverse Systems
- Personnel Safety and Machine Protection
- Hardware Technology
- Timing and Sync
- Software Technology Evolution
- Experiment Control
- Process Tuning and Feedback Systems
- User Interfaces and Tools
- Data Management, Analytics, and Visualisation
- Control Systems Infrastructure
- Mobile Opportunities and Challenges

**ABSTRACT SUBMISSION OPENS
19 JANUARY 2015**

**ABSTRACT SUBMISSION CLOSES
1 MARCH 2015**

**REGISTRATIONS OPEN
15 APRIL 2015**

www.icalepcs2015.org

Hosted by:

COMMITTEES

International Executive Committee

Roland Müller, HZB (Chair)	Christopher Marshall, NIF/LLNL
Lou Corvetti, AS	Ryotaro Tanaka, Spring-8
David Fernandez, ALBA	

International Scientific Advisory Committee

Roland Müller, HZB (Chair)	Kazuro Furukawa, KEK	Changbum Kim, PAL
Lou Corvetti, AS	Marco Lonza, ELETTRA	Javier Serrano, CERN
Mark Heron, Diamond	Hamid Shoaee, SLAC	Eric Bjorklund, LANL
Reinhard Bacher, DESY	Kevin Brown, BNL	Nick Hauser, ANSTO
Jin Dapeng, IHEP	Philippe Gayet, CERN	Dennis Nicklaus, Fermilab
Kuo-Tung Hsu, NSRRC	John Maclean, Argonne	Karen White, ORNL/SNS
Sheng Peng, FRIB	Young-Gi Song, KOMAC	Niko Neufeld, CERN
Matthew Bickley, JLAB	Peg Folta, NIF/LLNL	Noboru Yamamoto, KEK
Gianluca Chiozzi, ESO	Alain Buteau, SOLEIL	Ryotaro Tanaka, Spring-8
David Fernandez, ALBA	Andy Götz, ESRF	Jean-Michel Chaize, ESRF
Markus Janousch, PSI	Juan Guzman, ASKAP/CSIRO	Stephane Perez, CEA/LMJ
Christopher Marshall, NIF/LLNL	Lize Van Den Heever, Sth Africa SKA	

Scientific Program Committee

Markus Janousch, PSI	Eric Bjorklund, LANL	Kazuro Furukawa, KEK
John McLean, Argonne	Mark Heron, Diamond	David Fernandez, ALBA
Niko Neufeld, CERN	Matt Bickley, JLAB	Allan Casey, LLNL
Dennis Nicklaus, Fermilab	Marco Lonza, ELETTRA	Gordon Brunton, LLNL
Karen White, ORNL	Chris Marshall, NIF/LLNL	Changbum Kim, PAL
Ryotaro Tanaka, Spring-8	Young Gi Song, KOMAC	Reinhard Bacher, DESY
Jean Michel Chaize, ESRF	Andy Gotz, ESRF	Noboru Yamamoto, KEK
Stephane Perez, CEA/LMJ	Javier Serrano, CERN	Oscar Matilla, ALBA
Kevin Brown, BNL	Gianluca Chiozzi, ESO	Nick Hauser, ANSTO
Juan Carlos Guzman, ASKAP/CSIRO	Dapeng Jin, Institute of High Energy Physics	Enrique Blanco, CERN
Timo Korhonen, European Spallation Source	Lize van den Heever, Sth Africa SKA	

Local Organising Committee

Lou Corvetti (Conference chair), AS	Nick Hauser (Conference Program Chair), ANSTO
Andrew Rhyder, AS	Natalia Ferreira, AS
Kathleen Riches, AS	Phil McShane, ASN Events
Maree Overall, ASN Events	Annette McClellan, ASN Events
Gonzalo Conesa, AS	Emma Shepherd, AS

Editorial Board

Kathleen Riches, SLISA	Chief Editor
Andreas Moll, SLISA	Proceedings Editor
Marie Robichon, ESRF	Scientific Secretariat/Editor
Volker RW Schaa, JACoW/GSI	Proceedings Editor
Saji Choji, Spring 8	Proceedings Editor
Isidre Costa, CELLS-ALBA	Proceedings Editor
David Button, ANSTO	Proceedings Editor

Contents

Preface	i
Committees	iii
Contents	v
Papers	1
MOA3O01 – SKA Telescope Manager Project Status Report	1
MOA3O02 – The Large Scale European XFEL Control System: Overview and Status of the Commissioning . .	5
MOB3O03 – MAX IV Laboratory, Milestones and Lessons Learned	9
MOB3O04 – The Construction Status of the SuperKEKB Control System	14
MOC3O01 – Comprehensive Fill Pattern Control Engine: Key to Top-Up Operation Quality	18
MOC3O02 – PIDTUNE: A PID Autotuning Software Tool on UNICOS CPC	22
MOC3O03 – Automatic FEL Optimization at FERMI	26
MOC3O04 – System Identification and Robust Control for the LNLS UVX Fast Orbit Feedback	30
MOC3O05 – NSLS-II Fast Orbit Feedback System	34
MOC3O06 – The Laser Megajoule Facility: The Computational System PARC	38
MOC3O07 – Low Level RF Control Implementation and Simultaneous Operation of Two FEL Undulator Beamlines at FLASH	42
MOD3I01 – Bayesian Reliability Model for Beam Permit System of RHIC at BNL	46
MOD3O02 – Continuous Delivery at SOLEIL	51
MOD3O03 – Shot Rate Improvement Strive for the National Ignition Facility (NIF)	56
MOD3O04 – Introducing the SCRUM Framework as Part of the Product Development Strategy for the ALBA Control System	60
MOD3O05 – Use of Automation in Commissioning Process of the Undulators of the European X-Ray Free Electron Laser	64
MOD3O06 – Interface Management for SKA Telescope Manager	68
MOM302 – Python Software for Measuring Wavelength at Optically Pumped Polarized Ion Source (OPPIS) . .	72
MOM305 – Control System for a Dedicated Accelerator for SACLA Wide-Band Beam Line	74
MOM306 – Status of the PAL-XFEL Control System	79
MOM308 – XFEL Machine Protection System (MPS) Based on uTCA	82
MOM309 – Upgrade of the Beam Monitor System for Hadron Experimental Facility at J-PARC	86
MOM310 – Nonlinear System Identification of Superconducting Magnets of RHIC at BNL	90
MOM311 – ALMA Release Management: A Practical Approach	94
MOPGF001 – Use Interrupt Driven Mode to Redesign an IOC for Digital Power Supply at SSC-LINAC	98
MOPGF002 – Magnet Corrector Power Supply Controller for LCLS-I	100
MOPGF006 – The Renovation of the CERN Controls Configuration Service	103
MOPGF008 – Embedded Environment with EPICS Support for Control Applications	107
MOPGF014 – LLRF Controls Upgrade for the LCLS XTCAV project at SLAC	110
MOPGF015 – Fast Wire Scanner Upgrade for LCLS	114
MOPGF016 – Improving the Compact Muon Solenoid Electromagnetic Calorimeter Control and Safety Systems for the Large Hadron Collider Run 2	117
MOPGF019 – Experiences and Lessons Learned in Transitioning Beamline Front-Ends from VMEbus to Modular Distributed I/O	121
MOPGF020 – Detector and Run Control Systems for the NA62 Fixed-Target Experiment at CERN	125
MOPGF021 – Database Archiving System for Supervision Systems at CERN: a Successful Upgrade Story . .	129
MOPGF022 – SIS18 Upgrade: The FAIR Compliant Renovation of the Data Acquisition System for Particle De- tectors	133
MOPGF023 – Update of Power Supply Control System at the SAGA Light Source Storage Ring	137
MOPGF024 – Testing Framework for the LHC Beam-based Feedback System	140
MOPGF025 – Enhancing the Detector Control System of the CMS Experiment with Object Oriented Modelling .	145
MOPGF026 – Laser Beam Profiling and Further Improvements to the FHI FEL	149
MOPGF027 – Real-Time EtherCAT Driver for EPICS and Embedded Linux at Paul Scherrer Institute (PSI) . . .	153
MOPGF029 – Personnel Protection System Upgrade for the LCLS Electron Beam Linac	157
MOPGF030 – Upgrade of the Control and Interlock Systems for the Magnet Power Supplies in T2K Primary Beamline	160

MOPGF032 – Installation of a Hot-Swappable Spare Injector Laser System for the SLAC Linac Coherent Light Source	163
MOPGF033 – New Developments on EPICS Drivers, Clients and Tools at SESAME	167
MOPGF035 – Control System Status of SuperKEKB Injector Linac	170
MOPGF036 – Control System Developments at the Electron Storage Ring DELTA	173
MOPGF037 – Upgrades to Control Room Knobs at Slac National Accelerator Laboratory	177
MOPGF038 – Design and Commissioning Results of MicroTCA Stripline BPM System	180
MOPGF039 – TIP: An Umbrella Application for all SCADA-Based Applications for the CERN Technical Infrastructure	184
MOPGF040 – Keck Telescope Control System Upgrade	188
MOPGF042 – EPICS IOC Based on Computer-On-Module for the LNL Laboratory	193
MOPGF045 – MEBT and D-Plate Control System Status of the Linear IFMIF Prototype Accelerator	197
MOPGF047 – Revolution Project: Progress in the Evolution of Soleil Motion Control Model	201
MOPGF048 – IBEX - the New EPICS Based Instrument Control System at the ISIS Pulsed Neutron and Muon Source	205
MOPGF049 – 100Hz Data Acquisition in the TANGO Control System at the Max IV Linac	209
MOPGF050 – Tango-Kepler Integration at ELI-ALPS	212
MOPGF051 – ELI-ALPS Control System Status Report	216
MOPGF052 – A Framework for Hardware Integration in the LHCb Experiment Control System	221
MOPGF056 – Synchronising High-Speed Triggered Image and Meta Data Acquisition for Beamlines	225
MOPGF057 – Quick Experiment Automation Made Possible Using FPGA in LNLS	229
MOPGF058 – Neutron Scattering Instrument Control System Modernization - Front-End Hardware and Software Adaption Problems	233
MOPGF063 – The New TANGO-based Control and Data Acquisition of the Neutron Instrument DNS at FRM II	236
MOPGF065 – Motion Control on the Max IV Soft X-Ray Beamlines With Tango and Sardana	240
MOPGF066 – Synchronized Ramping of Magnet Power Supplies for Streamlined Operation at Energy Recovery Linac (ERL) and Electron Lens (e-Lens)	244
MOPGF067 – MeerKAT Control and Monitoring System Architecture	247
MOPGF070 – Report on Control/DAQ Software Design and Current State of Implementation for the Percival Detector	251
MOPGF071 – Sodium Laser Guide Star Emulation	255
MOPGF072 – Hot Checkout for 12 GeV at Jefferson Lab	258
MOPGF077 – Drift Control Engines Stabilize Top-Up Operation at BESSY II	262
MOPGF079 – European XFEL Cavities Piezoelectric Tuners Control Range Optimization	266
MOPGF080 – Control System of RF Stations for NICA Booster	270
MOPGF087 – TPS Booster Tune Measurement System	274
MOPGF088 – Integrating the Measuring System of Vibration and Beam Position Monitor to Study the Beam Stability	277
MOPGF090 – Control of Fast-Pulsed Power Converters at CERN Using a Function Generator/Controller	281
MOPGF091 – White-Rabbit Based Revolution Frequency Program for the Longitudinal Beam Control of the CERN PS	286
MOPGF092 – Integration of the TRACK Beam Dynamics Model to Decrease LINAC Tuning Times	291
MOPGF093 – Real-time Beam Loading Compensation for Single SRF Cavity LLRF Regulation	295
MOPGF097 – Architecture of Transverse Multi-Bunch Feedback Processor at Diamond	298
MOPGF098 – PandA Motion Project - A Collaboration Between SOLEIL and Diamond to Upgrade Their 'Position and Acquisition' Processing Platform	302
MOPGF099 – Upgraded Control System for LHC Beam-Based Collimator Alignment	306
MOPGF101 – High Level Controls for the European XFEL	310
MOPGF102 – The New Control Software for the CERN NA62 Beam Vacuum	314
MOPGF103 – The Upgrade of Control Hardware of the CERN NA62 Beam Vacuum	318
MOPGF104 – Consolidations on the Vacuum Controls of the CERN Accelerators, During the First Long Shutdown of the LHC	322
MOPGF105 – Device Control Database Tool (DCDB)	326
MOPGF110 – Design Strategies in the Development of the Italian Single-dish Control System	330
MOPGF111 – TANGO Integration of a Specific Hardware through HTTP-server	334
MOPGF112 – Measurements, Alarms and Interlocks in the Vacuum Control System of the LHC	338
MOPGF113 – Controls and Interlocks for the New Elettra Super Conducting Wiggler	342
MOPGF114 – Controls Interface into the Low-Level RF System in the ARIEL e-Linac at TRIUMF	346

MOPGF115 – LabVIEW as a New Supervision Solution for Industrial Control Systems	349
MOPGF117 – The Control System for Trim-Coil Relay-Selectors in J-PARC MR	353
MOPGF119 – Design and Development of the ECR Ion Source Control System	356
MOPGF120 – CAN Over Ethernet Gateways: A Convenient and Flexible Solution to Access Low Level Control Devices	359
MOPGF121 – Stripping Foil Displacement Unit Control for H ⁻ Injection in PSB at CERN	363
MOPGF122 – A Fast Interlock Detection System for High-Power Switch Protection	367
MOPGF123 – Upgrades of Temperature Measurements and Interlock System for the Production Target at J-PARC Hadron Experimental Facility	371
MOPGF125 – The General Interlock System (GIS) for FAIR	374
MOPGF126 – A Modified Functional Safety Method for Predicting False Beam Trips and Blind Failures in the Design Phase of the ESS Beam Interlock System	378
MOPGF129 – Understanding the Failure Characteristics of the Beam Permit System of RHIC at BNL	382
MOPGF131 – Interlock System for Machine Protection at ThomX Accelerator	386
MOPGF132 – Building an Interlock: Comparison of Technologies for Constructing Safety Interlocks	389
MOPGF134 – Design of Fast Machine Protection System for the C-ADS Injection I	393
MOPGF135 – Upgrade of the Trigger Synchronisation and Distribution System of the Beam Dumping System of the Large Hadron Collider	397
MOPGF136 – ADaMS 3: An Enhanced Access Control System for CERN	401
MOPGF137 – Interlock of Beam Loss at Low Energy Part of J-PARC Linac	405
MOPGF138 – Overview and Design Status of the Fast Beam Interlock System at ESS	409
MOPGF140 – Integration of PLC's in Tango Control Systems Using PyPLC	413
MOPGF141 – Upgrade of Abort Trigger System for SuperKEKB	417
MOPGF142 – Development of a Network-based Personal Dosimetry System, KURAMA-micro	420
MOPGF143 – Integration of Heterogeneous Access Control Functionalities Using the New Generation of NI cRIO 903x Controllers	424
MOPGF145 – Commissioning and Design of the Machine Protection System for Fermilab's Fast Facility	428
MOPGF146 – Safety Interlock System for a Proton Linac Accelerator	431
MOPGF147 – Realization of a Concept for Scheduling Parallel Beams in the Settings Management System for FAIR	434
MOPGF149 – Nuclotron and NICA Control System Development Status	437
MOPGF150 – Improving SOLEIL Computing Operation with a Service-Oriented Approach	441
MOPGF153 – Beam Instrumentation and Data Acquisition for CRYRING@ESR	446
MOPGF154 – Current Status and Perspectives of the Cryogenic Control System of EAST	449
MOPGF155 – Design and Status for the Electron Lens Project at the Relativistic Heavy Ion Collider	453
MOPGF158 – Sirius Control System: Design, Implementation Strategy and Measured Performance	456
MOPGF160 – ARIEL Control System at TRIUMF - Status Update	460
MOPGF161 – LANSCE Control System Upgrade Status and Challenges	464
MOPGF162 – MaRIE - Instrumentation & Control System Design Status and Options	468
MOPGF163 – Status of the Local Monitor and Control System of SKA Dishes	472
MOPGF164 – Status of the EPICS-Based Control and Interlock System of the Belle II PXD	476
MOPGF171 – Active Magnetic Bearings System Upgrade for LHC Cryogenic Cold Compressor, Radiations Miti- gation Project (R2E)	480
MOPGF172 – Bringing Quality in the Controls Software Delivery Process	485
MOPGF174 – Laser-driven Hadron Therapy Project	490
MOPGF175 – A Unified Approach to the Design of Orbit Feedback with Fast and Slow Correctors	494
MOPGF176 – Control System Challenges from an Upgrade to the Diamond Light Source Storage Ring	498
MOPGF177 – Robust Stability Analysis of Orbit Feedback Controllers	502
MOPGF178 – Uncertainty Modelling of Response Matrix	506
MOPGF179 – Status of the Solaris Control System - Collaborations and Technology	510
TUA3O01 – Detector Controls Meets JEE on the Web	513
TUA3O04 – CS-Studio Scan System Parallelization	517
TUB3O01 – Advanced Workflow for Experimental Control	521
TUB3O02 – Iterative Development of the Generic Continuous Scans in Sardana	524
TUB3O03 – The Modular Control Concept of the Neutron Scattering Experiments at the European Spallation Source ESS	529

TUB3O04 – The LMJ System Sequences Adaptability (French MegaJoule Laser)	533
TUC3I01 – Machine Protection and Interlock System for Large Research Instruments	537
TUC3O02 – Design, Implementation and Setup of the Fast Protection System for CSNS	543
TUC3O03 – Development and Realisation of the ESS Machine Protection Concept	545
TUC3O04 – Reusable Patient Safety System Framework for the Proton Therapy Centre at PSI	549
TUC3O05 – NSLS-II Active Interlock System for Fast Machine Protection	554
TUC3O06 – Machine Protection System for the KOMAC 100-MeV Proton Linac	558
TUC3O07 – Safety Integrity Level (SIL) Verification for SLAC Radiation Safety Systems	561
TUD3I01 – The LMJ Target Diagnostics Control System Architecture	565
TUD3O02 – Extreme Light Infrastructure, Beamlines - Control System Architecture for the L1 Laser	570
TUD3O03 – REMUS: The new CERN Radiation and Environment Monitoring Unified Supervision	574
TUD3O04 – The Virtual European XFEL Accelerator	578
TUD3O05 – Integrating Control Applications into Different Control Systems	581
WEA3O01 – The TANGO Controls Collaboration in 2015	585
WEA3O02 – Recent Advancements and Deployments of EPICS Version 4	589
WEA3O03 – Towards Building Reusability in Control Systems - a Journey	593
WEB3O01 – Open Source Contributions and Using OSGi Bundles at Diamond Light Source	598
WEB3O02 – quasar - A Generic Framework for Rapid Development of OPC UA Servers	602
WEB3O03 – Disruptor - Using High Performance, Low Latency Technology in the CERN Control System	606
WEB3O04 – Accelerator Modelling and Message Logging with ZeroMQ	610
WEB3O05 – Why Semantics Matter: a Demonstration on Knowledge-Based Control System Design	615
WEC3O01 – Trigger and RF Distribution Using White Rabbit	619
WEC3O02 – The Phase-Locked Loop Algorithm of the Function Generation/Controller	624
WEC3O04 – New Event Timing System for Damping Ring at SuperKEKB	629
WEC3O05 – Timing System for the HAPLS/L3 ELI Project	633
WEC3O06 – ERL Time Management System	636
WED3O01 – MASSIVE: an HPC Collaboration to Underpin Synchrotron Science	640
WED3O02 – Databroker: An Interface for NSLS-II Data Management System	645
WED3O03 – MADOCA II Data Logging System Using NoSQL Database for SPRING-8	648
WED3O04 – HDB++: A New Archiving System for TANGO	652
WED3O05 – Big Data Analysis and Analytics with MATLAB	656
WEM301 – Timing Systems for ATNF Telescopes	660
WEM303 – Virtualisation within the Control System Environment at the Australian Synchrotron	664
WEM304 – Status Monitoring of the EPICS Control System at the Canadian Light Source	667
WEM305 – LabVIEW Interface for MADOCA II with Key-Value Stores in Messages	669
WEM307 – Custom Hardware Platform Based on Intel Edison Module	673
WEM308 – A Multi-Modal Human-Machine-Interface for Accelerator Operation and Maintenance Applications	677
WEM309 – A Graphical Tool for Viewing and Interacting with a Control System	681
WEM310 – How Cassandra Improves Performances and Availability of HDB++ Tango Archiving System	685
WEPGF001 – The Instrument Control Electronics of the ESPRESSO Spectrograph @VLT	689
WEPGF002 – A Protocol for Streaming Large Messages with UDP	693
WEPGF005 – The New Modular Control System for Power Converters at CERN	697
WEPGF006 – Magnet Server and Control System Database Infrastructure for the European XFEL	701
WEPGF010 – Securing Access to Controls Applications with Apache httpd Proxy	705
WEPGF011 – Progress of the Control Systems for the ADS injector II	709
WEPGF012 – Information Security Assessment of CERN Access and Safety Systems	713
WEPGF013 – Increasing Availability by Implementing Software Redundancy in the CMS Detector Control System	717
WEPGF014 – A Data Acquisition System for Abnormal RF Waveform at SACLA	721
WEPGF015 – Drivers and Software for MicroTCA.4	725
WEPGF018 – Service Asset and Configuration Management in ALICE Detector Control System	729
WEPGF019 – Database Applications Development of the TPS Control System	732
WEPGF020 – A Redundant EPICS Control System Based on PROFINET	736
WEPGF021 – Design of Control Networks for China Initiative Accelerator Driven System	739
WEPGF023 – Controlling Camera and PDU	743
WEPGF024 – Interfacing EPICS to the Widespread Platform Management Interface IPMI	746
WEPGF025 – Data Driven Simulation Framework	749

WEPGF028 – A Self-Configurable Server for Controlling Devices Over the Simple Network Management Protocol	753
WEPGF029 – High Level Software Structure for the European XFEL LLRF System	757
WEPGF030 – The EPICS Archiver Appliance	761
WEPGF031 – The Evolution of the Simulation Environment in ALMA	765
WEPGF032 – EPICS PV Management and Method for RIBF Control System	769
WEPGF034 – The Power Supply Control System of CSR	772
WEPGF036 – Data Categorization and Storage Strategies at RHIC	775
WEPGF037 – Data Lifecycle in Large Experimental Physics Facilities: The Approach of the Synchrotron ELETTRA and the Free Electron Laser FERMI	777
WEPGF038 – A Flexible System for End-User Data Visualisation, Analysis Prototyping and Experiment Logbook	782
WEPGF041 – Monitoring Mixed-Language Applications with Elastic Search, Logstash and Kibana (ELK)	786
WEPGF042 – Scalable Web Broadcasting for Historical Industrial Control Data	790
WEPGF043 – Metastore: A Primary Data Store for NSLS-2 Beamlines	794
WEPGF044 – Filestore: A File Management Tool for NSLS-II Beamlines	796
WEPGF045 – Large Graph Visualization of Millions of Connections in the CERN Control System Network Traffic: Analysis and Design of Routing and Firewall Rules with a New Approach	799
WEPGF046 – Towards a Second Generation Data Analysis Framework for LHC Transient Data Recording	802
WEPGF047 – Smooth Migration of CERN Post Mortem Service to a Horizontally Scalable Service	806
WEPGF049 – The Unified Anka Archiving System - a Powerful Wrapper to Scada Systems like Tango and WinCC OA	810
WEPGF050 – Integrated Detector Control and Calibration Processing at the European XFEL	814
WEPGF052 – Development of the J-PARC Time-Series Data Archiver using a Distributed Database System, II	818
WEPGF053 – Monitoring and Cataloguing the Progress of Synchrotron Experiments, Data Reduction, and Data Analysis at Diamond Light Source From a User's Perspective	822
WEPGF056 – Flyscan: a Fast and Multi-technique Data Acquisition Platform for the SOLEIL Beamlines	826
WEPGF059 – The Australian Store. Synchrotron Data Management Service for Macromolecular Crystallography	830
WEPGF060 – A Data Management Infrastructure for Neutron Scattering Experiments in J-PARC/MLF	834
WEPGF061 – Beam Trail Tracking at Fermilab	838
WEPGF062 – Processing High-Bandwidth Bunch-by-Bunch Observation Data from the RF and Transverse Damper Systems of the LHC	841
WEPGF063 – Developing HDF5 for the Synchrotron Community	845
WEPGF065 – Illustrate the Flow of Monitoring Data through the MeerKAT Telescope Control Software	849
WEPGF066 – A Systematic Measurement Analyzer for LHC Operational Data	853
WEPGF068 – Formalizing Expert Knowledge in Order to Analyse CERN's Control Systems	857
WEPGF069 – Integrating Web-Based User Interface Within Cern's Industrial Control System Infrastructure	861
WEPGF070 – A New Data Acquiring and Query System with Oracle and EPICS in the BEPCII	865
WEPGF071 – Python Scripting for Instrument Control and Online Data Treatment	869
WEPGF072 – Parameters Tracking and Fault Diagnosis base on NoSQL Database at SSRF	873
WEPGF074 – FPGA Firmware Framework for MTCA.4 AMC Modules	876
WEPGF080 – Encoder Interface for NSLS-II Beam Line Motion Scanning Applications	881
WEPGF081 – Em# Platform: Towards a Hardware Interface Standardization Scheme	885
WEPGF083 – Single Neutron Counting Using CCD and CMOS Cameras	889
WEPGF084 – New Digitisers for Position Sensitive ³ He Proportional Counters	893
WEPGF085 – The Construction of the SuperKEKB Magnet Control System	897
WEPGF089 – CERN Open Hardware Experience: Upgrading the Diamond Fast Archiver	901
WEPGF090 – Design of EPICS IOC Based on RAIN1000Z1 ZYNQ Module	905
WEPGF091 – A Formal Specification Method for PLC-based Applications	907
WEPGF092 – PLCverif: A Tool to Verify PLC Programs Based on Model Checking Techniques	911
WEPGF093 – CXv4, a Modular Control System	915
WEPGF094 – A Modular Approach to Develop Standardized HVAC Control Systems with UNICOS CPC Framework	919
WEPGF095 – Application of PyCDB for K-500 Beam Transfer Line	923
WEPGF096 – Managing a Real-time Embedded Linux Platform with Buildroot	926
WEPGF097 – Local Monitoring and Control System for the SKA Telescope Manager: A Knowledge-Based System Approach for Issues Identification Within a Logging Service	930
WEPGF100 – DRAMA 2 - An Evolutionary Leap for the DRAMA Environment for Instrumentation Software Devel- opment	934

WEPGF101 – A Modular Software Architecture for Applications that Support Accelerator Commissioning at MedAus-	
tron	938
WEPGF102 – Solving the Synchronization Problem in Multi-Core Embedded Real-Time Systems	942
WEPGF105 – EPICS V4 Evaluation for SNS Neutron Data	947
WEPGF106 – CCLIBS: The CERN Power Converter Control Libraries	950
WEPGF107 – Multi-Host Message Routing in MADOCA II	954
WEPGF112 – Flop: Customizing Yocto Project for MVMExxxx PowerPC and BeagleBone ARM	958
WEPGF113 – Physics Application Infrastructure Design for FRIB Driver Linac	962
WEPGF115 – LabVIEW EPICS Program for Measuring BINP HLS of PAL-XFEL	966
WEPGF116 – PvaPy: Python API for EPICS PV Access	970
WEPGF117 – High Level Applications for HLS-II	974
WEPGF118 – Use of Tornado in KAT-7 and MeerKAT Framework	977
WEPGF119 – Bunch to Bucket Transfer System for FAIR	980
WEPGF120 – Timing System at MAX IV - Status and Development	984
WEPGF121 – Operation Status of J-PARC Timing System and Future Plan	988
WEPGF122 – Real-Time Performance Improvements and Consideration of Parallel Processing for Beam Syn-	
chronous Acquisition (BSA)	992
WEPGF124 – Application Using Timing System of RAON Accelerator	995
WEPGF126 – Prototype of White Rabbit Network in LHAASO	999
WEPGF127 – A Generic Timing Software for Fast Pulsed Magnet Systems at CERN	1003
WEPGF128 – Development Status of the Sirius Timing System	1007
WEPGF129 – CERN timing on PXI and cRIO platforms	1011
WEPGF132 – An Update on CAFE, a C++ Channel Access Client Library, and its Scripting Language Extensions	1013
WEPGF133 – TINE Studio, Making Life Easy for Administrators, Operators and Developers	1017
WEPGF134 – Applying Sophisticated Analytics to Accelerator Data at BNLS Collider-Accelerator Complex: Bridg-	
ing to Repositories, Tools of Choice, and Applications	1021
WEPGF135 – Using the Vaadin Web Framework for Developing Rich Accelerator Controls User Interfaces	1025
WEPGF136 – Development of iBeacon Based Equipment Inventory System at STAR Experiment	1029
WEPGF137 – Adopting and Adapting Control System Studio at Diamond Light Source	1032
WEPGF141 – Tools and Procedures for High Quality Technical Infrastructure Monitoring Reference Data at CERN	1036
WEPGF142 – Advanced Matlab GUI Development with the DataGUI Library	1040
WEPGF145 – A Structured Approach to Control System GUI Design for the Solaris Light Source	1044
WEPGF146 – GUI Style Guide for Control System Applications at ESS	1047
WEPGF147 – ALICE Monitoring in 3-D	1049
WEPGF148 – Unifying All TANGO Control Services in a Customizable Graphical User Interface	1052
WEPGF150 – A HTML5 Web Interface for JAVA DOOCS Data Display	1056
WEPGF152 – Time Travel Made Possible at FERMI by the Time-Machine Application	1059
WEPGF153 – Karabo-GUI: A Multi-Purpose Graphical Front-End for the Karabo Framework	1063
WEPGF154 – Visualization of Interlocks with EPICS Database and EDM Embedded Windows	1066
WEPGF155 – Improving Software Services Through Diagnostic and Monitoring Capabilities	1070
THHA2I01 – Developing Distributed Hard-Real Time Software Systems Using FPGAs and Soft Cores	1073
THHA2O02 – The LASNCE FPGA Embedded Signal Processing Framework	1079

SKA TELESCOPE MANAGER – PROJECT STATUS REPORT

L.R. Brederode*, SKA SA, Cape Town, South Africa

A. Marassi, INAF-OAT, Trieste, Italy

S. Riggi, INAF-OACT, Catania, Italy

Abstract

The Square Kilometre Array (SKA) will be the world's largest radio telescope once it is complete and will use hundreds of thousands of receivers, spanning Africa and Australia to survey the sky in unprecedented detail. The SKA will be ground breaking in many respects such as image resolution, sensitivity, survey speed, data processing and size to name a few. The SKA Telescope Manager Consortium is currently designing the SKA Phase 1 (SKA1) Telescope Manager Element that will orchestrate the SKA Observatory and associated telescopes. In this paper, we report on the current status of the SKA1 Telescope Manager pre-construction project, the development process and its high-level architecture.

INTRODUCTION

Telescope Manager (TM) is one of a number of elements within the scope of the overall SKA1 pre-construction project, where the TM element has three primary responsibilities [1]:

- Management of astronomical observations;
- Management of telescope hardware and software subsystems;
- Management of data to support system operations and all stakeholders;

The TM element can thus be seen as the nerve centre largely involved in controlling and monitoring the SKA telescopes by interacting with other elements, namely:

- Dish (DISH);
- Low-Frequency Aperture Array (LFAA);
- Central Signal Processor (CSP);
- Science Data Processor (SDP);
- Assembly, Integration and Verification (AIV);
- Infrastructure Australia and South Africa (INFRA-AUS & INFRA-SA);
- Signal and Data Transport (SaDT);

The TM pre-construction project was kicked-off in November 2013 and is primarily focused on performing requirements analysis, architectural design, interface definition and prototyping activities, with the aim to produce a data pack that enables procurement contracts to be placed during 2017. Once a contract has been awarded, the development of the TM will continue with low-level design, coding and testing, integration, qualification and installation related activities ultimately culminating with a transition of the TM into a fully operational state in 2022, as per current plans.

* rbrederode@ska.ac.za

At the time of writing, the TM pre-construction project had been in progress for roughly two years since kick-off. An international consortium, led by the National Centre for Radio Astrophysics (NCRA) in India, assumes responsibility for the delivery of the TM pre-construction phase data pack.

APPROACH AND STRATEGY

The development plan for the TM is based on a tailored set of lifecycle stages and associated processes derived from the IEEE 12207-2008 and ISO/IEC TR 24748-3 standards [2]. These standards have been chosen as a basis for the development plan given that the TM Element is predominantly comprised of software, and IEEE 12207-2008 is a recognised international standard that provides a comprehensive set of lifecycle processes, activities and tasks for *software* that is part of a larger system.

The technical processes are employed in an iterative manner at various levels within the TM product hierarchy, namely the element, sub-element and assemblies \ application levels [2]. Items at each level are subjected to a requirements and design review prior to a formal system-engineering baseline being formed. The baseline indicates that there is agreement in terms of what each item in the product hierarchy is required to do, what they will consist of, and how they will interact to achieve the required functionality. A critical design review (CDR) precedes the formation of the final design baseline during the pre-construction phase. Development of the various levels proceeds largely in parallel, however it is critical that a higher level be thoroughly reviewed and baselined before a lower level can be concluded.

The TM pre-construction project aims to deliver a detailed *system* design (element & sub-elements) and a high-level *software* design (applications). The construction phase project will commence with low-level software design.

A risk management plan sees to it that risks are identified, analysed, treated and monitored on a regular basis. Prototyping activities are aimed at mitigating many of the technical risks. Exploratory prototypes are used to prove design concepts, confirm technology choices, characterise interfaces and elicit requirements. These prototypes are not developed with reuse in mind; rather they will be discarded once they have served their purpose. This reduces their cost and time to delivery. The

development of a system wide evolutionary prototype is outside the scope of the preconstruction phase.

WORK PACKAGES

The TM Consortium is organised into the following work packages (WPs):

- Telescope Management (TelMgt): Engineering management of the telescope;
- Observation Management (ObsMgt): Usage of the instrument for astronomical observations;
- Local Monitor and Control (LMC): Monitoring and control of the TM itself;
- Local Infrastructure (LINFRA): Computational, communications, power and facilities infrastructure for Telescope Manager;
- Prototyping (PROTO): Development of the required prototypes needed for design purposes;
- System Engineering (SE): Engineering artefacts related to requirements, architecture and interfaces;
- Project Management (MGT): Consortium coordination;

TOOLS

Various tools are used to facilitate the development of the TM, such as Alfresco[®] for document management, eB[®] Director for configuration management, JIRA[®] for issue tracking \ project management and Google Drive[®] for collaboration purposes. A Model Based Systems Engineering (MBSE) approach is employed using Systems Modelling Language (SysML) for requirements management, interface analysis and design.

PROJECT STATUS

Definition and Preliminary Design

The initial year of the TM pre-construction project focused on definition and preliminary design activities. Element level requirements were specified including functional and performance requirements, with traceability to higher-level system requirements. A top-level architecture for the TM was identified, including the next lower level assembly. Internal and external interfaces were identified and defined in the architecture. A parameterised cost model for the TM was developed, and a cost analysis report was prepared. Preliminary assembly, integration and verification (AIV) plans were prepared. A preliminary analysis with respect to hazards and safety, radio frequency interference (RFI), electromagnetic compatibility (EMC), failure-modes-effects-criticality (FMECA) was performed. Preliminary construction and maintenance plans were prepared. Draft sub-system level requirement and design specifications were prepared.

Preliminary Design Review

A preliminary design review (PDR) was conducted roughly a year into the project (Jan 2015), attended by members of the SKA Organisation (SKAO) and a panel of

external experts. The primary findings of the review panel were:

- TM Consortium was found to be responsive and collaborative with a deep understanding of the key design issues;
- High quality PDR data pack had been submitted;
- Technology choices were outstanding;
- Telescope level operations concept was immature with the potential to impact the TM requirements and design;
- Scope changes as a result of construction cost constraints (referred to as ‘rebaselining’) needed to be considered;
- Graphical user interface (GUI) design and scripting approach was immature;

After some deliberation the SKAO indicated that a delta PDR review would be required to closeout the panel’s observations.

The delta PDR review has been scheduled to take place during the 4th quarter 2015. A revised data pack addressing the primary PDR observations has been submitted to the delta PDR review panel. It is expected that the delta PDR can be concluded during 2015, with the formation of a *development* baseline.

Technology Framework Selection

The TM Consortium hosted a workshop in Trieste, Italy during March 2015 that was attended by the SKAO, representatives from all SKA element level consortia and industry experts. The primary purpose of the workshop was to work towards the selection of a monitoring and control framework technology to be implemented as an SKA wide standard. Three main candidate technologies were considered, EPICS, TANGO and Alma Common Software (ACS). Evaluation criteria included:

- Scalability and monitoring and control design concepts;
- Industrial standards and fresh module development;
- Modernity and future direction;
- User support and documentation;
- Integration and re-use of precursors;
- Risk reduction;

Although both EPICS and TANGO were deemed to fulfil the core requirements, TANGO was selected based on its product-oriented harmony versus a fragmented design in EPICS, where concerns were raised regarding the long-term support of particular modules.

The workshop concluded that TANGO was deemed to be the better choice for the SKA project with a future lifespan of several decades to consider [3].

The TM Consortium will be releasing a set of documents during 4th quarter 2015 that establish Local Monitoring and Control (LMC) interface guidelines, roles and responsibilities, and TANGO implementation

guidelines, endorsed by the SKA Organisation as an SKA wide standard.

Detailed Design and Prototyping

The TM Consortium officially kicked off its detailed design and prototyping activities during the course of a face-to-face meeting in June 2015. Sub-element level development plans were presented at this meeting together with progress reports in terms of closing out the PDR observations. Additional inputs were received from the SKAO, and their implications were considered. Attention was paid to risks, gaps and effort estimates.

A prototyping plan was submitted to the SKAO in July 2015 detailing the types of prototypes that will be constructed, the associated technical risks that will be mitigated, the approach, strategy and planning for each

prototype. A technology baseline, detailing key technology choices, was formed and described in the prototyping plan. At the time of writing, prototyping activities had commenced with a view to producing documented results by mid 2016.

Furthermore, significant progress has been made with respect to TM sub-element development. Figure 1 illustrates aspects of a workflow that forms part of Observation Management. It denotes actors that are involved in transforming a scientific proposal through a series of workflow stages into a set of scheduling blocks (SBs) for execution. Executed SBs result in control directives being forwarded to the Telescope Management sub-element for processing.

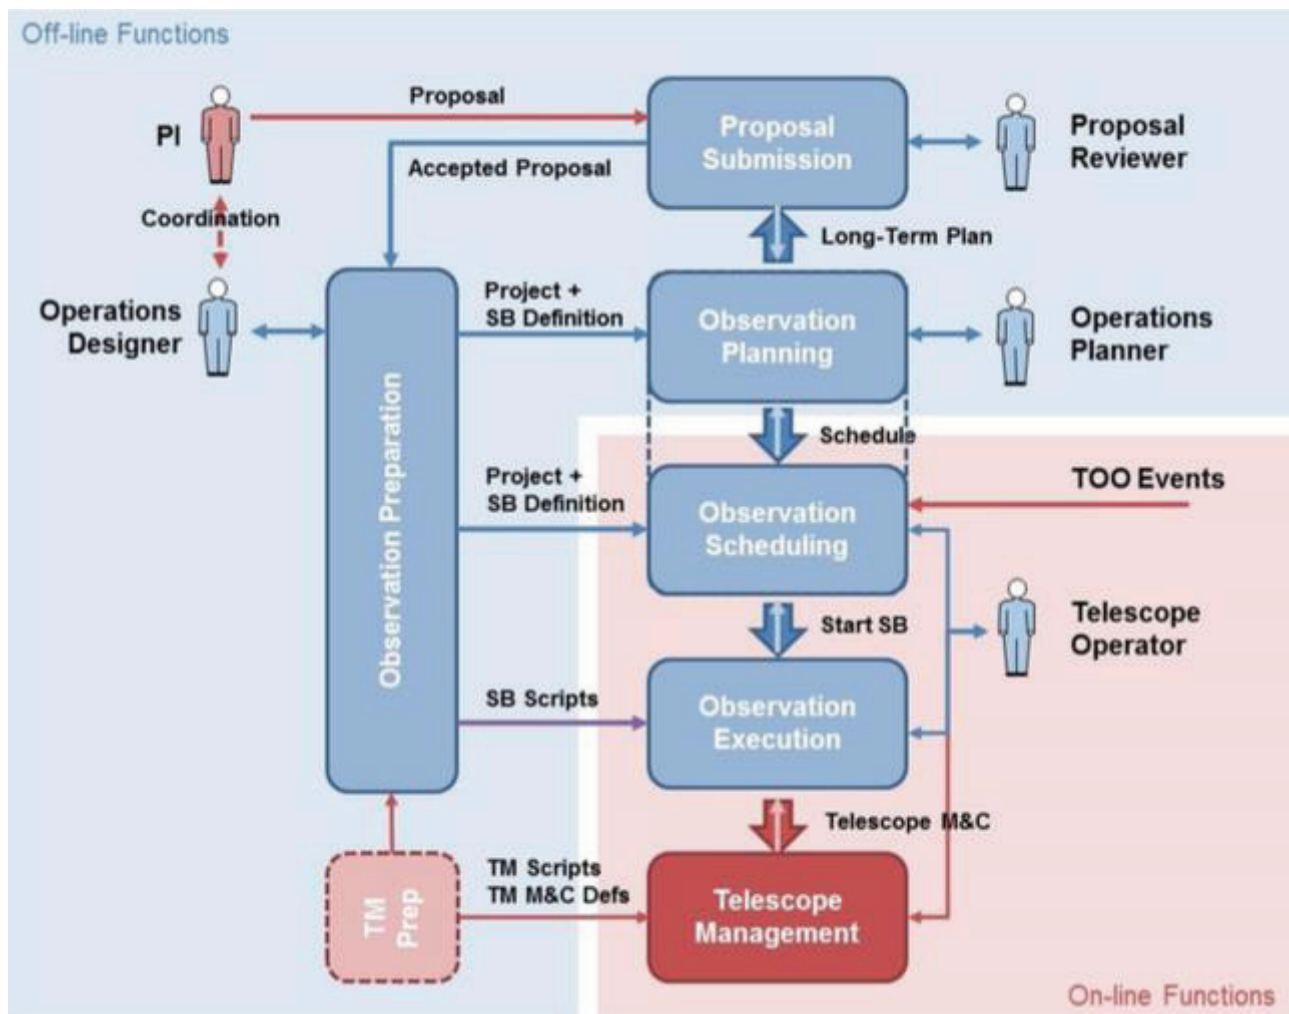

Figure 1: Observation Management High Level Functions [4].

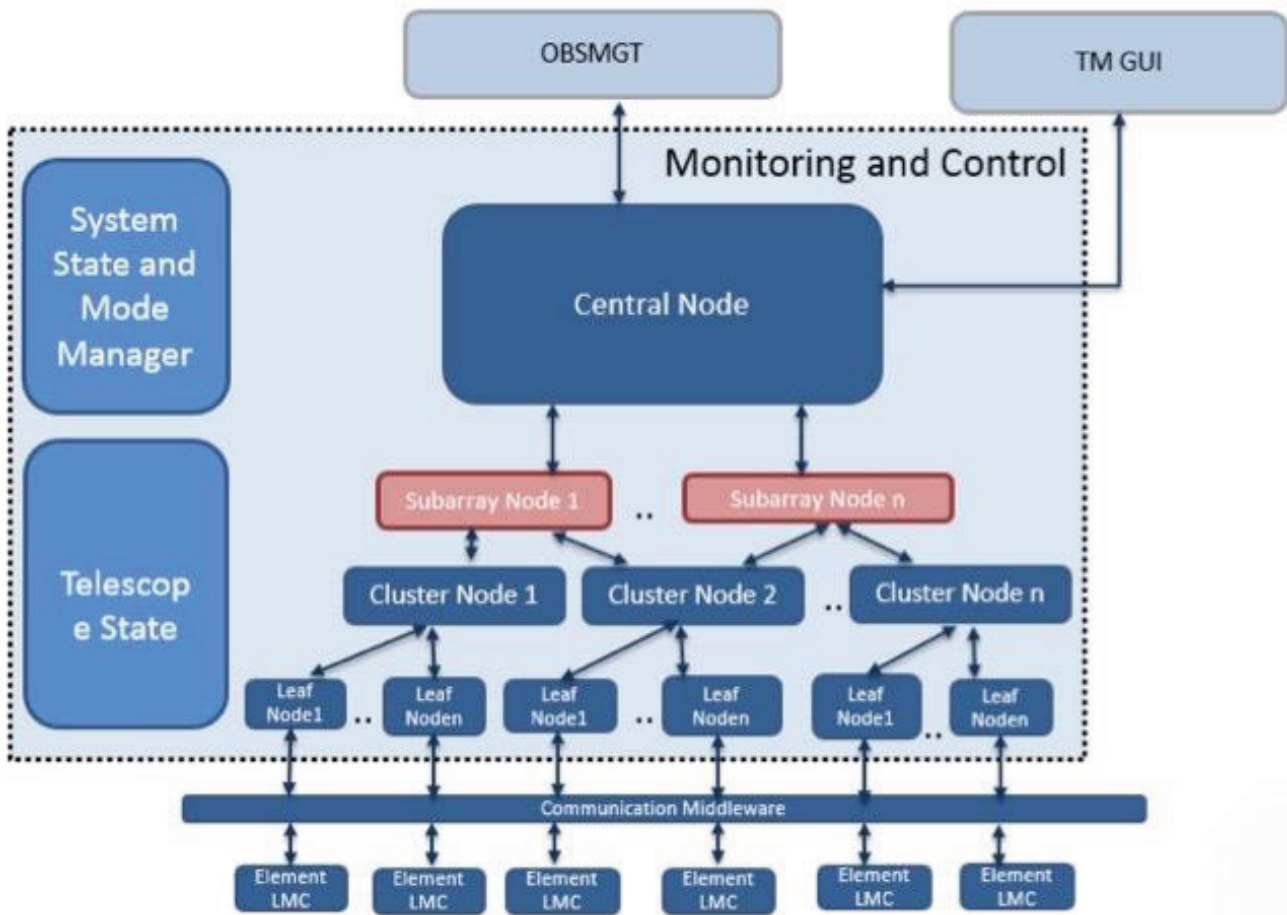

Figure 2: Monitoring & Control Interactions with Elements and Sub-elements [5].

Figure 2 depicts a hierarchy of control nodes, which form part of Telescope Management, responsible for gathering data from all Elements to obtain a real-time view of the state, health status and performance parameters of each Element, and the system as a whole. The control hierarchy enables execution of astronomical observations by configuring and controlling all Elements through commands. Interactions with other Elements are channelled via *leaf nodes* and Element LMCs.

CONCLUSION

The SKA Telescope Manager is an integral part of the SKA Observatory responsible for observation, telescope and data management functions. Significant progress has been made in developing the TM since project inception roughly two years ago. At the time of writing, a requirements and design baseline had however not yet been formed, and a schedule risk was beginning to manifest itself. Dependencies on higher-level artefacts and their level of maturity were contributing to the schedule risk. In order to mitigate the risks, the TM Consortium has adopted a strategy of making assumptions and continuing with the development activities. The next six to nine months would prove critical for the SKA1 TM project, as the assumptions would either be confirmed or shown to be false.

ACKNOWLEDGMENT

We would like to acknowledge the SKA TM Consortium partners responsible for the development of the TM, namely CSIRO (Australia), Engage SKA (Portugal), NCRA (India), INAF (Italy), NRC (Canada), STFC (UK), SKA SA (South Africa), Persistent Systems Ltd (India), SCISYS UK, and TCS (India).

Abstract

The European XFEL is a 3.4 km long X-ray Free Electron Laser in the final construction and commissioning phase in Hamburg. It will produce 27000 bunches per second at 17.5 GeV. Early 2015 a first electron beam was produced in the RF-photo-injector and the commissioning of consecutive sections will follow during this and next year. The huge number and variety of devices for the accelerator, beam line, experiment, cryogenic and facility systems pose a challenging control task. Multiple systems, including industrial solutions, must be interfaced to each other. The large number of bunches requires a tight time synchronization (down to picoseconds) and high performance data acquisition systems. Fast feedbacks from front-ends, the DAQs and online analysis system with a seamless integration of controls are essential for the accelerator and the initially 6 experimental end stations. It turns out that the European XFEL will be the first installation exceeding 2500 FPGA components in the MicroTCA form factor and will run one of the largest PROFIBUS networks. Many subsystem prototypes are already successfully in operation. An overview and status of the XFEL control system will be given.

INTRODUCTION

The European XFEL is a 3.4 km long X-ray Free Electron Laser (4th-generation light source) located in Hamburg, Germany. Its linear accelerator is based on superconducting RF-technology delivering 2700 electron bunches at energies of 10.5 GeV, 14 GeV, or 17.5 GeV with a bunch train repetition rate of 10 Hz. The undulator systems of the facility will produce spatially coherent photon pulses which are less than 80 fs long showing a peak brilliance of 10^{32} – 10^{34} photons/s/mm²/mrad²/0.1% BW in the energy range from 0.26 to 29.2 at beam energies of 10.5 GeV, 14 GeV, or 17.5 GeV. Installation work in the accelerator and beam line sections is progressing. Technical commissioning and set-up with beam will be performed in stages in 2015 and 2016. First lasing should be possible end of 2016.

The control system of the European XFEL is an effort of various distinct groups at DESY and the European XFEL GmbH. This paper describes the concepts and features of the individual solutions for accelerator, undulator, photon beam line, and cryogenic and utility controls. It addresses the challenges to be faced, discusses the interoperability between the systems and reports on the status of the whole controls project.

ACCELERATOR CONTROLS

The accelerator control system provides an environment to supervise, control, synchronize and protect the technical equipment of the accelerator. It includes among other things a large scale front-end electronics infrastructure based on the novel MTCA.4 standard [1], a timing system, a machine protection system, server software and driver libraries, communication protocols, a finite-state machine tool to facilitate process automation, and a design tool for graphical user applications. In addition, it provides a central Data Acquisition System (DAQ) aggregating and storing shot-synchronized, bunch-resolved data from distributed sources and supporting various software-based feedback systems. The environment is completed by a code repository, a repository to keep the configuration data for generating graphical user panels, various Web services, and common IT infrastructure.

Conceptual Design

Primarily the conceptual design of the accelerator control system follows the DOOCS control system ansatz in place at the FLASH facility, itself a quasi-template for the European XFEL. DOOCS-based controls cover all aspects of equipment dealing with bunch-synchronous fast data taking and algorithms. In addition, slow control such as vacuum or magnet controls is also handled by TINE-compliant control system components. TINE is the principal control system of the PETRAIII complex (3rd-generation light source). Both DOOCS and TINE are full-featured control systems and have been recently tuned to interoperate seamlessly [2].

System Components

More than 200 MTCA crates distributed along the accelerator host electronic plug-in modules with more than 2500 FPGAs executing tasks such as beam current read-out or low-level RF-measurements and control algorithms. Universal Linux drivers with hot-plug support are used as an interface to low-level DOOCS servers which provide board configuration and basic read-out. Data are distributed within the crate to device-specific DOOCS servers such as the beam current server via ZeroMQ and stamped with a unique, shot-related number.

Along with management/central data switching and CPU units, an integral part of a MTCA crate is the timing-system receiver module. Synchronisation is based on a hardware timing protocol distributed through a dedicated optical fibre system. Event triggers, clock signals and bunch-related data are sent to all front-end electronic modules with accurate precision (10 ps RMS jitter). A variable bunch pattern for the individual undulator beam lines can be transmitted prior to a bunch train.

The timing system hardware is linked to the Machine Protection System (MPS). Based on well-defined error conditions the MPS can restrict or inhibit the number of bunches to be sent through a specific accelerator section (e.g. injector only). Approximately 130 MPS modules are distributed along the accelerator. Input signals are directed through a dedicated optical fibre system towards two master modules located near the injector and the dump kickers for final logical processing.

In addition to the standard control system interface a fast data-driven protocol is used to send bunch-related data to central DAQ nodes. The sustained overall data rate to the DAQ system is of the order of 1.3 GB/s. Several DAQ instances are connected to a 10 GbE backbone network and operated in parallel. The nodes synchronize the data received from the distributed DOOCS front-end servers and store the data which belong together as a common, uniquely stamped data structure in a shared memory. All data are stored on disk for a few weeks for further analysis and can optionally be saved on tape.

In order to improve application software development and to verify and tune the global system performance the so-called Virtual-XFEL test bed has been put in place. Simulated data are sent at full rate to a dedicated DAQ system which forwards the data to specific middle-layer processes running within the DAQ run time environment. These servers are dedicated to preparing data for visualization or running software loops such as the transverse or longitudinal feedback. Other servers will provide beam optics data and calculate the actual energy profile along the accelerating structures.

Operating the accelerator is based on graphical user applications. Most applications run in the so-called jddd environment which generically displays user panels based on panel-specific configuration data. In addition, rich client like applications coded in Java, MATLAB or Python will be provided by scientists for measurement purposes.

UNDULATOR CONTROLS

Three undulator systems are used to produce the photon beams. Each undulator system consists of an array of up to 35 undulator cells installed in a row along the electron beam. A single undulator cell itself consists of a 5 m long planar undulator segment and a 1.1 m long intersection housing a phase shifter, magnetic field correction coils, and a quadrupole mover. Four servo motors are used on each undulator to control the gap between girders with micrometer accuracy. The current of magnetic field correction coils as well as the gap of the phase shifter are adjustable as a function of the undulator gap [3].

System Architecture and Components

Each undulator system has a length of about 200 m and is controlled by a distributed control system. It consists of a central control node (CCN) and one local control node (LCN) per undulator cell communicating through a real-time capable (EtherCAT) network used for device and motion control and an ordinary network used for monitoring, remote access and maintenance. Both networks implement the so-called “redundant ring topology” tolerating one single point of failure. The undulator control system provides flexible and sophisticated control of the K-parameters of all involved undulators. It allows full control by the accelerator control system and control of a limited set of relevant undulator parameters (gap, taper) by the beam line users.

In operational mode the CCN receives motion commands from the accelerator control system and translates those into individual commands for each LCN. It collects status data from each LCN and sends it back to the accelerator control system. In addition, it performs various maintenance tasks (updating device configuration data and operating system software) and provides an interface to the users.

The LCN is a Programmable Logic Controller (PLC) running on an industrial PC. It controls all Beckhoff TwinCAT-compliant front-end devices belonging to each single undulator cell such as motors, beam trajectory correctors, and valve controllers. In addition, it is involved in the synchronized tuning of undulator cells to the desired K value.

A configuration database and an engineering data management system complete the undulator control system.

PHOTON BEAMLINE CONTROLS

The supervisory control and data acquisition system of the photon beam lines must integrate hundreds of distributed and very different components such as mirrors, large 2D detectors or sample-handling systems into one homogenous software framework. It interfaces to programmable logic controllers for equipment control, fast FPGA-based electronics for timing and data acquisition, CPU and GPU based algorithms for online data monitoring, distributed calibration and analysis tasks.

Conceptual Design

To cope with diverse integration needs yet still keep a homogenous interface to users and developers, a novel software framework (Karabo) [4] has been created. The remote end-points (devices) of Karabo control beam line equipment (e.g. motors, pumps, and valves) or handle concurrent data processing and analysis tasks.

Devices communicate through a message-oriented middleware using a logically central but physically clustered asynchronous and event-driven broker mechanism for message routing. Additionally, specific point-to-point connections between devices can be established and are used for shipping large and fast data as needed for DAQ and processing pipelines.

Devices are completely self-descriptive regarding their parameters and functions. Hence, once loaded (plugin technology) a device is automatically controllable through a multi-purpose graphical user interface (GUI). Parameters and commands of any device can be composed into custom expert panels by dragging and dropping. Sequencing, scanning or other high level tasks are implemented in the form of Python macros, which - within the GUI - can be edited, executed and graphically controlled in expert panels.

Programmable Logic Controller Interfaces

Real-time synchronization and equipment protection relevant hardware is controlled via TwinCAT-compliant components and PLCs. Hundreds of physical devices such as motors or temperature sensors are being integrated by device-specific field bus terminals such as digital/analog inputs or outputs, motor drivers, encoder interfaces, and serial line drivers.

Groups of functionally related terminals mounted in crates are connected via a daisy-chained EtherCAT line to a common PLC. Using a specialized TCP/IP protocol each self-descriptive hardware or IO-channel is automatically reflected in the photon beam line control system as a Karabo device instance.

Fast Electronics and DAQ Interfaces

The architecture of the beam line data acquisition system foresees five layers: detector front end electronics, front end interfaces, PC farm layer, online data cache with computing clusters, and offline data archiving with offline computing clusters.

All detectors and sensors capable of acquiring data at the pulse frequency of 4.5 MHz are provided with synchronization signals, clocks and beam related metadata (such as unique bunch train IDs) from the common accelerator timing system. Sensor signals requiring digitization are treated using FPGA based modular digitizer systems and the MTCA.4 form factor. An in-house developed firmware framework facilitates algorithm implementation of the FPGA using graphical programming tools based on Simulink [5]. In addition, register mappings and variable descriptions are exported

as Karabo-readable XML files allowing instantaneous control system integration.

The large volume of data streams produced by multiple detectors (e.g. up to 10 GB/s of image data by a single 2D MPixel detector) and sensors are handled in the PC farm layer. Efficient handling of this huge data volume requires large network bandwidth (10 GbE switched links) and properly structured and tuned computing capabilities (PC layer, storage systems, and analysis clusters) interconnected by an Infiniband fabric. The PC layer nodes are highly optimized Karabo devices which periodically receive bursts of image datagrams, which need to be correlated with other fast and slow data. Data are integrated based on bunch train ID and forwarded to the storage system and to the online computing farm for further analysis. All PC layer devices are synchronized and orchestrated via the same finite state machine using a single-instance Run Controller device.

CRYOGENIC AND UTILITY CONTROLS

Control systems for cryogenic equipment are similar to process control systems for refineries or chemical plants. This is the domain of PLCs as deterministic calculations and control loops are here mandatory. PLCs are also partly used for the cryogenic system but only in those cases where machine protection or special turnkey system requirements apply. In general all process control functionalities reside in EPICS IOCs. The majority of the control functions (about 80%) consists of control loops and digital logic. The remaining 20% is implemented in complex state notation language programs used for sequential operations, state based operations as well as supervisory controls. In contrast, utility controls rely nearly 100% on PLC controls for their turnkey systems.

All parts of the cryogenic infrastructure are controlled by the same control system based on EPICS. Cryogenic and utility controls share the same control infrastructure. While the EPICS IOCs basically run basically core software with some custom extensions, the operators work at consoles running Control System Studio (CSS), which provides plugins for synoptic displays, trending, alarming, etc.

Continuous Operation and Reliability

Cryogenic systems typically run in a 24/7 mode with run periods of one year and more. This defines basic requirements for the control equipment. Sensors and actors as well as the process controllers must fulfill these requirements. Redundant sensors are in place wherever they are buried inside cryogenic boxes. Redundant process controllers are in place for every critical component. In addition redundant power supplies and networks are used to be prepared for component failures. This philosophy is in place throughout the whole control system.

The I/O System

Cryogenic systems are widely distributed. Even signals forming logical units may be spread over several hundred meters. I/O components are thus integrated into the system by means of Profibus field buses [6]. Profibus comes in two flavors: Profibus DP und Profibus PA where the latter also provides the power over the wires to the equipment. Individual Profibus nodes may consist of intelligent controllers gathering several tens of different signals as well as intelligent sensors and actors which in turn are connected to the PA variant of Profibus. The number of Profibus nodes adds up to 540 and results in 12.700 EPICS records.

Diagnostic Tools and Archiving

Widely distributed systems require good diagnostic tools with remote access to all basic information to diagnose error states and failures. In this case all Profibus lines are connected to individual diagnostic gateways which provide diagnostic information based on html (web) pages. In addition to this online information many diagnostic data are collected in the archive system for post mortem analysis.

INTEROPERABILITY

Basically all control systems used to operate the European XFEL are able to exchange a limited set of information between each other through a common Ethernet network. However, remaining issues related to naming conventions or authorization concepts might still require attention. In addition timing relevant data such as events or unique bunch train IDs can be distributed by the common accelerator timing system.

In order to facilitate device control and beam operation, both systems (DOOCS, TINE) used for accelerator control are tightly interconnected at both the client and server level. On the one hand the DOOCS client API can access any TINE server. On the other hand DOOCS servers can be configured to become defacto TINE servers. However, native TINE servers do not include DOOCS-specific DAQ system software, limiting the application of such servers to specific use cases.

The undulator control system integrates seamlessly into DOOCS. Each undulator system provides its own DOOCS-like server. Both experiment users and accelerator operators use DOOCS clients to control the undulators.

To facilitate the inter-communication with accelerator controls both Karabo and DOOCS clients will embed the others client API. In addition, Karabo must also integrate various in-kind contributions from external control systems (such as high-energy lasers, split and delay lines, etc.).

The interoperability between the cryogenic and the accelerator control system is still being discussed. Established solutions exist to exchange data between EPICS and DOOCS as well as TINE.

PROJECT STATUS

The installation of the general and in particular the novel MTCA infrastructure is progressing. Most aspects of the front-end hardware and software are in successful, routine operation at FLASH. Application development for the accelerator controls is still on-going. New software is either being tested or put into service at FLASH and the Virtual-XFEL simulation environment or directly in the gradual commissioning of already completed accelerator sections. So far the required performances have been demonstrated.

The basic concept of the undulator control system has been successfully tested at a mock-up. Extending the concept to a real undulator system and implementing the final controls software is under way.

Karabo is close to being fully featured. As of this writing it already controls a large pump-probe laser setup, several test stands (involving task like vacuum, motion, detector calibration and alignment, etc.) and will be in production for controlling the photon beamline components currently being installed in the SASE1 tunnels.

The cryogenic plant is successfully in operation for the past half year. Along with the installation of the accelerating structures the cryogenic equipment of the distribution system will be installed and tested. According to the staged technical commissioning of the accelerator sections, the cryogenic and utility control system will be put into service.

MAX IV LABORATORY, MILESTONES AND LESSONS LEARNED

V. Hardion, Y. Cerenius, F. Hennies, K. Larsson, J. Lidon-Simon, M. Sjöström, D.P. Spruce, MAX IV Laboratory, Lund, Sweden

Abstract

The MAX IV Laboratory is a new scientific research facility based on synchrotron light being built at Lund University, southern Sweden. The accelerator consists of one full energy linear accelerator providing two storage rings at 1.5 GeV & 3 GeV and a Short Pulse Facility. Additionally, more than 13 beamlines are planned to be built among which should be operational for the first users in 2016. The current status and approach of the control system is presented from its technical and organisational point of view, including the stakeholders, as well as the lessons learned from the commissioning as part of our continuous improvement for the future.

STATUS

Since the last ICALEPCS 2013 [1], the status of MAX IV Laboratory has moved toward the official operation milestones, the 21st of June 2016 when the inauguration will take place. In the mean time the current MAX-lab (MAX I, II, III) will be decommissioned at the end of 2015.

MAX IV Commissioning

The Linac commissioning started in 2014Q2 and for the next 6 months it was focused primary on the 3 GeV storage ring injection. This milestone was reached in February 2014 despite the occurrence of several incident including the replacement of the Thermionic Gun.

The 3 GeV commissioning has just started in August 2015 after 10 months of equipment installation and Sub System Test (SST) but, already, several intermediate milestones have been passed:

- 14th August, 2015: Beam injected
- 26th August, 2015: Beam stored
- 8th October, 2015: Beam stacked at 4mA

The 1.5 GeV installation is going to be installed from the end of 2015 but already SOLARIS[28] which follow the same design has proven the concept, the 1st of October, by achieving 20mA at 1.5 GeV.

Beamlines

In the mean time, SPECIES, a Max II beamline and, FEMTOMAX, a Short Pulse Facility beamline received their first photon with a standard MAX IV control system beginning of 2014. Both are being used as test bench for the standard control system that will be used in the rest of the MAX IV beamlines [2]. BIOMAX, NANOMAX, BALDER, VERITAS, HIPPIE, all 5 3GeV beamlines, have successfully passed the site acceptance tests for their Front Ends and part of their optics.

KONTROLL & IT SUPPORT

The “Kontroll & IT Support” (KITS) group is responsible for providing the development and the support of the standard IT and electronics equipment, spread along the accelerators, the beamlines and also the administration of MAX IV. The group is part of the Science division and divided into several teams organised by business fields, responsible to organise the resource the most efficiently possible while keeping included into different projects as well as the other group of MAX IV, a so-called Hard Matrix organisation.

The KITS project management is based on Lean[3] where the focus is to bring the user value incrementally and as soon as possible without technical overhead. The Control System (CS) has been delivered following the Kanban[4] and the Scrum[5] methods since 2012[1], while adapting continuously the rules to follow the pace and the nature of a synchrotron project.

Figure 1: 3 GeV installation Burn down chart between sprint 32 and 44. Sprint estimation in red and done in green, in arbitrary unit

Network and System

The networks are based on TCP/IP v4 with a physical separation between Machine, Beamlines and offices. Each of them is divided by a set of virtual networks, usually corresponding to a subsystem, to minimise the influence of broadcast equipment. The layer 2 is based on Ethernet with 2 levels of switches in order to have a maximum network distance of 4.

All the accelerator and beamlines servers & IOC are virtual machines running by a VMWare hypervisor EsXi cluster of a redundant 36 cores and 384 GB memory. The standard OS is CentOS 6[6] as many providers support the RedHat drivers. All the Tango servers run on virtual machines apart for some specific case where a local control is needed. The definition of this infrastructure profits of the advantage that many equipment are controlled via Ethernet.

Ansible [7] is used for the configuration management of all the CS computers from the OS settings to the

specific role (workstation, database or IOC) as well as the software versioning.

A Continuous Delivery process has been set up with the help of the RPM system, Jenkins a continuous integration server and Ansible. A dedicated MAX IV software toolkit, DSCONFIG, is used to reconfigure the Tango system and to track any changes in version with GIT.

Hardware

The standard motion equipment ICEPAP[8] is provided by the KITS group. Around hundreds of axes have been installed to mainly control the phase shifters, some diagnostic equipment like screens, lenses, scrapers and the diagnostic beamlines. All the beamline optics are steered through this controller except one axis. The EPU and InVacuum undulators will also be steered via ICEPAP.

The first standard Input Output Controller (IOC) have been installed in the SPECIES beamline to accurately read the encoder positions. The IOC is based on Adlink IPC, ADC, DAC and National Instrument for the counter card. This equipment is intended to be used as a General Purpose Input Output acquisition system on the experimental station of the beamlines

The IT group provides also the entire timing system[9] for the facility, based on Micro Research Finland (MRF). A special development of the Libera Brilliance Plus timing card, done by ITech, allows to use them as a compatible event receiver. The last status and development are described in another article[10].

The beamline control system will benefit to the standard equipment. The number of XBPM per beamline is estimated up to 20 per beamline, controlled by a new Electrometer[11] developed in collaboration with Alba, based on the first version deployed at Alba. The development consists of assembling 4 of the current amplifiers in the same chassis, controlled and synchronised through a backplane steered by an FPGA. This will allow synchronised measurement and the possibility to embed custom algorithm for a control loop to steer, for example, a piezo fine tuning based on current (Licence Open Hardware[12] and Open Source). In location where the signal/noise ratio is expected to allow it, a multiplexer will be used to reduce the number of amplifiers. This multiplexer is currently in development at MAX IV.

User Software

The control room workstation runs the client applications from several PC with a maximum of 8 screens each. The CS is driven with 39 GUI and monitored by 3 main web applications, the archiving & alarms database front ends and the maintenance scripts executor based on Jenkins. Additionally the operators have access to a logging system, ELOG[13] from PSI, to keep track of the commissioning progress and the changes on the system.

Among the applications several piece of software have been developed by the operators themselves[14]. Their GUI allows to monitor valves, rf structure, PSS, magnets resistances... These tools have been mainly develop with Tango JDraw[15], Taurus designer and Taurus gui[16] or Igor with the Tango binding.

The GUI proposed by KITS are mainly based on the Taurus framework that allow a rapid creation of the application without development (TaurusGUI). By this way several dedicated subsystem GUI have been developed for the commissioning of the Accelerator subsystems. The composition and the layout of the panels can be easily changed by the operators.

In the overall the initial specification of the accelerator control system allowed the reuse of widgets, panels and applications coming from the ALBA Synchrotron. The best example is the VACCA[17] application for the monitoring of the 3 GeV storage ring vacuum subsystem and also the beamlines.

Some requirement could not be fulfilled with the standard framework. This is the case of the Synoptic application[18], showing the logical representation of the system like a map and the State Grid application, showing the states of the control system by a reduced Subsystem by Location matrix. These applications make use of the web technologies.

Middleware

On the back end side the Tango control system version 8[19] is used as a middleware. For each type of equipment KITS develops the Tango device, software process to establish the communication with the hardware. In some case the drivers software have been contracted within a framework agreement with the manufacturers (Scandinova RF modulator[20], Libera Single Pass e and Brilliance Plus from ITech[21]) who have developed a compatible Tango server.

Additionally MAX IV received a software API from different collaborators and manufacturers. Budker Institut have provided a complete suite of software to control and set up their pulsed power supply via a web gateway[18] and Solaris has developed the Tango Server integration. Danfysik[22] and Itest[23] have provided a C++ libraries for their respective power supplies. In total 90 different classes of devices, mainly written in python, compose the catalogue of supported hardware and services for the MAXIV CS. For example on the accelerator the control system represents:

- 106 hosts
- 1187 server instances
- 7921 devices
- 287378 control points
- 132833 attributes
- 83735 commands

High Level Software

Parts of the control system can now be steered in the units of interest to the user, by putting a higher layer of intelligence on top of the minimal hardware control. For example, the magnets of the accelerator can be steered by magnetic field, via software on top of the power supply devices that interpolate the current-field calibration data provided by the manufacturer. The operators use Matlab high level scripts to set the required fields. The physical magnets are connected such that one power supply may control several magnets in series. An intermediate Tango device, the magnet-circuit, uses current-field calibration data that are an average of all the magnets on that circuit. This allows the operators to set an average field (converted to a single current set point on the power supply) but each magnet device in the circuit reports its own fields based on its individual calibration. Additionally, some magnets have a trim coils with independent power supplies that can be configured in different modes selected through a switch board (corrector, quadrupole, sextupole). The magnet Tango device must report the state of all its dependencies; the main and trim coil power supplies, the switch board device, temperature interlocks. The total field is also reported as a function of the main and trim circuits. For the operator the circuit device propose more features like the cycling and a redundant software interlock by monitoring the coil resistance.

Scientific Software

Matlab and the Matlab Middle Layer (MML) [24] have been the primary choice to run the scientific software on the accelerator thankful to the Tango Matlab binding[25]. The operators can easily program scripts and applications while reducing the lead time between requirement and operation. The MML is a collection of application to monitor and steer a Synchrotron. This software has been develop for the control of SLAC and extended by several facilities world-wide.

Data Management

The user of MAX IV will access a High Performance Computing (HPC) to run the off line analysis on their data through a remote CentOS desktop solution, ThinLinc[27], running the application in seamless mode from a native OS node (no emulation). A high performance storage system GPFS/InfiniBand will be installed next year.

The current user data policy is provided for giving the ownership to the users and for keeping the data during the next following 3 months after the experimentation. The HDF5 format and Nexus when applicable has been defined as the standard format for the data storage, and the control system component like Sardana[31] or the Fast Data Archiver[26] have proved their compatibility and performance.

All the IT systems at MAX IV will enforce a security at 2 factors authentication, One Time Password foresee. The

ability to connect through different ID providers like the Umbrella project is also part of the expectation. In this context MAX IV leverages the collaboration with the partners like the Lund University[28] and especially with LUNARC [29].

The Digital User Office system (PSI version adapted to our need) has been successfully tested at the current MAXLAB facility. Some experimentation has been done for the data catalogue with ISpyB[30] on one MX beamline. There is a plan to extend this application to a more general Laboratory Information Management System (LIMS) i.e to others fields than MX.

LESSONS LEARNED

Sharing Technology

A large effort was done by the beamline workgroups to use identical equipment where possible, saving by consequence the resource in development. The same strategy was applied for the storage rings where more than 80% of the equipments are reused from the Linac.

The CS team had to integrate a majority of “off the shelf” equipments. Although the level of integration was simply defined by having an Ethernet connection and an API, the choice the software API was longly discuss during the procurement with the supplier. This has paid off as several of the company sold their equipment along with Tango device and by consequence bringing Tango in the industrial scene.

Finally MAX IV benefits a lot of the experience and collaborations with other facilities. The reused software, like Sardana, reduce the pressure on the resources.

Agile and Lean

Lean give definitively the guideline for managing the MAX IV project by:

- keeping focus on the priority
- working on what is known
- bringing the user value as soon as possible and get from them a feedback on the progress
- avoiding spending resource on unused programs

The team was able to adapt quickly the organisation from SCRUM with 2 weeks iteration for the development phase to KANBAN during the 3 GeV commissioning phase to face the flow of operational issues as fast as possible. The Just In Time leads us to some trouble during the Linac installation because of the late delivery of the equipment. The simulation was not an option as it doesn't brings any value for the user representing only a perfect system. We learned at the opposite that the automatic test help to deal with this situation by securing the known part, the user interface.

The Agile method helped to handle quickly the features discovered during the testing phase. Together with the product owner the focus of the SST was changed

regarding the estimation of the sprint planning meeting to secure more the low level of the CS than the GUI. The daily standup meeting help to improve the communication within the team as well as the sprint planning meeting with the product owner, stakeholders.

Organisation: Conway's Law

The architecture of the system is the reflect of the company organisation. Since the MAC 2014Q2 the organisation of the project has changed to improve the communication channels with all the subsystems. Each one of the control team member is the contact person to one or several other subsystem like magnet, vacuum, PSS... A product owner, as defined by Scrum, has been settled to coordinate the overall requirement and make the priority between the hundreds of request, in synchronisation with the Scrum master. This organisation helped to be more focused and efficient on the most valuable features for the users.

In 2014Q4, a similar approach was defined for the beamlines projects. But in 2015Q1 a workshop organised by the beamline staff and the CS team revealed that the organisation should follow the technical structure instead of the company organisation. The constraint of resource would benefit on the following up of the common beamline components (monochromator, mirrors, front end, undulator...) whereas the management per beamline would cover the specific beamline requirements.

Test

The CS has make profit of the current MAX-lab Laboratory to test the system and from the operators to report an early feedback. But the Linac was a new installation involving the entire organisation. Many new issues were discovered during the installation and the start of the commissioning that the focus stayed on the basic control. For example the H/V correctors got inverted along with the polarity of the power supply or a lack of the robustness that keeping loosing the communication.

For the 3 GeV a large part of the project was spent on the subsystems tests. The goal was to deliver the system ready for the commissioning with the fewest experienced defects. The SST helped to discover the discrepancy in the connection chain. For example the steering and the protection system of every single magnet has been all tested from the power supply to the report of the correct field of the magnet on the synoptic GUI.

The configuration was indeed much more complex as it cover not only the hardware level of control but also the GUI. So, decided early in the 3 GeV planning, all subsystem had to include the CS in their test suites. The tests included the access to the functionalities but also the performance and the quality of the responses. The improvement in the configuration management allowed a very fast reconfiguration without regression for all the different subsystem.

The immediate results noticed by the operators is that they never experienced the same problem than the linac at the same phase. Only with the new 3GeV specific equipment that could not be fully tested causes trouble during the commissioning. The time and resource constraints to test more 'on the bench' the BPM as the accelerator could not be run without beam before to start the commissioning. Many false-positive alarms consider as counter productive for the commissioning were quickly disabled thanks to the high coverage of the configuration management.

Ethernet Based

MAX IV choose to participate to the development of a new Libera Brilliance Plus with the risk to use the commissioning time. But the new model simplify the integration to the timing system. The chosen architecture bring the advantage to be IOC free by relying on the Ethernet network for the primary CS. MAXIV learned a lot about industrial Ethernet integration. Even the PSS rely on the Ethernet switch it means more pressure on the reliability.

User Experience

The User eXperience (UX) has to be adapted to the culture and the context. Tango give more structure and standard compared to a home made CS. The CS representation looks like very complex but, thankful to the naming convention, very easy to navigate and to integrate new equipment. However the new comers may find difficult to deal with the control system because its complexity is still high. The heavy use of Matlab and command line, compared to the previous accelerator, give more flexibility for the experimental part of the commissioning. The user reported that the applications like the State Grid could have been helpful during the SST and especially for the Linac.

A progress has to be done on the integration of the recovery of the accelerator state. Hopefully more sequence and automation will progressively tend to push the functionalities to the GUI to have a better and simpler interface for the operators. On the other hand the Linac did not use too much scripts and leads to the development of the Synoptic GUI. The SPECIES beamline, as well, where a specific acquisition GUI has been develop to simplify the interact of their Users.

ACKNOWLEDGEMENT

The authors would like to thank the whole of the Controls and IT Group (KITs) and the Accelerator and Beamline Scientists, at the Max IV Laboratory, without the collaboration of which this work would not have been possible as well as:

- ESRF for TANGO, ICEPAP, MXCUBE
- ALBA with all the python software Sardana and Taurus, icepap, electrometer
- SOLARIS for sharing the experience and devices
- SOLEIL for the pulsed magnet, the nanoprobe, the wiggler, MxCube Web
- ESS, ELI, DESY by sharing the experience.

Abstract

We have designed and upgraded the accelerator control system for SuperKEKB, the next generation B-factory experiment in Japan. The SuperKEKB control system is based on the features of the KEKB control system, while additional technologies have been implemented. In this paper, we report the construction status of the SuperKEKB accelerator control system.

INTRODUCTION

SuperKEKB is the upgrade of the KEKB asymmetric energy electron-positron collider for the next generation B-factory experiment in Japan [1]. The designed luminosity is to achieve a 40-times higher luminosity than the world record by KEKB. The KEKB operation finished in 2010 June to start the SuperKEKB accelerator construction. Currently the construction is in the final stage to prepare for the 1st operation in 2016 Feb. Here the accelerator operation will be performed in three stages, Phase 1, 2, and 3. The Phase 1 is for the vacuum scrubbing and basic machine tuning, and is the operation without the final focusing magnet system (QCS) nor the BelleII detector. After the Phase 1 operation, there will be Phase 2 and 3 operations with QCS and BelleII without (Phase 2) or with (Phase 3) the vertex detector.

The KEKB control system was based on EPICS (Experimental Physics and Industrial Control System) [2] at the equipment layer and scripting languages at the operation layer. The SuperKEKB control system continues to employ those features, while we implement additional technologies for the successful operation at such a high luminosity.

We have developed the interface modules to control thousands magnet power supplies, and introduce the EPICS embedded PLC, where EPICS runs on a CPU module. In the timing system, the new configuration for positron beams is required. The faster response abort trigger system has been developed. For the stable status monitoring, we have introduced the new alarm system based on CSS (Control System Studio) [3]. For Phase 2 and beyond, we have developed the new data archiving system based on CSS. The new VME-based FPGA module is also developed.

This paper describes the design and status of the SuperKEKB accelerator control system.

[#]masako.iwasaki@kek.jp

HARDWARE INTERFACE FOR SuperKEKB

For KEKB and SuperKEKB, EPICS is used as the main software to control the accelerator at the equipment layer. The EPICS framework consists of the Operator Interfaces (OPIs) and the Input/Output Controllers (IOCs). In KEKB, our system was constructed with the EPICS base version 3.13. For SuperKEKB, we're going to update to the version 3.14, however there still remain IOCs which are based on the EPICS base v3.13. For the operation layer, several script language of SAD script, python are used.

In KEKB, VME single board computers with VxWorks are mainly used as IOCs. For SuperKEKB, as well as the VME/VxWorks, the PLC (programmable logic controller) with a CPU module where Linux is running, and the Linux PC are also used as IOCs.

Figure 1 shows the picture of the PLC modules for the beam mask controller. In the CPU module (Yokogawa F3RP61), Linux is running, and we install EPICS into the CPU module to control the PLC. For SuperKEKB, the F3RP61 module is used to control the many devices of, for example, the vacuum system, LLRF, the automatic calibration subsystem of the large-type-magnet power supply, and beam collimators [4].

Figure 1: Picture of the PLC modules for the beam collimator controller.

There are many kinds of fieldbus in SuperKEKB accelerator components, such as Ethernet, GP-IB, serial, VXI/MXI for BPM, ARCNET for magnet power supply, and CAMAC. For the magnet-power-supply control, we have developed the PSICM (Power Supply Interface

Controller Module) for KEKB. In SuperKEKB, significant number power supplies have been newly installed, and we have upgraded the PSICM [5], which is fully backward compatible to the previous PSICM.

Figure 2: The upgraded PSICM (Power Supply Interface Controller Module), used for the magnet power supply control, for SuperKEKB.

Figure 2 shows the picture of the upgraded PSICM for SuperKEKB. The new PSICM has features of the faster data transfer rate of 10Mbps or 5Mbps in addition to the 2.5Mbps of KEKB, 32-bit data handling to support the 24, 20, or 18-bit resolution DAC (the previous PSICM supports 16-bit only), and redundant timing-signal inputs. For the Phase 1 operation, we use both old and new PSICM due to the budget limitation, and 426 new PSICM (out of the 2162 magnet power supplies in LER and HER) have been installed.

DATA ARCHIVING SYSTEM

In KEKB, we have used KEKBLog as a data archiving system. In SuperKEKB, we continue to use the KEKBLog which is the file based logging system, as a primary data archiving system. In addition, the new data archiving system based on the CSS [3] Archiver is also developed. CSS is originally developed at DESY, and has many general software components for the device control. CSS-based Archiver is one of the CSS tools, which collects data using the EPICS Channel Access protocol, and stores the data to the backend relational database system. Here we use PostgreSQL for the database system.

The database can be directly accessed with CSS. We have also developed the data browser program which directly accesses the database, based on the ROOT [6]. ROOT is the software framework based on C++ developed at CERN, and is used by many experiments in high-energy physics, astrophysics, etc. User's PC with CSS or the ROOT based browser can remotely access to the database for the real-time, historical, or trend data monitoring.

Currently, the CSS Archiver with the PostgreSQL backend database is running on our system. It collects the

vacuum system data and the QCS cryogenic data, and works without problem so far.

NEW ALARM SYSTEM

In KEKB, we used SAD based alarm system. For SuperKEKB, we have constructed the new alarm system based on the CSS BEAST alarm handler software [7]. The alarm system monitors the severity of EPICS records, and updates the database which shows the alarm status of the monitored EPICS records. The system also uses the other database for the alarm history logging. We use PostgreSQL for both databases. Figure 3 shows the schematic view of the alarm system.

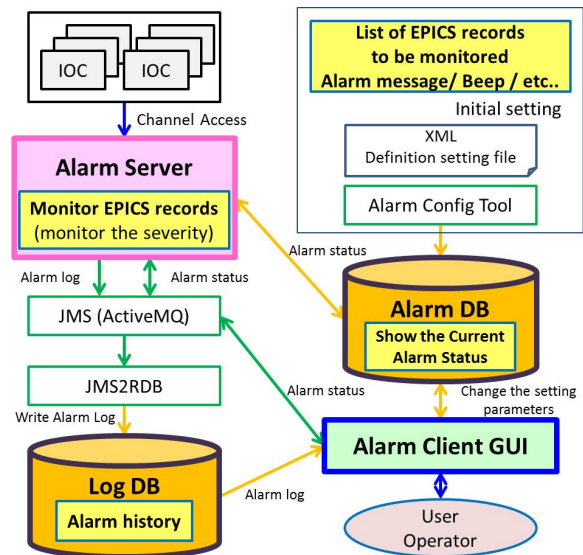

Figure 3: Schematic view of the new alarm system based on the CSS BEAST alarm handler software.

Though the CSS alarm system is already used in many accelerators, the evaluation test is important to ensure the new alarm system can stably operate under the SuperKEKB environment of several 10 thousands alarm points (~25,000 in KEKB). We did load tests using dummy records, and confirm the CSS alarm system works well under such huge number of monitoring points. We have also prepared the user interface software tools based on Python for the alarm system. Currently, the CSS alarm system is running on our system, and monitors the vacuum system data without any problem so far.

TIMING SYSTEM FOR SuperKEKB

In SuperKEKB, we construct the positron Damping Ring (DR) to produce the lower emittance beams. The KEKB timing system is based on a frequency divider/multiply and a digital delay technique. Since the KEKB ring RF (508.887MHz) is not a divisor of the Linac RF (2856 MHz), both of the KEKB ring and the Linac frequencies are locked with a common divisor frequency (10.385 MHz = 96ns cycle), which determines the injection timing. For the SuperKEKB positron injection, the injection timing of 96ns cycle for KEKB

becomes 11.34 ms, because of the properties of DR, if we use the similar configuration as KEKB.

Instead of this, we have developed the new timing system, which generates the injection timing signals [8]. Figure 4 shows the layout of the event timing system located at the Linac main trigger station for the SuperKEKB positron injection. The system consists with two layers of event generators (EVGs). As EVG detects

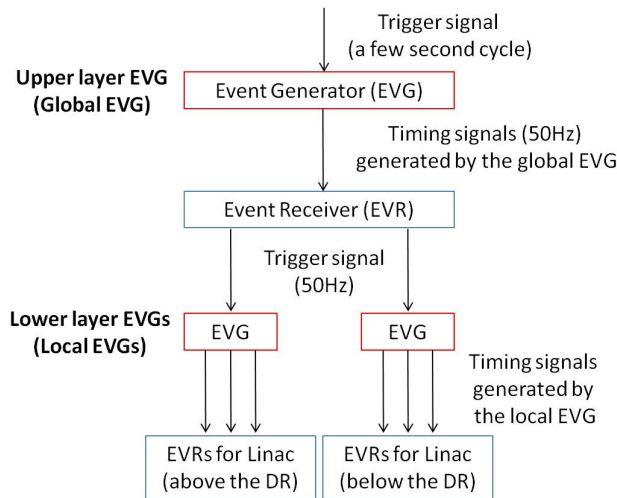

Figure 4: Layout of the event timing system at the Linac main trigger station for SuperKEKB positron injections.

the external trigger, EVG generates and sends the timing signal to the event receivers (EVRs). The trigger for the upper layer EVG (global EVG) is a coincidence between 50Hz and 11.34 ms cycle, which corresponds to a few second cycle. The global EVG sends the 50Hz timing signal for EVR. The EVR outputs 50Hz trigger signals to the lower layer EVGs (local EVGs). The local EVG for the Linac below the DR generates the timing signals, in taking account for the proper positron injections.

For SuperKEKB, we have developed the new Event modules, which are utilized to deliver triggers to the DR beam monitors. Figure 5 is a picture of the new Event Generator, VME-EVO, having 2 inputs and 8 outputs. The details of the VME-EVO module as well as the new Event Receiver VME-EVE, are described in Ref. [8]. The triggers for 84 DR beam position monitors will be managed with 5 new Event modules.

Figure 5: The new Event Generator, VME-EVO.

ABORT TRIGGER SYSTEM

We have developed the faster response abort trigger system for SuperKEKB [9]. Figure 6 shows the layout of the abort trigger system.

There are over 130 points which monitor the beam status and issue the abort signal. The abort signal is E/O converted, and received by the VME abort modules located at the local control rooms. 20 local abort modules are connected to the abort module in the SuperKEKB control room, which gathers the local abort module signals, takes OR of them, and issues the trigger signal to the abort kicker.

In KEKB, these modules are connected with wires, and low pass filters which caused time delay of $\sim 100\mu\text{s}$ were necessary for the noise reduction. For SuperKEKB, we have adopted the E/O conversion, replaced the wires with the optical cables to transfer the signal, and removed the low pass filters from the system. The total abort trigger system response time is improved to 20 μs .

Based on the feasibility tests with a prototype module, the new module design has been improved and fixed. The new system has been partially installed and has worked with the previous system.

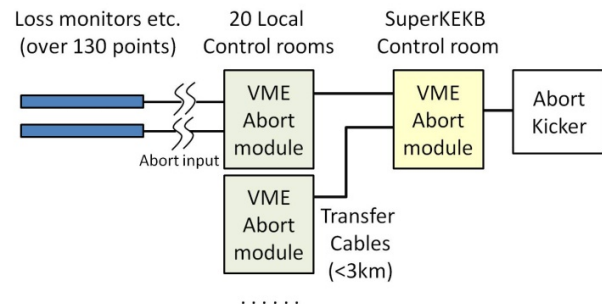

Figure 6: Layout of the SuperKEKB abort trigger system.

NEW SIGNAL TRANSFER SCHEME WITH FPGA BOARD

We have developed the new signal transfer scheme for the communication between SuperKEKB and the BelleII detector, e.g. injection control. In KEKB, we transfer E/O converted signals via $\sim 2\text{km}$ length optical cables for the accelerator and detector communication. In SuperKEKB, the number of signals to be transferred increases, while the above signal transfer scheme requires the same number optical cables as the signals to be transferred.

To save the optical cable, we have developed the new signal transfer scheme using FPGA, based on digital sampling, parallel to serial, and serial to parallel conversions, shown in Figure 7. We use SFP(+) for the optical signal interface. The number of the optical cables in this system is reduced to two, for incoming and outgoing signals, as shown in Figure 8. Since SFP has the signal transfer bandwidth of 1 Gbps ($\sim 5\text{ Gbps}$ for SFP+), the digital sampling rate of higher than MHz, which is the higher rate than the beam revolution frequency of 100 kHz, is possible in this scheme.

Figure 7: Injection-control signal transfer scheme for SuperKEKB.

In this scheme, we use a general purpose VME module with an FMC (FPGA Mezzanine Card) interface which is developed for Spring-8 [10], with a TTL-NIM-IO mezzanine card for NIM level and LVTTTL signal IOs which is developed for SuperKEKB [11].

We also apply the combination of the VME module with a TTL-NIM-IO mezzanine card for several systems, the beam gate open/close request signal transfer between SuperKEKB and injector Linac, the software abort request system, the quench detection system for QCS, etc. The first processing of the VME module with an FMC and the TTL-NIM-IO mezzanine card was done in 2014-2015, and several evaluation tests are carried out [12].

Both the VME module and the TTL-NIM-IO mezzanine card are developed as a project of Open-It (Open Source Consortium of Instrumentation [13]).

Figure 8: Injection-control signal transfer methods for KEKB and SuperKEKB.

RENOVATION OF THE CONTROL AND COMPUTING ROOMS

We did renovation of the control and the computing rooms in 2013-2014 for SuperKEKB. We removed old panel-board cabinets and server racks from the computing room. We installed new server racks and new power supply modules which are located in the new server racks. We also installed the new consoles into the SuperKEKB control room.

SUMMARY

We have improved the accelerator control system for SuperKEKB operations under the 40-times higher luminosity than the world record achieved by KEKB. Based on the KEKB accelerator control system, we have implemented the new features of the improved control hardware and software tools and interfaces, the new data archiving system, the new alarm system, the new timing system, the faster response abort trigger system, and the new signal transfer scheme based on FPGA. We have also renovated the computing and main control rooms and have been preparing for the SuperKEKB Phase 1 operation in 2016 Feb.

ACKNOWLEDGMENT

We thank T. Abe (Spring-8), M. Ikeno and M. Shoji (KEK) on the VME-FPGA module development, for their technical supports as a project of Open-It.

COMPREHENSIVE FILL PATTERN CONTROL ENGINE: KEY TO TOP-UP OPERATION QUALITY*

T. Birke[†], F. Falkenstern, R. Müller, A. Schälicke

Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany

Abstract

At the light source BESSY II numerous experiments as well as machine development studies benefit from a very flexible and stable fill pattern. The fill pattern control engine is based on a state machine that controls the full chain from gun timing, linac pulse trains, injection and extraction elements as well as next shot predictions allowing triggering the next user experiment DAQ cycle. Architecture and interplay of the software components as well as implemented functionality with respect to hardware control, performance surveillance, reasoning of next actions and radiation safety requirements are described.

INTRODUCTION

After starting user operation in 1998, the 3rd generation light source BESSY II provided users with synchrotron radiation in decaying beam mode with three injections per day for 14 years. During this time BESSY II offered specific support for time-resolved experiments, pioneered low- α mode with coherent THz-radiation and ps-pulses and established the most advanced femtosecond slicing [1] endstation with 100 fs pulses. A purity controlled high current camshaft bunch in the ion clearing gap enables pump/probe experiments as well as pseudo singlebunch experiments at full intensity with a mechanical chopper.

Switching to top-up mode [2] extended these possibilities with a thermally stabilized machine and higher average intensity. Today, more pseudo single bunch experiments with reduced intensity are possible by using pulse picking by resonant excitation (PPRE) [3] with a selected bunch close to the end of the gap.

All these specific bunches have to be topped up with minimal variation to programmable intensities.

CONSTRAINTS

Radiation Safety

Based on analysis of facility properties and various malfunction scenarios, several restrictions and modifications have been set up to guarantee minimized losses and to make all sources of possible damages measurable and hence allow beamshutters to be kept open during injections:

- Injection efficiency must be >60% for every shot.
- Average injection efficiency must be >90% over 4 h-blocks.
- Maximum allowed injection frequency is 0.1 Hz.

- Maximum increase in stored current per injection shot: 2 mA.
- Minimum current in booster. For reliable and accurate efficiency measurement, a minimum current of 0.3 mA during an injection is mandatory.
- Minimum and maximum current of stored beam together with a corresponding minimum lifetime. To control and limit the normal average loss, a limit of max. 60 mA/h has been defined. The nominal limits are 200 mA-300 mA stored beam with a minimum lifetime of 5 h.

Top-Up Interlocks

Two separate systems are responsible for efficiency measurement and interlock. During top-up operation, both have to permanently check all relevant parameters for compliance with the top-up radiation protection restrictions and approve top-up operation to continue. The efficiency interlock systems are part of the radiation protection system.

Any violation of any of the restrictions will activate the top-up interlock system and pause or terminate top-up operation while beamshutters are free to open. Top-up injections are continued as soon as all top-up conditions are restored. This may happen automatically (e.g. lifetime temporarily below limit) or may have to be accomplished by operations staff after closing beamshutters (e.g. last injection efficiency below 60%).

The fill pattern control engine operates in both top-up user-runs (beamshutters unlocked and free to open) and commissioning or machine development runs (beamshutters closed and locked). The latter is possible even without switching interlock systems to top-up mode. So the strict limitations of top-up mode are not enforced in this case and the top-up interlocks are inactive.

Injection Frequency and Timing

A proper compromise between minimizing variation in bunch currents and minimizing the number of disruptions due to injection kicker pulses had to be settled. The currently consolidated injection-scheme is, to fill a maximum of 5 bunches (reduced to e.g. 1 or 3 when filling dedicated single- or slicing-bunches) at every multibunch injection shot with the highest possible bunch currents. The decay phase between two injections currently ranges from 10 s to 200 s with an average of 120 s and every injection shot adds between 0.3 mA to 1.8 mA to the stored beam (ring current variation during top-up operation: ~0.5%).

TOP-UP SERVICE AND FILLPATTERN CONTROL ENGINE

These core automation center for top-up operation at BESSY II is the "Top-Up Service and Fillpattern Control Engine" that has been developed during tests, setup and commissioning of top-up operation mode.

It is implemented as a standard EPICS state-machine together with a corresponding realtime database hosted on a dedicated Software I/O-Controller (SoftIOC).

During runtime, this system communicates via EPICS ChannelAccess (CA) with several other I/O-controllers (IOCs).

Input Signals

State and processed data of top-up interlock systems

During top-up operation, the status of all top-up interlock systems is monitored to decide whether to continue top-up injections or to provide information about the reason of a top-up interruption. If efficiency decreases, a possible injection-free time at the beginning of the next 4h-block is indicated.

If top-up mode is not active and therefore the beamshutters are locked, it is not necessary to obey the top-up restrictions stringently. All this information has to be processed and displayed and may initiate state transitions.

Fillpattern Monitor To decide which positions and bunch combinations to fill on the next injection shot, the fill pattern monitor is the central source of information and core diagnostic components for proper top-up operation.

It is implemented using a stripline based high-performance ADC that delivers per bunch current measurement with high accuracy (up to 100 nA resolution) [4]. Delivering an accurate fill pattern measurement of bunchcurrents of all 400 possible bunches every second, it builds the foundation to decide where and how to place the next injection shot.

The fill pattern monitor needed to be reclassified when preparing of BESSY II for top-up operation. In the transition from an optional diagnostic element to an essential core system of top-up operation, it has been duplicated with a hot spare system and can be complemented with high-resolution photon counter based on an avalanche diode that produces an accurate measurement of the fill pattern every 15 s – 30 s.

Global beam current and lifetime measurement

Used to determine whether and when an injection shot is expected to be initiated.

Other inputs like the state of extraction- and injection-pulsers as well as the overall injector status from linac to booster synchrotron are monitored and evaluated to decide whether top-up injections can be carried on or not.

Controlled Elements

After an injection, the injector is switched into suspend mode by switching off the extraction trigger pulse for the

linac-gun as well as the trigger for the booster-injection-pulsers. This measure is taken to avoid activation of the septum as well as to protect the electron gun and the pulser klystrons from premature aging, because the complete injector is operated with a 1 Hz repetition rate.

When preparing for an injection, the injector is resumed, and the linac is set up to produce the determined number of pulses with the corresponding time interval in between. Currently, the number of pulses varies between 1 and 5 while the interval is typically 12 ns. This satisfies the requirements of the currently used fill pattern (induced by the timing granularity of slicing laser systems), but may change anytime.

When all preconditions are met and an injection shot is imminent, the timing system is configured to place the injected bunches at the selected position in the storage ring and the global injection trigger is switched on.

Program Structure

The main program consists of three independent parts:

The finite state machine implements the core engine that controls and reflects the state of the top-up system and the storage ring. It consists of five main states and some few transitional states (see Figure 1).

Combining all incoming status information from interlocks, measurements and configuration setup and performing the appropriate state transitions, the state machine provides full automation of the injection process for filling the machine from scratch as well as running BESSY II in top-up operation mode.

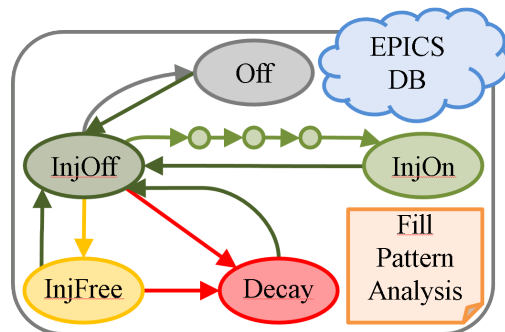

Figure 1: Simplified state diagram showing only main states and companion modules.

The fill pattern analysis asynchronously processes the measured fill pattern and decides which bunch group would be topped up with the next injection shot regardless of when it would actually happen.

This is a process that is triggered every second on incoming fill pattern measurement data. According to the current planned fill pattern, all possible positions and bunch groups to aim an injection shot at are checked, and the combination that lacks the most total current relative to the desired fill pattern is chosen.

The EPICS realtime database is the sole interface to control the state machine as well as the fill pattern analysis. It also reflects the internal status of the fill pattern control engine and holds many informational parameters for operations staff, analysis and statistics.

The advantage of using an EPICS realtime database as the sole control- and monitoring-interface to a background server process is, that all parameters, whether they are configuration or information, are provided as standard EPICS process variables (PVs) and hence integrate perfectly into the underlying control system. Other applications may access these PVs just like any other PV in the control system. They are archived and alarm-monitored and can be monitored and controlled from any control system console as well as displayed on user-information monitors and in web-based status displays.

In terms of control system infrastructure, the Top-Up Service and Fillpattern Control Engine behaves just like any other device in the BESSY II control system.

Human Machine Interface

The verbose user interface panel (see Figure 2) provides access to all configurable parameters of the control engine as well as all relevant diagnostic and interlock information and several parameters internal to the control software.

Target current and positions of all currently supported bunch-groups are configured through this interface and define the desired planned fill pattern.

A simple event/message log provides a quick overview of overall top-up operation events, and a reduced set of informational PVs like the result of the fill pattern analysis is displayed in this panel. The full set of internal status information is accessible in a separate more verbose panel.

Links to a few auxiliary software modules like injector standby/resume, linac controls and RF-knockout gap control are also provided for easy access.

The fill pattern diagram shows the current live fill pattern as well as the underlying desired fill pattern calculated from the configuring parameters. It also displays the position and scaled up shape of the latest increase in the measured fill pattern, which is the last seen injection shot. Optionally the range cleared by RF-knockout during every shot for 50 ms, to maintain a high purity of the camshaft bunch, is also displayed.

The top-up service determines some further diagnostic information that are not of immediate relevance for the top-up interlock systems, but might point to subsequent problems if not taken care of. An example is the per bunch booster current, that prevents injections on camshaft- or PPRE-bunch if it does not exceed the minimum limit.

Fillpattern Control Engine — Configuration

Development over the last three years lead to the current scheme of defining the desired fill pattern. The overall total current and four groups of bunches can be configured to match the current needs:

Multibunch fill The part of the ring that will be populated with equally filled bunches is defined by exclusion. The length and position of the ion-clearing gap are configured and hence define the multibunch fill, which can in turn be setup to have every single or every n-th bunch filled.

Camshaft bunch A single bunch at a fixed position in the purity-controlled gap. Only the current stored in this bunch can be configured. This bunch is used for standard pump/probe experiments, but also for single-bunch experiments at full rate and intensity using the phase locked MHz pulse selector [5], a chopper wheel synchronized to the circulating beam opening a 70 ns window for the light pulse at 1.25 MHz.

PPRE bunch For a different scheme of pseudo single bunch experiments, a dedicated single bunch in configurable distance, but close to the end of the gap, is filled.

Slicing bunches For femtosecond experiments, a group of three bunches, usually opposite of the camshaft bunch, are filled with higher currents than the standard multibunch bunches. These are to be sliced one at a time with a fs-laser at a 6 kHz rate.

All these four groups or any subset may be configured, defining the desired fill pattern for the next user-run.

Error Handling

Problems that may occur during top-up mode are divided into five classes:

Top-up interlock Causes pausing or termination of top-up operation (includes full or partial beamloss).

Positioning mismatch A shot that is not appearing at the position it was targeted at may be caused by a timing failure, or a diagnostic problem. No further reliable exact positioning is possible until resolved. Immediate fallback to round-robin positioning of injection shots.

Injector failure Resulting in insufficient booster current will suspend injections for some or all bunch groups.

Depending on the actual available booster current, the fill pattern control engine may leave out any bunch-groups that could not be filled without violating the minimum booster current limit for a proper injection efficiency measurement.

I²-limit exceeded Impedance related power deposit in components scales with the sum of the squared bunch currents. To protect sensitive components, an appropriate limit is defined.

Persistent efficiency problems Since top-up interlocks are inactive during beamscrubbing, the fill pattern control engine itself will suspend injections to avoid activation of components and damages.

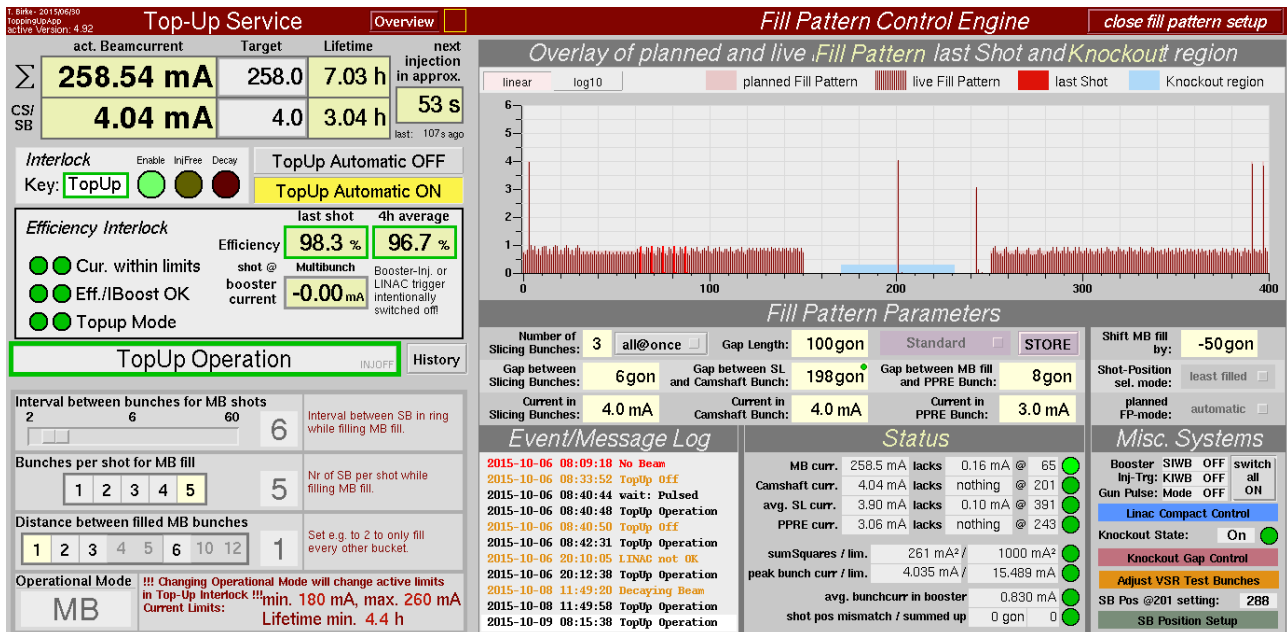

Figure 2: Top-Up Service and Fillpattern Control panel in standard multibunch hybrid mode. It contains a multibunch train, a purity controlled high current camshaft bunch in an ion clearing gap for pump/probe experiments and a mechanical pulse picking chopper, three high current bunches for femtosecond slicing and a specific bunch at the end of the gap for PPRE.

All these error conditions are handled properly by either suspending injections until the error-condition disappears or falling back into decay mode until problems are fixed manually by operations staff.

Reliable countdown

Sensitive experiments require a reliable prediction of start and end of the decay-phases between two injections.

In top-up operation mode, after each shot an estimation is made on when the next injection shot will be necessary depending on actual current and lifetime of the stored beam. Users can rely on this countdown, so even if beam-lifetime is decreasing e.g. due to insertion devices moving at low gaps, no injection is triggered before the reliable countdown has elapsed.

Fillpattern Control Engine – Next Steps

An update to the fill pattern control engine is currently in development, that has a more general approach. It will enable configuration of an arbitrary number of bunch-groups with a few general parameters:

- Affected bunches – range definition in MATLAB notation: *startpos:endpos:stepwidth*.
- Current to be stored in every bunch of this group.
- Additional flags e.g. whether the given current may be adjusted to match the desired overall target current.
- Prioritization of bunch groups.

Besides the currently supported fill patterns, this scheme will enable special fill patterns like alternating bunches with high and low current which is used as a test setup for BESSY-

VSR [6] studies, or additional bunches with varying currents (down to 5 μ A) for even shorter pulses in low- α mode.

CONCLUSION

A fully automated injection control software is absolutely essential for top-up operation with a fill pattern tailored to the users needs at BESSY II.

It has also completely replaced the manual injection procedure during low- α runs, machine- and beamline-commissioning and machine studies as well as for beam-scrubbing at high stored currents.

PID_TUNE: A PID AUTOTUNING SOFTWARE TOOL ON UNICOS CPC

R. Martí, B. Bradu, E. Blanco Vinuela, CERN, Geneva, Switzerland
L. Frutos, R. Mazaeda, C. Prada, University of Valladolid, Valladolid, Spain

Abstract

PID (Proportional, Integral and Derivative) is the most used feedback control algorithm in the process control industry. Despite its age and thanks to its simplicity in terms of deployment and its efficiency in most of industrial processes, this technique still has a bright future. The major challenge in using PID control is to find the optimal set of parameters to tune the controller. This may be a complex task as it mostly depends on the dynamics of the process being controlled. In this paper a tool able to provide the engineers a set of PID parameters in an automated way is proposed. The tool offers auto-tuning methods, both in open and close loop, and others can be added as it is designed to be flexible. The tool is fully integrated in the framework UNICOS (CERN Standard Control framework) and can be used to tune multiple controllers at the same time, directly from the supervision layer.

INTRODUCTION

The largest majority of controllers found at the regulatory layer in the process industry are of PID (Proportional, Integral and Derivative) type. At CERN, around 4900 PID controllers are employed on the LHC cryogenic control system, 870 are employed on cooling and ventilation installations. In total, more than 8000 PID controllers are used at CERN in control systems based on the UNICOS (Unified Industrial Control System) framework [1]. All these controllers are implemented in more than 300 different PLCs (Programmable Logic Controller). Therefore, a tool to automatically tune the PID parameters would be a valuable asset in terms of controller robustness and hence in improving uptime and operation of the CERN industrial plants.

Although the PID controller has only three parameters, it is not straight forward, without a systematic procedure, to find suitable parameters. The main goal of this work is to provide an auto-tuning tool where different methods are available. The initial implemented methods were selected to cope with real industrial process scenarios. Two main features are searched: easiness of use, to allow operators to perform the task, and flexibility to extend the tool with new methods to cope with complex processes.

The article is organised as follows: first, the real implementation of the tool is depicted, second, the different tuning methods included in the tool are described including their suitability on different processes. Then, real industrial use cases with different auto-tuning methods employed are depicted along with a performance comparison between them. Finally, the paper concludes with the most important ideas and future work.

ISBN 978-3-95450-148-9

TOOL IMPLEMENTATION

The PID structure taken into consideration to design the auto-tuning tool is the ISA (International Society of Automation) version used in the UNICOS framework. The control law can be seen in the formula (1)

$$K_c \cdot (e(t) + \frac{1}{T_i} \cdot \int e(t)dt + T_d \cdot \frac{d}{dt}e(t)) \quad (1)$$

The tool is fully integrated in the UNICOS framework at the supervision layer, the WinCC OA SCADA (Supervisory Control and Data Acquisition) from SIEMENS. It has been implemented in the WinCC OA control scripting language based on ANSI-C. The PID algorithm remains untouched in the PLC (control layer) and only its parameters are set once the tuning process is validated. The architecture and data flow is depicted in Figure 1.

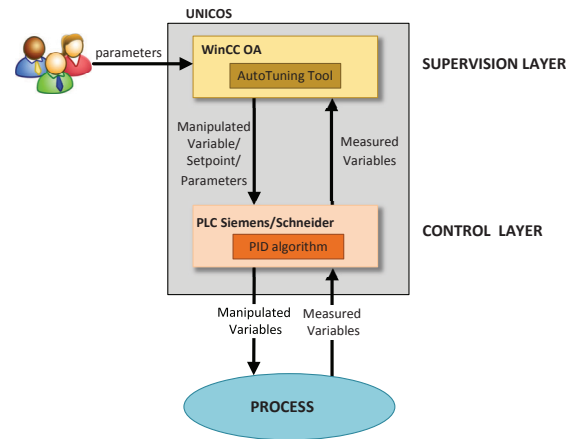

Figure 1: PID auto-tuning tool architecture.

The human interaction is made through dedicated interfaces embedded in the UNICOS controller faceplate. The user can select the method, configure its options, initiate the auto-tuning, evaluate the behaviour and ultimately set the new parameters to the controller. An example of such interface is shown in the Figure 2.

AUTOTUNING: BASIC CONCEPTS AND METHODS

The PID auto-tuning concept refers to the capability to automatically compute the parameters of a PID connected to the real plant. Many different approaches are available. This work focused on developing an auto-tuning tool, PID_TUNE, launched by the operators or the control engineers on their own initiative, performing the chosen tuning algorithm and

Figure 2: UNICOS auto-tuning user interface: Relay method.

presenting the results to the user who ultimately decides to apply them to the controller.

It is of general consensus that any skilled professional can tune a control loop better than any auto-tuning mechanism, however this task may be very time consuming. However the number of loops and the availability of experts can condition this assessment to the point that an auto-tuning tool can be of great help for the day to day operation of the plants.

The behaviour of an auto-tuning algorithm is based on what an expert would do when tuning that loop by his own. First a phase of observation, then in function of the control objectives selection of the method and finally applying the PID parameters. The first phase includes process data taking and this is done by stimulate the process by either moving the manipulated variable or the controller setpoint. Evidently this settles a first trade off of stimulating enough the process to get meaningful experimental data versus creating a process perturbation which can be fatal for the process itself. To make this feasible, several constraints must be taken into account: e.g. controlled and measured variable limitations, noise.

The selection of a method depends on the control needs which, in turn, depends on the analysis of the control problem. There is no a general rule although the methods available in the tool can cope with the majority of the processes as they are rather universal. Three methods has been included: Relay, SIMC and IFT.

Relay Method

The relay auto-tuning method was proposed to automate the Ziegler-Nichols ultimate cycling tuning method [2], where the critical gain (K_{cr}) and period (P_{cr}) are determined with a proportional-only regulator. The controller gain is gradually increased until an oscillation is obtained. The procedure concept is rather simple but difficult to auto-

mate ensuring the safety of the installation as the oscillation amplitude must be always kept under control. To overcome possible instabilities the relay incorporates a hysteresis [3].

The relay is connected in the feedback control loop instead of the PID controller (Fig. 3). It alternates the output between 2 values when the difference between the set-point and the controlled variable changes sign. This is the way it obtains a limited cycle oscillation.

Figure 3: Relay tuning.

Some practical issues must be addressed when implementing this method. First, the measurement noise may give errors in detection of peaks and zero-crossing, thus again a hysteresis is used. It is a common practise to start the method when a steady state [4], of the process is identified to facilitate the sustained oscillations although the tool includes an algorithm to automatically identify steady state [5].

The advantage of this method is the simplicity of its use. The user only has to introduce the amplitude of the hysteresis and the number of cycles to detect sustained oscillations (Fig. 2). The method fits in processes with unknown dynamics.

SIMC

Another well known group of auto-tuning methods is based on plant models [6]. Basically, two different steps compose the methodology, first a process identification phase and then the application of the tuning rules. Obviously this approach is heavily constrained by the availability of the process model.

The developed tool allows users to identify a first-order model by applying a step on the manipulated variable. In addition to this, a steady-state automatic identification algorithm has been included to fully automate the identification phase. Then the tool suggest the best parameters according to well known tabulated values.

The SIMC method was chosen due to its advantages regarding others model based techniques [7]. The main, the simplicity in terms of parameterisation: SIMC has just a single tuning parameter, the desired performance. Its selection is a trade-off between performance ("tight" control) and robustness ("smooth" control). Therefore, the operators or control engineers can easily choose what kind of response they desire in the feedback control loop. The method is applicable to stable and low order systems with not complex dynamics.

IFT: Iterative Feedback Tuning

The previous two methods have some notably drawbacks: on one side unpleasant disturbances are introduced to the process and, on the other, the need of a model of the plant. Also the algorithms need to disable the PID controller while the auto-tuning process is running. These justified the inclusion of a new method in the tool that ideally does not require the knowledge of any explicit model of the plant and its execution would not disturb much the nominal loop dynamics.

The IFT [8] is a technique inspired by the iterative parametric optimisation approach. It is entirely working in closed-loop and making random but contained perturbations in the loop to find the optimal parameters. It computes a cost function to minimise the current value of the measured value and a desired first order response.

The IFT algorithm is particularly suitable for the industrial use as it fulfils the requirements of being a model-free and closed-loop procedure which does not demand a very severe modification of the nominal conditions. The algorithm has the capability of rejecting efficiently disturbances, crucial for the regulatory control widely deployed in process industries. The IFT tuning algorithm included in the tool has been developed to ease the use of the IFT method, low parameterisation but still offers a minimum set of practical safeguards constraining the freedom of the underlying algorithm during the tuning procedure.

CASE STUDIES

In order to commission and validate the auto-tuning tool together with its algorithms, the tool was deployed in the LHC (Large Hadron Collider) cryogenics simulator. The simulator provides the same UNICOS engineering environment (SCADA and PLCs) as in any production system but connected to a simulated process. The second phase was to deploy it to a real case with complex dynamics, a cooling plant of the LHC.

Auto-tuning on the LHC Cryogenic Simulator

This real-time simulator is able to imitate the real transients of the LHC cryogenics and it embeds a identical version of the real control system. A flow control loop has been selected as candidate to perform the auto-tuning. This PI based control loop regulates the amount of gaseous helium circulating in LHC to maintain the thermal shielding of superconducting magnets around 80 K. It was originally too sluggish, generating flow oscillations and overshoots when disturbed by the circuit pressure changes.

All three methods (Relay, SIMC and IFT) were applied on this control loop to find its PI parameters. The parameters are compared with the original ones (Table 1).

A significant pressure disturbance was applied in the simulator ($t = 2$ min) in order to compare the controller performance with the different parameter sets (Figure 4). The three auto-tuning parameter sets are resembling and then

Table 1: Auto-tuning Results on the Cryogenic Simulator

Tuning	K_c	T_i	Overshoot	Oscillation
Original	1	200	22 %	6 %
Relay	9	12	0.5 %	1 %
SIMC	4.5	7	1 %	1.3 %
IFT	13	11	0.5 %	0.5 %

provide a controller similar response, but in any case faster and more stable than the original one.

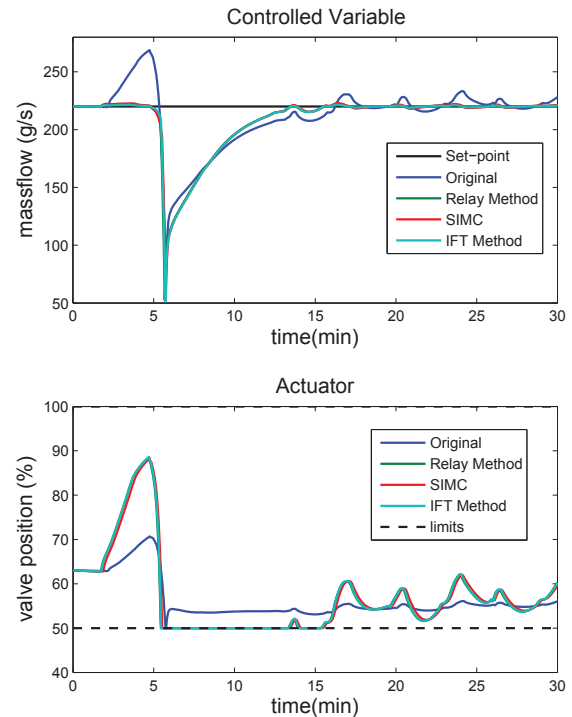

Figure 4: PI controllers performance in simulation.

Auto-tuning on a LHC Cooling Plant

As the first real test on a production system, the tool was used on a chilled water production unit providing water at 5 °C for LHC. The operation team observed instabilities on the condenser output temperature of the chiller at 25 °C. The tuning of the associated PI controller was troublesome because this process is always disturbed and unstable due to a noticeable delay time. The temperature deviation to operate the chiller should be less than 1 °C and indeed it was oscillating by around 2 °C with the valve moving wildly between 0 % and 100 %. The relay method was the first method used. This allowed to stabilise the temperature with a reasonable control effort on the valve. However there were important disturbances all the time, so the temperature was still oscillating too much (Fig. 5). Then, an auto-tuning in close loop using the IFT method was applied as disturbance

rejection is one of its features. The results were satisfactory regarding the operation requirements (Fig. 6).

The different tuning parameters found are compared in Table 2 with the corresponding oscillations measured on the controlled temperature ($|\Delta y|$) and on the valve ($|\Delta u|$).

Figure 5: Relay method results on a LHC cooling unit.

Table 2: Auto-tuning Results on a LHC Cooling Unit.

Tuning	K_c	T_i	$ \Delta y $	$ \Delta u $
Original	8	0.5	2 °C	100 %
Relay	8.3	311	1.3 °C	10 %
IFT	50.9	5666	0.5 °C	20 %

CONCLUSIONS

An auto-tuning tool for PID controllers is presented in this paper. It is fully integrated, at the supervision level, in the CERN control framework (UNICOS). The tool does not imply any PLC control logic modification. This tool allows operators and control engineers to apply different auto-tuning methods on the regulation loops depending on the process and on the operational constraints. Three initial methods have been implemented and tested: Relay, SIMC and IFT. The tool has been validated in a real scale simulator and then applied in a production system, a LHC cooling plant. It has demonstrated its usability and its performance where the proposed control loops have been properly tuned. In the coming months, this auto-tuning tool will be deployed on all CERN control systems using UNICOS. The tool is

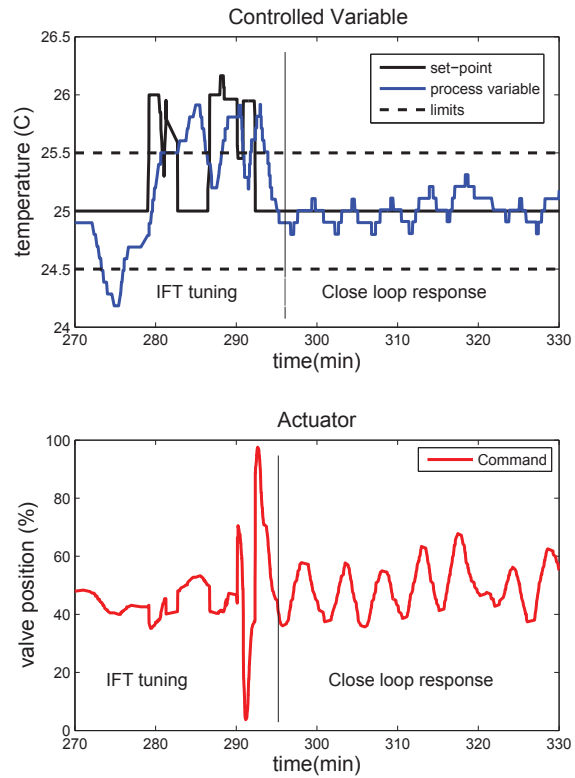

Figure 6: IFT method results on a LHC cooling unit.

designed in a flexible and open way so in the future, other methods could be easily added.

AUTOMATIC FEL OPTIMIZATION AT FERMI

G. Gaio, M. Lonza, Elettra Sincrotrone Trieste, Trieste, Italy

Abstract

FERMI is a seeded Free Electron Laser (FEL) located in Trieste, Italy. The machine setup and optimization is a non-trivial problem due to the high sensitivity of the FEL process to several machine parameters. In particular, the electron bunch trajectory and its spatial overlap with the seed laser beam represent one of the key aspects to optimize and then preserve during machine operation.

In order to ease the FEL tuning and to guarantee a long term stability of the photon beam, a software process integrated into the feedback systems performs automatic trajectory optimization of both the seed laser and the electron beams. The algorithm implementation, the results and the operational issues are presented.

INTRODUCTION

The FERMI machine setup is a non-trivial task. Although a deeper knowledge of FEL mechanisms in parallel with new diagnostic tools have reduced the time spent for machine tuning, new and more challenging requests coming from the users community have significantly increased the complexity of the accelerator setup and its operation during the experiments.

One of the priorities is the preservation of the FEL radiation quality in the long term. Over the years a number of feedback loops have been added in order to cope with subsystem instabilities [1]. However, even thermal drifts of only a few hundredths of degrees or requested changes of the machine working point tend to move the machine away from the optimum in terms of intensity, stability and spectral radiation purity.

In order to tune the machine for its best performance, a well established sequence of operations has to be carried out. At first, the photon-injector and seed laser systems have to be prepared, transversal and longitudinal electron beam dynamics in the linear accelerator (linac) have to be tuned, and then the FEL tuning process along one of the two undulator chains has to be performed. At the end, the photon beam is driven into the photon beam transport system and aligned in the experimental chamber. Before each users beam time one day is usually dedicated to machine preparation and tuning but, in case of non-standard experiments, up to five days have to be reserved for this task.

The tuning process which is performed by the physicists, in most of the cases consists of a number of manual or automatic scans of actuators versus machine variables, leaving to the physicist the final duty to set actuator to the optimum value. Instead, the optics matching, which imposes the design values of the Twiss functions to the electron beam [2], is completely automatic. There are two main reasons why the optics tuning is performed using the matching program: the first is that the problem is difficult to be managed (up to 6

dimensions in the linac optics). The second reason is that the model in terms of relations between quadrupole strengths and Twiss functions is well known. The availability of a system model reduces the optimization problem to a task that a proper algorithm quickly solves.

However, a system model cannot be always taken for granted. During the commissioning of a new system (e.g. a particle accelerator), the difference of the real system from the model could drive the model based optimization to frustrating results. In order to obtain a correct system model, software based simulators with adaptive and diagnostic capabilities have been developed and are currently supporting operations in several particle accelerators.

Although this kind of software could be applied to the entire FEL from the linac gun to the photon beam in the experimental chamber [3], its usage as an online tool has still to come. In particular, the multiplicity of the systems involved (photo-injector and seed laser beams, electron beam and FEL beam transport) and their nonlinearity have limited the adoption of these tools to only single well known subsystems, leaving to the manual intervention the rest of the machine preparation.

However, the manual tuning, which is a complex task, tends to be inefficient because the expertise of the personnel involved in machine operations is not homogeneous.

FEL PROCESS

The FERMI FEL design is based on an external seeding scheme. Two undulator chains, FEL-1 and FEL-2 operated one at a time, provide radiation in two different ranges, 100-20nm and 20nm-4nm respectively. In the modulator (first undulator) of both undulator chains, an external seeding laser in a tuneable range of 228-265 nm, overlaps in time and space the electron bunch provided by the linac. The resultant energy modulation of the electron bunch is then converted into charge density modulation by a chromatic dispersive section following the modulator. The electron bunch then passes through a series of undulators tuned in magnetic field so that coherent FEL radiation is emitted at one of the harmonics of the seed laser.

In FEL-2 the process is made in two stages. The radiation emitted by the first stage, that is similar to FEL-1, is used as seed in the second stage. In this way the seed laser wavelength is downshifted twice reaching shorter wavelengths.

The undulators and the seed laser are the most important devices involved in the tuning process. A software supervisor [4] taking into account the relations between the undulator magnetic strength, the electron beam energy and the seed laser wavelength, sets the

undulator gaps and the seed laser energy according to the user request in terms of FEL polarization and wavelength.

Other two key variables, the dispersive magnet strength and the seed laser power, are optimized by performing scans versus the FEL spectrum. Whereas the mentioned variables are changed according to the requested FEL parameters (power, wavelength and bandwidth), other variables have to be kept constant during this process. In particular, controlling the overlap of the seed laser and the electron beam in the undulators is one of the most important and challenging tasks due to the high number of variables involved.

Seed Laser Alignment

The alignment procedure consists in measuring the electron beam position before and after the modulator by means of two YAG screens. After inhibiting the electron beam, the position of the seed laser beam is acquired by the same couple of screens and moved in order to overlap the electron beam. The procedure, which is carried out manually, has the drawback of being destructive (a screen has to be inserted) and complex because the seed laser has to be steered on the two screens one at a time. At the end of the procedure, which could take several cycles of screen insertion/extraction, the screens are removed and a shot-to-shot feedback loop is activated to keep the seed laser trajectory stable on two CCDs. The first CCD is located about 8 m upstream the modulator. The second should have been located inside the modulator but unfortunately the laser beam is measurable only intercepting both the seed laser and the electron beam. In order to have an estimation of the laser beam size and transverse position, the seed laser beam is split before the modulator. A small portion of the beam follows an equivalent optical path inside a closed box and its transverse profile, the so called “virtual undulator”, is acquired by a CCD.

Although this solution gives a good estimation of the seed laser position and shape in the modulator, the virtual modulator is very sensitive to thermal drifts due to the multiple beam reflections in the box. Moreover, a mirror installed just in front the modulator, used to steer the laser beam into the modulator, increases the dependence of the whole system on thermal stability since its movement is not compensated by the feedback.

Another critical point is the dependence of the seed laser optical transport on wavelength change. Peaks of absorption of the mirrors at 250 nm cause an intensity drop of the profile acquired by the CCD, which can only in part be compensated by the automatic gain control of the CCD itself. As a result the estimation of the centroid of the laser profile at this wavelength becomes inaccurate thus reducing the benefit of running a trajectory feedback based on these CCDs.

Electron Beam Alignment

The mechanical misalignments of undulators and magnets have been fixed during the initial FEL commissioning. Instead, the electron beam steering based

on the photon beam emitted by each radiator is carried out before each machine run. In case the radiator emissions are not well superimposed, the electron beam trajectory is adjusted inside the undulators by changing the trajectory feedback set-points.

Although the optimal electron beam trajectory is then maintained constant by a feedback loop, offsets of a few tens of microns are often empirically applied to maximize the intensity of the FEL emission.

The alignment of the first stage of FEL-2 is one the most challenging task because no available diagnostics is able to discriminate the emission of the first and the second stage [5]. In this case the insertion of a screen acquired in single shot (to avoid high radiation doses) is the only available option. Once the screen is extracted, the FEL-2 first stage is virtually a black box leaving to the operator just the possibility to optimize blindly the electron beam trajectory.

AUTOMATIC TRAJECTORY OPTIMIZATION

Optimizing a multidimensional system is a difficult task when the relations between the system inputs and the objective function are uncertain. Humans tend to explore all the inputs in order to create a model. Random scans are essential to find the inputs that are most correlated with the objective function; these are then scanned one at a time to find best values and the optimization process is iterated until the objective function reaches a satisfying value.

A similar approach is also adopted by stochastic optimization (SO) algorithms. Contrary to deterministic optimization where the relation between the objective function and the input values is well defined, stochastic optimization is based on the random exploration of the system input space. Stochastic approximation, simultaneous perturbation, simulated annealing, random search and evolutionary algorithms are the most promising optimization methods. Their strategies slightly differ one from the other on how they introduce randomness in the search process and on how they define the climbing step to reach the optimum. Formally it has been demonstrated that the best search algorithm does not exist (see No Free Lunch theorems [6]) and the success of an optimization algorithm depends on how it fits its problem.

The search of the optimal seed laser and electron beam trajectories (array of horizontal/vertical beam positions) presents all the characteristics of an optimization problem that could be solved by this kind of algorithms. The system is multidimensional, non-linear and uncertain. In FERMI the objective function used so far is the FEL radiation intensity measured by a gas monitor or by a CCD camera. A more complex objective function to be used in the future could be a combination of FEL parameters (power, bandwidth and spectral purity) opportunely weighted.

The algorithm implementation takes advantage of a software communication protocol developed in house, called NRM (Network Reflective Memory) [7] that is used to distribute across the control system a shot-to-shot timestamp, the so called “bunch number”. Moreover, the NRM transmits all the variables involved in the feedback loops and the photon beam transport diagnostic values. This real-time network, which was mainly developed for the shot-to-shot feedbacks, replicates snapshot of all FERMI important parameters in all the computers of the control system, allowing shot by shot data analysis that go beyond the feedback system purposes.

The optimization process is strictly integrated into the trajectory feedback loops; it changes at each shot the feedback set points, acquires sensors and actuators and couples them with the objective function.

The algorithm consists of six steps:

- Collects N trajectories and the corresponding objective function values (ex. FEL output intensity);
- Sorts the trajectories according to the objective function value in descending order;
- Calculates a “**golden**” trajectory by averaging the first M trajectories (M is usually 10% of N);
- Calculates a “**reference**” trajectory by averaging the remaining $N-M-P$ trajectories where P is the number of the “**worst**” trajectories (P usually 10% of N);
- Sums the difference between the golden and the reference trajectory to the feedback set point;
- Go back to the first step until a reasonable result is obtained.

The optimization algorithm can run in active or passive mode. In the active mode the trajectory feedback injects a perturbation in the system by changing the set-point of a selection of sensors. In order to speed up the scan accordingly to the feedback system response, the perturbation applied to each horizontal/vertical position usually resembles a 2D square spiral. The spiral scans have to be opportunely desynchronized between different positions in order to maximize the number of trajectory combinations. The maximum spiral dimension is normally determined a priori according to the physical magnitudes of the underlying process. It can be constant during the whole optimization process or decrease in time according to simulated annealing principles. In case the initial spiral dimension cannot be determined, a warming-up process adjusts the spiral size until the absolute value of the Pearson correlation between the horizontal or vertical position and the objective function reaches a predetermined value.

The reduction of the convergence time is the main advantage of injecting a controlled perturbation. The drawback is an additional perturbation of the beam trajectory that could affect user experiments.

In passive mode the exploration is allowed by the shot-to-shot noise present on the beam, making this optimization process virtually transparent to the experiments. A trick for increasing the noise magnitude when it is not sufficient to improve the objective function consists in increasing the trajectory feedback gain.

In FERMI the alignment of the seed laser with the electron beam is based on the active optimization mode. The trajectory feedback starts rotating the seed laser spot on two CCDs and four iterations of 130 shots are sufficient to maximize the FEL intensity (see Fig. 1).

Figure 1: Increase of the FEL output intensity and stability achieved by running the seed laser alignment optimizer.

Usually the optimal electron beam trajectory in the undulator is found manually and then the optimization algorithm in passive mode is launched to see whether there is room for further FEL improvements. At least five iterations of 600 shots are necessary to get significant results. In order to avoid the optimization statistics been biased by residual dispersive trajectories, the matching between the electron energy beam and undulators configuration has to be verified in advance.

Alternatively to the gas monitor, a CCD in the experimental station can also be used to measure the FEL intensity. The advantage is that the optimized parameter is closer to the experiment, thus taking into account also effects occurring downstream the gas monitor (Fig. 2).

Figure 2: Profile of the FEL radiation on a YAG screen in the experimental chamber before (left) and after (right) the optimization of the electron beam trajectory in the undulators (15% of intensity increase).

CORRELATOR

The automatic detection of the machine parameters that most affect the noise of the FEL beam and the launch of the optimization procedure on those parameters allow a faster achievement of the optimal working point.

The number of the variables that have to be monitored and correlated with the FEL parameters is very large and

inhomogeneous, so at the moment the search is restricted to those involved in the FERMI beam based feedbacks.

In order to evaluate the best noise detecting strategies a software application written in Matlab, acquires every second the last N shots (N between 100 and 2000) of 214 sensors/actuators, correlates them with the FEL output intensity and finally sort them in descending order according to the correspondent correlation value.

In an ideal world the correlation between feedback variables and FEL should be as low as possible. Sensors with high correlation values indicate a displacement from the optimal values, whereas high correlation in the actuators could suggest a feedback malfunction (too high feedback gain, feedback loops crosstalk, sensor malfunction, etc.).

It has been empirically noticed that a gap of more than 20% between the top shots of the list and the rest is a clear indication of malfunction. For example, this tool can identify with a very good reliability the temporal and transversal misalignment of the seed laser with respect to the electron beam (see Fig. 3), glitches on the RF plants and in general a misconfiguration of any feedback system.

Figure 3: List of sensors/actuators most correlated with the FEL intensity; seed laser vertical positions on the two CCDs on top of the ranking indicate a seed laser transverse misalignment.

CONCLUSION

In order to cope with system uncertainties a procedure based on stochastic optimization principles has been developed and integrated in the seed laser and electron beam feedbacks. Beam nonlinearities and thermal drifts affecting the feedbacks systems could be well recovered by automatic optimization procedures based on stochastic

algorithms. In order to proactively detect the arising of system drifts that affect FEL radiation, a tool that correlates all the feedback sensors/actuators with the FEL output power has been developed. Recurrent patterns in correlation values are useful to detect noise sources and implement the appropriate countermeasures.

Being able to easily optimize the accelerator and the FEL will be a great value for the future FERMI experiments.

SYSTEM IDENTIFICATION AND ROBUST CONTROL FOR THE LNLS UVX FAST ORBIT FEEDBACK

D. O. Tavares[#], LNLS, Campinas, Brazil
D. R. Grossi, São Paulo University, São Carlos, Brazil

Abstract

This paper describes the optimization work carried out to improve the performance of the LNLS UVX storage ring fast orbit feedback system. Black-box system identification techniques were applied to model the dynamic behavior of BPM electronics, orbit correctors, communication networks and vacuum chamber eddy currents. Robust control techniques were employed to analyze and optimize closed-loop performance and robustness.

INTRODUCTION

The LNLS storage ring FOFB system has been operating for users since March 2013. RMS stability integrated from 1 Hz to 500 Hz is 1% beam size in the horizontal plane and 6% for vertical in worst case (1% coupling is assumed). Disturbances originating on floor vibrations account for less than 0.2% RMS in horizontal plane and 2.5% RMS in vertical plane. The dominant disturbance source to be attenuated by the FOFB system is Elliptically Polarizing Undulator (EPU) gap/phase variations, while orbit disturbances caused by power supply ripple (up to 5% beam size, in vertical plane) should not be significantly amplified. The following sections describe the approach adopted to optimize the system performance and robustness.

HARDWARE DESCRIPTION

The LNLS FOFB system is a multiple-input multiple-output feedback control system comprising 48 sensors (24 beam position readings per transverse plane) and 42 actuators (18 horizontal orbit correctors + 24 vertical orbit correctors) running at 3.125 kHz update rate.

The data acquisition and control system hardware is composed of one central real-time controller (PXI-8108) and 12 data acquisition nodes (CompactRIO-9144 EtherCAT chassis) with analog and digital interface modules. Each acquisition/actuation node has an FPGA available for digital filtering, currently used for decimation (from 100 kS/s oversampling to 3.125 kS/s) and dynamic response compensation for each BPM reading and orbit correct current setpoint. Two daisy chain EtherCAT networks are used as deterministic network for sensor and actuator data distribution to/from the controller and provides synchronization between all nodes below 1 μ s. Bergoz MX-BPM electronics are used for RF signals processing and delivers analog signals proportional to the beam position. In-house developed power supplies with analog interface and analog current regulator (Proportional-Integral type) are used to drive the orbit corrector magnets [1].

[#]daniel.tavares@lnls.br

SYSTEM IDENTIFICATION

Figure 1 depicts the general structure adopted for modeling the LNLS FOFB system using Laplace and Z transforms.

Figure 1: LNLS FOFB model structure.

The description of transfer functions and signals are given below:

- $Ga_{pj}(s)$: power supply + magnet impedance response of the j -th corrector of the p transverse plane (h = horizontal, v = vertical).
- $Gp_{pj}(s)$: magnet core + vacuum chamber magnetic field response (eddy currents) to coil current variations on the j -th corrector of the p plane.
- $H_{pi}(s)$: BPM electronics response of the i -th BPM of the p plane.
- $H_d(z)$: decimation filter response (discrete-time) at lower data rate (FOFB update rate) + communication network delay. Identical response for both BPM position reading and orbit corrector current reading.
- M_{p1p2} : static orbit response matrices ($p1$ plane BPMs and $p2$ plane orbit correctors). Horizontal and vertical plane matrices are represented by M_{hh} and M_{vv} , respectively. Crosstalk matrices (off-diagonal) are represented by M_{hv} and M_{vh} .
- u_{pj} : orbit corrector current setpoint (j -th corrector, p plane).
- u'_{pj} : orbit corrector current reading (j -th corrector, p plane).
- y_{pi} : actual beam position (i -th BPM, p plane).
- y'_{pi} : measured beam position (i -th BPM, p plane).

For black-box system identification the available ports for experiments comprise the discrete-time input signals u_{pj} and output signals u'_{pj} and y'_{pi} , with 320 μ s sampling period. $H_d(z)$ transfer function is accurately known *a priori*, since it is fully determined by CIC decimation filters (factor 32 decimation rate, 2 sections and 1 differential delay) implemented in the nodes' FPGAs and one-cycle time delay due to the EtherCAT network data distribution.

Static orbit response matrices are readily obtained through the traditional method of small amplitude (tens of μrad) bipolar steps on each orbit corrector. For all purposes of this paper, $M_{p/p2}$ will be assumed to be known, including their variations due to known optics changes: $\pm 2\%$ tune shifts and extreme values of insertion device gap and phase configurations during normal operation.

Experiments

After experimenting with different types of excitation signals (white noise, sum of sinusoids, PRBS), a choice has been made for the pseudo-random binary signal (PRBS) due to its appropriate spectral content, easiness of use and periodicity enabling time-domain average of the experimental data. Special care has been taken to choose the sequence length in such a way that no major spectral line of the beam position readings and orbit corrector current readings (mainly due to magnets power supply ripple) aligned with some of the excitation harmonics. Figure 2 shows the chosen excitation pattern (62 points sequence, 750 Hz bandwidth, 9.2 μrad peak-to-peak excitation) in time-domain and frequency domain. For illustration, the beam position spectrum of a particular BPM is plotted in background.

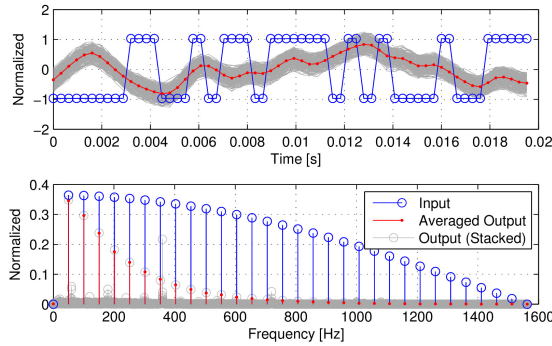

Figure 2: PRBS excitation signal of an orbit corrector and corresponding reading in a beam position monitor.

Each corrector was excited independently in order to simplify the identification process.

Input-Output Datasets

For orbit correctors, 42 datasets with 1 input (current setpoint) and 1 output (current reading) each were built from the acquired data. These datasets allowed black-box identification of discrete-time transfer functions in the form $Ga'_{pj}(z) = Ga_{pj}(z)H_d(z)$, that is, the combined response of power supply, magnet impedance, decimation filter and network delay.

For BPMs, 48 datasets with 1 input (filtered corrector current setpoint) and 1 output (beam position reading) each were built, where the orbit corrector to be excited was chosen as the corrector which produced the maximum static response at the BPM to be identified. The input data was then filtered by the identified model of the chosen orbit corrector resulting in the identification of the transfer function $H'_{pi}(z) = H_{pi}(z)Gp_{pj}(z)$, that is, the combined response of the i-th BPM and the magnet core

plus vacuum chamber response of the j-th orbit corrector. Since the magnet core and vacuum chamber of all correctors were known to have bandwidth higher than 1.25 kHz, that is above the frequency range of interest (500 Hz), the $Gp_{pj}(z)$ dynamics were neglected.

Black-box Identification

Among several existing parametric black-box system identification methods, the Autoregressive model with Exogenous Inputs (ARX) was chosen [2]. In order to avoid biasing on the identification parameters, each dataset was averaged in time-domain: the output signals were segmented in 161 periods of 62 samples (approximately 3.2 s of data), being the first segment discarded to remove the transient dynamics. From the remaining segments, 80 segments were averaged and resulted in 62-sample long estimation dataset. Another 80 segments were averaged to form the validation dataset. Orbit corrector models of order 8 (16 coefficients) and delay of 3 sample times were used. BPM models of order 2 (4 coefficients) and delay of 1 sample time were used.

Figures 3a and 3b show the frequency response of the identified models for BPMs and orbit correctors, respectively.

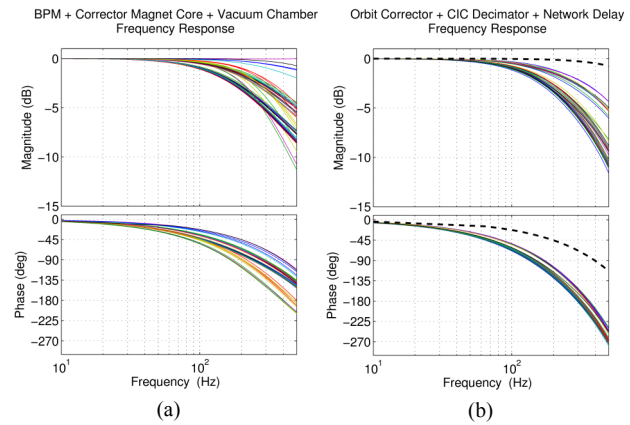

Figure 3: Frequency responses of identified (a) BPM models, and (b) orbit corrector models. $H_d(z)$ frequency response is plotted in dashed black curve for comparison.

The identified models presented normalized root mean squared errors (NRMSE) above 91% and 97% for BPMs and orbit correctors, respectively (100% meaning perfect fit and 0 meaning the fit is as good as of a straight line equal to the mean of the data). Residual analysis showed no statistically significant correlation between estimation errors (residues) and the excitation signal for all the identified models.

CONTROL DESIGN

A signal-based H_2/H_∞ optimal control approach has been adopted when designing the FOFB controller. A fixed-structure controller requirement was imposed by the available hardware, making the synthesis of an optimal controller not possible by classical tools or not computationally efficient [3]. Robustness was analyzed using uncertain plant subsystem transfer functions and worst-case singular values frequency response plots.

Weights

The key element of a signal-based control design approach is to establish inputs, outputs and transfer function weights which directly express realistic disturbances, sensor noise, actuator noise and performance objectives [4]. Closed-loop optimization is then performed based on an augmented plant as illustrated in Fig. 4.

Figure 4: Augmented plant for signal-based control.

The blocks $G(z)$ and $H(z)$ are the plant and sensor matrix transfer functions, respectively, and $W_d(z)$, $W_n(z)$ and $W_z(z)$ are the weights for disturbance, noise and performance objectives.

In the case of the LNLS FOFB system, the $W_d(z)$ transfer function matrix was chosen to reflect the main electron beam disturbances on the UVX storage ring: (i) variation of EPU gap (ramp type); (ii) variation phase of EPU phase (ramp type); (iii) mains ripple from 60 Hz to 360 Hz (second order peak filters). By means of experiments, the orbit distortion profiles of each of these disturbances were obtained.

$W_n(z)$ was chosen as a diagonal transfer function matrix where each element is the worst-case (lowest beam current on operation conditions) standard deviation of the corresponding beam position measurement broadband noise integrated over the entire bandwidth.

$W_z(z)$ was chosen also as a diagonal matrix transfer function where each element is a first-order low pass filter with a given bandwidth and gain given by the inverse of the nominal beam size, meaning all beamlines are considered to be equally sensitive to electron beam orbit disturbances up to the bandwidth.

Actuator noise and amplitude range limitation were both considered to be negligible.

Performance and Robustness Metrics

FOFB performance and robustness were assessed by means of H_2 and H_∞ closed-loop system norms of the augmented plant, with negative feedback from y' to u by a controller with $C(z)$ transfer function. The chosen performance channel was the summation of disturbance rejection and sensor noise transfer functions, with inputs d and n and output z , denoted by $\|T_{d,n \rightarrow z}\|_2$, for which the H_2 norm has direct correspondence with the RMS-integrated criterion typically used to analyze FOFB system performance. The chosen robustness channel was the sensitivity transfer function at y , denoted by $\|S_y\|_\infty$, for which the H_∞ norm simply means the worst-case multivariable gain from the disturbances to the actual beam position outputs. Despite being an indirect measure of robustness, it has straightforward practical meaning.

The H_2 and H_∞ norms were scaled in such a way that values below unity were said to satisfy the FOFB requirements. To this end, W_z was divided by a factor 0.1 to reflect 10% beam size stability requirement and by the square root of the number of beam position measurements (24, for each plane) in order to convert the 2-norm of the output vector to RMS value. Each input of W_d is divided by its expected maximum value, so that an unitary input means the worst-case disturbance. The sensitivity transfer function was divided by the allowed maximum amplification gain, $\sqrt{2}$ (3 dB).

Model Uncertainty

Despite adopting black-box system identification when modeling each BPM and orbit corrector dynamics, the transfer functions were assumed to have some level of uncertainty. In order to take this information into account when analyzing the control loop, classes of similar responses have been established from visual inspection followed by the determination of lower and upper bounds of the frequency responses through an input multiplicative uncertainty model of the type:

$$G_{\text{uncertain}}(z) = G_{\text{nominal}}(z)(1 + W(z)\Delta(z)) \quad (1)$$

where $\Delta(z)$ is a norm-bounded uncertain complex transfer function ($\|H(\Delta)\|_\infty < 1$) and $W(z)$ is a weighting transfer function of order 1. Figures 5a and 5b show the established frequency response classes.

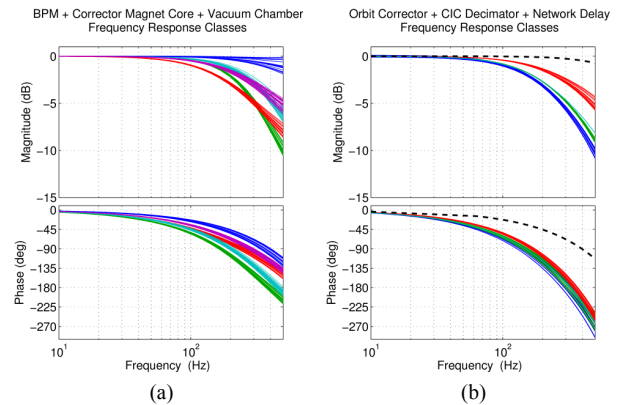

Figure 5: Classes of frequency responses of (a) BPM models, and (b) orbit corrector models. $H_d(z)$ frequency response is plotted in dashed black curve for comparison.

Control Optimization

Although mature frameworks for designing optimal controllers based on H_2 and H_∞ norms minimization exist (e.g. LQG, LMIs, μ -synthesis), these methods are not directly suitable for the LNLS FOFB system since the controller has a fixed-structure. For such class of controllers, optimizing the system norms would typically require nonconvex and nonsmooth optimization techniques. Although an efficient and scalable nonsmooth optimization method for solving this class of problems exists [3] and is available in Matlab Robust Control Toolbox since version 2010b, the present work has taken a simpler approach of exhaustive computation of system

norms for a grid of controller parameters. The next section describes simulation results which were obtained following this approach.

SIMULATION RESULTS

The feedback controller $C(z)$ on the simulated control loops had the following structure:

$$C(z) = M_C \frac{K \cdot T_s}{z-1} \quad (2)$$

where M_C is a decoupling matrix, K is the controller gain and T_s is the sampling time (320 μ s). M_C is the pseudo-inverse of the static orbit response matrix applying Tikhonov regularization as described in [5, 6]. The pseudo-inverse singular values $\hat{\sigma}_i$ have the following relation with the singular values of the orbit response matrix σ_i :

$$\hat{\sigma}_i = \frac{\sigma_i}{\sigma_i^2 + \mu} \quad (3)$$

where μ is a real parameter to be tuned.

The closed-loop norms $\|T_{d,n \rightarrow z}\|_2$ and $\|S_y\|_\infty$ of the augmented plant (nominal case, with no uncertainty) were calculated for different values of K and μ for three different bandwidths in the $W_z(z)$ transfer function. Orbit correction on horizontal and vertical planes were treated independently. Figure 6 shows the results for each value of K , μ and bandwidth. The optimal controllers are those with minimum value of $\|T_{d,n \rightarrow z}\|_2$ meeting the constraint $\|S_y\|_\infty < 1$, as summarized in Table 1.

Figure 6: $\|T_{d,n \rightarrow z}\|_2$ costs meeting the $\|S_y\|_\infty < 1$ constraint for each plane and beamline bandwidth: (a) horizontal, 25 Hz; (b) horizontal, 50 Hz; (c) horizontal, 100 Hz; (d) vertical, 25 Hz; (e) vertical, 50 Hz; (f) vertical, 100 Hz.

Table 1: Summary of optimal controllers.

Plane	BW	$\ T_{d,n \rightarrow z}\ _2$	$\ S_y\ _\infty$	K	μ
H	25 Hz	0.0855	0.7467	19.0	4.17e-1
H	50 Hz	0.1271	0.7294	10.5	2.81e-1
H	100 Hz	0.1710	0.7293	10.5	4.17e-1

V	25 Hz	0.7837	0.9746	111	1.17e-2
V	50 Hz	1.160	0.8585	61.6	5.30e-3
V	100 Hz	1.466	0.8480	61.6	7.88e-3

Figure 7 shows the frequency-dependent singular values of the sensitivity transfer function of the system for each controller in Table 1. The uncertainty on dynamics and orbit response matrix is taken into account. No closed-loop sensitivity function of the optimized loops significantly exceeds the 3 dB amplification reference line, indicating the uncertainties do not substantially degrade robustness. This was expected since the differences on dynamics are significant only for frequencies above the achieved closed-loop bandwidths.

Figure 7: Singular values plot of sensitivity functions with uncertain plant: (a) Horizontal plane (b) Vertical plane.

CONCLUSION

A complete approach to identify the performance limits of the LNLS FOFB system has been presented, from the system identification to the control loop optimization. From this study it has been concluded that the LNLS FOFB system is limited in about 15 Hz closed-loop bandwidth (~25 Hz 0 dB crossover on sensitivity function), the main limitation being a ~1.5 ms delay due to communication network, decimation filters and BPMs responses. Due to the effect of noise amplification for frequencies above the crossover, higher control loop bandwidths improves performance only when beamlines are less sensitive to electron beam motion at higher bandwidths. The simulation results herein presented still need to be validated against experimental data.

Abstract

This paper presents the NSLS-II fast orbit feedback (FOFB) system, including the architecture, the algorithm and the commissioning results. A two-tier communication architecture is used to distribute the 10kHz beam position data (BPM) around the storage ring. The FOFB calculation is carried out in field programmable gate arrays (FPGA). An individual eigenmode compensation algorithm is applied to allow different eigenmodes to have different compensation parameters. The system is used as a regular tool to maintain the beam stability at NSLS-II.

INTRODUCTION

NSLS-II is a third generation 3GeV storage ring with ultra-low emittance [1]. The low emittance requires a very stable electron beam orbit. Applying the common rule (beam stability < 10% of beam size), NSLS-II needs to hold submicron beam orbit stability. The stringent orbit stability requires the orbit feedback system to be able to suppress various noises from low frequency ground motion to high frequency mechanical vibration [2].

The NSLS2 BPM electronics generates high resolution turn-by-turn, fast acquisition (10kHz) and slow acquisition (10Hz) data. Fast acquisition data is used for global fast orbit feedback. To ensure sufficient bandwidth of the feedback loop, 10kHz data from all storage ring BPMs are distributed within a short period of time. A two-tier communication architecture is implemented to ensure the time budget for the FOFB system is satisfied. The first tier is the communication between local BPMs and the cell controller at each cell. The second tier is the communication between the cells around the whole storage ring.

The FOFB system is a typical multiple-input and multiple-output (MIMO) system. One common feature of the traditional singular value decomposition (SVD) based orbit feedback algorithm is that it applies the same controller dynamics (such as a PID controller) to all eigenmodes. Since each eigenmode has a different frequency response, it is desirable to apply a different controller for each of the eigenmodes and thus each eigenmode has different compensation in the frequency domain [3]. The challenge for such individual eigenmode compensation is that the feedback system needs to carry out much larger calculations within the time budget of the FOFB system. In this paper, we present the implementation and commissioning results of the FOFB system at NSLS-II.

TWO-TIER COMMUNICATION

One common task for a global orbit feedback system is to deliver BPM data to the calculation unit, and to send the calculated result, i.e. the corrector setpoints, to the power supplies. Many communication protocols are used in different labs.

To design the communication protocol at NSLS-II, we take advantage of the geographic locations of BPMs and correctors at NSLS-II. The NSLS-II storage ring is separated into 30 cells. There are 6 BPMs, 3 fast correctors, and 6 slow correctors in each cell. To effectively deliver the BPM and corrector data, we designed a hardware unit in each cell to collect local BPM data, deliver the BPM data around the ring, and to send corrector setpoints to the correctors. We call this unit the cell controller.

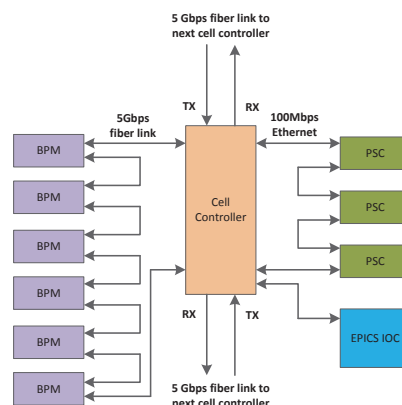

Figure 1: Two-tier communication.

By using cell controllers, two-tier communication is established, as shown in Figure 1. The first tier is the communication of the local data in one cell. In one cell, the cell controller and up to 12 BPMs are connected using fiber optic cables to form a ring structure. Currently, FOFB is only using 6 RF BPMs in the loop and it can be expanded to include 6 ID BPMs or X-ray BPMs. Each BPM sends its position data to its left and right neighbours, and passes through its neighbours' data. The data finally reach the cell controller and the cell controller saves the 6 local BPMs' data in its buffer. This communication protocol is called a serial device interface (SDI). On the other side, the corrector setpoints are sent from the cell controller to the local fast correctors via a similar SDI link. The only difference is that the power supply SDI link uses Ethernet PHY.

The second-tier communication is between the 30 cell controllers. The 30 cell controllers are connected using fiber optic cable to form a ring structure. Each cell

controller sends the local BPM data to its neighbour cell. Within 14us, each cell controller has all the BPM data. It is worth mentioning that the SDI protocol includes a clockwise and counter clockwise ring structure. The data communication has built-in redundancy.

COMPENSATION IN EIGENSPACE

The NSLS-II FOFB system applies a novel approach of feedback compensation in eigenspace [4]. Figure 2 shows the diagram of eigenspace decoupling and compensation in each eigenmode.

Figure 2: FOFB with eigenspace compensation.

In Figure 2, \vec{e} is used to represent the noise in the system and \vec{c} is used to represent the eigenspace projection of each input

$$\vec{c} = \mathbf{U}^T (\vec{d} - \vec{d}_{ref} + \vec{e})$$

For each of the components of \vec{c} , an individual digital controller can be designed for the compensation of each eigenmode. The MIMO problem is converted to many signal-input signal-output (SISO) problems, for which control theory has many standard solutions. We use $Q_i(z)$ to represent the digital controller applied only on i th eigencomponent of \vec{c} .

The above eigenspace compensation algorithm allows us to apply different compensation parameters (for example, PID values) to each eigenmode and thus provide a flexible controller according to each eigenspace's transfer function. On the other hand, such an algorithm needs much many calculations than the traditional algorithm.

Figure 3: A typical SVD-based FOFB system.

Figure 3 shows a typical SVD-based FOFB algorithm. It shows that to calculate one corrector setpoint, the system needs to multiply one row of the reverse response matrix by the orbit error. This needs M multiply-

accumulate (MAC) operations, where M is the number of BPMs. A typical PID compensator adds another 3 MACs. The total calculation amount is M+3 MACs.

For eigenspace compensation, as shown in Figure 2, the orbit error needs to first multiply each row of the \mathbf{U}^T matrix to decouple into eigen components in eigenspace. Then a compensator is applied for each eigenmode. The third step is to combine all eigen components into corrector space by multiplying the eigen components by the \mathbf{V} matrix. Apparently, due to the eigenspace decoupling, the amount of calculation increases by N times, where N is the number of eigenmodes. For NSLS-II, N is 180. Such a large number of calculation needs to be finished within the 100us FOFB timing budget. This is a challenge for NSLS-II FOFB system.

We solved the challenge by using hardware for the FOFB calculation. Instead of using a general CPU to do the eigenspace compensation, we used FPGAs for the calculation. Figure 4 shows that most of the calculation is in the decoupling process, where each row of the \mathbf{U}^T matrix multiplies the orbit difference. We noticed that this process can be done in parallel. Compared to serial computing using a CPU, FPGAs are well known for their parallel computation capability.

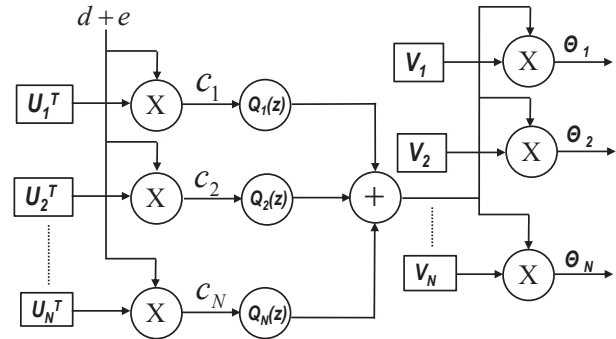

Figure 4: FOFB calculations with FPGA.

Figure 4 shows the basic calculation unit of FOFB inside FPGA. It includes the parallel decoupling in eigenspace together with the corrector setpoint calculation in parallel. Floating point calculation is used to make the calculation more accurate.

COMMISSIONING RESULTS

The NSLS-II FOFB system was commissioned and proved to meet the requirements of the orbit stability. Since June 2015, the FOFB system has been a regular tool to maintain beam stability.

Beam Stability Requirement

There are 30 double-bend achromat (DBA) cells in NSLS-II storage ring. The insertion devices are located at the straight sections of 15 high beta (long) and low beta (short) sections. Three damping wigglers are installed to reduce the bare lattice horizontal emittance from 2nm.rad

to 0.9nm.rad. Figure 5 shows the RMS beam size in one super cell.

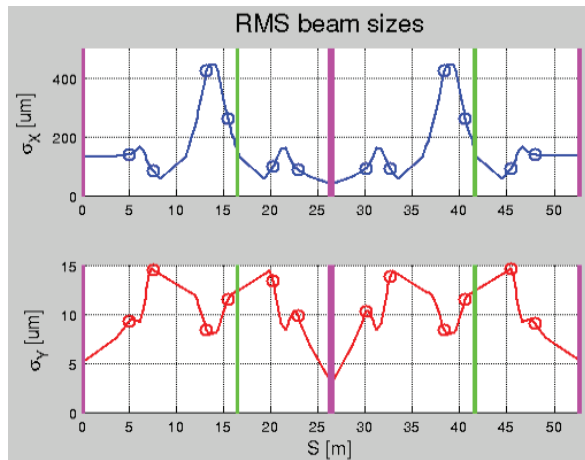

Figure 5: RMS beam size in one supercell using emittance of $\epsilon_x/\epsilon_y = 0.9/0.008$ nm.rad and energy spread of 0.09%.

The photon beamline source points are marked with green and pink vertical lines. The beam stability requirement for FOFB is that the beam movement is less than 10% of beam size. One can see that the most stringent requirement is to keep beam motion less than 300nm at s value about 27m, where the RMS beam size is 3 μ s.

Beam Stability Achievement

Figures 6 and 7 show the beam stability with FOFB on and off. Figure 6 is the power spectrum density (PSD) plot for FOFB on and off cases. The power spectrum of each BPM is calculated from 10 second synchronized 10kHz fast acquisition data. Different BPMs at different locations have different spectra. Figure 6 shows the average spectrum for all non-dispersion BPMs. There are three panes in Figure 6: the upper one shows the spectrum for the horizontal and vertical planes, the middle one shows the integrated spectrum where the integration starts from low frequency and the lower pane shows the integrated spectrum where the integration starts from high frequency. Figure 6 shows that the FOFB system is able to suppress noises up to 250Hz in the vertical plane and up to 50Hz in horizontal plane. During the commissioning, most of the effort was spent on vertical plane noise suppression. Feedback parameters can be further optimized in the future developments.

Figure 7 shows the RMS motion of 12 BPMs in one supercell (C02-C03) for both the horizontal and vertical planes. The data is calculated from the integration of PSD from 1 Hz to 500Hz. The dashed lines are drawn to indicate 1% of horizontal beam size and 10% of vertical beam size. In the horizontal plane, the RMS motion is suppressed within 1% of beam size when FOFB is on. This is well within the requirement. In the vertical plane, when FOFB is off, the beam motion is about 20% of

beam size. With FOFB on, the beam motion is suppressed down to about 5% of beam motion, which is also within the 10% of requirement. The HXN (Hard X-ray Nano Probe) beamline has the most stringent requirement for orbit stability. C03 IVU, which locates in the middle waist, is the insertion device for the HXN beamline. From the two BPM readings at the two ends of the insertion device, position and angle spectrum at the IVU center can be calculated. In the vertical plane, the integrated (from 1Hz to 500Hz) position and angle motions are 0.216 μ m and 0.136 μ rad, within the 10% beam size and 10% of beam angle divergence requirement.

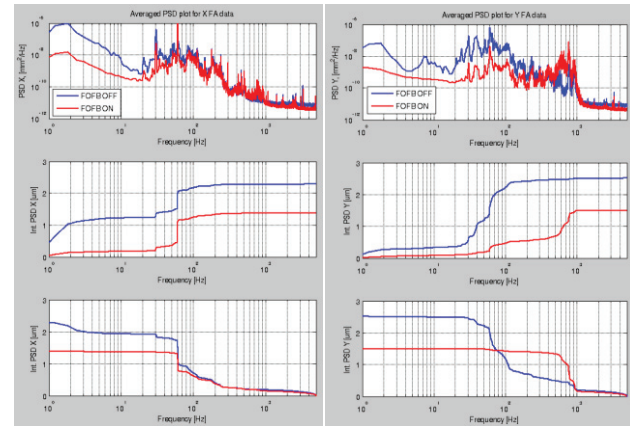

Figure 6: BPM 10kHz FA data PSD spectrum.

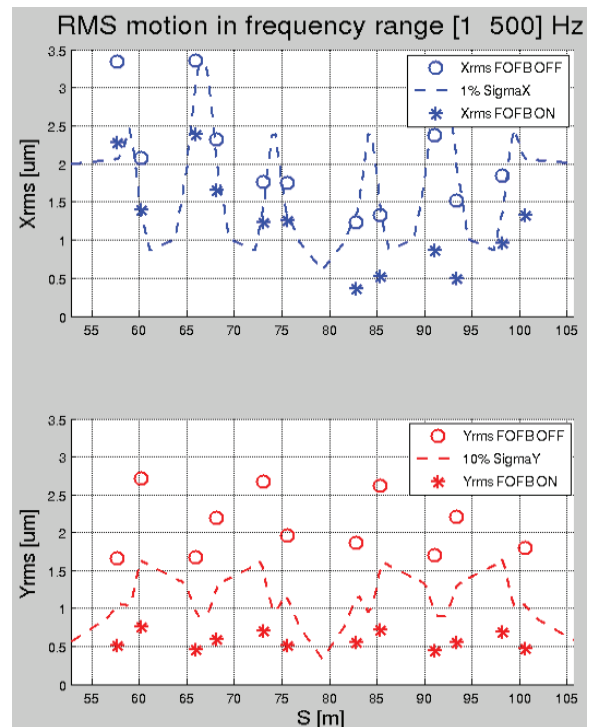

Figure 7: Integrated RMS motion(1-500Hz) for 12 BPMs in one supercell (C02-C03).

DISCUSSIONS

FOFB on During Injection

Before the top-off operation, NSLS-II had been operated with regular injection. Usually the beam was injected when the stored beam density drops to some level. During our beam study, we found that the beam orbit change during beam injection was small. This is due to the relatively small injection beam charge and the matched optics design between the storage beam and injection beam. The small disturbance allowed FOFB to stay on during injection.

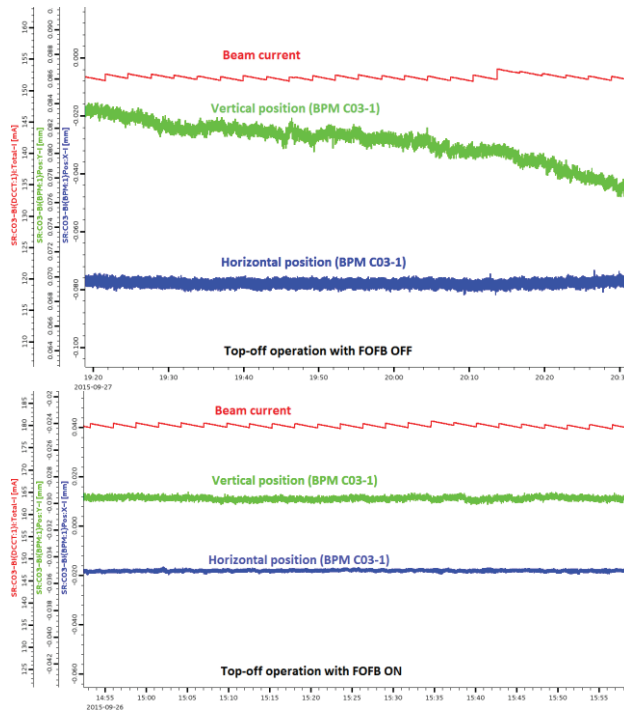

Figure 8: BPM position (10Hz data) during top-off operation with FOFB off (top) and FOFB on (bottom)

NSLS-II top-off operation was commissioned in September 2015. Figure 8 shows the BPM 10Hz reading during top-off operation with FOFB off and FOFB on. It shows the noise suppression effect of FOFB system. With FOFB on, the horizontal and vertical orbit disturbance during beam injection is negligible. Starting from October 1, 2015, NSLS-II is running with both FOFB on and top-off mode to provide users a stable beam current and stable beam orbit.

FOFB on with Insertion Device(ID) Cap change

Light source users regularly change the insertion gaps. The change brings some orbit disturbance. To keep the orbit disturbance small, lookup tables are carefully designed to compensate the disturbance caused by ID gap changes.

During commissioning, we verified that if ID lookup tables are designed well, the leaking orbit disturbance is small and the FOFB can compensate such disturbances.

One exception is the damping wiggler. The movement of the damping wiggler causes large orbit change and FOFB can't easily compensate it. Fortunately, the change of damping wiggler doesn't happen often. The FOFB can be turned off before the movement, and turned on after the damping wiggler movement.

FOFB with Local Bump Creation

During the NSLS-II beam line commissioning stage, beam line users are allowed to create a local bump for a specific angle and offset at ID center. A high level application has been designed to create such local bump using multiple local slow correctors. If FOFB stays on during local bump creation, the two systems fight with each other: FOFB is trying to keep the orbit to its own reference orbit and the local bump program is trying to create a new orbit. We have tested several methods to solve this problem. The principle is to quickly change the reference orbit of the FOFB system. We are in the process of testing different methods to change the FOFB reference orbit.

SUMMARY

This paper discussed the architecture, the calculation algorithm and the commissioning results of the NSLS-II FOFB system. It shows some of the novel approaches of the fast orbit feedback system: two tier communication protocol, eigenspace compensation, and FOFB calculation using FPGA. These novel approaches provide flexibility for FOFB control and they demonstrate the performance required to meet all NSLS-II sub-micron beam stability design goals with noise suppression up to 250Hz in the vertical plane. The FOFB system is commissioned and used as a regular tool for user operation. We also discussed various issues during FOFB commissioning.

ACKNOWLEDGEMENTS

Many critical subsystems are required to work well to make the FOFB system work. We thank O. Singh, K. Vetter, J. Mead, A. Dellapenna and Y. Hu for their efforts of BPM development. We also thank G. Ganetis, W. Louie and J. Ricciardelli for fast corrector power development.

Abstract

The Laser MegaJoule (LMJ) is a 176-beam laser facility, located at the CEA CESTA Laboratory near Bordeaux (France). It is designed to deliver about 1.4 MJ of energy to targets, for high energy density physics experiments, including fusion experiments. The assembly of the first line of amplification (8 beams) was achieved in October 2014.

A computational system, named PARC, has been developed and is under deployment to automate the laser setup process, and accurately predict laser energy and temporal shape. PARC integrates the simulation software MIRO. For each shot on the LMJ, PARC determines the characteristics of the injection laser system required to achieve the desired main laser output, checks the machine fine-tuning for equipment protection, determines the required diagnostic setup, and supplies post-shot data analysis and reporting.

This document gives the first results obtained with PARC. We also describe results obtained with the PARC demonstrator during the first experience on the LMJ facility.

PARC FUNCTIONALITIES

PARC must guarantee the laser performance according to a shot request. To achieve this goal, PARC is based on the simulation software MIRO which models each laser beam. PARC manages and updates one data model for each beam and validates them at the end of each shot.

Contribution in Experiment's Chronology

The LMJ monitoring system orchestrates the whole sequence of operations. It invokes PARC at each step of the sequence to deal with specific process.

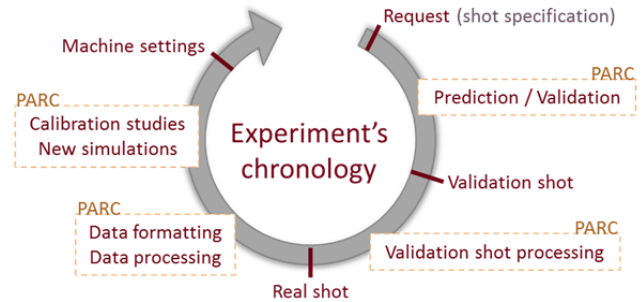

Figure 1: PARC in experiment's chronology.

The first step in the sequence is the production of a request that identifies all the desired laser output characteristics.

Predictive simulation is the first set of operations in the sequence chronology. It determines the LMJ equipment configuration and settings required to achieve the desired main laser output. The behaviour is performed by the software MIRO.

Validation is performed to check the ability of the machine to perform the shot in security and safety. Validation is also based on a simulation realized by MIRO.

Once the prediction and the validation are accepted, the sequence is composed of one or more validation shots to fine-tune data and equipment settings. A validation shot is like a real shot without the main amplifiers.

Data-processing of validation shot follows each validation shot. PARC performs data processing and provides parameters to check if the settings are compatible with the real shot. We also check that equipment's and diagnostics are operating normally.

The next step in the sequence is the real shot.

Data-processing of the real shot consists of supplying post-shot data analysis and reporting. Among other things, PARC compares the measurements to the request, to the results of simulations, performs new MIRO simulations from shots results to fine-tune calibration.

Calibration of computation models is performed at the end of each shot to correct the drift. The calibration uses the results and reports of several shots.

Autonomous Working

PARC provides an autonomous mode that allows operators to perform simulations and processing apart from the shot sequence.

Operators can prepare new shot campaigns and check the ability of a request thanks to dedicated prediction and validation algorithms.

They can calibrate MIRO simulations and PARC setting with specific data-processing codes from shots results.

PARC STAKES

PARC Position

Interfaces are a major issue in PARC. PARC has three main interfaces (Figure 2): the LMJ monitoring system, the users and the MIRO software.

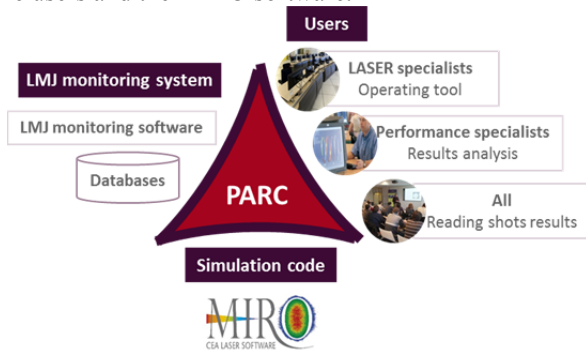

Figure 2 : PARC interfaces.

The LMJ monitoring system software (also called Supervisory system) invokes PARC, which provides reports in return. The LMJ monitoring system relies on several databases where raw data, shots results, settings and characteristics of the equipment are stored. PARC extracts and translates these data into its own formalism. The data are hence civilized to be used in processing and simulations.

Several types of users are interested in PARC functionalities.

Laser specialists, the main users, use PARC as an operating tool. They execute new simulations, study the results and reports, integrate new algorithms and modify existing codes and configuration data.

Performance specialists export the results processed by PARC to perform more analysis on separated systems.

All users want to see the reports on separated systems to show them in meetings for example.

The Miro software simulates the Laser propagation with numerical models. PARC prepares data and simulation characteristics, executes MIRO and reads and processes the results.

LMJ Structure and Variables

The particularities of LMJ structure have an important part in PARC algorithm structure. The LMJ is characterized by:

- 4 sections (Figure 3): pre-amplification, amplification, conversion and target,

Figure 3 : LMJ sections.

- 4 levels of granularity: beam, quad (4 beams), line (2 quads) and the whole system,
- 3 main characteristic variables: energy, temporal shape and spatial shape,
- 3 levels of data: prediction results, request, measurement results.

These four components form four dimensions in the architecture of PARC processing codes.

ARCHITECTURE

Hardware Architecture

PARC is a complete ecosystem of tools and technologies working together to achieve its objectives. The hardware platform consists in three components.

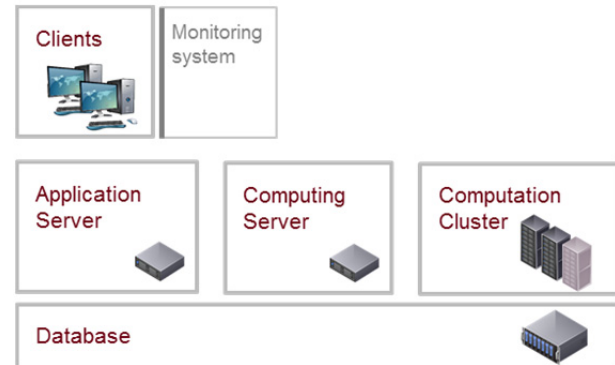

Figure 4 : Hardware architecture.

The Application Server is a server accepting connections from the various clients,

The Computing Server is a server orchestrating algorithm executions. It distributes tasks among the cluster nodes,

The Computation Cluster is a cluster of nodes performing the high-demand computation tasks such as MIRO beam propagation code. The modular structure of the cluster in racks allows high flexibility to gradually add laser lines with their installation and high performance regardless of the number of laser beams (a prediction simulation takes about 20 minutes).

These hardware components access the same distributed file system to share the data. The data are previously converted by a dedicated software civilizing

the various data types (file formats, units) injecting these into the PARC database.

Software Architecture

PARC software architecture is threefold:

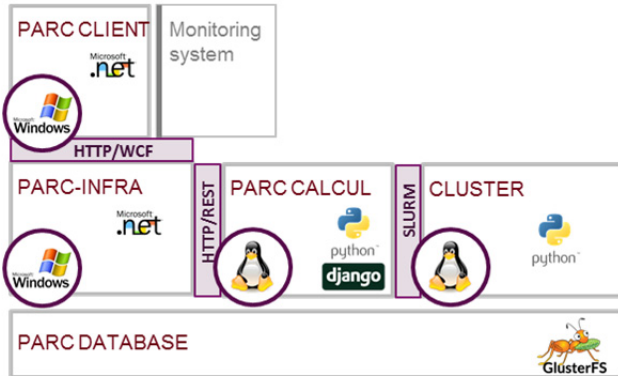

Figure 5 : Software architecture.

- PARC-INFRA: application server dealing with all the contextualization of scenario execution. Web application hosted by an IIS Web server, it exposes a set of WCF web services mainly to fine-tune data and initiate scenarios,
- PARC-CALCUL: Web Frontend to the computation cluster. Python Django application, it exposes a Rest web service interface to segregate the computing from the application management, running task orchestration, and perform task distribution,
- PyParc: Python library underpinning the execution of the elementary computation tasks.

FUNCTIONS COMPONENTS

Algorithm Components

In PARC, the algorithm associated with a function is named scenario. Scenarii are Python scripts based on two computation libraries.

The modules library is composed of elementary computation codes. We distinguish several kinds of modules:

- Basic calculation codes (two scalars relative comparison for example),
- Generic codes which implement generic functions as the execution of MIRO simulation for instance,
- Reading / writing data in PARC database,
- More complex codes which implement a part of a scenario algorithm. These modules manage data and elementary calculation codes.

The PyParc library is composed for generic functions which manage the scenario execution and provide tools for the implementation of modules. For instance, the distribution of modules is managed by PyParc functions.

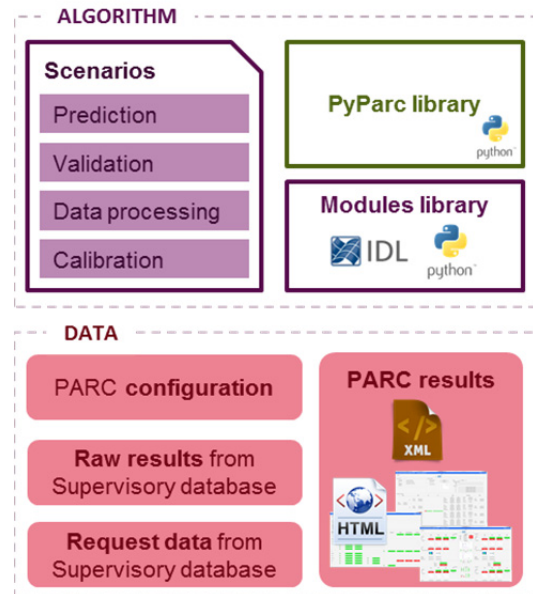

Figure 6 : PARC components.

Data Structure

PARC scenarios are run from different types of data files. PARC has its own configuration file including algorithm parameters and simulation data. But the main data is recovered from the monitoring system : the request data with equipment's settings and the raw results of the shots.

The scenarii results are stored in PARC database in XML (Extensible Markup Language) files and in the form of specific reports in HTML (Hypertext Markup Language).

PARC RESULTS

Prediction

Prediction algorithm performs simulations with MIRO to determine settings and equipment configuration for reaching the request. A report is generated at the end of the simulations using a specific GUI (Graphical User Interface). This report is composed of three synthetic views which gather the results. Each view corresponds with a level of granularity: system, quad and beam.

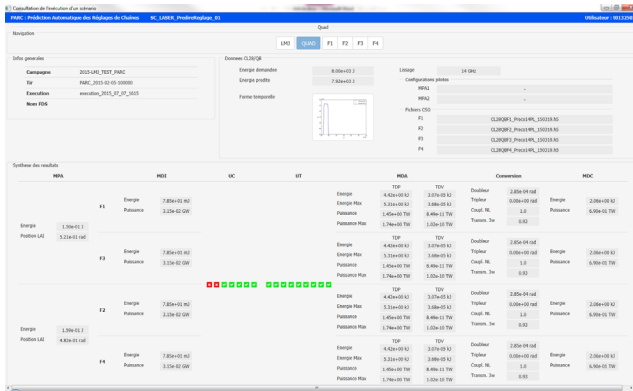

Figure 7 : Prediction quad results.

Figure 9 : Data processing quad results.

Validation

Validation algorithm checks the ability of equipment to perform the shot in security with the settings calculated by the prediction algorithm. A report is generated using a specific GUI. This report is composed of two synthetic views which gather the results for the system and for each beam.

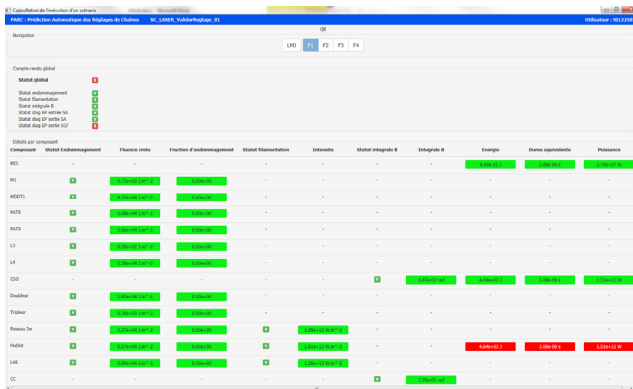

Figure 8 : Validation beam results.

First Experiment

We use the PARC demonstrator during the first experiment on the LMJ facility. This tool uses computation codes which are now integrated in the modules library of PARC. The Quad Energy for the October 17th 2014 shot is illustrated on the figure below. The request was 10kJ at 3 ω for each quadruplet. We measure respectively 10,2 et 9,8 kJ.

Figure 10 : First experiment.

Data Processing

Data processing algorithms perform calibration corrections, comparisons between measurements and prediction or between measurements and request, new simulations from the shot's results. A report is generated using a specific GUI. This report is composed by three synthetic views which gather the results. Each view corresponds with a level of granularity: system, quad and beam.

LOW LEVEL RF CONTROL IMPLEMENTATION AND SIMULTANEOUS OPERATION OF TWO FEL UNDULATOR BEAMLINES AT FLASH

Abstract

The Free-Electron Laser in Hamburg (FLASH) is a user facility delivering femtosecond short radiation pulses in the wavelength range between 4.2 and 52 nm using the SASE principle. The tests performed in the last few years have shown that two FLASH undulator beamlines can deliver FEL radiation simultaneously to users with a large variety of parameters such as radiation wavelength, pulse duration, intra-bunch spacing etc. FLASH has two injector lasers on the cathode of the gun to deliver different bunch trains with different charges, needed for different bunch lengths. Because the compression settings depend on the charge of bunches, the low level RF (LLRF) system needs to be able to supply different compression for both beamlines. The functionality of the controller has been extended to provide intra-pulse amplitude and phase changes while maintaining the RF field amplitude and the phase stability requirements. The RF parameter adjustment and tuning for RF gun and accelerating modules can be done independently for both laser systems. Having different amplitudes and phases within the RF pulse in several RF stations simultaneous lasing of both systems has been demonstrated.

INTRODUCTION

FLASH has been in operation as a user facility since summer 2005 [1]. In the mean time as a test facility, FLASH is in use for testing the superconducting accelerator technology for European XFEL [2] and ILC [3] projects. The first effort to operate accelerating modules at different gradients with alternating RF pulses was motivated by the ILC and European XFEL and initially has been demonstrated in year 2008 [4].

FLASH2 [5] is the second undulator beam line with variable gap built in a separate tunnel. It will make full use of the existing FLASH accelerator. Part of the bunch trains are kicked from the main beamline (FLASH1) into the new undulator beamline. In order to double the beamtime, users of both beamlines would need the 10 Hz repetition rate. A fast kicker in combination with a DC septum is used to deflect the beam into the second undulator line. In addition, the large variety in beam parameters should be available at both beamlines independently in order to ensure a maximum flexibility in planning of the beamtime. For this reason two cathode lasers are in use, each with its own bunch train. A variable delay between the two lasers within the RF pulse gun and accelerating modules ensures that users from both beamlines get their own set of parameters.

^{*} valeri.ayvazyan@desy.de

In addition, the start time of the kicker pulse is shifted with respect to the start time of the laser pulse and the RF amplitude and phase of the gun and each of the modules can be tuned for optimal conditions for both users. During the initial tests it was shown that the RF system is able to handle the flexibility needed to compress the beam independently for FLASH1 and FLASH2 beamlines.

LOW LEVEL RF CONTROL FOR MULTI-BEAMLINES

RF Control Specifics for Multi-beamline Case

During the multi-beam line operation, within limits given by the beam delivery system, the bunch pattern and beam energy should be adjusted independently for each beam line, suggesting a time-sliced operation. For the FLASH2 beamline RF amplitude and phase changes within the pulse are required within a short time (less than 50μs). Different beam loadings are foreseen for different beamlines. Particularly the ability of gradient tuning of the last two RF stations is needed for wavelength scans for the FLASH1 beamline and the ability of phase tuning at injector for variation in compression at FLASH1 and FLASH2. From the operation point of view, the most important requirement is to have the ability of independent RF operational parameters adjustments for both beamlines.

LLRF System Overview

The layout of the FLASH facility including the new beamline is described in [6] and shown in Fig. 1. Its accelerator comprises a normal conducting RF gun, a first 8-cavity cryomodule, a third harmonic cryomodule with 4 cavities, a first bunch compressor, a second accelerating RF station (16 cavities), a second bunch compressor, and another two RF stations, with 16 cavities each. FLASH is operated in pulsed mode with repetition rate 10Hz. RF pulse duration is 1.3ms, 500μs for filling and 800μs flattop (beam acceleration). The RF power coming from 10MW klystrons is equally distributed to all cavities through the waveguide distribution system. The current stage of the LLRF control is implemented based on the MTCA.4 system [7]. The goal of the system is to control the accelerating gradient in amplitude and phase for each RF station based on vector sum control of cavity gradients [8]. The main components of the LLRF system are depicted in Fig. 2. For every cavity, the forward (PFW), reflected (PREF) and transmitted signals or probes (PRB) are first down-converted to an intermediate frequency (IF) by the down-converters (uDWC) and then digitized

Figure 1: Schematic layout of the FLASH facility. The electron gun is on the left, the experimental hall on the right. Behind the last accelerating module, the beam is switched between FLASH1 and FLASH2 beamlines.

(uADC). The sampled signals are pre-processed by the uADC and then sent over the MTCA.4 backplane to the main LLRF controller (uTC) which performs all control computations. The uTC then generates the drive signal which is up-converted to RF frequency by the vector modulator (uVM). The LLRF drive signal is pre-amplified and then sent to the klystron (KLY). The master oscillator (MO) provides the 1.3 GHz reference signal (RF), required by the local oscillator generation module (LOGM) to generate the LO and clocks (CLK) signals used by the down-converters, and to distribute the reference signal to the uVM. The power supply module (PSM) provides DC voltages to external modules. Finally, the piezo driver module (PZ16M) digitizes the piezo sensor data and drives the piezo actuator for detuning and microphonics compensation. Communication between the PZ16M and the MTCA.4 system is performed through an optical link to the main LLRF controller, the uTC. This setup can be easily extended to control the sum of 16 cavities.

Brief Description of Control Algorithm

The feedback algorithm is implemented in FPGAs firmware and DOOCS [9] control system server. The control algorithm employs tables for feed-forward, set-point and feedback gain settings to allow time varying of those parameters. High frequency probe signals are used

to measure the accelerating field in the individual cavities. These 1.3 GHz (3.9 GHz) signals are down-converted to 54 MHz and sampled by uADCs at 81.25 MHz. The digitized signals are going to the digital field detector which extracts the real and imaginary parts of the cavity field vectors from the input stream. The resulting field vector of each cavity is multiplied by a rotation matrix to calibrate amplitude and phases. Then the sum of individual field vectors is calculated and rotated to adjust the loop phase. The vector sum of the cavities fields represents the total voltage and phase seen by the beam. This signal is regulated by a feedback control algorithm which calculates corrections to the driving signal of the klystron: the measured vector sum is subtracted from the set-point table and the resulting error signal is amplified and filtered to provide a feedback signal to the vector modulator controlling the incident wave. A feed-forward signal is added to correct the averaged repetitive error components. Beam current information is used to scale the feed-forward table to provide fast feed-forward corrections if the beam current varies. The controller server software handles: generation of control tables from basic settings, rotation matrices for the cavity field vectors, start-up configuration files, feedback and exception handling control parameters, etc. The interrupt service routines are used to start the data reading from the controller boards. The parameters of the feedback algorithm are modified by the FPGA programs in the time slot between pulses.

Application Software

A set of generic and especially devoted programs provides the tools for the operators to control the RF system. Some of them are created based on the MATLAB, others as DOOCS middle layer servers. The adaptive feed-forward is implemented on a front end server, to allow pulse to pulse adaptation. The application software includes vector sum calibration, automated operation of the frequency tuners, phasing of cavities, adjustment of various control system parameters, etc. Extensive diagnostics inform the operator about cavity quenches, cavity detuning, and an excessive increase in control power.

RF control functionality extension for FLASH2

The RF pulse is shared between the electron bunch trains for FLASH1 and FLASH2. For the full RF pulse length, the total maximum number of bunches, with bunch repetition rate of 1 MHz is 800. The bunch pattern (number of bunches and intra-train repetition rate) and bunch charge can be different for FLASH1 and FLASH2, which is realized by using two independent injector lasers. Timing events from FLASH accelerator are used to synchronize all accelerator subsystems and are managed by DOOCS timing server. Programmable timers are triggered by these events to generate the start pulses for the klystrons, FPGAs or uADCs. A timer unit provides several independent output channels. Some machine parameters that change from macro pulse to macro pulse are delivered to run all digital feedback loops in parallel. This information is available for the LLRF controller server. The control tables are generated through the LLRF library from the operational setting according to the provided timing information. Parameters such as beam start time, number of bunches, bunch repetition rates are extracted from the timing server for both beamlines. Other parameters like RF transition time, offsets with respect to beam pulse, etc. are adjustable. LLRF control software follows any changes of the timing parameters. Fig. 3 illustrates the timing setup for two beamlines.

Figure 3: An example of FLASH timing settings.

Figure 4: Energy and phase variation within RF pulse.

Energy and phase variations are possible to allow for charge dependent compression and wavelength fine tuning. A future extension with an additional beamline is already foreseen, as can be seen by the three different

levels of RF pulse (Fig. 4). Background colours show the beam start time and bunch train duration time for FLASH1 and FLASH2 beamlines. In order to avoid operational settings changes in unacceptable ranges, limits for FLASH2 operational parameters with respect to FLASH1 are implemented as well. An adaptive learning algorithm which minimizes repetitive control errors tends to limit these transition changes. In order to avoid oscillations, it is possible to deactivate adaptations for certain regions.

PERFORMANCE OF SIMULTANEOUS OPERATION OF FLASH1 AND FLASH2

In the initial stage of the project several tests have been performed to show that simultaneous operation of both beamlines is possible [10]. Fig. 5 shows lasing of two bunch trains which were generated with separate injector lasers, separated by 80 μs: a) with the same charge of about 0.5 nC and b) with a factor of 2 difference in charge, e.g. of 0.5 nC for the first and 0.25 nC for the second bunch train. The blue line indicates the actual SASE pulse energy produced by each individual electron bunch in the macro-pulse. The green line is the time average of this signal. The yellow line indicates the maximum SASE level which occurred since the measurement was started. Both bunch trains have a repetition rate of 1 MHz. The number of bunches in this case was 30 and 20 respectively. During this test only RF parameters were changed within the RF pulse and orbit was adjusted behind the FLASH2 extraction point. Because the FLASH2 beam line was under construction in that time, this test has been performed at FLASH1 beamline. Careful adjustment was done to make sure that both injector lasers hit the cathode under the same angle to make sure that the electron beams have the same trajectory. This condition was relaxed in the later situation, since the orbit in the FLASH1 and FLASH2 undulators can be adjusted independently to optimize lasing.

Figure 5: Lasing of two independent bunch trains with different charges and a variable delay in time.

Since 2014 tests have been performed with FLASH1 and FLASH2 in operation. First SASE operation in FLASH2 was achieved at wavelength 40 nm on August 20, 2014 [11] during FLASH1 operation with 250 bunches at 13.5 nm.

After the demonstration of the first lasing at FLASH2 the SASE operation was established at various wavelengths. So far, the maximum number of bunches per burst during a parallel SASE operation of both beamlines has been 400 bunches in FLASH1 and 30 bunches in FLASH2, both with a bunch repetition rate of 1 MHz. Fig. 6 shows the SASE pulse energy along the bunch trains in FLASH1 and FLASH2. During parallel operation achieved pulse energy at FLASH1 was about 200 μ J and about 100 μ J at FLASH2 in the period from June 2015 to August 2015.

Figure 6 : SASE pulse energy per bunch (in a.u.). Top: 400 bunches in FLASH1. Bottom: 30 bunches in FLASH2. Blue: actual value, green: average, yellow: maximum.

Figure 7: Photon wavelengths achieved in the FLASH1 and FLASH2 beamlines during parallel SASE operation.

In Fig. 7 [12] are shown photon wavelengths achieved in the FLASH1 and FLASH2 beamlines during parallel SASE operation in the period from August 2014 to August 2015. The photon wavelength in FLASH1 is

determined - due to the fixed gap undulator - by the electron beam energy. Variable gap undulators in FLASH2 allow different photon wavelength at fixed beam energies.

SUMMARY AND OUTLOOK

Low level RF control functionality has been extended which makes simultaneous RF operation of multi-beamlines possible. Changes in RF settings within RF pulse can be achieved which allow different compression settings for different charges (and therefore different bunch lengths) while maintaining the RF field amplitude and the phase stability requirements.

Simultaneous operation of two beamlines and lasing of FLASH2 at the wavelength 40 nm was achieved, while FLASH1 was lasing simultaneously with multi-bunch mode at different wavelength (13.5 nm). SASE operation at various wavelengths was established.

Gained experience with simultaneous operation of two beamlines at FLASH is a good basis for successful commissioning of multi-beamline facility European XFEL which is foreseen for the second half of 2016. At XFEL, operation of alternating RF pulses (from pulse to pulse) is foreseen as well. This operation mode requires additional changes in the firmware/software structure, e.g. extending the amount of control tables. Furthermore, requirements to the timing system are increased to reliably trigger the correct mode of operation.

BAYESIAN RELIABILITY MODEL FOR BEAM PERMIT SYSTEM OF RHIC AT BNL*

P. Chitnis[#], Stony Brook University, NY, USA
K. A. Brown, Brookhaven National Laboratory, NY, USA

Abstract

Bayesian Analysis provides a statistical framework for updating prior knowledge as observational evidence is acquired. It can handle complex and realistic models with flexibility. The Beam Permit System (BPS) of RHIC plays a key role in safeguarding against the faults occurring in the collider, hence directly impacts RHIC availability. Earlier a multistate reliability model [1] was developed to study the failure characteristics of the BPS that incorporated manufacturer and military handbook data. Over the course of its 15 years of operation, RHIC has brought forth operational failure data. This work aims towards the integration of earlier reliability calculations with operational failure data using Bayesian analysis. This paper discusses the Bayesian inference of the BPS reliability using a two-parameter Weibull survival model, with unknown scale and shape parameters. As the joint posterior distribution for Weibull with both parameters unknown is analytically intractable, the Markov Chain Monte Carlo methodology with Metropolis-Hastings algorithm is used to obtain the inference. Selection criteria for the Weibull distribution, prior density and hyperparameters are also discussed.

INTRODUCTION

The Beam Permit System (BPS) of Relativistic Heavy Ion Collider (RHIC) monitors the health of RHIC subsystems and takes active decisions regarding beam-abort and magnet power dump, upon a subsystem failure. The reliability of BPS thus directly impacts the RHIC downtime, and hence its availability. A Monte Carlo reliability model based on exponential competing risks was developed for BPS previously [1]. This model simulated the progression of basic component failures to system level catastrophic events. This work together with a quantitative fault tree analysis [2] helped characterize the failure rate and structural importance of each basic component of the BPS. RHIC has been operational for 15 years, and has gathered hardware failure data over this time period. This data represents the actual BPS failure attributes from a top level perspective. Bayesian analysis is a good candidate for combining these two information sources to get a combined inference about the system failure characteristics.

BAYESIAN PARADIGM

Bayesian statistics is branch of mathematics that deals

*Work supported by Brookhaven Science Associates, LLC under Contract No. DE-SC0012704 with the U.S. Department of Energy.
#prachi.chitnis@stonybrook.edu

with updating current knowledge about a system or process when new information is acquired. Statistical analysis follows two major approaches, namely frequentist and Bayesian. In the widely used frequentist approach, the probability distribution of an event is calculated by observing its occurrence over a large period of time, and the distribution parameters are assumed to be constant over time. In contrast, Bayesian approach keeps updating the probability distribution as new data arrives. The parameters of the distribution are treated as random variables that are modified according to the new information gathered. This becomes quite important when there are two sources of information about a system or process that indicate different results, and both sources hold significance to the inference.

The underlying framework for Bayesian analysis is Bayes theorem. Bayesian analysis involves the continuous form of the Bayes theorem [3], which is represented as

$$\pi(\theta|x) = \frac{L(\theta|x) \times \pi(\theta)}{f(x)}$$

The unknown parameter is θ , which defines the probability distribution of any process and is subject to change with the arrival of new information. Variable x is new source of information in the form of data observations. The term $\pi(\theta)$ is called as the prior distribution of θ , which can be elicited by using another parameter(s) called the *hyperparameter(s)*. $L(\theta|x)$ is the likelihood function for θ which is calculated by the gathering the new data. The term $\pi(\theta|x)$ is called the posterior distribution of θ , which is a combination of both prior and data likelihood function. $f(x)$ is the unconditional distribution of the variate x that acts as a normalizing factor in the equation. Because $f(x)$ is independent of θ :

$$\pi(\theta|x) \propto L(\theta|x) \times \pi(\theta) \quad (1)$$

This equation forms the foundation for Bayesian analysis discussed in this paper. We will discuss the selection of the prior distribution and data distribution (likelihood function) in subsequent sections.

PRELIMINARY ANALYSIS

Preliminary analysis is needed to find the suitability of Bayesian analysis to our problem and for choosing the distribution appropriate to the information sources we have. We analyze two the sources of information, the results from a Monte Carlo (MC) model [1] and the historical failure data obtained from the RHIC hardware maintenance records.

Source 1: Monte Carlo Results

The MC model defines the propagation of component failures to a system level, depending upon the states of other components and the structure of the system. As the component failures were taken from MIL-HDBK 217F [4] and the manufacturers' data, they provided point estimate for the hazard rate λ , with exponential survival distribution. These exponential failures might evolve as a different distribution on the system level. We combine the four system level failures modes in the MC model to a single failure for applying Bayesian analysis. Next we analyze the failure rate pattern of this single failure of BPS.

First, we check if the failure rate follows the Non Homogenous Poisson Process (NHPP) [5], for which specialized Bayesian analysis is needed. We plot the interval failure rates to see if it is time varying, and whether it follows a typical distribution. The number of failures in an interval of 10^7 hours is calculated, and the failure rate is plotted for each interval in Fig. 1. The rate is noisy but has a constant mean over the time. Thus we deduce that the MC model failure is not a NHPP.

Figure 1: Detection for NHPP failures.

Next, we find a suitable failure distribution function for the MC model. We run the simulation for $1.3E9$ iterations and the total failures are recorded as point processes. The times between failures are fitted with exponential, Weibull and gamma distributions with the forms specified in [6] using MATLAB® [7]. The goodness of fit is estimated by Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) [8].

Table 1: MC Model Failure Distribution

Distribution	Para meter	Point estimate	AIC	BIC
Exponential	λ	$8.831e-5$	3141125.52	3141136.15
	α	1		
Weibull	λ	$8.829e-5$	3141127.47	3141148.72
	α	1.00046		
Gamma	λ	$8.84e-5$	3141127.44	3141148.66
	α	1.00106		

As seen in table 1, the AIC and BIC are smallest for the exponential distribution, which indicates that the exponential distribution is the best fit to overall system failure. The failure rate is λ and the shape parameter is α .

Although the military handbook is quite old (1995), its applicability to the BPS can justified as RHIC has been

running since 1997, which was contemporary to the release of this version of military handbook

Source 2: Historical Failure Data

We analyze the past 15 years of hardware failure data of BPS, and select the system level failures that are similar to the ones analyzed by the MC model. We find overall 16 data points for the time between failures owing to high reliability of BPS. To analyze the distribution of this data, we fit Exponential, Weibull, Gamma and Lognormal distributions using MATLAB® and goodness of fit is estimated using AIC and BIC.

Table 2: Historical Failure Data Distribution

Distribution	Para meter	Point estimate	AIC	BIC
Exponential	λ	$1.20E-04$	322.9279	323.7005
	α	1		
Weibull	λ	0.000171	317.6438	319.189
	α	0.627457		
Gamma	λ	$6.03E-05$	318.1511	319.6963
	α	0.503074		
Lognormal	μ	7.7676	319.0121	320.5573
	σ	1.99141		

Looking at the table 2, we see that the AIC and BIC are now smallest for the Weibull distribution, asserting that the BPS has a Weibull survival distribution with decreasing failure rate. The historical data distribution represents the actual failure characteristics of the system, even if the MC model suggests that the system follows exponential survival distribution.

BAYESIAN RELIABILITY MODEL

The parameters of the posterior distribution reflect the tradeoff between the prior distribution and the data distribution (incorporated using likelihood function). This tradeoff level is determined by the relative strength of prior and data distributions. The influence of either can be changed by altering the hyperparameters. It is often desirable to choose a prior of a form such that the posterior distribution calculated is mathematically tractable. One of the techniques is to employ a “conjugate prior” that yields a posterior of the same form as the data distribution [3], but with different parameters. The posterior parameters specify the adjustment between prior and data.

For our Bayesian model, the prior information is an exponential distribution and the data is a Weibull distribution with shape parameter less than 1. We thus assume that the prior information is also a Weibull distribution with shape parameter equal to 1. Also scale parameters of both the information sources is different. Thus we need to choose a Bayesian model for Weibull distribution with both shape and scale parameters unknown. To implement this, we first need to choose a conjugate prior distribution that is suitable to the Weibull distribution of the data. There is no best way to define a prior distribution for Bayesian analysis. The following

sections outline the development of the Bayesian model step by step.

Data Distribution

Vidakovic [9] suggests a model for the Bayesian inference of Weibull distribution that is unknown in both shape and scale parameters. We follow this model throughout our analysis. Following is the Weibull distribution used by Vidakovic, with α as the shape parameter and $\eta^{-1/\alpha}$ as the scale parameter. Variable x is the times between failures data in years. This form does not have explicit posteriors for α and η . We will draw Bayesian inference for these two parameters.

$$f(x|\alpha, \eta) = \alpha \eta x^{\alpha-1} e^{-\eta x^\alpha}$$

The likelihood function is then equal to

$$L(\alpha, \eta|x) = \prod_i^k \alpha \eta x_i^{\alpha-1} e^{-\eta x_i^\alpha}$$

The α and η are treated as variables in the likelihood function, and have $[0, \infty)$ support. The most probable values are given by

$$\alpha = 0.6275, \eta = 1.2904 \quad (2)$$

Figure 2: Likelihood function plot with α, η .

These values are calculated by transforming the parameters from the Weibull distribution of data from table 2. Fig. 2 plots the 3D likelihood function with α and η as variables. Note that α and η values from Eq. 2 correspond to the maximum likelihood point.

Conjugate Prior Distribution

A conjugate prior distribution is proposed for the Weibull distribution in [9]. This is a joint distribution for α and η , with a hyperparameter β .

$$p(\alpha, \eta) \propto e^{-\alpha} \eta^{\beta-1} e^{-\eta \beta} \quad (3)$$

Note that we only use the kernel (omitting the proportionality constant) of the prior distribution. This is explained later in the posterior inference. The prior

parameter λ (and $\alpha=1$) representing the exponential distribution (Weibull with shape as 1) in table 1 are converted to α and η as

$$\alpha = 1, \eta = 0.7741 \quad (4)$$

These are the point estimates. We need to define the joint distribution of α and η so that it best represents our beliefs about the prior information. We choose the hyperparameter β equal to 3. The reason for choosing β is explained by the figures below. The 3D prior density from Eq. 3 is plotted with α and η as variables in Fig. 3. Note that the magnitude on the plot is unnormalized. The point estimates from Eq. 4 are plotted as a red dot on the same figure. Note that this point does not correspond to the peak of magnitude in the plot.

Figure 3: Prior density plot with α, η .

To get a clear picture we plot the 2D prior density for η with constant $\alpha = 1$ in Fig. 4a and the 2D prior density for α with constant $\eta = 0.7741$ in Fig. 4b.

Figure 4: 2D Prior densities for α, η .

In Fig. 4a, the point estimate lies almost on the peak of the density distribution which signifies our confidence in the value of scale parameter of the prior obtained from the MC model. But if we look at Fig. 4b, the point estimate

does not lie on the peak, rather much lower than the highest magnitude point. This is chosen because the shape parameter is a system characteristic, which is less likely to change. For the data distribution we saw that α is much less than one in Eq. 2. So we express more confidence in the lower values of α than the one obtained from the MC model. Thus the prior density is higher for smaller values of α in Fig. 4b.

Posterior Inference

The posterior distribution is a fusion of the prior and data distributions that contains all the information of the parameters of the system, in our case α and η . From Eq. 1 we get the proportionality equation (or kernel) for posterior as:

$$p(\alpha, \eta | x) \propto \alpha^k \eta^{k+\beta-1} \left(\prod_i x_i \right)^{\alpha-1} e^{(-\eta \sum x_i^\alpha - \alpha - \eta \beta)}$$

Here k is the total number of data points. As this is a complicated joint distribution of α and η , it is not possible to obtain independent and identically distributed samples directly from this unnormalized kernel. We use the Metropolis Hastings (MH) algorithm which is a type of iterative Markov Chain Monte Carlo (MCMC) technique [3]. The parameters α and η are calculated as sample averages of realizations of Markov chains, so one has to ensure that the Markov chain has converged before drawing the samples. To generate the random samples of α and η , a “proposal density” is used, given the samples from previous iteration. Following proposal density is suggested in [9].

$$q(\alpha', \eta' | \alpha, \eta) = \frac{1}{\alpha \eta} e^{\left(\frac{\alpha'}{\alpha} - \frac{\eta'}{\eta} \right)}$$

Here α', η' are the new samples and α, η are the previous samples. In MH algorithm first we draw samples from the proposal density. This sample is then accepted or rejected as per the acceptance probability given by:

$$a((\alpha', \eta'), (\alpha, \eta)) = \min \left\{ 1, \frac{p(\alpha', \eta') / q(\alpha', \eta' | \alpha, \eta)}{p(\alpha, \eta) / q(\alpha, \eta | \alpha', \eta')} \right\}$$

There is a typical advantage of MH algorithm that we need not consider the full conditionals because the normalizing factors cancel in the ratio of acceptance probability equation. For more details on the MH algorithm please refer to [3] and [9].

RESULTS

After running 25K iterations of the MH algorithm on the posterior density, we reject the initial 5000 samples to allow the Markov chain convergence. Next we plot the remaining samples to get a 3D plot of the posterior. Fig. 5 shows the samples (green dots) obtained from the MH algorithm, and a connecting surface is plotted.

To obtain the values of α and η from the posterior, we look at the samples obtained from the MH algorithm. Fig. 6 and Fig. 7 show the samples of α and η and their histograms.

As seen, the subsequent sample generation looks stationary [5], thus we can say that the Markov chains have converged. Also looking at the histograms in Fig. 7, they resemble the normal distribution, thus the means of the samples represent the meaningful inference for α and η parameters.

We obtain the following values of α and η for the posterior:

$$\alpha = 0.6327, \eta = 1.2225 \quad (5)$$

Figure 5: Posterior density for α, η .

Figure 6: α, η samples from MH algorithm.

Figure 7: α, η samples' histogram from MH algorithm.

DISCUSSION

Fig. 8 shows the cumulative failure distribution function of the prior, data and posterior distributions for Weibull using the parameters in Eq. 2, Eq. 4 and Eq. 5. According to our discussion on choosing the hyperparameter β , we expressed low confidence in the value of α being 1. This can be seen in Fig. 8 where the posterior shape is more like the data distribution, i.e. the relative strength of the data distribution is much more than the prior distribution.

Figure 8: Cumulative failure distributions for $\beta=3$.

To illustrate the concept of relative strength of prior and data, we increase the confidence in prior by increasing the hyperparameter value. Fig. 9 shows the prior, data and posterior distribution for β equal to 15.

Figure 9: Cumulative failure distributions for $\beta=15$.

The prior strength is now increased that is apparent on the posterior, which is now closer to the prior as compared to Fig. 8. The posterior parameters for $\beta = 15$ are a higher value of $\alpha = 0.6404$ and lower value of $\eta = 1.1249$. For our analysis, we uphold the value of $\beta = 3$, because it represents our high confidence in the actual machine failure data, with a mild influence of the MC model results.

CONCLUSION

RHIC beam permit system has been extensively studied for its reliability characteristics. The MC model provides many insights to the reliability performance of the BPS. This includes the marginal probability values of various system level catastrophic events, marginal probabilities of

failure modes of individual modules, importance of each component with respect to its failure rate and structural placement, paths of failure propagation and bottlenecks in the system. This helped understand very fine failure dynamics of the beam permit system. However it uses the military handbook which is quite conservative in its approach.

On the other hand, the historical failure data of BPS provides us with the actual failure aspects of the system. This helps to quantify the overall system failure distribution that emerged as a Weibull failure distribution with decreasing failure function. It represents the real survival behavior of the BPS. However due to high the reliability of BPS, we have a small data of only 16 failures points till date, which does not allow us to take a profound look into the system.

Thus it is necessary to emphasize the importance of both the information sources. Bayesian paradigm facilitates an excellent way to coalesce these two to furnish the most informed inference [10] about the BPS reliability, with flexibility to regulate the influence of either of the information sources according our confidence in them.

ACKNOWLEDGEMENT

This work would not have been possible without the guidance of S. T. Rachev, who helped built strong fundamentals in Bayesian statistical framework. We thank him for his continued support. We also thank T. G. Robertazzi for building basics in probability and statistics. Additionally we thank R. Schoenfeld and C. Theisen for help in mining the historical failure data.

CONTINUOUS DELIVERY AT SOLEIL

G. Abeillé, A. Buteau, X. Elattaoui, S. Lê, Synchrotron SOLEIL, Gif-sur-Yvette, France
G. Boissinot, Zenika, Paris, France

Abstract

IT Department of Synchrotron SOLEIL [1] is structured along of a team of software developers responsible for the development and maintenance of all software from hardware controls up to supervision applications. With a very heterogonous development environment such as, several software languages, strongly coupled components and an increasing number of releases of the entire software stacks, it has become mandatory to standardize the entire development process through a “Continuous Delivery approach”; making it easy to release and deploy on time at any time. We achieved our objectives by building up a Continuous Delivery solution around two aspects, Deployment Pipeline [2] and DevOps [3].

A deployment pipeline is achievable by extensively automating all stages of the delivery process (the continuous integration of software, the binaries build and the integration tests). Another key point of Continuous Delivery is also a close collaboration between software developers and system administrators, often known as the DevOps movement.

This paper details the feedbacks on how we have adopted this Continuous Delivery approach, modifying our daily development team life and give an overview of the future steps.

SOLEIL CONCERNS&ANALYSIS

Synchrotron SOLEIL is a service center that delivers photons to external scientific users. The 24/7 operation of the Synchrotron SOLEIL facility relies on developed software by the “Control and Acquisition Software” team. This team has to regularly deliver changes requested by the business; it has become a challenge to perform it in the right timeframe. That is why the Continuous Integration and Delivery concepts have been studied. The main objective of these concepts is to automate every single process from the code building up to its operation in production.

Continuous Integration

Continuous Integration is a practice for detecting software defects at the earliest stage possible within the full development cycle to limit them via the automation of every step. Continuous Integration relies on key elements such as:

- *Version Control*: everything must be checked in to a single version control repository: code, tests, build and deployment scripts...
- *Automated Build*: Every project must be built and tested from the command line and must be runnable into the Continuous Integration environment.

- *Team agreement*: The commitment of the whole development team is required. Everyone must frequently check in small changes; and agree that the highest priority task is to fix any change that breaks the application.

Continuous Delivery

Continuous Delivery goes a step further. It assures to deliver a fully working and tested software in small incremental chunks to the production platform. It enables frequent release and deployment. All phases of a software product lifecycle from its coding up to production maintenance have to be automated (Fig. 1).

Figure 1: Continuous delivery.

DevOps

Soleil DevOps philosophy strengthens up a collaborative mode between the Development and Operations staff to achieve the same objectives: provide a full set of IT services meeting both business and IT requirements in terms of functionalities, responsiveness, and availability. DevOps is the mandatory journey to obtain a fully operational continuous delivery process.

Expected Benefits

The main expected benefits for SOLEIL of these methods are:

- Reduce all potential error-prone manual actions
- Reduce time to delivery; improve the reproducibility, repeatability and reliability of the delivery process.
- Federate the team around a common work process
- Focus on coding business requirements rather than on tooling
- Improve the synchronisation between change management and operation; reduce the number of incidents

SOLEIL CONTEXT

Figures

The Soleil Control and Acquisition Software team is composed by:

- 4 full time equivalent Java developers
- 3 full time equivalent C++ developers
- 1 full time equivalent for system administration
- 1 full time equivalent for quality assurance

This team has to manage:

- 380 software modules in Java or C++.
- Production under Linux or Windows
- All source code and scripts are checked-in various version control repositories: 1 local CVS server and 3 remote SVN servers.
- The dependency management and build tool used for Java and C++ codes is *Maven 2* [4]. All code is continuously built and monitored within a “scheduler” web server called *Jenkins* [5]. It contains approximately 500 jobs.
- All the artifacts produced by Jenkins are stored in an artifact repository called *Nexus* [6]

The current CI platform architecture is the following (Fig.2):

Figure 2: Current CI platform.

Each member of the team has to manage a very high number of components and their dependencies. Figure 3 is dependency tree example that illustrates the complexity of mastering a module's dependencies:

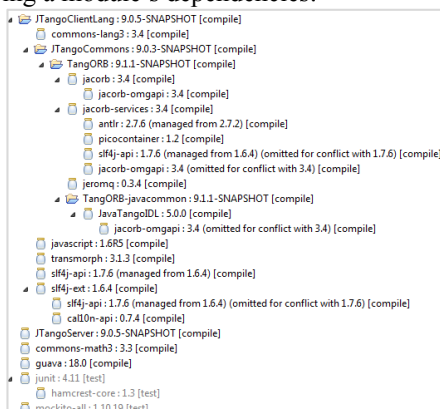

Figure 3: Dependency tree of a SOLEIL Java module.

Only a subset of our projects contains unit and integration tests.

“Zip” packages are assembled with Maven and delivered at every Machine shutdown (~ every 2 months) on 30 production platforms. The deployment process is fully automated with Linux shell scripts. The packages

ISBN 978-3-95450-148-9

deployment interrupts each production platform for approximately 2 hours. Very basic acceptance tests are run manually directly after deployment during this time-slot.

The production platforms have been standardized almost everywhere:

- All the Linux servers have been just virtualised with the container technology OpenVZ [7]. There are 145 containers in operation.
- 200 industrial PC that controls hardware with windows.
- 130 “exotic” PCs that are imposed by suppliers of detectors, power supplies...

Real Life Situation

With such heterogeneity, it is a daily challenge to maintain such a Continuous Integration platform. As the main issue of the current solution is due on its global complexity, a limited number of admin are able to administer this platform.

The number of failed jobs in Jenkins is still high as some developers are considering Jenkins notification emails just as spam emails.

The current solution suffers also from technical issues, i.e. we are stuck with legacy versions of the tools because the upgrade is far from trivial.

Moreover, some parts of the C++ modules are not even considered in the continuous integration system as some Maven C++ plugins are not fully compliant (i.e. mixing compiler versions or 32/64 platforms).

Our Continuous Delivery process highlights the complexity of our software and infrastructure which has required an audit of the current process. Some aspects have been totally revamped as detailed hereafter.

OUR CONTINUOUS DELIVERY SOLUTION

Some key aspects of the delivery pipeline must be reviewed considering both methodological and technical aspects.

Team Collaboration

A fully operational deployment pipeline relies primarily on the commitment of the entire development team. This aspect has been quite underestimated and it is essential to emphasize it. A background activity is now being driven to convince the team that improving the quality of their deliverables should be the highest priority. A first step is to encourage everyone to discuss and share on technical aspects or on work methodologies either during organized meetings or stand-up-meetings. Furthermore, SOLEIL has the chance that the Control and Acquisition Software team is a mix of both developers and system administrators, but there is still room for improvement regarding the DevOps movement:

- System administrators need to get closer to the business requirements for efficiently managing the infrastructure.
- Developers need to get closer to the operation so that it becomes a reflex to include key operational indicators and logging information for incident analysis when developing a software service.

The continuous delivery process also introduces a new central role for the quality assurance staff that is that a daily challenge considering the small size of the team and the business pressure for delivering. The quality assurance manager have to take in charge the building of the team cohesion, collaboration, communication to change for adopting the Continuous Delivery paradigm. He must have also a full DevOps profile to manage the whole deployment pipeline from assistance and training of developers to the administration and monitoring of the Continuous Delivery platform. And finally, he should constantly review and ensure that the delivery demands are respected.

Another key success factor is the involvement of the business since it is directly impacted by some aspects of the Continuous Delivery process (i.e. the deployment and the operation of our software deliverables). Exposing our process and our commitment through a service agreement enables the business to be part of the process of change management to validate, accept and plan every delivery.

Change Management

Today, many incidents are still raised due to direct modifications in the production environment. Forbid this bad habits and force a strict change management process are keys to limit incidents in production. Any change has to be tested before it goes live. Only an approved deliverable by both IT and business can be shipped to the production environment.

Simplification

For maintaining the whole Continuous Delivery platform at a reasonable total cost of ownership, the only solution is to reduce the number of parameters like:

- the number of software components;
- the number of target platforms;
- the number of Version Control System.

But the path towards simplification is tricky as it implies a deep reconsideration of our practices. Moreover, the cost of simplification can be huge.

Build lifecycle and Dependency Management

A software module metadata is split in various locations:

- Inside the build descriptor on the Version Control System
- Inside the project job configuration in Jenkins

To manage the large set of components, it is mandatory to provide a central service that manages the information and lifecycle of a project, for example:

- Version Control System information
- Authors: e-mail addresses
- Status: OPEN, CLOSED

To afford developers a simple way for managing their project dependencies, the only solution for SOLEIL is to enforce a “LATEST” strategy meaning that all retrieved dependencies of a component are automatically set to the latest version. It has been made possible by using some advance features of Maven 2. But the current Maven solution suffers from issues:

- The update to the latest versions is done by a polling mechanism and it contains many caches along the build process. The latest version is not always guaranteed.
- This latest strategy relies on a deprecated Maven key word “RELEASE”.

Consequently, we cannot upgrade to the latest build tools (Maven 3 [4] or Gradle 2 [8]) because of this “LATEST strategy”. Since there is no off-the-shelf solution, the only way is to design a totally custom one. The lifecycle of our components is imposed by Maven with only 2 statuses (SNAPSHOT and RELEASE). The review of the solution has led us defining new statuses and promotion in between. The new defined statuses are:

- *BUILD*: project under build
- *INTEGRATION*: project ready for continuous integration
- *RELEASE*: project build, integrated and tagged. Ready for packaging.

On the other hand, The Maven solution for C++ does not fulfil all the requirements. So the best solution is to move to a native tool for C++ build like for example Scons [9] or CMake [10].

User Acceptance Test (UAT) Platform

Acceptance testing ensures that the user needs, requirements and business process are met.

At SOLEIL, the only actual testing is done manually directly into production just after deployment by the IT and the business teams (when related to Machine equipment). The deployment operation is quite long and risky, with an iterative patching and re patching process until disappearance of incidents, regardless of user satisfaction.

It is obvious that an UAT platform that mirrors the production should be set. Then the continuous integration server will automatically deploy our fresh packages with the same deployment process as the production’s one. On this platform, we should at least run manual tests before establishing more and more automated tests.

Considering that 20% of our software controls hardware, with some of them unique (vacuum pumps, power supplies...), we have to develop a simulation strategy.

Deployment

Currently, only a system administrator deploys zip packages for linux and windows. A better solution is to

use the OS native packaging system such as rpm for our RedHat distributions so that libraries conflicts can be detected at the deployment time instead of runtime.

Moreover, all of our binaries are deployed on a central mounting point with Linux shell scripts. A better solution is to deploy only the necessary binaries directly of the right target with tools that allow easy large-scale deployment whilst adding consistence and compliance checks. So we need to include tools like Puppet [11], Ansible [12] or CFEngine [13]...for our deployment phase.

Monitoring

Enabling efficient and easy ways to monitor the operation of our deliveries is also one of the key success factors.

For the monitoring of the infrastructure we use Nagios [14]. Our system administrator is currently thinly tuning it to provide key performance indicators, so that every alarm will be considered as an incident that must be taken into account immediately.

Our software applications do not provide at this stage enough audit logging or monitoring indicators. We must standardize our application logging system for archiving all of them. Developers should also integrate runtime application indicators that can then be included in a monitoring system and thus raise alarms.

Our New Architecture

To address the whole technical points previously addressed, a new solution has been designed. Here is the overview of the architecture (Fig. 4):

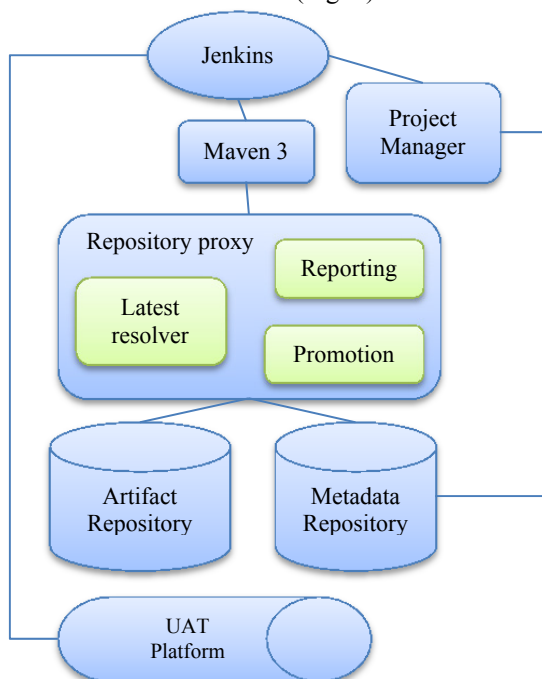

Figure 4: The new Continuous Delivery platform.

The “*Project Manager*” provides the service to create, update and close a project. This service will automatically configure the Continuous Integration server (Jenkins).

The “*Repository proxy*” is a service on top a collection of binary software artifacts and metadata. It provides some custom functions such as:

- *Latest Resolver*: it retrieves the latest version of a component.
- *Promotion*: it promotes a component ensuring the pre-defined lifecycle. For example, releasing a component will create a tag on the Version Control System and deploy the binary into the artifact repository.
- *Reporting*: provide audit reports like for example the list of promoted artifacts between two dates.

The whole solution is based on the Java technology. All services are provided as REST (REpresentational State Transfer) Web Services following the Microservices architecture [15]. The artifact repository is implemented with a MongoDB [16] document oriented NoSQL database. For the UAT automated tests, the technology choice is to be made.

Plan of Action

Putting in application the whole continuously delivery process is an enormous challenge given SOLEIL complexity and the limited resources allocated for this project. Hence, an iterative strategy has to be defined.

Firstly, the cases of Java and C++ have to be addressed separately. So a new continuous integration server will be set-up first for Java modules. The C++ case will be addressed later. Secondly, the continuous integration platform will be upgraded before moving on other aspects such as the UAT platform, the deployment and monitoring processes.

The new architecture is currently under development. The “project manager” service is fully operational and the “repository proxy” service is still under coding.

The SOLEIL infrastructure virtualization has opened up new possibilities. It is now faster and easier to set up and change the environment for development, continuous delivery, and acceptance platforms. So, the set-up and qualification of new solution platform is in progress.

The toggle to the new Continuous Integration solution for the Java part is straightforward for Java developers as the build tool is still the same. The only induced change should be in the management of the component lifecycle; the developers have to be trained on how to promote their components.

For the C++ part, the solution will depend on the workload. So the a-minima solution will keep Maven while the “deluxe” will use a native C++ build tool.

Moreover, at every new step or change, a continuous communication and training of the team must be driven to remind the IT and business teams why and how it will be applied. It is now obvious at SOLEIL that the methodologies and tool set up must follow the maturity of our team and not the other way round.

CONCLUSION

Continuous Delivery is a key activity for conducting the quality of. IT services. But, the cost for putting the process smoothly in operation is always underestimated.

The Continuous Delivery approach is holistic and challenges us on every aspect of our daily practices. It enforces to manage the total cost of ownership of a service from its inception up to its operation. A deployment pipeline automation goal is to reduce the time and cost of a delivery, so each special case can add more complexity and cost to it. Therefore there is no other solution than to standardizing and simplifying all our practices. In this context, SOLEIL is currently initiating the implementation of some ITIL practices which is a framework of best practices for managing IT services [17].

After a 10 years' experience of operation, SOLEIL still need to emphasize a close coordination between developers and system administrators following DevOps philosophy.

Continuous Delivery relies on strong convictions. You have to be intimately convinced and motivated to be able to convince the whole company including technical staff; managers; and even business users.

In conclusion, SOLEIL can finally see the light at the end of the deployment pipeline but putting in application the Continuous Delivery paradigm is really a long-winded task worthwhile the effort to obtain the requested quality level of service.

Abstract

The National Ignition Facility (NIF) is the world's largest and most energetic laser experimental facility with 192 beams capable of delivering 1.8 megajoules of 500-terawatt ultraviolet laser energy. The energy, temperatures and pressures capable of being generated allow scientists the ability to generate conditions similar to the center of the sun and explore physics of planetary interiors, supernovae, black holes and thermonuclear burn. NIF has transitioned to a 24x7 operational facility and in the past year significant focus has been placed on increasing the volume of experimental shots capable of being conducted so as to satisfy the demand from the wide range of user groups. The goal for the current fiscal year is a shot rate of 300 (> 50% increase over the previous year), increasing to a sustainable rate of 400 the year after. The primary focus areas to achieve these increases are; making more shot time available, improvements in experiment scheduling, and reducing the duration of a shot cycle. This talk will discuss the control system improvements implemented and planned to reduce the shot cycle duration and the systematic approaches taken to identify and prioritize them.

INTRODUCTION

The National Ignition Facility (NIF) laser system [1] provides a scientific center for the study of inertial confinement fusion (ICF) and matter at extreme energy densities and pressures [2]. Each NIF experiment, or shot cycle, is managed by the Integrated Computer Control System (ICCS) [3], which uses a scalable software architecture running code on more than 2000 front end processors, embedded controllers and supervisory servers. The NIF control system operates laser and industrial controls hardware containing 66,000 control points to ensure that all of NIF's laser beams arrive at the target within 30 picoseconds of each other and are aligned to a pointing accuracy of less than 50 microns. Every NIF shot cycle [4] consists of approximately 1.6 million sequenced control point operations, such as beampath alignment, configuring diagnostics and arming triggers.

NIF has transitioned to a 24x7 operational facility and in the past year significant focus has been placed on increasing the volume of experimental shots capable of

[#] brunton2@llnl.gov

being conducted so as to satisfy the demand from its wide range of scientific user groups and maximizing the return of experimental data. The goal for the FY15 fiscal year was defined as a shot rate of 300 (> 50% increase over the previous year), increasing to a sustainable rate of 400 the year after. Figure 1 depicts the historical shot rate achieved on NIF and the goals going forward. Also indicated are the planned methods for achieving these goals:

- Formalizing a 24/5 shot week and increasing the number of weeks per year performing experiments (increased to 44 weeks)
- Improving the NIF shot scheduling paradigm by grouping similar shots to minimize the frequency of mid-week diagnostic reconfigurations
- Reducing the shot to shot durations. This includes both the shot cycle duration and the activities performed between each shot

Figure 1: Historical and Planned NIF shot rates.

With both the increase in shot weeks and shot scheduling improvements commenced focus shifted to reducing the shot to shot durations. This work discusses the approach that was taken, a summary of the enhancements implemented and the results achieved.

ANALYSIS APPROACH

During each shot metrics are collected and archived that capture execution times of all phases and steps of the cycle. The mining of information from this vast data set was a critical component of the analysis and led to many of the identified improvements. To assist in rapidly visualizing these metrics the team leveraged the use of Splunk [5], a tool that we previously had extensively used

to monitoring the health of the control system [6]. Splunk quickly highlighted key metrics at a high level for each shot cycle by presenting the data using a Gantt-like view with detailed information associated with each phase.

NIF shot cycle durations vary considerably depending of the complexity of the experiment and thus the metrics were subcategorized as such. The most recent 3 months of metrics were analyzed and a baseline defined to measure future success. Table 1 highlights these baseline metrics

Table 1: Q4FY14 Average Shot Cycle Durations

Shot Cycle Category	Average Shot Cycle Duration (Hours)
Warm Simple	19.6
Warm Complex	22.7
Cold	24.0
Layered	45.2

A top-down analysis was performed to identify the major shot activity sequences and determine, given system requirements and constraints, whether any resequencing could be performed to reduce the overall critical path through improved parallelization. In doing so both the critical path and ‘close-to’ critical path sequences were analyzed to ensure the evaluation of savings was accurate.

A bottom-up analysis was then performed on significant critical path activities to identify whether any could be optimized. As with the top-down analysis, Splunk greatly assisted in providing a rapid and consistent method to mine, visualize and identify the key significant activities worthy of further detailed analysis.

Return on investments were calculated on each proposed enhancement to ensure sufficient savings were achievable and that each was assigned the appropriate prioritization. The following section summarizes the major control system enhancements selected and implemented.

ENHANCEMENTS SUMMARY

Laser Preparation Parallel Shot Cycles

Top-down analysis identified that although laser energetic qualification was performed once target and diagnostic alignment were completed it could in fact be performed in parallel. There was no system requirement for this constraint other than the presently imposed automated shot cycle sequencing. A shot cycle enhancement was planned and implemented to allow NIF operations to perform these functions concurrently in two parallel shot cycles and synchronize once complete. This allowed the laser setup activity to be performed off-critical-path which resulted in reducing the overall shot cycle by up to 1 hour. Figure 2 presents a simplified Gantt view of the major shot cycle activities and depicts how they are now executed across two parallel shot cycles

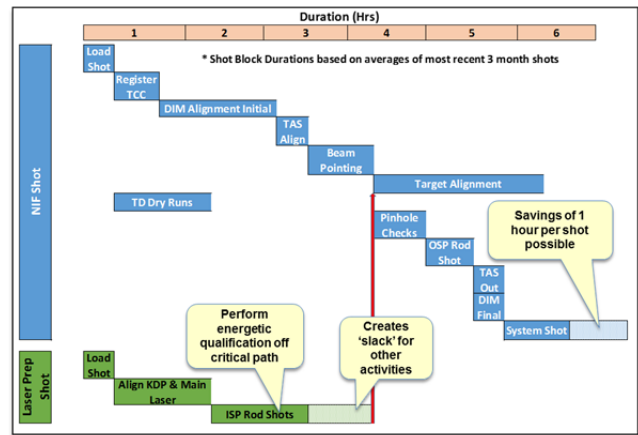

Figure 2: Parallel Shot Cycles Gantt View.

With the introduction of parallel laser preparation shot cycles two activities were identified to utilize the ‘slack’ time created. The first was the verification of amplitude modulation levels that is required following a facility wavelength reconfiguration (occurred 120 times during FY14). The second is the pulse shape calibration loop (Loop1) performed for high precision experiments (occurred 150 times during FY14). Both of these activities previously required discrete shot cycles to complete (2-3 hrs each).

Leveraging the new laser preparation shot framework, software modifications were implemented to optionally execute both these high frequency activities as part of the primary experiment and obviate the need for discrete shot cycles.

Target Alignment Assistance Tool

Target alignment sequences are typically one of the longest duration critical path activities and additionally had the greatest variances. Unlike NIF laser alignment, the target alignment process remains a largely manual process with some operator assists. The variations in NIF target types and alignment fiducials have historically made automating this process difficult. Much of the variance was identified to be caused by user input errors and experience levels in operational staff.

To aid with solving this, a new Target Alignment Assistance Tool (TAAT) was implemented. The tool uses Excel based script templates to semi-automate the manual alignment approach. The tool interfaces directly into the control system for measurement data provides the ability to embed alignment formulae, defined by subject matter experts, thereby removing opportunities for user input error. This data driven approach provides flexibility to adapt to novel target types and new alignment templates can rapidly be deployed without the need for any software modifications. Table 2 below details the reductions in user input achieved through use of the tool. In addition to a reduction of alignment time variance the use of the TAAT tool is saving approximately 30 minutes per alignment sequence over the previous manual approach.

Table 2: Comparison of User Input Savings Using TAAT

	# Measurements	# Moves	# Data Entries	# Move Choices
With Manual Alignment	1413	130	83	26
With TAAT	763	34	0	0
Savings (%)	46%	74%	100%	100%

New Positioner Rules Of Engagement

Another source of alignment duration variance was found to be operator availability and coordination. Until recently the majority of the positioner movement rules of engagement required 2 operators (move requestor and move approver/observer). Lack of availability of one of the two required operators, due to various disruptions and distractions, often impacted the positioner alignment durations. To reduce the impact the rules of engagement were revised. The new rules resulted in the ability for a single operator to perform 90% of the shot cycle positioner moves without a secondary approver/observer whilst still ensuring machine safety was not compromised. The control software enhancements provide verification that the new rules are enforced. Only the final fine alignment steps, when positioners are within very close proximity, now require a 2 operator rule. The revised rules allow single operator positioner movements under the following circumstances:

- Concurrent positioner movements (insertions and retractions) for positioners outside the safe handoff boundary (1.4m from chamber center)
- Single positioner moves when no other positioners are unlocked and no other positioners are inside the critical zone (50cm from chamber center)
- Concurrent positioner retractions (z-only moves inside safe handoff zone) if none are deemed to be entangleable

Critical Path Analysis Tool

There was a significant initial effort required in manual data analysis to identify the critical path for a single or group of shot. It was challenging to identify how much slack existed in a non-critical path segment so as to accurately evaluate expected benefits from reducing the critical path. As we fully expected to continue to optimize the sequencing of the shot cycle we invested in the development of a Critical Path Analysis Tool (CPAT) to ease the burden of this analysis and to aid in measuring benefits from enhancements and to identify further gains. The tool provides far more detailed metrics than the manual analysis. Figure 3 displays a screenshot of the CPAT tool showing the visualization of a critical path segment of the shot cycle. The tool has already been used to identify sub-optimal sequencing of the pre-amplifier (rod) shot activities. With resequencing, 5 minutes have been saved of each of the 1300 rod shots fired annually which equates to approximately 11 additional shot cycles.

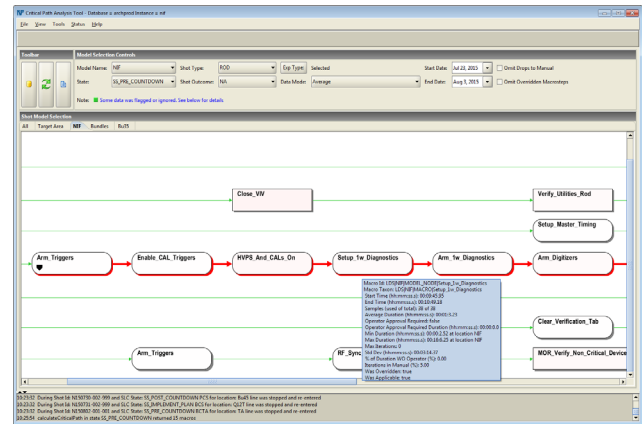

Figure 3: Critical Path Analysis Tool (CPAT) example.

Final Optics Damage Inspection Optimization

A long critical path activity that occurs between shot cycles is the inspection of the NIF final optics. The activity uses a single camera located at target chamber center and it is positioned to inspect each optic set using a hexapod manipulator. With only a single camera, that needs to inspect up to 192 beamlines, the process can take over 3 hours to complete. By analyzing source code debug logging during a scan it was identified that by disabling focus motor braking during the scan of a single beamline and performing moves in parallel with reconfiguration of the backlighting laser that significant savings were feasible. The software modifications yielded savings of 50 minutes per scan. With inspections required 2-4 times per week the savings totalled 110 operational hours per year.

Diagnostic Foreline Vacuum Automation

Diagnostic reconfigurations between each shot can be a costly activity to vent and pump down following the exchange. To reduce the impact, vacuum automation was developed for the valve and hi-vac pump management system drastically reducing the amount of human interaction from industrial controls operations staff. Automation was added for 3 diagnostic positioners, the Cryo Target Positioner and 5 of the fixed diagnostic packages. The automation allows operations staff to initiate vent and pump cycles with a few button clicks and the automation manages the valve and pump control. The automation has significantly reduced operator interactions thus avoiding availability delays and potential for human error. Savings obtained range from 15-30 minutes per diagnostic positioner/package.

SHOT RATE IMPROVEMENT STATUS

With the majority of the shot rate improvements having now been deployed benefits obtained from them were measured. NIF set itself a challenging goal of 300 target shots during FY15 which represented a shot rate greater than 50% more than FY14. Figure 4 details the monthly shot volume and the average weekly shot rates achieved this year. As shown, NIF completed its goal 1 month

ahead of schedule with an anticipated total annual shot count of approximately 350.

Figure 4: FY15 Shot rate metrics.

The two weekly shot rate threshold lines show the required rates for 300 and 400 annual shots respectively. During the final months of the year NIF exceeded the 400 shot rate threshold, with the exception of July due to a facility maintenance period, therefore we believe we are in an excellent position to meet the FY16 goal.

As a result of all the shot rate improvement initiatives, significant reductions have also been achieved in the shot to shot durations for all experiment categories as indicated in the table 3.

Table 3: Shot to Shot Average Duration Improvements

	Baseline Average Shot Cycle Duration (Hours)	Post- Optimizations Average Shot Cycle Duration (Hours)
Warm Simple	19.6	9.9
Warm Complex	22.7	11.7
Cold	24.0	12.3
Layered	45.2	23.0

FUTURE WORK

Although the majority of the shot rate improvement activities were completed in the past year NIF will be deploying three further major capabilities in the next two years to further benefit the shot rate.

‘Gatling’ shot cycle support to facilitate back to back system shots with only a single costly laser setup. Target exchanges are performed between each system shot and each uses a subset of the NIF beamlines. The first experiments are planned to be conducted this fall on NIF with a total of 8 shots expected to be performed in a 24 hour period which will represent a 3 hour saving for each additional shot performed in the series.

The Advanced Tracking Laser Alignment System (ATLAS) will use a laser tracking package for diagnostic positioner alignments and replace the existing alignment method using opposed port imaging systems. This method decouples the diagnostic alignment from the need to use the Target Alignment System (TAS) and thus removing the activity from the critical path.

Two additional Target and Diagnostic Manipulators (TANDM) are also being deployed over the next two

years. These multifunction positioners will allow continuous layering on the Cryo target positioner without impacting the shot schedule. The TANDM positioners require the ATLAS system as no opposing port alignment system (OPAS) is being implemented for alignment.

CONCLUSION

This paper presents the systems based approach taken to identify and implement the major enhancements to increase the NIF shot rate in FY15 and the results achieved. Historical metrics proved invaluable in the process to accurately assess the cost of shot activities and rapidly isolate where improvements would yield the biggest gains.

Both a top-down and bottom-up approach to analysis produced results but the former (i.e. big picture) typically yielded the biggest returns. Capturing accurate return on investments was very important as it aided in selling the need for change and to assign the appropriate prioritization.

System reliability is also very important to analyze in a highly parallelized control system as a single underperforming component can be very costly in a system with overall speed governed by the slowest cog.

System optimizations are often best left until system is complete however it is very important to consider throughout the system design phases to ensure constraints are not being unnecessarily imposed that would limit optimization potentials in the future.

INTRODUCING THE SCRUM FRAMEWORK AS PART OF THE PRODUCT DEVELOPMENT STRATEGY FOR THE ALBA CONTROL SYSTEM

G. Cuni, F. Becheri, D. Fernandez-Carreiras, Z. Reszela, S. Rubio-Manrique, ALBA-CELLS Synchrotron, Cerdanyola del Vallès, Spain

Abstract

The Controls Section at the Synchrotron ALBA[1], produces and supports the software to operate the accelerators, the beamlines and the peripheral laboratories. It covers a wide range of disciplines like vacuum, motion, data acquisition and analysis, graphical interfaces, or archiving. Since the installation and commissioning phases, we have been producing the software solutions mostly in single-developer projects based on the personal criteria. This organization scheme allowed each control engineer to gain the expertise in particular areas by being the unit contact responsible to develop and deliver products. In order to enrich the designs and improve the quality of solutions we have grouped the engineers in teams. The hierarchy of the product backlogs represents the desired features and the known defects in a transparent way. Instead of planning the whole project upfront, we try to design the products incrementally and develop them in short iterations mitigating the risk of not satisfying the evolving user requirements. This paper describes the introduction of the Scrum framework as the product development strategy in a service oriented organization like the Computing Division at Alba.

INTRODUCTION

Alba is a 3rd generation Synchrotron Light facility located in Cerdanyola del Vallès, (Barcelona), commissioned in 2012 with seven operational soft and hard X-ray beamlines, devoted to experiments in biosciences, condensed matter (magnetic and electronic properties, nanoscience) and materials science among others. Nowadays, two new beamlines are in construction (infrared microspectroscopy and low-energy ultra-high-resolution angular photoemission for complex materials).

In addition to the Controls Section, the Computing and Controls Division has other 3 sections devoted to management systems software, electronics design and support or Information Technology systems and network administration. The mission of the division is to offer services and give support to the beamlines, laboratories and accelerators, as well as to the whole installation to produce high quality experiments. The range of services comprises hardware and software solutions for control systems, personal safety, equipment protection, data acquisition, data analysis, high performance computing, document management, and networks and communications among others.

ORGANIZATION OF THE CONTROL SOFTWARE DEVELOPMENT DURING THE INSTALLATION AND EARLY OPERATION

The Controls Section was setup in the early 2005. During the phases of design, construction and installation the size of the team was progressively increasing until the current 16 members. The section was responsible for the design, installation and commissioning of projects in a wide range of disciplines, for both accelerators and beamlines. The fact of being a single support group for the whole facility showed important competitive advantages during the installation, where peak loads, could be better managed balancing manpower among the different customers. The software design, development, and the protection systems were scheduled in parallel for the accelerators and the beamlines, although the installation and commissioning of the accelerators engendered peak loads, which often took precedence in order to match the milestones and manage the critical paths for the deliveries. The project and the group relied on common tools, technologies, international collaborations and internal-developed transversal libraries and frameworks, crucial for keeping the service support manageable and the service level agreements.

The different products and subsystems were progressively delivered, and run in production. At this stage, the section started to share efforts between the ongoing projects and the service support with a number of bugs and defects to fix at the beginning, and later an increasing number of service requests and requests for change. The service desk relies on a ticketing system where every issue is registered with the relevant information to be classified by priority, unit (e.g. an accelerator's group, a specific beamline, etc.), and service (e.g. a subsystem like vacuum, motion, graphical interfaces, etc.). In this scenario, although all products were based on common tools, they were mostly developed by individuals, who ended up taking the responsibility for the related tickets (bugs or new feature requests), and therefore the particular knowledge of the product could not be spread.

Once the Control System has been delivered, during the operation, new features, bug fixes, and advanced functionalities need to be properly scheduled for deployment and commissioning in very restrictive time slots (mostly on shutdowns or "maintenance days"). Furthermore, during operation, the support and maintenance tasks for the running products gain priority

against new developments due to its critical effect on the stability, the performance, or new capabilities of the installation.

The combination of service management best practices and project management methodologies for the development of controls software has proven to be successful [2] allowing us to give support and rapidly respond to incidents as well as periodically provide updated versions of the software packages of the Alba Control System [3].

SPREADING THE KNOWLEDGE

Taking responsibility for a project is often a great motivation for a software developer. Making one single person responsible for the development, installation and support of a particular product is in many cases efficient. The developer feels immediately committed to the project and motivated for delivering a high quality product in time and within specifications. However, sometimes a project may be unmanageable by a single person, or in case of a deployed product in operation, the necessary knowledge needs to be spread and transferred to a bigger group to accomplish the required service level (i.e. 24/7). Having regular meetings among all the members of the group help to share information, functionalities, feature requests etc., so the team gets updated on the evolution of the products. However, although weekly meetings keep the group informed and the dedicated collaborative brainstorming sessions are also setup occasionally to inject fresh ideas into the project dynamics, the ownership of the products remains in the developer hands.

During the operation and support of the service, having the specific know-how of complex products centralized in one person has important risks. An urgent issue may be raised and require dedication of a person who had already committed 100% of his work time to another issue, a scheduled maintenance task or a delivery on a fixed deadline. Being the only developer able to do some tasks creates also internal stress when equally urgent high priority issues appear. Besides, the developers can get stuck inside their own knowledge, unable to reach beyond their projects' scopes, not being able to be open to other projects or perform other collaborative activities. Moreover, if a developer leaves the team, there is an impact on the pace of product delivery. The orphaned projects need to be distributed among the rest of the team, who although know the tools, need to learn about that particular project, and the newcomer will only be able to take over some projects after long learning period. The combination of the single-developer projects with the service support of the existing products given by individuals leads to the following difficulties:

- Single developer bottlenecks
- Single person of contact for services has to take decisions on priority when new issues arise
- The team knows the highlights of projects but not the insights

- Developers are not aware and therefore do not profit from other similar solutions already provided by the group
- Newcomers (50% of the team was renewed in the last three years) need to learn common tools, frameworks, and libraries. This requires a huge effort from senior members to setup trainings and give support to the newcomers

Once the Alba's operation started, for the reasons above stated, we decided to explore other alternatives for managing projects and services in parallel. Agile methodologies focus on the collaborative work and empower team culture especially needed when interests of the group take precedence over personal projects. Sometimes, projects require an extra effort due to deadlines or events that cannot be postponed, and a team has to work together for a while, leaving the individual projects in a frozen state.

THE SCRUM FRAMEWORK

The Scrum [4] process was conceived in the early 90's, based on a research stressing the importance of teams and indicated the excellent performance achieved when teams, as small and self-organized, are fed with objectives instead of tasks: *"the best teams are those that are given direction within which they have room to advice their own tactics on how to best head toward their joint objective. Teams require autonomy to achieve excellence"*.

Scrum is a framework for developing and sustaining complex software products based on an empirical process approach where more is unknown than known and predictions have little value given a high rate of change and uncertainty. In this environment, knowledge comes from experience and making decisions based on what is known. It is not a process or a technique for building products, but a framework that makes clear the relative efficacy of the product management and development practices enabling improvement.

The Scrum Team

There are three core roles that compose the Scrum Team: a **Product Owner**, the **Development Team**, and a **Scrum Master**. The Scrum Team is self-organized in order to accomplish the objectives, and has all the skills required to execute the work to be done. The Product Owner is responsible for maximizing the value of the product and the work done by the Development Team ensuring that **Product Backlog** items have clear definitions, they are ordered to best achieve goals, and confirming that the Development Team members understand them to the level they need. These people are the professionals that create the **Product Increment** functionalities based on the Product Backlog items, and the accountability belongs to the Development Team as a whole. The Scrum Master is the facilitator whose responsibility relays on ensuring that the Scrum Team as a group follows the rules to maximize the value to be created, and promoting the self-organization.

Scrum Events

Scrum suggests a set of events with a predefined maximum time length to fulfil all the coordination and management activities. The **Sprint** is the core event, it consists of the **Sprint Planning**, **Daily Scrums**, development work, the **Sprint Review** and the **Sprint Retrospective**. Sprints duration is often limited between a week and a month. Delivering products iteratively and incrementally maximizes opportunities for feedback and reduces the risk of changing requirements or increasing complexity. The Sprint Planning is a time-boxed event where next possible deliverable increments are selected, discussing how will be the work done. Daily Scrums are events of fifteen minutes fixed length, where the Development Team shares progress since last Daily Scrum, organizes the work paying attention on any blocking situation that may prevent reach the planned increments. At the end of the Sprint, the Sprint Review checks the work that has been done, and what has been not finished based on the original planning. The Sprint Retrospective analyses how the team has performed in terms of communication, coordination, and means to achieve the work, with the objective of identifying what can be improved for the next Sprint.

Scrum Artifacts

The Product Backlog is the main artifact of Scrum, it is a unique ordered list of items that describe what is still needed to be done for a particular product and it is responsibility of the Product Owner to expose which are the current known requirements. The Sprint Backlog contains the items that have been selected, and the tasks identified in the Sprint Planning which are needed to do the work. At the end of the Sprint, the Product Increment is a concept that combines all Product Backlog items that have been completed.

EMBRACING THE SCRUM FRAMEWORK

Evaluation Phase

By the end of 2013, the Controls Section had three individual projects that required an internal boost. There was a big opportunity to evaluate if Scrum would help in the organization, execution, and coordination endeavors. During the first half of 2014 this exercise was started by defining the roles and following the Scrum rules and events, planning sprints with well-defined user stories and focusing on small product increments. It was soon appreciated the benefits of the enforced communication and implicit collaborative activities in that controlled environment, and at the end of this first implementation, there were very satisfactory results. There are plenty of documented advantages of incremental agile software development, and the list below highlights the outcomes from that research experiment:

- Designing solutions by teams instead of individuals lead to more robust products and of better quality

since each member contributes from his experience and point of view

- Incremental and iterative approach helped in validating important assumptions fast what mitigated the cost of change
- Constant focus on delivering potentially shippable product increments enabled achieving earlier return of investment
- Self-organized development team did not require constant supervision and worked in a stress-less environment

These preliminary tests had proven that applying Scrum for complex software developments helps in achieving better results, and based on the size of the projects these are some recommendations:

- The best team size is from 4 to 6 members
- Two weeks sprint length has proven to be a good choice
- One controls engineer should not be part of more than one development team at a time
- Due to the support nature of the section, dedication of 60% of the time for the Sprint Backlog, keeping the other 40% for incidents, and high-priority individual service requests (which cannot be foreseen when planning) seems reasonable

Creation of the Scrum Teams

After this first contact with Scrum, a plan to enhance the Controls Section's development strategy was started. It was focused in incrementally changing the group organization for new developments and critical problems where collaborative work was clear to be an advantage.

The Scrum Master and Product Owner roles have been assigned at the beginning, sharing a common vision on how each project would enter in each team backlog. Our customers were informed about the change in how work will be planned.

During mid-2014 the first group built was the Beamline Control Systems Scrum Team. The communication channels between beamline scientists and controls-contacts didn't require any change, and it was enough to take care identifying those requests about complex problems for which design and implementation activities would be worth sharing. Those requests were then merged in a general, serialized and prioritized top-level product backlog that provided a clear view of what needed to be addressed during each sprint iteration for all beamline developments.

After few sprints, a second group mostly dedicated to internal software frameworks did the same transition, starting by defining specific product backlogs for all the individual projects that had been managed by each team member, and created a unified product backlog view that combined all the requirements that the team would have to work together when implementing them. While learning from co-workers, the developers enjoyed to contribute with their own points of view. At the end of 2014, we created a third team, and in the course of the

first quarter of 2015 we have started building the fourth and last squad.

Tools for the Scrum Artifacts

In the adoption of Scrum, it was enough to enrich the same platform that was already used for project tracking: Redmine which has plugins for managing product backlogs. Having a tool that provides at any point in time the possibility to monitor the Sprint progress is essential. The team can report progress by simply interacting with a shared board, inputting the remaining work which are very valuable inputs for the Daily Scrum, and can be simply extracted from auto-generated charts at any time.

Figure 1: Team Backlog, TaskBoard and BurnDown chart.

Sprint Reviews and Retrospectives

Sprint reviews and retrospectives offer great opportunities that let information flow, and over the time, some topics evolve while others remain. Additionally, those meetings gave a chance to really keep track of the project evolution as a whole by reviewing the work from the given value perspective, and considering how it was reached. In nearly all retrospectives, one concept that repeats quite often is to bear in mind that during the sprint, one should spend some time in backlog refinement even that this task does not add any value to the current sprint product increment, it is fundamental for the next planning. Clear “definition of done” explanation in backlog items help when preparing the tasks, when developing to fulfil those requirements, because it reduces uncertainty forcing that everyone understands it. Our

experience showed that it is really important to keep in mind some buffer of time reserved for support-oriented duties when calculating the sprint capabilities..

CONCLUSION

The introduction of the Scrum Framework as part of the product development strategy has proven to be very successful. It has been extremely important to start with a pilot program which facilitated the selection of the right tools, and gave hints on how the system could be tailored for our needs. Focusing on communication and the value given to our customers, as well as ensuring that there is a clear definition of what has to be done, helps during every stage of the development because all the team members are enforced to understand and agree on next steps. It is essential to have available a view of how the team is performing and what is still pending to be done within the Sprint. Also, having the Sprint Backlog defined upfront, indicates that the Product Owner admits that items not planned will be left for later phases, hence the team can concentrate the efforts in a limited set of projects. Actions like code reviews, pair programming and retrospectives about the process itself are activities that empower the team building process.

It is worth to mention that we still keep individual projects outside the Scrum Teams, mainly research activities, developments of proof of concepts and prototypes that are conceived as personal objectives and create personal and professional growth.

ACKNOWLEDGMENT

The authors would like to thank all Alba’s Controls Section members for their openness in this adoption, and the collaborative mind-set when brainstorming in order to find the best matching for the Scrum theoretical framework and our specific facility environment. We would also like to thank the whole MIS section for their partnership in updating Redmine and installing the plugins needed for this purpose, as well as our customers for their cooperation and comprehension during this transition.

USE OF AUTOMATION IN COMMISSIONING PROCESS OF THE UNDULATORS OF THE EUROPEAN X-RAY FREE ELECTRON LASER

Abstract

For operation of the three undulator systems of the European XFEL, a total of 91 undulators are needed and have been produced. For production, magnetic measurements, tuning and commissioning of these devices only two years were foreseen by the project schedule. For these purposes, automated and optimized procedures were needed to accomplish a number of workflows, time-consuming adjustments and commissioning tasks. We created several automation programs which allowed us to reduce the time spent on the commissioning of the control system by an order of magnitude.

OBJECTIVES

All undulators are planned to be commissioned and put into operation in two years, starting from 2013 until the beginning of 2015. Given the fact that European XFEL has three magnetic measurement labs available, 3 weeks were foreseen for commissioning of the control system and the magnetic measurements and tuning of each undulator.

For each undulator, the commissioning procedure includes the following main steps:

1. Installation and adjustment of the linear encoders to achieve an accuracy of $\pm 1 \mu\text{m}$.
2. Adjustment of the tilt angles of the undulator girders to better than $\pm 150 \mu\text{rad}$.
3. Alignment of the undulator relative to the magnetic measurement bench.
4. Magnetic measurements and field fine tuning.
5. Final measurements and documentation of magnetic properties of undulator.
6. Evaluation and implementation of the correction coefficients for rotary encoders of undulator-motors.
7. Calibration of the temperature sensors.

Items 3 to 5 are part of semi-automatized magnetic measurements and tuning procedures applied to each undulator. To proceed with these tasks, approximately 2.5 weeks are necessary. The items 1, 2, 6, 7, which took without automation 2 - 2.5 weeks, must be automated to be accomplished in less than 3 days.

BASIC APPROACH

The undulator control system is based on industrial components produced by Beckhoff Automation GmbH. Using the TwinCAT software, a programmable logic controller (PLC) can be run either on an industrial PC

which is used to control an undulator, or it can be run on a separate Windows PC carrying out the following steps:

- Initialization: Connection to the undulator PLC or to external controllers or devices, loading and initializing of configuration data.
- Data acquisition, depending on the configuration data.
- Data processing and analysis, graphical representation of the analysis results and calculation of required values.
- Formatting the output as required, such as creating ASCII tables, PDF protocols or configuration files for the undulator PLC

ADJUSTMENT OF THE LINEAR ENCODERS

The undulator gap is controlled by four servo motors. Each of them has its own, absolute rotary encoder. This allows an indirect measurement of the gap. A second, more precise system, is directly measuring the gap by means of two absolute linear encoders HEIDENHAIN LC 183 installed on both ends of the undulator girders (see Fig. 1). Both systems can be used alternatively to provide feedback to the motion control system.

Figure 1: Undulator control and adjustment components.

The installation of a profiled linear guideway, which holds an encoder head, has to be validated in order to ensure the requirements of the gap measurement accuracy [1, 2] in the full operational range. For this purpose, two HEIDENHAIN MT 101K reference gauges, are mounted next to the linear encoders and are used to verify the adjustment quality. In order to automate this task, a C++ program was developed. It communicates with the undulator control system and adjusts the undulator gaps from a configuration file using the feedback from rotary encoders. As soon as the desired gap is reached, it reads the position of the linear encoders and the reference gauges. The gaps from the reference gauges are obtained via an HEIDENHAIN ND 287 readout device equipped with an Ethernet interface. Gap values are read from the configuration file and adjusted one by one. Hysteresis effects are identified by increasing and decreasing the gap.

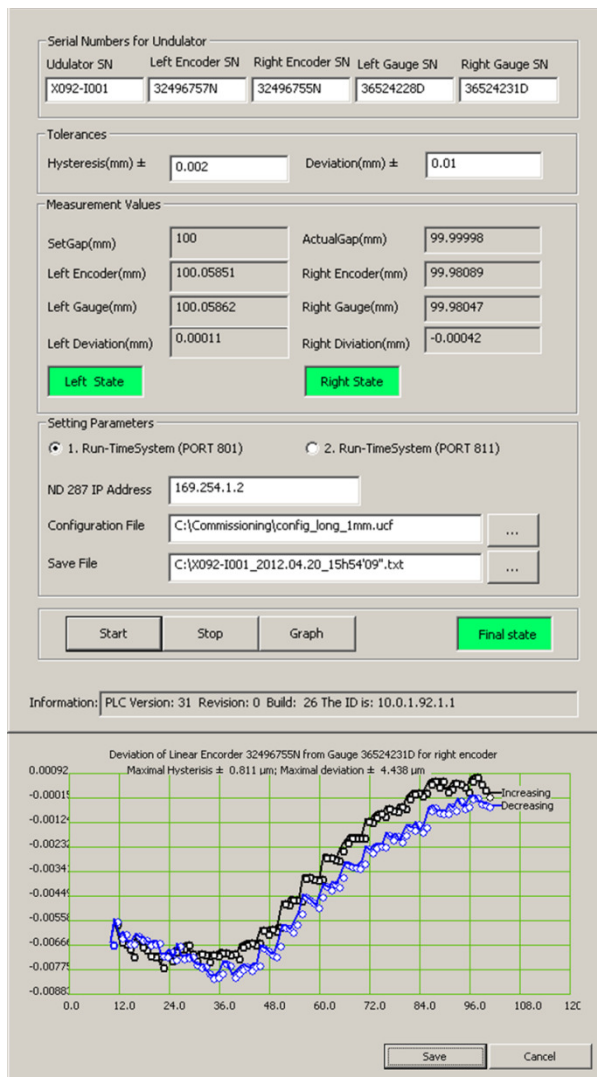

Figure 2: Main user interface and measurement results of linear encoder adjustment program.

A small hysteresis of about 1-1.5 μm in total between increase and decrease of the gap is seen in Fig. 2. After

the measurements, the program calculates the maximal hysteresis as well as the deviation between encoders and gauges. The prompt results are indicated by signal lamps. The measurement results are shown in graphical form to facilitate the search for the problems. If the results are out of specs, the adjustment procedure must be repeated. Otherwise, the measurement results can be saved in the form of PDF protocol.

ADJUSTMENT OF THE TILT ANGLE OF THE UNDULATOR GIRDERS

The magnet girders of an undulator have a rotational degree of freedom. Due to magnetic forces between the upper and lower magnet structures, the frame of an undulator bends and the girder tilt angle changes as a function of the gap. To minimize the influence of the horizontal component of the magnetic field, the girder tilt should be adjusted symmetrically around the vertical position over the full operational range of the gap (see Fig. 1).

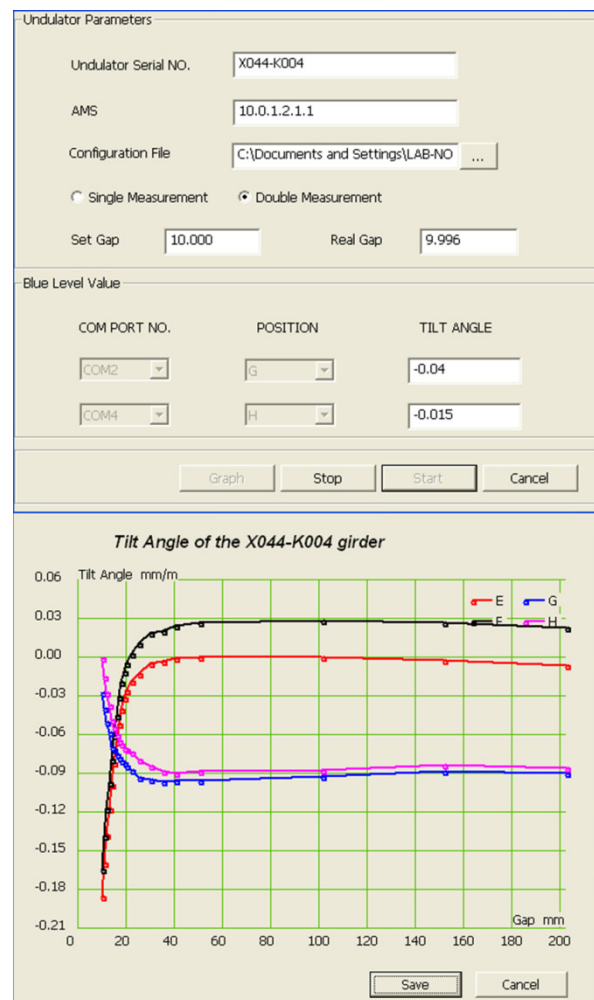

Figure 3: User interface and measurement results of girder tilt adjustment program.

A residual girder tilt of about $\pm 200 \mu\text{rad}$ is permitted. Tilt measurements are made on one girder at a time. Two

WYLER BlueLEVEL devices are used on two reference surfaces. For precise adjustment, this procedure needs to be repeated several times, and this turned out to be time consuming.

As in the previous case, an automated measurement program tool based on C++ was created. The program runs on a separate PC. This computer, using one of its interfaces, is connected to BlueLEVEL instruments via a COM port to read the tilt values. Via Ethernet interface, it is connected to the Beckhoff industrial PC. Communication is established using the TwinCAT ADS library. The program sequentially changes the gap value and reads the tilt angle of the girder. The results of the measurements are presented in graphical form and can be saved as a PDF document.

EVALUATION OF THE FEEDFORWARD CORRECTION COEFFICIENTS

When gaps are small and the magnetic field is strong, the magnetic force between the girders of an XFEL undulator reaches up to 170 kN and causes a significant elastic deformation of the undulator support frame.

Deviation between the linear and the rotary encoder readings results may reach 500 - 900 μm . The linear encoder measures the true gap, while the rotary encoder reading needs to be corrected for the deformation effects.

First, the linear encoders must be adjusted and validated against the reference gauges, readings of which are considered “true” gap values. Second, the deviation is measured in the operational gap range. Third, parameters of an appropriate fit function are calculated. Fourth, the fit function with its parameters is transferred to and used by the undulator PLC for feedforward correction. This is a standard feature in the Beckhoff Numerical Control package.

Fitting Algorithm

The Gauss–Newton least-squares algorithm was used to fit the nonlinear function $f(\mathbf{c}, x)$ with parameters $\mathbf{c} = (c_1, c_2, \dots, c_n)$ to the measured data (x_i, y_i) ($i = 1, 2, \dots, m$). This algorithm minimizes the sum of squares R of residual errors $r_i = f(\mathbf{c}, x_i) - y_i$. $R = \sum_{i=1}^m [f(\mathbf{c}, x_i) - y_i]^2$. Minimum is achieved when

$$\frac{\partial R}{\partial c_j} = 2 \sum_i r_i \frac{\partial r_i}{\partial c_j} = 0 \quad (j = 1, \dots, n)$$

The derivatives $\frac{\partial r_i}{\partial c_j}$ are functions of the independent variable and the parameters; therefore, these gradient equations do not have a closed form solution. An initial guess value $\mathbf{c}_j(0)$ must be substituted for the parameters. Afterwards, the parameters are processed iteratively, that is, the values are obtained by successive approximations: $c_j \approx c_j(k+1) = c_j(k) + \delta c_j$, where k is iteration number and $\delta \mathbf{c}_j$ is a vector of increments. Using first-order Taylor approximation of $f(\mathbf{c}, x)$ at $\mathbf{c}_j(0)$ results in

$$\begin{aligned} f(\tilde{\mathbf{c}}, x_i) &= f_0(\mathbf{c}, x_i) + \sum_j \left(\frac{\partial f_0(\mathbf{c}, x_i)}{\partial c_j} \right) \delta c_j \\ &= f_0(\mathbf{c}, x_i) + \sum_j J_{ij} \delta c_j \end{aligned}$$

The residuals then are given by $r_i = y_i - f_k(\mathbf{c}, x_i) - \sum_j J_{ij} \delta c_j = \Delta y_i - \sum_j J_{ij} \delta c_j$

To minimize R , the gradient equation is set to zero and solved for δc_j [3]. A fitting function of the form $f(\mathbf{c}, x) = c_1 + c_2 * e^{-\frac{(x-x_0)}{c_3}}$ was chosen and is used in the program

Program Performance

The program works in a fashion similar to the previous ones. It sequentially changes the undulator gap values, acquires the values of rotary and linear encoders, calculates the deviation values, fits the exponential decay function, and, finally, creates a file with the correction coefficients, which will be used later by the undulator PLC for feedforward correction of rotary encoders. Fig. 4 shows the control box and the graphic output created by the program.

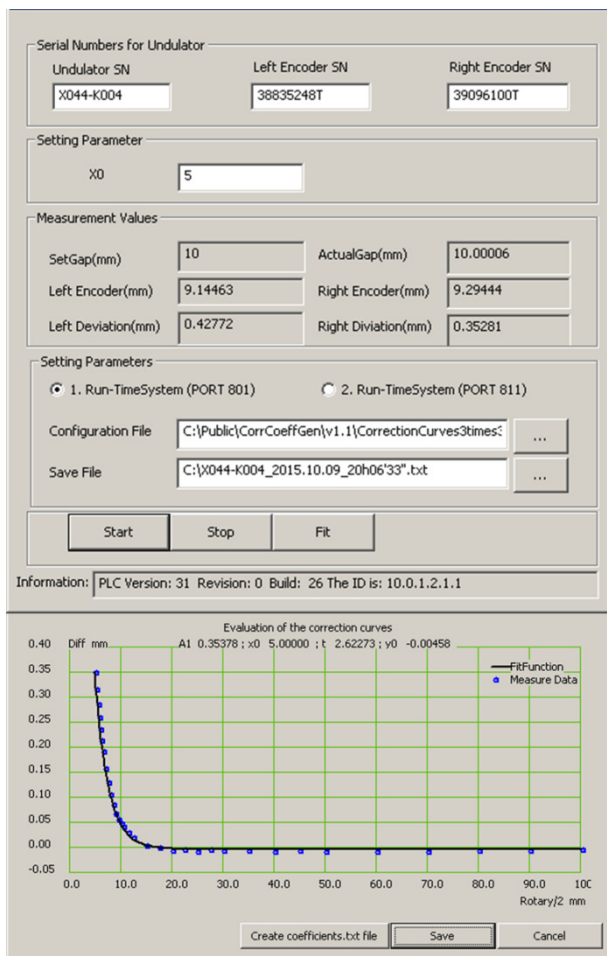

Figure 4: User interface and measurement results with fitting exponential decay function and evaluated coefficients.

CALIBRATION OF TEMPERATURE SENSORS FOR UNDULATOR CELL

NdFeB permanent magnet material is used for the XFEL undulators. The material has a reversible temperature coefficient η typically about $-1.1 \times 10^{-3}/^{\circ}\text{C}$. In order to compensate for the magnetic field change caused by temperature change, a correction of undulator gap is applied by the local control system. The gap correction Δg is calculated by the following equation: $\Delta g = \frac{\lambda_U \eta}{b + 2cg/\lambda_U} \Delta T$, where η is the temperature coefficient of the material, $\Delta T = T_{\text{Nom}} - T_{\text{Act}}$, T_{Nom} is the nominal temperature at which the K-parameter of an undulator has been measured, T_{Act} is the actual temperature of the magnet structures, λ_U is the undulator period length, g is the undulator gap, b and c are empirical constants, describing the gap dependence of the magnetic peak field. The threshold value for performing a change of the undulator gap is estimated to be between 0.05 and 0.2 $^{\circ}\text{C}$. The accuracy of the temperature measurement system is envisioned to be 0.03 $^{\circ}\text{C}$ or better [4]. To provide accurate temperature measurements, three PT100-3 sensors are mounted on the magnetic structures. A fourth one is used for the vacuum chamber temperature control system. All four sensors need to be calibrated before usage.

Calibration Method

All four temperature sensors together with a certified reference temperature sensor are thermally connected to an aluminum block and inserted into a thermally stabilized water bath in a thermostat. To proceed with calibration measurements that would allow finding of the offset and slope at 0°C for calibrating sensors, the temperature thus could be well controlled.

In order to automate the calibration procedure, a C++ program runs on a separate computer. This computer is connected to the Beckhoff industrial PC via Ethernet and reads the data from the four undulator sensors. It is also connected via COM ports to the HAAKE water bath and to a certified ALMEMO temperature measurement device with the reference temperature sensor.

The program has two operating modes - calibration and monitor. In the calibration mode, the program sequentially changes the temperature of the water bath from the minimum to the maximum values in selectable steps. Once the set temperature is achieved and stabilized, it acquires the data from calibration and reference sensors and calculates the coefficients to be applied. Each sensor is equipped with a memory block, which allows saving the calibration coefficients. After evaluation of the offset and slope, the program can write these values directly into the memory block of the calibrated sensor. The results of the measurement could also be saved as a text file.

In the monitor mode, the program compares the data of 4 calibrated sensors with the data of 4 certified reference sensors which are mounted close to undulator and vacuum chamber sensors. In case it is necessary, new offsets to the sensors are applied. The program also saves

data into a text file. Fig. 5 shows the control box of the program.

Figure 5: Main interface of the calibration program in monitor mode with evaluated coefficients.

Abstract

The Square Kilometre Array (SKA) project is currently in the Pre-construction Phase. During this phase, the telescope subsystems are being designed. The Telescope Manager (TM) is a supervisory control and monitoring subsystem in each of the two radio telescopes of the SKA (SKA1-Low and SKA1-Mid). The TM interfaces with a number of diverse telescope subsystems. Interaction between TM and these subsystems is a major source of requirements for the TM. Careful management of TM external interfaces is therefore important. This discussion is a case study of TM interface management. Firstly, how system architectural design aspects like separation of concerns in the control hierarchy reduce telescope complexity with regards to interfaces is discussed. Secondly, the standardisation approach for monitoring and control interfaces to facilitate early elicitation of interface requirements for the TM, and to manage the diversity of interfacing subsystems is discussed. Thirdly, the relations between interface definition and requirements analysis activities, using SysML representations as an example is discussed.

BACKGROUND

The SKA Phase 1 (SKA-1) Observatory will consist of the general headquarters and two radio telescopes: SKA1-Mid in South Africa and SKA1-Low in Australia. Each telescope consists of a number of sub-systems, which are in the SKA project referred to as Elements, of which a TM is one.

There are therefore two TM items, namely SKA1-Mid TM and SKA1-Low TM. For brevity, in this paper the focus is on SKA1-Mid TM (therefore omitting specifics of SKA1-Low TM) because the two telescopes are similar from the TM perspective in its function and interfaces. For less formal reading, "TM" is used when referring to common aspects of these two items, whereas "SKA1-Mid TM" refers to the TM of the SKA1-Mid telescope.

TM OVERVIEW

The TM is a distributed, computer-based supervisory Monitor and Control (M&C) system. TM is responsible for managing [1]:

- astronomical observations,
- telescope hardware and software sub-systems in order to perform those astronomical observations,
- data to support users in achieving operational, maintenance and engineering goals.

For observation management the TM: assists creation, assessment and approval of science proposals; generates schedulable observation units from science proposals; schedules observations; and coordinates execution of the observations to achieve the data products required by the end user.

Telescope management entails configuration and high level control of the telescope Elements and collection of monitoring data which allows the user to monitor the status of Elements, infrastructural support systems and environmental conditions that impact telescope operations.

The Telescope status and configuration data are managed to form a system model that describes the status of the telescope in real-time and historically. To achieve this, the TM collects and stores telescope configuration, telescope dynamic status and environmental data. Stored data are presented to users as current and historic telescope state to assist users during system integration, commissioning, operations and maintenance.

SKA1-MID TM EXTERNAL INTERFACES

This paragraph gives an overview of the external interfaces of the TM, using SKA1-Mid TM as an example (refer [1] par. 1.3). Figure 1 shows SKA1-Mid TM and the systems that it interfaces with.

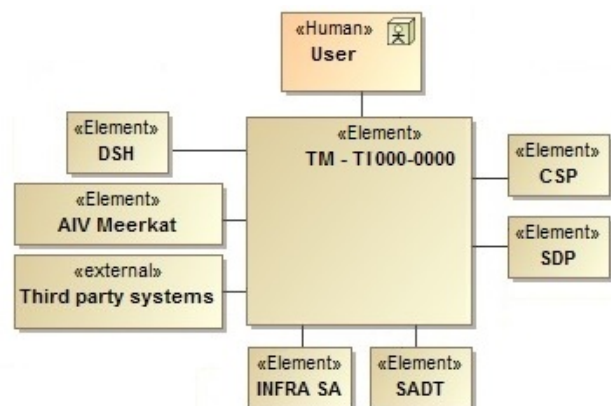

Figure 1: TM relations with SKA environment.

Interfaces with Telescope Elements

The TM has two basic types of interfaces with Elements: data exchange, and physical. The data exchange interface type is categorised into: M&C, general, networking and synchronisation and

*paul@ska.ac.za

timing. Categories of the physical interface type are: mechanical, power and cooling.

The TM has M&C data exchange interfaces with Elements that are to be monitored and controlled: Central Signal Processor (CSP), Science Data Processor (SDP), Dish (133 Dishes), 64 dish Karoo Array Telescope (MeerKAT) Local Monitor and Control (LMC) and Signal and Data Transport (SADT). For M&C of the MeerKAT telescope (to be integrated into SKA1-Mid telescope), LMC sub-systems are developed, which will interface with TM.

TM, via general data exchange interfaces, provides to CSP & SDP parameters required for delay tracking, beamforming, calibration, radio frequency interference mitigation, and auxiliary data that the SDP augments science data with.

Via synchronisation & timing and networking data exchange interfaces, the SADT provides services to TM.

Interfaces with Observatory Systems

TM provides the telescope's user interfaces (UIs) to scientists, observation planners, engineers, commissioners, maintainers, and operators. The TM has an application programming interface for users to programmatically create scheduling blocks. TM collects failure related data from Elements, and sends these to the Integrated Logistic Support System via a data exchange interface. TM has a data exchange interface with South African Infrastructure (INFRA SA) to obtain key indicators of INFRA status that affect telescope operations, and local weather data.

The TM uses infrastructural services (such as cooling and electrical power) provided by INFRA SA via physical (mechanical, thermal and electrical) interfaces with INFRA SA.

Interfaces with External Systems

The TM provides information from external systems (outside of the boundaries of the SKA observatory) to other SKA Elements and users, as required. These external systems are either custom experiment hardware or providers of services like: astronomical catalogues, flight information, earth orientation parameters, ionospheric prediction, satellite information, Virtual Observatory Events and weather information.

TM Interface Challenges

The TM interfaces with a diverse set of systems and implements a number of external interfaces. Interaction with such a large number of systems can be a major source of requirements for TM if interfaces are diverse and there is strong coupling between TM and interfacing systems. Careful interface management of TM external interfaces is required to address this diversity.

The SKA project is a collaboration of Element Consortia; each Element Consortium consists of a number of geographically distributed institutions, which poses the challenge of communication and coordination.

TM design work started before a comprehensive, central telescope architecture was available, causing some initial uncertainty of TM scope and boundaries.

The following paragraphs contain some strategies employed and experiences gained during TM interface management.

SKA OBSERVATORY ARCHITECTURE AND TM INTERFACES

The SKA Organisation introduced separation of concerns by allocating local M&C functions to each SKA Element (referred to as Element LMC). Building on this, and to reduce complexity, we defined a control hierarchy, with less frequent, judgement-based human intervention at the top, the TM with telescope and sub-array level coordination in the middle, and frequent real-time autonomous control by Element LMC at the bottom [3].

On the monitoring side, the Element LMC performs metering and low level, real-time monitoring, whereas TM collects sensor data and performs monitoring in the telescope or sub-array context, using sensor data aggregations provided by Element LMCs.

Layering of M&C responsibilities causes separation of concerns [5] and enabled M&C interface standardisation.

M&C INTERFACE STANDARDISATION

Development work at Element level started before a central, comprehensive telescope architecture was established. The absence of a functional model, that allocates specific functions to Elements, meant uncertain scope and boundaries w.r.t. telescope M&C. The TM Consortium launched an M&C standardisation effort to set initial scope and boundaries for TM and its interfacing parties, and to generate an early, basic set of interface requirements for TM, to be refined later. This M&C standardisation reduced interface diversity from an M&C perspective and also produced guidelines to improve technical communication between Element consortia.

Approach

Activities in each phase of the Telescope development life cycle were identified and analysed. This analysis was done from the point of view of understanding whether TM needed to play a role in any of these activities.

The exercise helped us to identify the key TM functions, TM role in SKA operations and dependencies on other SKA systems. The list of TM responsibilities includes facilitating integration of Elements, telescope management, maintenance and usage.

Each TM function that involves interaction with other Elements of SKA was analysed to understand the information dependency between them. This helped to arrive at the appropriate information content and protocol that the interface between TM and the Elements needed to support. Few examples of such information are the self-description of the Elements provided to TM to facilitate their integration in SKA, information about their operational interface such as commands, events, alarms

and so on that would be used by TM to control them. It also described behavioural aspects like control models.

We saw the need to standardize information content and created the LMC interface guidelines document. We used available standards from the public domain such as X.731 towards this standardization activity.

The LMC interface guidelines document was circulated to all the Element consortia for their feedback. The Element representatives provided their feedback on the content of this guideline which was then subsequently accepted as the standard to be used by all Element LMC's for interfacing with TM.

Selection of TANGO as M&C Framework

Standardization effort for interfaces between TM and Element LMCs includes the following aspects: general principles, required functionality, format and content of the messages and communication infrastructure. As soon as the general requirements for these interfaces were identified, the SKA team started investigations related to the communication protocols and frameworks to be used for implementation. TM Consortium provided leadership in this area and invited all other SKA Consortia to identify, investigate and suggest candidate technologies. TM Consortium developed a comprehensive list of requirements and criteria for selection of the communication framework for communication between TM and other SKA Elements. The list of candidate technologies and criteria for selection were reviewed by all SKA Consortia that implement M&C interface with TM. In March 2015, representatives of all SKA Consortia met in Trieste, Italy to discuss the proposed technologies and criteria for selection. The programme included presentations by the experts for the proposed technologies. At the end of the meeting TANGO Control System (CS) was identified as a technology of choice for implementation of the M&C interfaces between TM and other SKA Elements.

The decision to use TANGO CS for interface between the Elements does not mean that TANGO CS will be used for M&C function internal to the Elements; but the report from the meeting recommends to all SKA Consortia to use TANGO CS internally where possible and suitable. TM itself will use TANGO CS for internal M&C.

INTERFACE DEFINITION AND TM REQUIREMENT ANALYSIS

From allocation of Telescope requirements to TM in [2], a functional structure for TM was derived. TM functions were specified by TM requirements in [1]. TM interactions with other Elements were covered in TM requirements by referring to interfaces from requirement text, for example, "The SKA1_MID TM shall send time stamped desired pointing coordinates to the Dish via its I.S1M.TM_DSH.001 interface". Up to now, SysML (refer [6]) representations of TM behaviour were limited to use case diagrams (Fig. 2) and swimlane activity diagrams (Fig. 5).

The SysML specification [6] provides a precise model based representation for interfaces and interface instance integration [5]. We are currently working towards modelling information exchange between the TM and other Elements as SysML object flows. Once functions that are allocated to TM and other Elements have been modelled as SysML activities, and the activities have been allocated to TM and Elements via SysML blocks, the object flow between the TM and Elements can be shown. Thus the systems behaviour (functions) and system structure (interfaces) can be brought together by tracing each object flow to the allocated interface port and connector uniquely identified by its interface number (see Fig. 3 & Fig. 4).

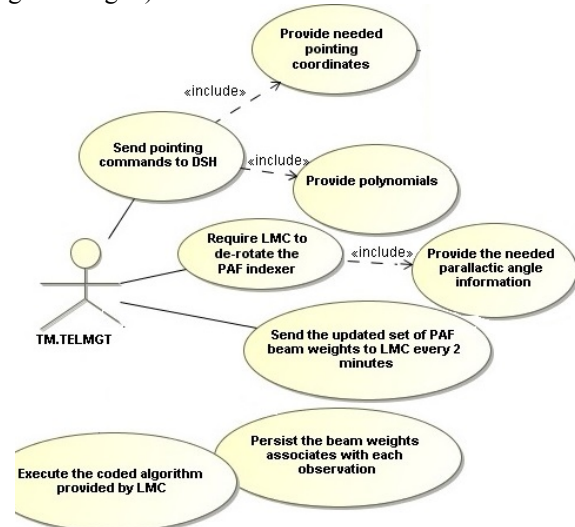

Figure 2: Dish pointing control use case diagram.

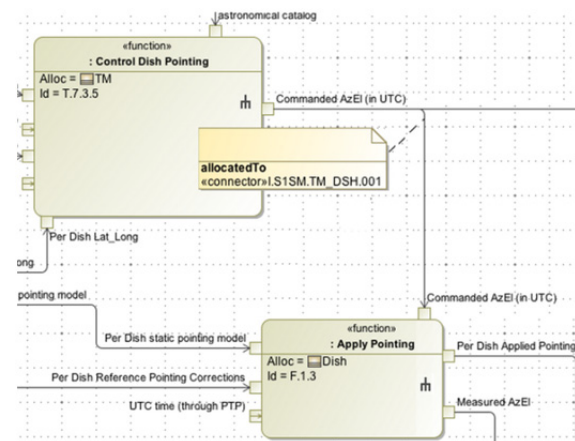

Figure 3: Behavioural view – interface and object flow.

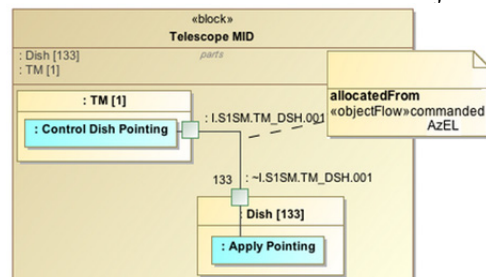

Figure 4: Structural view – interface & object flow.

USER INTERFACE DEVELOPMENT

A requirement is a documented physical and functional need that a particular design, product or process must be able to perform. Interfaces provide the specifications of relevant properties of a system or component that can be connected to other systems or components together with their actual interaction. When users interact with a computer system, they do so via a UI.

Starting from the requirements as defined, collected and organized in [1] & [2], and the SKA Concept of Operations and Use Cases documentation provided by the SKA Office in [4], a users and tasks analysis phase followed in order to develop a solid conceptual model of stakeholders and of the interfaces involved in the operation of the SKA Observatory from a TM point of view. Documentation of SKA pathfinders and precursors on operational concepts, actors and systems has been considered too.

A project glossary was used to unambiguously define and describe actors, roles and tasks in the application domain. SysML use case diagrams were used to represent system scenarios and interactions workflows, then detailed out with via textual descriptions and swimlane activity diagrams to fully describe dynamic behaviour (see Fig. 5 an example of TM interactions with Dish and the operator in a specific scenario.

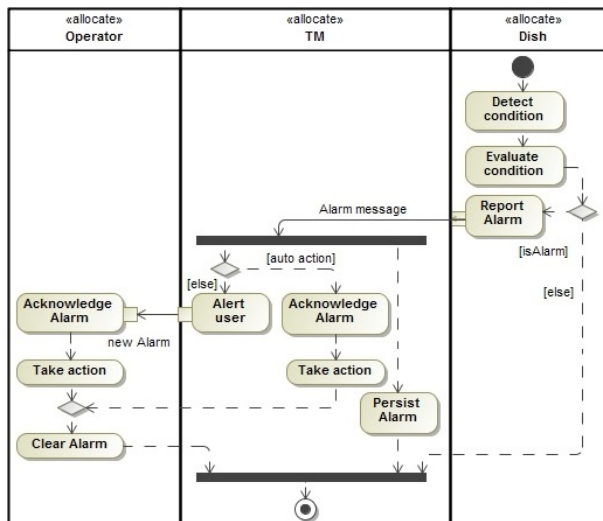

Figure 5: Alarm reporting SysML swimlane diagram.

A user-centred approach will be adopted in TM UI development. It will consist of several iterations, involving users' active contribution (interviews, brainstorming sessions, feedback) to fully understand user needs in performing the tasks that they have to perform while interacting with TM and the actual usage environment (organisational, social, and physical). User-centred design is hoped to optimize usability as Part 11 of the ISO 9241 standard [7] defines it as "the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use."

Prototypes will be used to elicit detail requirements and highlight possible critical dependencies between different components, drive out technical gaps, get stakeholders and end users feedback, test common framework tools and libraries, interaction flows and common look and feel, evaluate usability and accessibility.

Validation interviews will be performed with a subset of real users or user proxies.

SUMMARY

The external interfaces of the TM Element of the SKA are diverse and many. Resulting complexity is handled by M&C separation of concerns and interface standardisation while SysML is used in models that integrate interface definition with requirements analysis, and supports UI analysis and design. M&C standardisation and UI design and development are two of the focus areas of the TM Consortium in interface management.

ACKNOWLEDGMENT

The authors wish to acknowledge all past and present members of the Telescope Manager Consortium.

PYTHON SOFTWARE FOR MEASURING WAVELENGTH AT OPTICALLY PUMPED POLARIZED ION SOURCE (OPPIS)*

P. Kankiya[†], J. Jamilkowski, Brookhaven National Laboratory, Upton, NY 11973 USA

Abstract

Often diagnostic tools are packaged with proprietary software and it is challenging to integrate with native environment. The HighFinesse Angstrom Wavemeter used at OPPIS experiment for laser wavelength measurement is controlled using commercial software not supported by RHIC style controls. This paper will describe the integration of such a complex system and use of python for cross platform data acquisition.

INTRODUCTION

The control system environment at BNL's Collider Accelerator Division is a rich repository of control system applications developed in-house and supports complicated supervisory controls and data acquisition tasks, although is limited to supporting these tasks in the Linux environment. Very rarely do we have a requirement to support systems that require software development in a non-UNIX based platforms. We have explored a few solutions in meeting this limitation [1]. In this paper a solution to integrate windows binaries using python is presented. By implementing this solution it will be possible to log data and generate alarms, use synoptic displays etc after gathering measurements from foreign binaries.

SYSTEM IN USE

The polarized beam for RHIC spin physics experimental program is produced in the Optically-Pumped Polarized H-Ion Source (OPPIS), the RHIC polarized H-ion source is upgraded to higher intensity (5-10 mA) and polarization by using a very high brightness fast atomic beam source for enhanced luminosity RHIC operation. Pulsed laser is used to optically pump the rubidium vapour. It is important to measure laser wavelength synchronous to AGS cycle to ensure polarization in desired direction [2]. A high precision device that can measure pulsed laser parameters with high accuracy at a fast rate is needed. To meet this requirement Armstrong meter model shown in Figure 1 was procured with a vision that it will be integrated into RHIC control applications.

Data Acquisition Procedure

Wavelength meter is setup in pulsed operation and externally triggered mode. These control set up tasks are performed by using proprietary software supplied with the hardware. Operator can provide preferred unit of measurement. Operation is started by adjusting the exposure manually or selecting automatic manner.

ISBN 978-3-95450-148-9

For the purpose of integrating measurement results from this device into custom applications, all program values and settings are accessible for user via calls to a dynamic linked library (DLL) called wlmData.dll routines. The wlmData.dll uses shared memory for inter-process communication. The software requires that the server (the Wavelength Meter application) and the clients (any access and control programs) access the same DLL file and not just identical copies which leads to limiting the use of the interface software to one instance at a given time. Elimination of restriction of use of DLL by one client at a time and integrating the whole setup with in-house controls is important to make use of existing infrastructure and correlate data measurements.

Figure 1: High Finesse Wavelength measuring device interfacing a windows computer and a light source.

SOLUTION

There are three common approaches to solving the aforementioned problem:

1. Write your own low level library to communicate with the device.
2. Write an extension in C code to bridge the gap between the libraries and use a cross platform compiler for generating supported executable format.
3. Wrap the library using your **foreign function interface** (FFI) support. Foreign refers to the fact that the functions come from another language and environment.

Because the wlmdata.dll is not an open source file, option one cannot be implemented. Option 2 is more time consuming and limitations has been addressed in another attempt described in paper [1]. Option 3 is considered to be a pragmatic solution. From multiple foreign function

interface (FFI) languages available python was considered for deploying interface software due to availability of knowledge in the field.

IMPLEMENTATION

A python module known as ctypes [3] allows easy integration of C libraries directly without writing wrapper code in C. With help of ctypes the concerned DLL is imported into a python program called WLM. A class named wavelength meter is defined. All functions of the DLL are available for execution once an object of this class is instantiated. The source code provided with the DLL package contains header files with error codes and function definitions. The header files are re-written to be python modules. The return types of each method must be explicitly specified and must match the original definition. By not complying to translating C header to ctypes exactly will lead to segmentation faults at runtime.

Data acquisition is made simple by executing routines such as callback (CallbackProc/Ex) and wait-event mechanisms (WaitForWLMEEvent/Ex) which are prototyped one to one on the python side with help of ctypes. The mapped functions are called using standard C calling conventions as opposed to windows stdcall calling conventions [3]. These routines receive any measurement results and WLM state changing information.

The data collected from the python interface program can be then packaged and sent across Linux environment with help of RPC module and adolf protocol implemented in python [4].

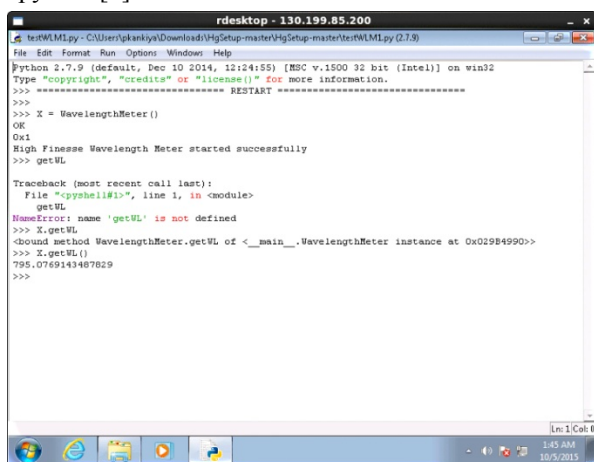

Figure 2: Simple object created from wavelength meter class and used to measure wavelength from get method.

DEVELOPMENT ENVIRONMENT

As described in a previous paper [1], to support C++ style ADO manager on windows we would have to port the existing code base on windows side with help of clear case remote client. Whereas, in case of what can be called a python manager a clearcase client is not required and any version control can be utilized due to non-dependency on legacy code. IDLE is used for editing and compilation of code. Figure 2 illustrates the use of python object to measure laser wavelength from an IDLE shell.

Python compilers are much lightweight applications as compared to CYGWIN like cross platform applications that have many OS dependencies and are complicated to install.

STATUS AND PLANS

A one to one map of wavelength meter package is developed in python with help of ctypes module. Measurement of data using the call-back and synchronous acquisition is tested. Work is under progress to port data to Linux side. This approach serves as a quickly deployable solution to integrating windows binaries to RHIC controls environment. For future projects it is advisable to find a solution such that developers do not have to fully repeat the C declarations. We plan to test this solution with operational data in the upcoming run of RHIC.

CONTROL SYSTEM FOR A DEDICATED ACCELERATOR FOR SACLA WIDE-BAND BEAM LINE

N. Hosoda, T. Fukui, T. Ohshima, T. Sakurai, H. Takebe[#], RIKEN/SPRING-8, Hyogo, Japan
M. Ishii, JASRI/SPRING-8, Hyogo, Japan

Abstract

The X-ray free electron laser facility SACLA has provided opportunities for the exploration of new science. However, these opportunities are severely limited, because only one beam line (beam line 3) is currently available for user experiments. Therefore, there is an urgent need to increase the number of beam lines available. One approach is to install an additional accelerator. We decided to move the SCSS prototype accelerator to an upstream space of beam line 1 in the SACLA undulator hall and reused it as a dedicated accelerator for the beam line. We started an RF conditioning of the dedicated accelerator in October 2014 using MyCC, a MySQL-based temporary data acquisition system compatible with MADOCA. After the RF conditioning, we smoothly transitioned the system from MyCC to MADOCA. The beam commissioning of the dedicated accelerator started in September 2015, and we successfully observed the first extreme ultraviolet free electron laser in October 2015. The control system ensures the coordinated seamless operation of the SACLA accelerator and the dedicated accelerator.

INTRODUCTION

The X-ray free-electron laser (XFEL) facility SACLA (SPRING-8 Angstrom Compact X-ray free electron LASer) aims to generate coherent X-ray beams with a wavelength of less than 0.1 nm [1]. It consists of a 400-m-long 8 GeV linear accelerator and a 120-m-long insertion device. In 2011, a commissioning of SACLA was started with beam line 3 (BL3). After the success of generating XFELs, the user experiments at BL3 started in 2012. The SACLA is providing opportunities for the exploration of new science.

Because an XFEL facility employs a linear accelerator, it provides an electron beam for only one beam line at a time. This means that its availability for user experiments is severely limited compared to that of a storage ring-type photon facility such as SPRING-8, which has 57 beam lines. Therefore, there is an urgent need to allow a multi-beamline operation of SACLA.

One approach is to deliver an electron beam to multiple beamlines pulse-to-pulse using fast switching magnets [2]. Originally, a DC bending magnet at the end of the accelerator was used to switch an electron beam path between beam lines. We replaced it with a fast kicker magnet and DC twin septum magnets in January 2015. As a result, we successively injected electron beams to beam line 2 (BL2) and BL3 and achieved simultaneous lasing in both beam lines.

Another approach is to install an additional accelerator. Prior to the construction of SACLA, we built a SCSS (SPRING-8 Compact SASE Source) prototype accelerator in 2005 to verify the feasibility of lasing using a thermionic gun [3]. We achieved the generation of SASE FEL with a wavelength of 50–60 nm in an extreme ultraviolet (EUV) region in 2007. After the initial purpose was accomplished, it was used for user experiments until 2013. We decided to move the SCSS prototype accelerator to an upstream space of beam line 1 (BL1) in the SACLA undulator hall, and reused it as a dedicated accelerator for BL1 [4].

The SACLA accelerator and the dedicated accelerator share one beam line, BL1. We had to coordinate both accelerator operations, while the independence was maintained as much as possible.

When we designed a control system for the dedicated accelerator, it was natural to use the MADOCA (Message And Database Oriented Control Architecture) control framework, which was already used at the SCSS prototype accelerator and the SACLA [5–7].

The requirements for the control system were as follows. The first priority was not to disturb SACLA user experiments. The RF conditioning was tightly scheduled to start in October 2014 and the beam commissioning was scheduled in September 2015. The human resources available to develop the system were limited. The period in which we could enter the undulator hall to test equipment was also limited. Moreover, the dedicated accelerator was operated at the SACLA control room.

Our strategies were as follows. We reused all control software developed for SACLA. At the start of the RF conditioning, we used a temporary data acquisition (DAQ) system compatible with MADOCA, because some RF components were not installed. After the RF conditioning and a completion of the construction, we switched the DAQ system from MyCC to MADOCA.

In this paper, the status of the dedicated accelerator is reported in terms of its control system.

THE DEDICATED ACCELERATOR FOR BL1

Figure 1 shows a schematic view of the dedicated accelerator for BL1 at the SACLA facility. Although we planned for five beam lines in the undulator hall, only three beam lines had been constructed until now. The bending angle of the transport lines from SACLA to BL1 is 3 degrees and BL1 is located 6 m apart from the SACLA accelerator in parallel. Therefore, a 110-m-long vacant space exists upstream of BL1. The dedicated accelerator was placed in that space.

[#] Present address: Okinawa Institute of Science and Technology (OIST)

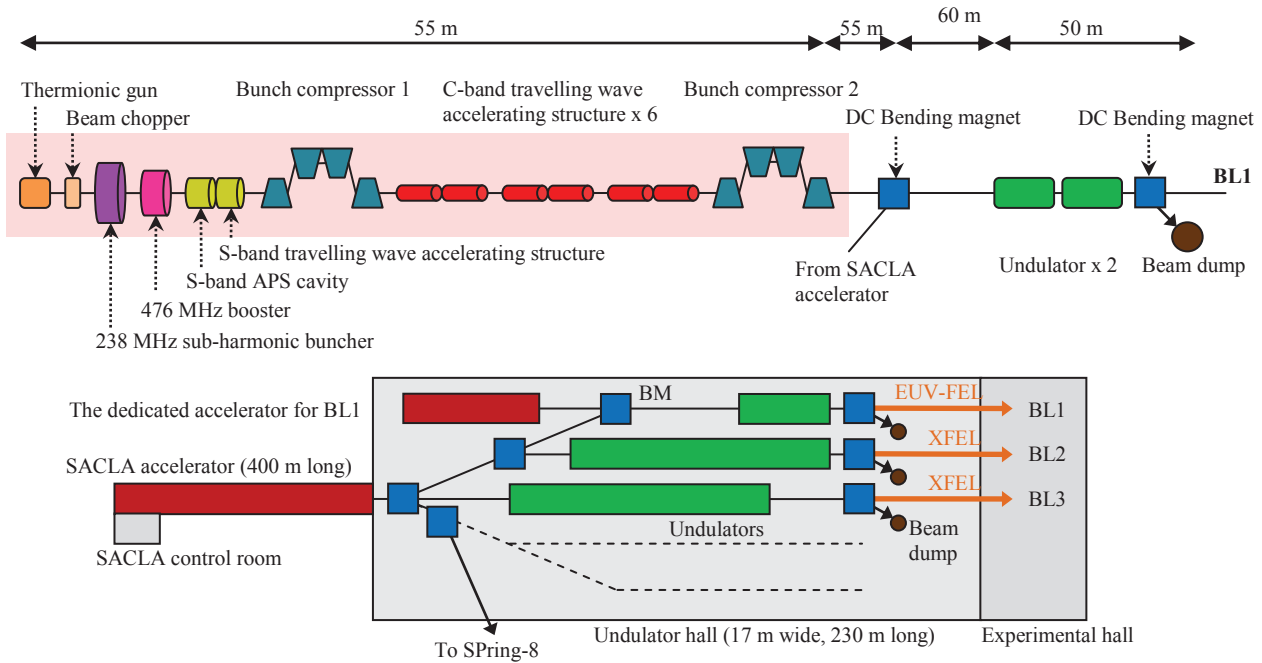

Figure 1: Schematic view of the dedicated accelerator for BL1 at the SACLA facility.

All RF components except C-band were reused from the SCSS prototype accelerator. The C-band accelerating structure was newly designed to increase the beam energy per unit length. We installed 3 C-band units at this stage. All low level RF (LLRF) modules, timing modules, and monitor modules, such as the beam position monitor and beam current monitor, were replaced by modules developed for SACLA to achieve higher stability and to standardize their control system. The design parameters of the dedicated accelerator are listed in Table 1. At the downstream of bunch compressor 2, a space of 9 C-band units is reserved for a future upgrade. If 9 C-band units are added, electron beam energy will reach 1.4 GeV and we can provide soft X-ray FEL to users.

Table 1: Design Parameters of the Dedicated Accelerator

Accelerator	Beam energy	420 MeV
	Bunch charge	0.3 nC
	Peak current	300 A
	Repetition rate	60 Hz
Undulator	Periodic length	18 mm
	K parameter	2.1 (max)
	Number of periods	460
FEL	Wavelength	42 nm ($K = 2.1$)
	Pulse energy	100 μ J

We had to concentrate the construction work in the undulator hall to summer shutdown periods, because we could not enter it during the user experiment periods of SACLA. In summer 2013, the injector part from an electron gun to bunch compressor 1 was installed. The remaining part was installed in summer 2014. However,

works outside of the undulator hall (for example, the installation of 19-inch racks containing the VME systems, programmable logic controllers (PLCs), and power supplies) were performed during user experiments on the condition that the works did not disturb user experiments.

EQUIPMENT CONTROL HARDWARE

VME System

We used the CPU board XVB601 (Intel Core i7), manufactured by GE, for the LLRF component, and SVA041 (Intel Pentium M), manufactured by Sanritz, for the other components.

The high speed A/D board MVD-ADC01 (238-MHz sampling, 16-bit resolution, and 4-channel input), manufactured by MELOS, is used for RF phase/amplitude detection of the RF components and readout of the beam position monitor/beam current monitor. The high speed D/A board MVD-DAC02 (238-MHz sampling, 16-bit resolution, and 4-channel output), manufactured by MELOS, is used to control the phase/amplitude of the driving RF signal of a klystron using an IQ modulator. The high resolution A/D board MVD-ADC04 (1-MHz sampling, 24-bit resolution, and 4-channel input), manufactured by MELOS, is used for a CSR bunch length monitor.

An 8-channel trigger delay unit (TDU), manufactured by MELOS, generates very low jitter trigger signals from a 60 Hz master trigger signal distributed via the SACLA master trigger/reference RF clock distribution system. This means the dedicated accelerator and SACLA work synchronously. The TDU has a function to count the number of master trigger inputs, and the function is used

to add a tag number to each A/D data in an event-synchronized DAQ process [8]. In the VME system without a TDU, an interrupt register board (INTREG) Axvme4900, manufactured by ARKUS, counts the number of master trigger signals.

To control the power supplies of the 97 magnets in total of the dedicated accelerator, an optical remote I/O system OPT-VME/OPT-DIO, manufactured by Hitz, is used. The OPT-VME is a master board and can control 4 OPT-DIO slave boards. Most of the OPT-VME/OPT-DIO boards used at the prototype accelerator were reused after cleaning and inspection to ensure that there was no degradation of quality.

To access PLC, we use a VME-based FL-net interface board. FL-net is one of the Ethernet-based open standard protocols for a factory floor network authorized by the consortium in Japan.

We prepared 24 VME systems for the dedicated accelerator. Table 2 lists the number of VME boards used. In basic terms, each VME system is located in the south klystron gallery near the equipment. However, the VME systems for FL-net are placed in the SACLA control room because that is the only network which requires it.

Table 2: Number of VME Boards for the Dedicated Accelerator

	FL-net	OPT-VME	INTREG	MVD-ADC04	TDU	MVD-DAC02	MVD-ADC01	CPU
LLRF	0	0	0	0	6	6	17	6
HPRF	4	0	0	0	0	0	0	2
monitor	1	0	3	1	0	0	11	4
timing	1	0	0	0	1	0	0	2
magnet	0	15	0	0	0	0	0	6
vacuum	3	0	0	0	0	0	0	2
utility	4	0	0	0	0	0	0	2
Total	13	15	3	1	7	6	28	24

PLC

PLCs are used where slow and rigid equipment control is required; for example, in the high voltage power supply of a klystron (HPRF), the cooling water system, the vacuum system, and the environmental parameter monitor of a 19-inch rack system. As mentioned above, PLCs are remotely controlled via the FL-net VME interface board. In addition, we prepared programmable graphic panels near the PLCs for local control.

Interlock System

The interlock system of SACLA consists of a personal protection system for human radiation safety, a machine protection system against the failure of the vacuum components or the magnet power supply, and a beam operation interlock system for the management of the beam route and the amount of electron charge/energy.

The beam operation interlock system for the dedicated accelerator was installed separately from the system for SACLA. However, both systems share the excitation current data of the DC bending magnet, located at a junction point of the two accelerators to manage which accelerator has the permission to inject an electron beam to BL1.

The machine protection system was modified to manage which gate valves should be closed if a vacuum leak occurred in one accelerator, because the user experiments of the other accelerator must not be disturbed.

SOFTWARE

Equipment Control

The operating system of the VME CPU is Solaris 11 (64 bit) for the LLRF component and Solaris 10 (32 bit) for the other components. In the VME system, three basic MADOCA processes are running. These are: a message server process which receives control messages from operator consoles, an equipment manager process which accesses equipment, and a poller process which collects data at a constant frequency, such as at 0.5 Hz. In LLRFs and the monitor VME, an event-synchronized DAQ process which collects data for all beams shot at 30 pps together with an event tag number is also running. Furthermore, in the LLRF VME, a PID feedback process to stabilize the RF phase/amplitude and an abnormal RF waveform acquisition process are running [9]. Although we are required to run such high-load processes in the LLRF VME, the VME system is still working well.

Database

As indicated by the unabbreviated name of MADOCA, the database is indispensable. The Sybase RDBMS is the main database in SACLA [10]. We use it for poller data logging, signal management, equipment setting parameter management, and equipment alarm management. We decided to treat the dedicated accelerator data in the SACLA database.

In October 2014 while SACLA user experiments were ongoing, we needed to start an RF conditioning of the dedicated accelerator. Before the start, new equipment data and tables related to the dedicated accelerator had to be added to the database. However, we did not want to do this because the smallest possibility of a disruption to user experiments caused by a mistake in database operation always existed.

We had developed a simple DAQ system, MyCC, which is compatible with MADOCA [11]. The target of MyCC is DAQ of a small number of signals in a limited acquisition period. This allows for frequent modification of the equipment system. The features of MyCC are as follows. A MySQL database dedicated for MyCC is used instead of Sybase. The three basic MADOCA processes on the VME CPU are used in MyCC without any change. The MyCC signal registration list is created from the MADOCA signal registration list. This means that if we

finish the configurations of the MyCC signal registration list, we do not have to modify the MADOCA signal registration list. The MyCC database API has the exact same function calls as those of the MADOCA database API. Therefore, without any source code modification, an operation GUI application works for both MyCC and MADOCA, with the only relinking the API libraries. For these reasons, we adopted MyCC for the RF conditioning.

About 2,800 signals were registered in MyCC, and the RF conditioning was started on schedule. In January 2015 during a winter shutdown, the DAQ was smoothly transitioned from MyCC to MADOCA using a proof signal registration list. The RF conditioning lasted until July 2015 and achieved a sufficient acceleration gradient and an acceptable RF trip rate.

In addition to the Sybase server, a MySQL server for the event-synchronized DAQ and a Cassandra server for the abnormal RF waveform acquisition are also used in SACLA. In August 2015 during a summer shutdown, we registered equipment signals to these servers. Table 3 lists the number of equipment signals registered in the databases.

Table 3: Number of Equipment Signals Registered in the Databases

	SACLA		The dedicated accelerator	
	Sybase	MySQL	Sybase	MySQL
Analogue data	43,668	1,612	2,519	103
Digital data	16,130	902	1,103	62
Total	59,818	2,514	3,622	165

Graphical User Interface (GUI)

The SACLA is operated at the SACLA control room. We used nine PCs (IA architecture, SUSE Linux Enterprise, dual displays) for the operator consoles. Operation GUIs were developed using X-mate, a GUI development support tool based on X-Window.

Because the SACLA accelerator and the dedicated accelerator had to be operated seamlessly, we developed the integrated operation GUIs.

Figure 2 shows an operation GUI for the magnet power supplies. When a section of the overall view in the upper part is selected, a detailed view of the section is displayed in the lower part. To decrease the chance of mistakes in operation, the background color of the detail view is changed to clarify which accelerator is selected. The equipment parameters of BL1, such as the magnet power supply, timing delay, and beam monitors, differ between the SACLA accelerator and the dedicated accelerator. Therefore, the GUI was developed to select appropriate parameters using beam route information.

Figure 2: Operation GUI for magnet power supplies.

CONCLUSION

We constructed the control system of the dedicated accelerator for BL1 at SACLA. The MySQL-based temporary data acquisition system, MyCC, enabled the RF conditioning of the dedicated accelerator without affecting SACLA user experiments. After the transition from MyCC to MADOCA and the completion of the preparation for the all-control system, the commissioning of the dedicated accelerator started in September 2015. We successfully observed the first EUV-FEL at BL1 using the dedicated accelerator in October 2015. The control system ensures the coordinated seamless operation of the SACLA accelerator and the dedicated accelerator. We will start user experiments at BL1 before March 2016.

Byoung Ryul Park, Woul-Woo Lee, Jihwa Kim, Heung-Sik Kang, and In Soo Ko,
Pohang Accelerator Laboratory, Pohang, Kyungbuk, Korea

Abstract

Pohang accelerator laboratory (PAL) started an x-ray free electron laser project (PAL-XFEL) in 2011 [1]. In the PAL-XFEL, an electron beam with 200 pC will be generated from a photocathode RF gun and will be accelerated to 10 GeV by using a linear accelerator. The electron beam will pass through undulator section to produce hard x-ray radiation. In 2015, we will finish the installation and will start a commissioning of the PAL-XFEL. In this paper, we introduce the PAL-XFEL and explain present status of it. Details of the control system will be described including a network system, a timing system, hardware control systems and a machine interlock system.

PAL-XFEL

Figure 1 shows a bird eye's view of the PAL facilities which is taken in the April 2015. A circular building in right hand side is the storage ring of the Pohang Light Source (PLS-II) and a new long building on the left hand side is the PAL-XFEL. The building construction was started in 2012 and it was finished at the end of 2014.

The length of the PAL-XFEL building is 1.11km which is consist of a 700 m long linear accelerator, a 250 m long undulator hall, and another 60 m long beam line hall. 10 GeV electron beam can be obtained from the 700 m long linear accelerator and 0.1 nm wavelength hard x-ray can be generated from the electron beam by using the self amplification of the spontaneous emission (SASE).

The total budget is 400 million US dollar and the project period is from 2011 to 2015. Installation of the components of the accelerator was started from the beginning of 2015.

Figure 1: Pohang Accelerator Laboratory.

Figure 2: Pohang Accelerator Laboratory.

Figure 3: Pohang Accelerator Laboratory.

Figures 2 and 3 show the klystron and modulator gallery and inside of the linear accelerator tunnel, respectively. 51 klystrons and modulators and 174 accelerating columns will be installed up to end of 2015.

CONTROL SYSTEM

The PAL-XFEL control covers a large range of hardware and software. An Experimental Physics and Industrial Control System (EPICS) will be used for the control system of the PAL-XFEL. A powerful network system was installed and a large number of Input Output Controllers (IOCs), for example about 700 magnet power supplies, will be connected to a high level control system. An event timing system will be used to send trigger signals to all the equipment and RF distribution system will be ready to supply the 2856 MHz RF signal for S-band RF stations. In addition, a machine interlock system will be prepared to protect important equipment.

Figure 4 shows the network system layout and core switches with Fiber Distribution Frames (FDFs). Duplicated core switches were installed for safety and local switches were connected to them by using 1 Gigabit or 10 Gigabit bandwidth optical fiber.

*chbkim@postech.ac.kr

Figure 7 shows layout of the RF distribution system. To generate RF power from 51 klystrons and modulators, 2856 MHz signal should be provided to them, however, such a high frequency can have serious loss in a long RF coaxial cable, so that 479 MHz signal will be generated from a Dielectric Resonator Oscillator (DRO) and sent along the linear accelerator by using a RF coaxial cable.

Figure 8 shows modulator with its controller. Yokogawa Programmable Logic Controllers (PLCs) are used for modulator control and an EPICS module is installed to make an EPICS IOC.

Figure 9 and 10 show installed undulators inside the undulator hall and its control layout, respectively. A Microsoft Windows based, real time capability, embedded pc controller is connected by using an EtherCAT network to a server motor driver which moves motors of the undulator.

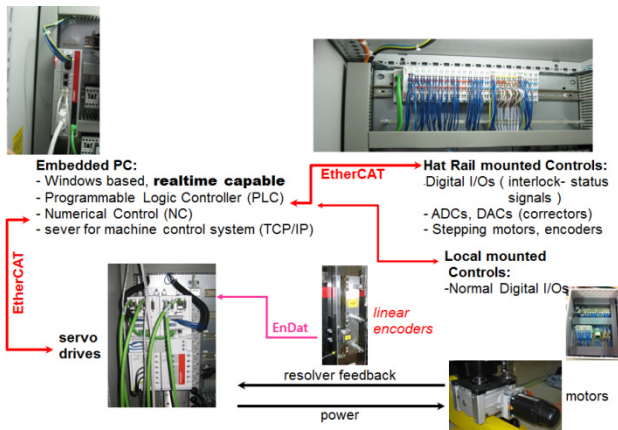

Figure 10: Undualtor control layout.

Figure 11 shows an uTCA based Beam-Position-Monitor (BPM) electronics. The BPM electronics consist of a chassis, a central processing unit, a channel manager, a network card, an event receiver, and analogue digital converters with rear transition modules. BPM electronics can measure the beam position with a time stamp which is generated by event timing system to make a beam synchronous acquisition.

Figure 11: uTCA based BPM electronics.

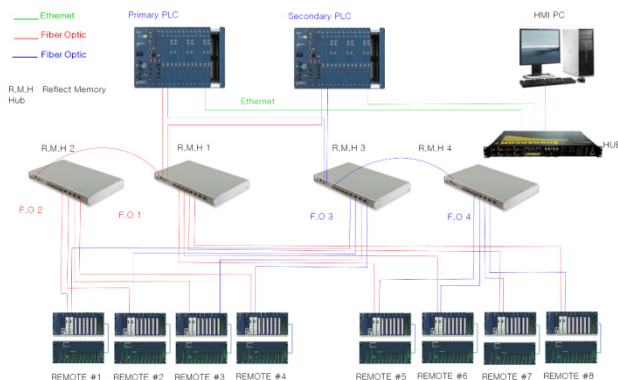

Figure 12: Machine interlock system layout

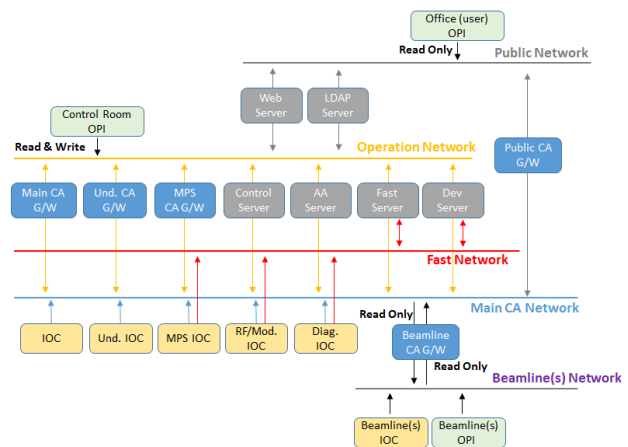

Figure 13: Control server connection.

Figure 12 shows layout of the machine interlock system. The machine interlock system will make interlock signal to protect critical component such as permanent magnets of an undulator which should be protected from a high energy electron beam. The machine interlock system will have duplicated main PLCs and local PLCs which are connected by optical fiber to reduce the communication time.

Figure 13 shows control servers and their network connections. There will be a public, an operation, a main channel access, a fast data, and a beamline network. Operation status can be monitored by using a web server and outside access will be controlled by a public gate way in the public network. Operation interfaces in the control room will be connected to control servers and gateways by using the control network. Local IOCs will be connected by main channel access network and protected by gateways from direct access of operators or outside users. The fast data network will be prepared for 60 Hz real time data transfer between IOCs and the fast data server.

SUMMARY

The PAL-XFEL will be installed until the end of 2015 and start commissioning in the beginning of 2016. After 1 year of commissioning it will be opened to public for user experiments. From the network system to the various kinds of servers, the control system of the PAL-XFEL is under construction and will be ready for the successful commissioning of the PAL-XFEL.

ACKNOWLEDGMENT

Authors would like to thanks to the collaborators such as the SLAC for the event timing system, the BPM electronics and the Cosylab for the high level control system.

XFEL MACHINE PROTECTION SYSTEM (MPS) BASED ON UTCA

S. Karstensen, M. E. Castro Carballo, J. M. Jäger, M. Staack (DESY, Hamburg).

Abstract

For the operation of a machine like the linear accelerator XFEL at DESY Hamburg, a safety system keeping the beam from damaging components is obligatory. This machine protection system (MPS) must detect failures of the RF system, magnets, and other critical components in various sections of the XFEL as well as monitor beam and dark current losses, and react in an appropriate way by limiting average beam power, dumping parts of the macro-pulse, or, in the worst case, shutting down the whole accelerator. It has to consider the influence of various machine modes selected by the timing system. The MPS provides the operators with clear indications of error sources, and offers for every input channel the possibility to set dedicated machine modes to facilitate the operation of the machine. In addition, redundant installation of critical MPS components will help to avoid unnecessary downtime.

This paper summarizes the requirements on the machine protection system and includes plans for its architecture and for needed hardware components. It will show up the clear way of configuring this system - not programming.

Also a look into the financial aspects (manpower / maintenance / integration) is presented.

INTRODUCTION

The European X-Ray Free Electron Laser (XFEL) linear accelerator will bring an electron beam to the energy of up to 20 GeV and use it to generate extremely brilliant pulses of spatially coherent x-rays in an array of undulators using the Self-Amplified Spontaneous Emission (SASE) process. With a design average beam power of 600 kW and beam spot sizes down to few micrometers, the machine will hold a serious damage potential unless countermeasures are taken. To ensure safe operation of the accelerator, dangerous situations have to be detected by closely monitoring beam losses and the status of critical components, and to react appropriately. This is the task of the fast machine protection system (MPS) described in this paper. Several design features of the system have been influenced by experience from existing facilities, particularly the Free Electron Laser in Hamburg (FLASH).

A high flexibility of the MPS is essential to guarantee minimum downtime of the accelerator. In contrast to a storage ring where a beam dump typically implies a time-consuming refill of the machine, a linac offers the possibility to limit the length of the bunch train individually for each macro-pulse. Hence the reaction to failures of subsystems or even parts of the MPS can be much more specific—a dynamic limitation of the total beam power or a selective veto on beam transport into a particular branch of the beamline are possible. Experience

with FLASH has also shown that the operation of the machine profits from an MPS whose behaviour can be changed or extended in a simple way. Apart from all of this, overall limitations, like power density, have to be respected.

XFEL ARCHITECTURE

The present chapter provides a brief overview of the XFEL facility (Figure 1). The major tunnel sections accommodate the following systems:

- injector
- linear accelerator (linac)
- beam distribution system
- undulators
- photon beam lines
- experimental stations

These components are distributed along an essentially linear geometry, 3.4 km long, starting on the Deutsches Elektronen-Synchrotron (DESY) laboratory campus in the north west part of the city of Hamburg, and ending in the neighboring federal state of Schleswig-Holstein, south of the city of Schenefeld, where the experimental hall will be located.

In the injector, electron bunches are extracted from a photocathode by a laser beam, focused and accelerated in a radio frequency (RF) gun and a superconducting acceleration module, and directed towards the linac with an exit energy of 120 MeV. After further acceleration, the bunches are longitudinally compressed in two bunch compressors, BC1 and BC2, at energies of 500 MeV and 2 GeV. In the subsequent main linac, the beam is brought to energies of up to 20 GeV (17.5 GeV is the energy foreseen for normal operation of the XFEL) before passing the collimation section. Afterwards, a fast kicker can send single bunches into a beam dump and the beam will be limited. The remaining bunch train can be sent into two undulator lines by the beam distribution kicker with a rise time of less than 20 μ s. Each of the undulator lines ends in an electron beam dump, and each of the three main beam dumps is designed to withstand only half of the nominal beam power, i.e. 300 kW.

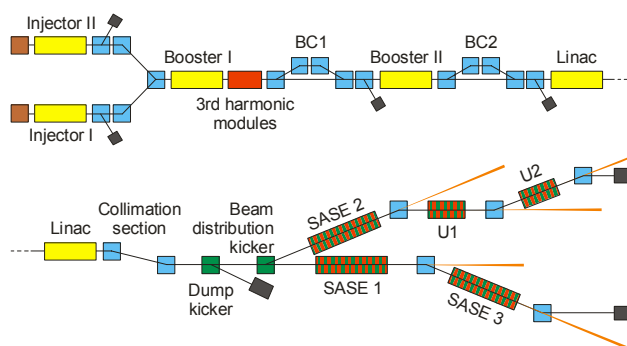

Figure 1: Schematic of the XFEL beam line.

REQUIREMENTS FOR THE MACHINE PROTECTION SYSTEM

The main requirements for the MPS may be summarizing in three points, in the order of their importance:

1. protect accelerator components and devices in the vicinity of the accelerator from direct and indirect damage by the beam
2. facilitate easy handling of the machine—impair machine operation only if necessary
3. limit activation of accelerator components to preserve their maintainability

While it is obvious that the protection from damage is of paramount priority, any machine can only serve its purpose if it can be operated. Beam time at the XFEL will be in high demand, and the goal should be to limit downtimes to their necessary extent. In this respect, it is of no importance whether downtimes are caused by hardware failures or operating errors; the MPS should be both highly reliable and “user-friendly”.

Failsafe Behavior

Since most of the MPS electronics will be located in the accelerator tunnel, an elevated radiation background must be expected. An analysis on the behavior of FPGAs has been carried out at DESY [1] and shows that neutron-induced single event upsets (SEUs) are the major source of malfunctions. Therefore, the design of the electronics should ensure as far as possible that SEUs do not lead to unsafe or uncontrolled behavior of the system. Problems caused by power cuts or simple cable breaks must also be considered.

Reaction Times

In the XFEL, the distance from the injector lasers to the last undulators is approximately 3 km. Thus, at the speed of light, a signal needs about 10 μ s to travel from one end to the other. Since the bunch frequency of the XFEL is 5 MHz, a maximum of 50 bunches could be moving within the accelerator at any given time.

Table 1: Minimum Number of Lost Bunches at Various Locations, According to Reaction Times of MPS, Assuming a Signal Velocity of 2/3 c

Beam loss location	Distance from injector	Distance from dump kicker	min. num. of lost bunches
Injector	0 m	−1970 m	0
bunch compr. 1	160 m	−1810 m	7
bunch compr. 2	360 m	−1610 m	15
linac center	1040 m	−930 m	44
linac end	1650 m	−320 m	69
beam distribution kicker	2010 m	40 m	2
last undulator	3010m	1040m	44

From this follows that, if beam losses are detected near the end of the machine, at least 100 bunches carrying a total energy of about 2.2 kJ would arrive at the position of the loss before the injector laser could be switched off.

To reduce this reaction time, the MPS clearly needs a second location for disposing the beam. The dump kicker, part of the beam switchyard at about 2.1 km along the machine, is the natural choice for this interaction. Table 1 lists the minimum possible reaction times and the minimum number of lost bunches at several possible locations of MPS alarms.

MPS ARCHITECTURE

The large scale of the XFEL imposes a severe technical issue: latency of electronics and signal transport speed of 3/4c in copper cables and 2/3c in optical fibers lead to a signal delay and in consequence additional lost bunches. To provide a short reaction time, the MPS implements a distributed Master/Slave architecture keeping short distances between components. Also every Master/Slave does a pre-processing of all incoming alarm signals that we have a here a real distributed system with distributed processing units.

The optical fibers are planned in a way that a set of fibers connects each RF section (4 cryogenic modules, 1 klystron) to the injector building XSE. Various points in the undulator sections are connected to the hall XS1, fiber sets from the experimental stations are collected in the hall XHEXP1. There are fiber connections between XSE, XS1 and XHEXP1. Each of the RF sections will be equipped with 2 MPS modules (Figure 2). Loops in the bunch compressors and SASE sections will contain 3 to 5 MPS modules.

Figure 2: MPS distributed in XFEL.

The backbone of the XFEL Machine Protection System consists of roughly 130 MPS slave modules distributed along the machine. Each of these modules has digital inputs for “beam OK” signals from critical subsystems, accelerator components, or beam loss detection hardware. It also has fast serial input and output ports to connect to other MPS modules; to avoid problems with electromagnetic interference, these serial connections use fibre optic cables.

All modules are developed to provide high flexibility. They could be used as an intelligent data distribution knot, as standalone knot or just as a simple data collector, with single or redundant communication links.

Two master modules are located near the injector and near the linac dump kicker (Figure 2). The FPGA logic of these “MPS masters” defines the behavior of the system.

They have direct connections to the injector lasers and to the dump kicker, allowing them to stop the production of new bunches and to dump bunches that are already in the machine. Both Masters are working very close together and can be seen as one Master. The latency between the two masters is negligible, as both masters have different tasks and the information interchange is only informal.

Referring to the XFEL Timing System [2], the complete MPS system is working asynchronously.

The serial connections between MPS masters and slaves form loops carrying a steady data stream. Within reasonable limits, the number of loops connected to each master can be chosen freely, while the number of slave modules in each loop is limited mainly by the desired latency of less than 1 μ s excluding cable delays.

Simulations have shown that with current FPGA technology, the input latency per board is in the range of 42 ns (RS 422 input \rightarrow FPGA).

Due to the used structure, the system is also easily scalable without major cabling work as of new slaves could be added to existing knots.

INTERFACES

The MPS slaves receive digital status signals from external systems via RTM / RS422 signal lines and information of the Timing System via the μ TCA backplane. A cable break or short circuit within the RS422 lines will be detected and reported as an alarm without distinguishing between real alarm or cable break.

The main MPS master is connected to the Timing System to provide the information about possible Beam Modes (Figure 3) and Section patterns (Figure 4). Beam Modes representing the maximum allowed bunches and power within the linac sections (1 Bunch, single, medium, full). Section Patterns are showing the health status of sections. Also, since MPS slaves and masters constantly communicate with each other, this communication is watched by special algorithms to guaranty a failsafe operation.

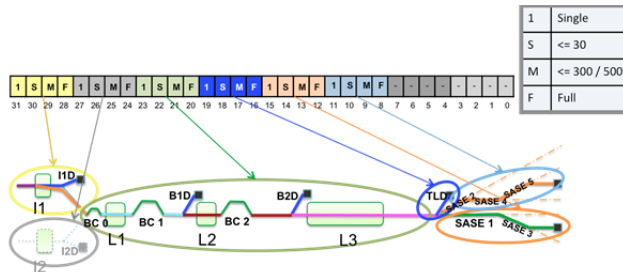

Figure 3: XFEL Beam Modes.

Figure 4: XFEL Section Patterns.

All incoming alarm signals are handled equally. There is no difference between slow (e.g. relay) or fast (e.g. electronic) signals.

μ TCA TECHNOLOGY

MPS as most of the control components of XFEL will use the μ TCA technology for the following reasons:

- Modular + modern architecture
- Reusability + PCIe + Ethernet
- High availability
- Redundant power and fan optional
- Well defined management protocol
- High performance:
 - o Very low analog distortions
 - o 4 lanes PCIe: 400 MB/s ... 3.2 GB/s

XFEL fast electronics will be based on MTCA.4: with more than 200 Crates [3]

HARDWARE

The Master and Slave stations are equipped with the DESY DAMC2 (FPGA, PCIe, SFP) board and the appropriate Rear Transition Module (RTM) (galvanic separated RS422 IOs).

This strategy offers a large flexibility in case of technical problems as the DAMC2 is used everywhere inside the XFEL and MPS will take profit out of external developments, soft- and hardware wise. To receive digital alarm signals at DAMC2, a Rear Transition Module (RTM) has been developed for MPS. A schematic diagram is shown in Figure 5.

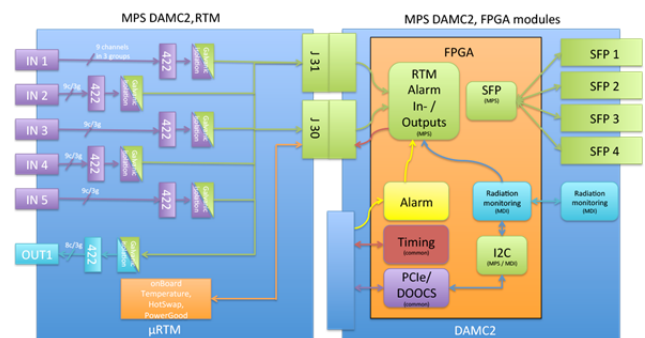

Figure 5: DAMC2 and RTM structure.

DAMC2 The DAMC2 board of Figure 5 has been developed by DESY and is equipped with a VIRTEX 5 FPGA. The documentation is available at DESY FEA group.

Figure 6: DAMC2 board.

MPS RTM The MPS RTM, shown in Figure 7, is the interface between RS422 in- and outputs and the DAMC2 board. It is developed at DESY and fulfills all requirements to be used with the DAMC2. The latency of an input signal from RTM to the FPGA of the DAMC2 has been measured with 42 ns per channel [4]. See also Figure 8 for more latency info. This has been measured in August 2013 and will be approved.

Figure 7: MPS RTM module.

Figure 8: Latency measurement of several combinations of MPS modules.

CONTROL SYSTEM

The XFEL MPS is embedded inside the DOOCS control system [5]. DOOCS provides all necessary instances like GUIs, data logging and archiving, server functionality and other overlapping functionalities. DOOCS is used as interface for MPS configuration. It is

not integrated into the safety-relevant process of the MPS. The MPS is running 100% self-reliance, if the connection to DOOCS is broken.

FINANCIAL ASPECTS

The importance to realize and design large facilities within a clear financial budget is evident. The amount of manpower and maintenance costs has to be taken into account from the beginning of every new project. For MPS it was calculated with 3 persons for the development phase and 2 persons for installation and running period. To achieve this goal, the MPS group has chosen existing hard- and software from the existing infrastructure. The only development of strictly necessary hardware inside this project is the μ TCA RTM. The firmware in all MPS DAMC2 modules is the same, the additional maintenance is reduced to a minimum.

As basic idea of the whole concept, the International Linear Collider (ILC) is the force behind the design with an order of magnitude more units.

GLOSSARY

Macro-pulse

A shot in the linac of a train of electron bunches with duration of up to $\sim 600 \mu\text{s}$ plus the filling and decay time of the cavities. Usually repeated every 10 Hz

Beam Mode

It defines the maximum number of bunches permitted per macro-pulse in a section of the accelerator. The MPS grants the mode by reading the machine settings and interlocks.

Section Pattern

Every bit in the pattern describes the status of a subsection. If the bit is set to '1', beam is permitted within this subsection

UPGRADE OF THE BEAM MONITOR SYSTEM FOR HADRON EXPERIMENTAL FACILITY AT J-PARC

Y. Morino*, K. Agari, Y. Sato, A. Toyoda,
KEK, High Energy Accelerator Research Organization, Ibaraki 305-0801, Japan

Abstract

Hadron experimental facility at Japan Proton Accelerator Research Complex (J-PARC) has been improved toward safety operation of high intensity beams. The monitor system of the slow-extraction beam line also has been upgraded to detect abnormal beam extraction. The rate monitor which measured the number of second particles from the production target with the rate of 1 kHz was prepared to detect short pulse extraction. The beam profile monitor was upgraded to read out the data at several times during a beam spill to detect a beam with the narrow width even for a short time. The beam loss monitor was upgraded to monitor beam loss with the rate of ~ 10 kHz to detect unexpected large loss immediately.

INTRODUCTION

Hadron experimental facility at Japan Proton Accelerator Research Complex (J-PARC) is designed to provide high intensity beams for particle and nuclear physics [1]. A 30-GeV proton beam show-extracted from main ring is injected to a production target (T1) at the hadron experimental facility. The acceleration cycle for the slow-extraction is 6 sec and the spill length is 1.5~2.0 sec.

Figure 1 shows an overview of the hadron experimental facility. In the beam switching yard, there are 33 beam line magnets in 250 m tunnel. In the HD-hall, the proton beams are injected to the production target (T1) and produce secondary particles. The proton beams are transported to the beam dump and absorbed safely. Several kinds of beam monitors are installed in the slow-extraction beam line. The beam monitors involving this paper are shown at Fig. 1.

On May 2013, a proton beam was instantaneously extracted to hadron facility in 5 msec. The short pulse beam molt the production target. After the accident, the beam operation was stopped at the hadron experimental facility. For the recovery of the hadron experimental facility, we upgraded the slow-extraction beam line in many aspects to sustain the abnormal beam extraction. The beam monitor system of the slow-extraction beam line was also upgraded to detect the abnormal beam extraction. The monitor system was developed based on EPICS [2]. The interlock system of the beam line was also improved based on the upgraded monitor system to protect the machines of the accelerator and the beam line.

The rate monitor was upgraded to measure the number of second particles from the production target with the rate of 1 kHz for the detection of short pulse extraction. The readout system of the beam profile monitor was improved to

detect a beam with the narrow width even for a short time. The main purpose of the rate monitor and the beam profile monitor is to detect the abnormal beam extraction which may damage the production target. The readout system of the beam loss monitor was improved to detect unexpected large loss immediately. The operation of the slow-extraction beam line was restarted on Apr 2015 successfully.

RATE MONITOR

The rate monitor measures the number of second particles from the production target by using plastic scintillation counters. The rate monitor is installed outside the shielding enclosure of the beam line. The rate monitor was upgraded to read out the particle count with the rate of 1 kHz. Since the number of the second particles is sensitive to the beam intensity, the rate monitor is used to monitor the time structure of the beam intensity. The signals from the scintillators are converted to short pulses with the width of ~ 60 nsec by a NIM discriminator. The number of the second particles is measured by counting the pulses with a VME module with a FPGA board (GNV-251). The EPICS Input/Output Controller (IOC) runs on Linux on a VME CPU modules (VME-7807).

Figure 2 shows the online monitor display of the rate monitor. The number of the particles per 1 msec is plotted as a function of time. The upper panel shows the example plot in the case of the normal beam extraction. The lower panel shows the predicted plot in the case of the short pulse extraction. In the case of the short pulse extraction, the measured count will increase instantaneously, while the integrated number of the measured count will decrease due to the dead time of the read out system.

The important roles of the rate monitor are the detection of the short pulse extraction and the generation of signals for the interlock system. The upper threshold is set for the number of the particles per 1 msec (instantaneous count). In addition, the upper and lower thresholds are set for the number of the particles per 3 sec (integrated count). In the GNV-251 module, the integrated count is compared with the thresholds for every spill and the instantaneous count is compared with the threshold for every 1 msec. When the particle count crosses the thresholds, the GNV-251 module generates the interlock signal immediately and then the interlock system stops the next beam extraction [3, 4]. The control system of the rate monitor was also developed based on EPICS. The timing of the read out and the threshold values are controlled via EPICS records.

* ymorino@post.kek.jp

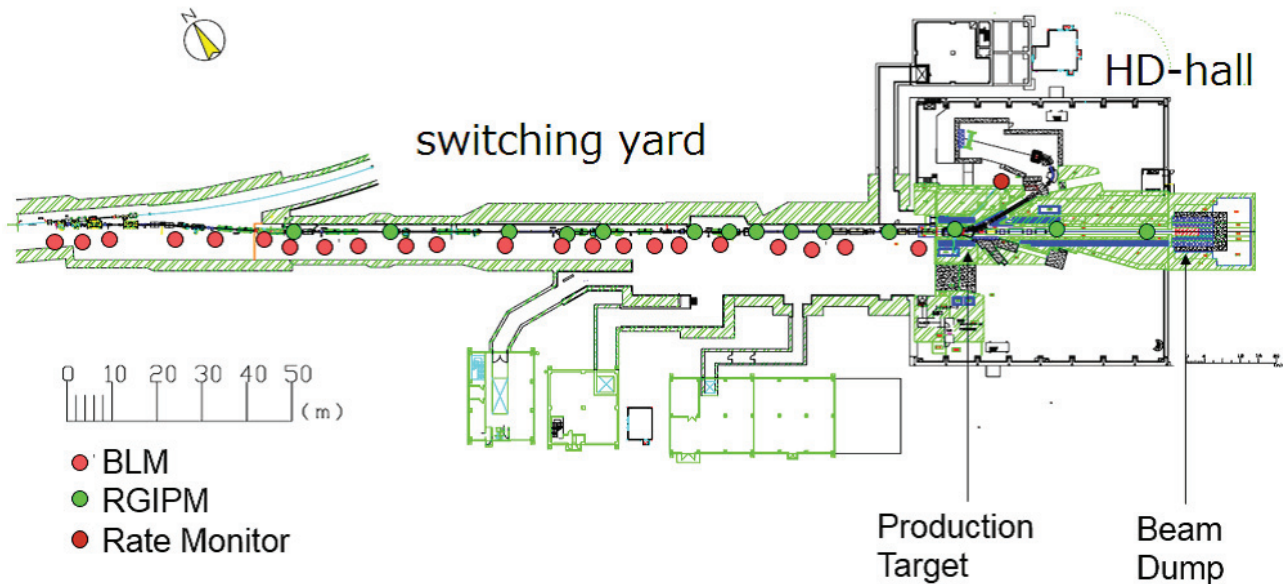

Figure 1: An overview of the Hadron Experimental Facility. Beam monitors involving this paper are shown.

Figure 2: The online monitor display of the rate monitor. The number of the particles per 1 msec is plotted as a function of time. The upper panel shows the example plot in the case of the normal beam extraction. The lower panel shows the predicted plot in the case of the short pulse extraction.

Figure 3 shows the summary results of the rate monitor at the 33kW beam power operation. Left panel shows the result of the maximum value of the instantaneous count per a beam spill. Right panel shows the result of the integrated count. The upper and lower thresholds are also shown at Fig. 3. The integrated count was rather stable. However, the average of the integrated count was different before and after the machine maintenance. It made a double peak structure at Fig. 3. The fluctuation of each peak of the integrated count is less than 1%. The upper threshold value for the

instantaneous count is 375. The upper and lower threshold values are 64000 and 37500, respectively. The performance of the interlock system related with the rate monitor was also confirmed.

Figure 3: The results of the rate monitor at the 33kW beam power operation. Left panel shows the result of the maximum value of the instantaneous count per a beam spill. Right panel shows the result of the integrated count. The upper and lower thresholds are also shown.

BEAM PROFILE MONITOR

The beam profile in the slow-extraction beam line is measured with Residual Gas Ionization Profile Monitor (RGIPM) [5, 6]. 14 RGIPMs are located on the slow-extraction beam line as shown at Fig. 1. The signals of the RGIPMs are integrated up to about 2 sec by using a VME slow integrator (GNV-370N). The integrated signals are recorded with a VME A/D board (Advme-2607) after every beam extraction. The EPICS IOC runs on Linux on a VME CPU modules (VME-7807).

The RGIPM located at the front of the production target (T1 RGIPM) was upgraded to read out eight times per a beam spill. The read out timing of the T1 RGIPM is controlled by the GNV-251 module via EPICS records. Figure 4 shows the online monitor display of the T1 RGIPM in the case of the normal beam extraction. The upper left panel shows the pedestal data measured in the interval of every beam extraction. The other panels show the measured beam profiles after the subtraction of the pedestal. The red lines and the blue lines represent beam profiles for horizontal and vertical direction, respectively. The number at each panel represents the order of the read out. The position and width of the beam profile do not change dramatically depending on the order of the read out in the case of the normal beam extraction.

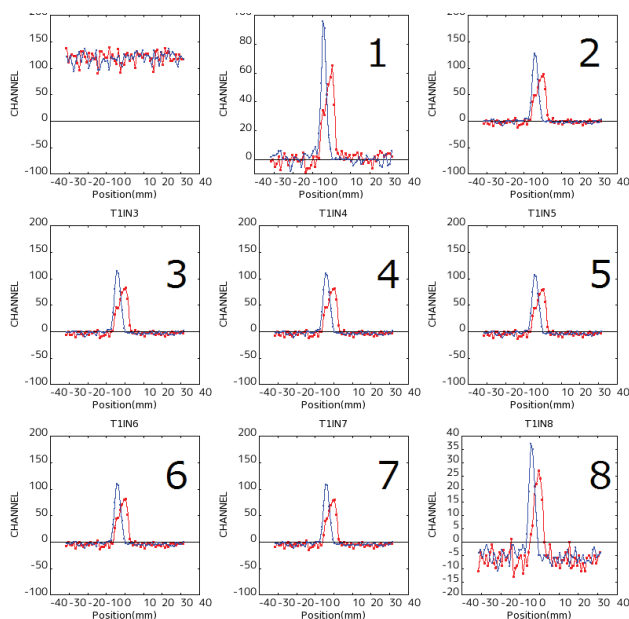

Figure 4: The online monitor display of the T1 RGIPM. The upper left panel shows the pedestal data measured in the interval of every beam extraction. The other panels show the measured beam profile after the subtraction of the pedestal. The red lines and the blue line represent beam profiles for horizontal and vertical direction, respectively. The number at each panel represents the order of the read out.

The improvement of the read out system of the T1 RGIPM aims at the detection of the abnormal beam extraction with narrow width even for a short time. The lower threshold is set for the beam width at the T1 RGIPM in every time window. The threshold values are also controlled via EPICS records. When the beam width becomes below the threshold in any time window, the signals for the interlock system are generated to stop the next beam extraction.

Figure 5 shows the summary results of the beam widths at time window 4 at the 33kW beam power operation. Left panel shows the result of the beam width for horizontal direction and right panel shows the result of the beam width

for vertical direction, respectively. The lower thresholds are also shown at Fig. 5. The typical beam widths at the T1 RGIPM were 2.6 mm and 1.8 mm for horizontal and vertical direction, respectively. The beam widths were rather stable. The fluctuation of the beam width was within 0.2 mm. The lower thresholds were ~ 1.9 mm and ~ 1.2 mm for horizontal and vertical direction, respectively. The performance of the interlock system related with the beam profile monitor was also confirmed.

Figure 5: The summary results of the beam widths at time window 4 at the 33kW beam power operation. Left panel shows the result of the beam width for horizontal direction and right panel shows the result of the beam width for vertical direction, respectively. The lower thresholds are also shown.

BEAM LOSS MONITOR

Beam loss at the slow-extraction beam line is measured by using air ionization chamber (BLM). 22 pairs of BLMs are located beside the beam line as shown at Fig. 1 to monitor unexpected large beam loss.

The signals of BLMs are integrated up to about 2 sec by the GNV-370N module in the same way as the RGIPMs. FAM3 Programmable Logic Controller (PLC) was introduced to read out the integrated signals of the BLMs to detect the accidental large loss immediately. Figure 6 shows a picture of the PLCs of the BLM read out system. A PLC sequencer CPU (F3SP71-4S), PLC A/D modules (F3HA12-1R) and a PLC output module (F3YC08N) are used to read out the integrated signals and to generate signals for the interlock system. The EPICS IOC runs on Linux on a PLC CPU module (F3RP61-2L) [7].

The PLC A/D modules digitize the integrated signals with the rate of 200 kHz. The ADC values of the integrated signals are compared with the thresholds every time the PLC sequencer CPU scans. The scanning rate of the PLC is ~ 10 kHz. When the ADC values exceed the thresholds, the F3YC08N module generates the interlock signals immediately. The ADC values are recorded as EPICS records for every 200 msec during the beam extraction for online-monitoring. Figure 7 shows the online monitor display of the BLM. Each panel shows the measured beam loss at each time window after the subtraction of the pedestal. The number at each panel represents the order of the read out. The measured beam loss is plotted as a function of the located position of the corresponding BLM. Blue bar represents one

of the pair BLM and red bar represents the other of the pair, respectively. The upper thresholds are set for the measured beam loss. The interlock system of the BLMs also worked well.

Figure 6: A picture of the PLCs of the BLM read out system.

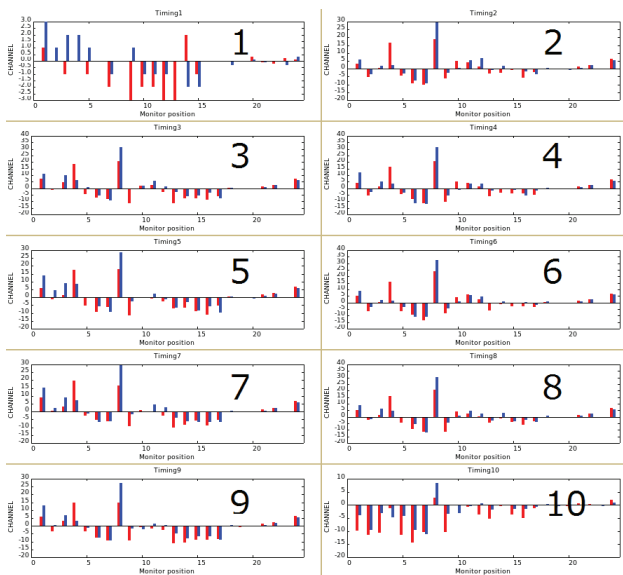

Figure 7: The online monitor display of the BLMs. The number at each panel represents the order of the read out. Blue bar represents one of the pair BLM and red bar represents the other of the pair, respectively. The measured beam loss are plotted as a function of the located position of the corresponding BLM.

SUMMARY AND OUTLOOK

The rate monitor, the RGIPMs and the BLMs have been improved to detect the abnormal beam extraction and investigate the status of equipment of the beam line. These monitors also generate the signals for the interlock systems to protect machines at the beam line when the abnormal beam injection is detected. The slow-extraction beam line was recovered on Apr 2015. The operation of the beam line was successfully done for ~2 months with the upgrade monitor and interlock system.

A new interlock system (Sx Abort) will be introduced from Oct 2015 so that the abnormal beam could be aborted even during the beam extraction. The Sx Abort system will be powerful method to protect the machines at the beam line. The 33 kW beam power has been achieved on June 2015, which corresponds ~1.5 times higher than one on May 2013. The beam power is planned to be increased further gradually. The beam monitor system and the interlock system of the beam line have been improved toward safety operation of the higher power beam.

NONLINEAR SYSTEM IDENTIFICATION OF SUPERCONDUCTING MAGNETS OF RHIC AT BNL*

P. Chitnis[#], Stony Brook University, NY, USA
K. A. Brown, Brookhaven National Laboratory, NY, USA

Abstract

The Quench Detection System (QDS) of RHIC detects the Superconducting (SC) magnet quenches by voltage sensing. The real-time voltage across the SC magnet is compared with a predicted voltage from a behavioral model, a deviation from which triggers the quench event and energy extraction. Due to the limitations of the magnet model, many false quench events are generated that affect the RHIC availability. This work is targeted towards remodeling the magnets through nonlinear system identification for the improvement in QDS reliability. The nonlinear electrical behavior of the SC magnets is investigated by statistical data analysis of magnet current and voltage signals. Many data cleaning techniques are employed to reduce the noise in the observed data. Piecewise regression has been used to examine the saturation effects in magnet inductance. The goodness-of-fit of the model is assessed by field testing and comprehensive residual analysis. Finally a new model is suggested for the magnets to be implemented for more accurate results.

INTRODUCTION

The RHIC Superconducting (SC) magnets store an energy of 70MJ in the form of magnet currents during a full energy run. The SC magnets are susceptible to quenches that lead to the development of tiny resistive zones. An operating current near 5000A (for a dipole magnet) can dissipate this enormous energy at this tiny resistive point causing catastrophic damage.

To safeguard against such failure, Quench Detection System (QDS) is employed. It monitors the SC magnets to detect the developing quenches and sends the magnet power dump signal and beam abort signal to the beam permit system [1]. Voltage sensing is employed for recognizing the developing quenches. The QDS consists of DSPs which store the electrical behavioral model of the SC magnets. The actual magnet output is compared to the model output, and a deviation is sensed as a developing quench, which generates a quench trigger.

The SC magnets exhibit a highly nonlinear behavior due to saturation and hysteresis of steel yoke [2]. Due to mathematically intractable nature of this behavior, the magnet model parameters are manually calibrated, which inhibit the accurate tuning of the model. Also it consumes valuable time when RHIC is running at 4K temperature. Inaccuracies introduce deviation in the model output,

which leads to false failures, and resulting in unnecessary machine downtime. Thus to improve QDS reliability, it is necessary that the model truly imitates the SC magnet behavior. The aim of this work is to facilitate automatic generation of accurate magnet models through nonlinear system identification that will improve the reliability and availability of QDS.

Original Magnet Model

The SC magnet circuit's electrical behavior is modeled as a pure inductor with a series resistor. The pure inductor represents the SC magnet and the resistance represents the current leads to the magnet. The model is

$$V_c = L \frac{dI}{dt} + RI$$

Here I is the current through the magnet, L is the nonlinear magnet inductance, R is the lead resistance and V_c is the calculated voltage from the model. This voltage is compared to the observed voltage V_o across the magnet in real time. When a quench develops, additional resistance will appear causing V_o to deviate from V_c . A difference more than 25 mV is triggered as a quench event.

The parameter L is highly nonlinear in nature. It exhibits saturation i.e. its value decreases with increasing current. Also the L vs. I curve changes with the change in current ramp waveform. The model stores lookup table for L vs. I values, which have to be updated manually every time a new current waveform is introduced. An L vs. I lookup table is shown in Fig. 1. This gives us a rough idea of the nonlinear behavior of L .

Figure 1: L vs. I lookup table values

SYSTEM IDENTIFICATION

Our aim is to find an accurate inductance variation with the current change to construct accurate L vs. I tables to be used in the DSP model. We analyze the magnet current and voltage data for a magnet tap named B1DSD9_5VT. For this particular voltage tap connected across dipoles, the R value is zero, so we are left with the following model

$$V_c = L \frac{dI}{dt} \quad (1)$$

One of the techniques that can be applied to solve for L is the linear regression, where the explanatory variable is the first derivative of the current and the response variable is voltage. We mine the voltage and current data from RHIC database using MATLAB® [3], which is found to be quite noisy. Particularly for the derivative of current, noise is highly amplified. Thus we attempt to clean the data first. We analyze the frequency spectra of the current and voltage data, and their variation over time through spectrograms shown in Fig. 2.

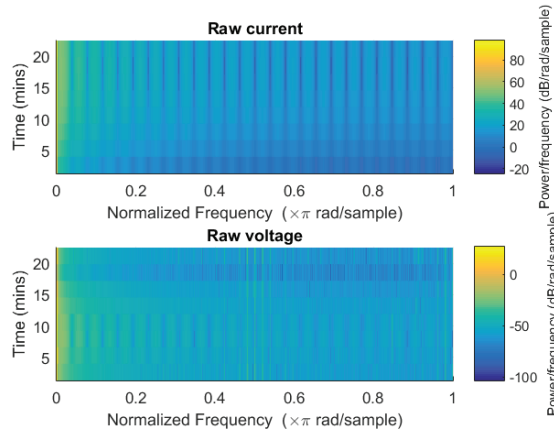

Figure 2: Spectrograms of voltage and current signals

Next we choose to filter the voltage and current data per the frequency characteristics in Fig. 2. The noise in the first derivative of current is now eliminated. Figure 3 shows the filtered (green) and raw (black) signals for the magnet current, first derivative of the current and voltage signals. The periodic noise and spikes in the data are now removed.

Now the data is ready for analysis after the preliminary processing. Consider the dI/dt waveform in Fig. 3. There are certain portions of the current where the first derivative of the current is either zero or has very low value. For a good fit of the linear regression model, the explanatory variable should have a substantial magnitude. Thus to apply the regression algorithm using Eq. 1, we eliminate small or zero values of dI/dt and corresponding values of V from the data. We have written a data classification algorithm to segment and identify the regions in current waveform where the first derivative is non-zero, second derivative is non-zero etc. The

segmented portions of the magnet current are shown in Fig. 4.

Figure 3: Raw and filtered I, dI/dt and V

Figure 4: Current segmentation

Figure 5: L vs. I curve from piecewise regression

We use Eq. 1 for regression in region where the first derivative exists. Now we address the nonlinear variation of L with increasing current. One method to deal with this is to use piecewise regression, where the current is divided into very small data sets, and regression is applied to each set for finding L value. The L is assumed constant for this small dataset. Now we plot these values of L with I in Fig. 5 that shows the saturation characteristics of L similar to Fig. 1, but much cleaner.

FIELD TESTING

Before testing the model in the field, we look at the residuals that we obtain from our analysis. The residuals between the filtered voltage and the calculated voltage are shown in Fig. 6. As seen the maximum value of the residuals is about 8mV, which is well below the 25mV limit.

Figure 6: Residuals between the filtered and fitted voltage

The piecewise regression generates a smooth curve of about 200 data points for L vs. I curve (Fig. 5). However the DSP model can only store 35 values of L values. We interpolate the L values for in-between I values. We generated L vs. I tables for DSP using this data, and a screen shot from the field testing on the same voltage tap is shown in Fig. 7. The difference signal (in blue) is the moving average of 100 values of the actual voltage difference (in grey), which is used for triggering quench event in case it goes beyond 25mV. The maximum value of the trigger signal is found to be 6mV which is quite below the 25mV level.

Figure 7: Field testing, quench trigger signal

Residual Diagnostics

The linear regression model validity can be established by residual diagnostics. We use the guidelines discussed in [4] for checking our model.

The true residuals of our model are obtained by the difference between the observed magnet voltage and the predicted voltage from the newly generated DSP table, as this table will actually be used in the field. Similar to the DSP, we find the predicted voltage from Eq. 1, by interpolating the L values for intermediate I values in the table.

We use the following rules for our residual diagnostics as discussed in [4]. It is to be noted that the shape of residuals in Fig. 6 will be visible in these residuals as well. We address this residual pattern later in this paper. First, the explanatory variable should be linearly related to the response variable. This can be observed by plotting the residuals against the explanatory variable. We already linearized our model by piecewise regression so that the residuals will be linear with respect to dI/dt . As seen in Fig 8, the trend is almost linear, with little variability.

Figure 8: Residuals vs. explanatory variable

Secondly, the residuals should have nearly normal distribution. This can be seen by plotting the histogram and quantile-quantile plot (Fig. 9). From the figure it is seen that the residuals are a little light-tailed but are not skewed, and are nearly normal.

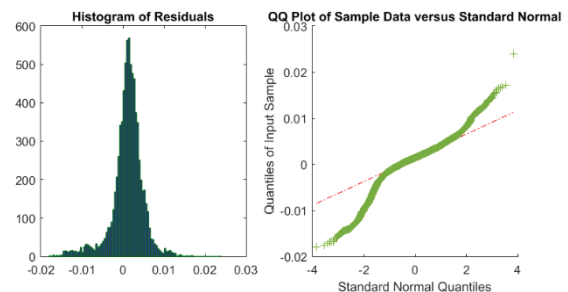

Figure 9: Histogram and QQ plot

Thirdly, the residuals should have constant variability. This can be checked by plotting the residuals against the response variable where the residuals should be randomly

scattered around the zero value. This rule is satisfied as seen in the Fig. 10.

Figure 10: Residuals vs. response variable

Lastly the residual values should be independent of each other. This can be checked by the scatter plot of residuals (Fig. 11). In all the residual plots we see a periodic structure, which is due to the Booster main magnet pulses disturbing the power line [5, 6]. Other than this, the pattern looks random.

Figure 11: Scatter plot of residuals

DISCUSSION

To further improve the model, the remaining variability in the residuals has to be analyzed. As seen in Fig. 7, we see a pattern in the residuals. This variation depicts a dependence on the second derivative of current, which is shown in Fig 12.

Figure 12: Negative of the second derivative of current

To accommodate this variance, we can modify the magnet model as the following equation.

$$V_c = L \frac{dI}{dt} + X \frac{d^2I}{dt^2}$$

Here X is a coefficient of second derivative of current, which can be a constant throughout the data, and might not need piecewise regression. This X parameter can then be modeled as an eddy current component and/or parasitic capacitance in the circuit. More accurate analysis can be done by performing the frequency response analysis.

CONCLUSION

We utilize the statistical analysis concepts to reveal the underlying saturation characteristics of the magnet, and validate our model using field testing and residual analysis. This will facilitate the automatic generation of the DSP tables without any manual intervention. This helps to save the valuable resources when the RHIC is running at 4K temperature. Going further, we have also developed an analytical memory model that quantifies the saturation and hysteresis behavior of RHIC superconducting magnets [7]. This will help forecast the L vs. I curve for particular current waveform, accounting for nonlinearities due to saturation and hysteresis.

ACKNOWLEDGEMENT

We would like to thank D. Bruno for his constant support, help with testing the inductance tables and providing the magnet data. We also thank G. Ganetis for his guidance in explaining RHIC magnet characteristics.

ALMA RELEASE MANAGEMENT: A PRACTICAL APPROACH

R. Soto, T. Shen, N. Saez, Joint ALMA Observatory, Santiago, Chile
J. Ibsen, European Southern Observatory, Santiago, Chile

Abstract

The ALMA software is a large collection of modules, which implements the functionality needed for the observatory day-to-day operations. The main ALMA software components include: array/antenna control/correlator, submission/processing of science proposals, telescope calibration and data archiving. The implementation of new features and improvements for every software subsystem must be coordinated by considering developers schedule, observatory milestones and testing resources available to verify new software. This paper describes the software delivery process adopted by ALMA since the construction phase and its evolution until these days. It also presents the acceptance procedure implemented by the observatory for validating the software used for science operations. Main roles of the software delivery and acceptance processes are mentioned on this paper by including their responsibility at the different development and testing phases. Finally, some ideas are presented about how the model should change in the near future by considering the operational reality of ALMA Observatory.

OVERVIEW

The software delivery process of ALMA Observatory has passed for several transformations aligned to observatory's project lifecycle. Thus, it changed from a static model (with few and big releases) to a dynamic schema with emphasis at the testing phases and reducing the integration time required for a new release. This paper will present the evolution of the ALMA Software Delivery Process and Release Management by describing the advantages/disadvantages of the models adopted. Final section will give an overview how the model will change in the near future.

SOFTWARE RELEASES IN THE PAST

The ALMA Observatory started its commissioning phase at the Chilean site during the end of 2009. It considered some antennas installed at the high site (5000m) and the deployment of the first quadrant for the baseline correlator. Additionally, the assembly, integration and verification activities (AIV) related to the new array elements delivered by manufacture vendors [1], continued more intensely at the Operation Support Facilities (3000m). This period was very intensive for the computing group, since simultaneous activities had to be supported in parallel. Commissioning process by using

direct observing systems (control and correlator software, front-end archive, etc.) was required at the Observatory and, at the other hand, the preparation, integration and testing of pre and post observing software (Phase 1 and Phase 2 proposal submission, time allocation committee support, data processing software, etc.) was demanded as an Early Science task, planned to be started at the end of 2010. In terms of software releases, a cycle of 6 months for the delivery of new features was established, which included capabilities for the observing systems and the proposal handling process as well. These cycles considered several phases (with a timeline predefined) before declare the software as accepted for AIV activities or Early Science observations as described at [2]: *Code Freeze Period, Initial Integrated Testing, Initial Site Testing, Computing Release, Routine Use, Acceptance Testing and Integrated Testing*. The model worked relatively well during early construction stages when the activities were concentrated at the ALMA Test Facilities [3]. Software was commissioned by using prototypes antennas and there was time available with the operational hardware for testing purposes. However, this approach was deficient when commissioning and AIV activities started at the operational site. There were less access to the hardware for testing and more pressure for having new software capabilities working in order to continue progressing into array commissioning.

Preliminary testing was initially executed in a simulated environment, which was not able to reproduce the exact behavior of the operational hardware. So, even a full battery of tests were executed, which considered new functionality and regression tests, there were not enough to deliver a mature software for the site testing. Many bugs were detected using the operational hardware, which increases the cost of correct them [4]. On the other hand, the big amount of features delivered per release also produced additional problems to distill the software. Thus, the stabilization of a new release took about two months after the integration and testing team delivered it. After that, science group should proceed with the routine use and acceptance testing, but the long integration period introduced big delays in the whole commissioning process. Given the current scenery, the integrated computing team looks for changes in the software delivery process adapting the model to the current reality.

THE CURRENT MODEL

Incremental Release Process

The model currently adopted differs from the previous one in terms of periodicity of the incremental releases delivered for science commissioning. We moved from 6-month period to bi-monthly schedule, which consider testing and integration as part of the cycle. Thus, a more frequent software delivery also implied that less features and improvements were included per release facilitating the integration, testing and debugging of the detected problems. Of course, these features and improvements are scheduled according to the observatory's milestone such as software needed for proposal submission, projects rating and starting of the observing cycle. This model also included the definition of different phases with formal handover between each one. Three phases were established:

1. **Phase A - Developer Integration & Testing:** Aimed to demonstrate that functionality is implemented as requested but based in unit tests. All tests must pass to move toward verification phase.
2. **Phase B - Verification:** Aimed to tests new functionality using both (largely) simulation and (when required) production environments. This include regression tests suite [5] for detecting bug and provide fixes to them. All tests must pass to proceed with the validation phase; otherwise features are "de-scoped".
3. **Phase C - Validation:** Aimed to validate additional capabilities and scientific data content. Performance and robustness aspects are also analyzed as part of validation tests (new releases should always behave better or at least no worse than the previous ones). Software acceptance requires both correct verification and validation test results.

The introduction of these formal phases also produced an optimization of the development and testing resources at the computing and science areas. A calendar with dates for every phase was prepared and circulated to developers, computing and science testers [6]. Also independent phases were parallelized (as showed in figure 1) which optimize the available resources. Release contents are fully tracked by using Atlassian tool called JIRA [7]. Every feature/improvement is registered in separate tickets, which also contain the testing results of every phase.

Figure 1: Incremental releases lifecycle.

Formal responsibilities were defined at the computing and science teams related to the planning and delivery of

the software. Thus, the *release* and *acceptance* manager roles were introduced. The first one is responsible for the planning and delivery of the incremental releases and the completion of the verification phase. Acceptance manager represents the clients or users point of view. He/she is responsible for reviewing the planning of the releases and make sure they are according to the Observatory's milestones and science needs. Acceptance manager has also the responsibility for the execution of the validation phase and prepare the acceptance plan for the software which has successfully passed verification and validation phases.

Acceptance Process

Once several incremental releases have been successfully verified and validated, they must be accepted in order to be used for official science activities (no commissioning ones) such as: Early Science observations, hardware commissioning, etc. The acceptance manager carries out the acceptance process and it is usually held very close to an observatory milestone. It consider the following steps:

- a) **Test Report Review (TRR):** This meeting has a goal the revision of the verification/validation reports for all incremental releases included at the acceptances. Important issues are also identified and the schedule to solve them is defined. It can be more than a TRR before the acceptance if there are many issues still pending to be solved. Once everything is OK from computing and science point of view, then the candidate branch is created and we move to the acceptance testing period.
- b) **Acceptance Testing Period:** During this period the final tests are performed over the candidate branch. The idea is not repeat the verification or validation phases but do a light regression tests of all applications to be deployed on production servers. These tests are performed in an isolated environment, which consider a recent image of the production DB in order to do them as much realistic as possible.
- c) **Acceptance Review:** The acceptance meeting considers the revision of the acceptance tests report and also the revision of the pending items. During this meeting the final decision is taken about to deploy the new software in production servers or postpone it until all the critical items had been solved.
- d) **Software Deployment in Production Environment:** This step considers the coordination with the different ALMA centers around the world for the deployment of the new software. It also included the changes into the database model needed for the new version of the applications. Usually it involves some downtime at the applications affected in order to deploy new versions. All the work is coordinated by the deployment manager who has to submit a report at the end with the status of the new software.

The Acceptance Manager is also responsible for preparing the acceptance calendar, which is aligned to the observatory's milestone and consider enough time to proceed with all the steps defined above. The acceptance calendar also contains the information about the incremental releases included into the acceptance. The calendar is distributed between scientists and developers and it represents the official information for any software planning activities.

The Software Change Control Board

Once a software release has been accepted, there is a formal process for introducing changes into the accepted branch. These requests can be associated to a software patch (related to a bug fix), to a change in the functionality requirements (called release change request), to a modification of the database schema (usually requested by software applications) or to a set of minor improvements for a specific application (called a service release). All software requests must be informed to the Release Manager by submitting a JIRA ticket [7].

A *Software Change Control Board* (SCCB) is a committee compound of various project stakeholders that typically fulfills the requirements for such a process. The group is formed for representative from computing, science and engineering sides. The SCCB (or a subset of them constituted mandatorily by the Release Manager and Acceptance Manager) will meet once a week to discuss and decide on outstanding software requests. Additional meetings may be called as required. Emergency requests need to be addressed immediately by a procedure properly established.

The decisions will normally be made by consensus. The nominated Acceptance Manager signs off all decisions. If no mutual agreement can be reached, the Release and Acceptance Managers together the head of the computing section responsible for the implementation must at least agree upon any decision. Otherwise the issue needs to be escalated to ALMA Observatory Management.

EVOLUTION TOWARD AN AGILE APPROACH

The ALMA observatory has concluded its construction phase and it is moving to full operations model. The transition implies more significance at the system robustness and stability in order to implement continuous observation model and a reduction at the time dedicated for commissioning and verification. For this reason, the software delivery process should be adjusted to the current observatory state. Thus, given the hardware restrictions, simulation capabilities will have a relevant role in the verification phase. The number of new features/improvements per release will be reduced but the emphasis at the software robustness becomes essential. System stability turns into a critical point in order to

maintain observatory working most of the time, therefore the downtime due to new software releases must be strictly controlled.

The New Approach

Based in the situation mentioned above, an agile approach for the software delivery process should be adopted by the observatory. The proposal is being developed and it expected to be implemented in the coming years. Basically, this approach is based in the existence of a stable branch, which is patched for verification, and validation of new capabilities. Developers should commit functionality in separate branches and verification team should patch stable branch for verification purposes. If verification passed, Science testers should validate same functionality. After successfully validation, the patch can be integrated at the stable branch and considered ready to be used for observatory's activities. This model differs of the previous one, since integration is controlled by verification team instead of developers. Stability should be also granted since less functionality is included per iteration. Features, which do not pass verification or validation phases are rejected and scheduled for another iteration. Observatory's technical times are also optimized since only features, which have passed simulation tests, are considered to be verified with operational hardware. Despite this approach has several advantages in terms of software stability and accelerate the process for having new capabilities in production environment (by eliminating or reducing software acceptance process), it also require some fundamental changes in the paradigm currently adopted. It considers more discipline at the development, verification and validation teams in order to accomplish with the tight schedule, optimizing resources available and delivering new capabilities according to the observatory needs. The figure 2 illustrates the core of the new process where the science branch (accepted) is created after the verification and validation phases have been completed successfully.

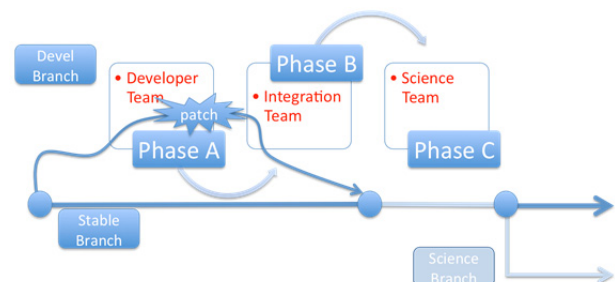

Figure 2: Proposal for agile approach.

CONCLUSIONS

This paper presented the evolution of the release management process in agreement with the life cycle of ALMA Observatory. There was a transition from a traditional and static development model, suitable for early construction phases, toward a dynamical one, which

considered commissioning restrictions. This new model takes into account the delivery of lite releases in terms of features but more stable as a whole. This also increased the frequency of the development cycles according to the observatory's milestones and decreased the integration/testing time required before the science commissioning phases. Formal phases were introduced as part of the process and responsible for every stage were properly identified and designated. This facilitated the process control, allowing a deterministic schedule for the entire cycle. There was also more emphasis for controlling changes over commissioned releases used for official science activities. The creation of a control board for approving/rejecting changes, evidenced the importance of maintain operational software stable as much as possible. The results showed at the end demonstrated this was the correct path since ALMA commissioning phase has been successfully performed from the software point of view.

However, there is still another important milestone to be completed by the Observatory in the coming years: the full operations model that will demand a new adaptation of the software delivery process in order to fulfill the operational requirements. Thus, an agile approach was proposed that considers the robustness and stability of the system as a mandatory goal over the introduction of new capabilities. It is expected that several improvements at the system simulation and continuous integration environment must be developed as part of the implantation of the model.

The experience reveals that the implementation of a new model is not a straightforward process. It will require several technical improvements but, more important and difficult, is the adaptation of human capital (developers, testers, validators) to new paradigm.

USE INTERRUPT DRIVEN MODE TO REDESIGN AN IOC FOR DIGITAL POWER SUPPLY AT SSC-LINAC

Shi An, Wei Zhang, Kewei GU, Junqi Wu, Xiaojun Liu, IMP, Lanzhou, China

Abstract

SSC-LINAC control system is based on EPICS architecture. The sub control system of digital power supplies is a kind of IOC send and receive custom command via Ethernet and TCP/IP protocol. The old IOC is designed to use period scan mode IOC, and there are so many digital power supplies, that we can't make sure every connect condition of digital power supply is fine. IOC must wait a long time if one of them can't connect correctly and other digital power supply's PV may also be blocked. An IOC that uses interrupt driven mode to avoid the shortcoming was designed. This will be described in this paper.

INTRODUCTION

SSC is a separated-sector cyclotron. To improve the efficiency of HIRFL, a linear accelerator is considered as a new injector for SSC of HIRFL [1]. The SSC-LINAC control system is based on EPICS. There are many sub systems such as power supply control system, vacuum monitor system and so on. The structure of SSC-LINAC control system is shown in Figure 1.

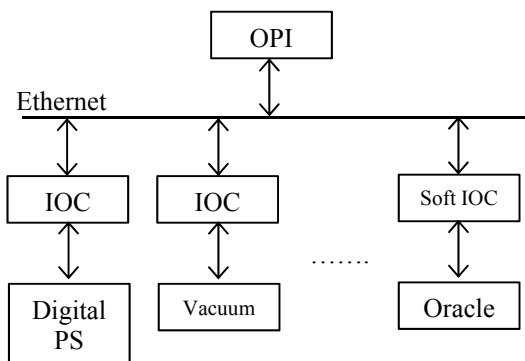

Figure 1: Structure of SSC-LINAC control system.

Almost all of the power supply in the system uses digital power supply. So control interface between IOC and power supply is Ethernet interface. IOC sends and receives predefined string command via the Ethernet with the PS (power supply).

DESCRIPTIONS

This part will description the old PS IOC design and new design of the IOC, also description implement of the new IOC. Descriptions include two sections and each section is introduced in detail as following. The structure of the PS IOC is shown in Figure 2.

Structure of the Origin PS IOC

The bottom of the structure is digital PS. Above the PS is Ethernet interface and use TCP/IP as low level transfer protocol. In the middle layer is device support of EPICS architecture. The device support has two functions. First function is a periodic that sends a read command string to PS in every one second and receives current state of the PS. The second function is sends a write command string to PS. The top of the structure is record support.

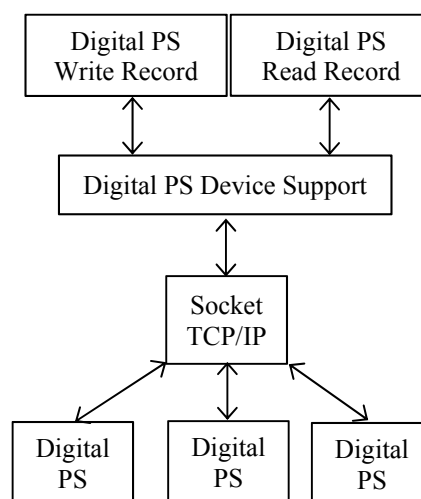

Figure 2: Structure of the PS IOC.

In the real case we create two PVs for every digital PS and there are 78 power supplies in SSC-LINAC. Actually all of PVs are run in one thread in the structure. If just one digital PS is down and all of other digital power supply's PV also be blocked (blocked time depend on the timeout setting). So we must design a new device support to avoid the bad situation.

Design a New Device Support for Digital PS

First switch the Record periodic SCAN ("1 second") to SCAN rate driven from a device specific source ("I/O Intr"). In our case separated thread for every one PS is used.

Second step is writing device support use interrupt model and implement in the following sections.

1. init

```
static long init(int phase)
{
    if(phase==0)
        initHookRegister(&start_ps_thread);
    return 0;
}
```

Register a hook function at the device support init(int) function.

2. Init hook

```
static void start_ps_thread (initHookState state)
{
    ELLNODE *cur;

    if(state!=initHookAfterInterruptAccept)
        return;

    for(cur=ellFirst(&allprngs); cur; cur=ellNext(cur))
    {
        struct prngState *priv = CONTAINER(cur,
        struct prngState, node);
        priv->generator = epicsThreadMustCreate(
        "psThread",
        epicsThreadPriorityHigh,
        epicsThreadGetStackSize(epicsThreadStack
        Small),
        &ps_thread, priv);
    }
}
```

The hook function starts a thread for each of the digital PS.

3. Digital PS thread

```
static void ps_thread(void* raw)
{
    struct prngState* priv=raw;
    char send_buf[16] = {0,};
    char buf[BUFF_SIZE] = {0,};
    char *endptr;

    //init socket
    int sockfd;
    struct sockaddr_in device_addr;
    .....
    //connect to PS
    .....

    while(1)
    {
        //send and receive something from the PS

        epicsMutexMustLock(priv->lock);
        //write useful data to record
        .....
        //queue a request
        scanIoRequest(priv->scan);
        epicsThreadSleep(interval);
    }
}
```

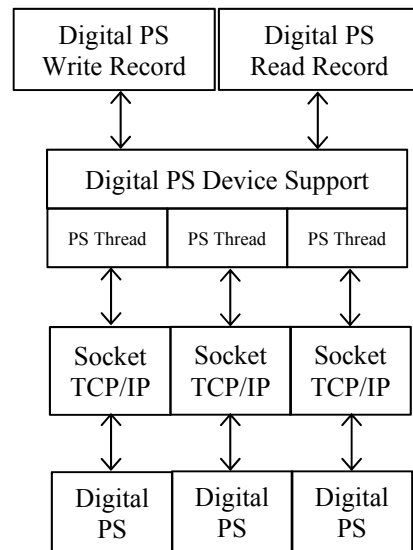

Figure 3: New structure of the PS IOC.

Every PS thread just connect to one PS and when the useful data is ready the function scanIoRequest () to process associated records. Figure 3 shows the structure of the new device support for digital PS.

CONCLUSION

The origin structure of PS IOC uses periodic method. All processing is done on a single thread. So any digital PS connect block will cause the entire IOC to become unresponsive [2].

New design uses separated thread to interact with each one of PS and results will push into record automatically. The new design solves the problem and make some new advantages.

First advantage is more real-time. Digital PS thread could run in a very fast loop and don't affect each other. So the up level records could get the data faster than before.

Second is more stability. One thread crash will not affect other thread, every thread just like run in a sandbox. Whole system become more stability.

MAGNET CORRECTOR POWER SUPPLY CONTROLLER FOR LCLS-I

S. Babel, K. Luchini, J. Olsen, T. Straumann, E. Williams, C. Yee, B. Lam, SLAC, Menlo Park, California, USA

Abstract

The MCOR 12 is a 16-channel modular architecture, precision magnet driver, capable of providing bipolar output currents in the range from -12A to $+12\text{A}$. A single, unregulated bulk power supply provides the main DC power for the entire crate. Currently the MCORs have a 1000ppm regulation on the B-field. The MCOR controller card upgrades, existing LCLS-I and future LCLS-II needed, controls for Magnet Corrector Power Supplies. The project shifts the existing functionality of the VME based DAC and SAM and an Allen Bradley PLC into a new slot-0 card residing in the MCOR chassis. Elimination of the VME crate and the PLC will free up rack space to be used in future. The new interface card has a long term stability of 100ppm and monitors ground fault currents and various other interlocks for the MCOR power supplies. The controller can interface to EPICS Channel Access and Fast Feedback system at SLAC using two Gigabit Ethernet ports and has an FPGA based EVR for getting “time stamps” from the Event Generator system at SLAC. The EPICS control system along with embedded diagnostic features will allow for enhanced remote control and monitoring of the power supplies.

INTRODUCTION

The MCOR (Magnet Corrector) Series is a multichannel corrector magnet driver system, capable of providing precision bi-polar output currents with minimal zero-crossing distortion. The MCOR design employs a modular architecture, consisting of a rack-mounted crate, with standardized slots for removable power modules, crate controller and diagnostics. A single, unregulated bulk power supply provides the main DC power for the entire crate. The MCOR power module is responsible for converting the unregulated DC bulk power into a precision bi-polar current source suitable for driving corrector magnets and beam line devices. The power modules are controlled using $+10$ to -10V FS analog command signals sent over the backplane from the control system. There are two types of available MCOR power modules: The MCOR12 (12A FS) and the MCOR30 as shown in Fig. 1 (30A FS). [1, 2] The MCOR30 uses a custom H-bridge configuration, operating in an overlapping volt-seconds feedback mode instead of a straight voltage mode to achieve a higher control bandwidth. The transfer function of input command voltage to output current is determined by resistor values on the programming (PGM) card. Each power module provides two independent measurements of its output current; one that closes the regulation loop, and another that returns an independent monitoring signal to the control system. [1, 2] Both of these independent

current measurements are available to the control card for diagnostic purposes. [1, 2] The MCOR12 uses a commercial switch mode servo driver (The AMC 30A8) operating in a voltage feedback mode to regulate the output current. The MCOR 12 system as the name suggests is a 16-channel precision magnet driver, capable of providing bipolar output currents in the range from -12A to $+12\text{A}$. The output current can be adjusted smoothly through zero. [1, 2] The MCOR 12 employs a modular architecture, so that any individual channel is serviceable without disturbing the operation of adjacent channels in the same crate. This feature significantly improves the overall availability of the accelerator, since in most cases the beam lattice can tolerate the loss of a single corrector and continue to operate, but could not handle the loss of an entire crate of correctors during the repair effort. [1, 2]

Figure 1: MCOR-30 Power Supply Card.

SYSTEM ARCHITECTURE

The LCLS Fast Feedback Loop Controller wants all MCOR controllers to be controllable at 120Hz (The MCOR Controller card must be able to write set points and read back at 120Hz). The MCOR Controller card must also receive set points in PVs from the Channel Access Network, but it is not necessary that it act on commands from both the Channel Access and the Fast Feedback Network at the same time. LCLS Users want to see the current set point (‘desired value’), read back (‘actual’ value), and status of each channel, regardless of which network the set point command came from. LCLS Users want features like Calibration of the DACs,

Ramping, Reset Interlocks, Ripple measurement for each MCOR corrector channel, so the controller card supports it. MCOR Controller card as shown in Fig. 2 has Gigabit Ethernet links to both Fast Feedback network and Channel Access to reduce latency. The MCOR Controller card has a long term temperature stability requirement of 0.01 % of maximum current for each MCOR channel. (100 ppm). The DAC accuracy for a desired set point is 0.1% [1000 ppm] of full scale output voltage. The MCOR controller card is able to operate within the ambient conditions 40 degree F to 122 Degree F (50 degree C). The controller card is able to read both the “Monitor” and “Feedback” analog outputs along with the digital “Fault” status from each MCOR module and an alarm is raised if any of the MCOR channels indicate a digital fault condition. There are 32 channels of 18 bit 100 KSps ADCs and 16 channels of 16 bit DAC outputs with settling time of less than 10uS interfaced to a Xilinx Virtex-5 FPGA. The controller card is able to do waveform capture and store for selected MCOR channel for diagnostics. The controller card incorporates an Event Receiver which is able to decode the LCLS Timing System [EVR] to provide timing information. The EVR supports Multi Mode/Single Mode and daisy chaining. The EVR may also have digital TTL outputs for triggering. MCOR Controller card monitors “GND fault current” and triggers an alarm if the GND fault current is not within limits (+/-25mA). It is able to read up to +/-100mA. The Bulk Power Supply is turned off if the GND fault current is not within limits. Beam Synchronous Acquisition (BSA) feature is also desired by LCLS, which is implemented on the EPICS IOC on board the controller card as a daughter card. The controller card uses a Computer On Module (COM) Express Type-2 daughter card as shown in Fig. 3 with an Intel Atom Processor to host the EPICS IOC. The COMX card communicates to a Xilinx Virtex-5 FPGA on the mother board to interface to all the DACs, ADCs, Digital Fault Signals, External Interlocks, Gigabit Ethernet and Voltage, Temp and Current Monitoring chips on the motherboard. The MCOR Controller runs a version of Linux-Real Time Operating system on the COMX based Intel Atom Processor. The Operating system is loaded on the Atom processor at boot-up using TFTP. Controller specific Board Support Package is then used to interface to EPICS. The block diagram is shown in Fig. 4.

Figure 2: MCOR Controller Motherboard.

Figure 3: MCOR Controller COMX.

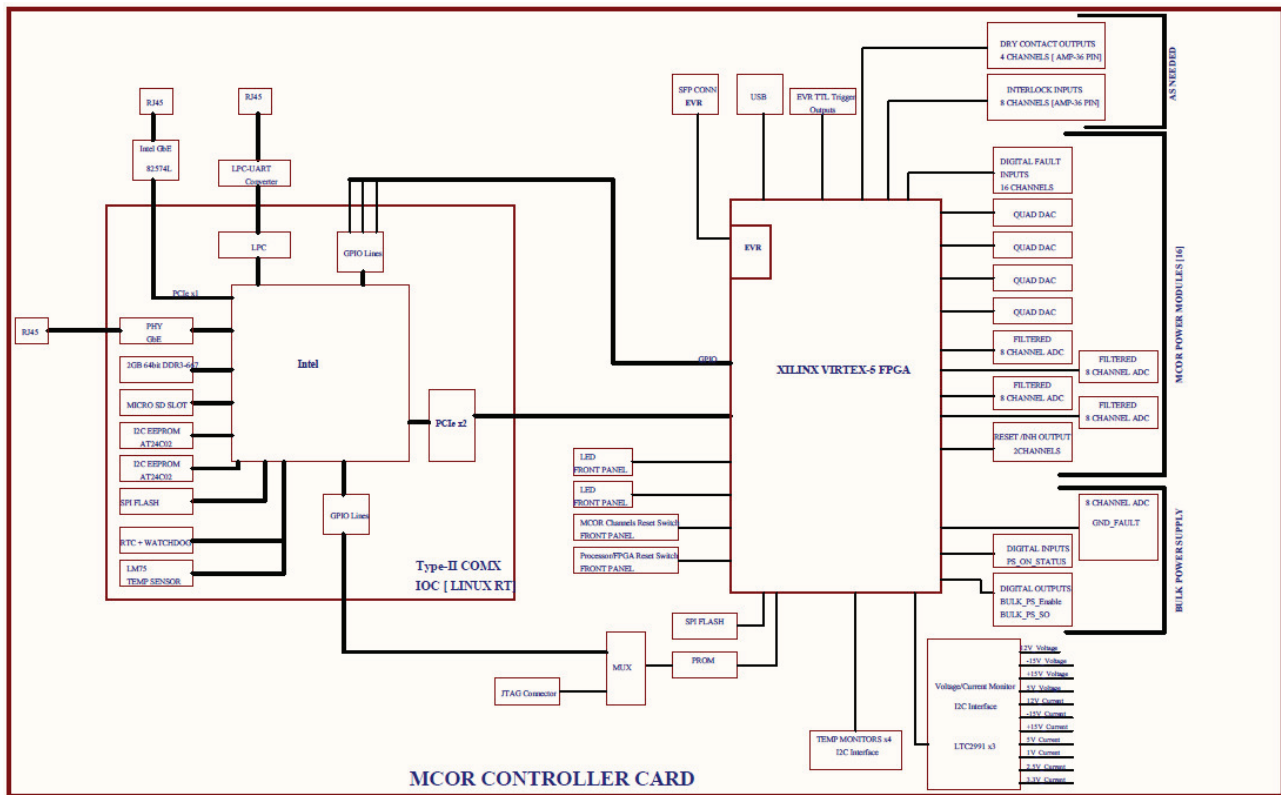

Figure 4: MCOR Controller card Detailed Block Diagram.

TEST AND RESULTS

The MCOR Controller was installed in LCLS-I gallery in Sector-28 of the Linac. Below is the result as shown in Fig. 5 that was obtained for 8 hours duration for MCOR-12 Power supply module.

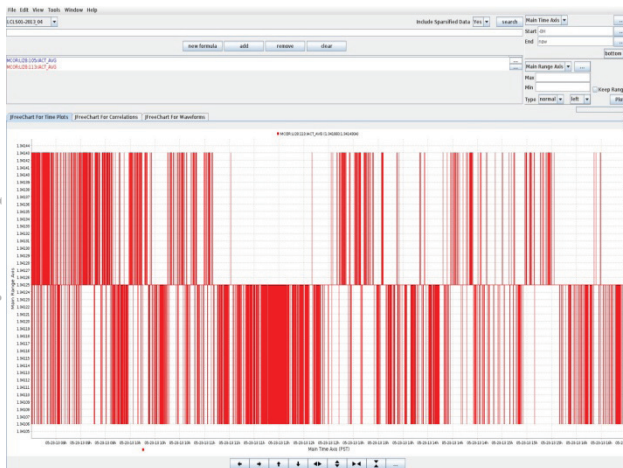

Figure 5: MCOR: LI28 Duration 8 Hrs, Iset: 1.34 A Iact Pk-Pk ripple 375uA.

CONCLUSION

The MCOR controller card upgrades, existing LCLS-I and future LCLS-II needed, controls for Magnet Corrector Power Supplies. The project shifts the existing functionality of the VME based DAC and SAM and an Allen Bradley PLC into a new slot-0 card residing in the MCOR chassis. The new interface card has a long term stability of 100ppm and monitors ground fault currents and various other interlocks for the MCOR power supplies. The controller can interface to EPICS Channel Access and Fast Feedback system at SLAC and has an FPGA based EVR for getting "time stamps" from the Event Generator system at SLAC. The EPICS control system along with embedded diagnostic features will allow for enhanced remote control and monitoring of the power supplies.

RENOVATION OF THE CERN CONTROLS CONFIGURATION SERVICE

L. Burdzanowski, C. Roderick CERN, Geneva, Switzerland

Abstract

The Controls Configuration Service (CCS) is a key component in CERN's data driven accelerator Control System. Based around a central database, the service also provides a range of client APIs and user interfaces - enabling configuration of controls for CERN's accelerator complex. The service has existed for 35 years (29 based on Oracle DBMS) [1]. To cater for changing requirements and technology advances there has been substantial evolution of the CCS over time. Inevitably this has led to increases in CCS complexity and an accumulation of technical debt. These two aspects combined have a negative impact on the flexibility and maintainability of the CCS, leading to a potential bottleneck for Control System evolution. This paper describes on-going renovation efforts (started mid-2014) to tackle the aforementioned issues, whilst ensuring overall system stability. In particular, this paper covers architectural changes, the agile development process in place - bringing users close to the development cycle, and the deterministic approach used to treat technical debt. Collectively these efforts are leading towards a successful renovation of a core element of the Control System.

INTRODUCTION

The CERN Control System is a data-driven multi-layer infrastructure including:

- *Low-level hardware and software* – e.g. timing infrastructure, equipment drivers, Front-End Computers (FEC), end-user developed C/C++ binaries representing operational “devices”, etc.
- *Middleware layer* – e.g. read/write access to processes running on FECs and Role Based Access Control (RBAC).
- *High-level software* – e.g. high-level settings management, data acquisition and archiving.

The Controls Configuration Service (CCS) helps bind all of the layers together by providing them with complete and coherent configurations that are necessary for the proper functioning of the Control system [2].

The current architecture of the CCS is based on:

- An Oracle database (2-node RAC cluster)
- A set of high-level client Java APIs
- Database level client APIs (PL/SQL interfaces)
- Numerous Graphical User Interfaces based on proprietary Oracle technologies: Application Development Framework (ADF) and Oracle Application Express (APEX).

The database is implemented using a relation model, with approximately 700 domain tables and ~7GB of core domain data (excluding binary, log and history data – which collectively accounts for ~115GB).

The criticality of the service for safe operation of the accelerators chain is high (though not required for their safe shutdown): The CCS is essential for proper accelerator configuration and start-up – especially during Technical Stops when equipment and other components of the Controls System undergo maintenance and upgrades.

The CCS exists for 35 years, during which the scope, architecture, implementation technology and development methodology have kept evolving. In the middle of 2014 the first major service-wide renovation and overhaul has started – marking the beginning of a new chapter in its long history.

RENOVATION STRATEGY

The motivation behind the complete renovation of the service can be summarized as the need to increase service flexibility while lowering total cost of development, and to advance service functionality to the state required by activities planned for the next CERN Long Shutdown (LS2 – scheduled start early 2019).

The cornerstones of the renovation strategy are:

- Suppression of the technical debt accumulated over the years.
- Changes in the overall architecture
- Adaptation of the Lean software development process [3].

All of these aspects are closely related as suppression of technical debt is essential in order to advance the system architecture, while taking proper architectural and design decisions prevent further “erosion” in the system and limit existing technical debt. The adapted software development process facilitates implementing changes: enabling a lower overall cost of development and increased agility. The first two aspects are a mid-to-long-term perspective (from mid-2014 to the start of LS2). The implementation of the Lean software development process is already well advanced and can be considered finished by the end of 2015.

In order to fully understand the context of the renovation efforts it is necessary to briefly look back at the evolution of the CCS scope and technologies used.

Service Evolution

The scope of the CCS was initially limited to the PS (Proton-Synchrotron) complex controls system, meaning that the service and its database were oriented towards a concrete accelerator and its specific control system. The first relational database was introduced in 1986. Over the years the scope grew following the evolution of CERN's accelerator complex [4]. 1995 marks the introduction of graphical user interfaces (GUI) based on Oracle Forms and PL/SQL Web Toolkit (OWA). The first Java based data access API was implemented in 1999 facilitating access for

high-level applications. Starting in 2006, another Oracle based GUI solution (ADF – a Java Server Faces implementation) was put in place to replace existing OWA and Forms applications. In 2009, APEX (a subsequent framework for building database-driven GUI's) was adapted alongside ADF.

Besides the technical changes, the service role and scope has been expanding in recent years:

- Multiple additional device-property models were introduced,
- The Front-End Software Architecture (FESA) framework reached the next major version [5],
- The service incorporated configurations specific to various sub-systems like:
 - Beam Interlock System,
 - Power Converters,
 - Role Based Access Control.

Together with these changes certain functionalities of the service became partially suppressed, specifically legacy high-level settings management, for which the functionality was incorporated into LSA [6] for the majority of the accelerators.

The following patterns emerge when we look back at the aforementioned evolution: reliance on Oracle proprietary GUI technologies, and the progressive growth of the service well beyond its original system design and architecture that was tightly coupled to a specific accelerator. Both of these aspects have contributed to the current state of the service and triggered the renovation.

ADDRESSING TECHNICAL DEBT

The evolution of every complex hardware and software system inevitably results in increased technical debt and progressive erosion. The availability of new technologies and solutions, as well as the human factor of growing experience – keep changing the perception of quality and adequacy of former technical decisions [7].

In most cases, end users are not directly aware of the technical debt but as software engineers we should perceive it as negative value. It is adverse to system architecture and design, which are planned, deliberate and visionary. By clearly establishing the system boundaries and facilities to assess and measure its evolution the technical debt can be addressed whilst minimizing impact on the end users.

Accidental Complexity

At its basis the technical debt is equal to accidental complexity happening in the system. On contrary to deliberately complex solutions for equally complex problems the accidental complexity happens by itself naturally along evolution of the system.

System complexity can be described by both quantitative and qualitative factors. For the CCS, the quantitative factors include: counts of tables, views, triggers, PL/SQL packages, number of grants, grantees, accounts, lines of code, length of packages and procedures, levels of views nesting etc. All such factors can be measured and

automatically classified as a potential problem based on established thresholds. The qualitative factors might be based on quantitative data but cannot nor should not be automated. Such factors are based on experience and often common sense – ultimately a human factor. For example, de-normalization of a database table may be justified by performance requirements or for the sake of clarity in a model, although in most cases it is a sign of shortcomings in the design.

The majority of complexity in a database-oriented system is caused by dependencies (direct and indirect), but rarely by algorithmic complexity. Examples of direct dependencies are relations between objects, database views referencing tables or other views, PL/SQL packages executing code based on database structures. Indirect dependencies include aspects like dynamic/background execution or exposure of the database objects to external users (grants) – an inevitable need contributing to coupling between systems.

Targeted Re-Factoring

In order to guarantee system stability during renovation – specifically when re-factoring areas with high technical debt – a methodical targeted approach with a clear strategy is essential. The CCS renovation efforts fall into two categories: targeted and ad-hoc re-factoring.

Ad-hoc refactoring is considered as a natural part of regular development and does not require extensive planning or analysis. For example: small improvements in the code base like eradication of “dead-code”, addition of missing test cases, updates to stale documentation, and re-naming inadequately named objects. In general, such activities shouldn't take more than an additional 20% of the base development time needed to deliver the required functionality.

Targeted re-factoring is predefined as a concrete group of tasks based on the following criteria:

1. *Identify boundaries* – to clearly know when the activity should finish.
2. *Identify clear gains* – to justify the effort. The gains should be tangible, based on facts, and ideally quantifiable.
3. *Identify risks* – to know the impact both within – and outside the service.
4. *Define rollback / fall-back strategy* – to limit any potential negative impact, mainly in critical areas.
5. *Estimate and prioritize* – to realistically plan the effort alongside regular development activities.

The value to be gained from the re-factoring can be classified into distinct areas, and includes in descending order of importance:

1. *Consistency* – i.e. limiting the likelihood of data corruption and/or of non-deterministic states.
2. *Performance* – improving the response times for data reporting and querying for clients.
3. *Maintenance* – lowering the total cost of development, likelihood of introducing new errors, and the usage cost paid by clients (e.g. by obscurity APIs or lack of documentation).

4. *Agility* – ensuring the extendibility of the architecture and limiting the cost / time of delivering new features to clients.

By following the assessment criteria above and understanding their associated gains, it is possible to identify and prioritize renovation activities alongside regular development.

Determinism and Static Code Analysis

Static code analysis (SCA) is the analysis of computer software source code on the contrary to dynamic analysis, which is based on code execution. SCA can be applied to any type of software including databases like Oracle. In this case the analysis includes both database structures (tables, views, constraints, indices, etc.) and executable stored procedural code (PL/SQL packages and triggers).

To match our needs a custom SCA framework has been developed which enables analysis within the database engine. The framework includes a pre-defined set of analysis rules, which can be customized and extended. The analysis can be executed on demand or periodically, and generates reports summarizing the number of rule violations, severity and links to the source. These reports are used to identify areas for in-depth analysis and planning of the re-factoring. Below is an example of a metric indicating the evolution of the count of invalid objects over the past year:

Figure 1: Count of invalid objects in development database, aggregated per months.

The analysis results, fluctuations and evolution of the metrics are the inputs to qualitative assessments and serve as a basis for future planning. The metrics cover various aspects ranging from standardisation concerns (e.g. code not adhering to naming standards, usage of disallowed or obsolete functions, etc.) to abstract complexity of the system (expressed via factors such as code size, table sizes, triggers counts, nesting of database views). With SCA in place we are able to evaluate our efforts over time, relying on factual data rather than assumptions.

ARCHITECTING FOR THE FUTURE

The renovation and supporting changes in system architecture fall into four main categories: suppression of accidental complexity and lowering overall system complexity, context based access to the data, phasing-out

of proprietary GUI technologies, and applying a system wide infrastructure for tracing, auditing and monitoring. Combined, these categories form the foundations for simpler, easier and agile development, with an increased quality of service.

The accelerator controls system domain is inherently complex; the corresponding software components are therefore inevitably complex accordingly. During the process of suppressing accidental complexity / lowering overall complexity, we have started to progressively adapt an event driven architecture which has proved to increase cohesion and lowered coupling of system components. New developments and on-going re-factoring conforms to GRASP [8] (General Responsibility Assignment Software Patterns) patterns of Object-Oriented design, tailored to the world of relational databases. To support these changes we have adapted Commons4Oracle (C4O) – a set of PL/SQL libraries for Oracle database, which is actively developed in the CERN Controls group. The library assures further standardization and foundations for future development. Moreover it streamlines solutions in the CCS with other core database projects of the Controls group thus enabling transfer of knowledge and expertise.

Based on direct feedback from CCS users and domain experts we are gradually increasing the scope of context surrounding the data entreated to the system. By utilizing Commons4Oracle extensions, a set of high-level domain specific events is being implemented. Triggering of such events can be based on direct user actions, or a workflow based transition. By attaching state information to core domain entities in the system (e.g. devices), we can now automatically notify users interested in a given “domain event”. For example when a computer hosting a device changes its state, the responsible for the device can be notified and take actions if necessary. It is important to add that such notifications may be filtered based on criteria specified by individual users.

The dedicated CCS GUIs are the primary means for end users to access or edit data. On average per day there are over 150 distinct user sessions (from a total of ~400 distinct registered users). Experiences of past years as well as user feedback contributed to the decision to phase-out the existing proprietary technologies in favour of widely adapted solutions of Java based RESTfull services and HTML5/JavaScript web interfaces. In addition this technology stack steadily gains popularity within the software engineering community and in turn facilitates hiring of well-trained specialists.

With tracing and auditing extensions in place, not only the time or user behind a given action is captured, but also contextual information like client IP address, database session and transaction IDs, and name of the program unit and invoked action. This information is used to augment historical data tracing, with which changes to any entity in the system are precisely tracked and can be presented back to users in a context specific manner (e.g. as a log of differences starting from a specific moment in time or by presenting dependencies between objects in a human readable way). This system-wide architectural extension

considerably limits the time needed to support users in investigating suspected data problems, and potentially recovering data.

PRAGMATIC AGILITY

As a part of CERN Controls System the CCS is actively used and maintained on regular basis. Its development lifecycle is similar to software products released to end-users that have continuous support for the new extensions and improvements. Such a lifecycle requires responsiveness when addressing end-user's needs but also requires realistic planning which fits into the tight schedule of accelerators operations. The challenges of undergoing renovation and aforementioned aspects motivated the adoption of a Kanban development process [9].

The Kanban emphasizes focusing on continuous improvement, importance of human factors and bringing maximum value to the organisation. Over just a few months the new Kanban development process has been implemented, and in less than six months the efficiency of the team increased noticeably. By visualising the work on a Kanban board, bottlenecks were quickly identified (e.g. too much work in progress, too many unrelated tasks started, or too many new features waiting in quality assurance queue). By not relying on fixed development iterations / sprints – trust from end-users increased as their requested features and bug-fixes are not systematically subjected to prolonged wait times due to extensively planned ahead sprints. The agility and reactivity of the team and CCS as a whole has increased thanks to the Kanban / Lean philosophy of just-in-time delivery and constant focus on activities that bring the most value to end-users. By separating planning and reviews into short-term (weekly / monthly) and mid-term (quarterly / yearly) the CCS team balances providing new functionality within realistic time frames with reacting quickly (hours instead of days) in case of urgent problems.

Thanks to the new methodology, the overall development throughput has increased. More importantly the satisfaction of both CCS users and team members has increased. Changing the way tasks are prioritized and visualized has led to a reduction in pressure and stress on developers. CCS end-users are now much more closely involved in the development process and act as true stakeholders thanks to effective visualization of work in progress and clearly identified stages of the development cycle. These human factors are proving to be essential to the success of the on-going renovation.

In retrospective, the adaptation of a Kanban approach has already resulted in high returns on the time invested into configuring supporting tools to the CCS team needs, and regular discussions and analysis of the changes being implemented. The returns from the Kanban are that more time is spent on delivering actual value, and assuring that new features and improvements are not over-planned nor hurried to production (which would result in faults and frustration of the end-users). Regular retrospectives and

critical analysis of changes applied to the working process have positively transformed the way the CCS team works.

CONCLUSIONS

The renovation of a mission critical service with many years of history is a challenge. Alongside changing requirements, growing expectations and needs to consolidate various sub-systems of the Control System, the CCS started to play an even more important role during recent years. The necessity to adapt to these changes and satisfy new requirements is the driver for the on-going CCS renovation. Progressively reducing technical debt increases overall agility, but more importantly it also helps to design a better system for the future. CCS users now have a much better understanding than previously of the value of these changes and together with their increased satisfaction the renovation and technical debt reduction is perceived as added value. The Kanban way noticeably improved the CCS team efficiency and contributed to increased end-user satisfaction. New architecture solutions lay foundations for an advanced, cohesive and agile system that embraces the context and workflows of how CCS users work. The renovation started over a year ago and marked the beginning of a new and exciting era in the long history of the Controls Configuration Service of the CERN Controls system.

EMBEDDED ENVIRONMENT WITH EPICS SUPPORT FOR CONTROL APPLICATIONS

Y. S. Cheng, Demi Lee, C. Y. Liao, C. H. Huang, K. T. Hsu
National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract

System on a chip (SoC) is widely used in embedded environment. Current generation SoC commercial products with small footprint and low-cost have powerful in CPU performance and rich interface solution to support many control applications. To deal with some embedded control applications, the "Banana Pi" which is a card-size single-board computer and runs Linux-based operation system has been adopted as the EPICS IOC to implement several applications. The efforts for implementing are summarized in this paper.

INTRODUCTION

Using a circuit board to implement functions as a computer is called SBC (single-board computer) [1]. Its applications cover in telecommunications, industrial control, blade and high density servers, and lately laptops and mini-PCs, etc. Thanks to latest generation SoC technology, putting all major functionality into an integrated chip, educational used credit-card size SBC [2] likes the Raspberry Pi (RPI) and BeagleBone Black (BBB) are highly successful products. The Banana Pi (BPI) is the latest product of such category with powerful CPU, low power consumption SBC indeed, and the area of circuit board is only as credit card size.

The Banana Pi which design idea is similar to the RPi-style SBC, and it is a fork of the RPi project using different components while maintain compatibility as much as possible. Moreover the Banana Pi is added the functions of SATA interface, infrared transmission, microphone, USB-OTG ports, power button, reset button, etc. Then the BPI has 26-pin/40-pin GPIO which is compatible with the RPi. The A20/31 SoC as CPU/GPU, 1GB DDR3 memory and Gigabit Ethernet connection are applied on the Banana Pi. The hardware specification of Banana Pi is shown as Table 1 [3-4]. Linux-based OS can be worked well on the Banana Pi.

Table 1: Hardware specification of the Banana Pi

The EPICS (Experimental Physics and Industrial Control System) [5] is a set of open source software tools, libraries and applications developed collaboratively and used to create distributed soft real-time control systems for scientific instruments such as particle accelerators. Many facilities have good practical experiences for the EPICS and adopt it as accelerator control systems. Many resources and supports are available as well as numerous applications for accelerator have been developed.

The TPS (Taiwan Photon Source) control system of 3 GeV synchrotron light source is also based on the EPICS framework [6]. The EPICS toolkit provides standard tools for display creation, archiving, alarm handling, etc. The big success of EPICS is based on the definition of a standard IOC (Input Output Controller) structure together with an extensive library of driver software for a wide range of I/O cards. The EPICS framework which has various functionalities is employed to monitor and to control on embedded applications of accelerator system.

BANANA PI AS EPICS IOC

The stability and performance of Banana Pi is enough as the EPICS IOCs for specific control applications. The EPICS framework can be built on the Linux-based Banana Pi successfully [7]. At the TPS project, some control functions, such as frequency divider, direct digital synthesizer, radiation-sensing reader, alarm announcer, etc., are implemented by use of the Banana Pi platforms with EPICS support. The efforts for implementing are summarized as followings.

Software Architecture

To implement the Banana Pi as the EPICS IOC for specific control applications, the EPICS base and modules are necessary to be set up on the Banana Pi platform which operation system can be the Debian or Ubuntu Linux. The device driver of SPI (Serial Peripheral Interface) bus is built for communicating with DAC/ADC modules, and the device support interface is also developed as the glue between the EPICS records and device drivers. The EPICS records support with databases are created according to the specific functions. The application module, such as "autosave" function, is installed for logging setting parameters values and recovering last setting parameters values automatically when the IOC is start-up. Based on the EPICS PV (Process Variable) channel access, the archive server is set up to record various parameters variations for long time observation, and the PHP webpage can be developed to show the status information. At the client console side, the operation interfaces are created by used of the EDM, CS-Studio, etc. to control and monitor via EPICS PV channel

ISBN 978-3-95450-148-9

access, and the archived data can be retrieved with using a form of graphical representation of the CS-Studio based data browser. The schematic is shown as Fig. 1.

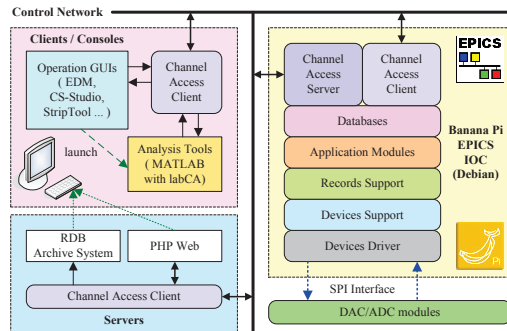

Figure 1: Software architecture of the Banana Pi with EPICS support.

Programmable Frequency Divider

Machine clock of the accelerator system generated discrete fast logic chip (ECL/PECL) or combined of fast logic and field programmable logic array (FPGA) usually. Typical jitter is in a few picoseconds order. The programmable clock generator has been implemented by using the AD9508 clock and delay generator to generate clock with 100 femtosecond jitter for some applications (laser clock, filling pattern measurement timing, etc.). The system schematic is shown as shown in Fig. 2. The chip divider and delay parameters can be controlled by use of the Banana Pi EPIC IOC via SPI interface. The implementation is shown as in Fig. 3.

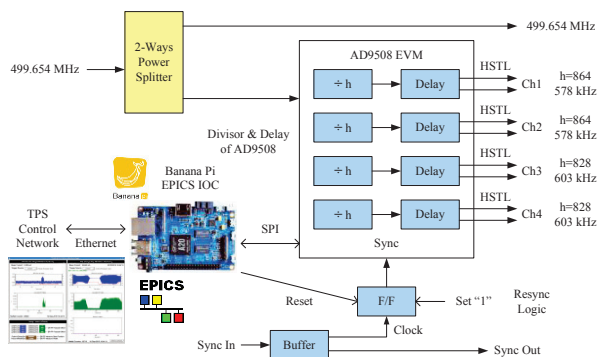

Figure 2: Block diagram of the programmable clock generator.

Figure 3: Photo of frequency divider unit for the TPS filling pattern measurement timing.

Direct Digital Synthesizer Control

To make possibility of different RF frequency without a similar multiplication factor (six) work for linear accelerator (Linac) and booster synchrotron to optimize machine performance without adjust too many parameters in Linac system, a RF signal generator direct digital synthesizer (DDS) which can synchronize at injection instance have been implemented. Functional block diagram of the prototype is shown in Fig. 4. The Banana Pi EPICS IOC is used to control the DDS to achieve goal. Synchronization is achieved to reset the phase of the DDS just before booster synchrotron injection to ensure constant phase relationship between RF system of Linac and booster synchrotron. Figure 5 shows the prototype DDS signal generator.

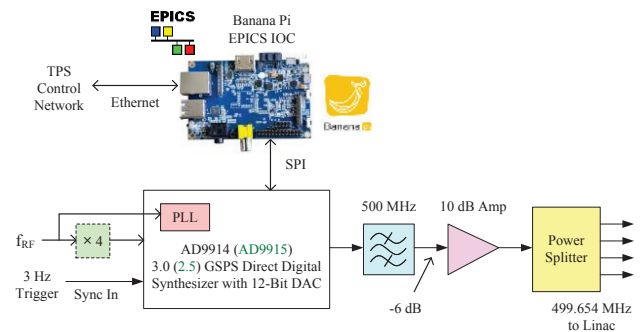

Figure 4: Block diagram of the direct digital synthesizer control.

Figure 5: Photo of the prototype DDS signal generator.

RadFET Reader

To investigate the beam loss and its distribution during commissioning and operation phases of TPS and TLS, a sixteen-channel readout box was initially designed and implemented to read the threshold voltage of the RadFETs (radiation-sensing field-effect transistor) which were installed at accelerator tunnel [8]. The initial version design was that the reader plays a role of remote I/O for the EPICS IOC and the IOC collects voltage from readers distributed at the accelerator to deduce the integrated dose and dose rate.

The next version design is that the EPICS IOC will be embedded into the RadFET reader box. The Banana Pi will be also adopted as the EPICS IOC for collecting the threshold voltage of the sixteen-channel RadFETs. The data transmission time between the IOC and SPI bus with ADC modules will be improved.

The EPICS IOC performs data acquisition, calculation, and publishes the specific EPICS PVs of dosage. Dosage rate is calculated by the EPICS record processing. All of the threshold voltage values based on the EPICS PVs channel access can be recorded into the archive server for further off-line data processing. The MATLAB toolkit can be also used to analyze the RadFET threshold voltage archived data which retrieved from the RDB archive system directly. The control system also provides on-line display for virtualization usage. The system schematic of RadFET reader is shown as Fig. 6. The test prototype of RadFET reader with the Banana Pi EPICS IOC is shown as Fig. 7.

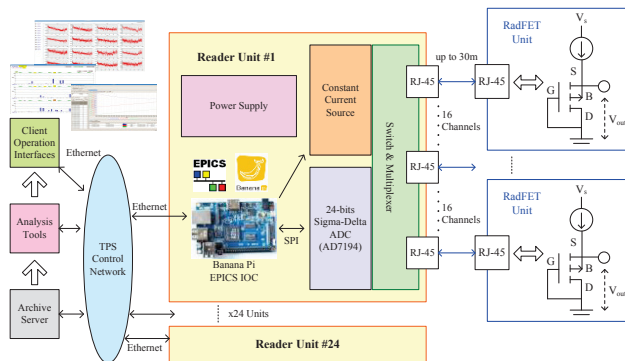

Figure 6: Block diagram of the RadFET readers system.

Figure 7: Photo of the prototype 16 channels RadFET reader with Banana Pi EPICS IOC.

Alarm Announcer

During the TPS commissioning and operation phases, the abnormal status may occur from one of sub-systems, and operators need to find out which sub-system problem happened from machine interlock interface. Due to many interlock signals need to be noticed, the sum signals of each interlock signals are necessary. According to the sum signals, the specific alarm message to be triggered and shown, and the Banana Pi is used as the EPICS IOC to receive the request and send alarm announcement sound to loud speaker for noticing. The system schematic is shown as Fig. 8.

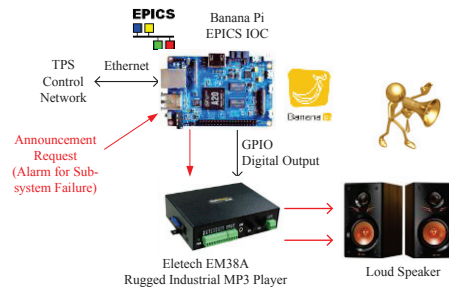

Figure 8: Block diagram of alarm announcer.

BEAGLEBONE BLACK APPLICATIONS

Vibration monitoring and voltage signal monitoring play an important role in the accelerators system for beam stability characterization. A commercial product DT7837 was adopted for this purpose. This device is a high accuracy dynamic signal acquisition module for vibration, and voltage signal measurements by the BeagleBone Black SBC [9]. Four 24-bit voltage input or IEPE sensor input data can be algorithmically processed in real time and the results presented to a host for analysis. Support of Linux-based OS and software development kit includes numerous components help the development. The EPICS is installed into the DT8837 for integration and data access. Synchronization interface is easy to integrate with accelerator timing system. Coherent data acquisition is under implementation.

CURRENT STATUS

Low cost credit-card size SBC is widely adopted for educational purpose and also suitable for small scale embedded applications. The BPi and BBB are chosen for several applications at the TPS control environment as auxiliary supports which are not suitable to use standard platform in existed control system due to economics, simplicity, speciality view points. More applications will be explored and implemented in near future.

LLRF CONTROLS UPGRADE FOR THE LCLS XTCAV PROJECT AT SLAC*

S. Condamoor[#], Y. Ding, P. Krejcik, H. Loos, T.J. Maxwell, J.J. Olsen
SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA

Abstract

SLAC's Low Level Radio Frequency (LLRF) controls software for the S-Band deflecting structures needed to be upgraded significantly when a new X-Band transverse deflecting cavity (XTCAV) was installed downstream of the LCLS undulators in Spring 2013 to assist in FEL diagnostics such as characterizing the temporal profile of X-ray pulses that vary shot-to-shot. The unique location of the XTCAV in the beamline posed several challenges. A new design of the Modulator and Klystron control Support Unit (MKSU-II) for interlocking was added at the XTCAV controls station that required new software development. The timing setup was also different from the rest of the Linac. This paper outlines the LLRF controls layout for the XTCAV and discusses the manner in which the challenges were addressed. XTCAV has now become a successful tool for gathering data that enables reconstruction of X-ray FEL power profiles with greater resolution.

XTCAV FOR DIAGNOSTICS

XTCAV is a powerful diagnostic tool for SLAC's Linac Coherent Light Source (LCLS) Free Electron X-ray Laser (FEL). This is a successor to SLAC's historic S-Band TCAV[1], two of which are still used in LCLS for electron beam bunch length measurements. XTCAV provides useful FEL diagnostics without interfering with LCLS operations since it is installed downstream of the LCLS undulators that are the source of the x-ray pulses. XTCAV deflects spent e-beam bunches after they have contributed to the lasing process just after they exit the undulators. Energy spectrometer is then used to capture and analyse in detail the profile of this spent e-beam stream on a bunch-by-bunch basis. Comparison of the longitudinal profile of these electron bunches when they are lasing against when lasing is suppressed allows us to reconstruct not only the longitudinal profile of the incoming electron beam but the time-resolved profile of the X-ray pulses generated during the lasing process. Figure 1 shows the general layout of this diagnostics system.

Figure 1: The system includes the transverse deflector "XTCAV", the magnetic spectrometer and the Ce:YAG screen located downstream of the FEL undulators. Horizontal streaking is followed by a vertical-bend dipole magnet for measuring the energy spectrum. A camera captures the transverse images of the electron beam density distribution on the diagnostic screen. (Image: Y.Ding et al., PRSTAB 14, 2011).

XTCAV'S HIGH POWER RF

The SLAC-designed X-Band RF cavity shown in Figure 2 below is powered by SLAC's XL4 50 MW X-Band Klystron that deflects the beam by giving it a 48 MV kick[2]. The Klystron operates at 120 Hz and delivers pulses that can be up to 1.5 μ s long. The structure fill time is 200 ns. A legacy 6575 modulator was reused from SLAC, the controls for which were upgraded recently.

Figure 2: Two one-meter long X-Band RF structures are in the beamline's path towards the e-beam dump. (Image: P.Krejci/SLAC).

XTCAV CONTROLS

The Controls hardware for XTCAV is located in a service building above the cavity in the tunnel. In addition to the klystron, this building houses the modulator, LLRF controls hardware, power supplies, waveguides, vacuum, temperature and water controls. The LLRF phase reference is derived from the 476 MHz Linac Reference via a heliax cable from the tunnel. Timing and trigger generation for controls is obtained with an Event Receiver

* Work is supported by the U.S. Department of Energy, Office of Science under Contract DE-AC02-76SF00515.

[#]scondam@slac.stanford.edu

module which receives precisely timed event codes from the LCLS Event Generator (EVG) on optical fibre links. Networking and serial communication devices are also located in this building. An upgraded model of the MKSU-II keeps the HPRF devices safe by interlocking the whole system with fault detection and protection.

XTCAV LLRF CONTROLS LAYOUT AND ITS CHALLENGES

Implementing the controls for the XTCAV station posed several challenges due to the unique nature of its location in the beamline. It was a structure that was added later to LCLS which meant that the supporting infrastructure needed for this add-on device did not exist when the upgrade project began.

XTCAV Location

While most of the LCLS RF controls are located either in the temperature controlled RF Hut or in the RF stations along the Linac's gallery, the XTCAV RF controls are located in a service support building farthest away from the rest of RF stations towards the end of the Linac.

This resulted in several key differences in the way the XTCAV station is setup as opposed to the other LCLS RF stations.

All other RF stations use the 476 MHz Phase Reference and other X-Band or S-Band RF signals that are distributed from a central location, amplified or boosted and synchronized locally as needed along the Linac. The XTCAV is located close to the end of the beam line and much beyond where the last of the RF stations end in Sector 30 of the Linac. This necessitated that the phase reference and other RF signals needed for the XTCAV station be derived locally. This problem was overcome by sharing the phase-stabilized 476 MHz Reference line from the tunnel that was used for the beam phase monitor in the vicinity of XTCAV. This Phase Reference was brought up to the service building via low-noise heliax cables. A local frequency generator used this reference to derive X-Band LO, Clock and all other RF which were then amplified and distributed locally.

LLRF Controls

In general, LCLS LLRF controls for each RF station comprises of an S-Band or X-Band Phase and Amplitude Controller (PAC), a Phase and Amplitude Detector (PAD) and an MKSU for modulator and klystron fault detection and protection. It may have an additional diagnostics PAD for monitoring the RF output from the PAC and the klystron forward and reflected power. A Master Controller controls a group of PACs and PADs at several stations to provide local or beam-based feedback. Figure 3 is a block diagram of the LLRF controls in service building B921.

Temperature and Feedback

The phase and amplitude stability provided by the closed loop LLRF feedback controls is tied very closely to the temperature of both the structure as well as the LLRF hardware. Unlike the rest of the Linac where the key feedback PAD digitizer is located in a temperature controlled environment to guarantee phase and amplitude stability within the tolerance limits, the XTCAV feedback PAD is located in a service building that is not temperature controlled and thus prone to ambient diurnal temperature variations. The X-Band PAC and PAD's temperature is regulated with water which minimizes this issue. Improvements to feedback algorithm further improved stability. The behaviour of feedback is also closely related to the overall accuracy of timing at the station which will be discussed next.

XTCAV TIMING

The PAC and PAD are controlled by an EPICS IOC running in a PowerPC based CPU board in a VME crate.

XTCAV was the first and is still the only LCLS RF station that has all EPICS controls and the new MKSU-II. This station does not have any of the older SCP, CAMAC or PIOP related controls that are used in combination with EPICS in several portions of the Linac. This minimized XTCAV station setup complexity but at the same time posed newer system integration challenges and some training challenges for the operators.

Unlike the rest of the LCLS controls which use just an EVR module, the XTCAV VME crate has the EVR-RF module for timing. This board has an event clock that is divided from the externally input 119 MHz RF signal. This 119 MHz RF signal is derived directly from the same 476 MHz Phase Reference which was used to derive locally all LLRF RF signals and clock for the PACs and PADs as discussed earlier. This special setup with the EVR-RF module ensures the best possible synchronization between local RF and timing system and provides accurate timing and triggers for all HPRF and LLRF components at the station. This is paramount for keeping the phase and amplitude of the very narrow X-band pulses stable since the XTCAV is located near the beam dump where tolerances for reference phase deviations may not be as stringent as in the rest of the beamline in the Linac.

The trigger setup complexity is minimized in the XTCAV station. Unlike the rest of the RF stations where a number of different triggers from a variety of sources provide discrete triggers for the modulator, PACs and PADs, and whose delays have to be setup up carefully in careful coordination, the XTCAV station takes in a single trigger output from the EVR and fans this out to all the LLRF HW via the MKSU-II that automatically routes the appropriate trigger based on the station's operating mode which can either be beam 'Accelerate' or 'Standby'.

LLRF and MKSU-II Controls lay out and Timing Distribution for LCLS XTCAV

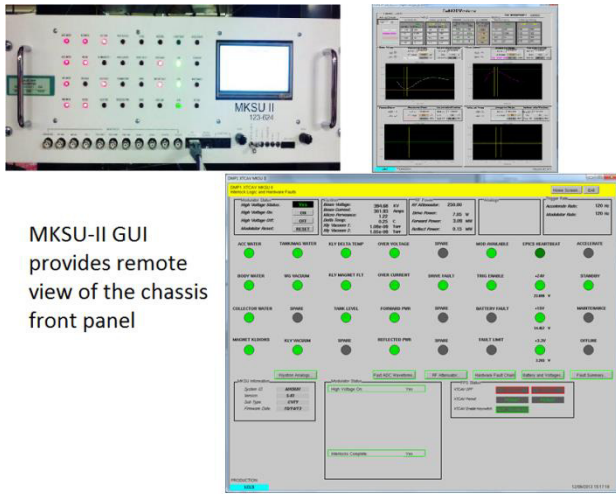

Figure 3: Block diagram of LLRF and HPRF controls layout in XTCAV service building.

MKSU-II

The XTCAV is the only LCLS station that has an upgraded Modulator Klystron Support Unit called as the MKSU-II. This chassis protects the Klystron by monitoring various sensors and removing high power pulse to the klystron when the system is compromised. The MKSU-II hardware and firmware were modified specifically for the LCLS XTCAV project. A new driver and accompanying business logic were written for it with a new user interface. The new UI mimicked the chassis front panel and provided a remote view of the current status of HPRF at the station. Among several other new features, the MKSU-II supports continuous monitoring of fast waveforms such as the klystron beam voltage and current and forward and reflected power. The MKSU-II chassis front panel, its user interface and fast waveforms are shown in Figure 4. XTCAV's new MKSU-II was clearly a big improvement in RF station fault detection and protection albeit the transition to this new hardware in a station that already differed from the rest of the RF stations in several aspects posed some challenges for operations. Training has improved adaptation.

MKSU-II GUI provides remote view of the chassis front panel

Figure 4: MKSU-II chassis front panel, user interface and fast waveform panel.

CONCLUSION

Commissioning of the controls for XTCAV came with its own set of unique challenges as outlined in this paper but each one of them were overcome in a manner that actually set the path for improvements in LLRF controls for the rest of the Linac. Ever since it was commissioned in May 2013, the XTCAV has become a successful tool in gathering data that enables reconstruction of X-ray FEL profiles with greater resolution. Its success has called for

further experimental upgrades which are already underway with the installation of a new SLED cavity at the station that is expected to double the peak power at the structure with longer RF pulses.

ACKNOWLEDGMENT

Several SLAC engineers contributed towards the XTCAV project and our thanks goes to all: Dan Van Winkle and the TID AR RF Department, Erik Jongewaard, John Eichner and the TID RFAR Department, Jim Lewandowski and the AD FACET and Test Facility Department, Dave Steele and AD ICD ACC Power System group, LCLS Operations team and AD ICD Controls Department Software and Networking team members for their valuable contributions during the development of the project and for their continued support in making it a very successful one.

FAST WIRE SCANNER UPGRADE FOR LCLS

J. M. D'Ewart[#], M. Campell, P. Krejcik, H. Loos, K. Luchini, SLAC, Menlo Park, CA 94025, USA

Abstract

Wire scanners are a main diagnostic tool for transverse beam size and emittance measurements at LCLS. The original SLAC wire scanners were not optimized for speed (taking minutes to scan), and can't perform at the desired level of position resolution necessary for measuring LCLS' small beam size. A new fast wire scanner, based on a dc linear servo motor, has been designed and installed in the LCLS. The new fast wire scanner has several advantages over the original wire scanner: scan times are reduced from minutes to seconds while minimizing wire vibrations. Rather than counting open-loop step pulses, the new fast wire scanner uses real time position capture for beam synchronous sampling of the wire position, enhancing beam profile accuracy.

INTRODUCTION

The primary purpose of the wire scanner system is to provide a high resolution measurement of electron beam profile averaged over many shots. Profile measurements can also be used to determine transverse beam emittance.

The LCLS wire scanner system had been based on a drive system consisting of a stepper motor and a ball screw [1]. A 10X gear reducer was added to the system reducing wire vibration, but also reduced maximum wire speed [2]. A linear variable differential transformer (LVDT) was used to calibrate the drive system. The motion was operated in open-loop with no feedback about actual drive or wire position.

The design goals of the fast wire scanner are: reduce scan time from minutes to seconds, minimize vibration during the scan, improve position resolution of the wire scanner motion to $1\mu\text{m}$ or better, incorporate real-time readback of the wire position through the data acquisition system, and to integrate the wire scanner into the LCLS EPICS control system [1].

The advent of the LCLS-II project at SLAC has also resulted in the need for a wire scanner that can move at speeds sufficient to prevent wire destruction during CW beam operation.

For the nominal LCLS-II beam parameters of 100 pC charge per bunch, a transverse emittance of $0.5\mu\text{m}$, and a bunch repetition rate of 0.6 MHz the minimum wire speed to avoid damage is calculated to be 0.34 ms^{-1} .

FAST WIRE SCANNER

The fast wire scanner, shown in Fig. 1, uses an external actuator for linear motion. The drive system is based on the LinMot dc linear motor [3]. The wires are mounted on an interchangeable card that holds an x, y and u wire at 45° to the beam. A scan of all 3 wires can be done in a

Figure 1: Wire scanner mounted at 45° .

single motion of the scanner before returning to the home position. An increment linear encoder is attached to the drive system and limit switches are used at the end of travel. The linear motor eliminates the discrete steps of a stepper motor and the linear encoder allows for closed-loop servo control.

CONTROL SYSTEM

Fast Wire Scanner Control System Architecture

The fast wire scanner control system architecture is based on the original LCLS VME wire scanner architecture. The original LCLS wire scanners use a VME crate with a MVME 6100, MRF EVR, CAEN V965 QDC board, Isig high voltage power supply module, and Hytec IP8601 stepper motor controller. The fast wire scanner uses an additional Prodex MAXv VME motion controller for servo motion control. A MAXv breakout chassis and LinMot panel are also installed into the control rack to support the fast wire scanner. The MAXv breakout chassis separates each of the 8 axis control and I/O signals and interfaces to the LinMot panel. The LinMot panel houses the servo drive as well as drive and logic power supplies. This architecture allows a rolling upgrade for current LCLS wire scanners. A block

[#]Work supported by the U.S. Department of Energy under contract number DE-AC02-76SF00515

[#]mdewart@SLAC.Stanford.EDU

diagram of the system is presented in Fig. 2.

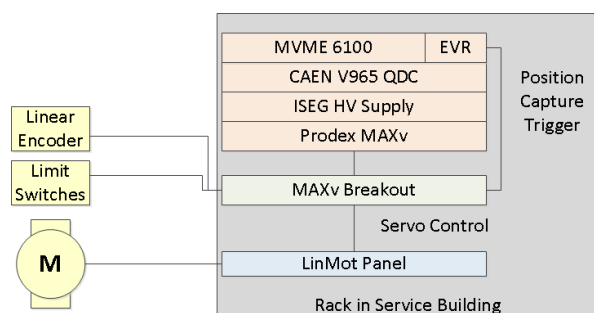

Figure 2: Fast Wire Scanner Control System Architecture.

Motion Control

The motion control system consists of an EPICS IOC (MVME 6100 running RTEMS), a Prodex MAXv 8000 VME motion controller [4], and a LinMot B1100 servo drive. The MAXv provides control for up to 8 servo or stepper axes. In servo mode the MAXv provides PID servo control with a 122 μ s update rate. The MAXv is capable of custom, parabolic, S-curve and linear trajectory profiles. The MAXv servo signal is connected to the LinMot drive panel through the MAXv breakout chassis.

The LinMot panel, shown in Fig. 3 and Fig. 4, consists of a LinMot B1100 servo drive as well as a 72 VDC and 24 VDC power supplies. A Beckhoff BK9000, along with terminals KL1408 and KL2408, is used for digital I/O to interface with the LinMot B1100 servo drive. The digital outputs enable the drive and the digital inputs monitor status. The LinMot panel interfaces to the LinMot linear motor power and feedback signals and the MAXv control signals.

Figure 3: LinMot Panel, Front View.

Figure 4: LinMot Panel, Rear View.

Encoder Processing

An incremental quadrature linear encoder is attached to the linear slide of the LinMot drive system. The linear encoder provides 1 μ m position resolution. The fast wire scanner system uses the real-time position capture feature of the MAXv. An EVR trigger is used to trigger a beam synchronous position capture event. The captured position data includes the axis, encoder position, positive and negative edge I/O bits, and home events [2]. The captured data is put in a ring buffer in VME shared memory and processed by the EPICS IOC. The position data is then processed by the beam synchronous acquisition (BSA) facility.

Homing Procedure

Homing is performed to ensure a consistent reference position subsequent to each power-up. The 45° install angle means to motor rests on the lower hard stop when no power is applied. The homing procedure is then as follows:

1. Power on motor
2. Move just off of hard stop
3. Move toward negative hard stop
4. Detect hard stop based on demanded torque and position error
5. Set known position on hard stop

Beam Synchronous Position Capture

The fast wire scanner uses the real-time position capture feature of the Prodex MAXv. An EVR trigger is used to trigger a beam synchronous position capture event. The captured position data includes the axis, encoder position, positive and negative edge I/O bits, and home events [4]. The captured data is put in a ring buffer in VME shared memory and processed by the EPICS IOC. The synchronously acquired position data is processed by a high level Matlab application to calculate beam profiles and transverse emittance.

Scan Trajectory

A high level Matlab application is used to initiate a scan. The wire scan application selects which of the three wires to scan and the appropriate scan speed based on beam rate. The wire scanner moves at max speed between wires and at the appropriate scan speed ± 2 mm of the nominal wire position. A full S-curve trajectory is used for the motion. An S-curve trajectory allows for smoother wire trajectory by setting jerk, the derivative of acceleration, constant. An ideal wire scan trajectory, covering all three wires, is shown in Fig. 5. A snapshot of the high level graphical user interface is shown in Fig. 6, along with x, y and u scan data.

Figure 5: Ideal wire scan trajectory.

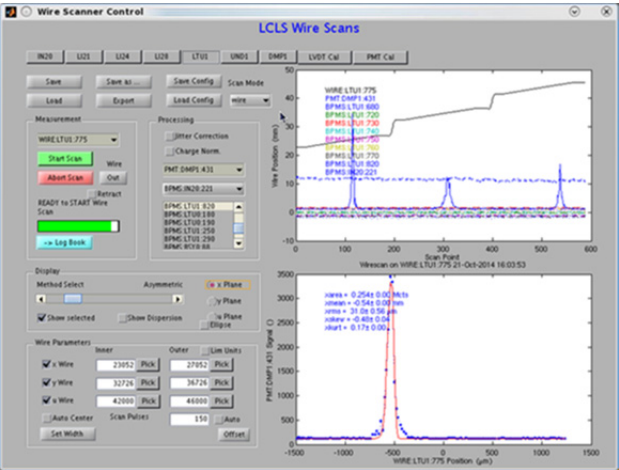

Figure 6: Wire scan graphical user interface showing x, y and u wire scan signals as well as motor position (top right) and individual wire scan profile (bottom right).

CONCLUSION

We have designed a new fast wire scanner based on a LinMot dc linear motor. The control system is designed to be backward compatible and allow for rolling upgrade of the LCLS wire scanners. Real-time position capture is used to beam synchronously acquire wire position. Three new fast wire scanners have been installed in the LCLS to date. The remaining slow wire scanners will be upgraded in a rolling fashion throughout the LCLS.

 S. Zelepoukine, University of Wisconsin-Madison, USA

Abstract

The first long shutdown of the Large Hadron Collider (LS1, 2013-2015) provided an opportunity for significant upgrades of the detector control and safety systems of the CMS Electromagnetic Calorimeter. A thorough evaluation was undertaken, building upon experience acquired during several years of detector operations. Substantial improvements were made to the monitoring systems in order to extend readout ranges and provide improved monitoring precision and data reliability. Additional remotely controlled hardware devices and automatic software routines were implemented to optimize the detector recovery time in the case of failures. The safety system was prepared in order to guarantee full support for both commercial off-the-shelf and custom hardware components throughout the next accelerator running period. The software applications were modified to operate on redundant host servers, to fulfil new requirements of the experiment. User interface extensions were also added to provide a more complete overview of the control system. This paper summarises the motivation, implementation and validation of the major improvements made to the hardware and software components during the LS1 and the early data-taking period of LHC Run 2.

INTRODUCTION

The Compact Muon Solenoid (CMS) [1] is a general-purpose particle physics detector built for the Large Hadron Collider (LHC) [2] at CERN. The CMS detector is composed of several types of sub-detectors: trackers, calorimeters and muon chambers. Based on the technical specifications and requirements of each sub-detector, custom Detector Control Systems (DCS) were designed, implemented and commissioned. A central CMS DCS [3] infrastructure provides general and common services, as well as the unification of controls and monitoring of all sub-detectors. A central CMS Detector Safety System (DSS) [1] is responsible for all off-detector safety-related matters. In addition, individual sub-detector safety systems are also available to provide extensions to the CMS DSS to guarantee the on-detector safety and integrity. The experience acquired during the first LHC long run (March/2010 – February/2013) ensured a better understanding of the detector operation and consequently the identification of possible fields for improvements to the DCS/DSS software and hardware components. The first long shutdown (February/2013 – June/2015) of the accelerator provided an opportunity for the

implementation of most of these improvements, systems extensions and the preparation of even more robust, efficient and reliable systems for the LHC Run 2. This paper discusses the main improvements made to both DCS and DSS of the CMS Electromagnetic Calorimeter (ECAL) [1] throughout the periods described above. Focus is given to hardware upgrades and system consolidation.

Full details of the architecture of the CMS ECAL DCS have been reported previously [4,5].

CMS ECAL DCS OVERVIEW

This section presents a general description of the CMS ECAL DCS software and hardware. A simplified block diagram of the complete system is illustrated in Fig. 1.

Software

The CMS ECAL DCS application has been developed with a Supervisory Control and Data Acquisition (SCADA) software package named SIMATIC WinCC OA from SIEMENS, formerly Process visualization and control system II (PVSS II) from ETM. To facilitate the development process, the JCOP Framework [6], developed by CERN to provide extensions to WinCC OA for the high-energy physics domain, is extensively used. Through a Finite State Machine (FSM), manual and automatic commands are issued to lower nodes and node states are propagated and summarised upwards. Furthermore, the main control and state monitoring of all sub-detectors are accessible to the CMS DCS via the FSM to enable global CMS control.

The partitioning of the control nodes follows the sub-detectors architecture, in this case: CMS ECAL Barrel (EB), CMS ECAL Endcaps (EE) and CMS ECAL Preshower (ES).

Hardware

The DCS hardware comprises all devices used for connection to the low voltage and bias voltage powering systems, the electronics for environment monitoring and for additional support services, such as remote crate power cycle units and bias voltage current measurements.

Due to software changes at the CMS DCS level, presented in the section “*Controls Software Redundancy*”, all field buses are being converted to Ethernet, allowing their physical decoupling from the DCS servers.

Spare parts and, in some cases, complete spare units are available to provide full and optimal support in case of hardware failures.

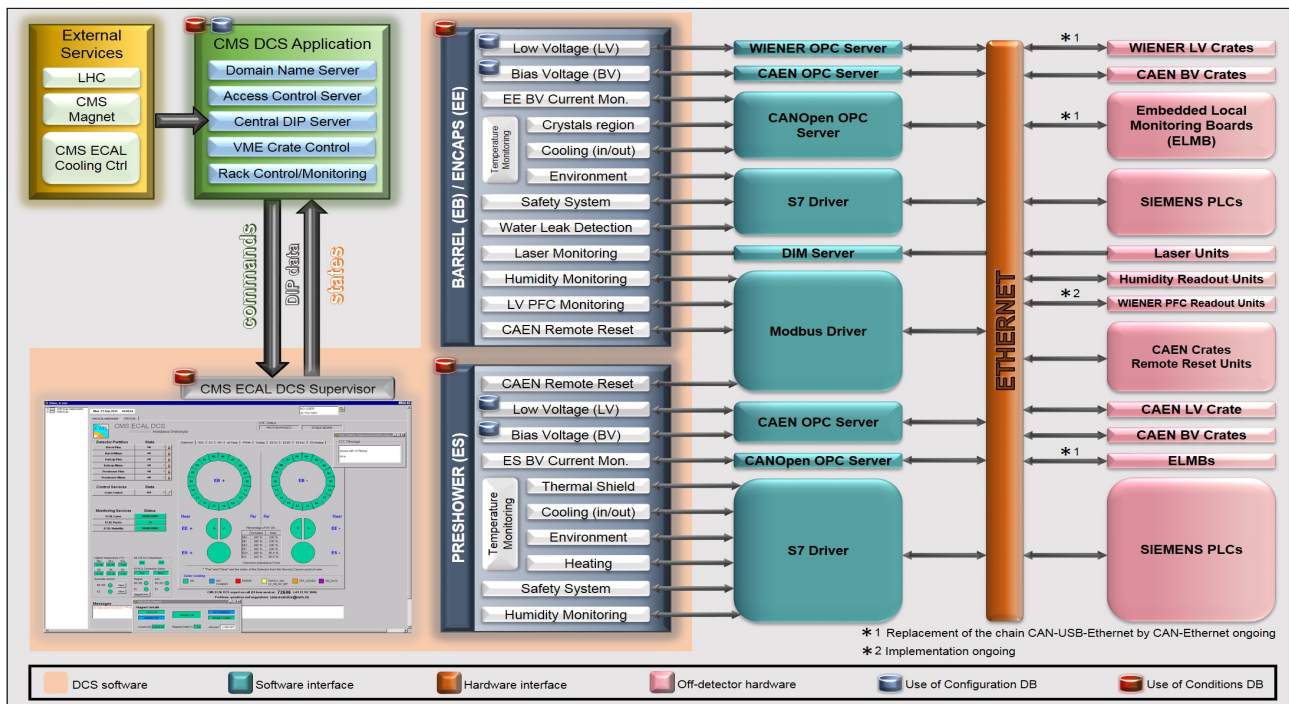

Figure 1: Simplified block diagram of the CMS ECAL Control System.

CMS ECAL DSS OVERVIEW

Designed to ensure the calorimeter safety and integrity, the CMS ECAL DSS [4,5] is based on a fully redundant SIEMENS Programmable Logic Controller (PLC) system with hardwired connections and interlocks to all relevant systems to ensure real-time actions in case of harmful conditions. Furthermore, it provides complementary resources to the main CMS DSS by monitoring parameters such as the cooling flow status and water leak detection for the low voltage power supplies racks.

UPGRADES AND IMPROVEMENTS

Controls Software Redundancy

Following a requirement from the central CMS DCS for running the complete control system in a redundant hot standby mode, with one set of servers installed in the experiment service cavern and another in the surface data centre, all sub-detectors had to confirm compatibility of their control system applications with this new operating environment. The preparation consisted of changes to the SCADA software and the adaptation of all hardware connections to Ethernet. The latter will be discussed in the next section “*Hardware Interfaces*”.

In line with the implementation of software redundancy, a complete project for merging the CMS ECAL DCS sub-applications to run in fewer servers was carried out. Applications were initially combined based on their role and in a second step grouped according to their software interfaces to the hardware. As an example, all bias voltage applications were re-designed to run side-by-side, and then grouped with the Preshower low voltage application that shares the same CAEN Object Linking

and Embedding for Process Control Data Access (OPC DA) Server.

The reduction from fourteen to three servers was a fundamental step towards the redundancy implementation. The software layer for the switchover mechanism was implemented by the CMS DCS group [7].

Hardware Interfaces

To allow the implementation of redundancy at the software level, the DCS servers had to be physically decoupled from the hardware. The Ethernet layer was chosen to ease the logical switchover between the two identical, but geographically separated, sets of servers. No changes were required for the connections to the PLCs and to the Arduino-based devices, which were originally Ethernet-based. To realise the connection to the EB/EE humidity readout units, commercial Modbus RTU-Ethernet adapters were selected and installed. Several approaches were evaluated for conversion of Controlled Area Network (CAN) buses. As no commercial CAN-Ethernet device was available at the beginning of this project, a chain of CAN-USB-Ethernet was tested. This solution worked for buses with few devices and/or low data traffic, but issues were identified with large, heterogeneous CAN hardware installations running in parallel on a single server. Furthermore, the latency added by this implementation triggers a significant number of false positive hardware disconnection timeouts.

In 2014, a commercial multi-port CAN-Ethernet adapter that fulfils the system requirements became available. Together with the necessary changes to the WIENER OPC server, the Triplicated AnaGate CAN Quattro was exhaustively tested and certified for installation at the end of 2015 [8].

Remote Reset of CAEN Mainframes

A complete analysis of all expert interventions during the LHC Run 1 enabled the identification of the most common failures and sources of the experiment downtime related to off-detector hardware. In particular, two cases were identified related to the CAEN mainframes that provide the bias voltage for the whole CMS ECAL and the low voltage for the Preshower. The first, the fact that after a power cut, some mainframes were not properly initialized and required a human intervention to perform a full reset. The second, occasionally, the communication with the mainframe was interrupted and only restored by a reset of the mainframe Central Processing Unit (CPU) controller. The minimum time of thirty minutes to identify the problem, access the experiment cavern and reset the faulty controller motivated the implementation of a remote reset unit, accessible through the main CMS ECAL DCS supervision panels.

As no commercial devices were suitable for an easy integration to the controls software, microcontroller-based units were developed. Each unit features fourteen ports and an implementation of Modbus over TCP on an Arduino Ethernet [9] for communication with the native Modbus driver from WinCC OA. The unit can issue Transistor-Transistor Logic (TTL) pulses with lengths of 200 ms for resetting only the CPU controller and 1000 ms for a full mainframe reset. A user-friendly panel allows the detector experts to trigger both actions in a few minutes for any of the twenty-three existing mainframes.

WIENER PFC Monitoring System

Another outcome from the analysis of the CMS ECAL DCS expert interventions was the need of an extension for the EB/EE low voltage application to read out the WIENER Power Factor Corrector (PFC) parameters. The failure of these devices was one of the most common hardware issues since the commissioning of the CMS detector. The monitoring of internal parameters might provide an opportunity to detect issues and schedule interventions prior to a total failure of the device during the detector operation.

To profit from the existing Modbus driver of WinCC OA, the readout Printed Circuit Boards (PCB) feature Modbus over TCP implemented with an Arduino Yún, which controls four ADG726 (dual 16-port multiplexer) to switch the RX and TX lines for up to 64 devices. In addition, the 5V and 9V required for the PFC serial circuit are permanently provided.

Humidity Monitoring System

The original design of the EB/EE Humidity Monitoring (HM) [4,5] system did not take into account the lengthy cables between the probes inside the detector and the readout hardware, which for some probes reaches more than 100 meters. The additional capacitance introduced by the cables and seen by the humidity transmitters imposed a limitation on the humidity readout range to 60 – 80%. To overcome this issue, a custom readout unit featuring

very low frequency (1 Hz) transmitters was designed. To evaluate any possible degradation of the probes due to their operation out of the manufacturer specifications, tests setups were built at CERN and in Belgrade. After more than a year of evaluation, the new hardware was certified for installation in the experiment.

A calibration procedure was developed and each individual readout channel was calibrated using the same type of probe from the experiment, inserted in a controlled humidity unit with a very precise humidity sensor as reference. The new readout units were installed in the experiment and are able to measure from 10 – 80% relative humidity.

PTM Readout – Improved Power Distribution

The Precision Temperature Monitoring (PTM) is an ELMB [10] based system responsible for the temperature monitoring of the EB/EE crystals region and cooling. In the original design, three 12V power supplies, one for the analog, one for the digital and one for the CAN part, powered all ELMBs in parallel. An event where a single failure of one ELMB degraded operation of the whole monitoring system motivated the upgrade and improvement of granularity of the 12V power distribution.

Two sets of 3x12V supplies were installed, one for each half of the detector. A terminal block with fuse was installed for each power line at the experiment service cavern, allowing the disconnection of a possibly faulty ELMB without compromising the complete system.

Preshower Bias Voltage Monitoring

The Preshower Bias Voltage (BV) is distributed through a fully flexible matrix patch panel [11], where any input channel can be connected to any detector element or group of elements. For each individual line, a resistor bridge containing a reference resistor and branches to scale down the voltages are available to measure the current delivered to each output channel.

The period between the patch panel production and their installation in the experiment was insufficient for a complete evaluation of the readout and consequently for the definition of a proper calibration procedure. These tasks were performed later with a spare patch panel.

All readout channels were calibrated for current measurements with precision better than 2%. A complete and successful validation was carried out with several values of current from 10 μ A to 2000 μ A.

Due to a configuration featuring multiple grounds without proper isolation between them, a condition that was not previously tested, the results at CMS were not as expected. The patch panel that was removed from the experiment is currently being analysed.

Safety System Preparation for the LHC Run 2

A complete re-evaluation of the safety system PLC code and hardware was carried out to not only identify possible improvements but also issues related to ensuring long term support.

- Replacement of PLC CPUs

The CPUs, which were operational throughout the LHC Run 1, reached the end of their life cycle in July 2015 and were discontinued by SIEMENS: no more spare parts, repair service or technical support. Both CPUs were replaced by a newer model, with full support guaranteed until October 2022. Spare parts for the complete PLC system are available 24/7 from the CERN PLC Spare Parts Critical Stock;

- Production of spare readout units

The non-commercial hardware comprises the units reading out the EB/EE water leakage and temperature sensors and the units handling the interlock signals. To ensure a number of spares representing a minimum of 33% of the complete system, four spare readout units were produced;

- Recovery mechanism for CP341 failures

The communication between the SIEMENS CP341 modules and the readout units described above is realised through a RS-485 bus with a custom protocol. Due to external conditions, such as electrical noise, associated with extremely sensitive conditions to trigger safety actions, communication issues have triggered unwanted detector shutdown events. To restore the communication to the readout units, a human intervention to power cycle the CP341 modules was required. A mechanism to recover communication without the need of a power cycle was implemented in the PLC code and is under evaluation. To avoid any impact on the system reliability, it currently can only be manually triggered. Once this mechanism is certified, an automatic recovery procedure will be implemented.

24/7 OPERATOR AND EXPERT SUPPORT

Since the commissioning phase of the experiment, the CMS ECAL DCS has maintained 24/7 support services to ensure the maximum availability of the calorimeter. Initially, three of the main developers of the system were responsible for the daily operation of the detector and expert support in case of failures. Due to the significant workload involved, the support scheme was reviewed and divided in two roles, operator and expert. The operator on-call can be any person from the experiment collaboration and, with some basic training, is able to handle the detector daily operations and basic failures, while the expert on-call provides the most advanced level of support, either to the operator or directly to other CMS ECAL experts for more complex failures or interventions. This solution has proven to be very efficient and results in more balanced workload and increases the pool of people who have operational knowledge of the CMS ECAL DCS.

A log of all system failures, related to both hardware and software, has been maintained by the operators and experts to allow further analysis and consequent improvements based on preventive actions. Furthermore, based on feedback from operators and shifters, the available monitoring resources and software tools are

periodically revised and, if required, extended to improve the system operation and troubleshooting.

CONCLUSION

The CMS ECAL DCS and DSS successfully supported the detector operation during the LHC Run 1. By logging the CMS shifters and DCS on-call operators and experts activities for over three years, several fields for improvements were detected. The LHC LS1 provided an optimal opportunity for these upgrades and system extensions. Efforts were made to ease operations, by providing additional troubleshooting tools and extended user-friendly operating panels. Most of the changes discussed in this paper have already been deployed and an excellent support to the CMS ECAL is being provided during the LHC Run 2.

ACKNOWLEDGMENT

The authors would like to thank the Swiss National Science Foundation and the Ministry of Education, Science and Technological Development of Serbia for the financial support.

EXPERIENCES AND LESSONS LEARNED IN TRANSITIONING BEAMLINE FRONT-ENDS FROM VMEBUS TO MODULAR DISTRIBUTED I/O

I. J. Gillingham, T. Friedrich, S. C. Lay, R. Mercado,
Diamond Light Source, Oxfordshire, UK

Abstract

Historically Diamond's photon front-ends have adopted control systems based on the VMEbus platform.

With increasing pressure towards improved system versatility, space constraints and the issues of long term support for the VME platform, a programme of migration to distributed remote I/O control systems was undertaken.

This paper reports on the design strategies, benefits and issues addressed since the new design has been operational.

INTRODUCTION

Diamond Light Source is a 3 GeV third-generation light source with a 561m storage ring (SR), a full-energy booster (BR) and a 100 MeV pre-injector Linac [1]. The photon output is optimised for high brightness from undulators and high flux from multi-pole wigglers. The current operational state includes 28 photon beamlines, with a further two beamlines in an advanced stages of design and construction.

In 2010, Diamond adopted a new control system design for future beamlines, adopting fieldbus distributed control as a viable alternative to the long standing VMEbus architecture [2]. In planning for the present phase of photon beamlines, in 2015, the control system architecture and choices of hardware used was revisited.

PREVIOUS CONTROL SYSTEM ARCHITECTURES

The original accelerator and beamline control systems at Diamond are based on VME systems. To support the interface requirements of the equipment, a range of I/O modules based on Industrial Pack (IP) modules (ADC, DAC, Serial, DIO) and VME modules (IP carrier, motion, scalar and timing) were used. The field signals are interfaced via either rear transition modules or front-panel connections. A VME microprocessor (MVME5500) runs VxWorks and EPICS to serve up the control information to client applications.

REASON FOR CHANGE

The original control system architecture served well for the existing accelerators and beamlines; however it was defined a number of years ago, so in the context of the recent and future phase of beamlines the opportunity to reconsider the standards was taken. In doing so, it is clear that not all the hardware capability of VME was required for beamline control; neither was the use of a hard real-time operating system such as VxWorks. It was also

apparent that most I/O functionality required for control of beamline and accelerator equipment can now be realised through Ethernet-attached I/O. There is also now good infrastructure for developing and managing Linux based EPICS IOCs on a PC architecture.

OUTLINE REQUIREMENTS FOR PHOTON BEAMLINES

In considering the requirements for photon beamlines, the following technical systems were identified:

- Motion control
- Vacuum instrumentation and other serial devices
- Video cameras
- Analogue and digital signals
- Programmable logic controllers
- Timing signals

The disturbance to beamline operation through restarting an IOC, should be minimised.

The I/O associated with the control system should be located close to the equipment being interfaced; i.e. for signals located in experimental and optics hutches, the I/O modules should be co-located in these areas. However, this is constrained by the possibility of radiation-induced damage to I/O in the optics hutches of high energy (~100keV) beamlines or Storage Ring (SR) vault and by the space available in the some beamline hutches.

NEW CONTROL SYSTEM ARCHITECTURE

Each EPICS IOC runs on a 1U Linux PC located within the relevant Controls Instrumentation Area (CIA). The Linux servers have several physically separate network connections to support the different systems.

Linux Server

The IOCs are standard Dell 1U machines (currently R320), without a hard-disk installed, that boot from an image over the network into a RAM based disk.

The current operating system is 64 bit RedHat Enterprise Linux 6, which has real-time extensions compiled in to facilitate determinacy for the EtherCAT driver, when used at high bandwidth.

On boot, the server picks up its host-name and IP address via DHCP, determined by the MAC address of eth0. The DHCP server also points to the TFTP server which provides the kernel and ramdisk image used to boot the machine.

A startup-script in the host's soft IOC directory is used to configure the server. For instance, network interface

eth1 could be assigned an IP address, the kernel-module for the event-receiver card could be installed and the EtherCAT service started. This gives users the ability to configure the machine using a version controlled script.

Remote I/O Interfaces

In order to manage various classes of signal associated with control and acquisition, two distinct types of interface have been adopted, PLC Remote I/O (PLC RIO) and EtherCAT. The following table lists and summarises the attributes of each type of interface:

Table 1: RIO Interface Types		
Interface	Attribute	Description
PLC RIO	Signal processing	Ladder logic in PLC generates machine protection interlock permits, in rapid and predictable response to input signals
EtherCAT	Interface with IOC	Ethernet or serial communications with slow bandwidth in the order of 1Hz. Sharing of field signals between the PLC and IOC is facilitated by mapping in PLC memory and reading it periodically from a client (e.g. IOC) using the FINS protocol.
	Signal processing	Various signal categories are supported for devices not necessarily associated with machine protection, i.e. for monitoring only. Analogue signals may be sampled at rates exceeding 10kHz.
EtherCAT	Interface with IOC	The EtherCAT network is scanned by a dedicated service on the IOC's host Linux server and readings made available to one or more IOCs via network sockets.. This can take advantage of preemptive real-time kernel extensions when high bandwidth, determinate signal processing is required.

NETWORKS

The servers are supplied with four network interfaces. This is to facilitate multiple dedicated and isolated networks, typically three are used as:

- Primary control network

- Instrumentation network (private to the server and network connected peripherals)
- EtherCAT network

The context of key network components is shown in Fig 1.

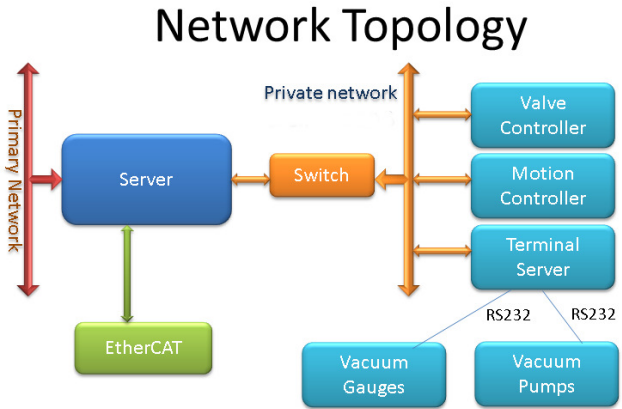

Figure 1: Network topology.

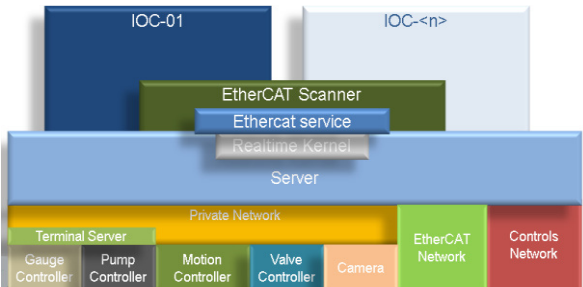

Figure 2: Logical Model.

Instrumentation Network

A number of instrument controllers are now equipped with network interfaces to facilitate control and data acquisition. It is desirable in most instances to secure these on a dedicated network, which is private to the Linux server. This avoids unnecessary traffic on the Primary Controls network and shields the instrumentation from connection outside the scope of the control system dedicated to that area.

EtherCAT Network

Where remote I/O (RIO) is required and not available on a RIO PLC, EtherCAT modules have been employed. The EtherCAT master module Linux may be used seamlessly with either Linux kernels with PREEMPT-RT enabled, or for standard development and "soft" test systems without the real-time extensions. For applications which require greater determinacy, such as high frequency analogue signal sampling, the pre-emptive real-time kernel extensions must be used.

Tests were performed to measure the effect of jitter on the master process [3]. The kernel patch pre-emptive real-time (PREEMPT_RT) reduces latency and adds the ability to pre-empt most kernel critical sections. However the user-space APIs are unchanged as the necessary calls are already present as part of the POSIX ADVANCED REALTIME standard [4], so that applications can be developed and tested on a standard system. For this application Diamond is using kernel 3.6.11.2-rt33 from MRG.

The following API features are used in the EtherCAT scanner:

- high-precision timers using clock_nanosleep
- SCHED_FIFO pthread scheduling
- PTHREAD_PRIO_INHERIT mutexes

The use of mlockall is mentioned in a previous publication [3] but has since been removed from the code. No adverse effect has been noticed.

Improvements have been realised by:

- Adopting a scheme of using a slave serial number as identifier to allow reconfiguration of the devices.
- Patching the Etherlab library to stop syslog messages overwhelming the system when a section of the bus is disconnected.
- Adding support to read and write Service Data Objects (SDOs) from the bus scanner application and from the higher level control system. The support for SDO came out of the need to support an LED controller, but has wider applications because SDOs are used to configure various EtherCAT Modules.

On a note on the hardware revisions of slaves, recent experience revealed that some PDO names vary between slaves' revisions in the EtherCAT Slave Information (ESI) files from the manufacturer. The scanner configuration files are generated from a description slave models and revision numbers. This information is then used to collect data from ESI files. The EtherCAT driver software propagates the slave information upstream as Asyn parameters. These name changes have prompted the need to revise the management of the slave information files from the manufacturer to screen for name changes before adopting the vendors' ESI files. The impact is limited to a subset of EtherCAT modules and solutions are being discussed to avoid revision specific version of templates. This simplifies hardware swaps in case of failure on an slave module.

The use of EtherCAT for acquisition and control of digital and analogue signals has been in use in beamlines and front ends built in the last four years. The devices have replaced VME signals and solutions have been developed for signal acquisition up to 10 kHz.

The separation of signal acquisition and the scanner publishing the bus signals over a socket, within a Linux server, allows for reusing a signal with different names in different EPICS IOCs. This feature, included in the original design, has proven useful when adding waveform acquisition from an ADC without the need to bring down the running system.

REMOTE I/O PLC

A new generation of Omron PLCs has been selected to enable the adoption of Remote I/O (RIO) and an Ethernet interface between the server and the PLC.

PLC RIO facilitates the reduction of cabling complexity and improving flexibility on deploying I/O into the field. PLC RIO uses standard Ethernet cabling and Profinet, and RIO modules are built up into the standard configurations, one for thermal monitoring and another for general purpose I/O. The Remote I/O does not perform any logic on any of the signals; it simply acts as a receiver and passes everything back to the PLC crate. This necessitates configuration of RIO output modules such that in the event of failure of RIO communication I/O fails to the safe state. The PLC logic is protected by a watchdog timer to protect against failures in communication with RIO.

The new PLC CPU (CJ2M) has a built-in Ethernet connection which allows both EPICS and the programming software to share the connection. EPICS communication is handled over UDP using FINS protocol whilst programming is realised over TCP/IP.

The remote I/O modules were originally prototyped into two standard configurations to enable spares to be maintained and allow faster recovery in the event of a problem. However the reality is that hot swap is not practical without interruption of the RIO communications bus and hence the PLC integrity, as a number of the modules have some intelligence which means that commands have to be sent to the card to configure them.

Problems that Needed Resolving

A significant issue, related to analogue modules, is that the values for temperatures freeze at the last known value when RIO communications is lost. Through the use of a watch-dog timer and detection of communications errors, the analogue is set to an error value.

Benefits of RIO

The biggest benefit of RIO is flexibility of design and the reduction in cabling. This has significantly reduced the number of connections to just those in interface boxes directly mounted out in the field. This has also significantly sanitised the wiring on beamlines. Often the beamline equipment is delivered with different sensors to those expected and we are able to adapt the system for this. The ability to add extra modules into the system as equipment arrives is very useful and suits the piece-meal commissioning of beamline equipment as more complex equipment is delivered.

SUMMARY OF PROGRESS TO DATE

The Diamond Control Systems now implement some 470 Linux based IOCs; a proportion of which utilise distributed I/O, such as EtherCAT. This design pattern has realised an integrated, versatile and maintainable control system, upon which enhancements and upgrades

can be confidently planned on platforms which provide inherent long term stability and support.

Abstract

The Detector and Run Control systems for the NA62 experiment, which started physics data-taking in the autumn of 2014, were designed, developed and deployed in collaboration between the Physics and Engineering Departments at CERN. Based on the commonly used control frameworks, they were developed with scarce manpower while meeting the challenge of extreme agility, evolving requirements, as well as integration of new types of hardware. The paper presents, for the first time, the architecture of these systems and discusses the challenges and experience in developing and maintaining them during the first months of operation.

INTRODUCTION

NA62 is a fixed-target experiment at CERN aiming at high-precision measurements of rare Kaon decays, currently taking physics data in its second run. Operation of the detector and its infrastructure is supervised with dedicated control systems, the most complex being the Detector Control System (DCS) and Run Control (RC). The two are similar in many aspects and share common infrastructure, as well as development and maintenance workflows. The Run Control has already been introduced in [1,2]. This paper focuses on the - often neglected - topic of complete architecture, including infrastructure, project organization and development life cycle.

The NA62 detector is composed of a set of sub-detectors developed and maintained by semi-independent groups. Some equipment is reused from previous experiments (such as the Liquid Krypton Calorimeter), while others must be built anew. Certain sub-detectors or their parts were not ready for integration before the first run, and they are added progressively. In consequence, the development, commissioning and maintenance of control systems is a *process* that spans over years. This is unlike many turn-key control systems in industry. Assuring consistency and long term maintenance in the project, taking into account a high-turnover of people in experimental collaboration is one of the primary challenges.

REQUIREMENTS

The DCS and RC systems for NA62 resemble those of other CERN experiments. Relative to the LHC

experiments they are an order of magnitude lower in number of devices, yet their complexity remains similar.

The systems have to allow for operation and monitoring of a variety of devices, react on value changes, evaluate alarm conditions and notify the operators about the alarms. The operators need to be presented with an alarm screen, as well as synoptic views that summarize the state of parts and subsystems of the experiment, and be able to drill down and quickly identify or locate the required device. They need to easily command individual devices, as well as groups of them (e.g. complete subdetectors).

The experts need to tune the set-points and alarm threshold, and bring up the trend plots of historical values. Reconfiguration should be applied to a selected device or using configuration sets (*recipes*) reflecting the run modes of the experiment. The experts must be able to detect and diagnose malfunctions and communication problems, and dynamically reconfigure the system, e.g. re-wire faulty sensors or mask alarms.

The history of acquired data (*conditions*) needs to be recorded to an Oracle database to be used in physics analysis. CERN computer security rules need to be applied. Robust infrastructure and hardware should be employed to guarantee round-the-clock operation during 8 months of data taking with minimal human supervision.

OPERATION

The independent operation of the DCS and RC is performed on dedicated consoles in the NA62 Control Room. The User Interface window requires authentication with CERN credentials, and enables access to shifter or expert operations, on various parts of detector, depending on privileges defined by administrators.

Standard shifter operation employs two tools: the alarm screen, displaying a time-sorted list of anomalous incidents ("alarms") and the hierarchical control supervision screen. The latter, also known as "FSM" (Finite State machine), abstracts out the hardware to present a tree view of the detector's parts and subsystems. Hardware states are evaluated and represented by colour-codes and text labels ("ERROR", "RAMPING"). These states are propagated in the upstream direction of the tree using summarization logic. This allows for rapid root-cause identification by expanding the coloured tree view. High level commands ("SWITCH_ON", "CONFIGURE") are broadcast down the tree allowing control of large parts

ISBN 978-3-95450-148-9

of the hierarchy with single button-presses. It is possible to exclude devices and sub-systems from central hierarchical operation and hand them over to an expert in a standalone or shared mode of operation. Whereas the shifters may only see the current values for set points, the experts can also modify them, as well as mask the alarms or change their thresholds. The principles of hierarchical operation, and the employed tools, are identical to those used by the LHC experiments.

Remote access and expert operation is also possible through dedicated Terminal Servers and secondary consoles which run the same "User Interface" application as the main control room console. Conflicting operations from two operators are avoided thanks to the concept of partitioned operation and sub-tree ownership.

PROJECT STRATEGY

Following the good experience with the LHC Detector Control Systems, it was proposed to develop and maintain the NA62 controls projects by a Central Team with assistance of experts from the CERN EN/ICE group. The Central Team, recruited from NA62 members, would work closely with sub-detector experts to implement their requirements; the experts would provide the necessary expertise, training as well as technical supervision of the projects. To maximize the use of scarce development manpower allocated for the projects, main developer(s) would work in proximity and under direct supervision of EN/ICE experts especially at the initial stage of project development.

A general policy was adopted to apply standard, centrally supported and recommended technologies and make use of existing services available at CERN. In addition, in order to enhance the stability of the running system, simplify long-term support and assure evolution of the project, guidelines and a development process with elements of quality-assurance and testing were agreed on.

ARCHITECTURE AND TECHNOLOGIES

The systems are developed with standard CERN set of technologies, and a layered architecture. Figure 1 presents

Figure 1: Architecture of the NA62 Control Systems with equipment location.

the geographically scattered layout of the system, with the Supervision, Process/Frontend and Field/Equipment parts.

In the Supervision Layer there is a set of 10 supervision applications: one for the Run Control, one per sub-detector (or a set of smaller ones), and one Central DCS application that orchestrates the execution of sub-detector applications. The cores of SCADA applications are running on dedicated control servers (located in the server room which hosts other CERN control systems) and the User Interfaces (UIs) programs running on a set of consoles located in the the control room. The server room and the experiment facilities are connected by a direct optical fiber link.

The Frontend layer is composed of dedicated computers, hosting hardware-interface cards (for CAN bus). They aggregate the traffic from hardware, translate the necessary middleware technologies eliminating platform-dependent factors and interface with the Supervision layer over a dedicated experiment network. A few PLCs are used to interface with relays and sensors.

The Field and Equipment layer is populated by the high and low voltage systems (over 4000 channels), electronics crates, and I/O boards with sensors. A significant number of custom frontend-electronics boards are configured and monitored.

Technologies

The supervision layer is built with the standard CERN controls software stack based on the commercial *WinCC Open Architecture* SCADA [3], and the *JCOP* and *UNICOS* frameworks [4,5,6].

Communication with the hardware layer is mediated by CERN's standard DIP, DIM [7] and OPC-DA middleware protocols; Ethernet and CAN bus media are used to reach the field layer.

Standard hardware used by other CERN Detector Control Systems integrated within the JCOP Framework [4] are used for high voltage, electronic crates and analog and digital I/O.

The readout for the unique, legacy Liquid Krypton Calorimeter is interfaced through a genuine solution based on the mixture of control frameworks and technologies. A PLC powered by UNICOS is used to control relays, ELMB I/O boards integrated through JCOP Framework are used for voltage readouts, while the electronics monitoring is provided by a dedicated low-level software interfaced through DIM.

A particularly challenging task was to interface the control for the thresholds frontend electronic boards. Initially interfaced using the CanOpen technology (used also by ELMB boards), they suffered from stability and performance issues in large setups over long CAN bus lines for the LAV detector. Efforts by the developers of the custom firmware as well as low-level protocol debugging brought only a moderate improvement. An alternative control channel was then exploited: a set of RaspberryPi mini computers connected over USB to the frontend boards was programmed to expose a control and monitoring interface over DIM, which allowed for

integration into the Run Control. DIM was also used to interface non-standard high- and low-voltage system for the STRAW subdetector.

A notable achievement is the part of DCS for the KTAG subdetector that performs a "pressure scan": it commands the NA62 Gas Control System, through the DIP protocol (uni-directional version of DIM) to set the gas parameters in the subdetector as necessary, and then automates the task of sequencing the parameters which otherwise would need to be executed manually by the operator using the Gas Control System console.

Infrastructure and Services

To reduce the maintenance effort, NA62 control systems share infrastructure and use available CERN services. Even though additional coordination is needed, technical expertise of others, for a wide range of technologies, is employed.

Numerous services provided by the CERN IT Department were employed to construct the infrastructure. A dedicated NA62 experimental network was set up, isolating the traffic for controls and data acquisition from the CERN General Purpose Network. Inter-network communication (such as the Technical Network or GPN) was configured to make the CERN central services (disk servers, domain controllers, DNS, DHCP or databases) available as necessary while securing the access to the experiment's equipment. Remote access to this internal network is provided by the Windows Terminal Server service, run on the CERN virtualization infrastructure, fully maintained by the service providers. The same virtualization infrastructure is used to form the integration test setup. The Oracle database service provides performant and highly-scalable storage for historical process data as well as for configurations. All the services come with the possibility of adaptation or upscaling and offer test and validation setups as well as expert's help.

Infrastructure maintenance for the supervision layer (hardware, operating system software installations, security, monitoring and backups) is in the hands of the experts from the CERN BE/CO group. The NA62 servers and consoles are maintained together with around 200 other production control servers and over 500 operator consoles by a team of experts.

The software and hardware for the Frontend Layer are specific to the equipment it controls, and hence their maintenance need to be under the responsibility of NA62 experts. Nevertheless, the computers were purchased with the help of the BE and IT Departments, to profit from established contracts for the long-term availability of spare parts and on-site support. Support for the PLCs, as well as the WinCC OA service, middleware software and standard protocols (OPC Server software) are provided by the EN department and guarded by maintenance and support contracts between CERN and hardware vendors.

The frontend computers, consoles and data servers are powered through UPS units providing up to an hour of autonomy in case of a power-cut.

SYSTEM DEVELOPMENT LIFE CYCLE

Control systems for physics experiments evolve constantly: subsystems are upgraded, replaced or added, hardware and software faults need to be resolved, infrastructures change, new versions of software packages installed. To optimize new operation modes new features are requested throughout the lifetime of the experiment. On the other hand, uncertainties in hardware prototyping often lead to late delivery of hardware and drastic changes in specifications and requirements. Requirements for operation may only be specified on very high level, and they evolve according to the phase of the experiment and operation experience. Planning and development of control systems, in particular with highly constrained manpower became complex, and the classical system development life cycle (SDLC) [8] workflows were therefore not applicable to NA62 controls projects. The boundaries between the classical planning, analysis, design and implementation phases are blurred and overlap. However, we tried the best practices from these models and came up with a method that tries to match the resources, constraints and requirements.

At the heart of the methodology is the requirement of maintaining a running system, while being able to constantly evolve and enhance it and fix issues. For that, we apply a policy of packaging all development into so called components, which are released with version numbers - the concept underpinning the JCOP Framework [4]. Engineering tasks are done on development machines, and changes are saved in the Subversion software repository. Then new features sets and bug fixes are released as a new version of the component, and installed in the integration setup to perform acceptance tests. Finally, they may be applied to a production system, with a possibility of a rollback.

This workflow goes against the need for rapid debugging and bug-fixing directly on the production system, often desired for operation. The changes prototyped in production need to be transferred to the code repository and go through the whole component release and acceptance process. While working under high time pressure, it is tempting to abandon the workflow, and proceed with development only on the production system. This results in software regression bugs whenever a new version is deployed. Potential time saving needs to be over-compensated by increased efforts in debugging.

The timing and phases of the development cycle are driven by the physics data-taking schedule. The system is only partially used during experiment shutdown time (winter/spring) which makes it the perfect time for scheduling development and maintenance tasks. Prior to the startup of the run, new requirements and new tasks for integration typically start to appear, as new hardware is becoming available. During the data-taking, feedback is given by operators and experts, who request new ad-hoc features to be necessarily added.

EXPERIENCE

The operation of the subsystems that are well advanced in their development, notably the Run Control and DCS for KTAG, GTK and LKr subdetectors was smooth. The availability of the infrastructure and services was very high, with smooth interventions and good coordination. Integrated operation of the detector through the Central DCS (rather than ad-hoc hardware control) has become regular, despite minor instabilities and rough edges. The priority areas where development efforts need to be intensified are the homogeneity and consistency of the hierarchical control (FSM tree) and consistent use of recipes stored in a configuration database. Experts demand more diagnostic tools for hardware communication and system integrity problems. Integrated with the supervision layer these should allow for better feed-back to operators. Overall stability of the, sometimes unstable, frontend software needs to be improved.

The component-based development method and integration tests worked well, even though it required significant initial effort from developers. Not only did it facilitate the integration of developments without affecting system stability, but also allowed for smooth migration to a newer version of SCADA software. Similarly, it makes the complete reinstallation of the system (in case of unlikely failure of hardware or infrastructure) possible within a short time.

A layer of NA62 common software components (e.g. widget libraries) allowed for new features to be easily deployed across all parts of the system. The use of standard hardware components supported by the JCOP Framework allowed for the rapid integration of significant parts of the system. For non-standard hardware, the use of DIM proved to be particularly effective, where applicable.

The development of certain systems benefited from having hardware that was at least partially installed before the physics run. This allowed the development chain to be completed in full before deploying on the production system and having the system operational in 2014.

We noticed that despite the fact that the core features and tools were planned and developed during the inter-run period, a significant amount of work was required during data taking. Many of the sub-system specific expert and diagnostic tools were requested as the need arose with the availability of new custom hardware. These needed to be implemented quickly to pursue the commissioning of the experiment.

Additional burden on development was induced by the non-standard, undocumented behaviour of hardware. Debugging and integration-testing needed to be interleaved with the development. Software that was initially modelled according to official documentation needed to be adapted (e.g. state transitions for the HV system).

We also stress the importance of the user requirement formulation process. Negligence, inaccuracies and "last-minute" changes led to important increase in development efforts or even the complete redesign of certain

subsystems. Combined with lack of developers, this delayed the delivery and commissioning tasks.

The complexity of the systems makes the learning curve for new contributors very steep and requires an education phase of a few months. A number of developers were trained only to leave the project shortly after they delivered initial (often not yet complete) results. In effect, it was not possible until now to put in place the collaboration model of the strong central team made of experienced users.

Drawing proper balance between (often very ambitious) requirements and available developer resources was among the main challenges in the project management.

CONCLUSION

We presented the architecture, project management and development life cycle for the NA62 control systems. By maximizing the reuse of existing components, applying standard solutions and best practices and using the services made available by CERN groups we were able to deliver working control systems, and perform their maintenance with minimal effort and very scarce resources. The need to enhance and maintain control systems throughout their life time was stressed by gathered experience. Constant effort and resources need to be assured in order to maintain the robustness of the system and to implement requests coming from the operators. High agility in project management is required to accomplish this task.

DATABASE ARCHIVING SYSTEM FOR SUPERVISION SYSTEMS AT CERN: A SUCCESSFUL UPGRADE STORY

P. Golonka, M. Gonzalez-Berges, J. Hofer, A. Voitier
CERN, Geneva, Switzerland

Abstract

Almost 200 controls applications, in domains like LHC magnet protection, cryogenics and vacuum systems, cooling-and-ventilation or electrical network supervision, have been developed and are currently maintained by the CERN Industrial Controls Group in close collaboration with several equipment groups. The supervision layer of these systems is based on the same technologies as 400 other systems running in the LHC Experiments (e.g. WinCC Open Architecture, Oracle). During the last two-year LHC Long Shutdown 1, the 200 systems have been successfully migrated from a file-based archiver to a centralized infrastructure based on Oracle databases. This migration has homogenized the archiving chain for all CERN systems, and at the same time has presented a number of additional challenges. The paper presents the design, the necessary optimizations and the migration process that allowed us to meet unprecedented data-archiving rates (unachievable for the previously used system), and liaise with the existing long-term storage system (LHC LoggingDB) to assure data-continuity.

INTRODUCTION

Storage and retrieval of historical process values and alarms is one of the invisible yet essential tasks of SCADA systems, and is always delegated to a dedicated *historian* or *archiver* tool. WinCC OA [1] offers three technologies for archiving: the file-based archiver ("valarch"), the simple database logging facility ("DBLogger", available as of version 3.13) and the high-performance, scalable Oracle database archiver ("RDB Archiver").

Even though a number of large control systems (Detector Control Systems for the LHC experiments) made use of the RDB archiver since the beginning, the control systems for infrastructure and LHC services initially chose to use the file archiver. The divergence in the choice of archiving technology stems from the requirements. The detector control system had to have the historical values available as the so called "conditions" in an Oracle database to make the data analysis possible, and it was this requirement that drove the collaboration between CERN and ETM to develop and optimize the database archiver. On the other hand, the priority for the LHC and infrastructure systems was the use of a stable, proven technology to maximize the reliable operation of the systems.

With an increasing number of control systems to deliver and maintain, and the need to scale-up applications to meet the challenges of Run II of the LHC,

it became clear that use of the file-based archiver reached its limit, and a migration to the more performant and centralized archiving architecture became a necessity. In addition, the centralized management of archived data offers several advantages such as better tools for data analysis, simplified management, easier handling of the SCADA server nodes, etc.

In the paper we present the process of migrating the 200 applications of the SCADA Application Service from file-based archiver to Oracle database archiver: the initial requirements, thorough testing and optimisation phase and proof of scalability, redesign of the long-term data storage architecture, actual migration effort. We will then summarize the current state of this enterprise.

EVOLUTION OF ARCHITECTURE

To enable the analysis of data from the control systems for the LHC, data needs to be transferred to a long-term storage Oracle database called the LHC LoggingDB designed to store large amount of data throughout the life time of the LHC [2].

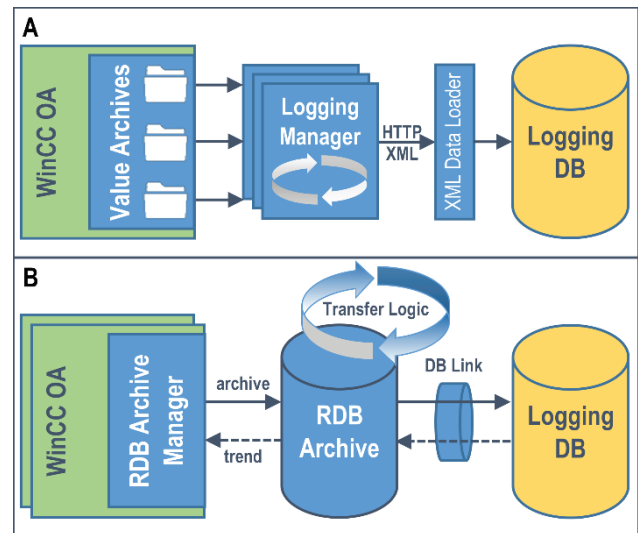

Figure 1: Archiving architecture: (A) with old logging manager; (B) with Oracle archiver and DB-link data transfer.

The evolution of the architecture for archiving is presented in Figure 1. System and process data retrieved by WinCC OA systems used to be fed to the LoggingDB using a dedicated program (Logging Manager) and complex infrastructure (XML Data Loader). This transfer was repeated every couple of minutes, and hence the data was available in the LoggingDB with a lag of

approximately 10 minutes. The reliability of the whole process was however affected by the complexity of the system and the significant number of points of failure. A number (sometimes exceeding 10) of WinCC OA archive manager programs needed to be configured in every control system, and configured correctly. Proper tuning of file archiver's parameters was also challenging for systems where the archive rate was varying during operation. Managing disk space and properly configuring data retention policies for disk-stored archive data was not an easy task. Many of these issues would vanish should one use the Oracle RDB archiver instead. Moreover, centralizing all archiving infrastructure in a single database service would simplify many management tasks.

With Long Shutdown 1 the LHC Quench Protection System had to be modernized in order to safely operate LHC magnets at the energy of 13 TeV to be achieved during Run II. The amount of data acquisition channels and data rates have been multiplied leading to the requirement to handle a sustained rate of 150 000 value changes per second, acquired and transferred to the LoggingDB. With the existing architecture, this was not possible to achieve. In addition, the XML Data Loader service of LoggingDB was going to be abandoned.

The new architecture for archiving was therefore proposed, based on the WinCC OA Oracle archiver and a central Oracle database (RDB Archive) providing service to all controls applications. Data transfer from the RDB Archive database to the LoggingDB would then be handled directly between the two databases, over a data link, using the already existing and recommended mechanism used by other clients of LoggingDB.

From a functionality point of view, the elements necessary to build the complete data path already existed and could be adapted using standard database development techniques and tools (views, database links, stored procedures, job scheduling) as well as standard features of the WinCC OA Oracle RDB archiver. However, initial tests uncovered that with existing tools and data organization, the archiving database would not be able to handle the throughput required. It became necessary to optimize the components of the system, starting at WinCC OA, through database schema and storage technology, up to the data-transfer database procedures.

Having data transferred from the RDB archive to the long-term LoggingDB storage resulted in a general policy for data retention for the former one: the data would only be kept for a limited period of time (typically three months). All the data that needs to be conserved for long term storage has to be transferred to the LoggingDB. This led to the formulation of another requirement: as the RDB and LoggingDB are already logically connected to assure data push, it should be possible to transparently retrieve historical data physically present in the LoggingDB from the RDB database; as a consequence, the operator could see the trends of historical values not limited to the three month data retention period.

RDB ARCHIVER OPTIMIZATIONS AND DATABASE REDESIGN.

To probe the performance of the archiver system a large scale test set-up was arranged for: a 2-node RAC Oracle cluster and around 50 servers capable of running up to 200 WinCC OA projects. A test database was provided by CERN's database service, with a highly detailed monitoring tool (Oracle Enterprise Manager) and the support of experts and database administrators interpreting the measured database metrics, providing guidance for tests and tuning database parameters. Similarly, the LoggingDB team provided a replica of their infrastructure and necessary expertise. This allowed us to proceed with integration tests and tuning of the performance of the transfer mechanisms.

The initial tests with the standard settings demonstrated that the requested performance would not be achieved. Even though the performance of data-insert was achievable [3], the readout of data was performing badly due to a bottleneck on the I/O subsystem (i.e. too slow access and low throughput to the disk-based large storage) of the database. Certain additional options like database block check-summing were identified as having high processing costs as well and were disabled.

The key ingredient for performance optimization was the optimization of the readout path, for the most critical task of data transfer to the LoggingDB. This operation requires that a vast majority of data stored into the RDB database is read-out within next 15 minutes to be pushed to the LoggingDB. Data needs to be accessed for all registered signals, one-by-one, for the specified period of time. This access pattern is common with another typical use case for SCADA systems, i.e. access to historical data for a specific signal, in a specific time period to make a trend plot of historical data, or to retrieve data for analysis.

The classical solution for this access pattern is the Index Organized Tables (IOT) data organization, whereby data is organized in the storage such that entries for the same primary key (in this case, the signal) are stored adjacently, making their lookup and retrieval faster. In the previous rounds of RDB archiver optimization efforts [3] the use of IOT was disfavoured for requiring more computing resources during the data-insertion process. We decided to re-visit the performance of IOT with modern hardware and software. To our surprise, the IOTs seemed to be only marginally (<5% of CPU load) more computing-intensive for workloads where 200 systems pushed their data at the accumulated data-change rate of 200 000 values/second. The estimated improvements in the data-readout performance was at least an order of magnitude. Moreover, due to the fact that the indexing data was stored in-line with data, storage space consumption dropped by more than 50% in certain cases [4].

This modification was introduced directly on the database schema, without impacting the source code, and with full compatibility. The optimization could therefore

be easily applied to new systems; for all existing systems the re-structuring of large existing data sets would be prohibitively time- and resource-consuming, hence the optimization could be performed for newly gathered data, while keeping the old data in unmodified structure.

However, the database still suffered from the I/O throughput problems related to the so-called REDU log size (auxiliary structure which allows for the restoration of the database in case of failure). The only viable method of reducing its size while still keeping the high data rate was to reduce the size of a row inserted to the database. Then we compared the average row size in the RDB Archive, 59 bytes when using IOTs (or 120 with no IOTs and with additional indices) to 19 bytes in the LoggingDB. It became clear, that a lot of reduction could potentially be achieved.

We reviewed the meta-data stored with every data row of archive data, and identified those containing non-vital information. An extension was then proposed to the already existing concept of WinCC OA *archive groups* to have the archived meta-data parameterizable. The implementation required modification of the database schema (layout of tables, stored procedures), and the WinCC OA Oracle RDB archiver (C++ source code, configuration panels). A prototype was developed at CERN, in collaboration with ETM, and put to test in a test set-up. Fast-changing data generating the bulk of the throughput was directed to the specially crafted custom archive group, where meta-data was truncated to the minimum, whereas data for other signals were archived into the default archive group, with all the details intact. The reduction in data throughput (and also disk space consumption) approached a factor of three, and allowed to keep the performance at the required level.

With a growing amount of data accumulated in tables over time, the performance of data queries may degrade. Even with the queries that access data according to index organization, scanning the huge index tree penalizes the overall performance. We reached for one more optimization level by applying time-based data partitioning. At the same time we also optimized the native data segmentation of RDB archiver, based on table sets and a view accumulating them, by applying pushed predicates (an Oracle hinting technique) on the view. As a result, again, the overall perceived performance of interactive data access as well as data retransmission improved significantly.

With the above optimizations in place we conducted the ultimate performance test to simulate the "worst case scenario" in a set-up mimicking the LHC Quench Protection System, with conditions presented in Table 1. WinCC OA systems were generating value changes with varying rates of changes per second; the data was stored into RDB Archive test database and then transferred to the integration database acting as the LoggingDB. After 24 hours of stable work at this nominal throughput we simulated the scenario of RDB database failure by shutting it down completely. As expected, WinCC OA projects reacted by storing pending data in a buffer

formed on their local disks. Then, the database service was re-established and we observed the buffered data being pushed to the RDB test database and then retransmitted to the LoggingDB test database at maximum achievable rate. At the same time, new data was still arriving at the steady rate.

Table 1: Test Setup for QPS Database-Recovery Scenario

WinCC OA projects	50
Archived signals	150 000
Accumulated data input rate (values/s)	200 000
Database outage duration	8 hours
Recovery time	2 hours
Peak recovery rate (insert + transfer)	1 mln rows/s

Even in a degraded mode, with only a single database node in service, it was possible to recover the buffered data. The transmission rate to the database was largely exceeding the rate at which data was generated, resulting in complete recovery in an acceptable time.

The results of these tests convinced us to deploy a production database service for our controls applications. Two dedicated (dual-node) databases were arranged for, maintained by CERN central database service. One database, called QPSR, is dedicated for the QPS applications due to the very high throughput and data reliability requirements. The other, called SCADAR, is used to archive data from all other applications.

Managing data partitions for around 200 database schemas, and executing partition-maintenance tasks (allocating new ones, dropping unnecessary ones) would not be possible without an automated tool. Partition management code contributed by the LoggingDB team was adopted, and then enhanced to allow for more dynamic control on partition allocation. Partition management allowed us also to easily configure and apply data-retention policies for each application: majority of them will have up to 90 daily partitions kept in a moving-window policy, and older ones would automatically be dropped. For some applications specific policies are applied according to requirements (e.g. hourly partitions and 20 days data retention period for the QPS). In any case, data that needs to be kept for longer is preserved in the LoggingDB.

As has happened already in the past, the collaboration between CERN and ETM allowed us to work with the source code of WinCC OA, and have the changes reviewed, accepted and included in the official WinCC OA distribution. Migration tools for existing projects were developed and made available to CERN users.

MIGRATION AND CURRENT STATUS

Migration of existing applications to the new archiving architecture infrastructure was a challenging task not only

from a technical standpoint, but also from a coordination point of view. Many of the tasks such as the reconfiguration of WinCC OA projects were automated using the central deployment tool [5]. Provisioning of database accounts (one per application) and maintenance of account credentials was streamlined yet still required manual coordination. A WinCC OA configuration and diagnostic tool for the LoggingDB transfer was developed from scratch and delivered on time to migrate the applications. Each application in turn needed to be migrated with human-supervision. A lot of attention was required when reconfiguring and initiating the LoggingDB transfer for every application to minimize possible data loss. Even though the migration was performed during the Long Shutdown 1 of the LHC (June-December 2014), many applications needed to be already available for pre-commissioning of the LHC (cryogenics, QPS), or were in production (Cooling & Ventilation). This required that the migration, requiring application downtime, is performed as quickly as possible (no longer than 4 hours). During the migration and first months of operation we encountered numerous performance and stability problems, mainly due to improper configuration of data-retention and time-based partitioning. These have since been resolved.

The migration was successfully completed in January 2015 for all production applications. Assistance was also given to the LHC experiments to upgrade their archiving systems and activate the new optimizations.

As of September 2015 there are around 200 WinCC OA projects which make use of the RDB archiver for historical data and data transfer to the LoggingDB. The statistics for the two production databases are summarized in Table 2. We consider that the old method of data transfer to the LoggingDB may therefore be decommissioned now.

Table 2: Statistics for Production Archive Databases

	SCADAR	QPSR
Projects (DB schemas)	140	48
Registered signals	2 000 000	135 000
Rows recorded/transferred	20 mln/h	400 mln/h
Storage space used	11 TB	11 TB
I/O throughput	40 MB/s	70 MB/s

Efforts are currently under way to generate and present daily reports with database statistics, so that the experts might detect unexpected changes in the data rates for their applications and also tune data-reduction (smoothing) algorithms. With the large number of applications to cover and huge data payload this is a non-trivial task.

CONCLUSION

The migration of archiving system for controls application in CERN SCADA Application Service was completed with success and on time for Run II of the LHC. Single, consistent archiving technology is deployed in production CERN-wide, and the need to maintain custom programs for the transfer to the LoggingDB was eliminated. After the initial adaptation and tuning period, the reliability and performance of the service is acceptable, and new functionality was delivered to users.

ACKNOWLEDGMENT

The success of the migration presented in this paper is a fruit of collaboration of experts from three CERN departments: Engineering, Information Technologies and Beams. We would like to express our particular gratitude to Oracle database administrators and LoggingDB experts: Zbigniew Baranowski, Luca Canali, Emil Pilecki, and Chris Roderick. We also acknowledge the development and testing effort of Kacper Szkudlarek, who worked as an ETM/Siemens openlab fellow on improvements in the WinCC OA Oracle archiver.

SIS18 UPGRADE: THE FAIR COMPLIANT RENOVATION OF THE DATA ACQUISITION SYSTEM FOR PARTICLE DETECTORS

R. Haseitl, H. Bräuning, T. Hoffmann, K. Lang, T. Milosic
GSI Helmholtzzentrum für Schwerionenforschung GmbH, Darmstadt, Germany

Abstract

In preparation of FAIR, several well-established beam instrumentation systems of the GSI heavy-ion synchrotron SIS18 and its connected high-energy beam transfer lines (HEBT) have to be modernised. In this contribution, the data acquisition upgrade of particle detectors such as ion chambers and plastic scintillators is described. This covers the replacement of outdated custom-built readout- and control hardware by modern FMC (FPGA mezzanine card) based I/O hardware, new multi-channel high voltage power supplies and a new data acquisition system (DAQ) for the VME based scalers. The latter will replace the old Kylix-based ABLASS software by LASSIE (Large Analog Signal and Scaling Information Environment) to fit into the new FAIR control system concept. LASSIE is based on FESA (Front End Software Architecture). FESA was originally developed by CERN and enhanced by GSI-specific modifications. Furthermore, the new particle detector DAQ will be able to take full advantage of the new FAIR timing system which is based on the White Rabbit protocol.

INTRODUCTION

For the upcoming FAIR project, many parts of the existing GSI facility have to be modernised. The new control system for FAIR is already operational and currently under test by different GSI departments. It is based on the FESA framework [1] which originally was created by CERN and is now being developed in a collaborative effort with GSI. FESA controlled devices are automatically integrated in the control system and can be accessed in a standardised way. If existing hardware has to be replaced or new hardware is installed, a FESA class is programmed to provide future-proof operation. Recently, a renovation project was started to replace outdated high voltage power supplies and to upgrade the readout software called ABLASS [2] of the SIS18 and High Energy Beam Transfer (HEBT) particle detectors.

HIGH VOLTAGE CONTROL FOR PARTICLE DETECTORS

Several particle detector systems need high voltages (HV) to operate. Currently three main types of particle detectors are used by the GSI beam instrumentation (BI) group in the synchrotron and the HEBT: secondary electron monitors (SEM), ionisation chambers (IC) and plastic scintillators (SC). It is possible to mount these three detectors onto a single pneumatic actuator which is called Particle Detector Combination (PDC). Along the existing synchrotron and the HEBT 13 PDCs are installed. Besides the PDCs, also other devices like beam loss monitors or profile grids need

HV resulting in over 120 required channels. The different detectors need specific voltages ranging from -1500V to +1500V.

The existing HV system is based on SY127 40-channel crates by the company CAEN [3]. The crates have been in operation for over 20 years and replacement modules are slowly phasing out. Moreover they are controlled via the slow CAENET bus which can delay new settings for HV channels.

Succeeding HV systems from the companies Wiener [4], iseg [5] and CAEN are already installed at GSI and prepared for operation. These systems provide Ethernet enabled controllers and various HV modules with different voltage and current ranges.

Although both systems are controlled over Ethernet, they use different protocols: The crates from Wiener, called MPOD, are accessible via SNMP (Simple Network Management Protocol). The HV modules for MPOD are manufactured by the company iseg and are also fully controllable via SNMP. At GSI, two different MPOD systems are used: The 'MPOD Mini' crate with 4 slots (see Fig. 1) and the standard MPOD crate with 10 slots for HV modules. The most commonly used HV modules at GSI are 16-channel modules providing a positive or negative voltage up to 3000V at a maximum current of 3 mA.

Figure 1: MPOD mini crate with four HV module slots. The lower two slots are populated with iseg modules.

CAEN features a different communication approach: The company provides proprietary libraries to interface with the hardware via Ethernet. The libraries are available for Windows and Linux and can be easily integrated into custom applications like FESA classes. The library offers an efficient monitoring feature for the current line of crates (SY4527 and SY5527). The so-called 'event mode' allows subscriptions to all available crate, board and channel properties. Whenever one of the subscribed values like current, voltage or status registers change, the hardware notifies the application of the change via the library. This way, the devices don't need to

ISBN 978-3-95450-148-9

be polled periodically reducing unnecessary network load significantly.

Due to the different communication methods, two separate FESA classes have been created to control Wiener and CAEN HV systems respectively. The FESA classes were designed with a common interface in mind. In most cases, it is not important for the control system or a human operator which underlying hardware is providing HV to a device. Using the same software interface in FESA, the hardware is completely hidden from the upper control layers. When voltages, current limits or ramping speeds are set, the FESA class for the specific HV system passes the values to the hardware over the hardware-specific protocol. Any settings or status bits that are specific to one particular HV system are mapped to special fields in the FESA classes and can be controlled through an expert's GUI.

DATA ACQUISITION UPGRADE FOR PARTICLE DETECTORS

The readout of the different particle detector types follows a common principle: Electrical pulses are counted in VME scaler modules. Several VME crates are equipped with Struck SIS3820 scaler boards providing 32 channels each.

Previous DAQ System

The ABLASS system (A Beam Loss measurement And Scaling System), in operation since 2004, is collecting the scaler values and presents them in various GUI applications in the main control room. It is a Kylix based application and hard to adapt to new hardware and software conditions like the new control system. Critical system components like custom-built timing receivers will be replaced with White Rabbit [6] timing receivers in the near future. Therefore, also ABLASS is replaced with a new system called LASSIE (Large Analogue Signal and Scaling Information Environment) [7].

Software Upgrade: LASSIE

LASSIE is already in operation and gradually replacing ABLASS. An overview can be seen in Fig. 2. The signals of the detectors are pulse shaped and fed into VME scaler modules in three VME crates. The readout is done with FESA classes which provide the measurement values to the control system and GUI applications. Two crates are responsible for the readout of ICs, SEMs and SCs detectors. The third crate is used for advanced signal analysis. It provides the possibility to sample dedicated channels with higher sampling rates. Several GUI applications in the main control room allow the timing related correlation of multiple detector channels. Additionally, other data sources like magnet ramps or signals of rf systems (e.g. synchrotron cavities) can be displayed in conjunction with detector data to provide a powerful tool to the machine operators.

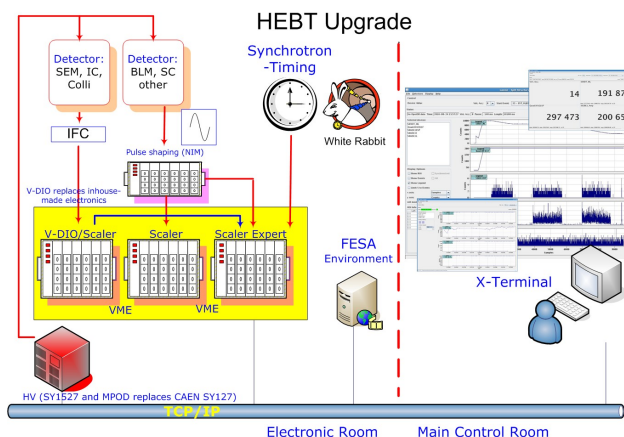

Figure 2: LASSIE overview. Signals from the hardware are fed into scaler modules in three VME crates. FESA classes running on the crates acquire the values and provide the data to the control system or specialised GUI applications.

Hardware Upgrade: V-DIO

SEMs and ICs do not provide a countable signal directly. They provide their measurement value as an electric current which is converted by a specialised hardware called IFC (Current to Frequency Converter) [8] into a countable signal.

The IFC hardware has several discrete control lines for calibration, test signal activation, range setting and polarity setting. Besides the countable measurement signal, it also provides hardware status information via separate lines for overload, device id and gas flow.

The IFCs have been integrated into the old GSI control system using a in-house built hardware setup. The upcoming new control system and the lack of replacement parts for the old hardware made the development of a replacement solution necessary: The VME Digital IO (V-DIO) system was developed by the company MagentaSys [9] based on GSI specifications.

The V-DIO System

The V-DIO system is the new control hardware for the IFCs at GSI and FAIR. To make it more versatile, also a 'general purpose' mode has been implemented, bringing NIM or TTL inputs and outputs for arbitrary applications into the control system. The VDIO system consists of several boards which can be seen in Fig. 3:

- FMC (FPGA Mezzanine Card): Provides ten outputs, two inputs and status LEDs at the front panel.
- SVEC (Simple VME FMC Carrier): Carrier board for up to two FMCs. It was designed by CERN as a White Rabbit Timing receiver and FMC carrier board [10].
- RTM (Rear Transition Module): A 80mm VME RTM board offering four slots for mezzanine boards.
- Mezzanine boards: Mounted on the RTM and connect directly to an IFC. They can be switched to 'general purpose mode' to provide I/O lines for arbitrary use. A close-up can be seen in Fig. 4

Figure 3: The different boards of the VDIO system. From left to right: small FMC board with front connectors mounted on a 6 HE SVEC VME board, RTM carrier with four rear mezzanine boards, deported IO baseboard with attached mezzanine, single rear mezzanine board.

Figure 4: Close-up of the mezzanine board.

- Deported I/O: Optional external baseboard to avoid long IFC cables. It is connected to a special mezzanine on the RTM via separate Cat 5 patch cables for data and power which can be up to 350m long. For data transmission, the I²C protocol over RS485 is used.

The IFCs are directly attached to the mezzanine boards on the RTM module. The SVEC board hosts an Spartan 6 FPGA which is able to route any signal from the mezzanines to the front connectors of the FMCs. From the FMC, the signal is plugged into a scaler module for pulse counting.

Moreover, the mezzanine boards provide power to the IFC electronic. The flexibility of the system is very useful for debugging purposes: The signal of an IFC can be sent to the control system through one FMC output and can be observed using an oscilloscope or an expert system on a second output in parallel.

The front FMC connectors have even more capabilities: They can provide signals with different frequencies and can be logically combined with any input of the FMC modules.

Besides the functionality to control an IFC, the V-DIO hardware can provide and acquire arbitrary I/O signals. Each mezzanine board has 16 I/O lines which can be individually configured as in- or output at TTL or NIM level or as an open-collector output.

The whole V-DIO setup is controlled via FESA. The signal routing from the mezzanines to the FMC front connectors is freely configurable using the FESA instance file. This is an XML-based, editable file to configure the FESA class at startup. To make FESA development for the VDIO system easily adaptable, all hardware-specific functionality has been separated into an external C++ library. This way the IFC and 'arbitrary I/O' modes of the V-DIO system can be implemented quite easily in any application.

CONCLUSION AND OUTLOOK

During the 2015 beamtime, only the low energy beamlines of GSI have been in operation. Therefore, all HV dependent detectors in the synchrotron and the HEBT lines have been upgraded to the new HV system without machine interrup-

tion. The new system is currently under extensive testing and will be put in operation with the next beamtime starting in March 2016. LASSIE is already running since 2011 and replacing the old ABLASS system successively. The IFC hardware will be upgraded to the new V-DIO system after the 2016 beamtime, since White Rabbit Timing is not yet available at the existing SIS18 synchrotron.

UPDATE OF POWER SUPPLY CONTROL SYSTEM AT THE SAGA LIGHT SOURCE STORAGE RING

Y. Iwasaki[#], T. Kaneyasu, Y. Takabayashi, S. Koda, SAGA Light Source, Tosu, Japan

Abstract

The control system for the SAGA Light Source storage ring power supplies is being upgraded to increase the ramp-up speed and allow the stored beam energy to be easily changed. By replacing the CPU module in the PLC used to control the power supplies, the ramp-up time was reduced from 4 to 2 minutes in a test bench prepared for the upgraded system. Until now, the allowable beam energy has been restricted to certain fixed values during ramp-up operation due to the original specifications of the PLC ladder program. To operate the storage ring at an arbitrary energy, the algorithm used in the PLC program was changed. The resolution at which the energy can be changed is less than 1 MeV. The upper layer of the control system, which uses National Instrument LabVIEW and ActiveX CA, was also reconstructed to produce a flexible GUI. Preliminary measurements of the energy dependence of the beam size and lifetime were carried out using the updated control system.

INTRODUCTION

The SAGA Light Source (SAGA-LS) is a middle-scale synchrotron radiation facility, at which electrons from a 255 MeV injector linear accelerator are injected into a 1.4 GeV storage ring [1]. The electrons are ramped up to 1.4 GeV in the storage ring during a period of 4 minutes. The storage current is 300 mA. The storage ring lattice is a double-bend type with 8-fold symmetry (see Figure 1). The power supplies for the storage ring magnets are listed in Table 1.

Figure 1: Unit cell of SAGA-LS storage ring.

The control system for the power supplies is constructed using personal computer (PC) and programmable logic controller (PLC) [2]. National Instruments LabVIEW is used for the graphical user interface (GUI). ActiveX CA [3], which provides EPICS channel access for Microsoft Windows, is adopted as the data communication protocol between server and client PCs.

[#]iwasaki@saga-ls.jp

Although the original control system worked stably, two problems existed with it. The first was the ramp-up speed. The ramp-up pattern file consists of 10,000 elements for each main power supply, and is stored in the internal register of a CUP module in the PLC. The ramp-up speed was limited by the performance of the CPU module. The second problem was a restricted accelerated beam energy. The allowable energy was fixed at certain values due to the original specifications of the PLC ladder program. We therefore replaced the CPU module: F3SP58-6S (YOKOGAWA Electric Corporation) with F3SP76-7S, and modified the algorithm of the ladder program slightly to allow arbitrary energy settings. The upper layer of the control system using LabVIEW and ActiveX CA was also reconstructed. Preliminary measurements of the energy dependence of the beam size and lifetime were performed using the updated control system.

In this paper, we describe the design of the control system for the power supplies at the SAGA-LS storage ring, the control algorithm and GUI, and the preliminary experimental results.

Table 1: Power Supplies for SAGA-LS Storage Ring Magnets

Power Supply	Control Interface	Number
Bending	16bit Digital	1
Quadrupole	16bit Digital	7
Sextupole	16bit Digital	2
BM-Corrector	Analogue , Digital	16
Q-Corrector	Analogue , Digital	40
Steering	Analogue , Digital	80

CONTROL LAYER FOR POWER SUPPLIES

A schematic view of the control layer for the power supplies is shown in Figure 2. Local control of the power supplies is performed by PLC. The PLC consists of one CPU module, an Ethernet module, I/O modules, and optical link bus modules. One CPU module controls all the power supplies of the storage ring. Sub-modules of the PLC are connected to the main unit with optical link bus modules. At the SAGA-LS storage ring, synchronization among power supplies is important, since the electrons are ramped up from 255 MeV to 1.4 GeV in a short time. The PLC outputs 10,000 set points for each

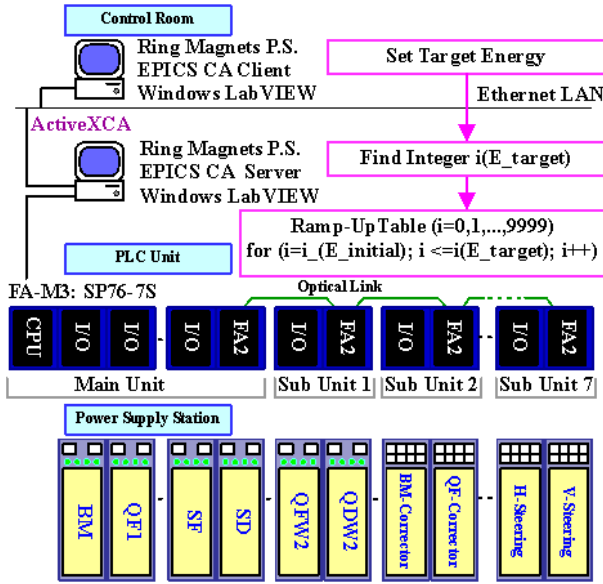

Figure 2: Control layer for power supplies.

of the main power supplies (bending and quadrupole magnets) during the ramp-up period. The configuration of the PLC (one CPU module, I/O devices, and optical linked sub-modules) ensures the synchronization among the power supplies.

Since the lattice of the storage ring is compact and the bending and quadrupole magnets are strongly excited (e.g., the maximum magnetic field produced by the bending magnet is 1.46 T and the maximum magnetic gradient in QF1 is 25 T/m), the ramp-up pattern for these power supplies is not linear. The sextupole and analogue controlled power supplies (BM-correctors, Q-correctors, and steering magnets) are excited in proportion to the QF2 power supply, because the magnetic field produced by the QF2 magnets, for which the maximum magnetic gradient is 18 T/m, increases in proportion to the excitation current. As a result, these magnets are excited linearly with the beam energy.

The server PC running ActiveX CA with the PLC acts as a PC IO controller (PC-IOC). The ActiveX CA client is used to access the server PC with the Process Values. The server and client applications are developed in LabVIEW.

In 2014, two new power supplies (QFW2 and QDW2) were installed for a second superconducting wiggler. The I/O and optical link bus modules for these power supplies were added to the existing PLC modules. An overview of the project for the second superconducting wiggler has been previously reported [4].

ALGORITHM AND GUI

The beam energy E in the storage ring is a function of the excitation electric current I in the bending magnet power supply,

$$E = f(I).$$

The function $f(I)$ is determined from magnetic field measurement data. The power supply current for the

bending magnets is determined by an integer i ($i = 0, 1, \dots, 9999$) stored in the internal register of the PLC,

$$I = g(i).$$

Thus, the beam energy is expressed in terms of i as

$$E = f\{g(i)\} \equiv E(i).$$

If the target beam energy E_{target} is given, then the integer i_{target} is easily obtained as

$$i_{\text{target}} = E^{-1}(E_{\text{target}}).$$

Figure 3 shows the subroutine for finding i_{target} , which is estimated by linear interpolation of $E^{-1}(E_{\text{target}})$ and rounded off to the nearest whole number.

Figure 3: Subroutine for finding an integer for target energy (LabVIEW).

This calculation is performed in the server PC. When the button “Set Target Energy” is pushed on the client PC, the target energy value is sent to the server PC, which then calculates i_{target} and sends it to the PLC. During the ramp-up period, the PLC outputs the ramp-up pattern data for each main power supply from i_{initial} to i_{target} (see Figures 2 and 4). The accelerated beam energy can be easily changed using this PLC and PC based control system.

Because the ramp-up pattern consists of 10,000 set points for each main magnet for energies between 255 MeV to 1.4 GeV, the resulting energy resolution is less than 1 MeV. However, the absolute accuracy of the beam energy depends on both the precision with which the magnetic field produced by the bending magnets can be

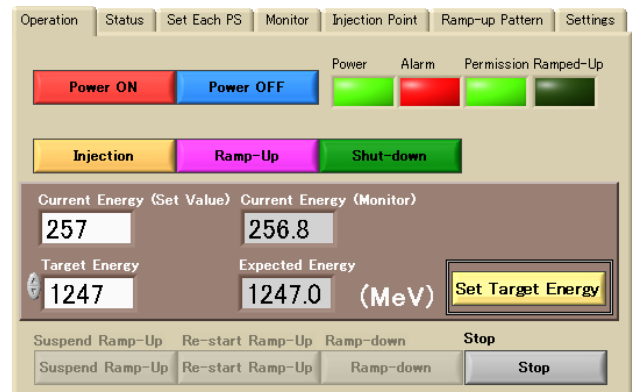

Figure 4: GUI of energy ramp-up client PC.

measured and the form of the function f in the formula $E = f(I)$. In addition, the stability and the setting precision of the bending magnet power supply influences the beam energy. The absolute energy should be calibrated using another method. At a nominal beam energy of 1.4 GeV, the actual energy was estimated to be 1417 ± 4 MeV by a laser Compton scattering experiment [5].

PRELIMINARY ENERGY DEPENDENCE EXPERIMENTS

Preliminary measurements of the energy dependence of the beam size were carried out using the synchrotron radiation (SR) interferometer system [6]. Figure 5 shows the transverse beam size for injection energies of 255 MeV to maximum energy of 1.4 GeV. Since the SR interferometer system was optimized to measure the beam size at 1.4 GeV, the results indicating horizontal and vertical beam sizes of greater than 800 and 1000 μm , respectively, are unreliable.

At the same time, the beam lifetime was measured. The product of the beam current and lifetime is shown in Figure 6. The peak at an energy of about 0.6 GeV may be

Figure 5: Dependence of transverse beam size on energy from 255 MeV to 1.4 GeV.

Figure 6: Energy dependence of product of beam current and beam lifetime.

related to the increase in the vertical beam size. Since the betatron tunes strongly vary during the ramp-up period (i.e., horizontal: 0.13, vertical: 0.11) at the SAGA-LS storage ring, quantitative estimation of the beam lifetime should take into account the optical modulation at each energy. Detailed measurements and quantitative estimations of the energy dependence of the beam size and lifetime have not been performed yet. However, energy-dependent experiments can be easily carried out using the updated power supply control system. In addition, we plan to investigate the beam energy dependence of ion trapping and intra-beam scattering (IBS) effects using this system.

SUMMARY

In order to increase the ramp-up speed of the SAGA-LS storage ring, we replaced the CPU module in the PLC. The ramp-up time was reduced from 4 to 2 minutes in a test bench prepared for the upgraded system.

The algorithm and the GUI for the control system were also modified to change the operating energy of the storage ring. The resulting energy resolution was less than 1 MeV. The accelerated beam energy can be easily changed using this PLC and PC based system.

Preliminary measurements of the energy dependence of the beam size and beam lifetime were carried out using the updated control system. The observed lifetime peak at about 0.6 GeV may be related to an increase in the vertical beam size. In a future study, we will investigate the beam energy dependence of ion trapping and IBS effects at the SAGA-LS storage ring.

TESTING FRAMEWORK FOR THE LHC BEAM-BASED FEEDBACK SYSTEM

S. Jackson, D. Alves, L. Di Giulio, K. Fuchsberger, B. Kolad, J. Pedersen
CERN, Geneva, Switzerland

Abstract

During the first Large Hadron Collider (LHC) [1] shut-down period, software for the LHC Beam-based Feedback Controller (BFC) and accompanying Service Unit (BFSU) [2] was migrated to new 64-bit multi-core hardware and to a new version of CERN's FESA [3] real-time framework. This coincided with the transfer of responsibility to a new software team, charged with readying the systems for beam in 2015 as well as maintaining and improving the code-base in the future.

In order to facilitate the comprehension of the system's 90'000+ existing lines of code, a new testing framework was developed which would not only serve to define the system's functional specification, but also provide acceptance tests for future releases. This paper presents how the BFC and BFSU systems were decoupled from each other as well as from the LHC plant's measurement and actuator systems, thus allowing simulation-data driven instances to be deployed in a test environment. It also describes the resulting Java-based Domain-Specific Language (DSL) which allows the formation of repeatable acceptance tests.

INTRODUCTION

LHC operators rely on a feedback system in order to stabilise/correct and adjust the beams' closed-orbit, betatron tune, energy and radial loop [4] during the various stages of the operational cycle from filling to flat-top. The system is triggered at up to 25Hz by input signals from over 1'000 Beam Position Monitors (BPM), along with 6 tune measurements from Base-Band Q (BBQ) [5] measurement systems. The BFC sanitises this data, before calculating the necessary currents to send to various LHC steering dipoles and quadrupoles - The effects of which should be observed in the next iteration of the feedback loop (via the BFSU 1Hz instrumentation layer).

When a new team took charge of the existing codebase, it was apparent that many changes would be required to port the code to new 64 bit hardware, and to migrate to the latest FESA framework. This meant that testing the new software before the LHC start-up would be imperative. Testing using real signals from over 1'500 I/O devices round the LHC would not only be difficult during the machine's shutdown, but would be impossible when the LHC became operational. Consequently it was decided to create a testing framework which could emulate the BFC's input signals, the effect of which could then be observed via the BFSU at 1Hz. Test cases would then be written, for asserting that the BFC and BFSU were reacting correctly to the conditions defined by the

test. It was also acknowledged that test developers may not be software experts, and may therefore be uncomfortable learning how to use a potentially complex API. In this context, a descriptive DSL would abstract the testing framework to be easily used by test creators.

Realising the framework, would not only require new testing code, but would entail many changes to the BFC and BFSU themselves, in order to allow instances of the software to be deployed outside their specialised operational hardware. Also, spoofing the BFC's input data would require relaxing of the BFC's data integrity checking mechanisms without compromising security in the operational system.

ADAPTING TO LIFE IN THE LAB

During 2014, the BFC and BFSU were ported to the new 64 bit architecture / FESA3 framework and the team had a release candidate ready for testing. Before any testing framework could be developed however, several changes to the software would be required to allow the software to be tested.

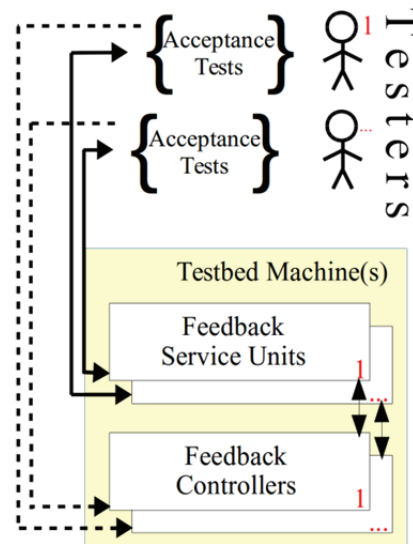

Figure 1: Software adapted so any number of BFC / BFSU pairs can be started, even on the same machine.

The new operational feedback system comprises of 2 multi-core Linux based (with Red Hat's MRG* kernel extension) HP Gen8 Blade machines. In order to assure real-time performance, the BFC is isolated from the LHC control system, with the BFSU acting as a client-facing data / setting proxy. A 2nd Ethernet link is used to transfer (~130Mb / sec) data between the BFC and BFSU

* Messaging Real-time Grid.

during operational conditions. Reproducing this exotic hardware configuration would be both costly and unnecessary for our testing framework, so the code was modified to allow any BFC instance to be connected to any BFSU on any IP address including loopback (i.e. both on the same machine). Deploying in loopback proved problematic with the original software design, as the BFC and BFSU were both bound to similar network ports, so the 36 existing hard-coded port numbers were converted into offsets with respect to a single configurable base-port. This way, any number of BFC / BFSU unit pairs could be started on the same machine without having any port clashes (see Fig. 1).

The BFC design is different to most of the real-time software developed for the LHC due to its tight real-time constraints. Consequently, the system was compiled and linked on the operational hardware itself, using machine optimized compilations of CERN's Root libraries. This was not ideal for compiling and testing via the new framework, so the system build was adapted to use the standard SLC6 environment. It was assumed that with the latest 64 bit hardware increasing CPU power from 4 core to 24 core machines, real-time constraints would not be compromised.

TEST SYSTEM OVERVIEW

While testing a system would traditionally start with writing unit tests for individual components and then building integration and acceptance tests on top of these fundamentals, the approach taken here was a bit different. Starting with unit tests was problematic, because classes on the BFC have a high inter-dependency. Our main goal was to bring the system (focussing mainly on the BFC) into a test harness in order to observe and verify the global behaviour while gaining confidence for future changes. To accomplish this, it became clear that the BFC's I/O channels (UDP packets, described later) could already provide us with a clean way to inject our tests. This choice has the following advantages:

- Minimal changes required in the BFC.
- UDP is language independent; we were free to choose any language for the test system.

Given the option of choosing any language, we decided to use Java as the implementation language for the testing framework, for the following reasons:

- Java is widely used in the LHC environment, so more people will be able to easily use and extend the framework providing more tests.
- Interactions with other parts of the control system (e.g. settings management) are natively possible in Java. This allowed us to easily write tests involving operational settings and/or even verify consistency of such settings with the framework.
- It allowed us to gain first experience in the behaviour of Java in a real-time environment.

An important aspect taken into account in the design of the testing framework was the fact that tests of different

layers would be required. We identified the following types of tests:

- **FESA mechanics:** e.g. asserting that setting a value in one FESA property has the desired effect in another. Despite the fact that this functionality is only for interfacing with the control system, these tests turned out to be the most frequently required, due to the complexity of the BFSU's API.
- **Communication:** e.g. send some predefined values for an orbit and check if the values are correctly processed through the layers.
- **Control loop behaviour:** e.g. send a constant orbit verifying the resulting corrections. From an operational viewpoint these are the most interesting tests, as they highlight instabilities and allow error predictions.

These different abstraction layers are reflected in the testing framework's DSL as described later.

PLANT VIRTUALISATION

Without input signals the feedback system does nothing apart from reporting timeouts. To operate correctly, the BFC needs the following (see Fig. 2):

- **BPM packets:** Sent at 25Hz from the BPM systems, they contain position measurements (~500 values per beam and plane).
- **BBQ packets:** Sent between 1 and 100Hz from 3 BBQ systems, they contain the measurement values for the tunes (1 value per beam and plane).
- **Orbit trigger:** Hardware trigger at 25Hz, which starts orbit averaging in the BPMs, and also data collection in the BFC. On reception of this trigger, the BFC opens an acceptance window (~10 ms), in which arriving packets are processed for one feedback iteration.

In order to test the system, the testing framework must virtualise these BPM, BBQ and Orbit Trigger input signals as well as capture the output signals (to avoid sending to the correction magnets). Luckily, most of the input signals already arrive via UDP packets, so spoofing the data was feasible. The only exception in the new feedback system is the Orbit Trigger which arrives via a cable from the Beam Synchronous Timing (BST) [6]. To facilitate the spoofing of this input signal, code was modified in the BFC, and the trigger's interrupt was handled in a dedicated thread which delivered the trigger into the BFC's main loop via a UDP packet. Although this added a small jitter to the trigger, the additional overhead of passing through a local UDP port was deemed acceptable.

All the operational I/O systems communicating with the BFC are written in C++, and the UDP packets' content are declared as C structs. Our chosen language for the test however was Java, so these structs had to be emulated by Java classes which could be de-serialised / serialised to / from a stream of bytes which mimicked exactly the structs from the real systems. Also, the contents of our packets had to adhere to the strict data

quality rules specified by the BFC, including information used for diagnostics. Even if we were not interested in testing things such as temperature from our framework, this diagnostics data must be within sane limits.

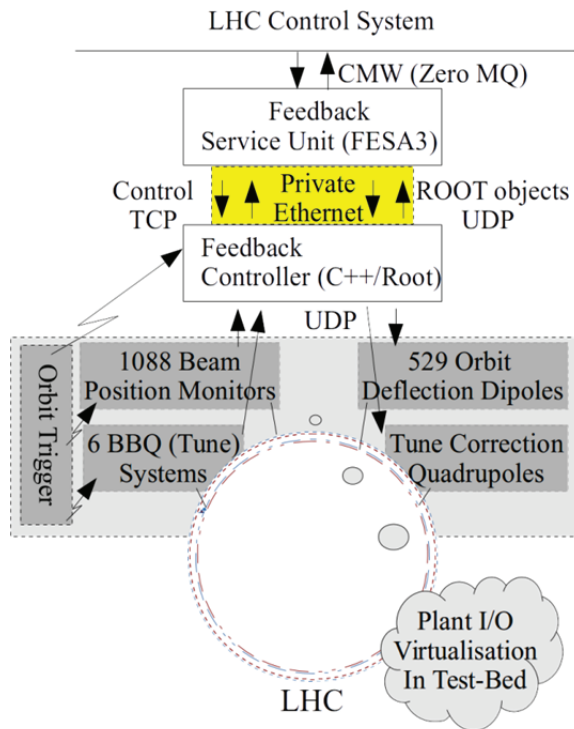

Figure 2: Framework must virtualise LHC I/O signals and decouple from private Ethernet dependency.

TEST FRAMEWORK ARCHITECTURE

Figure 3 shows the core components of the testing framework and their different layers as follows:

- The main work and internal logic is done in the service layer. It combines data from the lower layers and provides convenient methods for the upper layers for dedicated tasks (e.g. ‘create an orbit with certain properties’).
- The lowest *backend* layer contains various adaption / delegation classes for subscribing to FESA devices, creating simulated orbits, reading settings, creating UDP packets, etc.
- From a functional perspective, the service layer would be sufficient to write the tests. However, to make tests more expressive and readable by non-programmers, we followed domain driven principles and put a layer of a Java-embedded Domain Specific Language (eDSL) on top. It was implemented as a fluent Java API, using method chaining as the main syntax concept. The starting points for all the fluent clauses are grouped by topic in classes (e.g. OrbitCreationSupport for clauses which create different orbit types).

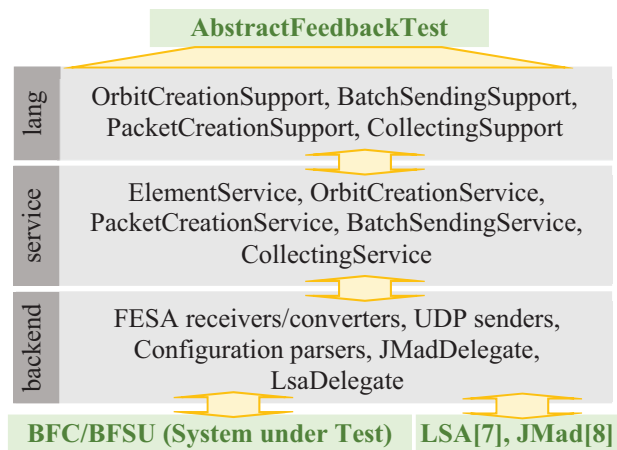

Figure 3: Overview of the testing framework architecture.

As a framework to execute our tests, we chose the JUnit framework, which simplified test creation and report generation as well as using well established matching libraries (hamcrest, assertj) to formulate assertions. The framework provides an abstract class, *AbstractFeedbackTest*, which can be used as a base class for all tests. It is preconfigured with instances of each support class and provides delegation methods to them, so that inheriting tests can formulate fluent clauses without instantiating any additional objects.

THE DOMAIN SPECIFIC LANGUAGE

To get a general impression of the different features of the testing framework and the eDSL in particular, we will show some selected examples. Since the execution of the tests is based on JUnit, the skeleton of a test will always look something like this:

```
public class ExampleFeedbackTest extends AbstractFeedbackTest {
    @Test
    public void assertThatSomeValueIsCorrect() {
        /* Test Code goes here */
    }
}
```

Most tests involve communicating with the BFC, so the language provides the means to construct packets of a particular type and send them:

```
Burst burst = dummyBpmPackets(NUMBER_OF_PACKETS_PER_BURST,
    constant("X"), BEAM_POSITION);
prepareSendingOf(burst).during(5, SECONDS).
    every(40, MILLISECONDS).andStartAndAwait();
```

A burst represents a set of packets which simulate the state of the LHC at a moment in time (i.e. one orbit). A more meaningful test would be to construct an orbit with all zero values and send it (this time using defaults for duration / period, spawning the sending in the background, checking the publishing from the BFSU and then awaiting the termination of the sending):

```
prepareSendingOf(zeroOrbit()).andStart();
MultibeamOrbit acquiredOrbit = from(MultibeamOrbit.class).
    skip(1).and().awaitNext();
awaitLastSending(); /* assertion here */
```

Creation of other orbits is also supported. e.g. Constant single outliers or (artificial) flat orbits with constant values:

```
MultibeamOrbitReading first =singleOutlierOf(1.2f, MILLIMETER).  
    at(Bpm.ofName("BPM.24R2.B1"), HORIZONTAL);
```

```
MultibeamOrbitReading second = sameValueOrbitOf(4, MILLIMETER);
```

Finally, the language also provides a convenient way to retrieve and manipulate FESA properties and fields.

```
String opticsName = from(OPTICS).doGet().getActiveOpticsName();
```

```
to(ACTIVE_OPTIC).partially().setFetchOfC_object(true);
```

This last feature turned out to be very useful for other applications and will be extracted in the near future to a dedicated package to facilitate its re-use by others.

RESULTS

Within minutes of first beam, the new feedback system was supplying operators with orbit data, as well as successfully applying orbit and tune feedback. When operators tried to load different reference optics however, the new software didn't behave as expected. Despite testing most of the basic system functionality, the framework didn't have a dedicated acceptance test for reference optic changes, but the team were able to quickly reproduce the phenomenon in the testbed, solving the problem without further disturbing operations. Another problem not covered by the tests involved a rogue BPM system sending corrupted timestamps which caused the Software Interlock System[9] to dump the beam several times. Again, the team reproduced the phenomenon in the testbed, and quickly supplied a patch to fix the problem operationally.

A weakness of the framework was highlighted during the first few months of operation, when problems with the delivery of timing events occurred during optics reference changes. In this case, the testbed was unable to reproduce the problem unless an accompanying test framework for the timing event delivery was also available. In the long term, it is hoped that such a framework will become available, but in order to solve this issue, the operational system had to be used to diagnose and solve this problem.

FUTURE PLANS AND OUTLOOK

The acceptance test coverage is still relatively low, so the team plans to continue developing new tests for existing functionality as time allows. However, any new feature added to the BFC or the BFSU must have accompanying acceptance tests if possible.

During the next 12 months, the team plan to implement a new streamlined BFSU API which will use new features now offered by the latest FESA3 framework. The delivery of this new API will be progressive, and released in parallel with the existing API. In order to assure that the new API is functionally equivalent, the plan is to duplicate the existing tests and adapt them to the new API. A third set of tests will then assert that the results of the tests with the old API and new API are equal.

Presently, the output of the BFC in test conditions is muted. There is an ambitious plan to capture the BFC output (UDP packets destined for the corrector magnets) within the acceptance test, and combine it with the input signals for the next iteration. With this in place, we

effectively close the feedback loop within the testing framework.

There are also plans to use the experience from this testing framework to test other systems. Several systems such as the BBQ tune measurement system and the LHC beam-loss monitoring system will also require porting to the new FESA3 framework, and will therefore benefit from offline testing. Whilst the scope of tests on these systems will be less than for the feedback system (they rely on dedicated hardware), basic I/O tests can still be performed. In the long term, these systems could also benefit from more extensive acceptance tests, if like the feedback system, the systems are re-written to accommodate simulated data in place of acquisition cards for example.

CONCLUSION

The testing framework enabled the new software team to understand the code they inherited, and provided functional documentation in the form of test assertions. The tests highlighted many bugs which would probably have gone un-detected until the LHC start-up; bugs which would have hindered the operators during a very critical period. Importantly, the testbed has also given the new software team the confidence to roll out several changes to the software during 2015, citing the testbed assertions as confirmation that the new release should be acceptable. Of course the testbed will never guarantee that a new release is bug-free, but the confidence is certainly increased.

The resulting framework has proved that one of the most complex pieces of software in the LHC can be tested offline, and should serve as an inspiration to develop other test frameworks for other critical systems at CERN.

ACKNOWLEDGMENT

The team would like to thank Jörg Wenninger from the Operations group, Vito Baggiolini from the Controls group and Markus Zerlauth from the Machine Protection and Electrical Integrity Group for their considerable contribution of time and advice during the project.

Abstract

WinCC Open Architecture (WinCC OA) is used at CERN as the solution for many control system developments. This product models the process variables in structures known as *datapoints* and offers a custom procedural scripting language, called Control Language (CTRL). CTRL is also the language to program functionality of the native user interfaces (UI) and is used by the WinCC OA based CERN control system frameworks. CTRL does not support object oriented (OO) modelling by default. A lower level OO application programming interface (API) is provided, but requires significantly more expertise and development effort than CTRL. The Detector Control System group of the CMS experiment has developed CMSfwClass, a programming toolkit which adds OO behaviour to the *datapoints* and CTRL. CMSfwClass reduces the semantic gap between high level software design and the application domain. It increases maintainability, encapsulation, reusability and abstraction. This paper presents the details of the implementation as well as the benefits and use cases of CMSfwClass.

INTRODUCTION

The Detector Control System (DCS) applications of the CMS experiment are written with WinCC OA, mostly using the native CTRL language with the process variables being modelled in tree-like data structures, called *datapoints*. *Datapoints* are the default persistence layer and they are used by the runtime database to hold the process variables. CTRL language does not include a type definition syntax to declare and manipulate new structures. This can only be done by means of functions from the standard library or through the WinCC OA graphical editing interface. Low encapsulation and coupling between CTRL language and WinCC OA *datapoints* make data manipulation complex, compared to other languages.

The design of software, from the software engineering point of view, must be an independent process, unaware of the technology specifics [1]. During the formalization of a software design, abstract domain problems need to be transferred into algorithms and organized in data models. For that reason, the resources available in the programming

platform, such as data structure definition mechanisms or programming language features, have a direct impact on the project implementation. When the semantic distance between the modelling language (e.g. UML) and the programming language is large, then the time and complexity of the translation process increases. Also other aspects of the software may be affected, like the readability of the code and maintainability of the entire software.

The CMS DCS team has attempted to close this gap by creating a development toolkit to add OO behaviour as well as code and data encapsulation down to the *datapoint* level. CMSfwClass toolkit revises the original WinCC OA and JCOP framework [2] device modelling concepts, enabling more abstract and powerful software architectural designs.

CMSFWCLASS TOOLKIT

The toolkit is composed of two different layers. The first layer is the back-end to add object orientation into WinCC OA. The second toolkit layer is a graphical user interface to provide easy and comprehensive access to the object oriented abstraction layer.

Figure 1: CMSfwClass toolkit modules.

Though the OO back-end has been designed to work in any WinCC OA project, the *GUI* has a certain level of integration with the CERN JCOP framework. Classes can be registered and accessed as JCOP device definitions. The *GUI* also uses CERN made libraries for syntax checking capabilities.

CMSfwClass OO Back-end Features

The OO back-end of CMSfwClass provides most of the commonly used features of modern OO programming and some custom object management features:

- Single inheritance and method overriding.
- Interface definition.

- Subtyping and interface polymorphism.
- In-memory objects (without *datapoints*).
- Object serialization in files.

The toolkit provides a default base class (CMSfwObject). This class serves as a baseline for other classes and provides several useful methods to handle objects at any level in the class hierarchy. CMSfwClass implements some custom features to express other design aspects of the model, such as specialization of objects at runtime, or composition and aggregation relations between objects. These features facilitate object management; for instance cascaded object deletion.

CMSfwClass toolkit GUI features

The CMSfwClass GUI was conceived as a computer-aided software engineering tool. The user interface guides developers during the process of creating classes and objects. The user drives the development process through different panels where attributes and methods can be introduced, while consistency and programming best-practices are assured by CMSfwClass.

The most relevant features of the GUI are the following:

- Code generation.
- Guided development process.
- Syntax checker.
- Object management.

The user interface provides code generation capabilities and live messages to remind the user how to proceed during the construction of a class. When a new class is created based on a super class, the constructor already includes code for inheriting the behaviour of the super classes. Then developers can override the default behaviour. When a new attribute is added to a class, *datapoint* structures are automatically altered to include the new element. The toolkit GUI offers the developer the possibility of creating accessor methods (getters and setters) for all class attributes. To insert method implementation details, the WinCC OA CTRL language editor is opened automatically for the scope of the method.

Apart from enforcing many of the development guidelines in the auto-generated code, CMSfwClass toolkit drives the users through different panels and pop-up messages to avoid several classic programming mistakes. For example, when adding a new attribute of class type (by composition), the toolkit warns the user about the need of updating the constructor and destructor methods.

Since CTRL language is an interpreted language, there is no compiler at our disposal. Basic syntax checking is provided in a library created at CERN. The library gives information about common defects of the code such as missing variable declarations, missing return statements and other problems that would otherwise only be discovered at runtime. It also contains some other useful functionality to extract function signature information and function location in the analysed files.

Another important aspect of the GUI is the object browser and operation interface which give a comprehensive visualization of the data structures. From

the class browser, users can navigate across the class hierarchy, edit class definitions, access object collections and execute the methods of any object.

DEVICE MODELLING USING CMSFWCLASS

WinCC OA *datapoints* allow engineers to model pieces of hardware and logical entities in a hierarchy of basic data structures. The JCOP framework additionally provides utilities to register, configure and handle *datapoints* as devices [3]. CMSfwClass toolkit goes one step further and adds full encapsulation by putting together the device data structure and its behaviour in a single file. A class definition file also contains a description of how the model interacts with other classes and libraries. Classes are written in CTRL language and include the following sections:

- Header: Libraries and constant values.
- List of attributes: primitive types or class types.
- Interactions: parent class, implemented interfaces.
- Class methods.

With CMSfwClass we can model hardware entities and connections between them using classes. To do this, we need to classify components by their common features, to make a proper division of concerns

A possible device classification is in Figure 2, where the model starts with a generic channel class definition inheriting from the baseline class CMSfwObject. An object of this class implements the basic behaviour of a channel. For example, actions to switch the device ON/OFF or a method to access the status of the channel. The original behaviour of a channel baseline class can be overridden to compile with different specifications for high and low voltage channels.

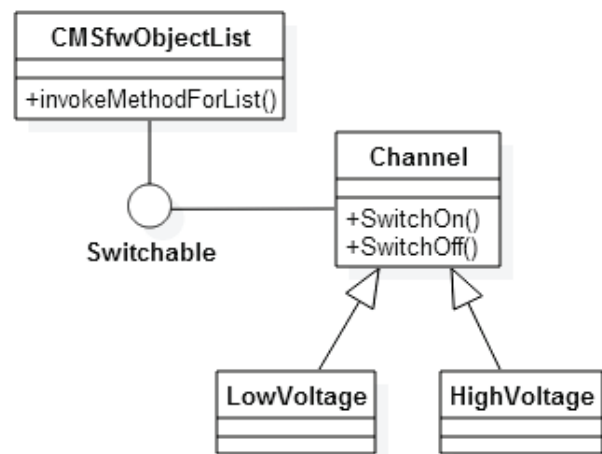

Figure 2: hardware model example.

This particular organization of entities implemented in objects can be useful when handling large, heterogeneous item collections. We can treat them in the same way since they inherit from the same base class “channel” and they implement the interface “Switchable”. We can easily go across the collection and perform the “SwitchON”

operation, abstracting from the detailed implementation required for every channel.

ARCHITECTURAL DESIGN USING CMSFWCLASS

In addition to modelling devices, developers can use CMSfwClass to model abstract domain problems. The CMS DCS team decided to refactor a small application called CMSfwScheduler, to get a more maintainable and clean implementation of the program. A comparison of the two implementations, with and without CMSfwClass, is shown in Table 1.

Table 1: Code Metrics

	Procedural	CMSfwClass
Code files	4	2
Core code lines	545	369
Auto-generated	0	329
Total	545	698

In this example, we see there is 47 % of code that has been automatically generated by CMSfwClass to perform OO consistent operations. As a result, by implementing the same program with CMSfwClass, the developer wrote 32% fewer lines of code. This comparison does not count the time spent on implementing data structures, defining naming conventions to handle data or creating user interfaces to access the data. These features are available by default in CMSfwClass and also speed-up the development process.

When control system software reaches a certain complexity, it is much easier to translate to code using OO than a procedural approach. The implicit mechanisms of OO modelling are meaningful during the software design but also in the code. CMSfwClass empowers the code by doing complex operations in fewer lines. Design patterns can also be applied in this context, providing tested, proven development paradigms.

TOOLKIT IMPLEMENTATION DETAILS

One of the goals of CMSfwClass is to help create a proper separation of concerns when modelling software. For that reason, the engine itself complies with modern software engineering principles such as modularity, encapsulation and information hiding. The toolkit is composed of different modules.

Model Data Hierarchy

The first time a class file is used in the toolkit it has to be registered. The registration of the class file creates the necessary internal structures to operate with the class, establishing the relation with other available classes and binding the library to a particular *datapoint* type. For every class in the hierarchy there will be a *datapoint* type using the class name and grouping the specific attributes for that class. For every object there will be one *datapoint* per

implemented class. The tool transparently handles a parent-child representation of the classes to determine where to find a particular attribute in the hierarchy. Thus CMSfwClass maintains a clear separation of concerns between attributes and objects of different classes.

OO Syntax in CTRL Language

The implementation of OO features is subject to certain limitations of the CTRL language. Methods and object names have to fulfil the following naming convention and rules:

- A method always uses the first parameter to transfer the object name inside the function scope.
- References to objects and class names are stored in variables of type string.
- A method is uniquely identified by its signature, using the class and method name with underscore in between: `<class name>_<method name>`
- Overriding a method implies changing the signature of the function, using the class name where the method is implemented.
 - `<class-A>_<method name>`
 - `<class-B>_<method name>`
- Object names are unique.
- An object can implement many classes, and its attributes are distributed in many *datapoints* (one per class) using the following convention:
 - `CMSfwClass/<class-A>/<object>`
 - `CMSfwClass/<class-B>/<object>`
- Objects can be referenced by any of its *datapoint* names.

Subtyping and Interface Polymorphism

Object information and behaviour can be hidden using subtyping and interface polymorphism. CMSfwClass considers that the relation between a class and its super class is an inclusive specialization of the superclass (subtyping). Therefore, methods written in the super class can operate on objects of the subclass. This feature enables treatment of objects of a specialized class as if they were instances of any of its super classes. Indeed, since CMSfwClass distributes the class attributes through different *datapoints* (one structure per implemented class), we can use any of its *datapoint* names to reference the same object. In CMSfwClass this feature is called *object shapes*.

Interfaces are also used to abstract and hide object details. Interfaces can be used to define what objects must offer in different parts of the software and to limit contexts only to objects implementing a certain interface.

Single Inheritance and Method Overriding

CMSfwClass implements single inheritance. This means that a class can only extend the functionality of a single super class. This mechanism provides children classes not only with all the attributes declared in the extended class and above, but also with all the behaviours described in the class hierarchy.

There are two different ways of invoking a method. Developers can explicitly invoke a method using its

original function name, or they can delegate to CMSfwClass to perform a dynamic method invocation (using wrapper functions). Dynamic method invocation verifies the method's accessibility and looks for the most specialized version of the method. The class an object is instantiated determines the method implementation to be executed. However, the shape of the object determines the accessibility of its attributes and methods. Since there might be more than one method implementation, CMSfwClass performs a search across the hierarchy from the instantiated object class to the less specialized class.

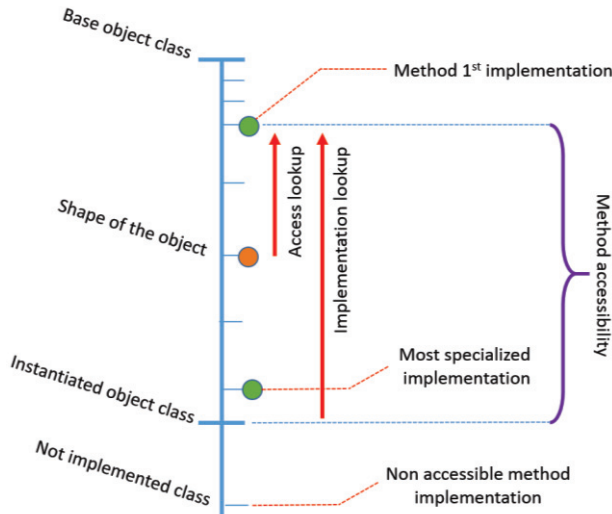

Figure 3: Method lookup

Interface Definition

CMSfwClass provides a mechanism to define sets of method signatures by class interfaces. When a class implements an interface, CMSfwClass toolkit enforces the creation of the methods defined in the interface. This mechanism adds a level of homogenization, flexibility and modularity from the point of view of software engineering. A class implementing an interface provides a first implementation of the methods. The following sub-classes extending from the parent class comply with the interface definition and therefore also implement the interface.

In-memory Objects

While in other languages, data structures are allocated in memory by default, *datapoints* are not. CMSfwClass introduces the possibility of instantiating objects in memory, eliminating unnecessary I/O operations to the persistence layer. This feature has a positive impact in terms of performance for volatile data, but adds extra complexity used for persistent data. An object can be instantiated directly in memory, or can be copied from *datapoints* to memory and vice versa. All class elements are created in a global memory variable. CMSfwClass

provides a set of functions to manipulate and add event-driven messaging functionality to in-memory objects.

Object Serialization in Files

The file format to export and import *datapoint* structures in WinCC OA can be complex and hard to manipulate from a text editor. CMSfwClass includes a tool to export object collections into XML formatted files. This can be particularly useful for backing up and recovery tasks.

CMSFWCLASS STANDARD LIBRARY

As mentioned before, CMSfwClass includes a set of basic classes to help developers in the construction of the software. They form the standard CMSfwClass library, and provide with an OO version of common programming features such as:

- Polymorphic object lists and sets.
- Runnable interface for object threading.
- Event-driven object messaging.
- Design pattern solutions for object visualization.

CONCLUSION

The software described in this paper has been built, tested and used in the DCS context for the CMS experiment. The CMS DCS central team identified multiple use cases for CMSfwClass before and after releasing the first version of the toolkit. It has been proven to be an efficient environment for creating complex and high abstraction software architectures with a short development time.

Apart from the implicit benefits of using an OO oriented programming approach, CMSfwClass toolkit helps in the construction of more robust software. The real-time semantic checks and the enforced best practices in the code generation are propagated throughout all software layers.

The toolkit has helped CMS DCS team to balance the amount of time spent in different tasks of the software construction process, spending more time in designing quality architectures rather than writing code.

LASER BEAM PROFILING AND FURTHER IMPROVEMENTS TO THE FHI FEL

H. Junkes, W. Schöllkopf, M. Wesemann, FHI, Berlin, Germany

Abstract

The free-electron laser facility at the Fritz-Haber-Institut (FHI FEL) started regular operation in November 2013. Currently, the FEL provides continuously tunable, powerful pulsed laser radiation at any wavelength between 3.6 and 50 μm covering the mid-infrared (MIR) wavelength range. The first 1½ years of operation have opened up new possibilities for research in gas phase spectroscopy of molecules and clusters, non-linear optics, and surface chemistry at the FHI. The EPICS software framework was chosen to build the control system of this facility. Actions have been taken for laser beam profiling and characterization as well as improvements to the infrastructure like the archiver system. This paper presents the next upgrade step and lessons learned during the first time of operation.

DESIGN OF THE FHI FEL

The FHI FEL includes two oscillator FELs; a MIR branch for wavelengths up to about 50 μm and a far-infrared (FIR) branch for wavelengths from, possibly, about 40 to 400 μm . The MIR FEL has been commissioned and is fully operational whereas the FIR FEL has been projected as a future upgrade. A normal-conducting linear accelerator provides electrons of up to 50 MeV energy with a beam transport system feeding either of the two FEL branches or the electron diagnostics beamline as illustrated in Fig. 1 [1].

Electron Accelerator

The accelerator system was designed and built by Advanced Energy Systems, Inc.. It combines a thermionic electron gun, a sub-harmonic buncher cavity, and two S-band (2.99 GHz) standing-wave copper linacs. The first of the two linacs accelerates the electron bunches to a constant energy of 20 MeV. The second linac accelerates or decelerates the electrons to a final energy between 15 and 50 MeV. The accelerated electron bunches from bunch trains (macro-bunches) containing thousands of micro-bunches at a repetition rate of 1 GHz. The micro-bunch length can be compressed down to a minimum of 1 ps rms by a chicane between the linacs. The macro-bunches are repeated at 5 or 10 Hz [2].

Undulator and Cavity

In the MIR FEL a planar hybrid-magnet undulator is located within the IR cavity. The undulator is 2 m long containing 50 periods of 40 mm. It employs permanent magnets made out of NdFeB. At a minimum gap of nominally 16.5 mm, a maximum root-mean-square undulator parameter K_{rms} of more than 1.6 is reached. This, in combination with the minimum electron energy of 15 MeV, corresponds to a theoretical maximum wavelength of more than 50 μm for the MIR system.

The 5.4 m long MIR FEL cavity is formed by an end mirror and an out-coupling mirror. These are gold-plated copper mirrors of concave spherical shape. The waist of the cavity mode is located at the undulator center. A motorized in-vacuum mirror changer permits to select one out of 5 out-coupling mirrors with different outcoupling-hole diameters of 0.75, 1.0, 1.5, 2.5, and 3.5 mm for optimized performance at different wavelength regions. In addition, the cavity end mirror is mounted on a precision translation stage allowing for fine adjustment of the cavity length with 1 μm repeatability [2].

Figure 1: Overview of the FHI FEL installation.

LASER BEAM PROFILING

The IR pulses coupled-out from the FEL cavity pass through the evacuated IR beamline and propagate a distance of 18 m from the FEL vault to the diagnostic station located in the lab building. There the spectrum of the IR radiation is measured by an in vacuum Czerny-Turner grating spectrometer allowing for online monitoring of the FEL spectrum for each individual macro pulse. In addition, various commercial IR detectors are in use to determine the intensity of the FEL-pulses at different levels of sensitivity and temporal resolutions [2].

Fast IR Detector

A very fast IR detector (VIGO PEM-10.6) with sub 250 ps time resolution and an active area of 2 mm x 2 mm is used to detect individual micro-pulses. Figure 2 shows a measurement with this detector used in combination with a fast (4 GHz) oscilloscope without additional electrical amplification. At the standard micro-pulse repetition rate of 1 GHz individual micro-pulses are clearly resolved with a modulation depth of more than 50%. As can be seen in Fig. 2 this detector allows observing intensity changes on the single micro-pulse level.

Pyroelectric Linear Array

A pyroelectric linear array detector with 128 elements and a total width of 1/2" (DIAS Infrared 128LT) is

mounted to the spectrometer and allows for monitoring the FEL spectrum in-situ for each individual macro-pulse (Fig. 3).

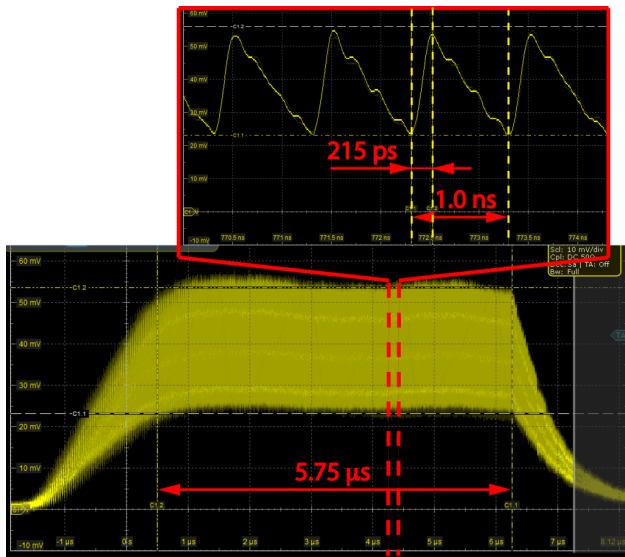

Figure 2: Detection of an FEL macro pulse at 6 μm wavelength with partial resolution of micro pulses.

The interface to the array is realized with a rtd DM6430HR 16bit, 100kHz Analog I/O PC104 module connected to a syslogic NETIPC/6. Debian Linux is used on the CPU board booting from CF card. The EPICS Input Output Controller (IOC) running on this board implements device support for 'pyroArray'. A waveform record holds the profile of the last laser shot.

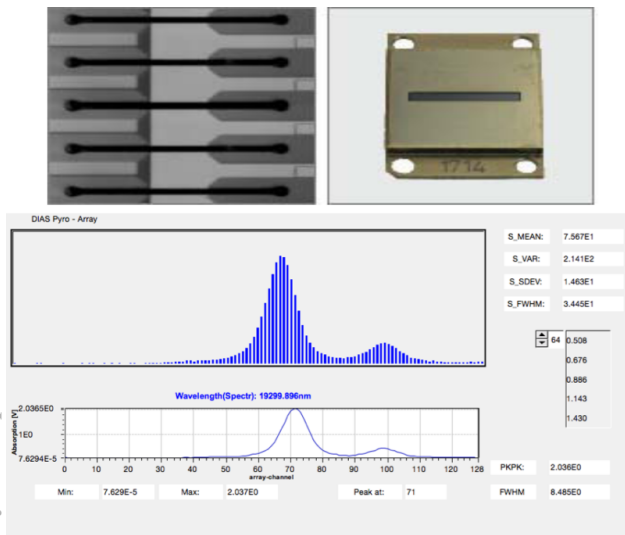

Figure 3: Pyroelectric Linear Array, OPI.

Standard Commercial Detectors

A 46 mm diameter, large area powermeter (Ophir PE50BB) is used on a daily basis to determine macro-pulse energies. Several small area (4.5 mm x 4.5 mm) pyroelectric detectors (Eltec 420M7-0) combined with in-house made amplifiers are in use to monitor the temporal shape of the FEL macro-pulses.

Pyroelectric Cameras

With pyroelectric cameras images of the laser beam profile can be obtained. Displayed in 2D or 3D views, the operator can immediately recognize beam characteristics indicating laser performance. This instantly shows detrimental laser variations. This allows for timely correction and real-time tuning of laser parameters. We use the following two camera systems :

- Spricon Pyrocam IV, 1.06 – 3000 μm , 320 x 320 elements, 80 μm x 80 μm element size, pulse rate up to 1 kHz, external trigger.
- DIAS PyroView 160L compact+, 8 – 14 μm , 160 x 120 elements, fixed measurement frequencies (70 Hz, 35 Hz, 17.5 Hz, ...).

Both cameras are read out and controlled by the EPICS areadetector framework. The aravis lib is used, the camera interfaces follows the GenICam standard.

The Spiricon camera fulfils our needs but is expensive. We looked about for alternative systems. The DIAS camera works just in a limited range from 8 to 14 μm and uses fixed internal trigger frequencies. Nevertheless we could integrate the DIAS PyroView by triggering the FEL with the internal clock of the camera at 4.375 Hz.

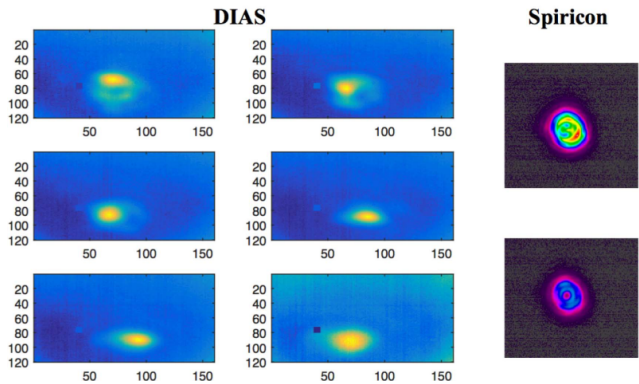

Figure 4: Images taken with areadetector.

Autocorrelation Measurement

In addition, a sensitive liquid-nitrogen cooled mercury-cadmium-telluride (MCT) detector (Judson J15D24) is used for detection of low-intensity signals such as, for instance, higher harmonic signals. Even for the fast IR detector (Fig. 2) the time resolution is by far insufficient to reveal the length and shape of the individual ps-long micro-pulses. For this reason we have installed an autocorrelation setup, shown schematically in Fig. 4, to characterize the micro-pulse shape. FEL pulses are split by a 50:50 ZnSe beam splitter (Edmund Optics). The length of one of the beam paths can be varied by a precision motorized translation stage to adjust the relative temporal delay between the two partial beams. Both beams are separately focused by 6" focal-length mirrors onto the same spot on a CdTe crystal (MaTeck GmbH) with an angle of $\approx 30^\circ$ between the beams [2].

At temporal overlap of the pulses from both paths, nonlinear effects in the CdTe crystal lead to the generation of second harmonic (SH) radiation which is emitted in the direction exactly in between the reflected fundamental beams. After spatial filtering to block the fundamental beams, the SH signal is detected with the liquid-nitrogen cooled MCT detector.

Figure 5: Autocorrelation setup, second harmonic signal.

ARCHIVER APPLIANCE

The previously used EPICS ChannelArchiver was replaced by the ArchiverAppliance developed by Murali Shankar at SLAC. We run two server systems (DELL PowerEdge R730/0599V5) in a cluster configuration. These systems are equipped with 128 GByte main memory, 4 SSDs and two 10 Gbit/s ethernet interfaces. The operating system used is Ubuntu 14.04.3 LTS. The two systems (aa0 and aa1) operate different networks. Within the FEL-LAN (10.0.0.0/23) aa1 is sampling the requested PVs, aa0 archives the data in the FHI-LAN (141.14.128.0/20). See Fig. 6. The previously used ChannelArchiver was only connected to the FEL-LAN. We could easily import the ChannelArchiver XML configuration files into aa1. The FEL-LAN is still the “PV-hotspot”. We are planning further experiments at the FHI to operate with EPICS and also want to archive the data obtained there. The access to the archived data at any appliance is ensured by a proxy function implemented in the ArchiverAppliance.

The ArchiverAppliance can use multiple stages of storage. For the short term storage (STS) we use 64 GByte of the main memory (ramdisk) with the granularity of an hour. The mid term storage (MTS) with the granularity of one day is realized with SSD storage. These two storage areas are local to the server systems. For the long term storage (LTS) both systems are using one storage gateway (Crossroad StrongBox) with the granularity “forever”. The connection to the StrongBox is realized with 10 Gbit/s ethernet, NFS is used to mount the LTS.

The StrongBox is a networked-attached storage (NAS) appliance. It includes a object-based Amazon S3 interface with an underlying RESTful API. The system supports file (NFS/CIFS) and object (S3) storage. By fusing disk for nearline storage with Linear Tape File System (LTFS) tape technology for archiving, the system delivers the performance of disk with the economics of tape in one solution. One can expand the nearline capacity by adding external FC/SAS disk arrays. A tape library (IBM TS3200) with two LTO 6 tape drives (SAS) and 48 data cartridge slots was chosen and connected to the StrongBox. This gives us a capacity of more than 240 TByte. The system can be easily expanded with additional/other tape libraries.

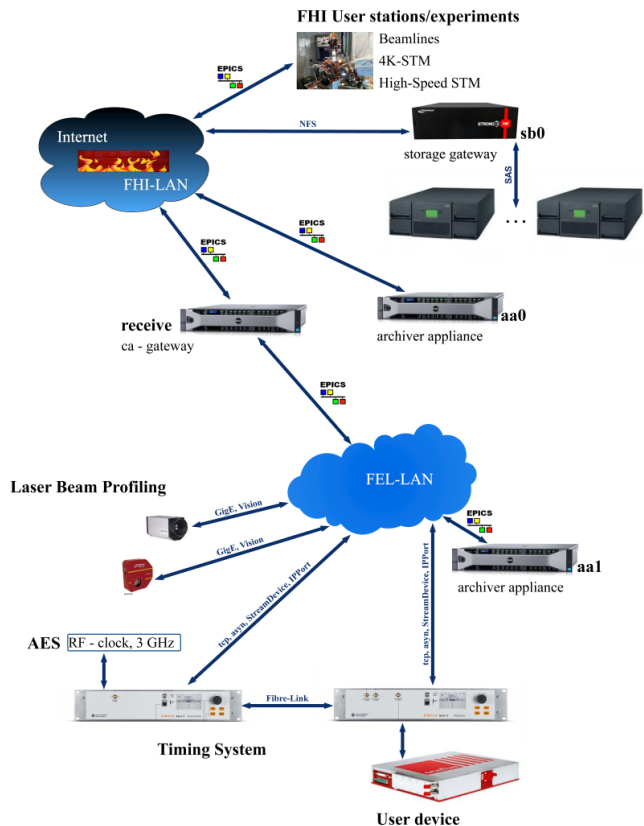

Figure 6: ArchiverAppliance setup.

MOBILE APPLICATION

To allow the operator to move freely in the institute during machine operation an iPad application was developed. The operator in charge can thus intervene at any time in the process and operate the machine (start trigger, stop trigger, adjust LLRF amplitudes and phases). A few important OPIs have been reimplemented (Fig. 7) using the Xcode development framework. These parts are now written in ObjectiveC. The communication takes places via https to a gateway running a standard Web-Server (apache, modPHP). This gateway reads the PVs out of the EPICS-IOCs using channel access (perl) and caches some of the PVs (trend data) into a SQL database on the gateway.

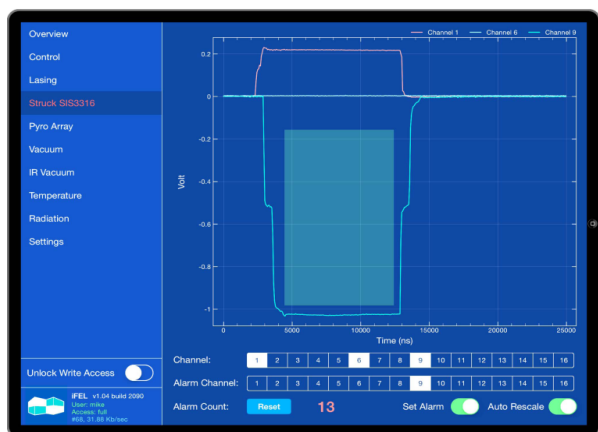

Figure 7: Screenshot iPad App.

TIMING SYSTEM

To enable pump probe experiments (see following section) the clock signal of the accelerator must be delivered jitter free to the user stations. A Libera Sync 3 system was chosen for transmitting the high-performance RF-oscillator to such an beamline end-station. The system assures clock signal distribution with down to femtosecond-level added jitter. The libera system is integrated in the EPICS control system using StreamDevice with asyn over IP. See Fig. 6 [3].

FUTURE MACHINE UPGRADE

Over the last century, linear optical spectroscopy, especially when being performed in the IR, contributed substantially to our understanding of molecular structures. In addition, the usage of ultrashort laser sources has allowed to go further by studying not only structure, but also the dynamics of energy flow between different modes in molecular and condensed phase systems, providing a wealth of additional information. Traditionally, these dynamical processes are studied using pump-probe techniques where two time-delayed optical pulses are applied to the sample, and the dynamics and interactions are derived from the sample response as function of time delay between the two pulses and there frequency or fluence, respectively. Typical single-color experiments allow monitoring the population relaxation of vibrational modes; however, two-color approaches give access to mode-couplings and thus may significantly enhance the attainable microscopic understanding. In particular, both MIR-near-infrared (NIR) and MIR-MIR two-color experiments are interesting, addressing couplings between vibrations and electrons and between different vibrational modes, respectively. Ultimately, it would be intriguing to make use of the high pulse energy delivered by the FEL to also “pump” (drive) molecular processes, reactions or to create new transient states by controlling multiple vibrational motions in a concerted fashion.

Furthermore, it would also be highly interesting to extend the wavelength range accessible by the FEL to longer wavelengths to study lower-frequency vibrations at

THz frequencies. The modes of interest here are vibrations involving heavier atoms, for example in clusters, collective motions in bio-molecules and correlated atomic motions in complex solid materials. As these experiments address optical thin samples or require a high field strength they can be only made possible using an FEL.

We propose an extension of the FHI FEL which would enable these new classes of experiments and make the FHI FEL a worldwide unique instrument. We hereby follow two independent directions, to allow for MIR-NIR and MIR-MIR two-color operation, respectively, with the IR pulse wavelength tunable beyond the current limit of 50 μm . MIR-NIR spectroscopy will be enabled by installation of a femtosecond tabletop laser producing pulses at 1 μm synchronized with the FEL. MIR-MIR two-color operation could be achieved by installation of a second, longer wavelength undulator. Specifically, we envision this new undulator to be operational simultaneously with the existing one. This would be possible by implementing a unique design, in which an additional RF cavity is used to feed alternating electron bunches into both undulators, respectively. This is illustrated in Fig. 8. Such an approach is novel and has not been implemented yet at any other FEL facility [4].

Figure 8: Future upgrade, two-color operation.

ACKNOWLEDGEMENT

Important contribution regarding the machine are provided by Sandy Gewinner (laser engineer) member of the FEL facility staff.

REAL-TIME ETHERCAT DRIVER FOR EPICS AND EMBEDDED LINUX AT PAUL SCHERRER INSTITUTE (PSI)

Dragutin Maier-Manojlovic, Paul Scherrer Institute (PSI), Villigen, Switzerland

Abstract

EtherCAT [1] bus and interface are widely used for external module and device control in accelerator environments at PSI, ranging from undulator communication, over basic I/O control to Machine Protection System for the new SwissFEL accelerator. A new combined EPICS/Linux driver has been developed at PSI, to allow for simple and mostly automatic setup of various EtherCAT configurations.

The new driver is capable of automatic scanning of the existing device and module layout, followed by self-configuration and finally autonomous operation of the EtherCAT bus real-time loop. If additional configuration is needed, the driver offers both user- and kernel-space APIs, as well as the command line interface for fast configuration or reading/writing the module entries.

The EtherCAT modules and their data objects (entries) are completely exposed by the driver, with each entry corresponding to a virtual file in the Linux *procfs* file system. This way, any user application can read or write the EtherCAT entries in a simple manner, even without using any of the supplied APIs. Finally, the driver offers EPICS [2] interface with automatic template generation from the scanned EtherCAT configuration. In this paper we describe the structure and techniques used to create the EtherCAT software support package at PSI.

INTRODUCTION

To support external device data acquisition and equipment control both for existing research facilities, such as Swiss Light Source (SLS), and for facilities being built at the time this text was written, like Swiss Free Electron Laser (SwissFEL) [3], an EtherCAT software interface was needed at PSI. Unfortunately, none of the existing commercial and non-commercial solutions we have reviewed and tested was able to cover and satisfy all of the requirements for the EtherCAT support.

General requirements were divided in two broad categories – the first was the full support for EPICS control system and the complete range of standard EPICS record types currently available, with the possibility for flexible addressing of EtherCAT modules and entries. The second requirement was to have a system that can provide the EtherCAT interface for common applications, both applications running locally, normally on the Ixos IFC 1210 VME Board (equipped with the PowerPC P2020 CPU) and remotely, on a standard desktop PC or mobile device running any operating system capable of supporting network-based file systems, such as Linux, UNIX, Windows, MacOS, FreeBSD and others.

CONCEPTS

Providing support for such a wide range of applications in a single package presented a problem, since not every requirement or possible scenario for usage could have been satisfied with a single piece of software.

EPICS control system support requires its own type of dedicated device support driver. Unlike its kernel counterparts, EPICS driver has to run in Linux userspace, since EPICS system itself is a userspace application. Aside from EPICS, the system has to support other types of applications, both local and remote.

Local applications can be both userspace and kernelspace applications, which in turns mean at least two separate local APIs had to be created. Remote applications, on the other hand needed a generalized way to access EtherCAT data regardless of the operating system used.

EtherCAT Data Addressing

To describe an address of a given EtherCAT data entry, several variables have to be included: EtherCAT Master number (since there can be multiple masters running on the same host), Domain Nr. (domain is an arbitrary, user-defined collections of PDO (Process Data Object) entries sharing the same domain buffer memory and TCP exchange frame rate), Slave Nr. (Slave is another name for an EtherCAT Module), Synchronization Manager Nr. (SyncManager or SMs group objects by their exchange direction (input/output) or other criteria), Process Data Object Nr. (PDOs group entries by some arbitrary purpose defined by the Module producer) or Process Data Object Entries (PDO Entries or PDOE hold the actual data).

The user should be able to easily describe which data entry (or entries) should be addressed, in a consistent yet simple manner. To solve this problem, we have devised a new addressing schema for EtherCAT data:

Figure 1: New schema for EtherCAT data addressing.

Master (m_a) and domain (d_b) can be omitted when $a=0$ or $b=0$, i.e. for the default master and domain. Similarly, the PDO entry (e_i), PDO (p_k) or SyncManager (sm_j) can be omitted as well (in that order), when the user wants to address multiple entries included in a larger parent container, instead of a single entry. For example, *s1.sm4.p0.e1* would be the address of the “entry 1 of PDO 0 of SyncManager 4 of slave 1”, whereas the string *s1.sm4* would mean “all entries contained in all PDOs of SyncManager 4 of slave 1”.

To increase flexibility, we have extended the addressing to include various modifiers, hence not rigidly connecting an EPICS record to a single entry of the same type. The possible modifiers or addressing modes (as of v2.0.6) are:

- [*.o<offset>*] - forced offset (in bytes), allows shifting of the starting address of the PDO entry in buffer
- [*.b<bitnr>*] – forced bit extraction, allows extraction of single bits from any larger PDO entry data types
- [*.r<domregnr>*] – domain register addressing, replaces address modifiers *s*, *sm*, *p* and *e*, using relative entry addressing inside a domain instead
- [*.lr<entryrelnr>*] – local register addressing, replaces any (group) of the address modifiers *s*, *sm* and *p*, allowing for local relative addressing of all entries inside a slave, inside a SyncManager, or inside a PDO regardless of their actual parent container or containers
- [*.l<length>*] – length modifier, in bytes. Used primarily to define the length of stringin/stringout EPICS records
- [*t<type>*] or [*t=<type>*] provides means for forced typecasting or type override, changing the default type of the data entry when applied. Many types are provided, from *int/uint* (8-, 16-, 32-bits), *float*, *double*, *BCD*, etc.

It is worth noting that the addressing modes or modifiers listed above can be freely mixed as needed – for example, the address *s1.sm4.p0.e1.b4* would mean “extract the bit 4 of the 32-bit entry *s1.sm4.p0.e1*”, and the address *s1.sm4.p0.e1.o2.b4* would mean “extract the bit 4 of the 32-bit entry *s1.sm4.p0.e1*, but shifted by 2 bytes (.o2)”, which would effectively extract the bit 20 ($2*8+4=20$). Similarly, the address *r45.o2* with the modifier *t=float* would mean “domain register 45, shifted by 2 bytes, typecasted to float”.

EPICS SUPPORT

Since PSI almost exclusively uses EPICS control system for its accelerators, integrating EPICS support was a top priority. For the system employing EtherCAT components, the EPICS Core is running on the Ioxos IFC 1210 Boards [4], equipped with two separate Ethernet interfaces, a PowerPC P2020 CPU and the VME Bus backplane. The operating system installed is a Linux with the appropriate PREEMPT-RT patch.

Since EPICS has its own interface for device drivers, a special EPICS userspace driver had to be developed, using high priority real-time threads for the control loop. Without the real-time capabilities provided by the PREEMPT-RT Linux, timing and execution of the control loop would not be reliable and hence not real-time capable.

For the EPICS support, the timing control loop is maintained by the EPICS userspace device driver. EPICS records are registering the entries they are “interested in” at the IOC boot time, and the driver then carries the exchange between the records and the EtherCAT control loop.

Additionally, EPICS support has to provide both “normal” reading and writing, not synchronized with the EtherCAT control loop, and I/O Interrupt mode, to allow each Ethernet packet to trigger an interrupt, at which point the new values can be read and written to the buffer. This was accomplished with double-buffering technique between EPICS and the driver.

Another problem to solve was the fact that EtherCAT modules are not always required to accept the write values – a write request may, for example, fail for a number of reasons – and that means that the Ethernet TCP packet on a return trip may contain write values which differ from the content of the write buffer.

This means that not only the refreshed read values, but also the write values has to be transferred back to the write buffer at the end of every cycle. Yet, the newly received write values, unlike new read values, cannot be simply copied over the old values in the buffer, since that would effectively overwrite the new write request values which were already accepted since the last cycle. To solve this, a multithreaded double-buffering with the write-mask for write requests was implemented (see Figure 2).

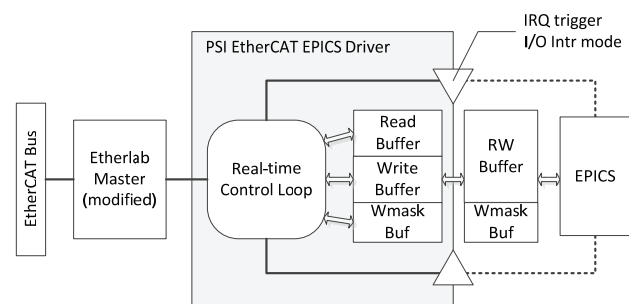

Figure 2: EPICS driver structure.

All EPICS records use a single driver type (DTYP) called *ecat2*. Scan rates for records can be set to any valid EPICS scan rate, including *Passive* and *I/O Intr*.

All of the extended addressing modes and modifiers, including typecasting, can be used in EPICS as well. Almost all combinations are allowed - even in EPICS, with its rigidly defined record types, it is possible to achieve high level of flexibility.

For example, it is possible to extract a single bit from a *mbbi* record without additional *calc* records, or to have a complete bit field extracted from a record of any length. Type override and other modifiers can be used for all record types, including array-type records (*aailaao*). Length modifier (*.l<length>*) is used to define the length of the string for string-type records (*stringin/stringout*).

Additionally, several special types of records are provided. These records signify status of the EtherCAT Master, aggregate status of the slaves (modules), EtherCAT network link status and status of each slave (module) – preoperational, operational, error, etc.

GENERAL SUPPORT

To support the local and remote applications wishing to connect to and use the EtherCAT hardware, the second part of the driver package was created. We have developed three different subsystems to allow application developers a highly flexible way to access the entries and other data:

- Kernelspace API
- Userspace API
- Procsfs-based tree(s)

All of the above are included in the Linux-based PSI EtherCAT kernel device driver and supporting tools and libraries. The driver provides support automatic scanning of the EtherCAT bus and automatic configuring of domains and found entries, and manual configuration for some or all modules as well.

Additionally, the driver automatically constructs and maintains procsfs trees throughout its operation, and takes care of triple-buffering and write-masking process needed for data exchange with the client applications. Description of the each of the access modes is presented below.

Kernelspace API

Kernelspace API (kAPI, Figure 3) is a set of functions providing the easy access to driver control loop parameters and EtherCAT data entries.

The driver provides an internal real-time control loop for buffering and exchange of TCP packets over Ethernet, Timing of the control loop is based on the host high resolution timers, but can be driven by an external source as well, such as a timing system input.

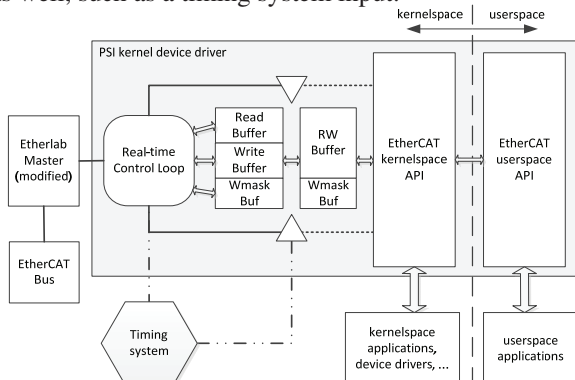

Figure 3: PSI EtherCAT driver structure.

Multiple kernelspace applications and/or drivers can use the API, however, the RT-priorities of various application kernel threads has to be set carefully, in order to allow both the driver and the rest of the kernel to run properly.

Userspace API

Userspace API (uAPI, Figure 3) is a set of functions providing (almost) the same functionality found in the kAPI. The functions library can be used statically or dynamically with userspace applications as needed.

The only difference is that there is no possibility for external timing input for the control loop (since the control loop is located in the kernelspace part of the driver), only timing triggering for data acquisition (or delivery) can be used.

Procsfs Trees

To allow local and remote applications to access the EtherCAT data, but without the need for an API or a dedicated remote server and client, we have developed the concept of procsfs trees. Procsfs trees are a series of directories and “files” constructed on-the-fly by the drivers in the Linux host proc file system.

Each directory represents some kind of a parent container, such as a slave, a syncmanager, a PDO, a domain or a master (Figure 4). Each file in these directories represents either a direct representation of a EtherCAT PDO entry, or a utility file representing the data about the system or about the containers present.

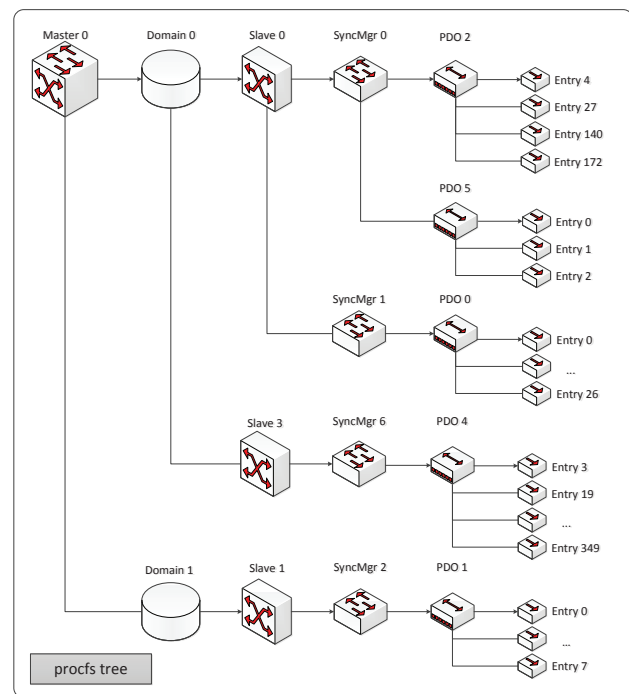

Figure 4: procsfs tree general structure.

There is also a special *cmd* entry provided in the *procs tree*, allowing a CLI or application to interactively talk to the driver, sending commands (for example, add entry,

add PDO, add slave entries, list data, etc.). Also, entry data can be read or changed using the CLI as well.

The complete procfs tree directory/file structure is updated automatically each time something changes in the system – during bus scans, when an entry is added to a domain and similar actions.

The files in the structure can be read from or written to – this allows any application programmer to easily access the EtherCAT data without having to meddle in the API programming at all.

EXTENSIONS AND UTILITIES

The PSI EtherCAT support package offers several extensions and tools. The most important ones are described below.

Slave-to-Slave Communication

It is often the case that the data on the EtherCAT bus has to be transferred from one EtherCAT device or module to another, preferably in real-time. For this kind of communication, two different directions of transfer can be observed, *upstream* and *downstream*.

Upstream slave-to-slave communication is transfer of data from a module further away on the EtherCAT bus from the master to a module closer to the master. Downstream communication is the transfer from a closer module to one further “down the stream” from the master. The stream in this case represents the path an EtherCAT TCP packet is travelling, and its direction remains constant as long as there are no physical changes in the bus configuration and modules present.

From real time point of view, this communication is highly deterministic, yet not identical – downstream communication (send on one module, receive on another) can, theoretically, be done in the same bus cycle, hence costing exactly zero bus cycles to execute. Upstream communication, due to the way TCP packets are handled by the EtherCAT, will take exactly one bus cycle to complete.

We have decided to implement the slave-to-slave communication (*sts*) with constant cost of completion, in this case, exactly one bus cycle for both upstream and downstream communication requests.

In EPICS, sts-communication transaction requests can be inserted as follows:

```
ecat2sts <source> <destination>
```

For example:

```
ecat2sts r8 r0
```

```
ecat2sts r2.b0 r0.b6
```

```
ecat2sts s2.sm0.p1.e0 s1.sm0.p1.e0
```

```
ecat2sts s3.sm3.p0.e10.b3 s4.sm2.p1.e0.b7
```

As can be seen in examples above, any valid addressing mode and/or modifier can be used for source and destination. API access is done by calling a function to

register a transaction request, but the addressing remains the same.

Support for Programmable Modules

The PSI EtherCAT drivers and utilities also support setting up and live programming of programmable EtherCAT modules and devices, such as, for example, EtherCAT network bridges (EL6692, EL6695), motor controllers, and so on.

From EPICS, any module can be programmed by using *ecat2cfgslave* set of commands, for example:

```
ecat2cfgslave sm <arguments...> - configures one Sync Manager for the given slave.
```

```
ecat2cfgslave sm_clear_pdos <arguments...> - clears (i.e. deletes) all PDOs for a given Sync Manager (SM)
```

```
ecat2cfgslave sm_add_pdo <arguments...> - adds a PDO with index pdoindex to a Sync Manager.
```

```
ecat2cfgslave pdo_clear_entries <arguments...> - clears (i.e. deletes) all PDO entries associated with the given PDO.
```

```
ecat2cfgslave pdo_add_entry <arguments...> - creates a new PDO entry and associates it with the given PDO
```

Network bridges even have their own, simplified commands for programming entries:

```
ecat2cfgEL6692 <netbridge_nr> in/out <numberofbits>
```

CONCLUSION

In this paper, we have presented the PSI EtherCAT software support package and described its components. The system is already successfully used at PSI in the last several months.

As is usual with such systems, it is to be expected that changes will be made to this package in the future to accommodate needs and new requirements of expanding number of users of the system, the existing features will be extended and streamlined and the new features and components will be added.

PERSONNEL PROTECTION SYSTEM UPGRADE FOR THE LCLS ELECTRON BEAM LINAC*

M. Cyterski[#], E. Chin,
SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA

Abstract

As facilities age and evolve, constant effort is needed in upgrading control system infrastructure. This applies to all aspects of an accelerator facility. Portions of the Personnel Protection System of the Linac Coherent Light Source are still relying on a 50 year old relay based Safety System. This presents a substantial risk to the facility's ability to reliably perform its mission. An upgrade is underway to modernize these systems using Siemens S7-300 Safety PLCs and Pilz PNOZMulti programmable controllers. The upgrade will be rolled out over multiple years requiring the implementation to be fully compatible with adjacent legacy system while setting the foundation for the new generation system. The solution is a modularized safety system which can be deployed in a short time (1 month) while being flexible enough to adapt to the evolving needs over the next 20 years. Once fully deployed, the upgraded PPS System will provide not only greater availability to users, but also a higher level of Personnel Safety than previously provided.

BACKGROUND

The 3 mile Linac has been in operation at SLAC National Accelerator Lab for more than 50 years. In that time many upgrades have been made to support successful operation of the facility into the future. In 2014, a multiyear project was begun to upgrade the Personnel Protection System for the section of Linac used for operation of the Linac Coherent Light Source (LCLS).

The Personnel Protection System (PPS) at SLAC is composed of a system of interlocks whose function is to prevent personnel from being exposed to radiation within the accelerator enclosures.[1] In the Linac this is done by controlling the ability of the Klystrons to produce RF for the accelerator waveguides. The SLAC Linac is composed of 30-100meter long sections. Pairs of these sectors are configured as 15 stand-alone PPS zone.

The system currently used is composed of telephone relays and has operated safely for many years. In order to continue to support the high level of facility uptime demanded by LCLS, a modern replacement is needed. The LCLS Linac is composed of the final 10 sectors. The new system will provide a substantial increase in diagnostic information available to the operations staff as well as new functional modes. These modes will reduce facility downtime following personnel access to the accelerator housing.

*Work is supported by the U.S. Department of Energy, Office of Science under Contract DE-AC02-76SF00515.

[#]cyterski@slac.stanford.edu

Completing an upgrade of this size on an operational facility presents an additional level of difficulty. Annual maintenance down time is on the order of two months, with half of this time needed for recertification of all PPS installations. This only leaves four weeks to complete the removal, installation, and commissioning of a new system.

REQUIREMENTS

In addition to the standard requirements of a Personnel Safety System, this upgrade must meet two additional project specifics requirements. [2][3]

The first is the need for a personnel controlled access. Currently any access into the linear accelerator requires the operations staff to manually go into the tunnel and verify that no one is inside before closing the facility for beam operation. Depending on the number of sector pairs accessed this can take a substantial amount of time. Controlled Access will allow for trained personnel to enter the accelerator housing using a safety token and return the token once complete.[4] This eliminates the need for an operations search.

Secondly, due to the installation window time constraints, the upgrade must be deployed in phases. Each phase will be staged and modularly assembled while the facility is in operation and then deployed during a maintenance downtime.

DESIGN

The new system is composed of 3 separate PPS zones instead of the 5 sector pairs it's replacing. Each zone is deployed in a different annual maintenance down time. The three stages are listed in Table 1.

Table 1: Installation Stages

Zone	Controlled Access	Installation
Sectors 24 & 25	No	September 2014
Sectors 21-23	Sectors 21-25	September 2015
Sectors 26-30	Sectors 21-30	TBD 2016

Personnel Access to the accelerator regions is handled by three distinct access states at SLAC. No Access is the condition in which beam operation is allowed as long as the interlocks are met. Permitted Access allows free access to individuals to the PPS zone. This always requires an operations search of the region prior to machine recovery. Controlled Access allows for access without the need to search the PPS zone.

There are two methods to access the Linac housing in sectors 21 through 30, a vertical ladder in each sector which requires fall protection equipment to be used and a stairwell located at Sector 24. Because of the need for additional equipment and training to use the vertical ladders, only the sector 24 stairwell is instrumented as a PPS Entry location. This means that a controlled access scheme requires the ability to move between the three zones without violating individual zone security and requiring an operations search of the area. The ladder located at each sector can still be used as entry point under permitted access conditions. Each stage is a stand-alone installation; the number of signals shared between zones is minimized to facilitate the staged deployment of the system. Controlled access was not fully implemented until the second stage at which point it provided an operational benefit. Controlled Access allows for the boundaries between the three zone to be opened without violating zone security as long as each zone is in controlled access and is secure

For each zone the PLC architecture used to implement the system is based on three PLCs as shown in Figure 1. Two Pilz PNOZMulti controllers are implemented as the safety interlock controllers. These handle all the safety critical sensors,

Figure 1: PLC architecture.

Emergency Off hardware and permits to radiation hazards. These communicate with a Siemens S7-315F processor over Profinet. This PLC is responsible for all non-safety critical functionality. This includes interfacing with the Experimental Physics and Industrial Control System (EPICS), controlling indicators throughout the region, and other non-safety critical functionality. EPICS is used to control and monitor all aspects of the PPS systems at SLAC. The individual status of all inputs as well as the ability to release safety tokens and grant access is done through EPICS. As an additional level of safety all PPS installations include a hardwired enable which is used at the PLC installation to gate all

commands received over EPICS. If this signal is not present then the system ignores the control system request.

INSTALLATION

In order to meet the installation schedule, a large amount of staging and pre-assembly work was required.

New terminal cabinets and copper trunking were mounted and routed to the rack locations during LCLS Operation. These trunks were terminated in the rack once the rack hardware was upgraded. Because existing racks were repurposed, it wasn't possible to pre-wire a new rack. Instead an assembly jig was constructed to allow the rack hardware to be prewired and then installed as a single unit in the repurposed rack. The upgraded rack assembly can be seen in Figure 2. This single rack installation replaces 4 racks in the case of Stage 1 and 6 racks in the case of Stage 2. At the completion of Stage 3 it is expected that 2 racks will replace 10 racks. Once the prewired assembly is installed in the rack, the copper trunks are terminated.

Figure 2: New Installation in repurposed racks.

The existing zone wiring was removed and the conduit, inspected. New wire was pulled in the existing conduit and connected to the previously mounted terminal boxes. Field hardware was replaced at each entry way and throughout the tunnels. The sector 24 entry way was upgraded to support its new function as a controlled access point. Sector 24 entry before the upgrade and after can be seen in Figure 3.

Figure 3: Sector 24 entry way.

The legacy system uses redundant constant current loops which run the length of the Linac in order to sum the state of the individual subzones. Each zone is capable of breaking the continuity of these loops. There is a global PPS system which looks at these loops as well as other inputs and ultimately issues the hazard permits to the RF. The interface to this system is unchanged; the loops pass through dry-contact outputs on the respective Pilz Safety Processors. This allows for the upgraded and legacy installation to operate side-by-side without any intermediate solutions.

CONCLUSION

While completing the first two stages of this upgrade, a strong dependence on pre-planning and execution was necessary to deploy a large scale upgrade in a comparatively short amount of time. This project would not have been achievable without the strategies employed. When the third stage is executed, the project will benefit from the lessons learned to date and successful completion of a substantially larger geographical upgrade.

UPGRADE OF THE CONTROL AND INTERLOCK SYSTEMS FOR THE MAGNET POWER SUPPLIES IN THE T2K PRIMARY BEAMLINE

Kazuo Nakayoshi, Ken Sakashita and Yoshiaki Fujii

High Energy Accelerator Research Organization (KEK), Tsukuba, Ibaraki, Japan

Abstract

T2K is a long-baseline neutrino oscillation experiment at J-PARC in Japan. A high intensity neutrino/antineutrino beam is generated and propagates 295km to Super-Kamiokande. The high intensity proton beam which reached 350 kW in May 2015, is extracted from the Main Ring synchrotron and guided through a primary proton beamline to a graphite target using normal-conducting (NC) magnets and super-conducting combined-function magnets. In October 2014, we replaced all of the power supplies (PSs) for the NC magnets with newly developed PSs. We also developed a new control system based on the Experimental Physics and Industrial Control System (EPICS) and PLC, putting emphasis on the safe operation of power supplies, and integrated it into the existing interlock system. Consequently the latency time for the interlock system was improved. We report the actual implementation and operation results of these developments.

INTRODUCTION

The T2K (Tokai-to-Kamioka) experiment [1] is a long-baseline neutrino oscillation experiment at J-PARC (Japan Proton Accelerator Research Complex) in Japan. A high intensity neutrinos/anti-neutrino beam is produced, and propagates 295 km from J-PARC to Super-Kamiokande.

Figure 1: T2K primary beamline.

The T2K neutrino experimental facility is composed of primary/secondary beamlines and a near detector (ND280). The high intensity proton beam which reached 350 kW in

May 2015, is extracted from the Main Ring synchrotron (MR) and guided through the neutrino primary beamline to a graphite target. Figure 1 shows the T2K primary beamline, consisting of the preparation (PREP), arc and the final focusing (FF) sections. Fourteen doublets of super-conducting combined function magnets [2] are located in the ARC section and bend the beam towards Kamioka. In the PREP section, the extracted proton beam is tuned with a series of 11 normal-conducting (NC) magnets. Ten NC magnets in the FF section guide and focus the beam onto the target. The power supplies (PSs) for the PREP section are located at the utility building-1 (NU1) and those for the FF section are located at the utility building-2 (NU2).

Some critical primary beamline issues are:

- A single failed beam shot, caused by a trip of the NC PSs, for example, results in serious damage of beam-line equipments.
- The NC magnet power supplies were made mostly in 80's and required increasing effort for maintenance.

In order to solve these problems, we developed new power supplies for the NC magnets with a power supply company, and replaced all of the PSs in the summer of 2014.

NEW POWER SUPPLIES

The requirements for the new PSs for the NC magnets were (1) improvement of the safety interlock, (2) precise and stable operation, (3) improvement of maintenance, (4) upgrade of the control system and (5) downsizing. We report on each requirement and its actual implementation.

Table 1 shows the types of PS, corresponding to each magnet, its rated current, and its unit count. Figure 3 shows pictures of the new PSs.

Table 1: New power supplies for the normal conducting magnets in the T2K primary beamline.

Magnet type	DC OUT (A) / (V)	Converter type	Current stability(A)	# of units
Dipole	1500 / 100	chopper	0.1	4
Quadrupole	1000 / 100	chopper	0.1	9
Steering I	$\pm 400 / \pm 40$	chopper	0.05	1
Steering II	$\pm 200 / \pm 20$	switching	0.05	2
Steering III	$\pm 100 / \pm 10$	switching	0.05	5

The output current stability is 0.1 A for the dipole and quadrupole magnet PSs and 0.05 A for the steering magnet PSs. The stability is superior to the previous PSs and the

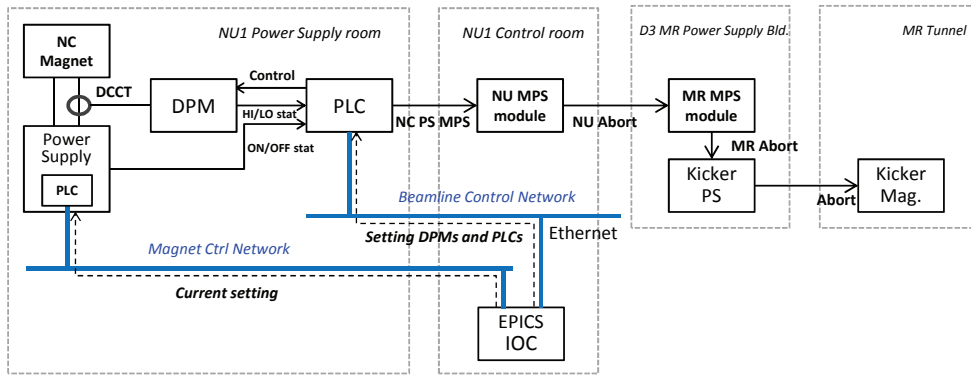

Figure 2: Schematic of the control system for the new power supplies for the normal-conducting magnets.

Figure 3: Pictures of the new power supplies for the normal-conducting magnets. The left photo shows a power supply for a dipole magnet and the right shows four steering magnet power supplies installed in a rack.

output current ripple is reduced. There are two DCCTs in each PS; one is for feedback control and the other is for current monitoring used in an interlock system. Each PS has a LCD touch panel on the front for local operation. For safer operation, control of the PS is password-protected. We succeeded in saving space (about -67%) by installing four steering magnet PSs in a single rack (see Figure 3).

IMPROVEMENT OF THE CONTROL SYSTEM

The control system for the old PSs was not designed to support EPICS [3]. Therefore, we chose to use a relational database as an interface between the old control system and EPICS. A relational database (MySQL) that includes the status of each magnet was prepared. We could access the magnet data via MySQL tables. For the new PSs, we changed the framework of the control system to a less complex configuration: we got rid of our unique control system and adopted standard Programmable Logic Controllers (PLCs) with EPICS. We built two EPICS IOCs, one for PSs at NU1 and another for those at NU2. Figure

2 shows a schematic of the control system for the new PSs at NU1. The IOC communicates with a PLC [4] built into each PS over Ethernet. We separated the new PS's control network from the existing beamline control network in order to separate it from EPICS broadcasts. The new NC PS's output current is monitored by the existing interlock system for current fluctuations as described in the next section.

IMPROVEMENT OF THE INTERLOCK LATENCY TIME

We developed a current-fluctuation interlock system for old NC PSs using digital panel meters (DPMs) in 2012 [5]. The DPMs continuously sample and digitize the DCCT output voltage of the PSs and determine whether it has stayed within a preset range. HI/LO status outputs of the DPM are connected to PLC input-modules. The input-modules aggregate the HI/LO status from all DPMs and an output-module outputs MPS (Machine Protection System) signals. The MPS is an interlock to stop the MR beam and protect beamline equipment from the high intensity beam or a cascade of equipment failures. The DPM is able to change the number of input voltages used in a moving average to remove the fast component of electrical noise.

Latency Time of the Old PSs

We measured the latency time of the DPM and PLC for the old PSs while changing the number of voltages used in the moving average. Figure 4 shows the results of the measurement. The latency of the PLC was measured to be 14 msec, which was nearly constant, as expected. The total latency of the DPM increases in proportion to the number of every used in the moving average. The ripple on the output current of the old PSs was large. Therefore we increased the number of voltages used in the to use as a digital filter. For 100 samples used in the moving average latency time of ~100 ms was expected at the DPM. In order to reduce the latency time, a smaller number of samples was required.

Figure 4: The interlock latency time vs. number of averaged voltage samples times on a digital panel meter (DPM). The open triangle shows the latency time of the PLC. The open square shows the latency time of the DPM. The closed circle shows the sum of the PLC and DPM latency times.

Latency Time of New PSs

In the new PS, we use one of two DCCTs in each PS for the interlock system. The ripple on the output current of the new PSs was small so that only one sample was required in the DMP moving average for each new PS. We measured the interlock latency time of the DPM and PLC while changing the threshold current value of the DPM for the PS for PD1, one of the dipole magnets.

Figure 5: The interlock latency time vs. LO threshold current on a digital panel meter (DPM). The closed square shows the latency time of the DPM. The closed circle shows the latency time of the PLC. The closed triangle shows the sum of the PLC and DPM latency times.

Figure 5 shows the results of the measurement. The results show that the latency time of the PLC is almost the same as the previous measurement. The latency time of the DPM was about 4 ms due to no averaging required at the DPM. The total latency time of the DPM and PLC is about 16 ms with a ± 5 A threshold window, the settings used during beam operation. An additional latency time from the PLC to the fast extraction kicker magnet in the MR of 0.07ms was measured, but time is negligibly small compared to the latency of the DPM and PLC. We drastically reduced the latency time of the interlock system of the NC PSs, reducing the risk for damage of beamline equipment by high intensity beam.

SUMMARY

We have developed new NC PSs in collaboration with a power supply company, and upgraded the control system for safety and stable operation of a high intensity proton beam. We integrated the new NC PSs into the existing interlock system which checks for NC PS current fluctuation. The latency time of the interlock system was drastically reduced. We developed an EPICS-based control system for the new NC PSs which is simpler and less complicated than old one.

The mirror mounts would have control along three axes – transverse tilt control Left/Right and Up/Down for the mirror itself, and longitudinal In/Out on a linear stage to insert and retract the mirror entirely from the laser path. Additionally, two solenoid driven shutters for Drive Laser and two for the Heater Laser would be used to block the unused beams or block both beams while the mirrors are inserting or retracting. These all need to be controlled remotely over the EPICS Channel Access network with automated code to assist in fast switching.

IMPLEMENTATION

For simplicity and to help with maintenance costs we chose to stick with the same or compatible hardware devices already used elsewhere in the laser system wherever possible (Figure 2).

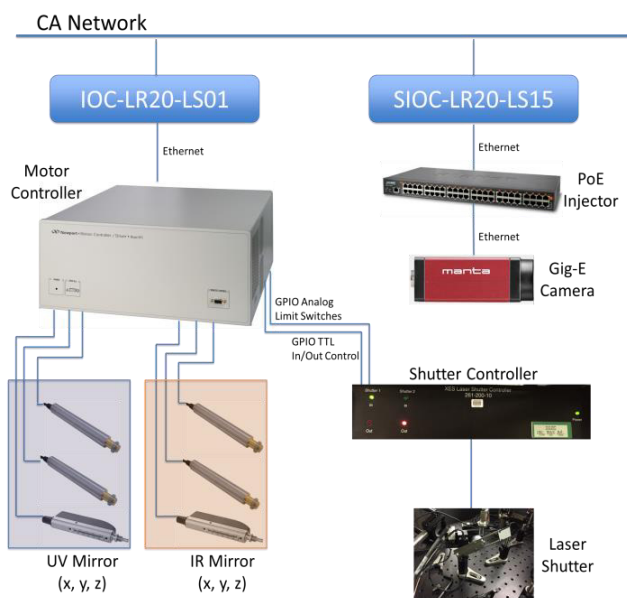

Figure 2: Hardware architecture for installation.

Motion Control

For motor control in the LCLS Laser System we typically use the Newport XPS-Q8 smart motor controller in conjunction with compatible stepper or servo motors also from Newport. We kept to this trend and chose the LTA-HS stepper motor for the In/Out control and used TRA6CC steppers for the transverse steering control.

Shutters

The shutters we use are SLAC built devices consisting of a black high absorption (non-reflective) material on a solenoid driven arm. The fully open and closed positions have photo-interrupter limit switches. Control is managed by a SLAC built controller chassis which provides local status and power for the shutters and can in turn be controlled via TTL output and position switch read back signals. Since we were already using the Newport XPS controller for the mirror motors, it was a simple decision to use the built-in GPIO ports to handle control and read back of the shutters as well.

Cameras

In order to monitor the spatial profile and alignment of the spare laser while not in use, a camera was installed which the Laser Operators can monitor daily and ensure that the spare is in good condition. We used an AVT Manta G033B Gig-E camera with Power-Over-Ethernet (PoE) and the cover glass removed by the vendor to enable use with UV.

A Soft IOC is run on a Dell PowerEdge R620 server where all image processing is done. As raw image data from the camera can require a lot of bandwidth, the cameras are run directly to the server on a local DHCP managed IP address before being processed down and set out over the Channel Access network. A Planet HPOE-2400G PoE Injector is used between the camera and the server to provide power to the camera.

TWO-BUNCH CONSIDERATIONS

In addition to the primary goal of fast remote switching between the two laser systems, it was also desired by the physicists to allow for both lasers to be run simultaneously separated slightly in time. To accomplish this, the switching mirrors are replaced with beam splitters which are left in place and the shutters alone select which beam (or both) is allowed down into the injector vault. The time delay can be adjusted either by varying the EVR trigger delay one of the laser's RF phase-lock-loop (PLL) or by using the existing motorized delay stage in the pulse stacker.

Safety

The Beam Containment System (BCS) safety system uses toroids to measure the electron beam current at various points along the accelerator and trips off the machine if it measures losses exceeding the limits allowed by the Radiation Safety group. These toroid comparators use gated ADCs and to ensure that they do not miss the beam, photo-diodes in the laser are required to measure the laser pulses within a timing gate shared with the toroid comparator system. If the laser falls outside of this 40 ns wide gate, the beam is shut off.

With the addition of a second laser pulse it was necessary to ensure that this photo-diode system could see both pulses and act to make sure that they both fell within the timing gate. As long as both pulses were contained within the 40 ns gate we found that the toroids would successfully average over them both to give an acceptable measurement of the total beam losses.

SOFTWARE

All hardware for the project is controllable through EPICS R3-14-12 with an EDM gui interface (Figure 3). Position setpoints both for the In/Out positions and steering are saved for each laser and can be changed by Laser Operators to compensate for alignment differences between each laser line.

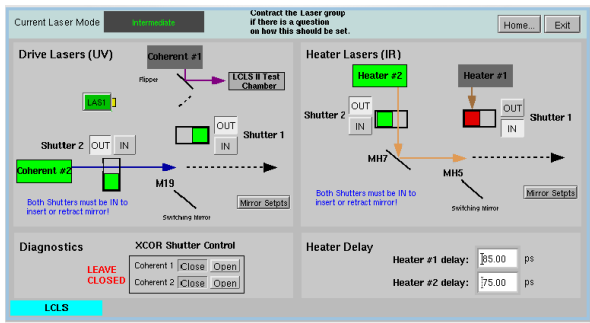

Figure 3: EDM switching interface.

An additional PyQt4 application was also written in cooperation with the control room Operators to provide an automated interface to load and change parameters when switching between lasers (Figure 4).

Figure 4: PyQt4 Switching Interface. Camera image shows the laser on the virtual cathode after the switching mirrors to ensure that beam is aligned properly.

CONCLUSION

With the old laser setup, switching lasers in the event of a failure would often take several hours. With the new remote switching controls in place however, the Control Room Operators have successfully managed to perform the switch on many occasions in less than 15 minutes. This drastically reduced the downtime incurred by laser equipment failure as well as allowed for more opportunities for the Laser Operators to request that the lasers be swapped so that they may perform scheduled maintenance which in turn has improved the long term performance of the injector laser system as a whole.

We have also now had several experimental shifts running with the new two-bunch operation mode [2] and have successfully seen both laser pulses within the BCS timing gate (Figure 5).

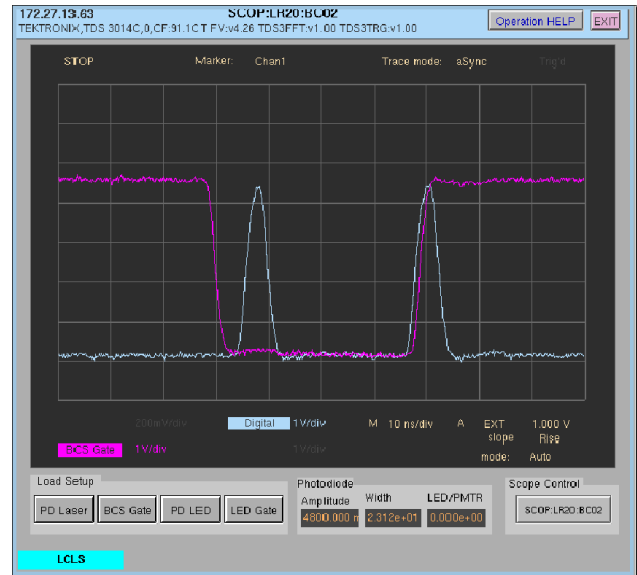

Figure 5: BCS Timing Gate on oscilloscope. Magenta trace shows the toroid timing gate and the blue trace shows the two laser pulses.

Having proved that the Toroid Comparator system is able to integrate across both beams simultaneously and trip the beam appropriately in the event of losses, we were approved to use this technique to create XFEL for experiments. Taking the light emitted in the Undulator Hall from the two bunches through the into the FEE diagnostic area showed that we were indeed able to lase on both bunches separately by ionizing gas and reading out the scattered particles on PMT detectors (Figure 6).

Figure 6: Gas Detector raw waveforms (above) show a 2.5:5 ratio after the laser heater was timed for the first bunch. The spike in the front is an instrumental reaction to coherent synchrotron radiation. Therefore the integrated GDET signal typically uses the counts from 250 to 400 ns.

The two-bunch XFEL was also taken to one of the user hutches where they were imaged hitting a single injected water droplet simulating the use case for experimentation (Figure 7).

Figure 7: XFEL beams imaged by camera in CXI experimental hutch hitting water droplets. Single bunch beam is seen on the left and two-bunch on the right. The arrows indicate the XFEL beams.

NEW DEVELOPMENTS ON EPICS DRIVERS, CLIENTS AND TOOLS AT SESAME

I. Saleh, Y.S. Dabain, A. Ismail, SESAME, Allan, Jordan

Abstract

SESAME is a 2.5 GeV synchrotron light source under construction in Allan, Jordan. The control system of SESAME is based on EPICS and CSS.

Various developments in EPICS drivers, clients, software tools and hardware have been done. This paper will present some of the main achievements: new linux-x86 EPICS drivers and soft IOCS developed for the Micro-Research Finland event timing system replacing the VME/VxWorks-based drivers; new EPICS drivers and clients developed for the Basler GigE cameras; an IOC deployment and management driver developed to monitor the numerous virtual machines running the soft IOCs, and to ease deployment of updates to these IOCs; an automated EPICS checking tool developed to aid in the review, validation and application of the in-house rules for all record databases; a new EPICS record type (mbbi2) developed to provide alarm features missing from the multibit binary records found in the base distribution of EPICS; a test of feasibility for replacing serial terminal servers with low-cost computers.

INTRODUCTION

SESAME consists of a 22 MeV Microtron, an 800 MeV Booster Synchrotron and a 2.5 GeV Storage Ring. Control System Implementation uses (EPICS) base R3.14.12. Servers are implemented as EPICS Input/output Controllers (IOCs). Clients are implemented using a custom build of Control System Studio (CSS) based on V.3.16. Siemens S7 PLC controllers are used for the machine interlocks. An Allen Bradley PLC controller is used for the Personal Safety System (PSS). VME hardware is used for the timing system. Development and administration platforms use Scientific Linux 6.4. A Git version control is used to track development and documentation. All clients, servers, and controllers are connected to an isolated machine network. There are twelve virtual servers reserved to run the IOCs, archive system, alarm system and Git repositories.

The control systems have been implemented for the Microtron, Transfer Line 1 (TL1) and Booster. The Booster's control system is divided into seven subsystems: vacuum, power, RF, diagnostics, cooling, timing and Personal Safety System (PSS). Each control subsystem consists of one or more clients, servers, and controllers [1]. This paper will focus on the developments on EPICS drivers, clients and tools at SESAME.

TIMING SYSTEM DRIVER

The timing system for the Booster consists of one event generator VME-EVG230 and one event receiver VME-EVR230, both of which are connected to the EPICS network over TCP/IP. New Linux-x86 EPICS drivers were developed for the timing modules from Micro-Research Finland.

The VME-EVG230/VME-EVR230 are traditionally controlled over the VME bus. Both modules can also be programmed over the available Ethernet port however. Building an EPICS driver for controlling the timing modules over Ethernet instead of the VME bus has the following benefits:

- Drops the dead weight: The VME crate, the VME CPU card, the RTOS that runs on the CPU card (along with any required licenses), and the debug terminal that connects to the CPU card are no longer needed.
- Lowers the cost of implementation: A direct consequence of the point above.
- Confines the required development skills to Linux/x86 platforms. Knowledge in VME-bus, VxWorks, or any other RTOS/OS is not required.
- Maintains coherency in the control infrastructure. This point may be specific to SESAME only since all of the IOC's at SESAME run on Linux/x86 platforms.

The device layer uses the traditional asynchronous processing model of EPICS support modules. The driver layer uses the remote programming protocol of the timing modules to control them. This protocol uses UDP. The drivers add feedback, retransmissions, and timeouts to create reliable communication over UDP.

Both drivers are LGPL'd and can be found as public domain on Github [2]. The client of the timing system is implemented in Control System Studio (CSS) and is shown in (Fig. 1).

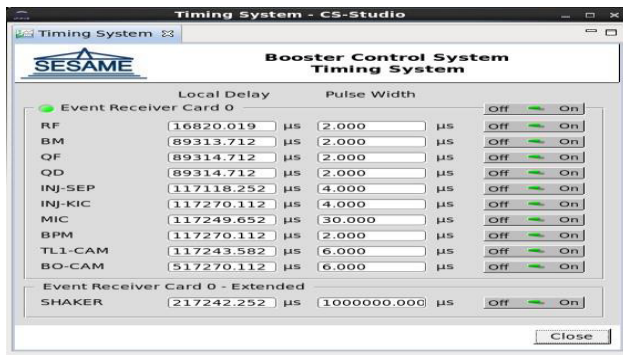

Figure 1: CSS Timing OPI.

BASLER GIGE CAMERA DRIVER

New Linux/x86 EPICS driver was developed for the GigE camera series from Basler. The device layer uses the traditional asynchronous processing model of EPICS support modules. The driver layer uses the Pylon libraries from Basler to control the cameras over Ethernet. Once configured, the driver starts a separate server thread for each camera. Each server thread listens for commands such as image capture or gain and exposure settings. A set of mutexes and signals are used to synchronize operation between the various threads.

BASLER GIGE CAMERA CLIENT

To connect to the Basler GigE camera driver, a custom client was built at SESAME utilizing the EPICS channel access libraries. The client is responsible for providing a graphical user interface to render the camera's video stream possibly doing some image post-processing like colour mapping and to control the camera image settings.

The camera client uses the EPICS channel access libraries to monitor and control the various records provided by the driver. A waveform record contains the grayscale image data and various analog input/output records provide access to camera's gain, exposure, ROI and trigger source. Once the camera client is started it connects to the driver and enables the camera. The camera is usually disabled if unused to save network bandwidth. Once the camera is enabled, the waveform record containing the grayscale image starts updating as the camera is triggered. On each update, a call-back is called in the client to copy the image data to one of two buffers used to render the image. One of the buffers is being read from while the other is written to. And once the image buffer is completely written to and ready, a switch is done so that the next render uses the new image data. The double-buffering is used so that no tearing happens in the rendering of the image.

The client is written in C using OpenGL, SDL, AntTweakBar and of course EPICS channel access libraries.

OpenGL is an API to do high performance 2D and 3D rendering on computers. In the client, it is used to render the image frames maintaining a high framerate while consuming low CPU cycles and RAM memory. SDL is a

cross-platform library used to provide access to keyboard, mouse, and windowing system and graphics hardware via OpenGL. AntTweakBar is a library that works with SDL and OpenGL to provide a light graphical user interface to interactively tweak parameters and settings in an application. It is used to control and show the camera image settings like region of interest, framerate and trigger source.

Both driver and client are LGPL'd and can be found as public domain on Github [3]. (Fig. 2) shows the camera client presents colour mapping option.

Figure 2: Camera Client.

IOC MANAGER

The control infrastructure at SESAME uses 12 virtual machines to run the different IOC's and 8 physical machines to run the clients and for development purposes.

The IOC manager is a Linux/x86 EPICS driver developed for the purpose of managing all the machines that are part of the control infrastructure at SESAME.

Specifically, the IOC manager provides the following services:

- Hostname and user of the IOC
- Date, time, and uptime of the IOC
- Drive, memory, and CPU utilization
- Control over which IOC's to run
- Enabling/disabling of the IOC's
- Build system

The date/time information give diagnostics on whether or not the IOC is synchronized with the NTP server. The drive, memory, and CPU utilization are indicators on the health of each IOC. They are connected to the alarm handler at SESAME. Control over which IOC's to run enables us to run different IOC's on different machines, and lets us know which IOC's are running where. Enabling/disabling the IOC's allow us to manually shutdown, turn on, or reset the IOC's. Finally, the build system of the manager synchronizes the IOC with the main Git repository, builds the source, and restarts the IOC's.

Each IOC is run inside a separate terminal multiplexer session. This allows us to a remotely attach/detach to a session whenever we need to access the IOC itself.

The driver layer uses traditional synchronous EPICS processing model of EPICS support modules. The device layer uses standard POSIX API to access machine information. Bash scripts are used to synchronize with the main Git repository. The client of the IOC manager is implemented in CSS and is shown in (Fig. 3).

The screenshot shows the 'Main Control System Machine Control' window. It contains a table with columns: Username, System Time, IOC Uptime, Free RAM, Free Space, Average Load, Application, Enable, and Sync. The table lists various machines under categories like Virtual Machines, Service Area, Control Room Machines, Lab Machines, and Infrastructure. Each row shows details for a specific machine, including its name, control status, uptime, and resource usage.

Figure 3: IOC Manager Client.

DB-CHECK TOOL

The db-check tool is a command line tool built at SESAME that automatically analyzes, validates and aids in applying continually evolving in-house rules for EPICS records databases. It was primarily built to help in reviewing, unifying and maintaining the numerous EPICS databases present.

Features provided by the db-check tool include: listing all records by name, or by type; querying a record to show all of its details and Process Variables (PVs); producing reports of records usage in each system, and what fields are set in those records; producing up-to-date alarm and archiver XML configuration files; and checking some in-house rules that PVs should follow.

Examples of the PV rules applied include: always having a DESC field present in all records; always having a ZNAM, ONAM, ZSV and OSV for BO records; always having the name of PVs to start with a one of a predefined set of prefixes (eg. is, get, set, reset, enable or disable)..

The way the db-check works is by parsing the DB and DBD files using a PEG grammar. The tool is built in D programming language and using pegged library for the parser [4]. The D programming language was chosen because it provides modelling power, efficiency and high performance in a coherent set of well-thought features, and because it interfaces easily and natively to the C programming language. An important feature that specifically helped in this project is compile-time function evaluation (CTFE) and mixins. This feature is used in pegged to build the parser using the grammar definition at compile-time instead of depending on a separate build step. And it reduced the compile-run-debug cycle time.

MBBI2 RECORD

Mbbi2 is a new record type developed at SESAME to overcome some limitations present in the official mbbiDirect record type in regards to alarms. An mbbi2 record is almost exactly the same as an mbbiDirect record except for its ability to specify alarm states for individual bits.

Frequently, devices provide read access to status registers where different bits mean different things. Some of those bits hold on/off status, others hold warnings and others hold interlock status. Using an mbbiDirect record to model this in EPICS creates a problem for alarm handling as value alarms are not supported. To support this without introducing a new record type will require using multiple CALC fields. The way mbbi2 resolves this is by setting an alarm severity on zero and one for each bit. The alarm severity for the record is equal to the highest alarm severity of its bits.

The main problem of introducing a new record type is the maintenance requirements of integrating it with the different drivers and their build systems.

TERMINAL SERVER

The terminal server is an experiment to provide simple serial to Ethernet converters using low cost computers. The computers have multiple serial ports that are mapped using the accompanying software to TCP ports available over an Ethernet network. The software was built to run primarily under minimal x86 or x64 Linux systems using libevent2 for asynchronous non-blocking communication. The software, once started, reads a configuration file and accordingly connects to a serial device on the specified baud rate and starts listening for clients on a TCP port. Once a client connects, data coming from the serial device is forwarded to the TCP connection and vice versa. Some simple statistics are printed periodically to the console for simple diagnostics.

Tests for the system showed that it was working well, but it has not been used in a production settings as of yet.

CONCLUSION

The control system of SESAME is based on EPICS and CSS. Development of new drivers, clients and tools at SESAME is important to make the control systems up to date and more consistent. Standards are used for both EPICS databases and CSS client OPIs.

Abstract

The KEKB project has successfully ended 13 years operation in the June of 2010. The construction of SuperKEKB main ring has almost completed for aiming at the peak luminosity of $8 \times 10^{35} \text{ cm}^{-2}\text{s}^{-1}$. The injector linac upgrade is also going on for increasing the intensity of bunched charge with keeping the small emittance. The key upgrade issues are the stable operation of a new positron capture system, a low emittance photo-cathode rf electron source, and the establishment of low emittance preservation. The injector linac beam commissioning started in the October of 2013. The control system performance determines the beam operation efficiency of injector linac, and it eventually has a strong impact on the experimental results of physics. In this decade, the linac control system has been gradually transferred from the in-house system to the Experimental Physics and Industrial Control System based one for the high availability of beam operation. In this paper, we present the detail of SuperKEKB injector linac control system.

INTRODUCTION

The linac beam control system is based on a standard client and server model with three layers. It comprises a client, a server, and a local controller layers. At the beginning stage of KEKB operation, the original linac control system has been developed by using the in-house software libraries based on the remote procedure call (RPC). The client user interfaces have been implemented by a command line interface based on shell script and a graphical user interface based on Tcl/Tk scripting language. Around a decade ago, the middle phase of KEKB operation, the linac control system has been upgraded to a new framework based-on the Experimental Physics and Industrial Control System (EPICS) [1] to improve the affinity between the linac and KEKB main ring control systems. These improvements make it possible to conduct the correlation analysis of linac and main ring parameters in much easy way. Such analysis can strongly help to find a source of injection rate deterioration and any other troubles.

After introducing the EPICS framework, the new client side user interfaces have been implemented by Python scripting language since its rich library modules and functionalities can accelerate the software development process. For the simultaneous top-up injection of KEKB

and PF rings, an event based timing system has been installed to enable the pulse-to-pulse beam modulation [2].

OUTLINE OF CONTROL SYSTEM

Computer Environment

In the beginning phase of KEKB project, the six Compaq Alpha servers based on the Tru64 UNIX operating system were utilized as the server computers. All server programs were basically run on them. Two of them were connected to the RAID disk drive via SCSI bus interface, and they can work as the active/standby redundant NFS servers for aiming at the high availability operation. Since the Tru64 UNIX was obsoleted, all server machines have been gradually replaced by the Linux-based servers. Eventually, we made decision to use the Linux base system without cluster functionality after the evaluation of several different types of high availability cluster system based on Linux. For keeping the high availability of server machines without cluster scheme, the blade server system was installed as the high reliability server. Currently, fifteen Linux based blade servers are utilized as the server computers with CentOS 5.11 x86_64. Both of server and client side control software are running on the server machines. CentOS 6.7 and 7.1 running on two blade servers are currently tested by using VMware vCenter of the virtual computing technology.

The Tektronix X terminals and touch panel displays based on PC9801/DOS machines have been originally utilized as the operator terminals. These terminals were replaced by the Linux based PCs and Windows based PCs with the X server application software of ASTEC-X and

Figure 1: Photograph of the KEK electron/positron injector linac main control room.

[#] e-mail address: masanori.satoh@kek.jp.

Reflection X. Figure 1 shows a photograph of the linac main control room. Three large liquid crystal displays (LCDs) with 55" show the alarm, operation, and interlock statuses. Sixteen LCDs with 27" are used for running the beam operation software and its development.

Network Environment

In the previous linac control network system, Cisco Catalyst 4506 and 3750 have been utilized as the master network core and slave switches, respectively, for enabling the active/standby failover. Each of them was independently connected to 45 edge switches of Catalyst 2950 via single or multi-mode optical fibers with 100 Mbps bandwidth. For the network connection between the edge switches and the local controllers like a programmable logic controller (PLC), the optical fiber is used for avoiding the noise generated by the klystron modulators.

Toward SuperKEKB operation, the core switch system was replaced by 6 of Cisco Catalyst 3750X. They can work as the active/active redundant system based on the virtual switching system technology. We replaced also the edge switch by Catalyst 2960S, and the network connection speed was improved up to 1 Gbps bandwidth. In addition, the wireless network was installed into the beam line tunnel for improving maintainability.

Local Controller

For the injector linac control system, many kinds of different local controllers are utilized for the injector linac component control as listed in Table 1. The ladder PLCs control the magnet power supplies, vacuum pumps, and safety related signals. About one hundred seventy CAMAC and VME based timing delay cards have been replaced by the 25 event timing cards based on VME64x bus for the pulse-to-pulse beam modulation. The

Table 1: List of the Network Attached Local Controllers used for the Linac Control System.

Devices	Accelerator components (# of components)	# of local controllers
VME64x	Event based timing system (MRF EVG-230, EVR-230RF)	25
PLC	Magnet (363) Vacuum (333) Klystron (5) Charge interlock	59 26 5 3
Network attached power supply	Magnet (105)	105
Linux based PLC	Profile monitor (100)	30
Embedded Linux	Klystron (66)	66
Data logger	Temperature (690)	28
Oscilloscope	BPM (90)	23
NIM modules	Timing watchdog (15)	15
Total		385

reduction of number of timing modules improves the system availability. The PLCs used for the klystron modulator control have been gradually replaced by the new embedded controller of Armadillo. The EPICS Input/Output controller (IOC) can run on it. The Windows based digital oscilloscope as the BPM readout system will be replaced by a new one based on VME card soon. Its measurement precision is around 3 μm [3].

EPICS ENVIRONMENT

Overview

In the linac control system, the EPICS IOCs were originally implemented with the base R3.14.9 for wrapping the existing in-house control system. Table 2 shows the total number of IOCs for each subsystem. The EPICS process variables (PVs) are just communicating with the existing system based on RPC when the software access any PVs. Toward higher reliability, the server applications were remodeled for the direct communication between the IOCs and local controllers by EPICS base R3.14.12. All EPICS IOCs are running inside the vncserver sessions as shown in Fig. 2.

Table 2: Number of EPICS IOCs used for each Subsystem.

Subsystem	# of IOCs
Safety	2
Monitor	48
RF	57
Magnet	19
Vacuum	1
Operation	3
Timing	21
Temperature	2
Total	153

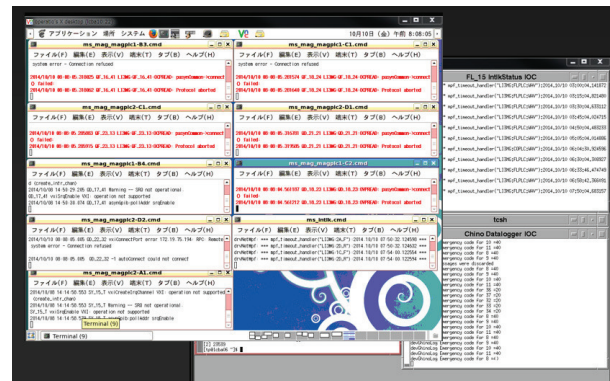

Figure 2: All EPICS IOCs are Running in the Vncservers.

Alarm

The independent in-house alarm applications were originally developed and utilized for each subsystems. For the comprehensive alarm management, we adopted the EPICS Control System Studio (CSS) [4] alarm 3.0.0 together with PostgreSQL 9.1.4 as a backend database

engine. Around 1000 PVs are currently registered to the CSS alarm. The graphical user interface (GUI) showing the alarm status was developed by the Python scripting language. The panel shows the both of summary and detailed information of alarm status. The more detailed historical list of alarmed PVs can be also displayed in the other windows. Since the total number of registered PVs will be increased toward SuperKEKB operation, we are evaluating the speed performance and the robustness of CSS alarm with the large number of PVs.

Archiver

In the original linac control system, we developed the simple archiver tool recording the parameters into a text file together with the dedicated viewer software. After the implementation of an EPICS based control system, the EPICS channel archiver and CSS archiver 3.2.2 together with PostgreSQL 9.1.4/9.3.3 have been utilized. The total number of PVs registered to each archiver is currently 44063. The daily disk space usages are approximately 2 GB and 4.5 GB for channel and CSS archiver, respectively.

The web based data browser is utilized for the CSS archiver though the standard java based viewer is used for the channel archiver. The web based one was developed with Flex 4.6, PHP 5.3.6, and Amfphp 1.9. It can provide the easy access to archiver data from the any client devices including mobile one. It has the functions of correlation plot, multiple vertical axes, PV name search, and autocomplete for the quick parameter analysis.

The data retrieve speed of CSS archiver is slower than that of channel archiver. For improving these issues, the `pg_reorg` option was added into PostgreSQL database. It can reduce the CSS archiver database size by 33%, and improve the data retrieving time to a certain extent. For the further improvement of data retrieving speed, another scheme using the NoSQL type database of Casandra as a backend is now being evaluated.

OPERATION SOFTWARE

Outline

The original linac operator interface was developed by the Tcl/Tk scripting language and command line interface. For the rapid application development, the main software development language was transferred to Python scripting language. The communication between the operation software and EPICS PVs can be established via PythonCA module developed for the KEKB project.

Operation Status Display and Electronic Logbook

The real-time linac operation status is given through the Web-based application which can be run on the multiple operating system without installing specific software. This web application was implemented by using WebSocket together with Node.js and Socket.IO library. WebSocket can reduce the CPU load on the server machines in comparison with the other technologies like Ajax or Comet since its protocol can provide a full-duplex

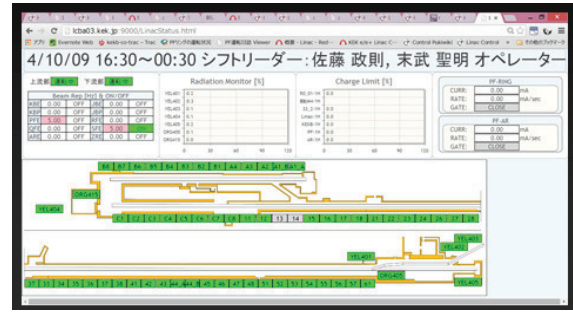

Figure 3: Web-based linac operation status.

communication channels over a single TCP connection. This application shows the information of present beam repetition, high power klystron status, radiation monitor status, and so on as shown in Fig. 3.

The electronic operation logbook system (OPELOG) can enable the rapid operation information sharing between the accelerator operation team and hardware group. We developed an OPELOG system with Flex 4.6, PHP 5.3.6, Amfphp 1.9, and PostgreSQL 9.4.0. It comprises the summary and detailed information screen for each operation shift. OPELOG can automatically record the all routine operation state transition like the status change of beam repetition and klystron failure. In addition, a snapshot of operation GUI image can be easily imported into the detailed information screen. Moreover, OPELOG has the quick search function of past log by a key word combination set during a specific time period. It can be a strong help to find a solution of similar trouble occurred in the past.

CONCLUSION

Towards SuperKEKB project, the injector linac upgrade and commissioning are now on going for aiming at the 4 ring simultaneous top-up operation. Since the middle phase of KEKB operation, the linac beam control system has been gradually transferred from the in-house system based on RPC to the EPICS based one. Many operation software are developed by the Python scripting language. The data retrieving speed performance of archiver and the rapid development of advanced commissioning tools are recent main issues.

CONTROL SYSTEM DEVELOPMENTS AT THE ELECTRON STORAGE RING DELTA

D. Schirmer*, A. Althaus, F. Bahnsen

Center for Synchrotron Radiation (DELTA), TU Dortmund, Germany

Abstract

Increasing demands, mandatory replacement of obsolete controls equipment as well as the introduction of new software and hardware technologies with short innovation cycles are some of the reasons why control systems need to be revised continuously. Thus, also at the EPICS-based DELTA control system [1], several projects have been tackled in recent years:

(1) Embedding the new CHG¹-based short-pulse facility for VUV and THz radiation [2-4] required, for example, the integration of IP-cameras, Raspberry-Pi PCs and EtherCat/TwinCat wired I/O-devices [5, 6].

(2) The request for a staff-free control room led to the programming of new web applications using Python [7] and the Django framework [8]. This development resulted in a web-based interlock system that can be run, amongst others, on Android-based mobile devices.

(3) The virtualization infrastructure for server consolidation has been extended and migrated from XEN [9] to the kernel based KVM [10] approach.

(4) I/O-units which were connected via conventional fieldbus systems (CAN, GPIB, RS-232/485), are now gradually replaced by TCP/IP-controlled devices.

This paper describes details of these upgrades and further new developments.

INTRODUCTION

DELTA, a 1.5-GeV electron storage ring, is operated since 1999 by the TU Dortmund University as a synchrotron light source for campus-based, regional and international users. Since 2011, the facility has been extended by a short-pulse source for VUV and THz radiation making use of the CHG principle. An upgrade to EEHG² is in preparation [11]. Not only for these reasons the EPICS-based DELTA control system has been revised and complemented in many fields.

NEW SOFTWARE

Network Administration Tool

Since the number of control system network devices and, thus, the complexity of the network topology increased constantly, it was mandatory to develop a DELTA-specific management tool. With the help of this tool, all individual devices and their connection properties are registered centrally. It administers network interfaces, IP/MAC numbers and assignments to domains. Furthermore, it generates consistent DNS/DHCP configuration

files as well as location and network plans. The program is implemented as a web application and is based on the high-level Django/Python framework [7, 8]. All data and configurations are stored in the DELTA MySQL [12] database.

Web Applications

The local radiation safety authority has given its consent to a non-permanent attendance of the control room during standard machine operation. For security reasons, however, it was necessary to develop an additional alert system, which notifies the operator to machine malfunctions via a mobile phone.

For real-time monitoring of the accelerator interlock warnings, a web-socket connection is performed, which keeps a full-duplex communication link between a client (e.g., an Android-based mobile phone) and a server continuously open. The connection uses WAMP¹ [13], a web-socket sub-protocol (with RPC² and publish & subscribe mechanism).

On the server side (see Fig. 1 below), *Crossbar.io* [14] is the central software component. It interacts as a message WAMP-router for different so-called service nodes. One node provides the service to read EPICS records another calculates and triggers interlock warnings (all implemented with Python). In addition, it launches web services that provide panels accessible from various URLs. There are web pages for machine status (e.g., beam current, lifetime, insertion device status), interlock notifications as well as the electronic logbook (see Fig. 2).

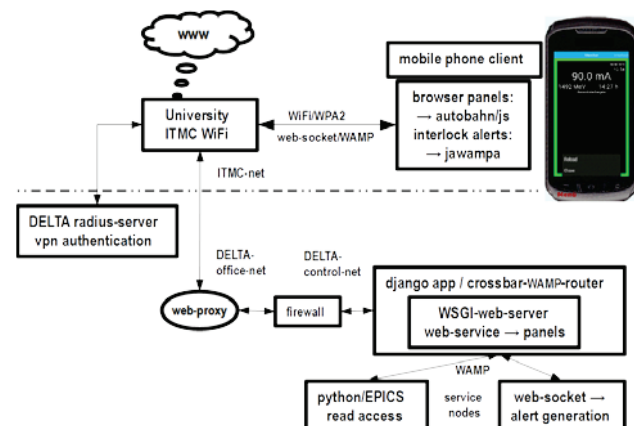

Figure 1: Software setup of the WiFi alert system.

On the client side (see Fig. 1 top), e.g., an Android-based smartphone, an *Autobahn/JS*-application [15] (an implementation of WAMP in javascript) displays the

*detlev.schirmer@tu-dortmund.de

¹Coherent Harmonic Generation

²Echo -Enable Harmonic Generation

¹Web Application Messaging Protocol

²Remote Procedure Call

server-side spawned panels, and a *jawampa*-application [16] (library to support WAMP to Java) indicates the interlock warnings, all in real-time. The communication is established via WiFi inside the DELTA building. For security reasons, all WiFi-clients must connect to a specially preconfigured ITMC¹-WiFi controller including an authentication mechanism (radius server [17]). After a successful login, a web-proxy inside the DELTA office network relays the link through a firewall to the dedicated web server/WAMP router within the machine control network, from where EPICS access is possible. An acoustic and vibration alarm will be activated on the mobile phone in the case of a machine alert or server connection lost (see Fig. 1).

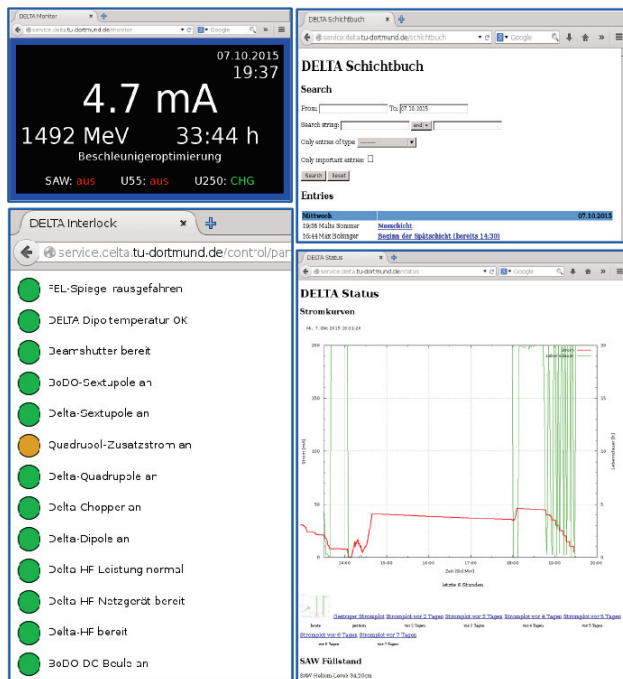

Figure 2: Web applications (panels for: DELTA monitor, logbook, interlock and status).

As another consequence, the central display server for all status monitor panels in the machine hall and the office corridors uses the same standardized web service (see URLs as already discussed above). Also PC-client access to the web-based logbook (elog) or the interlock panel is provided within the DELTA-Intranet or via VPN-access even worldwide. Dedicated permitted URLs are also accessible directly from the Internet (see Fig. 2).

Furthermore, a new acoustic message announcement system has been implemented. Alarms triggered by electron beam losses, temperature warnings, and orbit control problems as well as the injection timer are now audible in the control room and the machine hall. A PyEpics [18] script evaluates corresponding Epics records and plays appropriate speech announcements (pre-arranged voice-files).

¹IT & Medien Centrum of the TU Dortmund

Server Consolidation

Since 2009, the XEN paravirtualization technique [9] was successfully in use. It was an ideal basis to consolidate and modernize the DELTA client/server control system network [19]. Nowadays, all server-CPU's support hardware-assisted virtualization (VT, AMD-V) and, in addition, kernel-based virtualization (KVM [10]) is by default merged into the standard Linux kernel. The migration to this kind of full virtualization was required for maintenance reasons. KVM is driven by *qemu* [20] and provides an API to control VMs with GUIs like *virt-manager* [21]. In the course of this migration, all server and virtual machines have been upgraded to the latest operating system (Linux Debian 7/8 [22]). This upgrade implies also the introduction of *systemd* [23], a new system and service manager for Linux-OSs and the successor of *sysvinit* [24]. Thus, even all EPICS soft IOC shells are now centrally managed by this powerful OS-integrated software package.

Also for the purpose of maintenance the default installation of all servers is now centrally and automatically managed by the software suite *Ansible* [25]. This software package provides a simple way to automate administration tasks and to setup a complete server infrastructure. Essentially, it is a model-driven configuration management and ad-hoc task execution tool. The in-house developed network tool stores primarily all IT devices including their connection properties in database entries. Based on this information, *Ansibel* generates, updates and transfers the corresponding configuration files and restarts all affected servers subsequently. Thus, the complete DELTA network configuration such as DHCP, DNS, VPN, NTP and user/group installation as well as login accounts (ssh keys, passwords) are automatically supervised site-wide.

INTEGRATION OF NEW HARDWARE

Today, real-time requirements are fulfilled satisfactorily by specially designed fast electronic circuits (e.g. DSP-driven booster synchrotrons [26] or FPGA-operated fast orbit feedback systems [27, 28]). But in most instances accelerator control applications do not need strong real-time features. As many hardware units provide standard Ethernet interfaces, they can be controlled over the TCP/IP network. Thus, for example, the error-prone RS232-serial to CAN-bus readout of the vacuum gauge control units has been replaced by MOXA port communication devices [29] that allow to control different kinds of serial devices directly over a TCP/IP-based Ethernet, avoiding the extensive VME-CAN-controller (VxWorks [30]) middle-layer.

For the same reason, several PLCs (e.g., electron gun control, valve and vacuum-pressure interlock) were subsequently equipped with TCP/IP communication modules. Even recent power supplies for the storage ring quadrupole magnets, also prepared for Ethernet connectors, are now driven directly over the TCP/IP control network, as far as synchronized magnet ramping

on a sub-second timescale is not required. The I/O-bus interface for the EPICS device support is realized by use of the well-established StreamDevice [31]/asynDriver [32].

More special hardware and software is necessary in order to drive mirrors, for example, in the evacuated laser beam lines of the short-pulse facility. Because the current system has been discontinued, a new control unit is being evaluated. Here, stepper motors [33-35] are controlled over EtherCAT [6], a vendor-initialized real-time Ethernet (see Fig. 3).

Figure 3: Hardware setup of stepper motor control [35].

The hardware configuration, such as a setup of motor parameters, is managed by the TwinCAT system manager [5], whereas the motor movement logic is programed on a PLC controller. The link to EPICS is accomplished via a vendor specific OPC¹-server [36] and an EPICS IOC-shell with OPC driver support (OPC client) [37]. OPC is an interoperable standardized platform for industrial automation [38]. All three software levels are running on the same Windows-PC internally communicating over DCOM [39] (see Fig. 4).

Figure 4: Software setup of stepper motor control [35].

As the software encoding of the stepper motors is imprecise due to slippage and x/y motion coupling, the determination of the true mirror position must be realized by high-accuracy contact sensors and additional limit switches [33]. The analog sensor signals are connected to converter device providing a standard serial (RS232) communication interface. This port can be used again by RS232 EtherCAT terminal or by a single board controller (SBC, Raspberry-Pi) running Linux and PyEpics [33, 40]. A similar readout is possible for the digital signals of the limit switches (see Fig. 5).

Figure 5: SBC for mirror position read back.

SINGLE BOARD COMPUTER (SBC) PROJECTS

SBCs are more and more the system of choice for “quick-and-dirty” all-round solutions. They run as central display-servers in the control room to present live images of oscilloscopes which are distributed inside the storage ring hall, or work as DHCP/DNS/VPN backup servers for the office network. Further examples are:

Test Bed for DAC Controller Cards

The DELTA booster synchrotron (BoDo) is ramped rather slowly by VME-IOC computers (from 70 MeV to 1.5 GeV and back in approx. 7 seconds). The ramp curve is user-defined and has to fulfil several sensible conditions. All booster magnet power supplies are driven by 16-bit DAC boards. The functionality of these boards is quite crucial and must be checked in advance by a simple SBC-based test bed. A python script on the SBC converts the booster ramping curve to a 16-bit digital I/O signal which is mapped via a photocoupler adapter card for voltage level matching and finally fed to the DAC-board input. The resulting analog DAC output value is measured and analyzed under several test conditions (e.g. ramp cycle frequency, curve shape, temperature variation) by a circuit analyser.

Laser Beam Alignment Diagnostics

For near-field angle measuring of the beam guidance in the laser laboratory, a SBC, equipped with a standard 5-megapixel CCD camera, is in preparation (see Fig. 6). A converging lens focuses the beam on the CCD chip. Changes of beam angle yield a shift of the focal point of the Gaussian intensity distribution. A python script quantifies this displacement and writes the measured value to EPICS records. Background radiation can be reduced via a SBC-GPIO triggered slit. This basic cost-saving setup allows angular measurement within very short distances with a resolution of 50 μ rad in both transverse directions [40].

¹Open Platform Communication

Figure 6: Test setup for laser beam diagnostics [40].

CONCLUSION AND OUTLOOK

The already existing hardware and software at the DELTA storage ring undergoes continuous modifications, mainly pushed by short industrial development cycles. The integration of new experimental setups described in this paper and others not discussed here are primarily for the self-evident purpose that accelerator and laser components can be remotely controlled or read out. To keep track of the increasing number of devices and their complex networking, the installation of new administration tools was necessary.

The future work will still put emphasis on the development of advanced web applications for machine control and monitoring. Furthermore, data-mining and post-processing has increasingly become an important task. Therefore, to optimize data analysis processes, an entire redesign of the DELTA MySQL database is essential.

ACKNOWLEDGMENT

We would like to thank all colleagues of the DELTA team for permanent support. In particular we thank Dennis Zimmermann, Carsten Mai and Boris Sawadski for constructive discussions and for providing detailed information about mirror control system, laser beam diagnostics and single-board controller applications.

UPGRADES TO CONTROL ROOM KNOBS AT SLAC NATIONAL ACCELERATOR LABORATORY *

S. Hoobler#, S. Alverson, M. Cyterski, R. Sass, SLAC National Accelerator Laboratory, Menlo Park, CA, 94025, U.S.A

Abstract

For years, accelerator operators at the SLAC National Accelerator Laboratory (SLAC) have favored hardware knobs in the control room for accelerator tuning. Hardware knobs provide a tactile, intuitive, and efficient means of adjusting devices. The evolution of separate control systems for different accelerator facilities at SLAC has resulted in multiple flavors of knob hardware and software. To improve efficiency, space usage, and ease of use, the knob systems have been upgraded and integrated.

BACKGROUND

SLC Knobs

In the 1990s a knob system was developed for the SLAC Linear Collider (SLC), using hardware knob chassis designed by Miranova Systems. SLAC developed software and a DOS knob controller to interface the knob chassis to the SLC VMS control system [1].

EPICS Knobs

The Linac Coherent Light Source control system is based on EPICS (Experimental Physics and Industrial Control System). EPICS software was written to interface the existing knob hardware to the LCLS control system. At that time, it was presumed that the VMS control system would soon be decommissioned and no effort was made to integrate the two systems.

Knob Use at SLAC

To date, the VMS control system and its knobs are still used by the Facility for Advanced Accelerator Experimental Tests (FACET) and the Next Linear Collider Test Accelerator (NLCTA). EPICS knobs are used at LCLS, the SPEAR storage ring, and NLCTA.

Until recently, the VMS and EPICS knob systems were still not integrated, making an inefficient use of space and knob hardware. To improve this, the knob software and hardware have been updated to allow individual boxes to be used by multiple control systems simultaneously.

DESIGN CONSIDERATIONS

Backward Compatibility

To stay compatible with the legacy knob hardware and software, the new system supports the existing communication protocols.

*Work supported by U.S. Department of Energy under Contract Number DE-AC02-76SF00515

System Performance

The system should maintain the performance standard of the previous systems.

- Good knob resolution.
- Quick response.
- Allow same device to be assigned to multiple boxes simultaneously without conflict.
- Ability to restore device to original value.

Enhancements

To support operation of multiple facilities from the same location, the system was enhanced to allow a single box to be used with multiple control systems simultaneously.

Maintainability

The system will initially use the legacy protocols to remain backward compatible. As older systems become decommissioned, it may be desirable to migrate to other protocols. The software should be modular to facilitate this.

Flexibility

Unlike the legacy SLC control system, the LCLS EPICS control system is distributed. There is no pre-defined list of devices that may be attached to knobs. Any EPICS process variable may be attached. The software should be flexible to handle generic cases and should also provide support for device-specific settings and facility-specific conventions.

SYSTEM IMPLEMENTATION

A knob system consists of the elements shown in Figure 1. The Knob Controller handles all communication with the hardware knobs. The hardware knob boxes and the Knob Controller together act as a server to the Knob Users. The Knob Users are the accelerator control systems which wish to attach devices to knobs. The Controller is the interface between the Users and the hardware knobs and will accept requests from any User in the system.

In this implementation, the knob hardware uses a serial protocol while all software entities use Ethernet protocols. A terminal server performs the conversion between serial and Ethernet packets. An individual knob box has four knobs, each of which can be independently controlled by a different control system. A Knob Controller and terminal server can support up to 16 knob boxes.

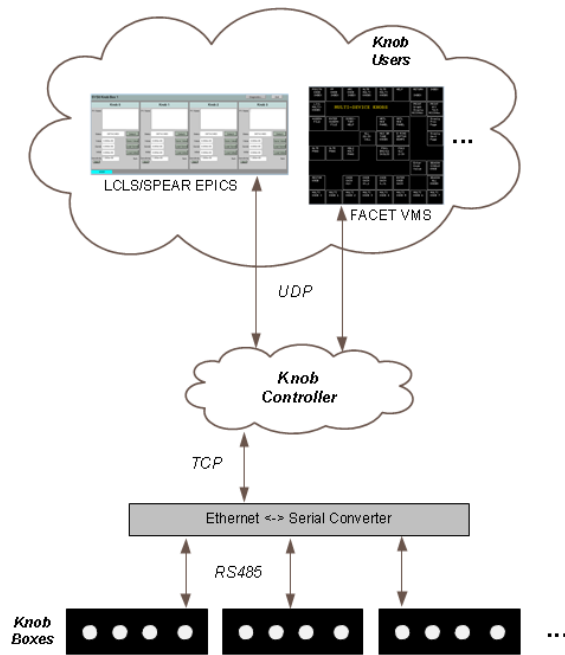

Figure 1: Knob system overview.

HARDWARE

The new knob box hardware is a small desktop chassis. It has four knobs, each with a LCD display, a disable button, and a button used to restore an attached device to its original value. Figure 2 shows a photograph of the new knob box hardware.

Figure 2: Photograph of the Knob Box Pro.

The knob box tasks are separated into two main processes, each of which is executed by a microcontroller, the 16 MHz PIC16F1937. One controller is dedicated to counting rotational ticks and determining direction from the knob optical encoders. The second handles communication with the various devices: the LCD displays, the knob encoder microcontroller, and the software Knob Controller, the latter of which uses the RS-485 serial protocol. This separation of responsibility helps prevent missed knob turn counts and improves the response time to the Controller.

In addition to the optical encoder, each knob also has two associated buttons. The first is a latching switch that toggles the knob between disabled and enabled (counts for that knob are 'zeroed' while it is disabled). The second button is a momentary switch which is coupled to a 555 timer integrated circuit. When depressed by the

user for 5 seconds, the microcontroller will set the 'restore' flag in the message to the Knob Controller, causing the software to set the device back to its original value.

The box contains two rotary potentiometers to control brightness and contrast of the LCD screens. These are read back through the analog-to-digital converter on the communications microcontroller. Each box also contains an internal set of eight DIP switches which can be used for assigning an 8-bit hardware address for the RS-485 communication protocol. Figure 3 shows a block diagram of the knob box system.

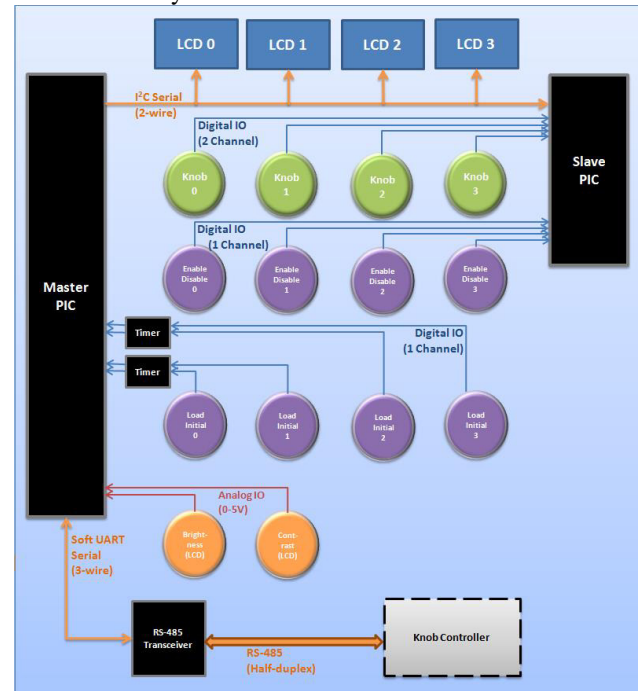

Figure 3: Knob box hardware block diagram.

SOFTWARE

The Knob Controller and EPICS Knob User are software processes running on Linux servers. They are comprised of 'C' code running in the context of EPICS IOC (Input Output Controller) processes. The legacy VMS Knob User is a combination of 'C' and Fortran software running on an Alpha.

Knob Controller

The Knob Controller handles communication with the hardware knobs. While devices are assigned to knobs, it polls the knobs for changes and sends the information to the Knob User. The Controller writes updated device information to the knob hardware display when requested by the User.

The Controller uses multiple threads to optimize performance, primarily by performing slow serial operations in parallel.

A single thread processes incoming messages from Users. It listens on a dedicated UDP port, awaiting requests. When a new attach request is received, the Controller assigns the requesting User to be the new knob

owner. It saves the User's information for future messages and identification. Other than attach requests, any message that does not come from a knob's owner is ignored. When a User takes ownership of a knob, the Controller notifies the previous owner.

Additionally, each knob box has a dedicated thread. It polls the attached knobs for changes, sending the results to the User. It receives and handles additional information from the box, including notification of a restore request, a recent reboot, and the box's revision information. These last features are only supported by the Knob Box Pro.

Figure 4 shows the architecture of the Knob Controller software.

Figure 4: Knob Controller architecture. Blue sections are implemented in callbacks.

EPICS Knob User

The Knob User is specific to a control system. It provides the graphical user interface (GUI) for attaching devices to knobs. When a User receives knob turn information from the Controller, it converts knob turns to engineering units and sets the attached device to its new setting. In addition to attaching and detaching devices, the GUI provides the ability to modify and save knob sensitivity values and to save and restore device settings. Figure 5 shows the architecture of the Knob User software.

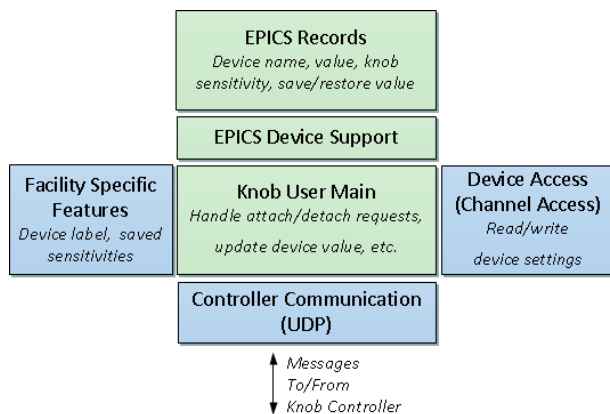

Figure 5: Knob User architecture. Blue sections are implemented in callbacks.

FUTURE IMPROVEMENTS

- Indicate on knob hardware which system owns each knob.
- Allow users to save device label to be used on knob display next time (this is already done for sensitivity).
- Allow users to save device precision to be used on knob display next time.

DESIGN AND COMMISSIONING RESULTS OF MICROTCA STRIPLINE BPM SYSTEM*

S. Hoobler#, R. Larsen, H. Loos, J. Olsen, S. Smith, T. Straumann, A. Young, C. Xu, SLAC
National Accelerator Laboratory, Menlo Park, CA, 94025, U.S.A.

H. Kang, C. Kim, S. Lee, G. Mun, Pohang Accelerator Laboratory, Pohang, Kyungbuk, Korea

Abstract

The Linac Coherent Light Source (LCLS) is a free electron laser (FEL) facility operating at the SLAC National Accelerator Laboratory (SLAC). A stripline beam position monitor (BPM) system was developed at SLAC [1] to meet the performance requirements necessary to provide high-quality stable beams for LCLS. This design has been modified to achieve improved position resolution in a more compact form factor. Prototype installations of this system have been operating in the LCLS LINAC and tested at the Pohang Accelerator Laboratory (PAL). Production systems are deployed at the new PAL XFEL facility and at the SPEAR storage ring at the Stanford Synchrotron Radiation Lightsource at SLAC. This paper presents the design and commissioning results of this system.

BACKGROUND

At LCLS, stripline BPMs measure the transverse position of the electron bunch in the injector, Linac, and transport lines. Each BPM is instrumented with a SLAC-designed chassis that houses analog conditioning electronics, a digitizer, and a CPU. After digitization, the processed data is transmitted over a dedicated network to a VME processor that calculates pulse-by-pulse beam position. An online calibration scheme injects a tone into the system between beam pulses in order to compensate for gain variation and drift. This process occurs at the beam rate, which is 120 Hz.

For recent projects, it became desirable to use electronics in a smaller form factor while maintaining the performance standard of the LCLS design.

SYSTEM DESIGN

A new system was developed, using the MicroTCA (Micro Telecommunication Computing Architecture) crate architecture. In this system, electronics for several BPMs are housed within a single crate, with digitizers located in the front of the crate and the analog conditioning electronics in the rear. Digitized data is transferred along the PCIe backplane to the CPU for processing.

The first version of this system [2] was tested in the LCLS Linac and found to meet the performance

requirements. Two of these BPMs have been deployed in a SPEAR transport line.

Later, this design was further modified to achieve improved position resolution for the PAL XFEL facility. Revised electronics, including a different operating frequency, larger bandwidth, and faster digitization rate, provide position resolution improved by a factor of two. Prototypes of this system were tested in the SLAC Linac and at the PAL Injector Test Facility (ITF). Hardware design details presented in this paper are for this improved design.

Analog Front End

The analog front end (AFE) is used to reduce the signal bandwidth and set the signal level before digitization. To achieve the desired system resolution at low bunch charge, it is important to minimize losses in the system. This is most important in the signal cables and the AFE components up to the first amplifier.

The SLAC-designed AFE contains two stages of amplifiers and attenuators. The attenuators can be adjusted from the control system to maintain reasonable signal level when the bunch charge changes. The bandpass filters select a processing frequency of 300 MHz with a bandwidth of 30 MHz. Figure 1 shows a block diagram of a single input channel of the AFE.

Figure 1: Analog Front End block diagram.

As in the LCLS system, the AFE performs a self-calibration process between beam pulses. A 300 MHz tone is injected into a single stripline and the coupled response is measured from the two adjacent striplines. This is performed for both the horizontal and vertical transverse planes. The calculated calibration ratios are applied to the beam position calculation to compensate for thermal drift and gain variation among channels. Figure 2 shows a block diagram of the calibration scheme.

*Work supported by U.S. Department of Energy under Contract Numbers DE-AC02-76SF00515 and WFOA13-197

Figure 2: Calibration scheme.

Digitizer

To meet the resolution requirements, the analog-to-digital converter (ADC) must provide sufficient effective number of bits and signal-to-noise ratio. A commercial off-the-shelf product, the Struck SIS8300, was selected.

It is important to select a digitization rate that centers the signal well within the Nyquist zone. This reduces unwanted signal leaking in from neighboring zones, which decreases signal quality. This effect is also improved by good filtering and selection of analog bandwidth. In this system, the 300 MHz BPM signal is undersampled at 250 MSPS, which centers the 30 MHz-bandwidth aliased signal well in the first Nyquist zone. Figure 3 shows the 300 MHz BPM signal, the 250 MSPS digitization rate, the Nyquist zones, and the frequencies of the aliased BPM signal.

Figure 3: Nyquist zones and aliased signals.

Timing

The Micro Research Finland Oy (MRF) PMC Event Receiver Card (EVR) is used to receive global timing data and to provide hardware triggers for data acquisition.

Data Processing

The system uses embedded Linux with a real-time patch to provide deterministic processing. New software drivers were developed for the Struck digitizer and the new AFE. These new software components were

integrated into the existing BPM application. Figure 4 shows the BPM software architecture.

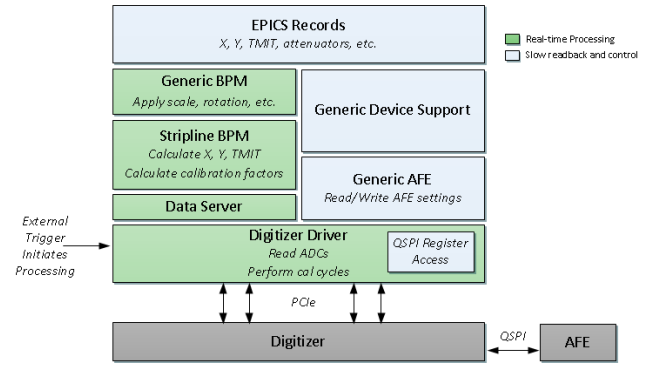

Figure 4: BPM software architecture.

The BPM data acquisition and processing is event-driven. At beam time, an external hardware trigger from the EVR initiates the beam data acquisition. Once this is complete, the software internally triggers a calibration cycle. To reduce overhead, a DMA engine is used to transfer data to the CPU. The software receives an interrupt when the transfer is complete. Figure 5 shows the process flow of two consecutive acquisition cycles.

Figure 5: Data acquisition cycles.

The AFE firmware state machine executes the calibration routine and initiates digitizer data acquisition. The AFE has direct connections to the digitizer for real-time data acquisition handshaking. It also provides a QSPI interface to the digitizer for slow monitoring and control. Figure 6 shows the connections and data flow between the AFE and digitizer.

Figure 6: AFE-Digitizer interface.

INITIAL RESULTS

Prototypes of this system have been tested in the LCLS Linac and at the PAL ITF [3].

Figures 7 and 8 show the measured beam position resolution of LCLS Linac BPMs, including the prototypes. The four red data points show the prototype data. The two points on the left are early prototypes; the two on the right are later prototypes with improved resolution.

Figure 7: LCLS Linac BPMs measured beam position resolution at 160 pC bunch charge.

Figure 8: LCLS Linac BPMs measured beam position resolution at 20 pC bunch charge.

Figure 9 shows data taken at LCLS, plotting the position resolution as a function of bunch charge, from 20 pC to 150 pC. Within the dynamic range of the system, the position resolution should increase linearly as bunch charge decreases, until it reaches its resolution limit. Units BPM27201, BPM27301, BPM27401 are early system prototypes. The other two are legacy LCLS BPMs. The PRD limit shows the resolution requirement for the early prototype.

Figure 9: LCLS Linac BPMs dynamic range.

The BPMs at PAL ITF are on movers, which can be used to compare measured position as a function of actual position. The BPM system is expected to be linear within ± 1 mm from the BPM center in the X and Y transverse planes. Figures 10 and 11 show X and Y data for a single BPM.

Figure 10: PAL ITF BPM measured versus actual X position.

Figure 11: PAL ITF BPM measured versus actual Y position.

FUTURE USE

The PAL XFEL facility will use this system for its 144 Stripline BPMs. This system will be commissioned with beam in early 2016.

SPEAR is currently using two of these BPMs in its transport line and plans to install more in early 2016.

TIP: AN UMBRELLA APPLICATION FOR ALL SCADA-BASED APPLICATIONS FOR THE CERN TECHNICAL INFRASTRUCTURE

Ph. Gayet, P. Golonka, M. Gonzalez-Berges, L. Goralczyk, J. Pache, P. Sollander, F. Varela[#],
CERN, Geneva, Switzerland

Abstract

The SCADA package WinCC Open Architecture (WinCC OA [1]) and the control frameworks (JCOP [2], UNICOS [3]) were successfully used to implement many critical control systems at CERN. In the recent years, the Industrial Controls and Electronics (ICE) group of the Engineering Department (EN) at CERN, supported other groups to re-implement the supervision of technical infrastructure, like Electrical distribution (EL), and Cooling and Ventilation (CV), using these tools. However, the fact that these applications are highly independent from the operation point of view, as well as their increasing number, renders operation uncomfortable since shifters are forced to continuously switch between them. In order improve the integration, EN-ICE is developing the Technical Infrastructure Portal (TIP) to provide centralized access to all WinCC OA applications, and extending their functionality including links to external databases and to a powerful localization system based on GIS. In addition the tool offers an environment for operators to develop views that aggregate data from different sources, such as cooling and electricity. This paper also describes the challenges faced during the implementation of TIP due to the large degree of heterogeneity across applications, although they are made out of common building blocks.

INTRODUCTION

For the construction phase of the LHC, a big emphasis was put in the use of industrial tools for the control systems. This was complemented with the development of frameworks that provided the necessary adaptations to the CERN environment (JCOP, UNICOS). This approach showed to be very successful and many systems were built following it in both the experiments (e.g. Detector Control Systems, Detector Safety Systems, Gas Control, etc.) and the accelerators (e.g. Cryogenics, Machine Protection, Vacuum, etc.). The result was a big gain in manpower and a high homogenization across systems.

Building on this success, an effort was started in 2009 to use the same tools for the CERN infrastructure systems. These systems cover areas like Cooling and Ventilation, Electrical Distribution or Radiation Monitoring. There is now a large number of them that have benefited from this standardization effort, and there is an ongoing process to converge to the same technologies for most of the applications, if not all. The homogenization that results from this convergence process, opens the door to further integration at the SCADA layer and better operations efficiency. This paper

shows the first initiative to build a hypervisor system on top of the existing applications across several domains for this purpose.

OPERATION OF THE CERN TECHNICAL INFRASTRUCTURE

Operators on shift in the CERN Control Center (CCC) are in charge of monitoring the Technical Infrastructure (TI) 24 hours a day, 365 days per year. Their duties are to detect problems, make first diagnostics and decide on actions to take. The TI encompasses the entire CERN electrical distribution network from 400 kV down to 48 V, the CV installations for all accelerators, detectors and other important facilities such as the computer centre and other systems (controlled access, safety monitoring systems, etc.). Anomalies are detected through a centralised alarm display, LASER [4], to which all systems across CERN are connected. Diagnostics are made using the application specific supervision systems.

There are more than 100 standalone CV systems around the CERN sites and their corresponding supervision systems have been developed over time with different technologies and by different people. This makes difficult for the operators to treat each non conformity as there is no standard way to establish a correlation between an alarm reported in the LASER console and the corresponding synoptic view of the process experiencing the problem. This requires that the operators have a very detailed knowledge of the various systems and makes the learning curve for newcomers very steep. Moreover, each of these applications requires individual login making daily life very tedious for the operators.

TI PORTAL

Main Requirements

TIP shall centralize the access to all WinCC OA applications deployed for the CERN TI simplifying the work of the operators in the control room. TIP must provide access to all synoptic views and trend plots available in every remote application, and must use the access control schemas locally defined in each of these applications:

- a single log-in shall be sufficient to grant the operator access to every single remote application,
- the operation can be performed by both the equipment group expert and the central operators with privilege associated to their level of expertise,
- the data shall be presented to the operators and experts in exactly the same way,

[#]fernando.varela.rodriguez@cern.ch

- the auditing functionality shall differentiate if the actions on the equipment were initiated by the equipment team or by the TI operators.

As the operation in the control room is driven by critical or summary events presented to the operators through the LASER console, TIP must grant access to every single alarm generated by the remote systems, it must also differentiate unambiguously LASER alarms from detailed process alarms.

TIP shall not disturb the remote systems and minimize the impact on their performance. Additionally, it must integrate the remote systems as they are, i.e. no changes to the remote applications shall be required to connect them to TIP.

It shall be possible to reconfigure dynamically TIP to cope with changes done in remote applications: the migration of many controls applications (e.g. CV) is a continuous process that will span over many years. At any moment, old applications can be ported to WinCC OA and enter production. Moreover, due to the fast pace evolution of some systems, like the CERN electrical network, control applications may be reconfigured at any time. TIP shall be able to adapt to these changes with minimal effort, i.e. TIP must be able to discover new applications, to detect the changes in existing ones and to configure the hooks necessary to handle the new setup centrally. Moreover, the re-configuration of TIP shall be as transparent as possible to maximize the availability of the application since it is required 24/7.

The portal application shall also allow TI operators to create their own views and combined trends where they combine data from different sources to display dependencies between systems.

TIP shall also provide means to easily integrate data published by non-WinCC OA sources as the data required for operation are gathered using different technologies.

Architecture

Figure 1 presents the architecture of TIP, the connections with other systems, the different kind of operators and illustrates its central role in integrating data from various sources. TIP is part of a distributed WinCC OA application. This native feature of the SCADA allows access from TIP to all data from the remote systems and offers seamless display of views without any extra effort. Other systems can be added to and removed from this distributed network at any time giving flexibility and future-proof design.

TIP is built using the same control frameworks and share the same GUI principles as the remote applications giving a familiar environment to the operators and drastically shortening learning curve.

TIP makes usage of a local file repository which is periodically synchronized with the file systems of the remote applications such that TIP always has an up-to-date copy of the scripting libraries and user interface files.

Another important feature is the possibility to access historical measurement data. This is achieved by

connecting TIP to the central ORACLE database used by the applications.

CERN network database (LANDB), is also used by TIP to provide detailed information about devices, like displaying the geographical location of the PLCs in the CERN facilities.

Finally, the Alarm Help application is used by the TI operators to display very detailed information about LASER alarms like intervention procedures, list of affected devices, consequences, etc. TIP interacts with this application bi-directionally to provide navigation from the LASER alarm to the remote WinCC OA synoptic view of the process and vice-versa.

User Interface

It is necessary to acknowledge that many of the features of TIP presented here are inherited from the underlying frameworks and the distributed nature of WinCC OA which greatly decreased effort needed to develop the application. Figure 2 shows an example screenshot from TIP main user interface. The top area is occupied by the TIP Global Toolbar, which enables access to general functions of the application i.e overall alert screen that shows alarms from every single connected WinCC OA system.

The information in TIP is organized into different views. For example, in Figure 2, the CV process information such as status of pumps, flows, pressures, etc. are shown in the first tab, whereas the status of the readout systems, PLCs, data-servers, WinCC OA projects, are shown in the infrastructure tab. TIP features multiple points of view targeted to different users, in order to provides a window to a subset of the information handled by the application.

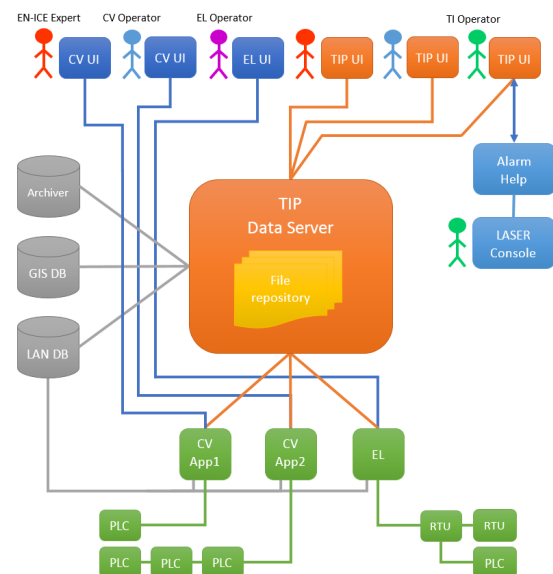

Figure 1: TIP architecture and context.

The information is organized in a tree-like structure where leaf nodes in the tree represent a set of LASER alarms and the systems applications (here CV) whereas top level nodes group them geographically. Each node in

this tree used colours that represent the presence of active LASER alarms. The colour of the nodes is propagated all the way up enabling operators to easily localize active alarms by expanding the tree. Selecting a node in the tree causes the main area of TIP to be updated with the synoptic view associated to the node.

Figure 3 and 4 show examples of graphical interfaces, which are displayed as the operator navigates in the tree. Figure 3 shows the main operational parameters of the LHC CV systems. TIP makes usage of modern visualization techniques like spiderweb graphs and the Javascript visualization package Highcharts [5] whenever applicable to enrich the user experience. This was achieved by extending the WinCC OA HMI functionality to integrate web technologies as presented in [6].

Figure 4, shows some of the main parameters involved in the safety of the Point 1 of LHC. These user interfaces merge information from the electrical network, elevators, the LHC access control system, and the status of the Oxygen Deficiency Monitors.

GIS Integration

The TIP GIS Module combines geographical data with LASER alarm location information. The buildings shown in the map are also coloured according to the presence of active LASER alarms. This provides operators with very valuable information on the location of the problem that helps in the discussions with the intervention teams. Navigation is also possible using the GIS Module. By clicking on a red or green location it will cause the module to zoom on this area and display applications that are present in this particular location. The operator

selection of a node in the impact tree also causes the GIS Module to be updated by zooming on the area where application, or group of applications, is located.

LASER Integration

The LASER Alarm Info box shows detailed information about the alarm like its description, unique identifier for equipment, localization and responsible.

Although TIP focusses on LASER alarms, using the Remote Application Toolbar, operators can interact directly with the remote application and access its Alarm Screen, pre-configured trends or check the PLC statuses.

Challenges Faced

All applications developed by EN-ICE are using common building blocks: WinCC OA as SCADA system and the JCOP and UNICOS frameworks. Moreover, within a particular application domain, e.g. CV, all applications are largely similar and homogeneous. However, fundamental differences may exist between domain, e.g. between CV and EL. In such cases, applications may implement different device and alarm models, together with distinct access control schemas.

Furthermore, the mapping between devices, alarms and associated synoptic views may also differ depending on the application domain. To ease the creation of similar portal applications, a central database containing these metadata would be desirable. Therefore an effort is required to improve the coherency across application domains.

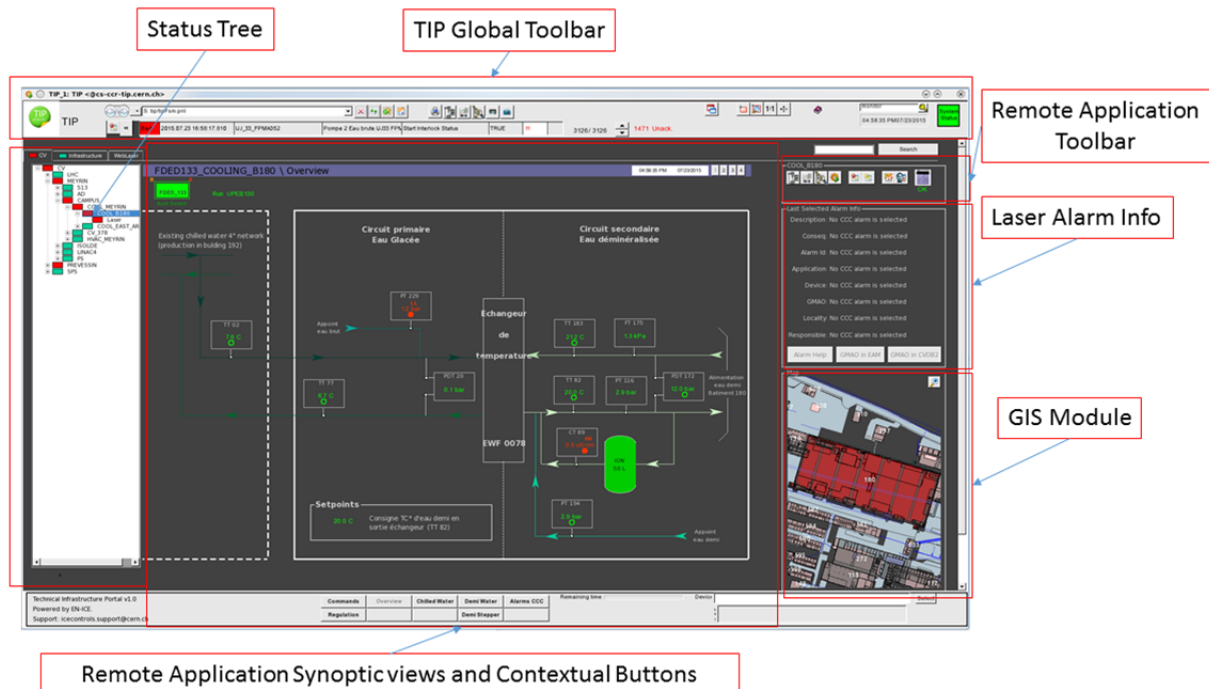

Figure 2: Main user interface of TIP.

During the implementation of TIP, it was also necessary to extend the functionality of existing tools to be able to work on large distributed systems. These enhancements will now be integrated in the core functionality of the package.

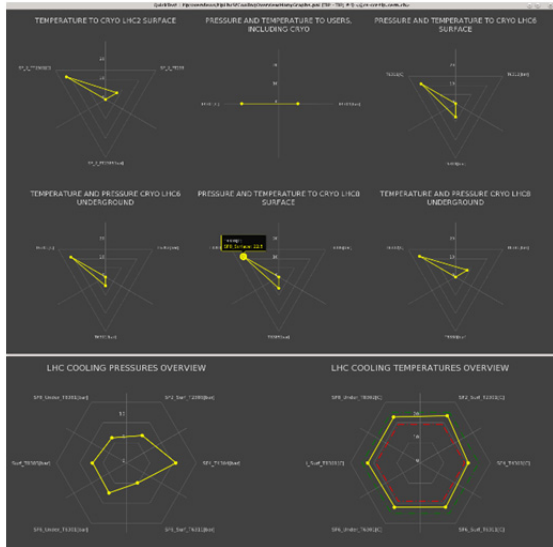

Figure 3: TIP Dashboard example.

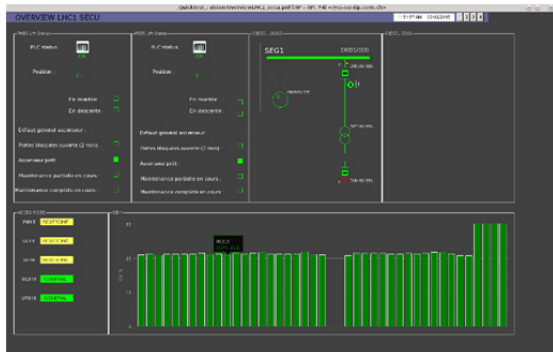

Figure 4: Compound User Interface of TIP showing information from multiple safety systems of the LHC.

STATUS AND OUTLOOK

TIP entered production in Summer 2015 and despite of the short time in use, it has already proven to be a significant improvement for the operators of the CERN TI and also for the equipment groups and the EN-ICE experts. Table 1 summarizes at the time of writing this paper, the applications that have been integrated in TIP and the number of synoptic views that can currently be accessed from TIP.

In the coming months we plan to extend the TIP to cover new domains (Radiation Monitoring system,...), and to show dependencies across different domains. In

addition, TIP will be used to speed up the integration of all CERN CV systems including the legacy ones into a single tool. This is motivated by the need to provide a unique operation solution despite the long timespan of the migration process that is expected to be finished in 2025. Hence, the set of non-WinCC OA data accessed by TIP will be significantly enlarged.

Table 1: Applications under the Umbrella of TIP

Application Domain	Controls applications	Synoptic views	LASER alarms
Cooling & Ventilation	137	1846	1364
Electricity	1	211	13719
Lifts	5	0	0
Monitoring	1	335	0

To conclude, this promising start for the CERN TI, has awoken the interest of developing similar umbrella applications for many other domains like the LHC Cryogenics or Power and Interlock systems.

ACKNOWLEDGMENT

The authors of this paper would like to thank Benjamin Bradu, Jean-Charles Tournier and very especially to William Booth for all input and feedback provided during the implementation of the TIP.

KECK TELESCOPE CONTROL SYSTEM UPGRADE

K. Tsubota, J. A. Mader, W. M. Keck Observatory, Kamuela, Hawaii

Abstract

The Keck telescopes, located at one of the world's premier sites for astronomy, were the first of a new generation of very large ground-based optical/infrared telescopes with the first Keck telescope beginning science operations in May of 1993, and the second in October of 1996. The components of the telescopes and control systems are more than 15 years old. The upgrade to the control systems of the telescopes consists of mechanical, electrical, software and network components with the overall goals of improving performance, increasing reliability, addressing serious obsolescence issues and providing a knowledge refresh. This paper is a continuation of one published at the 2013 conference [1] and will describe the current status of the control systems upgrade. It will detail the implementation and testing for the Keck II telescope, including successes and challenges met to date. Transitioning to night time operations will be discussed, as will implementation on the Keck I telescope. Throughout this paper the telescope control system will be referred to as TCS.

TCS OVERVIEW AND CONTEXT

Each of the Keck telescopes is over 8 stories tall, weighs in excess of 300 tons, uses an alt-az mount and has the equivalent of a 10meter mirror which is comprised of 36 individual segments. A general diagram is shown in Fig. 1. The telescope supports a wide range of instruments at various focal locations in addition to providing both a natural guide star and laser guide star adaptive optics.

Figure 1: Keck Telescope.

TCS consists of a supervisor and set of subsystems that work together to provide Status and Control of:

- Telescope mounts
- Dome and shutter positions
- Facility rotators
- The secondary mirror

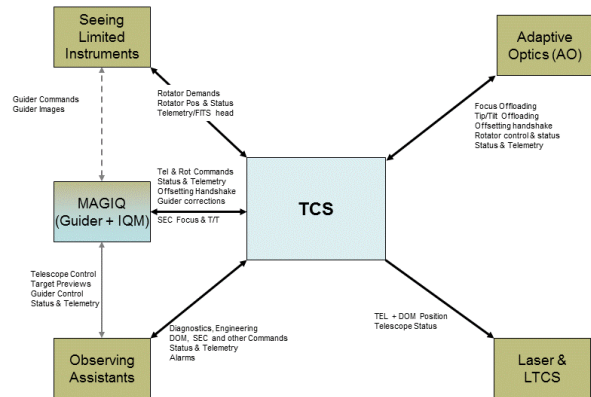

Figure 2: TCS System Context.

Figure 2 shows a high level context diagram for the Telescope Control System (TCS). It and the other Observatory principal systems interact through well-defined interfaces to accomplish the desired behaviour. Systems are tied together by the use of an Ethernet Bus. The main purpose of the TCS software is to accept the target position of a celestial object (which can be given in a variety of coordinate systems) and then calculate the mount, rotator and dome/shutter positions, so that the target is imaged perfectly at a given point in the focal plane. Furthermore, the TCS is characterized by the need to integrate a number of heterogeneous subsystems, which exhibit complex interactions. These interactions, although not hard real-time bounded, need a high level of synchronization. All this has to be done in a manner that protects the staff and equipment.

TCS operates the mechanical components of the telescope through a number of computer subsystems which control the telescope mount assembly, the dome enclosure, secondary and tertiary mirrors and facility rotators. The subsystems are responsible for the actual servo or hardware control, while the TCS coordinates their activities.

- The Telescope Axes (AXE) subsystem controls the telescope mount assembly, including the elevation and azimuth drives and other components associated with the mount operation.
- The Dome subsystem (DOM) operates the enclosure, which includes the dome carousel, dome lights and shutters, and other auxiliary equipment.

- The Secondary (SEC) subsystem controls the secondary mirror, including its tip-tilt-focus and thermal requirements. It also handles the monitoring of thermistors placed around the telescope tube which is used for focus compensation.
- The Rotator (ROT) subsystem controls the cassegrain, forward cassegrain, bent cassegrain and nasmyth facility rotators and positions the tertiary.
- The Telescope Safety System (TSS) handles the safety interlock system. It includes items such as Estop, limit switches and interlock processing and is implemented using a PLC. There are multiple interlocks including module handler deployed, crane deployed, horizon lock deployed, and so on.
- The Timing subsystem (TIM) handles time synchronization for each subsystem in addition to providing accurate triggers and time conversion routines

PROJECT OVERVIEW

Keck follows a standard development process that includes concept, preliminary and detailed design, full scale development, followed by integration and test, and commissioning. The TCS Upgrade project is at the end of the integration and test phase for the Keck II telescope and working towards commissioning. This will be followed up with integration and test of the Keck I telescope

A philosophy for the TCS upgrade project was to remain backwards compatible with the existing system. This was particularly critical for instruments and clients that were expected to communicate with TCS. As a result of this philosophy the project chose an architecture that uses proven hardware and software, is primarily COTS, leverages the open source community, is inherently backwards compatible, is viable for 10+ years and allows the subsystem controllers to be upgraded without affecting I/O. It was a conservative approach; all existing top level EPICS records can be reused, there is 100% reuse of the Keck Task Library and, if necessary, all existing UIs and tools can continue to operate.

Another key philosophy was to minimize the need for any telescope down time and to allow continuous night time observing. This meant allowing the use of both systems in parallel and to provide a failsafe fall back to the old system during commissioning. The overall approach taken to minimize telescope downtime was to implement a physical switching solution.

IMPLEMENTATION

The new redesigned telescope axis encoder systems have been successfully implemented and tested on Keck II and are currently being installed on Keck I. The EL design uses existing surfaces for mounting two read heads to a rigid yoke main triangle structure. The AZ design uses a compact, on-axis annular design with four read heads mounted to rigid and fixed structure at the center of the telescope structure. This second generation simplified

encoder design has saved the project considerably in cost and effort by being easier to fabricate and install with no telescope downtime as compared to our original design. It also allows the new encoding system to run in parallel with the operational encoding system for a side by side comparison.

From the beginning TCS had a requirement to minimize operational downtime. This led to the design and implementation of a switching solution [2] to allow quick and easy switching between the operational system, referred to as Drive and Control System (DCS), and TCS. The switching solution and all significant preparation work such as cable pulls was performed well before summit I&T.

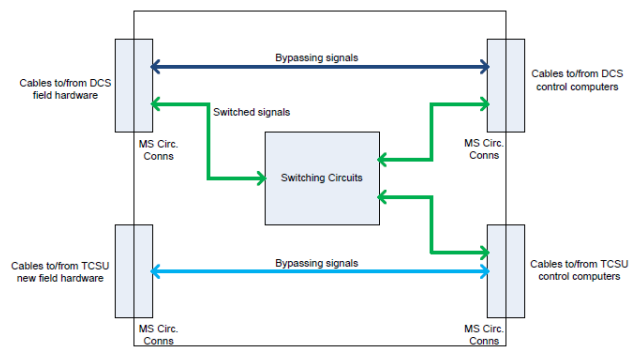

Figure 3: Switching Solution.

Figure 3 shows the basic switching implementation. The switching solution was very easy for the secondary and basically consists of cutting the existing cables and terminating them with connectors so that they can be switched between DCS and TCS with the addition of relay switches. The solution for AXE and ROT was a bit more complicated and relied on banked sets of DIN mounted relays to be switched. Switching occurs at the subsystem level. The number of switch points was reduced by utilizing the ability to simply run signals such as limit switches etc. in parallel between DCS and TCS. This not only reduced cost but also reduced implementation complexity.

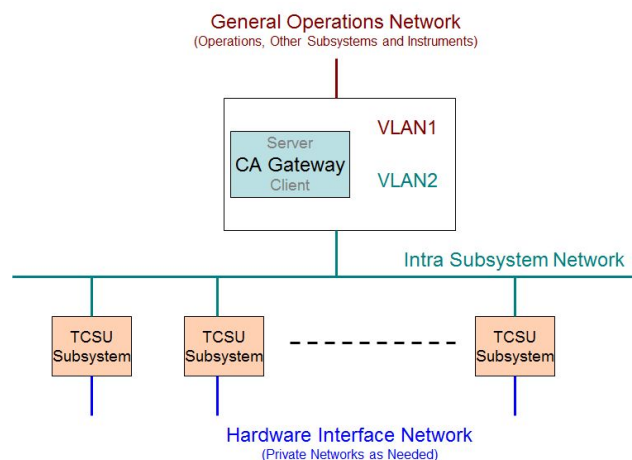

Figure 4: Network Layout.

Software also has a similar switchover concept. Fig. 4 above shows the basic network layout. TCS is implemented on a separate network and tied to the operational network by a single supervisory server with dual network interface cards (NIC). One of the NICs is on the operational network and the other on the TCS network. During standalone TCS testing all subsystem EPICS IOCs communicate through an EPICS gateway with a non-standard EPICS channel access server port running on the dual NIC server. When switching the software over to operations, the operational VxWorks control systems are halted and the TCS EPICS gateway changed to communicate on the standard port. This allows all existing operational clients access to the new TCS control systems.

TESTING

Testing is a critical aspect of system development. Once components have been built and unit-tested, they must be tested in relation to the system as a whole. Two general principles were followed: test functionality and performance at the lowest level possible. When it could be avoided no hardware or software whose functionality and performance had not been verified was integrated. Of course it wasn't always possible to follow these principles, e.g. sometimes software must be integrated with hardware before either can be meaningfully tested.

TCS identified various levels of testing and are briefly described here.

- Developer testing
- Hardware Checkout
- Unit Testing
- Functional Unit / Subsystem Testing
- System/Acceptance Testing

Starting from developer testing and hardware checkout, each subsequent layer essentially builds on the last providing more complete and encompassing testing. Initial testing took place at our HQ lab environment where the basic hardware was installed with minimal functionality followed by summit testing after everything was installed in its final configuration.

An official deliverable of the testing phase is the documentation of the requirements acceptance testing. For each requirement the project developed a standard test acceptance form and sorted them by subsystems. In cases where one requirement spanned multiple subsystems, each subsystem had a copy of the test acceptance to complete. The major sections of the test acceptance form are the requirement to be tested, the test procedure, the test results and disposition, the test conductor name, and the date of the test. As the tests are completed and documented, they are checked off in the requirements matrix and the individual sheets are compiled into a system notebook.

SUCCESSSES

The TCS Upgrade project has had a number of successes that has proven invaluable. The

implementation of the hardware switching solution allows quick and easy switchovers during the day and at night. Since switchover involves three switches and a couple of cable moves and a simple procedure, anyone not familiar with the system can do it.

Implementing the switching solution on a subsystem by subsystem basis also gave more freedom in testing. It allowed TCS to selectively switchover a single subsystem as needed, especially if another subsystem was not available because of operational needs.

From the software perspective the use of a separate network and EPICS gateway implementation to isolate the software and make it public only when needed by switching the port number allows the project to run the software in parallel day and night.

Insisting on software backwards compatibility freed the project from having to change and re-validate existing client applications, of which there are many.

All these have led to successfully integrating and testing the full TCS system prior to on-sky engineering.

CHALLENGES

During the integration phase on the summit, considerable planning and coordination with operational tasks and projects as well as for personnel support was involved. There are processes in place for this but it still took a more time and effort than originally planned. Understandably, operations are the highest priority and could bump anything on the schedule for preparation of the nights observing. Also the longer it took for integration the more TCS had to deal with competing projects for telescope access.

Another challenge was getting on-sky test time. These nights are scheduled months in advance and you need to ensure you will be ready for the testing. Missing a night of testing could mean a month or more delay. Not being fully ready but going on-sky is also a waste of resources. There was one night where the project team thought they were prepared but failed to fully test all interfaces to the existing system and the project ended up dead in the water when a part our target selection tool interface failed after it had to be restarted and it was too late to give back for other projects to make better use of the time. The interface issue was eventually resolved the next day but it had already prevented the project from doing the tests that were originally planned. There is also the weather for which we don't have much control over and that the project has experienced this first hand. Just recently this past August, two scheduled partial back to back nights where weathered out preventing any TCS upgrade on-sky validation. To compensate for weather delays, this the project has requested contingency nights.

Another challenge the project ran into and is still dealing with is the tuning of our telescope axis closed loop servo performance. By design, the internal velocity loop was digitized with a FPGA which allow for much more freedom and sensitivity and driven with a 100Hz position loop. While attempting to tune the servo loop, an intermittent timing issue with our 100Hz event trigger

would crop up. This was eventually traced down to a termination issue in the initial signal generator setup. This was difficult to trace because whenever probes were added to monitor the signal it would change the loading in a positive way and generate a solid 100Hz signal so the problem never occurred. It took nearly a full week to get to the bottom of the issue. The bad part was that this was not the final operational configuration. The signal generator was initially setup as a way to help facilitate testing but ultimately it costed the project more time. The final configuration was to have the timing card (Bancomm 635 with a crystallized oscillator) internally generate the 100Hz event signal. Another challenge was dealing with investigating and resolving a 1Hz period oscillation in our servo performance. The FPGA velocity loop has been looking at the tachometers as its feedback. These tachometers have been noisy in the past and cleaning them have helped. However, it was decided to add a derivative term to our servo loop to supplement the use the tachometers. Another option is being implemented to replace the tachometer feedback with an encoder velocity feedback calculated in software and feeding into the FPGA in place of the tachometer feedback.

TRANSITION TO OPERATIONS

As the TCS Upgrade Project nears completion of its Keck II performance testing, a path for transitioning to operations is being actively developed. As part of this transition, Keck standards dictate that all projects undergo an Operational Readiness Review (ORR) prior to release. This is an external review of our readiness for operations by documenting that all requirements and performance specifications have been satisfied. It also verifies that all necessary as-built design documents, procedures is complete and in place for handing over to operations. The ORR also shows that all required training has been completed and that the project has proven that the system is stable and can be reliably operated by documenting the engineering and shared risk nights and results.

CURRENT STATUS

Currently all Keck II telescope subsystems (AXE, ROT, SEC, DOM, TSS, TIM) have been fully integrated and tested as designed.

The full TCS system has been successfully run on-sky at night and the pointing model based on pointing data test results using actual stars was completed and updated.

Fine tuning our telescope axis servo performance continues as well as completion of all remaining test procedures. Completion of all as-built documentation and procedures continues as well as identification of and training preparation. The Keck II TCS Upgrade Project ORR is scheduled for December 2015 with plans to fully deploy the Keck II TCS upgrade in late January 2016.

Performance

Some of the performance requirements are very tight and difficult to achieve, even if the system were to have been designed from scratch. As shown in Table 1, the current system does not meet the original settling time requirement for offset moves but has improved it over the current control system. With the TCS upgrade, the settling times for small moves in azimuth using the double path with feedforward turned on are nearing the original requirements and have met them in some cases. Double path means that the base position is separated from the offsets and the two are applied separately. In elevation, performance is close between the single path with feedforward and the double path with feedforward but both perform close to or better than the current system. With the continuing servo upgrades and tuning, TCS hopes to improve even more from the current system and get even closer to the original requirements.

Table 1: Keck II Offset Moves Settling Times

Telescope moves (arcsec)	1	5	10	50	100	1000	10000
Time Requirement (sec)	0.3	1	1	3	3	10	20
AZIMUTH							
DCS System (2011)	0.8	2.7	2.8	-	5	9.9	19.2
TCS no feedforward	1.8	2.4	2.5	3.9	4.8	-	-
TCS one path w/FF	1.1	1.2	1.5	2.7	3.3	-	-
TCS two path w/FF	0.7	0.9	1.2	2.4	5.8	-	-
ELEVATION							
DCS System (2011)	3.2	2.6	2.6	-	5.7	10.3	23.4
TCS no feedforward	2.7	4.2	5.1	6	-	-	-
TCS one path w/FF	0.9	2.6	3.1	3.7	5.2	-	-
TCS two path w/FF	2.1	2.9	2.6	3.8	5.1	-	-

MOVING TO KECK I

As TCS nears completion of fine tuning the Keck II system, the necessary hardware upgrades to Keck I is being actively installed. To date the majority of the switching solution is installed. The dome, secondary, and rotator upgrades, which are fully installed, have been tied into the switching solution. The drive control and encoder system for the telescope axis are currently being tied in with the switching solution. All Keck I hardware installation will be complete by November this year with integration testing starting immediately after. The Keck I full system integration and validation completion is expected by the end of March 2016 followed by the Keck I TCS Upgrade Project ORR and handover in May 2016.

ACKNOWLEDGEMENT

The W. M. Keck Observatory is operated as a scientific partnership among the California Institute of Technology, the University of California and the National Aeronautics and Space Administration. The Observatory was made possible by the generous financial support of the W. M. Keck Foundation.

EPICS IOC BASED ON COMPUTER-ON-MODULE FOR THE LNL LABORATORY

J. Vázquez, D. Pedretti, R. Ponchia, INFN/LNL, Legnaro, Italy

M. Bellato, R. Isocrate, INFN, Padova, Italy

M. Bertocco, UNIPD, Padova, Italy

Abstract

At LNL it is being carried out an upgrade campaign of the control systems of the accelerator complex. The two main goals are standardization of hardware and software and system interoperability. EPICS has been chosen as the standard framework for developing new control systems; this will address software standardization and system interoperability. In order to achieve hardware standardization, a new EPICS IOC is under development, which will become a basic construction block for all future control systems. The COM (Computer-on-Modules) form factor has been chosen as the hardware platform for the IOC, along with the peripheral devices needed for developing all the foreseen control system at LNL. Prototypes of this IOC have been developed using ADLINK's Type 6 COM Express modules on generic carrier boards with DIO, ADC and DAC expansion boards. These prototypes have been tested under typical applications at LNL in order to validate the hardware platform choice. Experimental results show that the performance of the IOC in terms of effective resolution (ENOB and bias error), sample rates and CPU usage is suitable for satisfying the requirements of the control systems.

IOC DESCRIPTION

The IOC is intended as a standard system with the necessary interfaces in order to be able to control the instrumentation present on all the foreseen system at LNL. EPICS tools will be used for software development in a standard way. For each application, a custom-made control algorithm will be developed under the framework.

COM form factor has been chosen as the hardware platform for the IOC. In particular, the type 6 COM Express standard was selected [1].

The COM will be installed on a custom carrier board, designed at LNL. This carrier board will contain peripheral devices such as digital IO, ADCs, DACs, stepper motor controllers, and communication interfaces, among others, connected to the COM. Its design is under careful considerations in order to cover all the common needs for the current and the foreseen future control systems at LNL.

Some interfaces are already available directly from the COM. Others will be controlled using USB ports. Many others will be controlled by a FPGA that will communicate with the COM through a PIC Express lane. Figure 1 shows a simplify block diagram of the IOC.

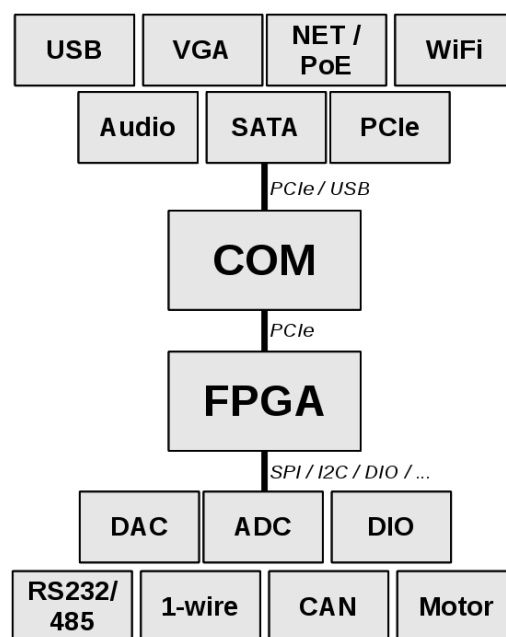

Figure 1: IOC simplify block.

IOC PROTOTYPES IMPLEMENTATION AT LNL

In order to test the validity of the COM as hardware platform for IOC developments, prototypes were developed using commercial devices. These prototypes, at the same time, allowed developing the software part of control systems.

The developed software is mostly independent from the hardware implementation, due the fact that the selected COM uses Intel CPUs allowing the use of a standard Linux environment for the implementation. In this way, once the custom IOC will be ready, the software would be easy transport to the new hardware platform.

On the other hand, prototypes were used to develop and implement diverse control systems at LNL. This allowed testing them under real operative conditions, as well as to develop critical control system without waiting for the final custom IOC to be available.

Hardware Architecture

The prototypes have been developed using Adlink [2] Type 6 COM Express module on a generic carrier board. Commercial Digital IO, ADCs and DACs PCIe boards were installed on the carrier board in order to provide IO capabilities to the IOC.

Adlink's DAQe-2214 boards were used as ADC inputs. Each board uses one x1 PCIe interface and provides 16 16-bits, 250 KSample/s, ± 10 V channels. It also provides 24 digital IO channels.

In the same way, Adlink's PCIe-6216 boards were used as DAC outputs. Each board provides 16 16-bits, ± 10 V channels, using a 1x PCIe line.

On Figure 2 it is shown a picture of a prototype with the COM on a generic carrier board with a DAQe-2214 and a PICE-6216 boards.

Figure 2: IOC prototype.

Software Architecture

Adlink provides linux drivers for the expansion boards used on the prototypes. The drivers provide common APIs. In order to interface the EPICS IOC device supports to Adlink drivers, asynDriver [3] was used.

The analog input acquisition is performed using a periodic scanning function on the asynDriver software. This function reads the ADC inputs and do callbacks updating the recently read values into the parameter library. In this way, the EPICS record attached to an analog input receives an interruption request each time a new value is available. Inside the scanning function loop, an adjustable delay was introduced in order to allow changing the sample rate of the inputs. The same procedure is done for digital inputs acquisition.

On the other hand, for the analog outputs, a function that writes the DAC channels was implemented on the asynDriver software. This function is called each time a new value is written to an EPICS record attached to an analog output, passing it the written value. The same procedure applies for digital outputs.

EXPERIMENTAL TEST AND RESULTS

A soft IOC was deployed on a prototype IOC in order to test its performance. The COM used on the prototype was the model "Express-IB-i3-3120ME" which has an Intel Core i3-3120ME CPU at 2.4GHz and 4Gb of RAM. The COM was installed on a generic carrier board model "Express-BASE6" with a DAQ-2214 and a PCIe-6216 boards. A picture of this prototype is shown on Figure 2.

Fedora Core 17 with kernel versions 3.3.4-5.fc17.x86_64 was installed on the IOC with the board drivers installed on the system. EPICS R3.14.12 and asynDriver R4-23 were also compiled and installed. On this system, an EPICS IOC application consisting only on analog inputs and analog outputs records linked to the physical ADCs and DACs using the driver written with asynDriver.

This IOC application was used to compute the CPU usage by the application and the resolution of the ADC channels.

Acquisition Rate and CPU Usage Performance

This test was performed in order to estimate the maximum sample rate that be achieved with this IOC, as well as the correlation between the sample rate and CPU usage by the application. The test consisted on measure the CPU usage by the EPICS application (which include the driver interface) for different samples periods.

The sample period was changed using the delay inserted on the scanning function on the asynDriver described earlier. Four different scanning rate were targeted. The first one correspond to the faster scanning rate achievable, setting the delay to zero. The latest one was set to around 10 Samples/s, which it is a usual value used as sample frequency on several applications at LNL. Finally, other two rates were selected in between these values, i.e. 200 Samples/s and 1000 Samples/s. The test was performed both, only acquiring a single analog input channel, and acquiring all 16 analog input channels. The results are presented on Figure 3.

Figure 3: CPU usage versus sample frequency results.

The results show that the highest sample rate that can be reached scanning only one channel is almost 4.4 KSample/s, while when scanning all 16 channel it is around 1.1 KSample/s. However, for reaching these rates, the application uses all the available CPU, due to the fact that the acquisition loop continuously read the input channels, without any delay.

The CPU usage decreases drastically when a delay is set, lowering also of course the acquisition rates. Furthermore, it is evident that more CPU is needed for achieving higher rates on all channel respect to the case with only one channel, as it is expected.

Particularly, for application when only one channel is needed, the second obtained value is a good compromise, achieving a sample rate of almost 900 Sample/s using only 18% of CPU. For application when all channels are needed, the third case is a good choice, using only 15% of CPU reaching rates of almost 55 Samples/s. Finally, low acquisition rates of some units of Sample/s, typically used on the LNL applications, the CPU usage is negligible.

Analog-to-Digital Performance

In order to determinate the performance of the ADC inputs, tests were performed for estimating its effective number of bits (ENOB) of resolution, following the method using frequency domain described on [4].

The ADC input range was set to ± 10 V, with a 90% full-scale input sine wave signal. For each test, more than 205888 samples were taken, at a rate of 890 Sample/s. The frequency of the input signal was 400 Hz, chosen in order to be lower than the Nyquist frequency. The calculations were performed for other six lower frequencies: 200 Hz, 100 Hz, 50 Hz, 10 Hz, 5 Hz and 1 Hz.

A plot of the obtained ENOB for the different input signal frequencies is presented on Figure 4.

Figure 4: ENOB obtained for the analog inputs.

It can be seen that for low frequency signals (lower than 150 Hz approximately) the obtained ENOB is higher than 17 bits, reaching even 19 bits. For a signal of 400 Hz, the ENOB is around 15.5 bits. The reason for accomplishing resolution greater than 16 bits (the ADC resolution) for the lower frequency signals is the effect of oversampling the input signal.

CONTROL SYSTEM IMPLEMENTATION AT LNL

Four different systems were selected for the prototype implementation. The control system for these four systems contains most of the elements that will be necessary on all the future implementations. Therefore, testing the prototype on all of them will demonstrate that the IOC could be implemented on any other system at LNL.

The Beam Diagnostic Data Acquisition

Beam diagnostic units are one of the most important and widely used elements on any accelerator facility. At LNL, a standard beam diagnostic unit is formed by a

Faraday Cup for measuring the beam current, and a Beam Profiler for measuring the spatial distribution of particles of the beam.

An IOC prototype was designed for acquiring the data from this beam diagnostic unit. On the IOC an analog input channel is used to read the output of the pre-amplifier of the Faraday Cup, while two digital outputs are used to set its gain. On the EPICS database, the read signal is converted back to the corresponding beam current.

The pre-amplifier of the beam profiler is formed by forty transconductance amplifiers with variable gain, similar to the one used on the Faraday Cup pre-amplifier. The 40 signals are multiplexed to a single analog output. On the IOC, an analog input channel is used to read the output of the pre-amplifier, while one digital output is used to generate a clock signal to control the analog multiplexer and two digital outputs are used to set the gain. In this case, a scanning function was implemented on the asynDriver driver that generates the clock and synchronously reads the analog input. At the end of a scanning sequence, the data are placed on a 40-value vector, which is passed to an EPICS waveform record.

The Electrostatic Beam Focalization and Beam Extraction

Beam focalization devices are of paramount importance on an accelerator facility, used even more extensively than the beam diagnostics. A large number of electrostatic beam focalization units are installed along the low energy beam line. These devices are driven by a series of high voltage power supplies.

On the other hand, the beam extraction system, even though it has a completely different function, its control system implementation is very similar to the beam focalization system. It consists of a single high voltage power supply that sets an electric potential between the ion source and the extraction electrode.

An IOC prototype was designed for controlling the beam extraction system and an electrostatic beam focalization unit. The focalization unit comprises a steerer and a quadrupole triplet group.

For each power supply, both the output voltage and current can be set using four analog signals. On the IOC, two ADC channels, two DAC channels and a digital output are used to control each one of the power supplies. Inside the EPICS databases, Proportional-Integral-Derivative (PID) algorithms were implemented in order to automatically control both the current and voltage, according to the set points imposed by the operator.

The Magnetic Beam Steerers

Magnetic steerers are part of the beam transport elements. They are widely used at LNL for the transport of high energy beams. A magnetic steerer unit is formed by four coils, two vertical and two horizontal, installed on the beam line. They are connected in series of two, and piloted using two high current power supplies.

The IOC configuration is exactly the same respect to the electrostatic beam focalization described on the previous section.

The ECR (Electron Cyclotron Resonance) Negative Beam Source

At LNL, one of the stable ion source present is an Electron Cyclotron Resonance (ECR) source [5] [6]. The ECR ion source is controlled by a large number of instruments: nine power supplies with analog control, five power supplies and measure instrument with serial communication port (RS232), one faraday cup for beam diagnostic, and one PLC.

The IOC developed is equipped with 16 DAC channels, 32 ADC channels, 96 digital IO and 8 serial ports, in order to be able to control all the instrumentation on the system. Most of the software components were taken from the previously described prototypes, as for example, PIDs algorithms for the analog controlled power supplies, and conversion algorithms for the beam diagnostics. On the other hand, for the instrumentation with serial communication, new algorithms were produce.

CONCLUSION

Standardization of the control systems of the accelerator complex at LNL is being addressed with the development of the new EPICS IOC.

It will be based on highly integrated Computer-on-Modules, installed on a custom tailored carrier board, equipped with all the necessary IO interfaces for satisfying the requirement of all the foreseen control systems. EPICS as a framework will bring a homogeneous software architecture with added benefits as total interoperability between the systems, and essential services as data archiving and logging.

Tests showed that the ADC inputs could reach high sample rates, around 4.4 KSample/s at the cost of high CPU usage. Nevertheless, good tradeoffs are available; a

good choice for the LNL applications is the rate of 900 Sample/s using only 18% of CPU. Furthermore, sample rates of tens of Samples/s could be easily reached, with negligible use of CPU. Also, ENOB between 15.4 and 19bits were obtained on the ADC inputs.

In order to validate this hardware platform as suitable for developing the control systems at LNL, prototype IOCs were developed and implemented using commercial devices. These IOCs have been tested under real applications at LNL, with the implementation of four control systems: the beam diagnostic data acquisition, the Front-End beam extraction and focalization, the magnetic beam steerer and the ECR source systems. All the installed prototypes have shown that the hardware platform is suitable for the development of the LNL control systems using EPICS.

Although the performance is not optimal, the prototype IOCs have shown that they are suitable for controlling the selected systems, satisfying the operation requirements. However, much higher efficiency is expected from the custom IOC design.

MEBT AND D-Plate CONTROL SYSTEM STATUS OF THE LINEAR IFMIF PROTOTYPE ACCELERATOR*

J. Calvo[†], D. Jiménez-Rey, E. Molina Marinas, J. Mollá, I. Podadera. Ciemat, Madrid. Spain

Abstract

Linear IFMIF¹ [1] Prototype Accelerator (LIPAc) [2], Rokkasho, Japan, comprises a succession of devices and systems that accelerate a deuteron beam up to 9 MeV with a current of 125 mA, generating a power of 1.125 MW, and transport it up to a beam dump. The beam power becomes critical from the point of view of losses; even tiny losses must be avoided. This fact, and the complexity of the accelerator operation, requires a coherent strategy when designing, commissioning and optimizing the accelerator control system, specifically focused in the control systems of the Medium Energy Beam Transport (MEBT) and the Diagnostic Plate (DP, a movable set of diagnostics). Both systems are essential to validate the performance of the accelerator and particularly the ion source, Radio Frequency (RF) and Radio Frequency Quadrupole (RFQ) systems. This contribution will describe the recent advances in the control architectures and the EPICS based developments achieved in MEBT for the motion control of bunchers and scrapers, control of the power supplies in quadrupoles and steerers, and refrigeration and vacuum. Besides, control of fluorescence profile monitors (FPMs) in the D-Plate is displayed.

LIPAC CONTROL SYSTEM

LIPAc control system consists of the remote control, monitoring and data acquisition of all devices, systems, subsystems and operations carried out in the accelerator vault with intense radioactive environments. It uses EPICS [3] as the main set of control software tools, providing the control with distribute and real-time features. It is composed of five main elements, namely, accelerator Central Control System (CSS), Local Area Network (LAN), Personal Protection System (PPS) [4], Machine Protection System (MPS) and Timing System (TS). Within each LIPAc subsystem there is a Local Control System (LCS).

LIPAc control system development is an unique and complex work due to the special characteristics of the prototype accelerator and its beam dynamics, that are, the unprecedented high beam intensity inducing the simultaneous combination of high beam power and high space charge. Therefore, MEBT and D-plate control system development is related with general accelerator characteristics in the following way:

¹ IFMIF, the International Fusion Materials Irradiation Facility, is an accelerator-based neutron source that will use Li (d, xn) reactions to generate a flux of neutrons with a broad peak at 14 MeV equivalent to the conditions of the Deuterium-Tritium reactions in a fusion power plant. IFMIF is conceived for fusion materials testing.

- LIPAc is aiming to produce a very powerful CW deuteron beam (1.1 MW @ 9 MeV). The unavoidable beam losses [5] along the accelerator lead to an important rate of neutrons and radiations that must be properly controlled. On the other hand, the power of the beam itself could, in case of accidental or abnormal operation conditions, damage or destroy highly valuable parts of the machine.
- Beam losses must be observed and studied in order to fulfil beam stability in terms of transverse position and shape. To obtain this fundamental information several diagnostics devices have been installed along the accelerator line, these devices require an specific control and a fast data acquisition.

LIPAc Local Control Systems (LCSs)

The main function of the LCSs is, obviously, to control its own subsystem, displaying their own process variables (PVs) for the rest of LCSs and enabling access and modification of these PVs by the CSS. Safety, device protection and optimization activities are also included among its functions. LCSs are composed of different elements but following three layers architecture based on EPICS, Fig. 1. The lower level consists of equipment (power supplies, diagnostics, sensors, motors) connected to the intermediate level via specialized links. The middle layer consists of EPICS front-end systems (so-called input-output controllers (IOCs)). The upper layer, part of the CCS, consists of workstations, which either play dedicated roles, offering a man-machine interface function. These two levels communicate through TCP/IP on Ethernet.

Figure 1: LIPAc general distributed process control.

MEBT LOCAL CONTROL SYSTEM

The MEBT subsystem [6] is responsible of the transport and matching of the RFQ beam into the SRF Linac.

Figure 2: MEBT subsystem 3D scheme.

In order to minimize the beam losses caused by the strong space charge forces affecting the beam in this area, while keeping the sufficient freedom in beam optics optimization, a very compact scheme based in two sets of quadrupole magnets with steerers and two re-buncher cavities has been proposed, Fig. 2.

MEBT Local Control System interfaces the MEBT and the rest of the accelerator control system, the complete MEBT LCS architecture is shown in Fig. 3. Control of the main devices that make the MEBT up is explained in the next sections.

Control of the Bunchers

There are two re-buncher resonant cavities, see Fig. 4, with power couplers to supply the RF to the resonator, and a tuning system. That means temperature measurements for the water cooling and motion controls for the tuners (two stepper motors) including position readbacks (linear potentiometers) and limit switches. The stepper motor shifts a copper plunger in order to keeps resonance frequency constant during operation, potentiometers and limit switches are necessary to manage the motor. Cooling channels at the bunchers are used to keep copper temperature at 20 °C. The whole buncher control is managed by a Siemens [7] PLC S7-300 except the stepper motor control which is externally carried out by the low level RF system [8]. Communication between PLC and EPICS is achieved using S7plc EPICS driver.

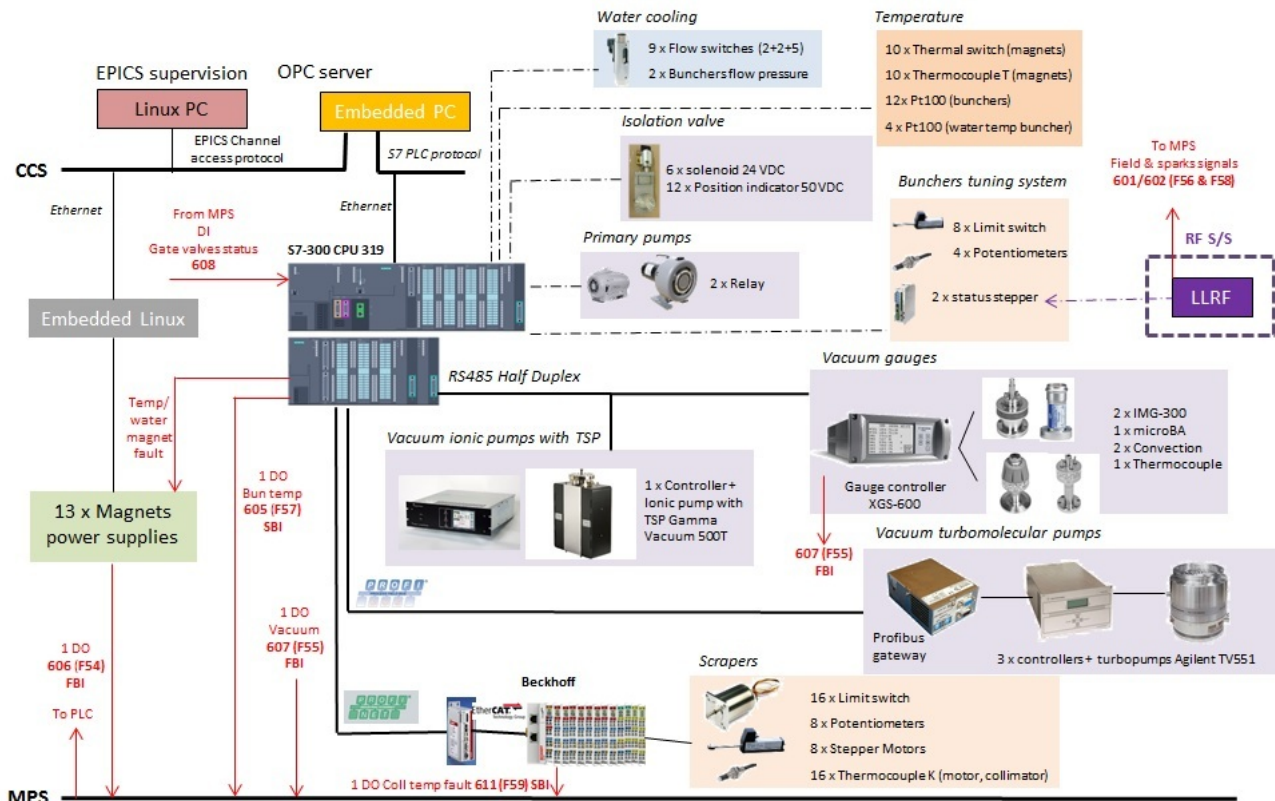

Figure 3: Global MEBT control architecture.

Figure 4: MEBT buncher cavity.

Control of the Scrapers

The two scrapers must stop the out-of-emittance beam particles before injection into the SRF Linac. Thus, they are movable items so they need motion control (eight stepper motors) including position readbacks (linear potentiometers) and limit switches. The scrapers motion control is managed by a Beckhoff [9] system. This solution system is based on CPU CX1020 model with digital input/output modules for limit switches. The communication from the Beckhoff system to EPICS is carried out using S7plc EPICS driver.

Control of the Quadrupoles

Transverse and longitudinal focusing for the beam is carried out using quadrupoles and steerers, as shown in Fig. 2. Therefore, the LCS controls settings and monitoring of the five quadrupoles power supplies and the eight steerers bipolar power supplies and temperature measurements for the water cooling. The beam size in the RFQ is small (phase advance 90 deg/m) while in the HWR-Linac the phase advance is comparatively lower (20 deg/m) where the distance is much longer between focusing sections. Consequently, the MEBT must have a very compact structure to limit the beam emittance growth. Thus, four quadrupoles, see Fig. 5, are used for transverse focusing and one more is needed to limit the beam size in the MEBT itself. The control of the five quadrupole power supplies and the eight steerers bipolar power supplies is being carried out with EPICS over Modbus protocol.

Refrigeration and Vacuum

Four pumping units and four valves are used to maintain the vacuum level, ten gauges are utilized to read it. A PLC is in charge of the control of these devices; its communication with EPICS is carried out using S7plc EPICS driver.

Figure 5: MEBT quadrupole magnet.

D-PLATE LOCAL CONTROL SYSTEM

Beam Instrumentation (BI) subsystem must warranty the successful operation of the accelerator from commissioning phases of RFQ, MEBT, Superconducting Radio Frequency (SRF) Linac and High Energy Beam Transport (HEBT), to the full power operation. Hence, its main objective is to provide all necessary information to properly transport and accelerate the beam from the source to the beam dump, then, to fully understand and measure all beam characteristics and operation optimization. Most of the diagnostics are concentrated inside of the Diagnostics Plate (DP or D-plate). DP is a movable set of diagnostics, see Fig. 6, that is placed downstream from the SRF Linac, in the HEBT. Main parameters of the beam will be measured in the DP, e.g. current, phase, beam position, transverse profiles, mean energy, emittance measurements, micro losses, energy spread, etc. Beam measurements play a critical role in LIPAc due to its uncommonly high beam current and high beam power. A global control strategy is thus necessary to clearly decide between the different measurements categories. The scope of this paper includes only the recent advance in the control of the fluorescence profile monitors (FPMs).

Figure 6: D-Plate support integration at Ciemat.

Control of the Fluorescence Profile Monitors (FPMs)

The objective of these devices is to develop a non-interceptive beam transverse profiler (in X and Y axis) based on the residual gas fluorescence originated by the beam-gas interaction. FPMs (two in HEBT, two in D-plate) could be used as well for the emittance measurements with quadrupole scans.

The control of the FPMs is based on a Vertilon [10] data acquisition system (PhotoniQ Model IQSP482). High voltage control for the PMT is required; therefore the acquisition system delivers 64 data points for both FPMs of the D-plate.

Control software is based on client-server architecture, see Fig. 7. Vertilon device is accessed from an EPICS IOC (client) using TCP/IP protocol, connecting with a LabVIEW application (server), which is the one that gets direct access to the device.

Figure 7: FPMs client-server support architecture.

CONCLUSIONS AND OUTLOOK

The objectives and requirements of LIPAc have been partially explained being the rationale for the design and development for each of the local control systems. The ability to make EPICS run in each of the devices and subsystems presented is not trivial, but the benefits provided against other centralized solutions are absolutely overwhelming. A large and complex facility like LIPAc, whose operation opens unstudied ways, cannot be conceived with independent subsystems, centralized at a single point or unable to understand each other.

LIPAc beam power provides unique characteristics that make the control system an unique and heterogeneous elaboration. For MEBT and D-Plate subsystems, their local control systems design has been revealed, explaining the main features and showing its architecture. Local control systems fit in a mostly distributed architecture and properly respond to the specific function for which they are designed, however, they are not isolated entities, they communicate with each other and follow the same multilayer structure.

Since there is no previous experience in operating a machine like LIPAc, all EPICS PVs are available for the central

control system, which is the one and only that can manage the whole accelerator and can take decisions based on the information given from every subsystem. Making all the PVs visible for the central control system becomes the next step in order to finish the integration of the whole LIPAc control system.

ACKNOWLEDGMENT

We would like to thank the help from LIPAc EU-HT in the design of the LCSs architectures. We also want to acknowledge the suggestions from Álvaro Marqueta. A warmful thank to the Universidad Politécnica de Madrid for the valuable help in the development of the FPMs control system.

REVOLUTION PROJECT: PROGRESS IN THE EVOLUTION OF SOLEIL MOTION CONTROL MODEL*

S. Zhang[†], F. Blache, D. Corruble, C. Kheffafa, YM. Abiven, SOLEIL, Gif-sur-Yvette, France
S. Minolli, NEXEYA SYSTEMS, La Couronne, France

Abstract

SOLEIL is a third generation synchrotron radiation source located near Paris in France. REVOLUTION (REconsider Various contrOLLer for yoUr motion) is the motion controller upgrade project currently in progress at SOLEIL. It was initiated to maintain the facility operations by addressing the risk of hardware obsolescence in motion control but at the same time making room for complex applications requirements to face new high performance challenges. In order to achieve these considerations, SOLEIL's strategy move was to go from a single controller for all applications to two motion controllers. A first Controller GALIL DMC-4183 was chosen to succeed the previous version DMC-2182. Both controllers can be integrated in the existing architecture with little hardware and software adaptation enabling full compatibility with the existing architecture. A second controller, Delta Tau Power Brick, has been selected as a HIGH PERFORMANCE solution providing advanced functionality.

The CLASSIC controller upgrade is about to be completed and the integration of Power Brick into the SOLEIL control system is ongoing. The system complexity is abstracted by embedding processing functions into low-level code and giving end-users a simple high-level interface. The work done to structure the interfacing and standardization of the controller are detailed in this paper.

CONTEXT OF REVOLUTION AT SOLEIL [1]

Motion Control Status and Upgrading Motivations

SOLEIL needs to upgrade its standardized GALIL motion controller in order to address two challenges: First, the current motion controller used in SOLEIL is dated and in risk of being discontinued and we must have an updated product before this happens. Nevertheless, this is not expected to occur in the next few years. Secondly, new motion control applications demand a higher performance and more advanced features that can not be reached by our current controller.

Strategy: Change Model

To achieve the next three goals of "Increasing performance, maintaining operational continuity, and controlling overall cost", SOLEIL decided to replace the current model

of a "single and universal controller" by a model with two kinds of motion controllers:

- CLASSIC motion controller, mainly used and suitable for "simple and classic" applications. This controller is fully compatible with the existing hardware and software motion control architecture.
- HIGH PERFORMANCE controller, used in few cases, suitable for "complex and fast" applications. The hardware and software motion control architecture is designed to be close to the existing architecture for the CLASSIC controller.

CLASSIC CONTROLLER EVOLUTION

The GALIL DMC-4183 controller was chosen to succeed the current Galil DMC-2182. Its implementation needs some hardware and software developments which are currently being done to make it compatible with current architecture. On the software aspect: a new firmware was developed by GALIL which includes the new "Continuous Closed-Loop on Stepper motors" feature. It was validated by SOLEIL by an operational application done on the monochromaters of LUCIA and TEMPO beamlines. To use this feature, a new microcode (embedded code) was developed and validation tests are ongoing. For the hardware: in order to use the current ControlBox rack (same size, same pinouts), an interface board (MIG-4121) has been developed which adapt the DMC-4183 to the internal pinout of the ControlBox rack. The integration in the rack has been validated and is now operational.

HIGH PERFORMANCE CONTROLLER STANDARDIZATION

Controller Product

Delta Tau Power PMAC in the Power Brick LV-IMS format was selected for the new "HIGH PERFORMANCE" solution after a long evaluation process.

Figure 1: Power Brick LV-IMS.

Power PMAC is a general-purpose embedded computer with a built-in motion and machine-control application which offers: powerful computing capacity, multi-axis synchronization, encoder processing, virtual control through

* Work also supported by XT. Tran, M. Cerato, G. Renaud, E. Fonda and SAMBA Beamline staff, C. Engblom, Delta Tau Ltd., IMO JEAMBRUN AUTOMATION, Observatory-Sciences Ltd...

[†] szhang@synchrotron-soleil.fr

kinematic equations, non-linear trajectories, built-in software PLCs (programmable in Power PMAC script and/or C language) etc. Moreover, around Delta Tau products there is an international user community in large research facilities.

The Power Brick LV-IMS rack (see Figure 1) is now available with a SOLEIL standard compatible connectivity for motors and encoders. It comes with the configuration of a Power PMAC CPU and 8-axis integrated amplifier circuits for 2-phase and 3-phase motors direct-drive. The number of axes can also be expanded through a MACRO fiber optics network. As an option, it can be configured to support different encoder feedback protocols among a wide variety of choices.

Control Architecture

For reasons of consistency and usability we intended to keep a control architecture as close as possible to the existing one. Considering the performance benefits of the product, most process functions are embedded into low-level to abstract the system complexity for the high-level software. In order to make the controller easy to use and maintain in normal operations, we developed some standard functionalities for the hardware low-level configuration and in the embedded software.

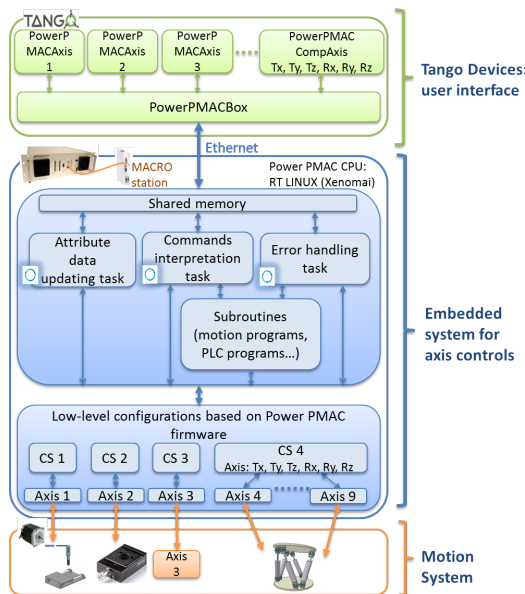

Figure 2: Power PMAC embedded system structure with an example of motion system application.

High-level Software for User Interface

In order to structure the end-user interface, the software high-level architecture shown in Figure 3 has been developed. The software consists of Tango devices for axis controls and general rack controls. The rack controls communicate over the "PowerPMAClib" and "DeltaTauLib" libraries.

The Tango device interface for the new HIGH PERFORMANCE controller is designed to be very similar to the standard CLASSIC controller. A single Device Server

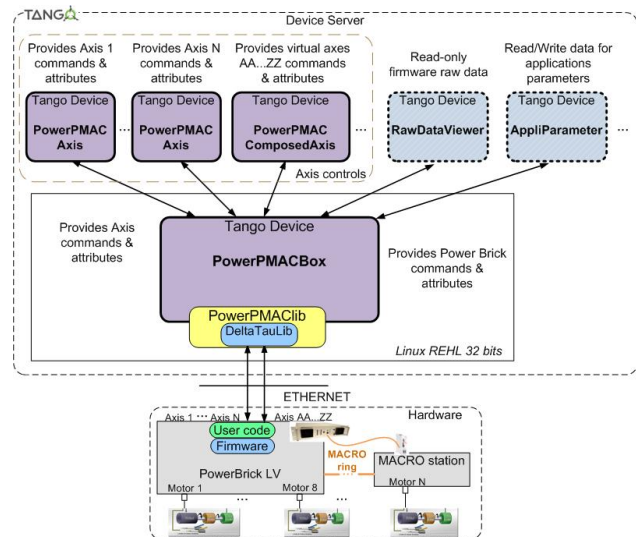

Figure 3: High-level software architecture.

"ds_PowerPMAC" including the main set functionality is composed with the following devices:

- Device **PowerPMACBox** for the controller and general data.
- Device **PowerPMACAxis** for driving physical axis.
- Device **PowerPMACComposedAxis** for driving composed virtual axes (one device/CS).

To complete the functionality supply, some devices are planned to be realized in the near future:

- Device **RawDataViewer**, a diagnostic tool providing read-only raw firmware data of Power PMAC for specified axis.
- Device **AppliParameter**, a tool providing read and write data of the controller for users to parametrize their application-dedicated variables.

The Tango devices access the Power PMAC level through "PowerPMAClib", which encapsulates "DeltaTauLib". "DeltaTauLib" is supplied by Delta Tau to provide access to the firmware and embedded "user" data via Ethernet [2]. The "PowerPMAClib" library, developed by SOLEIL, presents in its interface the access to general controller functions (e. g. connection, status, temperature, operating time, reset etc.) and the axis control functions (e. g. position, speed, stop etc.). Within axis controls, the library makes the link to the data structures stored in the shared memory of the controller for data exchanging and command settings. The information in the data structures are accessed and updated from the embedded programs in parallel from the Tango devices.

Embedded System Structure

Power PMAC uses Linux OS with the Xenomai preemptive real-time kernel which runs a single real-time application to handle tasks of different priorities [3].

In order to better manage the controller in an operational condition with different motion system applications, we implemented a generic Power PMAC project independently of the application system which is organized in 3 layers:

an embedded software layer for Tango axis control interface, a subroutines layer for functional sub-programs, and a hardware layer for low-level configurations (see Figure 2).

Embedded software layer: interface for Tango axis control For physical- or virtual- axis control: all commands, property settings, attribute reading/writing, and state/status requests from the Tango software go through the embedded software layer to access the firmware. Via predefined indexed data structures in the shared memory of the controller, this layer acts as an intermediate between the Tango software and Power PMAC firmware. Data structures are shown in Figure 4.

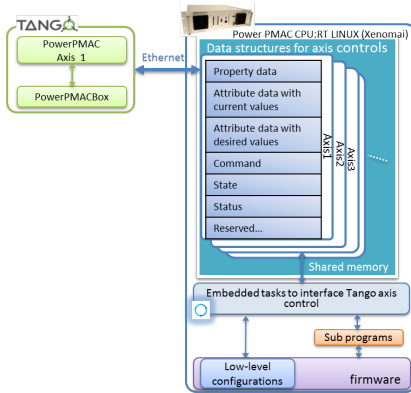

Figure 4: Predefined indexed data structures in Power PMAC shared memory for Tango axis control.

The features of this layer are:

- Interpretation of commands provided by the Tango device and that they only run if operating conditions allow.
- Attribute data updating: for exchanging high-level attributes with low-level parameters, parameters being changed only within allowed conditions.
- Error handling: setting flags in the state/status variables when certain errors/warnings occur.

These features are realized by 3 different tasks running in 2 threads with separately adjustable cycle times. One single thread is used for the tasks of interpretation and error handling. In the scope of the high-level polling frequency, this thread has higher priority than the thread used for updating data attributes.

Subroutines layer: functional sub-programs definition This layer implements some sub-programs that can be called or stopped by the software layer command request to perform a processing function or trajectory followed moves. These programs can directly use firmware functions and act on low-level hardware settings. Their execution status are continuously checked on by the interface layer for safety handling.

Some application-dedicated programs, including motion- and PLC- programs, will be defined and implemented depending on the needs. Some common programs will be part of the generic project:

- Motion programs for reference-position initialization.

- Duty cycle PLC program for motor stops within a certain period.
- Vacuum mode PLC program to itch motor current depending on the motor status (moving or stopped).
- System start-up PLC program to initialize the amplifier and reset the embedded system.

Hardware layer: low-level configurations Some typical hardware setups need to be standardized to minimize and simplify installation work. These setups have been identified of which the configuration files have been templated:

- Encoder conversion setups: Quadrature, Sin/Cos, SSI, BiSS-C...
- Motor setups:
 - 2-Phase stepper motor setup: closed Loop & micro-stepping
 - Motor setup using third-party drives with PFM signals output
 - 3-Phase brushless servomotor setup
 - DC brush motor setup

Based on the tested and validated templates, a GUI tool (see Figure 5) has been developed to automatically generate configuration files according to preselected parameters: channel number, motor type, encoder type, motor current etc. Hardware commissioning will however require a tuning process followed by manual modifications of the files. The PID regulation can be done using the Power PMAC IDE tuning tool. From then, the CS (Coordinated System)

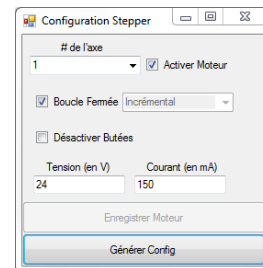

Figure 5: Hardware configuration file generator tool.

configurations will be added in the files to create the relationship between controlled axes and motors (see low-level configurations part in Figure 2). To properly benefit from the "Power PMAC CS" functionality, an individual motor is associated to a CS for physical axis controls, same as for virtual axis controls. Each CS configuration is made by a set of Kinematic forward & inverse routines.

A step-by-step procedure on low-level installation configurations and files archiving procedures for maintenance will be defined.

Integration Test Results

Unitary tests of the standardized software and hardware have been realized and validated. The integration test in the SOLEIL control system is validated with the Power Brick LV in a laboratory setting. Some details need to be finalized.

Several low-level tests have been accomplished or are ongoing on some beamline applications: DCM (double

crystal monochromator) on PLEIADES, DCM on SAMBA, NANOPROBE (joint project between Synchrotron SOLEIL in France and MAXIV in Sweden) [4]. The integration tests are also scheduled for these Beta-tester applications.

SAMBA beamline DCM control upgrade (see Fig. 6)

Currently the system is controlled by the CLASSIC solution. This upgrade aims to achieve a low-level direct energy control and thereafter a continuous energy-scan operation, which is expected to significantly reduce the experiment duration with faster execution and reduced Ethernet communication

Figure 6: SAMBA beamline DCM motion system.

The control of the 7 main axes (R_x , T_{s2} , T_{z2} , C_1 , C_2 , R_{z2} , R_{s2}) have been installed on a Power Brick unit. It includes a DC brush and 6 steppers for which the low-level settings have been tested and validated. The kinematic equations have also been implemented to provide direct energy control, detailed as following.

Equation between E and the main axis $R_x(^{\circ})$ is shown as below, in which E is the photon energy in eV, d is the lattice spacing in Å, θ is the angle of the main axis of the monochromator R_x in $^{\circ}$.

$$E = hc \frac{1}{\lambda} = \frac{hc}{2d \sin(\theta)} \quad (1)$$

The remaining motors need to be synchronized with the main axis to obtain the desired energy.

T_{s2} and T_{z2} are the two translations of the second crystal:

$$T_{s2} = \max(T_{s2}^{Min}, \frac{H}{2 \sin(\theta)}); T_{z2} = \frac{H}{2 \cos(\theta)} \quad (2)$$

C_1 and C_2 are the positions of the two motors of the second crystal bender. As shown in the equations below, R is the radius of the crystal obtained; $\frac{1}{R}$ is the curvature. $A_{i,j}$ are coefficients:

$$C_1(\frac{1}{R}) = A_{1,0} + A_{1,1} \frac{1}{R}; C_2(\frac{1}{R}) = A_{2,0} + A_{2,1} \frac{1}{R} \quad (3a)$$

$$\frac{1}{R} = \frac{1}{2 \sin(\theta)} (\frac{1}{p} + \frac{1}{q}) \quad (3b)$$

R_{z2} and R_{s2} follow empirical correction curves. Shown in the equations below, p and q are the source to monochromator and monochromator to sample distances.

$$R_{s2} = P_n(\theta, c_{R_{s2}}); R_{z2} = P_n(\theta, c_{R_{z2}}) \quad (4a)$$

$$p_n(\theta, c) = \sum_{i=0}^n c_i \theta^i \quad c = \begin{pmatrix} c_0 \\ c_1 \\ \vdots \end{pmatrix} \quad (4b)$$

Tests in low-level with the kinematic conversions have been done and integration tests with the Tango devices will be done soon. The additional functions of enabling or disabling one of the relations for test or to perform a scan, will be realized with the Tango Device "AppliParameter".

New Complementary Product

To meet the required applications when external drivers are in use, a new complimentary product Delta Tau Power Brick controller is now specified. It contains the same CPU (Power PMAC) as Power Brick LV without the built-in amplifier, providing PFM and analog signals for third-party drives. In addition, this product should be fully compatible with the CLASSIC controller in respect to cabling connectivity; an eventual control upgrade would be fairly direct and easy.

The same tool settings as well as skill-sets would be used to configure the new controller. It is expected to be integrated in the SOLEIL control system without extra development.

CONCLUSION

The new strategy of moving from a model with a single universal motion controller to a model with two specialized controllers is being implemented. Operational continuity is ensured with the new CLASSIC controller while at the same time improving some functionalities. The chosen HIGH PERFORMANCE controller, Delta Tau Power Brick, is very powerful and versatile which allows it to handle high performance systems.

The main challenge with this controller is to offer the high-performance of the Power Brick and the DMC-4183 to the end user while still keeping an easy-to-use interface. Both controllers are now ready to be used for simple functionalities and the next step will be to train the electronic group to have the necessary skill-sets to maintain these products in operation. Advanced functions, such as compensation tables and remote managing of motion programs, will be improved. The HIGH PERFORMANCE controller will bring value to different control upgrade applications in projects such as monochromator, Flyscan, Nanoprobe and Goniometer.

Abstract

Instrument control at ISIS [1] is in the process of migrating from a mainly locally developed system to an EPICS [2] based system. The new control system, called IBEX, was initially used during commissioning of a new instrument prior to a long maintenance shutdown. This first usage has provided valuable feedback and significant progress has been made on enhancing the system during the facility maintenance period in preparation for the move onto production use. Areas that will be of particular interest to scientists in the future will be linking feedback from live data analysis with instrument control and also providing a simple and powerful scripting interface for facility users. In this paper we will cover the architecture and design of the new control system, our choices of technologies, how the system has evolved following initial use, and our plans for moving forward.

BACKGROUND

The ISIS pulsed neutron and muon source has been providing world-class science since the mid-1980s and currently has over thirty beamline instruments producing world-leading research. The software and hardware used to control these beamline instruments plays a significant part in the productivity of ISIS.

The current instrument control system, known as the SECI system, consists of LabVIEW [3] drivers for equipment control alongside in-house developed software for scripting, data collection and experiment management, etc. This control system has performed well for many years; however, the construction of new beamline instruments and the refurbishment of older instruments has led to significantly more complex experiments becoming possible and, as a result, are pushing beyond the boundaries for which the current control system was designed. With this in mind, and with the prospect of even more complex instruments being built in the future, it was decided to create a new control system based on EPICS.

HARDWARE ARCHITECTURE

The IBEX control system runs on a Windows 7 x64 Virtual Machine (VM) which is hosted on a rack-mounted Windows 2012 server. Each beamline instrument has its own independent server. Windows was chosen for a number of reasons, such as:

- The controls team have significant experience and expertise with running control systems on Windows

- ISIS has an IT support group that can assist with installation and maintenance
- Easier interfacing to existing site infrastructure (e.g. data archiving, system backup/replication)
- Can use existing LabVIEW drivers more easily
- Ability to do a phased migration, running either in parallel or a mixed IBEX/SECI system

The beamline instrument server and equipment are usually placed on the general ISIS network; however, network sensitive equipment can be placed on a private network. This private network is implemented using a Virtual Local Area Network (VLAN) which can be routed back to the main computer room. As the virtual machines are replicated to the computer room it is possible to rapidly restore and run an instrument from there in the event of beamline server failure.

Most beamline and sample environment equipment in use on ISIS instruments are controlled via serial (RS232) communication. For ease of access and flexibility MOXA [4] NPort serial device servers are used to expose the serial devices to the network.

SOFTWARE ARCHITECTURE

A system based on EPICS lends itself naturally to a client-server style architecture and this is how IBEX has been implemented. Figure 1 shows the basic flow of information relating to the experiment; the dashed line indicates the separation between the client and server side components. Where possible the system uses EPICS Channel Access (CA) for communication between the client and server side.

Figure 1: The flow of experiment information for a beamline instrument.

EPICS Input/Output Controllers (IOCs) are the standard way of communicating with the devices used on

the instruments. The procServ [5] package is used to host the IOCs as it provides telnet access to the IOC console. The conserver program [6] is used to provide remote access to these consoles for diagnostic and support purposes and the procServControl [7] package adds support for starting and stopping the IOC remotely via Channel Access.

The BlockServer is the brain of the control system; it coordinates the client and the server side to meet the needs of the type of science being performed on the beamline instrument being used. The BlockServer is responsible for managing the setting up of the system for the particular experiment being performed. The information for each required collection of devices is stored as XML files – these XML files make up what is known in ISIS as a configuration. The configurations contain the following information:

- Which IOCs to start and key IOC macro values
- Which Blocks to create
- Metadata relating to the type of experiment
- Information for configuring the IBEX graphical user interface (such as Block display grouping)

At the most basic level a Block is a scientist friendly alias for an EPICS Process Variable (PV). For example, rather than working with a complicated PV like IN:LARMOR:EUROTHERM:TEMP1 an alias can be created called SampleTemp. This simple science specific name is much more intuitive for a scientist. Blocks are usually created for key experiment parameters and the values are logged for inclusion in the NeXus data file [8] created at the end of the experiment. Block PVs are implemented using aliasing on a PV Gateway [9] which in this instance is running on the loopback interface of the server.

All important PVs on an instrument are automatically logged via the Control System Studio [10] archiver application running on the server. As Blocks are experiment based they are logged in a second instance of the archiver to allow easier adjustment and tailoring of archiving performance. The archiver pushes the log information into a MySQL database [11] on the server. The historical log can be used for monitoring and diagnosing problems and the Blocks log provides information for inclusion in the NeXus data file.

Storing information for configuring the IBEX graphical user interface (GUI) on the server side means that the GUI is instrument independent. This is very convenient for the scientists and support staff as it allows quick switching between different instruments through one GUI. Having a common GUI across all instruments also makes support and maintenance easier.

Although it is not shown on Figure 1 there is also a second PV Gateway on the server which is used to control access to the PVs. Using the CA security built into the Gateway it is possible to restrict access to the PVs on the server; this can be based on user name and/or the machine being connected from. By default, access to the IBEX

server is restricted to being read-only, but read-write access is allowed from certain machines.

One of the weaknesses of the SECI system was that there was only one GUI client instance available and that was on the server. This meant that the system could not be viewed easily by multiple people at the same time. IBEX has been developed to allow multiple instances of the client to be run at the same time from any PC on the ISIS network. By default these clients will be read-only but the intention is to develop a baton handling system to allow clients to request to have sole read-write access for an appropriate amount of time.

Also not shown on Figure 1 is the messaging system which allows messages from the IOCs and BlockServer to be passed to the IBEX GUI. The messaging system is part of Control System Studio and is based on the Apache ActiveMQ implementation of the Java Messaging System (JMS) [12]. A new log server process replaces the usual IOC log program and routes IOC messages into this JMS system. A historical record of the messages is stored on the server inside the MySQL database and these historical messages can be searched via the IBEX GUI.

One of the challenges for a control system at a user facility like ISIS is incorporating new bespoke equipment quickly; for example, a user from a university may bring a prototype piece of sample environment equipment to use on an instrument. To handle these use cases there are different technologies which have been developed at ISIS for handling LabVIEW and other simple serial devices.

As the SECI system was based on LabVIEW it was desirable to be able to quickly enable existing drivers into the EPICS system. For this, a driver based on Asyn [13] was created, called lvDCOM [14], which communicates with LabVIEW via DCOM [15]. The creation of the lvDCOM driver is mostly automated and because the LabVIEW driver requires no modification it is quick and simple to create an IOC which wraps the LabVIEW driver. It is reasonably common for bespoke equipment to have a LabVIEW driver, thus lvDCOM can be used in those cases. For more complex situations it is possible to use the NetShrVar driver [16] to access National Instrument network shared variables [17] instead.

SDTest is a simple generic serial solution based on the EPICS StreamDevice [18]. With knowledge of the command strings to send to the device and how to interpret the corresponding response a StreamDevice driver can be quickly created as part of a configuration.

THE IBEX CLIENT

For IBEX it was decided to create a GUI based on Control System Studio. Control System Studio was chosen as it was the most feature complete of the modern EPICS GUI implementations. Control System Studio itself is based on the Eclipse Rich Client Platform (RCP) framework [19].

The overall design of the IBEX GUI was based on the GUI of the SECI system (see Figure 2) as the ISIS scientists and users liked this design.

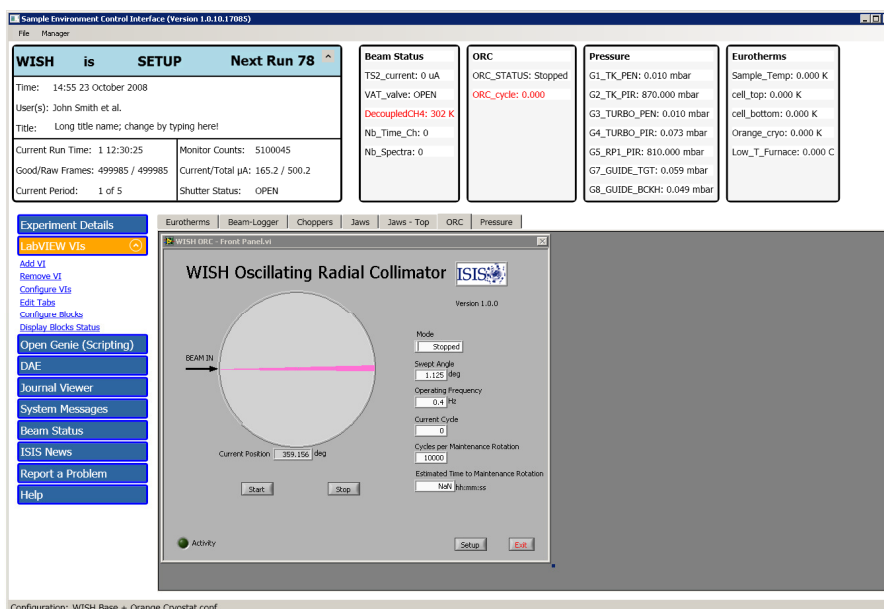

Figure 2: The GUI for the SECI system.

Figure 3: The new IBEX GUI showing an instrument synoptic.

The key features of the design that needed to be reproduced were:

- The data collection dashboard in the top-left corner
- The Block values displayed in groups in the top-right corner
- The navigation bar on the left-hand side

To achieve this it was necessary to create a screen layout very different from a typical Control System Studio screen. ISIS specific views were created and some of the GUI features that are provided by Control System Studio needed to be either hidden or disabled. The current IBEX GUI is shown in Figure 3. New key features

required for the IBEX GUI were a synoptic, a data browser and an embedded Python console for scripting.

The synoptic (as shown in Figure 3) provides an overview of the status of the instrument in terms of the layout of the instrument and key values. By selecting an item on the synoptic it will open a window showing more information about that particular item. For this Control System Studio's BOY screens are used, an example of which is shown in Figure 4. An instrument may have multiple synoptics, either for different experiments or for showing various areas of the beamline separately. The layout information for the synoptics is served and managed by the BlockServer which is one of the ways the IBEX GUI is kept instrument independent. The GUI also

has a graphical synoptic editor which allows the scientists to create new synoptics or modify existing ones.

The data browser is a plotting tool developed as part of Control System Studio; it is designed to show historical PV values as a function of time. In the IBEX GUI it is used to plot the history of Blocks as well as standard PV values. The historical data is retrieved from the MySQL database mentioned previously.

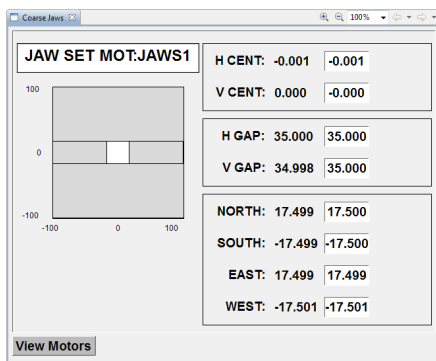

Figure 4: An example BOY screen.

The SECI system used an in-house scripting language called Open GENIE [20] for creating scripts to automate a series of experiments. For the IBEX system Python was chosen as the replacement for Open GENIE because it is easy to learn and many scientists will already be familiar with it. PyDev [21] is a Python integrated development environment and because it is an Eclipse RCP application it was simple to incorporate the PyDev Python command line directly into the IBEX GUI. To enable Python to communicate with the IBEX control system an in-house library was created called *genie_python* which uses CaChannel [22] for sending and receiving information over Channel Access and provides scientists with a set of useful control commands.

STATUS UPDATE

The IBEX system has been successfully used to commission the LARMOR small angle scattering instrument and is now being used to perform user experiments. The scientists using a prototype IBEX system to commission LARMOR provided invaluable testing time and feedback for the development of the system. Now IBEX is being used for performing user experiments more feedback is being received which will be used to direct further development.

One of the goals for IBEX was for it to be easy to incorporate bespoke equipment quickly. With this in mind lvDCOM, NetShrVar and SDTest were developed. Users on LARMOR have already successfully used SDTest to enable their own specialist equipment to be used within IBEX.

The intention was to develop a system where an instrument could be observed from multiple instances of the GUI at the same time and this has been achieved. Being able to monitor an instrument without disturbing the user has been a very useful feature for both the

controls team and the scientists. Overall the IBEX GUI has been well received by the scientists - maintaining the familiar look of the SECI GUI whilst adding powerful new features like the synoptic has proved popular.

The general flexibility of having a system based on EPICS compared to LabVIEW has allowed a more future resilient control system to be developed. Being part of wider collaborations, such as EPICS and Control System Studio, have reduced the amount of development required to create the new control system.

THE FUTURE

The Mantid data analysis framework [23] is widely used at ISIS for analysing data after an experiment but there is a desire amongst the scientists for “intelligent data collection.” An example of this might be stopping data collection when the signal to noise ratio of the data reaches a certain level. As Mantid is Python-aware it is possible to either call *genie_python* from Mantid or vice versa – this could be a way of providing intelligent data collection. Initial investigations into enabling Mantid to communicate with the control system have proved promising. This is an area which will be explored further.

IBEX is currently being used to commission the new IMAT instrument which presents a new set of challenges. IMAT is an engineering beamline and, thus, is very different to LARMOR; however, this is the kind of challenge IBEX was developed to handle.

After IMAT there will be another new instrument called ZOOM which will also be commissioned using IBEX. Over time the existing instruments running the SECI system will be migrated to IBEX.

100 Hz DATA ACQUISITION IN THE TANGO CONTROL SYSTEM AT THE MAX IV LINAC

P. Bell, V. Hardion, V. Michel, Max IV Laboratory, Lund, Sweden

Abstract

The MAX IV synchrotron radiation facility is currently being constructed in Lund, Sweden. A linear accelerator serves as the injector for the two storage rings and also as the source of short X ray pulses, in which mode it will operate with a 100 Hz repetition rate. The controls system, based on TANGO, is required to collect and archive data from several different types of hardware at up to this 100 Hz frequency. These data are used for example in offline beam diagnostics, for which they must be associated to a unique electron bunch number. To meet these requirements, the timing performance of the hardware components have been studied, and a TANGO Fast Archiver device created. The system is currently in the deployment phase and will play an important role in allowing the linac and Short Pulse Facility reach their 100 Hz design goal.

INTRODUCTION

The accelerator complex at the MAX IV laboratory consists of a 3 GeV, 250 m long full energy linac, two storage rings of 1.5 GeV and 3 GeV and a Short Pulse Facility (SPF). The repetition rate of the linac is a maximum of 10 Hz when serving as the injector for the rings and 100 Hz when providing pulses for the SPF.

The control system has a three-tier architecture, with specific hardware handling the real-time tasks and TANGO [1] representing the middle tier as the primary control system. Most equipment is interfaced directly to TANGO via TCP/IP. For the client layer, physicists and operators can interact with TANGO via its Python and MATLAB bindings or through the SARDANA [2] layer, which brings a macro server and standardised Graphical User Interfaces based on TAURUS [3].

In the operation of the linac it is necessary to be able to archive data through the TANGO system at the repetition rate or bunch frequency of the electrons. For example, oscilloscope devices connected to Current Transformers at various locations along the length of the linac are used to record the distribution in time of the charge of the passing electron bunches. These waveform data will be used, for example, in the offline diagnosis of any beam loss. The capturing of information from the control system at high frequency is referred to as Fast Archiving, since it must perform at up to 100 Hz to record every electron bunch when the linac is operating in SPF mode. The same system will also be used to read data from the linac and the storage rings at 10 Hz, where it will be used, for example, in the Slow Orbit Feedback system.

The work that is reported here has so far has focused on the integration of TANGO devices for controlling oscillo-

scopes into the Fast Archiver, though the inclusion of other equipment such as power supplies is foreseen in the future. The first section of the report documents how the performance of the many devices that will participate in the Fast Archiving is being systematically measured. The second section then describes the design and functioning of the Fast Archiver and how the oscilloscope devices have been adapted for inclusion in the system.

TIMING PERFORMANCE STUDIES

Timing performance studies are being performed on the TANGO devices that will take part in the Fast Archiving. The performance studies first check that the hardware itself is capable of sending or receiving commands at a sufficiently high frequency. An example is shown in Fig. 1 for a certain type of power supply used at Max IV.

Figure 1: Distribution of time taken to read the current from a power supply over a direct raw socket connection (green) and via the “Current” attribute in its TANGO device integrated to the control system (blue).

A script is used that repeatedly reads, for example, the value of the current from the power supply hardware and plots the distribution of the time needed to receive a reply. In this example the distribution (in green) is well within the 10 ms envelope needed for 100 Hz operation. The performance of the TANGO device is then checked by measuring the distribution of the time needed to read the attribute “Current” once the device has been interfaced to the TANGO control system. The difference between the two distributions gives an indication of the overhead of the control system, including the network performance. In this case, the distribution (in blue) remains within the 10 ms envelope though adds a few ms to the “raw” performance of the hardware over a direct TCP/IP connection. It can be concluded that this hardware should be suitable for 100 Hz operation.

At the present time we are using these simple tests to identify which devices will need improvements in their communication speed if they are to participate in the Fast Archiving in the future.

THE FAST ARCHIVER

Oscilloscope Device Adaptation

Similar studies to those described above have been performed on the Rohde and Schwarz RTO oscilloscopes [4] that are used in the linac to measure the charge-time distributions of the passing electron bunches. For these devices, the attribute of interest is the “Waveform” which is a spectrum attribute with length of up to 10,000 corresponding to the captured data from the Current Transformer hardware. This attribute can be read from all channels of the oscilloscope simultaneously in around 3 ms as shown in Fig. 2, so the hardware performance is proven to be acceptable.

Figure 2: Distribution of time taken to read the “Waveform” attribute from the Rohde and Schwarz oscilloscope TANGO device. The device reads all four channels in the same request.

The oscilloscopes receive an external trigger synchronised with the repetition rate of the linac. Libera timing modules [5] make this trigger signal available in the TANGO system, with the Libera TANGO devices sending TANGO events as the trigger counter increments. The event system in TANGO is known to perform many times faster than 100 Hz. In the first attempt to synchronise the reading of the waveforms to the trigger counter, the oscilloscopes were configured to continually capture waveforms on the external trigger, while the TANGO device subscribed to events from the Libera. The reception of an event from the Libera prompted the request of the the waveform data, which at that moment should correspond to the previous trigger. However, to guarantee that the waveform read out corresponds to the one just captured by the hardware, this mechanism relies on the event jitter being less than around 7 ms (given the 3 ms needed to read out the waveform data) which could not be assured. A method that did not rely on the timing performance of the TANGO event system was

therefore sought. The oscilloscopes are now configured to wait for the external trigger and block until a new waveform is captured. This ensures that any waveform read out after the block is released is guaranteed to correspond to the previous trigger. The TANGO device implements a thread which repeatedly runs these single acquisitions. Each time a new acquisition is made, the device sends an event containing the waveform data (and its timestamp). In this way the oscilloscopes respond to their external triggers but do not rely on any further software triggering of the readout of the waveform data; rather, the oscilloscope TANGO device is responsible for pushing events as the oscilloscope receives external triggers.

Fast Archiver Design

The purpose of the Fast Archiver is to associate data collected from any participating TANGO device to a unique electron bunch number in the linac. The bunch number (or trigger counter) comes from the Libera timing modules; as described above the Libera TANGO devices are configured to send TANGO events containing the trigger number each time it increments, and these events also contain the timestamp of the trigger. The only requirement on the TANGO devices participating in the Fast Archiving is that they send events containing the data to be archived with a timestamp, as explained above for the case of the oscilloscope device. Given these constraints, the design of the Fast Archiver system is then shown in Fig. 4.

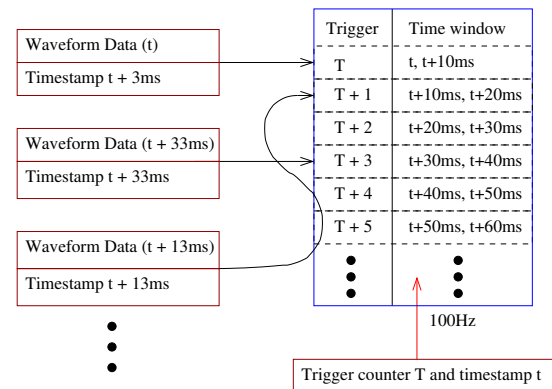

Figure 3: The Synchroniser device receives events containing the trigger counter, T, and timestamp, t, from the Libera device and events containing the data to be archived and corresponding timestamps from one or more other devices. Irrespective of the order in which the events arrive, the data to be archived can be associated with the correct trigger number by comparing timestamps. In this example, waveform data will typically arrive 3 ms after the event from the Libera.

The system comprises one or more Synchroniser devices (Fig. 3) which receive events from the Libera and also from one or more devices that are pushing data to be archived. The Synchroniser devices make the association of the data with the correct trigger number by comparing the timestamp

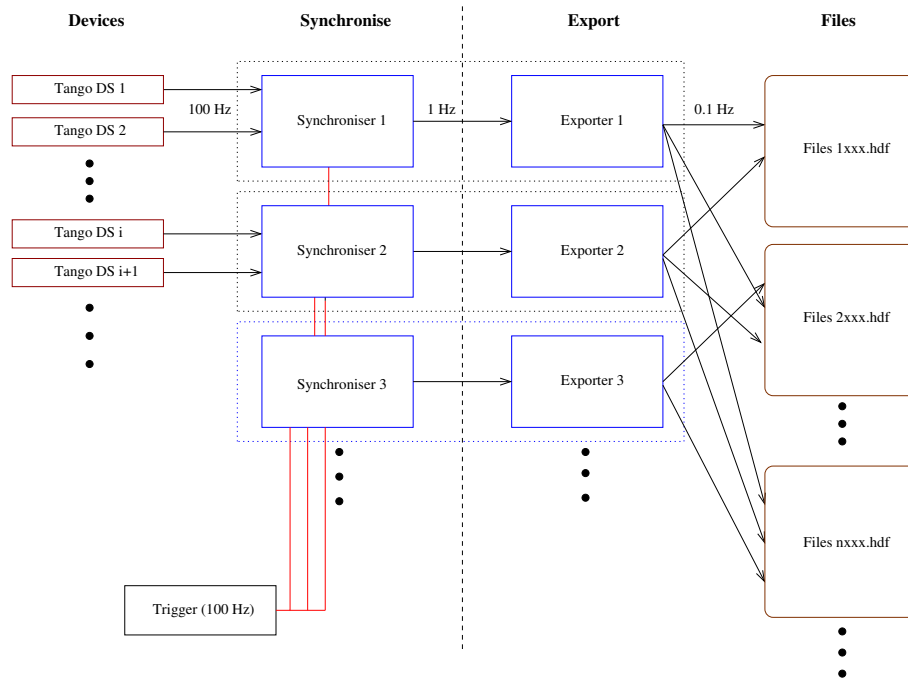

Figure 4: Design and operation of the Fast Archiver in 100 Hz scenario. Multiple Synchroniser devices subscribe to events from the participating hardware, arriving at 100 Hz. An Exporter process buffers these at 1Hz in association with the correct trigger number (see Fig. 3). Every 10 s the data, now with an associated trigger number, is written to files.

of the Libera events to the timestamps that come with the data to be archived. In this way the data from the hardware participating in the Fast Archiving becomes correctly associated with the unique bunch number, irrespective of the order in which the events arrive at the Synchroniser. A validity flag is used to handle any ambiguities in the association of the trigger number, for example if two data events arrive with timestamps that may both be matched to the same trigger.

The Synchroniser devices each implement an Exporter process, which takes the data buffered with the corresponding trigger counter and writes them to an hdf5 file. A single file is created to hold a certain number of events, and is written to by all Synchroniser devices. As such, the data from all participating hardware for a given range of trigger numbers ends up in the same file.

CONCLUSIONS

A system has been designed to allow the archiving of data from the TANGO control system at up to 100 Hz, assuming that the data originates from devices that are capable of addressing their hardware within a 10 ms time interval and can push the data together with their timestamps as TANGO events. A single Fast Archiver device taking the data from a single oscilloscope device has been successfully tested in the laboratory at 100 Hz. For the MAX IV linac a Fast Archiver comprising 18 Synchroniser devices has been

deployed. These are currently archiving 152 waveform attributes from 38 oscilloscope devices, though the maximum repetition rate of the linac has so far been 0.50 Hz.

ACKNOWLEDGMENT

The authors would like to thank the whole of the Controls and IT Group (KITs) at the Max IV Laboratory, along with the physicists and operators, without the collaboration of which this work would not have been possible.

TANGO-KEPLER INTEGRATION AT ELI-ALPS*

Péter Ács, Sándor Brockhauser, Lajos Jenő Fülöp, Veronika Hanyecz, Miklós Kiss, Csaba Koncz, Lajos Schrettner, ELI-ALPS, Szeged, Hungary

Abstract

ELI-ALPS will provide a wide range of attosecond pulses which will be used for performing experiments by international research groups. ELI-ALPS will use the TANGO Controls framework to build up the central control system and to integrate the autonomous subsystems regarding software monitoring and control. Beside a robust central and integrated control system, a flexible and dynamic high level environment could be beneficial. The envisioned users will come from diverse fields including chemistry, biology, physics or medicine. Most of the users will not have programming or scripting background. Meanwhile workflow system provides visual programming facilities where the logics can be drawn, which is understandable by the potential users. We have integrated TANGO into the Kepler workflow system because it gives a lot of actors for all natural scientific fields. Moreover it has the potential for running the workflows on HPC or GRID resources. We demonstrated the usability of the development with a beamline simulation. The TANGO-Kepler integration provides an easy-to-use environment for the users therefore it can facilitate e.g. the standardization of measurements protocols as well.

INTRODUCTION

ELI-ALPS is one of the three pillars of the European Extreme Light Infrastructure project. The Attosecond Light Pulse Source (ALPS) facility will provide a wide range of ultrafast light sources (such as coherent XUV and X-ray attosecond pulses) for performing material, condensed matter and surface science, chemical, biological, physical or medical experiments. Besides, the development of the technology for generating 200PW peak intensity pulses is also a main mission. As a research facility, the infrastructure will contain a large number of experimental devices and equipment which have to be managed and controlled by a robust and flexible system. We found that the TANGO Control system [1] is able to address this complexity, it has already been used at several large research infrastructures for more than a decade.

TANGO Controls is an open-source control system framework which provides a foundation to develop control systems. Architecture of a TANGO-based control system has three main components: the Device Server, the Database and the Client. The Device Server component is the base element that provides monitoring and control capabilities over a set of devices. The Database includes

information about the Device Servers and Devices. A TANGO Client may connect to Device Servers using the reference acquired from the Database to perform actions on a certain Device. Experimentalist and scientist users may create programs by using the available APIs. However, not all of the users have a programming or scripting background necessary for such a task.

Scientific workflow systems [2-3] provide a graphical interface to create scientific applications without a deep scripting and/or programming background. A workflow is basically a collection of jobs connected to each other. Each job has input(s), performs a specific function and produces output(s) that can be used by other jobs. The jobs are usually represented as boxes with input and output ports. This kind of graphical representation of unit jobs increases productivity and helps maintainability. It allows the user to save the workflows as well as to share them with others.

The motivation of the paper is to develop a prototype integration of the Kepler scientific workflow system [4] with the TANGO framework. This way a high-level graphical environment could be provided for the users to create programs controlling and monitoring research equipment. Some other institutes already follow a similar approach [5-6]. However, this work has some further motivations, e.g. to collect relevant experience about how to integrate the TANGO framework into other environments.

THE INTEGRATION

A Kepler workflow has an arbitrary number of actors and exactly one director. Every actor represents a job with its necessary input and output ports, and an additional configuration dialog may help to fine-tune the behaviour. Actors communicate by sending messages via interconnected ports. The role of the director is to supervise the execution of the workflow, e.g. it manages the number of executions, enables parallelization if possible, etc.

A fundamental component of the TANGO Control System is the TANGO Device Server, which represents a set of devices with all of their attributes, commands, events and other relevant information. The goal was to create a universal *TANGO actor* in Kepler, which can dynamically adopt any functionalities (commands, attributes, etc.) a TANGO Device may have. However, it is implemented in a way that when the TANGO actor is instantiated, then the necessary functions can be chosen and will only be available afterwards.

It is not completely obvious how to represent and execute a TANGO workflow in Kepler because the functional structure of Kepler is fundamentally different from that of TANGO. As it was mentioned before, a Kepler workflow is controlled by directors.

* The ELI-ALPS project (GOP-1.1.1-12/B-2012-000, GINOP-2.3.6-15-2015-00001) is supported by the European Union and co-financed by the European Regional Development Fund.

[†]<https://www.eli-alps.hu/?q=en>

Kepler inherited five directors from Ptolemy II: PN (Process Network), DE (Discrete Events), CT (Continuous-Time), DDF (Dynamic Dataflow) and SDF (Synchronous Dataflow). Every director is suitable for a different kind of task. For example an SDF might be an appropriate choice for a simple data transformation, however, for example it is not the right decision if one would like to create time-based simulation workflows, because it has no understanding of passing time.

Examining the directors we found that the PN Director is the best choice as a TANGO workflow execution supervisor. A process network director models a workflow as a network of processes where each actor is running on a dedicated thread and generates output data only if all of the input ports have available input tokens to process [7]. Using this model, actors can run simultaneously without blocking each other unnecessarily. Therefore a TANGO actor can continuously gather data from a TANGO device while another TANGO actor is waiting for an event to be triggered from the same TANGO device. With the flexibility of the PN Director a workflow is able to reach that level of functional variety that the TANGO system requires. Figure 1 shows the architecture of the TANGO Controls System and the place of the integration in the system (Kepler-Tango binding in the top-right part).

Figure 1: TANGO Controls architecture with Kepler and scientific workflows.

Main Concept

A universal actor is created that behaves as a Device Server, e.g. handles the execution of commands, reads/writes attributes while supervises the connection between the Device Server and the actor. The requirements the solution has to fulfil:

- A TANGO Actor represents a TANGO Device
- The user is able to select a TANGO actor from the list of the available ones (i.e. the TANGO Devices in the TANGO database). TANGO Devices may have a complex name which is easy to mistype, therefore bypassing this interaction makes the user's job more convenient and efficient.
- An input/output port of a TANGO actor represents an attribute or a command of the corresponding TANGO Device
- The user is able to filter which TANGO attributes and commands appear as ports of the corresponding TANGO actor. A Device Server may have tens or even hundreds of commands/attributes, therefore filtrating of them makes the user's job more convenient and efficient.

Steps of the Development

The development is separated into four phases. Each phase is ended by a test sub-phase.

Hard-coded Integration. In this phase a basic workflow component with only the necessary functions was implemented. The goal was to discover the Kepler workflow system whether it is capable of adopting unique functionalities of TANGO.

The developed component is able to handle the connection to a predefined, hard-coded device, manage the execution of a preselected command and read/write of some attributes with different types.

Database Level Integration. The TANGO Database may have thousands of entries of devices, therefore it might lead to complex device instance names that the user may not be able to memorize easily and correctly. When one wants to deploy a TANGO device component on the workflow canvas, it requires the domain name of the TANGO Device so the workflow will be able to connect to and perform actions on that. The basic solution would be that the user types in the full path of the device which is time-consuming, inconvenient and the risk of mistyped name is not ignorable. A more sophisticated solution is needed in a form of a list of available devices with which the user is able to put the actors on the workflow canvas easily.

The developed extension is able to query the available devices from the TANGO Database as well as to integrate it in a way that the user can conveniently deploy TANGO devices as TANGO actors. This feature appears in the context menu, in a combo box as well as in a separate tab.

Complete Type Conversion. One of the biggest and most significant challenges of integrating TANGO into Kepler was the complete type conversion.

TANGO has all the main and basic datatypes, e.g. bool, double, string, etc. However, TANGO defines some unique types which makes the process of conversion ambiguous, e.g. array or 2D array of scalar types, doublestringarray and so on.

In Kepler, data is passed with data tokens, and each data type has its own structural type. If one wants to use data coming from a TANGO device, one has to convert the TANGO data into an environment-dependent structural type, and then wrap it into the corresponding data token. For basic datatypes, the conversion is obvious: TANGO's SCALAR DevBoolean can be converted into a Boolean variable, and then wrapped into a Boolean token.

For IMAGE DevString (matrix of strings) the conversion is more complex. First the data has to be converted into an array of array of strings. Although Kepler has a Matrix token, it is not available for strings, therefore the matrix has to be wrapped into an arrayType(arrayType(string)) token. Although these datatypes conversions may take time to implement, they can be hidden from the user. However, there are exotic types in TANGO, which is a challenge for the developer. In case of DoubleStringArray type of TANGO, which is an array of doubles and string, the

Figure 2: Beamline control system architecture.

developers have to agree on a general integration of how to instantiate it into Kepler.

Configuring ports (attributes, commands). As mentioned before, one TANGO Device may have large number of attributes and the same is true for commands. Most of the components of workflow systems display individual ports for every possible inputs and outputs. Following this concept, a TANGO actor may have hundreds of input and output ports for attributes and commands, which leads to an untraceable communication of workflow actors. Therefore limiting the number of ports for a more user-friendly appearance is a must.

The base concept is that the users should choose the ports (TANGO attributes/commands) in advance. However, the solution should guarantee the opportunity to add and remove ports later as the workflow may change.

In addition, it is restricted that an actor can have only one command, so the role of the actor stays clear and will be easier to handle.

BEAMLINE SIMULATION

For a proof of concept, a simple control system workflow is created on top of a simulated beamline to demonstrate the usability of the prototype. The architecture of the system is shown in Fig 2.

In the beamline simulator the initial InfraRed (IR) beam is split in two parts with a special mirror with a hole in the middle (Holey mirror1). After the beam splitting, both arms have a beam dump with motorized mirrors. The outer ring is focused into a gas cell to generate the XUV attosecond pulse. The generated beam is cleared out from the initial beam by a holey mirror (Beam Dump3). The next element in the beamline is a grazing incidence ellipsoidal mirror with 3D tilting option, and the light is directed to the Holey mirror2. The other arm is delayed with a delay stage and directed to the same mirror. Both beams are directed to the target area. The final beam is cleared out of the IR

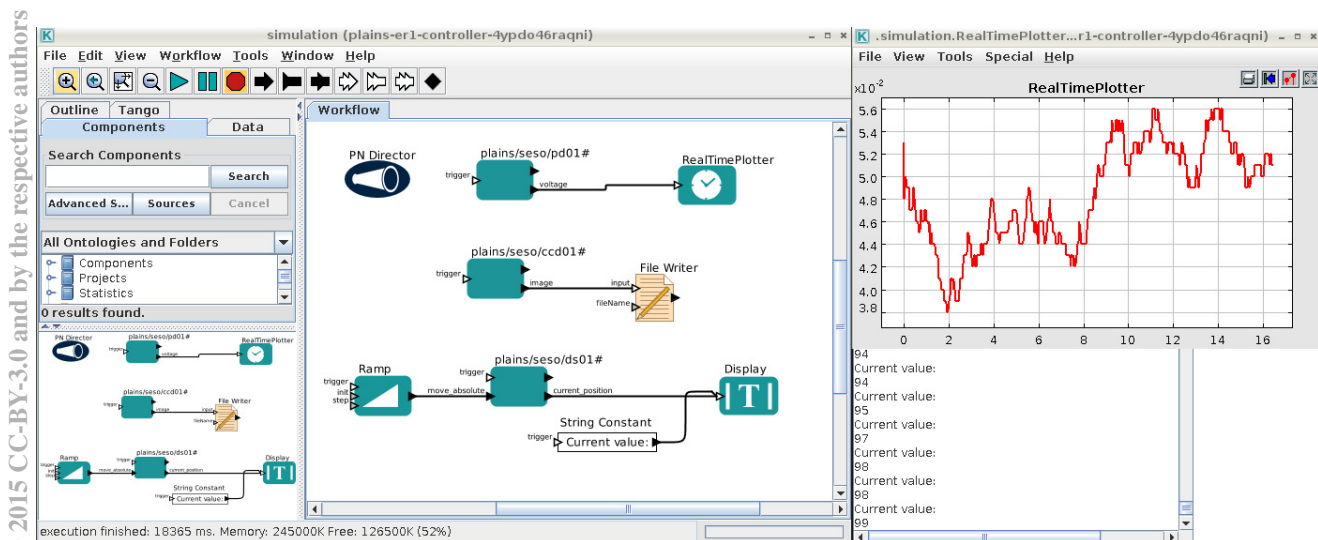

Figure 3: Kepler-TANGO integration: workflow and displayed output.

beam (Beam Dump4) and the XUV pulse is directed by a toroidal mirror to the Grating and detected by the CCD camera unit. A photodiode is placed in the toroidal mirror's chamber for the pulse intensity monitoring. The delay stage has an important role in the recombination process, so called pump-probe experiment. It is delaying the IR pulse to the XUV pulse. The elliptical mirror and the toroidal mirror are positioning the generated XUV beam. The beam dumps with sliding mirrors (1 and 2) can block the beam in both arms.

From control side the following parts are static: holey mirrors, gas cell, beam dump 3 and 4 and target area while beam dump 1 and 2, ellipsoidal mirror, spherical mirror, photodiode and CCD camera can be controlled. In this Kepler demonstration only the delay stage was moved.

A demonstration of the integration can be seen in Fig. 3. The workflow has eight actors plus one director. The plains/seso/pd01 actor represents the photodiode detector, which provides voltage values every time the director executes the actor. The output port of the voltage parameter is connected to a RealTimePlotter, which draws the voltage value on a plotter as the time goes by. The output of the plotter can be seen in the top right corner of the figure.

The second TANGO actor is the plains/seso/ccd01, which provides images from the CCD camera on its output and which will be saved in a file with the help of the File Writer actor.

The last TANGO actor is the plains/seso/ds01, which represents the delay stage component of the control system. Its move_absolute input port is connected to a Ramp actor. The Ramp actor counts from an initialized value to a maximum or infinite with defined steps. With every step, the magnitude of the delay increases with a short delay. With the help of the display actor, the current value can be followed on a dialog on the bottom right corner.

CONCLUSIONS AND PERSPECTIVES

The ELI-ALPS facility will use the TANGO Control system for managing and controlling the experimental devices and equipment. A prototype integration of TANGO with the Kepler Workflow system has been developed. This development could facilitate the creation and modification of experimental protocols. It could be a big benefit for the users and developers, too.

ELI-ALPS CONTROL SYSTEM STATUS REPORT *

Lajos Jenő Fülöp, Sándor Brockhauser, Sándor Farkas, Veronika Hanyecz, Miklós Kiss, Miklós Tamás Koncz, Árpád Mohácsi, Kwinten Nelissen, Lajos Schrettner, Balázs Szalai, Péter Szász, Chris Turner, ELI-ALPS, Szeged, Hungary

Abstract

ELI-ALPS will provide a wide range of attosecond pulses which will be used for performing chemical, biological, physical or medical experiments by international research groups. It is one pillar of the first international laser facility for the scientific user communities. ELI-ALPS use the TANGO Controls framework to build up the central control system and to integrate the autonomous subsystems regarding monitoring and control. It will be also used for the implementation of some autonomous systems' control system while others will be implemented differently. The central control system and the integration strategy of the autonomous systems is designed. The centralization and integration needs are surveyed and the requirements are collected. Prototypes have been developed to clarify the requirements and to test the designs. Requirements elicitation, designing and prototype development follows a Lean-Agile approach and includes several fields: device drivers and simulators; integration logic; central supervision, archiving, logging and error recovery; graphical user interfaces and so on.

INTRODUCTION

ELI-ALPS is one of the three pillars of the European Extreme Light Infrastructure project. The Attosecond Light Pulse Source (ALPS) facility will provide a wide range of ultrafast light sources (such as coherent XUV and X-ray attosecond pulses) for performing material, condensed matter, surface science, chemical, biological, physical or medical experiments. Besides, the development of the technology for generating 200PW peak intensity pulses is also a main mission. As a research facility, the infrastructure will contain a large number of experimental devices and equipment which have to be managed and controlled by a robust and flexible system. We found that the TANGO Control system [1] is a good candidate, it is already used by several research institutions, mostly in synchrotrons, but also in laser projects [2]. The basic layout of ELI-ALPS is the following: different primary laser sources generate laser pulses with different characteristics that are delivered by the beam transport lines to the secondary sources, which then generate attosecond light pulses for the experiments.

In the first phase of the development of the ELI-ALPS Control System the fundamental concepts, the high-level architectural design and the frames of the development

process have been identified. In this paper the most important requirements, concepts, aspects, and prototypes are summarized briefly.

REQUIREMENTS

The general requirements are to follow public standards [3] as well as in-house policies and handbooks that also declare the application of frameworks such as TANGO and Taurus [4]. In order to maximize efficiency, different techniques are planned to be used. Automation techniques will be applied as much as possible, e.g. automatically registering devices [5], generate and configure GUIs and so on. Simulation environments, mimicking the devices and some key relationships will allow to perform most of the software development and testing independently from the real hardware.

Scientific Systems

Laser sources will be delivered as black-box, turn-key systems together with hardware and software. The secondary source systems are addressed by dedicated projects. The requirements, the technical design, as well as the hardware shopping list are provided by expert institutes of the corresponding secondary source field. The beam transport systems are addressed by a dedicated in-house project, which provides the requirements, the technical design and the hardware. Software and integration will be covered by another dedicated project.

Central Control System

The Central Control System will include the following services. The *archiving* subsystem collects all the preconfigured local or central variables for later usage and trends. The *alarms* subsystem collects and shows all the local and central alarms that are the result of evaluating predefined formulas on attribute values. The *logging* subsystem collects all the logs.

The *Integration Platform* supports, manages and orchestrates the collaboration of the systems (lasers, secondary sources, beam transport, etc.). Each system provides a gateway for communication. The gateways should be accessible only from the central system. For the other systems the central control system defines a uniform interface in order to provide controlled access to the gateways of a connecting system. A locking mechanism of the central system is responsible for system (proxy/gateway) allocation (i.e. granting exclusive access, when a system can be allocated to only one other system at a time). Moreover, it is preconfigured which systems may allocate a certain system for monitoring and control purposes.

* The ELI-ALPS project (GOP-1.1.1-12/B-2012-000, GINOP-2.3.6-15-2015-00001) is supported by the European Union and co-financed by the European Regional Development Fund.

† <https://www.eli-alps.hu/?q=en>

Figure 1: Control System Architecture.

The *Overview GUI* provides a general overview, monitoring all the systems. This GUI can be (semi-)generated based on the Gateways.

Data Acquisition

The data acquisition system will provide a framework for acquiring and processing experimental data originating from all of the experiments, as well as augmenting the data with metadata. Secondary sources and experiments should apply and adopt this framework. Data acquisition will use the common facility level timestamps for both triggering the experiments and timestamping the acquired data (the timing system is to be delivered by an external provider). Already existing solutions and results will be considered [6]. The experiment execution framework should have data processing capabilities at different granularities.

Each experiment will have a unique ID. An experiment consists of a series of **batches**, each batch has a unique batch ID. During a batch, low level data acquisition takes place that may involve low level reduction/ compression and pre-processing done in the low level device and electronic logics layers (e.g. by FPGAs).

After the completion of a batch, **higher level post-processing** can take place, maybe invoking scientific algorithms run on local machines or on a cluster accessible on the network (HPC services). The results of post-processing can influence the execution of the next or subsequent batches, this provides a feedback mechanism during experimentation (online data processing).

SYSTEM DESIGN

The following system design concepts have been identified based on the requirements and constraints given above.

Systems and Subsystems

Briefly, a subsystem incorporates the devices and electronic components (represented by rectangles at the bottom of Figure 1), as well as the subsystem specific software layers: device servers are implemented for physical devices on multiple levels (low level, compound, software logics). These are represented by ellipses in the Figure.

The higher level compound device servers implement gradually higher level functions. These device server components are organized in a layered structure, each layer providing services to the layer(s) above and using services of the layer(s) below.

Systems are composed by combining subsystems. These can be organized into different levels, indicated by boxes in Figure 1. The level name (e.g. Beam Transport Level) is indicated in the top-left corner, while the actual instances (the corresponding systems) are indicated on the right side of the box (e.g. BT-SYLOS): 4 laser sources, 4 beam transport lines and 11 secondary sources are listed.

The Scientific Systems include three levels: the *lasers* will be delivered by external suppliers as turn-key solutions; the *beam transport* systems use the services of beam transport-specific subsystems and the corresponding laser system; the *secondary source* systems use the services of subsystems located in a designated area, and the beam transport system (as well as the central system).

The Infrastructure systems (built on top of localised subsystems) are provided either internally (in this case subsystem device servers are white-box and accessible) or externally (in this case subsystem device servers are black-box and not directly accessible). The various systems comprise an architecture built on top of the TANGO bus. The design makes it possible to control devices located in a designated area of interest (e.g. secondary source room, beam transport area), and also to

control, monitor and manage all the devices of the systems supporting the same functionality (e.g. vacuum, power supply, computer and network monitoring, etc.)

Layers

Each system (and its subsystems) has some layers and each layer has to address hardware and software aspects (see Figure 2). The layers from bottom to top are the following.

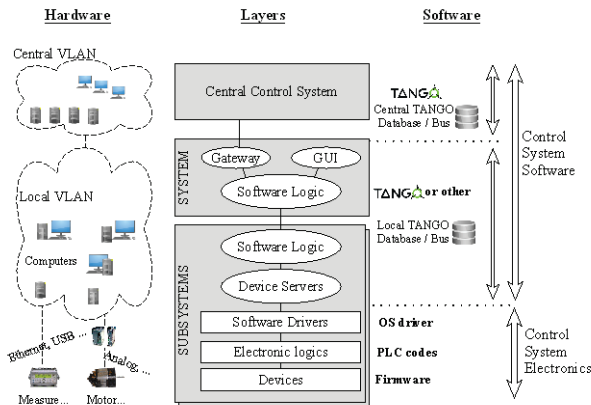

Figure 2: Control System Layers.

Control System Electronics. The *Devices* layer includes the elementary building blocks; it is an electronically controllable device, e.g. a detector or a motor. The *Electronic logics* layer controls the device and provides fast logics through an electronic controller, e.g. a relay or a PLC. The *Software drivers* layer connects the electronic and software worlds: a device or controller can be connected to a local or remote computer controlled by operating system or other drivers (e.g. LIMA, etc.).

Control System Software. The *Device Servers* layer makes the software devices available on the TANGO network and hides all the underlying layers. One computer can host several device servers on the local network, and one device server can provide access to several devices. The *Software Logic* layers provide functionalities on sets of related devices on subsystem and system levels, respectively. These are also implemented as TANGO device servers and are hosted on one or more computers. The *GUI* (Graphical User Interface) layer gives interactive access to the software logics and to the devices for the operators and users. TANGO provides generic GUI clients as well as toolkits to create custom ones. The *Gateway* layer is the access point towards to the central control system. It is implemented also as TANGO device server(s).

It is important to protect the different systems from each other in order to avoid unintentional interactions. A particular system should have its dedicated (virtual) computers, terminals and (Virtual) Local Area Networks; as well as it should have a dedicated TANGO database/bus. Similarly to the systems, the central control

system will have its own (V)LAN and TANGO database/bus.

The layer concept can be applied only to the Beam Transport, Secondary Source and Internal Infrastructure systems (those that are not delivered by external suppliers as black-box systems).

PROTOTYPES

Two types of prototypes have been developed in order to validate the design concepts. A vertical prototype includes all layers of a small demonstrational system with physical devices. A horizontal prototype includes the software layers of almost all systems (laser sources, beam transport lines, secondary sources) with software simulated devices.

Vertical Prototype

A simplified optical system was assembled and gave the basis of a vertical prototype (see Figure 3). It was suitable to build up a prototype with TANGO. In the software logic layer there were two loops for stabilizing the manually pre-aligned beam. The GUI (Figure 4) displays these loops and also gives action buttons to the users.

Figure 3: Layout of the vertical prototype.

Horizontal Prototype

This prototype includes a skeleton of the four laser sources and the ten secondary sources: the prototype is based altogether on 700 simulated devices. The prototype provides GUIs for each system, and a central one. The simulation was implemented on the *device servers* layer. This prototype was not generic enough and reusable directly for development and testing, therefore a simulation framework has been elaborated.

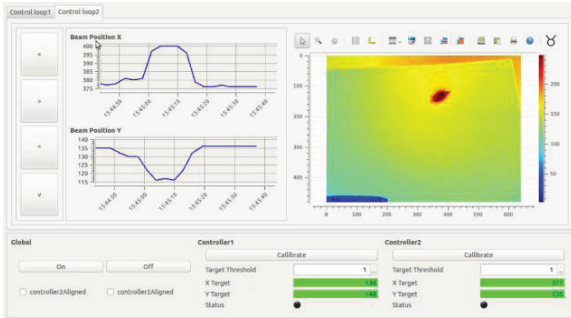

Figure 4: GUI of the vertical prototype.

Simulation Framework

Building on the experiences gained from the constructed vertical and horizontal prototypes, a framework has been designed that aims to cover as many aspects of the ELI-ALPS control system development as possible.

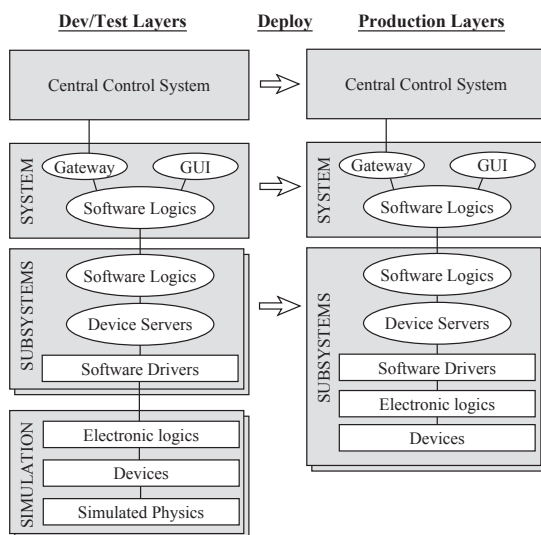

Figure 5: Architecture for development and testing purposes with simulation back-end.

The framework is based on the simulation concept, the system is clearly separated into two parts: the control(ing) environment (left side of Figure 5: top 3 grey boxes) and the controlled environment (left side of Figure 5: bottom grey box). The connection between the controlling and the controlled (simulated) parts can

completely be described by a configuration file. This separation provides many advantages because most of the development can be done without the target hardware environment: unit testing, functional and integration testing, deployment test, prototyping, operator training etc. It is important to note that the simulation environment is not expected and does not have to exhibit the same real-time behaviour as the target environment in order to be useful. In fact, different simulation levels can be defined ranging from the provision of the expected interface to gradually higher degrees of realism.

Figure 6: OpenStack environment of the demo system.

A demo system has been developed as a proof of concept for applying the simulation framework that utilizes OpenStack technology as a supporting infrastructure. The demo system consist of a laser source and its beam transport system, two secondary source (experimental) areas and a central control room. The OpenStack environment provides the necessary (virtual) machines for both the simulation (bt_sim, er-1_sim, er-2_sim) and control side (bt_control, er-1_control, er-2_control, central), and an isolated network area per system (Figure 6).

The simulation environment contains components for a sufficiently broad set of equipment: laser source, motors, motor controllers, mirrors, beam dumps, as well as photodiodes and CCD cameras as detectors. The connection to these equipment is described in a configuration file, which is fed into the controlling side to be able to connect the two together. The controlling side provides several functions accessible on GUIs: The central system provides overview status information for the operators. The beam transport system has setup functions as well as can be instructed to set its configuration so that the beam propagates to one of the secondary source areas. In these areas, it is possible to calibrate the local beamline (adjust beam target position and beam diameter, set delay step granularity), as well as start/stop a simplified pump-probe experiment involving an automatic scan through a range of delays between the pump and probe pulses.

CONCLUSIONS

The conceptual system design has been defined according to the requirements. Different kind of prototypes have been developed in order to check the

design. There is a lot of work in the future because the requirements of the scientific systems will be continuously changing and evolving in addition to new ones arriving.

A FRAMEWORK FOR HARDWARE INTEGRATION IN THE LHCb EXPERIMENT CONTROL SYSTEM

L. Granado Cardoso, C. Gaspar, R. Schwemmer, J. Barbosa, F. Alessio, CERN, Geneva, Switzerland
P-Y. Duval, CCPM, Marseille, France

Abstract

LHCb is one of the 4 experiments at the LHC accelerator at CERN. During the upgrade phase of the experiment (planned for 2018), several new electronic boards and Front End chips that perform the data acquisition for the experiment will be added by the different sub-detectors. These devices will need to be integrated in the Experiment Control System (ECS) that drives LHCb. Typically, they are controlled via a server running on a PC which allows the communication between the hardware and the experiment's SCADA (WinCC OA). A set of tools was developed that provide an easy integration of the control and monitoring of the devices in the ECS. The fwHw is a tool that allows the abstraction of the device's models into the ECS. Using XML files describing the structure and registers of the devices it creates the necessary model of the hardware as a data structure in the SCADA. It allows then the control and monitoring of the defined registers using their name, without the need to know the details of the hardware behind. The fwHw tool also provides the facility of defining and applying recipes - named sets of configurations which can be used to easily configure the hardware according to specific needs.

INTRODUCTION

The LHCb experiment is one of the detectors collecting data at the LHC accelerator at CERN. It is specialized in b-physics and is composed of several sub-detectors and subsystems. All of these subsystems have specialized custom electronic boards and devices to acquire the data from the events produced by the collisions of the LHC beams in the detector. In order to easily and reliably control and configure these devices they need to be integrated in the SCADA System (WinCC OA) [1] so they can be driven by the Experiment Control System (ECS). Due to the custom nature of these devices, their description varies greatly between subsystems, so, to effectively integrate these devices in WinCC OA there was the need to create a tool that could abstract the description of the hardware, model it into the data structures used by WinCC OA and provide a layer to interface with this hardware.

THE FWHW TOOL

All the LHC experiments at CERN use as their SCADA system the software WinCC OA. In order to reduce duplication of development, the JCOP (Joint Controls Project) [2] was created in order to provide common controls solutions for the four experiments. JCOP provides a framework for the creation of JCOP

components - WinCC OA packages containing all the required user panels, libraries, scripts and other software - that can be easily installed and distributed.

The framework Hardware tool (fwHw) [3] is developed as a JCOP component, allowing for easy installation by the sub-detectors. The tool provides a user interface, which allows for the easy modelling and configuration of the existing hardware devices and can also serve as a debugging tool. However, its purpose is mostly setting up the system and the different sub-detectors or subsystems should then implement their hierarchical control Finite State Machine (FSM) trees and their own user interfaces more suitably geared to the operation of their electronics.

Hardware Abstraction

The fwHw tool models the hardware into WinCC OA datapoint structures. The WinCC OA data structure is a tree-like structure, where a logical model is defined in Datapoint Types, which can be instantiated in datapoints that share this logical model.

Similarly the fwHw tool produces the logical model of the electronic devices as Datapoint Types, but providing an interface more adapted to the modelling of electronic devices.

In the fwHw tool, the data is hierarchical organized with the following types:

- Registers.

The registers are the representation of a register on a real hardware device. A register can be of any size and implement any type of protocol. The hardware tool allows the configuration of each register according to the settings necessary to access the hardware via the different protocols, the size of the register and the type of readout it will require.

The registers can also represent a local variable, i.e. a logical data item of a given area (e.g. a string which holds a filename to configure a given area).

These are the leaves or the lower level nodes of a hardware device model tree.

- Areas/Sub-Areas

Areas are logical groups of registers and/or other areas, which represent a logical division of a part of the hardware device (e.g. a chip or a group of chips). Defined areas can be declared as sub-areas of other areas and can be used multiple times. For example, in Figure 1 we can see that both areas 2 and 3 have the same type and thus have the same structure. The defined areas can also be used by different Device Types, so if some devices share a common structure, there is no need to duplicate similar structures.

- Device Types

The topmost node of the description of the hardware is the Device Type. The device type is the definition of a device (e.g. a board) with the areas and registers that compose it and the definition of the interface to the hardware they will have.

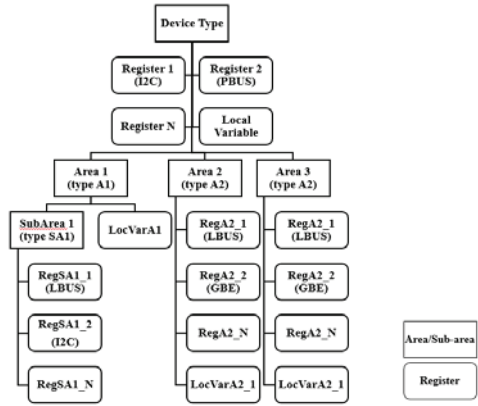

Figure 1: Example of a model of a device.

After the model of the hardware device is defined, we can create as many instances of that model as required and configure the particular settings for those devices.

The created models hide the complexity of the communication with the hardware. Settings like the specific protocol, addresses, sub-addresses and all others necessary to access the hardware registers are included in the model and this allows the access of the hardware registers simply by using the name defined in the model.

Hardware Model Creation

There are three ways to create the model of an electronics device using the fwHw tool:

- via the User Interface Panels:

The fwFw tool provides a user interface, which can be used to create the models of the electronics devices to be configured. It is intuitive and easy to use, however it can be cumbersome to create a device model with many registers/sub-areas, as the registers need to be created one by one and the sub-areas will also need to be included one by one into other areas. Another disadvantage is that it is not particularly easy to update a given model if the changes required are somewhat extensive.

- via scripts:

The tool also provides the functionality of using a script to create the hardware models; this improves the creation of big hardware models as well as improves the update or modifications to those models. It can also be used to automate the creation of devices quite easily. It requires writing of scripts using the provided library functions, which requires a learning curve and the scripts may be quite long.

- via XML description files:

There is also the possibility of creating the hardware models by describing them in XML files. These XML files will then be used to generate the scripts, which will create the hardware models in the fwHw tool. The usage

of an XML hardware description file has the advantage of being easily readable, being validated against an XML schema file and being easily changed or updated. It is also foreseen in the future to have these XML files generated automatically from other descriptions (e.g. an FPGA firmware file).

The implementation of the configuration via XML description files allows also for the easy export of the currently defined models of hardware in a project to be adapted by different sub-detectors or sub-systems.

Hardware Interface

The electronics devices in LHCb are controlled using specific interfaces. Currently two interfaces are used according to the location of the devices to be controlled:

- SPECS [4] – Serial Protocol for the Experiment Control System – used in radiation areas;
- CCPC [5] – Credit Card PC – a small embedded PC running Linux – used in non-radiation area;

A third interface will be used in the future:

- GBT [6] – Giga-Bit Transceiver – a radiation hard chipset – used in the future upgrade of LHCb

The type of registers available depends on the type of interface. A summary of the available register types is shown in table 1.

Table 1: Types of Registers per Interface

CCPC	SPECS	GBT
I ² C	I ² C	I ² C
JTAG	JTAG	JTAG
LBUS	PBUS	Memory Bus
GPIO	REG	PIA
GBE	DCU	SPI
-	-	ADC
-	-	DAC

These interfaces provide the connection between the ECS and the hardware devices. They run a server that communicates with the fwHw tool; this server is based on DIM (Distributed Information Management system) [7], which can easily be interfaced from WinCC OA.

DIM is a communication system for distributed / mixed environments and it provides a network transparent inter-process communication layer. It is based on the server/client paradigm and it uses the concept of publishing/subscribing services and commands.

The way these interfaces are integrated into WinCC OA require also the installation of specific components for each interface, which provide the communication between the fwHw tool and the DIM server running on the interface PC. These components provide the lower-level functions to access the different types of registers, which are used by the fwHw tool. They are appropriately named

fwSpecs, fwCcpc and fwGBT for the SPECS, CCPC and GBT interfaces respectively.

After an electronic device is modelled in the fwHw tool, devices of this type can be instantiated. Specific settings need then to be set, in order to configure the interface (or more exactly the DIM server) with which the device will connect.

Once the devices are instantiated in the fwHw tool it is needed to make available to the DIM server the names of the declared registers of the model. The configuration is automatically passed to the DIM server at startup, and the server is then aware of all the existing registers of the hardware as well as all the settings necessary to access them, their size and the desired readout mode.

In Figure 2 we can see the fwHw tool user interface, showing declared hardware types on the left and the registers of that hardware type on the right.

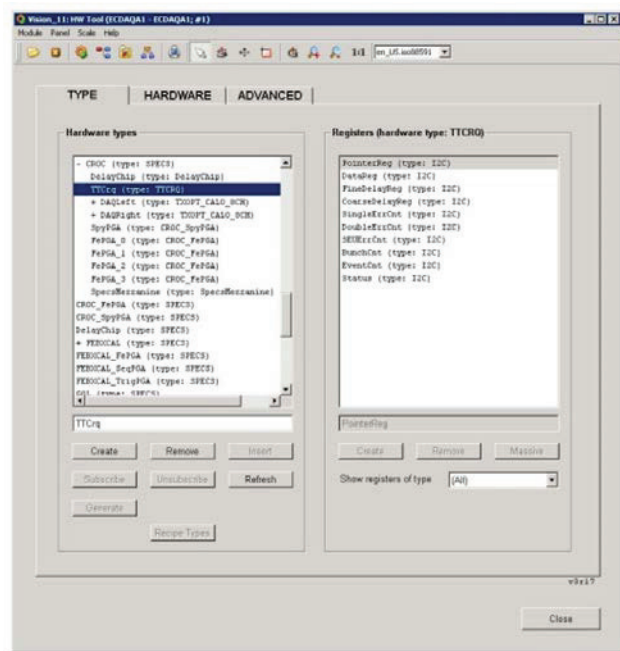

Figure 2: fwHw User Interface showing an existing model and the named registers for one device of this type.

As mentioned earlier, in the upgrade of LHCb, the new interface GBT will be used to interface the hardware both in radiation and non-radiation areas (it will link to both back-end and front-end devices). The GBT is a common CERN Serializer-Deserializer radiation-hard chipset for data, fast and slow control distribution to and from the electronics for the upgraded LHC experiments. This new interface requires the development of the new component fwGBT, which contains the lower level communication interface and the GBT DIM server.

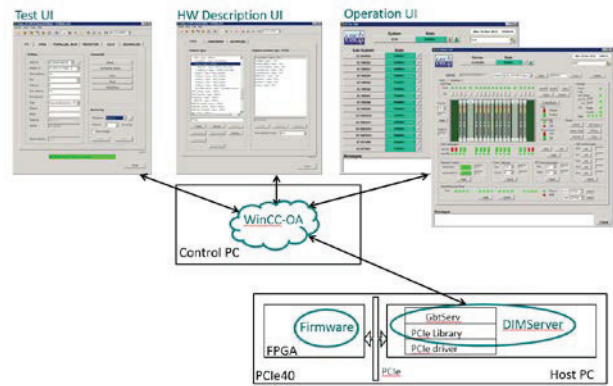

Figure 3: Architecture of the framework solution for the GBT Interface.

In Figure 3, we can see the schema of the architecture of the whole solution for the GBT Interface (the SPECS and CCPC interfaces share the same architecture), with a control PC running WinCC OA, which has the framework components installed (fwHw and fwGbt) and where the hardware is modelled and available for the FSM Control Tree and User Interfaces. The control PC is connected to the host PC where the DIM Server is running via the network. The DIM Server is aware of the modelled devices, the necessary settings to access them, and the required readout modes (poll, update on change, etc). It integrates the lower level libraries to communicate with the devices via the several available protocols.

Configuration DB and Recipes

One of the components provided by JCOP is the fwConfigurationDB [8]. This component provides a way to store and apply different sets of data to WinCC OA datapoints. It introduces the concept of recipes - named configurations for a given device or set of datapoints. These configurations can be both static configurations in order to setup equipment (e.g. configuring a spare device that is replacing one that failed) as well as dynamic configurations (e.g. configure the devices for different LHC modes of operation).

The fwHw Tool provides an interface for the configuration of recipes for the defined hardware models and this allows for the easy configuration of the devices according to specific needs. For instance it is possible to set specific values to the registers of the devices when the LHC provides physics conditions for data taking.

The created recipes can be both cached locally in the systems where they will be used and also stored on an Oracle database.

CONCLUSION

The fwHw tool provides an easy and reliable solution to integrate custom electronics devices into the LHCb Experiment Control System. Even though the existing electronics devices in LHCb are of varied types, this tool provides a way to easily abstract and create models of these devices and control them from the global

Experiment Control System. It is also easy to modify the already existing models without major impact to the existing system.

The tool is able to facilitate the integration of the sub-detectors electronic devices as it provides a base for the sub-detectors to integrate their devices into their ECS control trees and develop their specific user interfaces (Figure 4), communicating with the hardware using the functions provided by the fwHw tool libraries.

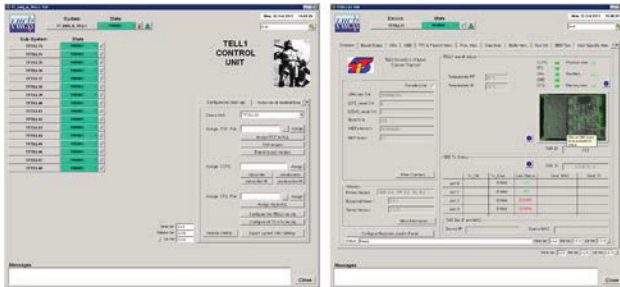

Figure 4: Control Tree and device panel for one of the LHCb sub-detectors.

This tool also makes possible to easily control the devices by providing a way to interface the registers of these devices using named registers. This hides the complexity of the communication from the user and enables the possibility of using the configuration DB and recipes to configure the electronics according to the specific needs of the experiment in different operation modes. It also provides a base for increasing the automation of the running of the experiment [9].

In the future upgrade of the LHCb, new interfaces will appear to replace or work along the existing ones. Due to the generic nature of the fwHw tool, these new interfaces can be easily integrated.

SYNCHRONISING HIGH-SPEED TRIGGERED IMAGE AND META DATA ACQUISITION FOR BEAMLINES

N. De Maio, A. P. Bark, T. M. Cobb, J. A. Thompson
Diamond Light Source Ltd., Didcot OX11 0DE, UK

Abstract

High-speed image acquisition is becoming more and more common on beamlines. As experiments increase in complexity, the need to record parameters related to the environment at the same time increases with them. As a result, conventional systems for combining experimental meta data and images often struggle to deliver at a speed and precision that would be desirable for the experiment. We describe an integrated solution that addresses those needs, overcoming the performance limitations of PV monitoring by combining hardware triggering of an ADC card, coordination of signals in a Zebra box [1] and three instances of areaDetector streaming to HDF5 data. This solution is expected to be appropriate for frame rates ranging from 30Hz to 1000Hz, with the limiting factor being the maximum speed of the camera. Conceptually, the individual data streams are arranged in pipelines controlled by a master Zebra box, expecting start/stop signals on one end and producing the data collections at the other. This design ensures efficiency on the acquisition side while allowing easy interaction with higher-level applications on the other.

INTRODUCTION

The kinds of data rates coming out of a typical modern synchrotron beamline continue to push up against the current limits in experimental complexity, processing power and storage space. Ongoing improvements in automation and computing infrastructure help scientists get past those limits, decreasing the time individual scans of a sample take to set up and carry out.

When it comes to taking data, a number of well-established technologies and beamline designs provide stable frameworks to acquire as much as possible across a number of different devices and channels. Each of these comes with its own requirements with regards to configuration and operation. Each of these may or may not also provide its own native mechanisms to sample data at user-defined regular intervals.

Getting these devices to perform their measurements in a synchronised way poses some unique challenges. If the samples are taken a sufficient time apart, the middleware layer provided by the controls software can, and often does, take on the role of coordinator. But there is a point where the interval between two samples gets too small to guarantee accurate time stamps. Different devices may also expect different kinds of triggers, and every additional layer of software mediating between those makes the delays between the data acquisition system and the hardware more unpredictable. Figure 1 illustrates this problem.

Figure 1: Unsynchronised trigger and data flow during image acquisition.

ARCHITECTURE

The answer to coordinated sample acquisition at small time scales is to use hardware triggering. Using a Zebra box [1], we present a design for a fast data acquisition system intended for sampling rates within the range of 30Hz and 1kHz. It not only coordinates the different hardware triggers involved but also bundles the acquired samples in three parallel pipelines, resulting in three files containing measurements for the same time frame.

Figure 2 gives an overview of the architecture. As Diamond Light Source (DLS) uses EPICS [2] as its control system, we rely on the areaDetector framework [3] and the EPICS implementation of the Zebra driver for configuring and collecting data from the underlying devices. We also rely on areaDetector plugins to post-process this data to some extent and to redirect it to files.

The control signal flow in our model is driven by the Zebra box. In our beamline-specific application, it receives an external trigger signal of its own. That signal causes the Zebra to produce one or more outgoing pulses, which are then forwarded to the connected devices. The incoming pulse need not be another hardware signal. Arm or Acquire commands to the relevant PVs are just as suitable because it is the configuration of the FPGA logic in the Zebra that ultimately decides what kinds of pulses to send out in response, and how many.

If individual devices expect different pulse shapes as trigger signals, the Zebra box acts as a mediator between incoming and outgoing triggers while ensuring that all outgoing pulses are sent off at the same time. If they are capable of receiving external triggers, they should be set to operate in this way. If they are not, the trigger signal needs to be recorded on one of the data channels so it can be extracted

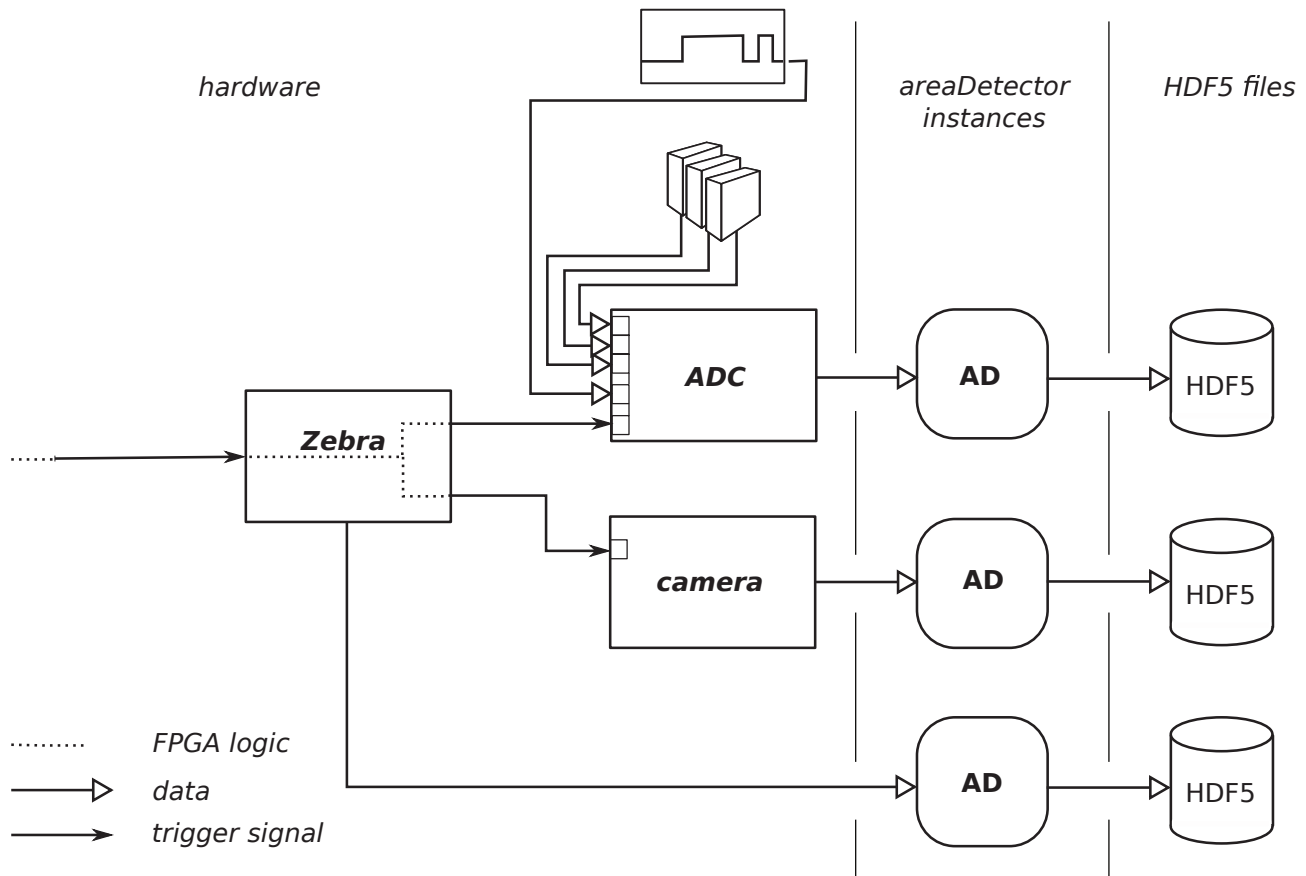

Figure 2: Zebra-driven data acquisition architecture.

later. We describe an EPICS-based way of doing that in our beamline-specific application in the next section.

The number of devices controlled in this way is only limited by the number of outgoing connectors on the Zebra box. So it is completely possible to trigger more than one type of detector or ADC card at once - or any other device that meets the requirements outlined in the previous paragraph.

Each of the devices involved has an instance of *areaDetector* associated with it. They ensure a consistent interface to EPICS and enable the architecture to write generic frames to, typically, HDF5 files. They also provide a well-defined set of parameters to interact with when configuring a specific scan or experimental run.

It is also worth pointing out that the entire design is self-contained within the EPICS control system. So once the three pipelines are set up and configured, all a larger application needs to do is send start and stop commands to one end and pick up the data files at the other.

IMPLEMENTATION

Besides the *areaDetector* framework, the EPICS control system also provides drivers for a number of different cameras. These typically derive from *areaDetector* and use it in the conventional way, to acquire a series of image frames. Although an essential part of our data acquisition system,

we did not need to extend any of them to make them work within it. So they will not be discussed further here.

The Zebra box and the ADC card, on the other hand, do not produce image frames but time series of samples across a set of channels. So the interpretation of a frame changes: it no longer represents an image in the traditional sense but a kind of ribbon of sampled values. Because we group several channels together, we continue to acquire two-dimensional data. As such, the *areaDetector* framework remains a suitable abstraction layer for this kind of measurement. The width of such a frame is fixed and corresponds to the number of available input channels. By contrast, the height has to be set by the user. As we explain below, approaches on what to set it to vary depending on the device.

The hardware triggering presented another, unrelated set of problems. While external trigger signals are a native feature of the Zebra box, our choice of ADC card does not really have this feature in a way that is useful to us. So both devices needed different kinds of drivers and driver extensions, which needed to be in line with the requirement that they both fit into the *areaDetector* framework. But on top of that, our ADC cards need to have the trigger signal fed in as data so one of the *areaDetector* plugins can extract it later. We will discuss each of those aspects in turn.

areaDetector Driver for Zebra

The original Zebra driver, developed at DLS, derives from class `asynPortDriver` and uses a serial port to communicate with the hardware. It also stores samples from ten different channels (encoder inputs, results of some of the logic blocks) in individual waveforms whenever a trigger is issued. So the time series for all of the channels are already available but there is no time stamp to go with them, and no native way of writing them to file.

Changing the inheritance chain of the Zebra to `ADDriver` turns it into an `areaDetector`. As `ADDriver` itself derives from `asynPortDriver`, no existing functionality is lost. Instead, the new parent gives the Zebra driver access to all of the `areaDetector` data structures. Figure 3 shows the details of the old and new parent class relations.

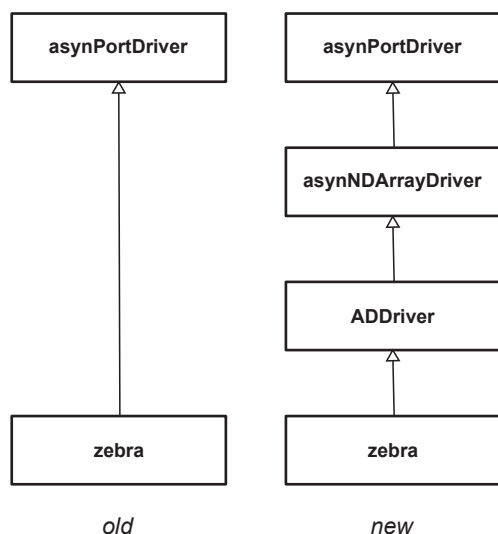

Figure 3: Old Vs. new inheritance tree for a Zebra driver in EPICS.

Every time the ten channels are sampled for the waveforms, we now store the same values as an `NDArray` in an `areaDetector` frame. A time stamp is added as the eleventh column. The Zebra's native interpretation of the Arm and Disarm commands as representing the beginning and end of a scan makes them equivalent to the start and stop points of an `areaDetector` acquisition. We extended the driver to treat them equally as a result. So while we acquire a stack of `N` frames from the camera during a scan of `N` points, we also get a stack of `N` one-line frames from the Zebra.

areaDetector Driver for D-tAcq ADC

DLS developed the original version of the `areaDetector` driver for the D-tAcq [4] ADC card. It connects to TCP port 4210 to read a continuous stream of data from the ADC, and to TCP port 4220 to send control commands to it. As the ADC samples its channels at a fixed rate, the driver's main task is to collect the samples reliably and store them as lines in a frame.

The sampling rate of the D-tAcq ADC far exceeds the frame rates we expect to see during our scans. Since we have

no way of turning the data stream on and off, the driver's main focus is on capturing everything in sensible chunks for further combined processing in the downstream plugins. One of those chunks corresponds to a frame of raw data. This turns the user-defined frame height into more of a performance parameter: because everything runs in continuous mode, the length of a scan is defined in the file writer plugin instead.

The fact that there is no way to connect a native external trigger signal to the device was one of the most difficult conceptual challenges to overcome. In the end, we achieved it not within the device driver itself but by using a specialised `areaDetector` plugin. Using the trigger signal recorded on one of the data channels, it turns the massively over-sampled raw data into a series of one-line frames after the fact.

Using areaDetector's Reframing Plugin

The key to extracting the ADC samples from the raw data stream at the appropriate rate lies in the reframing plugin for `areaDetector` developed at DLS. It needs to be told which channel the triggers were recorded on in the raw data frame, and what the threshold value for a trigger pulse was for the application at hand. It then uses this information to downsample the incoming data by picking out those lines that have a trigger pulse in them. Each time a trigger is found, it reads out a user-defined number of lines - one in our case - into a new frame, creating a second data stream. It is this post-processed stream that is handed over to the downstream plugins. Figure 4 explains the exact relation between the two streams.

Every time a raw frame reaches the reframing plugin, there is a burst of re-sampled frames going to the downstream plugins, followed by a pause until the next raw frame arrives. So there are some practical considerations that need to be observed when setting up the core driver and plugins. As mentioned, the frame height in the raw data stream influences performance. During our tests, it became apparent that a size that corresponds to about one frame per second strikes the best balance between filling up the queue for the reframing plugin and overwhelming those of the downstream plugins during bursts. Even so, the queue sizes need to be far larger than for other `areaDetector` applications. A value around 1000 lets them cope with bursts every second or so with a comfortable margin.

The reframing plugin also expects a threshold voltage to be able to identify trigger pulses from the raw data frames. Since the pulse comes from a Zebra and we trigger on a rising edge, a value of 3V has turned out to be appropriate for this purpose in the early tests.

INTEGRATION

While it is perfectly possible to use the pipeline manually, its real power comes from controlling the endpoints using either Python scripting or a data acquisition package - GDA [5] in our case.

As long as the high-level application knows about PVs, it

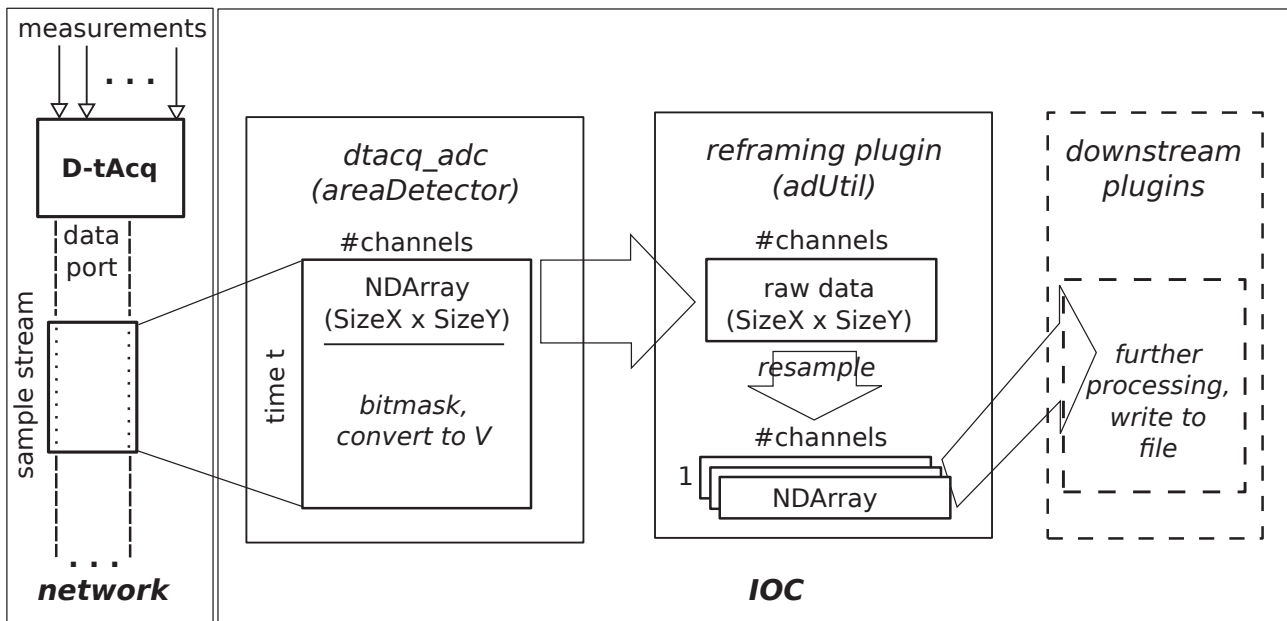

Figure 4: Data flow in the areaDetector plugin chain. Unusually, the raw data stream is discarded after the downsampling step in the reframing plugin and a stream of new frames of a different size is passed on to the downstream plugins.

can configure and monitor the lower-level devices using caput, caget and camonitor. It can also aggregate the results into NeXus files that provide a single entry point into the collected data from the three pipelines. Because it knows about the rest of the experimental setup, it can start and stop acquisitions and file captures at the appropriate times.

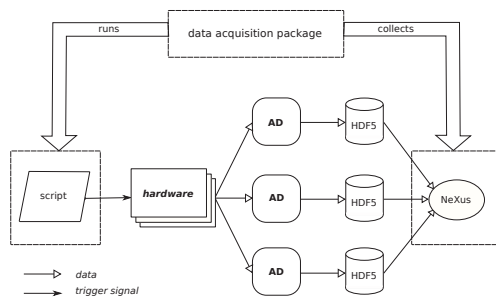

Figure 5: Role of high-level data acquisition package.

Figure 5 shows how GDA or a similar application brackets the lower-level components during a scan, acting in a kind of management role. This approach turns the entire integrated data acquisition system into a single building block within the beamline infrastructure.

CONCLUSION

Using hardware-based trigger signals in combination with the Zebra box's programmable FPGA logic ensures exact timing and synchronised acquisition of data and meta data at higher sampling rates. EPICS drivers derived from areaDetector provide a well-defined interface to configure the sys-

tem as a whole, all the way down to its individual components. Structuring the controls and data flows in three parallel pipelines allows us to integrate such a system into the rest of the beamline software infrastructure in a modular way. While there are some performance parameters to keep in mind when interacting with the 'pipeline-within-a-pipeline' chain of areaDetector plugins, using them is essential and ultimately adds to the overall flexibility when choosing individual hardware components. Fine-tuning and testing of the complete system is ongoing and we expect to deploy it to one of our high-throughput tomography beamlines at some point next year.

ACKNOWLEDGEMENT

The authors would like to acknowledge that the original Zebra driver was developed by Tom Cobb, DLS, the D-tAcq driver by Adam Bark, DLS, and the areaDetector reframing plugin by Edmund Warrick, DLS.

QUICK EXPERIMENT AUTOMATION MADE POSSIBLE USING FPGA IN LNLS

M. P. Donadio*, H. D. Almeida, J. R. Piton
CNPEM / LNLS, Caixa Postal 6192, Campinas - 13083-970, Brazil

Abstract

Beamlines at LNLS are being modernized to use the synchrotron light as efficiently as possible. As the photon flux increases, experiment speed constraints become more visible to the user. Experiment control has been done by ordinary computers, under a conventional operating system, running high-level software written in most common programming languages. This architecture presents some time issues as computer is subject to interruptions from input devices like mouse, keyboard or network. The programs quickly became the bottleneck of the experiment. To improve experiment control and automation speed, we transferred software algorithms to a FPGA device. FPGAs are semiconductor devices based around a matrix of logic blocks reconfigurable by software. The results of using a NI Compact RIO device with FPGA programmed through LabVIEW for adopting this technology and future improvements are briefly shown in this paper.

INTRODUCTION

Experiments at LNLS historically were made using software running in conventional operating systems. Our first software for beamline control centralized all the operations, sensor reading and actuators controlling in a single thread. This was the cause of lots of disturbances in motor movement, when the user moved a mouse or selected a menu item, which almost never ran in a smooth pattern. We could see also a big dead time caused by many tasks running sequentially rather than in parallel.

In 2010 we started to use EPICS [1] and, this way, we could decentralize all the access to the devices. Doing so, we could get many improvements in motor controlling and reduction of dead time. The system became easier to maintain as each device is accessed by a single piece of standalone software. Another advantage was to provide the infrastructure to build a web system named LabWeb [2], based on Science Studio [3] developed and applied at the Canadian Light Source (CLS), that became possible for users to operate the beamline from their universities.

From 2010 until recently in the current year not only the software, but most of the control hardware was replaced in all beamlines. After some years developing, improving and using the new EPICS based system, we faced a new challenge: the beamlines had its photon fluxes and detector sensitiveness increased by the hardware improvement and software was again the bottleneck for some experiments. EPICS can provide a good experiment control using only

software and not firmware, in conventional operating systems, if there is no concern about times lesser than 100 ms. Control loops quicker than 10 Hz are not guaranteed to be attended inside a good error limit. To go beyond this limit we needed to change the paradigm adopting a real-time system, for example, or implementing the fast piece of the experiment in hardware.

The first beamline to see this limitation was IMX [4], followed by XRF [5]. Both needed to synchronize motor position, detector shot and shutter in a few milliseconds with error margin of some microseconds.

The third beamline case was SAXS1 [6], whose system is presented in this paper. The development of the system for SAXS1 was used also to test the approach to the beamlines that will be built in Sirius [7], the new Brazilian Synchrotron. The timing for Sirius beamlines needs to be in the microsecond loop or faster.

SAXS1 HARDWARE

We need a system with low jitter between the trigger signal and the start and the end of data acquisition. Going near the hardware is an approach to reduce jitter and that is the motivation to choose FPGA technology. We had available in our inventory a cRIO NI 9144 [8], a unit with FPGA, so this was a natural choice to use in the work. cRIO NI 9144 can be connected to a PXI [9] only by an EtherCAT connection.

Figure 1 shows the connection between the cRIO and detectors and actuators.

There are two main detectors, a Pilatus [10] 300K to measure SAXS and a Pilatus 100K to measure WAXS. Pilatus 300K is configured to collect data in a determined frequency and sends a trigger TTL signal every time an acquisition is being done. cRIO is responsible to send a TTL trigger to Pilatus 100K as it can start acquisition.

Two photo-diodes provide the beam intensity data through a Stanford SR570 [11]. One of the photo-diodes is located in the beam stopper and receives radiation after the sample. The other one is located before the sample and receives the reflection of a small part of the beam thanks to a mylar or kapton thin film positioned in a 45-degree angle related to the beam. cRIO reads the voltage data from Stanford SR570 using a NI 9215 module [12].

cRIO also controls a fast shutter to limit to a minimum the time the sample is irradiated, by opening the shutter only when Pilatus is acquiring.

A cRIO is used to:

- run the FPGA code that sequences the experiment
- read voltage from Stanford using a NI 9215 module

* marcio.donadio@lnls.br

Figure 1: SAXS1 Hardware Connections.

- read trigger signals from Pilatus and to write trigger signals also to Pilatus and to the fast shutter using a NI 9402 module [13].

Figure 2 shows the connection between cRIO, PXI and EPICS clients.

Figure 2: SAXS1 cRIO - PXI connection.

Data collected in cRIO is transferred to the PXI through an EtherCAT connection to be used by a software running in LabVIEW RT operational system inside the PXI controller.

ISBN 978-3-95450-148-9

Data from LabVIEW RT is passed to the Linux running in the same PXI by Hyppie [14, 15]. In Linux we have an EPICS IOC that sends the collected data to client software by using the beamline network.

FPGA IN cRIO

FPGA in cRIO is programmed using LabVIEW [16]. FPGA code is responsible to control the experiment sequence: receive trigger signal → open shutter → collect voltage from Stanford until trigger signal is low → close shutter → calculate voltage average during the time the trigger signal was high → save the data.

Figure 3 shows the loop where data is collected from the analog input module and summed over the time. When the trigger signal goes TTL low, a division of the sum by the number of loop iterations is made to calculate the voltage average while the detector was acquiring. Not shown in this picture, this average is saved in a FIFO for later use. Let's call this FIFO as FIFO_PdN.

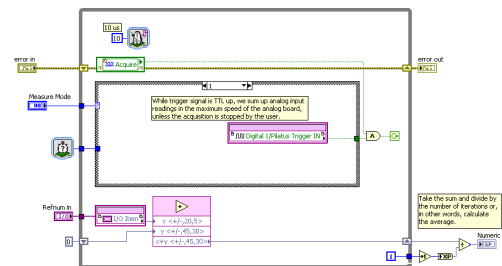

Figure 3: FPGA Voltage Acquisition.

The code is also responsible to administrate data sending over EtherCAT. This is the part of the FPGA code in the deterministic domain. Figure 4 shows a loop where cRIO waits for the rising edge of Scan Engine [17] clock. When

it arrives, an inner loop gets all data from FIFO_PDn and writes it to a sequence of 50 shared variables per photo-diode, emulating an array. As the Scan Engine speed of cRIO is set to 500 μ s in this experiment and 100 data values are sent per EtherCAT packet, we guarantee that the software is able to collect one analog data per photo-diode each 10 μ s and send it to the PXI with no data loss. Each data uses fixed point representation with 5 bits for integer part and 20 bits for decimal part. No handshake is implemented because transmission of data over EtherCAT is deterministic and lossless. In fact, we ran millions of tests at the maximum rate and never got a single data loss. Nevertheless it is possible to diagnose when a data is lost and, in this case, the experiment is aborted.

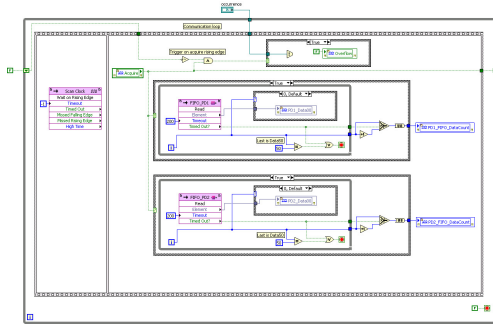

Figure 4: FPGA sends data to LabVIEW RT.

SOFTWARE IN LabVIEW RT

Inside LabVIEW RT there is a LabVIEW software responsible to get information from cRIO and to send it to the shared-memory between LabVIEW RT and Linux. The program collects data using a real-time loop synchronized with the scan engine period (Fig. 5). This is the part of the LabVIEW RT code in the deterministic domain. Doing so it is guaranteed that no data will be lost, as long as the loops fit within the scan engine cycle period, because the EtherCAT cycle is synchronized to the scan engine cycle. In the case of communication failure, experiment is aborted.

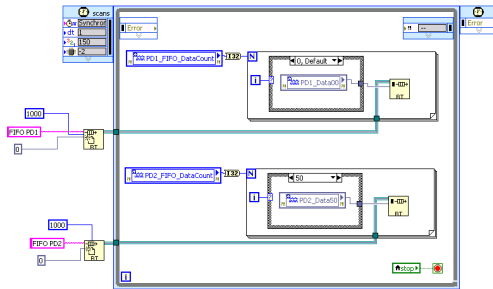

Figure 5: LabVIEW RT software gets data from FPGA.

The collected data is written in an array and is sent to the shared-memory asynchronously. The array is passed to the Linux IOC using Hyppie. The Hyppie shared-memory structure used is described in Table 1 and 2. The tables show the description of each memory address and points which

software is responsible to write in it: software running in LabVIEW RT or the IOC running in Linux.

Table 1: Shared-memory Structure - Part 1

SOFTWARE IN LINUX

In Linux we developed some device supports [18] that read data from the shared-memory, using Hyppie to access memory addresses described in Tables 1 and 2. This IOC provides PVs [19] to configure, start, stop and read parameters from the experiment sequencer programmed in cRIO's FPGA. To access these PVs we are using Py4Syn [20] and CS-Studio [21] as EPICS clients.

RESULTS AND DISCUSSION

Figure 6 shows on the top the trigger signal that is sent to the system, with 1.25 μ s high and 20 μ s low, resulting in

a total period of $21.25\ \mu\text{s}$. On the bottom we can see the signal that indicates when FPGA stopped to read the voltage signal and detects that the trigger signal was low. We could run all the algorithm in FPGA cyclically with a worst case period of $21.25\ \mu\text{s}$ (see the red square in Fig. 6). In the best case we could get $13.6\ \mu\text{s}$, as seeing in the first trigger pulse shown in Fig. 6. The acquisition time of NI 9215 module is approximately $10\ \mu\text{s}$ and we read it inside a loop. The time difference between the best and the worst case happens when the trigger signal goes low in some point of the start of this loop. So FPGA runs another complete acquisition time before detecting that the measurement needs to be stopped.

Figure 6: Time to detect trigger unset signal.

CONCLUSION

This entire system is used in simple SAXS and WAXS acquisitions, using or not chemical kinetics or any other complex experiment using synchronization of the system with the sample, as temperature and tensioning forces acquisitions with good stability. The period of $21.25\ \mu\text{s}$ outranges the frequency needed by SAXS1 beamline - 20 Hz - as the fastest image acquisition that can be done is 50 ms, due to available x-ray flux. Even with sufficient flux, the next bottleneck would be the fast shutter that opens in 25 ms and closes in 15 ms.

Despite that, the presented system was built to be prepared for new challenges in Sirius. In fact, the new Coherent and Time-Resolved Scattering beamline that will be built in Sirius, named CATERETE, will study fast kinetics in microfluidic and the beamline will need a few microseconds in resolution. So we could say that the architecture presented here is a strong candidate for Sirius beamlines control solutions. Nevertheless, we will need to build faster systems to achieve our new nanoseconds frontier and keep the work that was started with the presented system.

ACKNOWLEDGMENT

The authors want to acknowledge SAXS1 beamline staff Florian Edouard Pierre Meneau, Tiago Araújo Kalile and

Carolina Vieira Comin who tested this system over and over, adding valuable comments and suggestions to improve reliability, correctness and precision of the solution.

NEUTRON SCATTERING INSTRUMENT CONTROL SYSTEM MODERNIZATION - FRONT-END HARDWARE AND SOFTWARE ADAPTION PROBLEMS

M. Drochner, L. Fleischhauer-Fuss, H. Kleines, M. Wagener, S. v. Waasen
FZ Jülich / ZEA-2, Jülich, Germany

Abstract

When the FRM-2 neutron source went into operation (2002) and many instruments were moved from the closed-down Juelich reactor to the new facility, it was agreed on a choice of front-end hardware and the TACO middleware from ESRF. To keep up with software standards, it was decided recently to switch to TACO's successor - the TANGO control software. For a unified "user experience", new graphical user interface software "NICOS-2" is being developed by the software group at FRM2.

While general semantics of TACO and TANGO don't look very different at a first glance, and adaption of device servers seemed to be straightforward at first, various problems in practical operation were found, due to difference in state handling, timing behavior and error reporting. These problems, and the changes that had to be made to ensure reliable operation again, will be described.

INTRODUCTION

After some different developments turned out to be rather short-lived, partly due to political reasons, partly due to manpower issues, the "NICOS2" instrument control and user interface framework got administrative backing and developer personnel to be further maintained and adopted by neutron scattering instruments at FRM-2. (See [1] and [2] for some historic information.)

For device access, it was decided to abandon TACO and rewrite device servers to use the more modern TANGO framework. Since the basic functionality of TANGO device servers, the remote, synchronous, execution of commands, is quite similar to that of TACO, an easy migration was expected. It was assumed more or less that the old implementation of device server commands just needed to be adapted to a slightly different API syntax.

BOUNDARY CONDITIONS, DEVICE SERVER ARCHITECTURE

A number of device servers, in particular those which handle detectors, have a structure as shown in Fig. 1.

It is often a matter of discussion whether detector data which come as individual events should be histogrammed immediately during data acquisition. It is not subject of this paper to discuss this design decision – it should just be considered that real-time histogramming needs to be done anyway, because instrument operators want a live picture of measured data. If single event data provide no additional advantage, the cost (both in terms of runtime overhead and

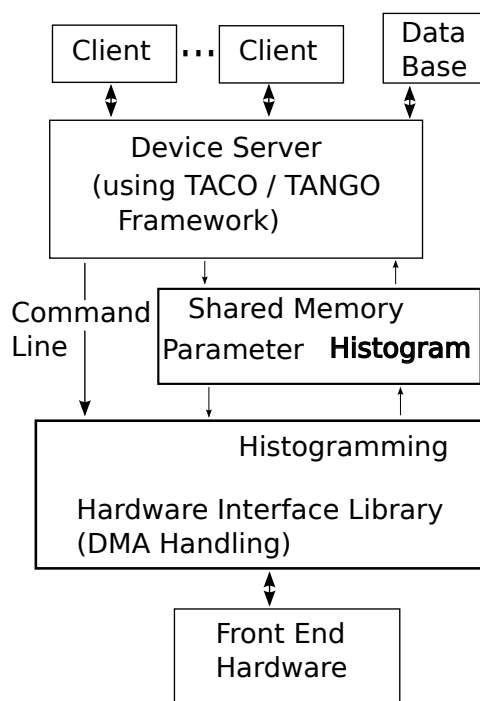

Figure 1: Structure of a detector device server which does real-time histogramming of incoming data.

storage media) can be saved. Up to now, no compelling reason for single event data was found.

Since TACO is not multithreaded from the beginning, and very likely not prepared to run with multiple threads active (actually, it was seen some years ago that even the underlying RPC library was not thread-safe), detector access was put into a separate process which runs asynchronously to TACO command execution. Another advantage of this was that the detector code could be run from a standalone process, for tests when the TACO manager and database services were not available.

Communication between the server core and the detector access program uses shared memory — keeping a table telling detector parameters (e.g. TOF slot settings) in one direction and the detector data histogram in the other. The shared memory was implemented as a memory-mapped file. This was helpful for debugging because the histogram data could be looked at everytime just using standard UNIX command line tools like `od(1)/hexdump(1)`.

NICOS is a comfortable user interface to control the instrument, define and run measurement scans, show a live display of detector data and support logging and event han-

dling. Figure 2 shows just a little part of it, a window which shows results of instrument state polling.

This comes at a cost – it scans the instrument state permanently and accesses device servers from multiple threads.

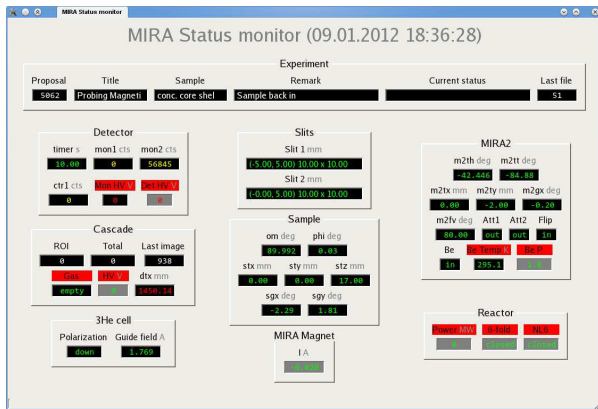

Figure 2: Screenshot of a status display window of the NICOS UI.

PROBLEMS SEEN, ANALYSIS AND SOLUTIONS

While the new TANGO device servers worked well in tests using just simple clients which do a single action at a time, strange errors occurred when the full NICOS interface was used. Commands to start or stop a measurement failed due to timeout for no apparent reason (which is considered fatal), and the background task updating process variables for status display got timeouts as well (which is not fatal but leads to slow UI updates and logged error messages). Bumping the TANGO client timeout, even to unreasonably high values, did not help.

The error messages did indicate a "serialization timeout" in the depth of TANGO. After asking the original developers (see [3]) this led to the explanation that not the command currently executing is to blame for being too slow, but a command started previously by some other client task.

Each TANGO client connection is handled by its own thread. As Fig. 3 illustrates, these threads need to synchronize before hardware is dealt with, or if data global to the device are accessed. The maximum time to acquire this synchronization mutex is fixed to 3 seconds within the TANGO server framework.

Since the status display part of TANGO polls the state of devices permanently, and measurement control is done from another thread, there is a certain likelihood that calls collide and need to be resolved by the synchronization mutex. With TACO (see [4]), there was just a single thread multiplexing all client connections (select(2) in UNIX). An incoming request did stay in the network buffer queue until the server got ready to handle it, without any timeout. As long as the TACO clients had set their transaction timeouts large enough to cover the worst case, no error was reported – just sluggish user interface behaviour was possibly noticed.

ISBN 978-3-95450-148-9

Figure 3: TANGO timeouts for transaction and serialization.

This means in effect that no command within the TANGO server can be allowed to take more than 3 seconds, because subsequent commands or data accesses might be issued by another client within that time window. All commands which operate on slow hardware, and which we could just easily deal with before by bumping the TACO timeout need to be split into two halves – one which initiates the action and one which polls for the result.

One might argue that the fixed 3-second timeout can be easily fixed and made adjustable, but, on the other hand, any limit might be too small if a certain number of client threads is in the waiting queue. So it would have been a possible solution to handle errors differently in the clients and allow retries if possible. This would lead to practical problems however because client code is written by different people (most notably the NICOS developers), and it is not always obvious which commands are idempotent or where side effects can occur.

So it was decided to make sure that all TANGO commands are executed within much less than 3 seconds. It has shown that even simple operations like starting (fork(2) in UNIX terms) or stopping the external histogramming process mentioned above can take longer, depending on usage history (whether the program and data needed are already in cache) and operating system background activity. It even happened that the act of zeroing the histogram data array (256MBytes – for 64 channels and 20 bits time resolution) was not done in time after a period of inactivity, obviously because the data were paged out to swap space. The machine these problems were observed on, and where the problems were tracked down, is a Core2Duo with 2GBytes of memory. This is certainly not a powerful system by today's measure, but absolutely appropriate for a front end computer which just has a single task to fulfill.

To be able to finish the TANGO calls in time, command semantics had to be redefined to be asynchronous. The command now just initiates the actions and returns immediately, actual work is done in a background thread. The TANGO server returns some "busy" state until the command is finished. The client needs to poll the state before it issues another command. This kind of side-steps the serialization mechanism described above, but it allows for more flexibility because clients can wait as long as appropriate for command completion.

Unfortunately, we could not add individual "busy" states telling all clients what the server is currently waiting for. The semantics of TANGO states is well-defined and custom values would cause confusion in other parts of the framework.

CONCLUSION

One can't assume that a TANGO installation works like "TACO, just using CORBA instead of Sun-RPC", even if just the subset of TANGO was used which is analogous to functions provided by TACO. The changes in timing behaviour are subtle, but require design changes towards asynchronous operation if any command can possibly take more than three seconds.

This three seconds limit must be met, even if the operating system (which is not aware of real-time requirements) has dedicated memory and CPU resources to other tasks. On unfortunate occasions, even seemingly innocuous acts like clearing some hundreds of megabytes of histogram data hits that time limit.

A standard desktop installation comes with many service tasks which potentially eat up system resources and slow down intended uses, and there is a tendency that memory requirements grow on each software upgrade. Thus, hardware upgrades need to be done early enough.

THE NEW TANGO-BASED CONTROL AND DATA ACQUISITION SYSTEM OF THE NEUTRON SPECTROMETER DNS AT FRM II

H. Kleines, M. Drochner, M. Wagener, L. Fleischhauer-Fuss, S. Keuler, F. Suxdorf, R. Möller, S. Janasche, S. van Waasen, K.-H. Mertens, M. Bednarek, K. Bussmann, Y. Su, Forschungszentrum Jülich, 52425 Jülich, Germany

Abstract

Forschungszentrum Jülich has been operating the neutron instrument DNS at the neutron source FRM II for about 10 years. DNS is a time of flight neutron spectrometer with polarization analysis that experienced a major upgrade in 2014 and 2015. During the upgrade DNS was equipped with new electronics and a new control and data acquisition system, including a transition from the existing TACO system to its successor TANGO. On the client side the NICOS software developed at FRM II is used for the implementation of measurement operations and user interface. The design of the new control and data acquisition system is presented and the lessons learned by the introduction of TANGO are reported.

INTRODUCTION

Forschungszentrum Jülich developed and operates about 20 neutron instruments at its outstations ILL in Grenoble, the Spallation Neutron Source in Oak Ridge and at the FRM-II in Garching near Munich. The control and data acquisition systems of almost all these neutron instruments are based on the so-called “Jülich-Munich Standard”, a joint effort of ZEA-2 (central electronics institute of Forschungszentrum Jülich) and Technical University Munich (TUM) to define a common framework for the electronics and software of neutron instruments that is followed by most instruments at the FRM-II [1]. It is based on the TACO [2] control system developed by the ESRF and the extensive use of industrial type front-end equipment, e.g. PLCs, fieldbus systems or remote I/Os. Because TACO is considered to be outdated now, there was the decision to introduce its successor TANGO [3] at FRM-II as joint effort between TUM and ZEA-2. Since the neutron instrument DNS experienced a major upgrade it was selected as one of the pioneer instruments for the introduction of TANGO, simultaneously with the neutron instrument BIODIFF. At the same time the new instrument control software NICOS (developed by TUM) was implemented on both instruments.

THE “JÜLICH-MUNICH STANDARD”

The “Jülich-Munich standard” is a framework for the selection of technologies and components at each level of the control system. The definition of this framework was motivated by synergy effects and the reduction of spare parts on the shelf. A guiding principle for the framework was to minimize the development efforts and to acquire as

much from the market as possible. A key component of the framework is the consistent use of industrial technologies like PLCs, fieldbus systems or decentral periphery in the front end. Main motivations are:

- low prices induced by mass market
- inherent robustness
- long term availability and support from manufacturer
- powerful development tools

A control system according to the Jülich-Munich Standard is organized hierarchically into the following levels:

Field level: The field level is the lowest level, at which devices that are not freely programmable reside, like motor controllers, SSI controllers, PID controllers, analogue and digital I/O modules, or measurement equipment. For all industrial type of I/O modules PROFIBUS DP based decentral periphery is recommended. Siemens ET200S is the preferred one. The ET200S modules 1STEP and 1STEPdrive are the predominantly used the stepper motor controllers.

Control level: The control level resides on top of the process level. Devices at the control level are freely programmable. They must meet real time requirements and guarantee robust operation in a harsh environment. At the control level Siemens S7 PLCs are used, because they dominate the European market.

Process communication: Process communication covers the communication of devices at the field and control level with supervisory controllers or computers. For lab equipment GPIB and proprietary RS232/RS485 connections are unavoidable. For industrial automation equipment PROFIBUS DP and PROFINET are the recommended choices. They are the dominating fieldbus systems in Europe and naturally supported by S7 PLCs and many other devices. A major reason for their success is the technological and functional scalability based on a common core as well as the programming model, which easily maps to PLC operation.

Experiment Computer: For economic reasons, all experiment computers should be PCs. Linux, being well established in the scientific community, is the only supported operating system. There is no definition of a specific kernel version or distribution. Direct device access should not be implemented on conventional PCs but on CompactPCI systems. CompactPCI allows deploying a variety of existing software in a mechanically more robust platform that fits into 19” racks.

Middleware: Since the framework aims at an inherently distributed system, software support for the transparent distribution of services between systems is

required. For this purpose TACO has been selected as the middleware system. TACO is a client-server framework developed for beam line control at the ESRF in Grenoble. In a TACO environment each device or hardware module is controlled by a TACO server. The server offers a set of device-specific functions, which can be accessed by TACO clients via a RPC-based mechanism over a TCP/IP network. To make its functions available to clients, the device server registers itself with the so called manager process and the data base server. The manager in combination with the data base server operates as a name server, which is consulted by clients to get the actual location of a device server. TACO includes a simple database for sharing of configuration data and operational variables between clients and servers.

Application level: On the client side, two variants of application programs are used: Where flexibility is desired and no GUI is needed, the scripting language Python is used. More static GUI applications are implemented in C++, using the “Qt” class library, with TACO access provided by device specific C++ wrapper classes.

NICOS

NICOS was developed around 2000 at TUM mainly by Tobias Unruh as general purpose instrument control software for neutron instruments at the application level on client computers[4]. It follows a client server approach and uses a consistent object-oriented device model on top of TACO.

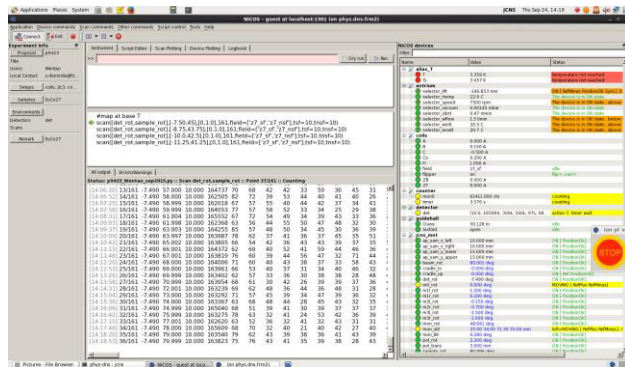

Figure 1: NICOS GUI for DNS.

Recently it has been completely rewritten, mainly by Georg Brandl from Heinz Maier-Leibnitz Zentrum (MLZ) [5]. It experienced major functional extensions, while keeping the essential ideas of the original implementation. NICOS is written in python using PyQt for the GUI. It supports TACO as well as TANGO.

NICOS offers scripting in python and in a simpler command language as well as a configurable GUI for graphical user operation. Functionalities comprise electronic logbook, history plots, detector data plots,....

Due to its power and flexibility it was decided to use NICOS at all MLZ instruments in order achieve a homogeneous environment for instrument users and to reduce the overall maintenance effort.

BIODIFF and DNS were the first neutron instruments of Forschungszentrum Jülich in the process of replacing the existing instrument control software by NICOS. The NICOS implementation on DNS was done by ZEA-2. Besides configuration issues, extensions for detector readout and data storage had to be implemented. A snapshot of the NICOS GUI for DNS is shown in Fig. 1.

TRANSITION FROM TACO TO TANGO

TANGO is a successor of TACO based on the middleware system CORBA. Contrary to TACO, it is consistently object-oriented and removes many of the deficits TACO had. As an example, it provides generic multi-threading, data caching and proper event handling. Additionally, it comes with many standard tools not available in TACO, e.g. alarm system, logging system, code generators for device servers, process data base, graphical editor for the configuration data base, start up tool.

As a consequence, TANGO is much more complex than TACO and the code base is huge – e.g. it is not possible to compile a complete TANGO distribution on low end front end systems in a reasonable time. Due to the much higher complexity of TANGO, it was clear that its introduction would be a major effort and that performance and stability could be serious issues.

Since TANGO is well-documented and has many structural similarities to TACO, e.g. the device access via functions/methods (contrary to process variable interface of EPCIS), it was relatively easy for developers to get acquainted with TANGO. Even more important, these similarities enabled a quite standardized approach to porting our existing TACO device servers to TANGO, which allowed reusing a major part of the existing code with minimal effort. Tests with simple clients showed a stable behaviour of our TANGO installations with good performance. But in real instruments experiments with NICOS clients we experienced several serious problems:

- NICOS relies on the consistent use of TANGO device states which is different from TACO.
 - TANGO device servers are internally multithreaded (one thread per client) leading to problems with our existing code written for the single-threading model of TACO.
 - An internal thread serialization timeout of TANGO requires special care in servers for slow hardware.
- All these issues could be solved with an additional software effort in the implementation of device servers.

THE DIFFUSE NEUTRON SCATTERING INSTRUMENT DNS

DNS [6] is a versatile time-of-flight diffuse neutron scattering instrument for cold neutrons with polarisation analysis shown in Fig. 2. It is equipped with a supermirror-based polarizer and a large double-focussing monochromator. Lead blocks in the monochromator shielding automatically open in the direction of the outgoing beam, when the secondary spectrometer is

moved in order to change the neutron wavelength. A failsafe system controlling shutter and lead block movement has been implemented. DNS is equipped with a liftable selector and a chopper system. About 20 mechanical axes with stepper motors are used for variety of slits, movement of sample, detector bank,...

One detector unit for polarized neutrons consists of 24 standard ^3He detector tubes and one detector unit for unpolarised neutrons consist of 128 position-sensitive ^3He detector tubes.

Figure 2: The diffuse neutron scattering instrument DNS.

THE DNS CONTROL AND DATA ACQUISITION SYSTEM

Physical Architecture of the Control System

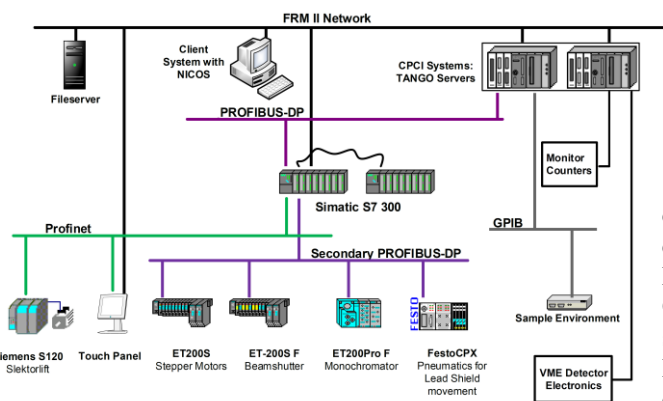

Figure 3: Physical architecture of the DNS control and data acquisition system.

According to Fig. 3 the control and DAQ system is implemented as a distributed system with a hierarchical architecture. On top of the system resides the so-called control computer with all application software – GUI-based as well as script-based. Via the experiment network the control computer accesses the “server computers”, to which all front end systems (detectors, position encoders, motor controllers, digital IOs, analogue IOs, ...) are attached. On the “server computers” TANGO servers are

running, which access the peripheral devices via dedicated device drivers.

The “slow control” peripherals are indirectly connected to the “server computers” via a PROFIBUS segment with the main S7-300 PLC equipped with the failsafe CPU 319F-3 PN/DP. This CPU contains both the “standard” program as well as the failsafe program for the personal protection in parallel.

Figure 4: Main cabinet with PLC and 3 ET200S systems.

Stepper motor controllers and SSI modules as well as digital and analogue I/Os reside in three modular ET200 decentral periphery systems, which are connected to the PLC via an additional subordinate PROFIBUS segment. One ET200pro failsafe system and one Festo CPX systems are connected to the same PROFIBUS segment. Both modular systems with protection class IP65/67 are directly mounted on the monochromator without any cabinet. All failsafe signals are connected to special failsafe input modules in one ET200S system and in the ET200pro system.

A Sinamics S120 frequency converter for the selector lift drive and a touch panel for local operation of the PLC are connected to the PLC via a subordinate PROFINET segment.

The readout of the 24 standard ^3He detector tubes is done via time-stamper modules from Struck Innovative Systeme GmbH in a VME crate, which is connected via a SIS1100 optical link to the server computer. The readout of the 128 position-sensitive ^3He detector tubes is not yet

in routine operation and will be done by a Mesytec MPD system.

Software Architecture

As shown in Fig. 5, the implemented software is distributed between three levels of the system hierarchy. All software below the lower dashed line runs on the PLC in the front end. The software modules shown between the dashed lines are running on the server computers. This comprises TANGO servers and device drivers for dedicated HW modules, e.g. detector electronics, counter/timer board, PROFIBUS controller or GPIB controller. The TANGO middleware is the glue that connects the server computers to the control computer, where the client application programs as well as the TANGO database server (all above the upper dashed line) are running. Since TANGO is location-transparent, the application programs could run on any Linux-based system. The instrument control software NICOS, which internally has a client server architecture, resides as a client on top of TANGO using the pyTango interface.

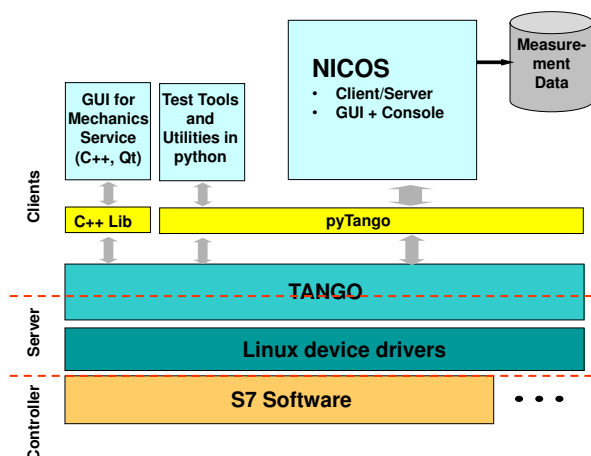

Figure 5: DNS software structure

CONCLUSION AND OUTLOOK

TANGO and NICOS have been successfully implemented in the new control and data acquisition system of the diffuse neutron scattering instrument DNS. After solving problems coming from the architectural differences between TACO and TANGO the instrument is in stable user operation, now.

On the base of the experiences with DNS, TANGO and NICOS will be used for all future neutron instruments of Forschungszentrum Jülich at FRM II and existing TACO-based instruments will gradually be upgraded to TANGO and NICOS in future.

MOTION CONTROL ON THE MAX IV SOFT X-RAY BEAMLINES WITH TANGO AND SARDANA

M. Lindberg, J. Forsberg, L. Kjellsson, A. Milán,
C. Sâthe, P. Sjöblom, S. Urpelainen, MAX IV, Lund, Sweden

Abstract

MAX IV Laboratory, a synchrotron facility in Lund, has selected TANGO as the control system framework for the entire facility. On the beamlines that are being built the Python-based SCADA (supervisory control and data acquisition) system Sardana will be used for experimental control.

SPECIES, one out of eight new soft X-ray beamlines, is used as a test bench for evaluating the chosen standards. Sardana is used to control the energy setting of the PGM (plane grating monochromator) as well as to provide macros and other utilities for the user. Generic Taurus GUIs and a SVG-synoptic give the user a way to interact with the control system and display relevant information. The standardized graphical interfaces give a familiar look and feel across the entire facility.

All motorized axes are controlled with the IcePAP motion controller. For the axes of the PGM, the IcePAP driver operates in hardware closed loop. Special care is taken in order to avoid slow and inaccurate movements of the PGM energy due to the non-linear relationship between the motors and the angular encoders.

INTRODUCTION

MAX IV Laboratory [1] will be a cutting edge synchrotron located in Lund, Sweden, and it is currently commissioning its main storage ring. This new facility builds on the experience from the previous MAX-lab in Lund, which is being decommissioned after 25 years of successful service to users from all over the world.

At this stage fourteen beamlines are funded and some are already in the process of being assembled at the MAX IV. The first users are expected in 2016. The SPECIES soft x-ray beamline [2,3] is currently commissioned and taking users at the older facility MAX-lab with the intention to serve as a test bench for the control system that will be used at all the other beamlines at MAX IV.

During the commissioning of the SPECIES beamline, several motorized optical elements needed to be controlled to adjust the alignment of the beamline and its two branches, 40 meter long in total, as seen in Fig. 1. Also, the characteristics of the photon beam must be well known. This is achieved by using a set of macros making calculations from motor positions and current measurements.

MAX IV BEAMLINE CONTROL SYSTEM

By making use of control system standards already in use at other facilities, it is ensured that there are several tools such as pseudomotors, predefined scans and generic GUIs available from the start of the beamline commissioning. For

the majority of the motorized axes the motion depends linearly on the corresponding encoder which makes it straight forward to achieve precise closed loop control but the PGM requires more effort which is further described below.

Control System Standards

The control system for the MAX IV facility [4] applies several standards for both accelerators and beamlines, that have been adopted with the aim to make the deployment and maintenance of a complex machine and a large number of beamlines more efficient and also to grant some familiarity to the user community.

Some of these standards are the TANGO Controls toolkit [5], the beamline SCADA Sardana [6], and the PyQt based Taurus GUI framework [7]. The IcePAP motion controller developed at the ESRF [8] has been chosen as a facility wide standard. Other common references and tools have been developed at MAX IV such as the MAX IV unified coordinate system and the SVG-synoptic interface [9].

Tango, Sardana and Taurus are all open source software and, since they have been developed and used at several other synchrotron facilities such as ESRF, Alba, and Soleil, code and experience have been accumulated over time. To deepen the transfer of knowledge and to contribute to the community, MAX IV is a part of the Tango collaboration, the Sardana collaboration, and the IcePAP collaboration [10].

Commissioning with the Control System

During the development a generic Taurus GUI was used to access motors and configure them, to run predefined scans and modify the scan parameters. The generic Taurus GUI is fast to set up and flexible to use. During the progression of the beamline installation and commissioning new panels for each equipment were added as each set of motors was configured. An example can be seen in Fig. 2.

After the commissioning a synoptic like the one in Fig. 3 will replace the development GUI. The synoptic gives a good overview of the beamline based on the physical location of the equipment. It also shows alarm states and allows quick access to detailed panels for all equipment when the user clicks the corresponding icon. Commonly used functions such as acquisition GUIs may also be launched from the synoptic.

MOTION CONTROL

Motion axes at MAX IV, including the ca 60 axes of SPECIES, will mostly be motorized using 2-phase stepper motors controlled by the IcePAP motion controller [11]. Sardana interfaces well with IcePAP and provides the possibility

Figure 1: The general layout of the optical elements of the SPECIES beamline showing the main elements that guide the photon beam to the experimental station. Starting on the left: the undulator, a mirror, a set of baffles, the plane grating monochromator, a switching mirror to choose between the two branches, exit slits, more baffles, focussing mirrors and finally the HP-XPS and RIXS endstations.

to define pseudo motors to create complex motions, such as roll, pitch, and yaw, as well as compensate in software for mechanical nonlinearities.

Controlling the Energy of the PGM

The PGM has six motorized axes, but the most important are the mirror axis and the grating axis. On each of those axes, there is a non-linear relationship between the motor steps counted by the stepper motors and the counts of the angular encoders placed on the turning points of the mirror and grating mechanics.

The IcePAP driver operates the PGM axes in hardware closed loop, connecting the encoder signals as positional input to the IcePAP. This is done to ensure that the position is maintained with high accuracy. For the PGM it is important to overcome the non-linear relationship mentioned above, otherwise movements may be slow and inaccurate. The IcePAP accepts only motor steps as input for the desired position, but with a well tuned closed loop and a carefully chosen approximation of the encoder resolution as expressed in motor steps, the motor moves until the encoder value equals the wanted position.

CONCLUSION

Using the control system standards and tools described above we have achieved a stable control system for the SPECIES beamline. Much insight was gained along the way that will be applied for the commissioning of the new MAX IV beamlines.

Results for the PGM Energy

Measurements show a resolution of $0.5 \mu\text{rad}$ for the mirror and $0.3 \mu\text{rad}$ for the grating. A one-step movement in closed loop with the highest resolution, including the settling time, takes less than 0.1 ms for the mirror and the grating.

SPECIES' PGM uses RON905UHV angular incremental encoders from Heidenhain. These possess a small well known built in error. The error is visible when the two sine-shaped currents (phase shifted $\pi/2 \text{ rad}$) from an encoder head moving over one encoder line are plotted against each other. Instead of a perfect circle, the graph is elliptical and offset. The solution is Heydemann correction [12].

In Fig. 4, at the left, this error is visible as a non linear increase in DAQ values during a linear motion. Especially the grating shows this cyclic error, isolated in the right plot in Fig. 4. From the cyclic error in the grating encoder head a correction table was created and each encoder value can now be corrected based on its DAQ value. This correction is implemented in a pseudomotor and the corrected positions are then used to calculate the energy.

To illustrate the performance increase, an N_2 absorption spectrum has been recorded in Fig. 5 and the width of the peaks as well as the distance between them are much more equal with the correction than without, just as expected. The maximum energy correction is 80 meV .

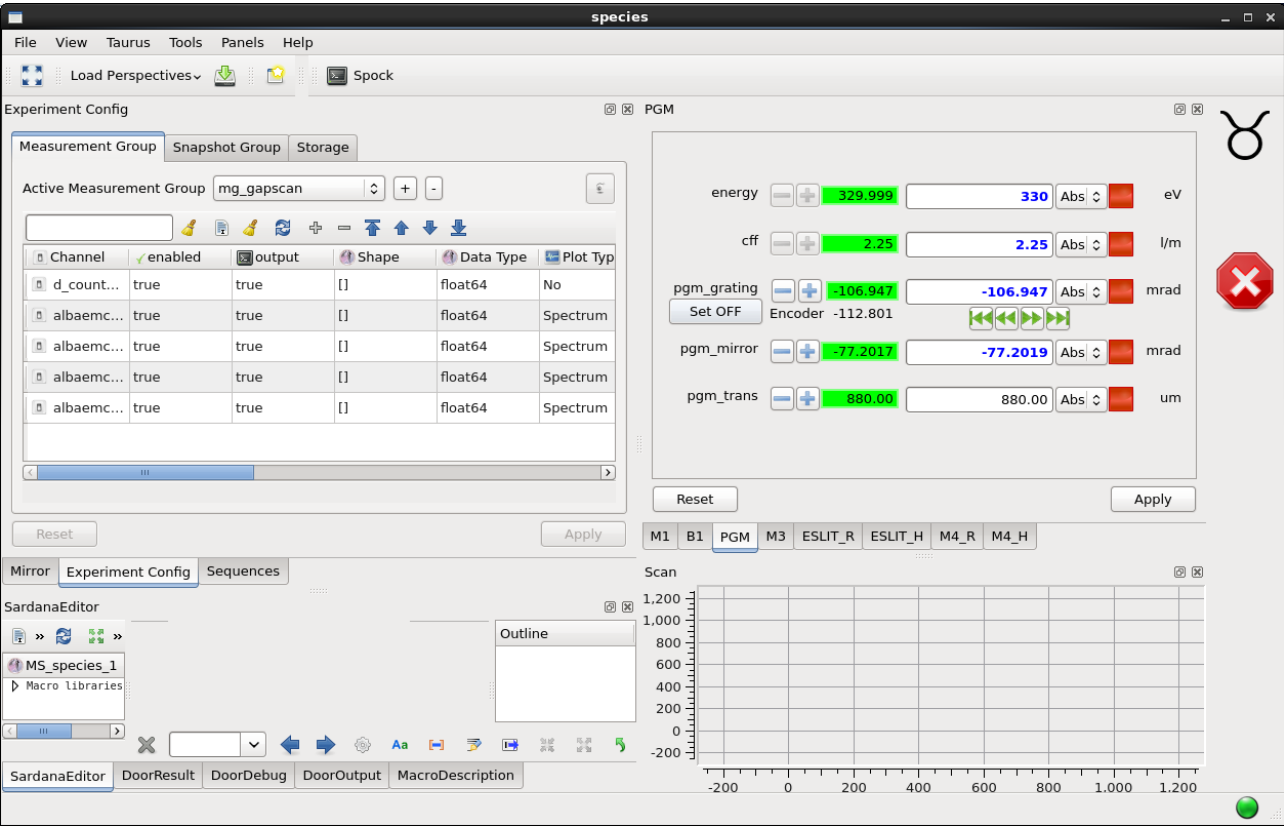

Figure 2: The commissioning GUI is a generic Taurus GUI which allows panels to be added with any combination of equipment and signals available in the control system. In the image above there are panels defined for the motors of each optical element. The GUI is also connected to the experimental control of Sardana.

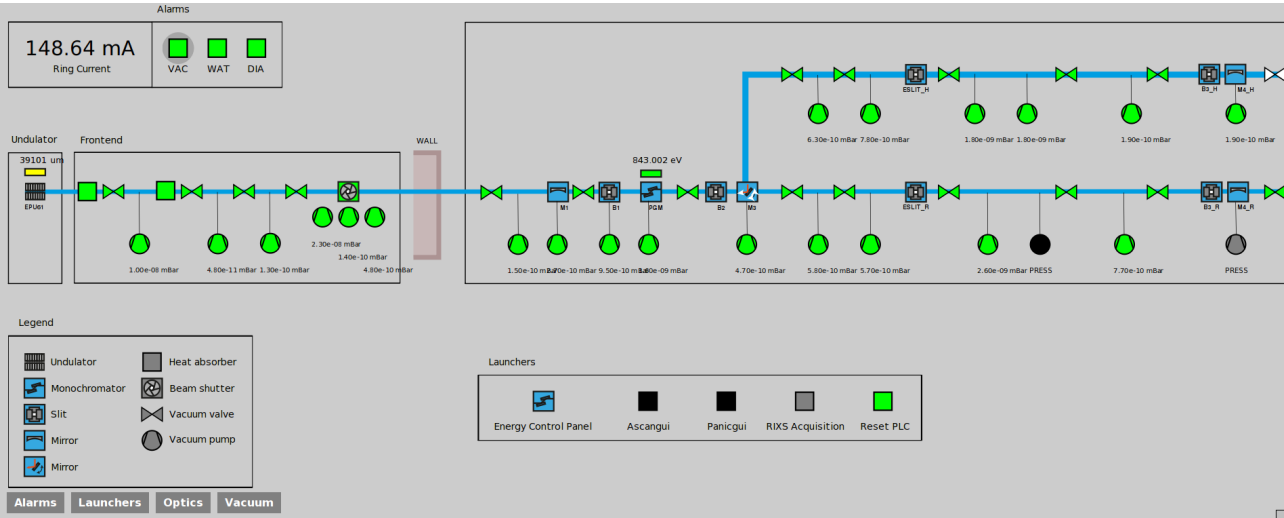

Figure 3: The SPECIES beamline synoptic provides an overview of the entire beamline with the possibility to display information about and control each piece of equipment. The view is defined by an SVG-image which is connected through a Python backend to the control system.

Figure 4: The left plot shows how encoder value increases in a linear motion and it is clear that the grating encoder suffers from a cyclic error. The right plot shows the cyclic error while the encoder passes a few encoder lines.

Figure 5: N_2 absorption spectrum with and without energy correction. The maximum correction is 80 meV.

SYNCHRONIZED RAMPING OF MAGNET POWER SUPPLIES FOR STREAMLINED OPERATION AT ENERGY RECOVERY LINAC (ERL) AND ELECTRON LENS (e-Lens)

P. Kankiya[†], J. Jamilkowski, T. Samms

Brookhaven National Laboratory, Upton, NY 11973 USA

Abstract

Synchronous ramping of an assembly of magnets is critical for operation of beam in an accelerator. Magnet currents must remain within the operational limits to avoid dis-alignment of electron beam. In order to comply with the design specifications of ERL and e-Lens project, two different software control mechanisms have been developed. The ramp profile is automated and maintained by tracking current in all dipole magnets at ERL and superconducting solenoid magnets at e-Lens. This mechanism speeds up operations and adds a level of protection. The purpose of this application is to reduce unnecessary interlocks of the personnel protection system. This paper will describe the power supply arrangement, communication mechanism and the state machine algorithm used for feedback and control. A report on operating experience will be presented.

INTRODUCTION

In year 2015 Energy Recovery LINAC project went under commissioning and their operations required design of special magnet ramp sequence to ensure compliance with accelerator design. The Energy Recovery LINAC (ERL) is designed to serve as a test bed for future projects such as LeReC, eRHIC and CeC. The lattice is unique and has been designed with a significant amount of flexibility in order to cover the required operational parameter space [1]. Another accelerator project with special ramp profile requirements is the RHIC electron lens (e-Lens) [2]. The Yellow and Blue e-Lens assemblies have a collection of 17 superconducting magnets. Current reference waveforms for these solenoids are generated by high level software applications and are preloaded to the VME based Waveform Function Generator (WFG) modules which are custom boards developed in-house.

ERL MAGNET MANAGER

ERL's R&D prototype is currently installed with an assortment of magnets including several quadrupoles, dipoles and solenoids shown in Fig 1. The large beam size and very low longitudinal emittance of the e-beams dictate that the tolerances on the magnetic fields are very tight. Significant misalignment in the electron beam could lead to stray radiation; therefore very strict radiation safe functional bounds are enforced by an independent system called the Particle Accelerator Safety System (PASS). This system is designed to protect personnel working in

the areas near ERL by interlocking critical devices under specific abnormal conditions. In order to avoid unnecessary PASS interlocks due to mismatched critical dipole magnet currents, it was advised by the external reviewers of the project that software controls be modified. The intent is to reduce accelerator downtime, since each interlock of this type requires a sweep of the blockhouse by trained personnel. Another role of this software that has been added to the operational requirements is to manage magnet power supply controls and ERL e-beam orbit feedback corrections.

Figure 1: 3-D schematic of magnets in ERL beam line.

Software Implementation

Different COTS power supply systems with small amount of customisation are purchased and mounted to interface with various magnets based their on functional specifications. These supplies communicate over TCP/IP by means of custom multiple types of software developed using the Accelerator Device Object ADO framework [3].

“erlMagMan” is a program consisting of two levels of object oriented entities controlling power supplies which interface directly with the magnets. The first level is an ADO class representing each magnet and consists of magnet properties such as bending angles of each dipole and nominal current at designed bending angle. These coefficients are provided by system experts and are obtained by direct measurements or simulations. Desired magnet currents are calculated at a given level of energy or at adjustment of trim angles. This energy will be entered manually by the shift operator or through the orbit correction program. Reverse conversion logic for translating magnet current to correction angles is also in place.

The second ADO layer acts as a governing class which interacts with all magnet ADOs simultaneously. It broadcasts the change of energy so all power supplies are configured with the correct current set point at the same time.

[†] pkankiya@bnl.gov *Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. DOE

An asynchronous receiver client set up in the magnet ADO monitors the relationship between main dipole magnet output current and selected downstream dipoles. A threshold value of 2% less than PASS trip threshold is enforced and if any dipoles violate the limit, an alarm is generated alerting the machine operator to terminate beam in order to avoid a PASS interlock.

e-Lens WFG MANAGER

Designed to improve the proton beam luminosity in RHIC, an electron lens (e-lens) magnet system has been built at BNL in the 10 o'clock Interaction Region at the RHIC [4]. For the e-lens to function efficiently and facilitate the necessary cooling of the proton beam, the electron beam must be generated with a comparable size and aligned parallel to the proton beam within the acceptable magnetic field region of the main superconducting solenoid (Fig. 2).

Figure 2: The Main superconducting magnet and corrector solenoids of blue e-Lens.

Software Implementation

The ramp design parameters of the software are provided by power supply engineers who are responsible for setting up the power supplies and quench protection system. Four different operating modes are defined, involving which magnets (main and fringe) are to be controlled and which e-Lens (Blue or Yellow) is targeted. The ramp rate of each magnet varies at different stages and direction of the ramp, increasing or decreasing current. As listed in Table 1, the ramp rate of each magnet has been predetermined and must be maintained while ramping. This is critical to prevent the superconducting magnets from quenching, as each quench will lead to machine protection system interlocks of the e-lens as well as interrupt the operation of RHIC during recovery. The latter can be a costly affair and must be avoided.

Table 1: Maximum Ramp Rates for Stable Operation

Magnet Type	Ramp Rate (A/s)
Main Solenoid (Up/Down)	0.4/0.2
Fringe Solenoid	1

A test involving powering of all of the solenoids simultaneously to maximum power was performed. This situation proved to be problematic due to Quench Detector (QD) trips from large induced voltages generated by interactions between the coils and resulted in frequent trips of the anti-fringe solenoid QD and one quench of the main solenoid. In order to resolve this problem, system experts specified a new scheme such that the solenoid circuits will be ramped alternately in steps equal to 10% of the maximum test current. Hence, the software shall ramp main magnets first and fringe afterwards in an alternating fashion to reach the desired magnetic field level (see Fig. 3).

Figure 3: Ramp profile of yellow e-Lens main and fringe solenoids for 5 Tesla field. Each step is 50Amps.

The current set points of each magnet depend on the desired solenoid field, and these values have been established after systematic testing as described in [4]. Other software requirements include the ability to halt the ramping sequence.

Class Description

A C++ ADO class known as `elensWfgControl` is constructed to control all magnet supplies which are also represented as ADOs in the Controls System. In order to reduce the complexity of ramp sequence, it is partitioned into elements of state machines based on concepts such as states, transitions, and actions. State machines for the fringe and main magnets are performed separately, although the two associated threads are executed simultaneously. When the main magnet is ramping the auxiliary coils are in and idle state. Ramp step size and wait time between ramps referred to as park time are configurable via the control ADO interface.

Figure 4: Ramp profile of blue e-Lens main and fringe solenoids with smooth ramp for 5 Tesla field.

Upgrades to e-Lens Wfg Manager Program

Soon after commissioning of the ramp manager software, repeated testing showed that it is actually possible to ramp magnets in one step instead of 50Amps per step. The only caveat to this revelation is that the start of ramp has to be at a much slower rate. Keeping this in mind, a special scheme of slow ramps were implemented within the WFG code to reduce the current ramp rate by 20% during the first 20% of the ramp cycle. Figure 4 displays same level of magnetic field reached with significant reduction in ramp time using the smooth ramps.

ACKNOWLEDGEMENTS

Author would like to thank Dmitry Kayran at Brookhaven National Lab C-A Department for contributing design specifications of ERL magnets, and Al Marusic also at C-AD for designing the algorithm used for “soft” ramps of the e-Lens magnets.

CONCLUSION

A software scheme to generate two unique sets of magnet current ramping profiles has been created and deployed. Both resulted in successful beam steering in case of ERL and in determining the electron beam size and trajectory by the field in the solenoid in case of e-Lens. During operations and considerably reduced expert man hours by reliably automating each set of processes. A similar software management scheme is under consideration for the corrector magnets associated with the e-Lens system.

MeerKAT CONTROL AND MONITORING SYSTEM ARCHITECTURE

Neilen Marais*, SKA South Africa, Cape Town

Abstract

The 64-dish MeerKAT radio telescope, currently under construction, comprises several loosely coupled independent subsystems, requiring a higher level Control and Monitoring (CAM) system to operate as a coherent instrument. Many control-system architectures are bus-like, clients directly receiving monitoring points from Input/Output Controllers; instead a multi-layer architecture based on point-to-point Karoo Array Telescope Control Protocol (KATCP) connections is used for MeerKAT. Clients (e.g. operators or scientists) only communicate directly with the outer layer of the telescope; only telescope interactions required for the given role are exposed to the user. The layers, interconnections, and how this architecture is used to meet telescope system requirements are described. Requirements include: Independently controllable telescope subsets; dynamically allocating telescope resources to individual users or observations, preventing the control of resources not allocated to them; commensal observations sharing resources; automatic detection of, and responses to, system-level alarm events; high level operator controls and health displays; automatic execution of scheduled observations.

INTRODUCTION

The MeerKAT Control and Monitoring (CAM) subsystem is the high level control system that enables all the other subsystems to operate cohesively as a single telescope. Most of the CAM design principles were presented at ICALEPCS 2013 [1]. While much detail design and implementation has been done since then, the only major architectural addition to CAM is the concept of telescope subarrays and the subarray-manager components that implement them. An unusual feature for the control architecture of a large scientific instrument is the lack of any messaging middleware or message bus.

A brief MeerKAT status update is given, and a high level overview of the MeerKAT CAM architecture is presented with a description of how it is used to meet CAM requirements in practice. The scalability and reliability of this architecture are discussed.

MeerKAT DESCRIPTION AND STATUS

MeerKAT will be a 64-receptor¹ aperture-synthesis interferometric radio telescope array. Receptor antennas are offset Gregorian antennas with a 13.5m main reflector in a feed-low configuration. An offset optical configuration has been chosen because its unblocked aperture provides optimal optical performance and sensitivity with good rejection of unwanted radio frequency interference from satellites

and terrestrial transmitters. It also enables the installation of multiple receiver systems in the primary and secondary focal areas and provides a number of operational advantages.

The antenna platform supports up to four receiver systems mounted on a carousel, allowing the telescope to switch frequency bands within minutes. The initial design committed to cryo-cooled L-band receivers. Some experimental uncooled K-band receivers are installed during commissioning. Since then, the MeerKAT project has committed to installing UHF-band receivers and the Max-Planck-Institute for Radio Astronomy has committed to funding and building S-band receivers for MeerKAT.

MeerKAT receptors directly digitise the received signal, without transmitting analogue signals to a central facility – a first for radio telescopes. A central Time and Frequency Reference (TFR) subsystem using a GPS-disciplined Rubidium clock provides a highly accurate absolute time reference and a sub-picosecond accurate clock signal for phase-coherent digitiser operation. The clock and timing pulses are distributed to the receptors via dedicated fibre links. The TFR will later be upgraded to a MASER timing source.

Signals are transmitted from the receptor digitisers via multiple bonded 40 Gigabit Ethernet (40GbE) fibre links to the Correlator-Beamformer (CBF) subsystem in the Karoo Array Processor Building (KAPB) using the packetised SPEAD [2] format. A separate physical Ethernet network is used for CAM traffic from the receptors.

The CBF subsystem performs the first level of signal processing and data reduction using the SKARAB open FPGA platform [3], and multicast capable commodity 10/40GbE switches as a data fabric. It produces correlated visibilities for imaging, and beam-former voltage data that is consumed by the Science Processing (SP) subsystem and optionally by user supplied equipment provided by third parties. SP is a software subsystem running on general purpose computers in the KAPB, utilising GPU- and/or other forms of acceleration. SP processes the CBF output into images and other relevant science outputs, and also archives observation data.

Ancillary subsystems include: the MeerKAT site Camera subsystem; the weather monitoring subsystem; the KAPB building management subsystem that monitors ambient conditions and RFI-door intrusion detection where appropriate; the Power Distribution Units (PDUs) of several subsystems to facilitate emergency power shutdowns. These subsystems are not directly involved in observations but are monitored to ensure safe and reliable operation of the telescope.

All subsystems are coordinated and monitored by CAM using a logically separate CAM network, using Ethernet as a fieldbus. Communication with all other subsystems is via the Karoo Array Telescope communications protocol (KATCP) [4]. CAM Device Translators are used to provide a KATCP interface where this is not available natively.

* nmarais@ska.ac.za

¹ A receptor logically groups the subsystems of a single antenna dish.

MeerKAT's full functionality is divided into six Array Release (AR1-AR6) milestones with the goal of deploying AR1 in H1 2016. During 2014 all the earthworks, power and other civil infrastructure were completed, including installation of fibre to all the receptor sites and construction of the underground, RF-shielded KAPB that hosts the MeerKAT data centre. First light was achieved with the first of the 64 receptors, confirming that the system as designed will significantly exceed the 220 m²/K system sensitivity requirement once all 64 receptors are installed. This would make MeerKAT the most sensitive L-band radio telescope in the world. During 2014 the CAM subsystem team completed feature development for the Receiver Test System (RTS), and commenced detail design and development of the MeerKAT AR2 features.

During 2015 the RTS was deployed to site. RTS is a stand-alone mini-telescope system that can work with up to four receptors for receptor acceptance testing and commissioning. RTS implements the minimum telescope functionality needed to commission receptors. Antennas under test are separated from the rest of the MeerKAT telescope data network by patching their physical data fibres into the RTS data-network switch, while the physical CAM network is shared between RTS and MeerKAT through configuration procedures.

Eight receptors are on site as of October 2015 and are at various stages of integration, commissioning and acceptance testing. Rolling construction and deployment of the remaining receptors will take place through 2016 and into 2017. New receptors are first added to RTS before graduating to the operational MeerKAT system for science use.

During 2015 the implementation of the AR2 milestone CAM functionality was completed and verified against simulators pending the completion of other subsystems' functionality. AR2 requires 16 science-ready receptors and a CBF that produces a limited selection of correlator data products, and an SP subsystem that ingests said products in real time. Furthermore, basic subarray functionality is required.

The early phase of MeerKAT development is mostly about constructing and commissioning the 64 Receptors and procuring a sufficient number of SKARAB boards to provide proposed CBF functionality. The later phases, while less visible, encompass the majority of the "construction" effort. Telescope functionality is added through software (CAM, SP and CBF local control) and FPGA firmware (CBF).

COMMUNICATION LAYERS

The CAM architecture is divided into three layers of components as shown in Figure 1 with connections strictly from higher to lower levels, and a fourth category of CAM controller components that collaborate as models and controllers in the Model-View-Controller software model. Apart from **katportal** clients that use http and websockets, all connections are made using KATCP over TCP/IP; each directed arrow starts at a client making a TCP connection to a KATCP server running at a well known IP and TCP port. For sub-

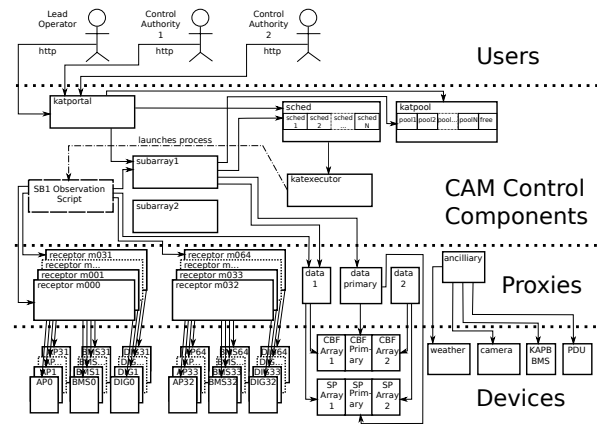

Figure 1: CAM Layers and Observation Control.

systems external to CAM the IPs and ports are assigned by System Engineering (SE), while CAM components have IPs and ports assigned internally by CAM within the CAM IP range². These IPs and ports are maintained in the CAM config (**katconfig**). All these connections are made via the CAM network³.

Members of the Devices layer each expose a KATCP interface, that is the interface between CAM and other subsystems; they are described using Interface Control Documents (ICDs) that are under SE configuration control. A single subsystem may have multiple instances, e.g. Antenna Positioner (AP) has an instance per receptor; each instance runs a separate KATCP server at a separate IP. These KATCP interfaces represent the controller of a specific piece of hardware, while the CBF and SP subsystems have their own internal control systems and present virtual devices. Devices make no KATCP connections via the CAM network, and act strictly as KATCP servers.

One level up are the CAM Proxies that make KATCP connections to devices, and act as KATCP servers to CAM controller components and to observation scripts. Each proxy exposes a single KATCP interface, but may connect to multiple logically related devices. Each proxy is managed by **katpool** (see next section) as a telescope resource. Devices are interrogated for KATCP sensors and requests, and these are proxied to the proxy's KATCP interface. Multiple instances of a proxy may exist, e.g. one receptor proxy per physical receptor, one data proxy per logical subarray. A proxy may implement special configuration/control for a device; e.g. the receptor proxies implement pointing corrections for the antennas.

Next come the CAM controller components that collectively implement the "intelligence" of the CAM subsystem. They may make KATCP connections to proxies and among

² The telescope network is treated as an infrastructure subsystem. IP ranges are assigned to various subsystems by SE.

³ The CAM network is further segmented to avoid inappropriate communication between layers; the **katportal** component interfaces with the rest of the telescope LAN.

themselves. At the top are the external telescope users. They connect to the **katportal** component using web browsers over authenticated http connections. They are allowed telescope control on the basis of their assigned roles. The two roles considered here are: Lead Operator (LO); and Control Authority (CA). The LO manages the assignment of telescope resources to subarrays, and the assignment of logged-in users as CAs of a particular subarray. The CA manages observations on a specific subarray. See [5] for more details of the operator interface.

OBSERVATION CONTROL

Figure 1 shows the main component interactions during observations. MeerKAT will initially have four⁴ subarrays, but in the interest of space and clarity only two subarrays and the interactions of only one subarray are shown.

katpool is purely an accounting component; it keeps track of telescope resource allocations to subarrays and assignment to observations of resources within a subarray. Commensal observations are facilitated by only assigning controlling access of a resource to a single Observation Scheduling Block (SB)⁵, while assigning non-controlling access to commensal observation SBs. **sched** manages the observation schedule of all the subarrays. **subarray1** is the subarray controller for “array1”, managing its lifecycle.

The LO signs in to **katportal** and puts **subarray1** in configuration mode. She assigns (via the web GUI [5]) the SBs of the observations planned for her shift to **subarray1**, and assigns a subset of receptors and CBF product resources to **subarray1** as required by the scheduled observations. **katportal** requests **sched** (the CAM scheduler component) to assign the requested SBs to **subarray1** and requests **katpool** to allocate the requested resources to “pool1” (**subarray1**’s resources). **katpool** moves the resources from the “free” pool to “pool1”, making them unavailable to other subarrays. Satisfied with the configuration, the LO requests subarray activation. **katportal** requests **subarray1** to activate.

subarray1 observes **pool** to get its resource assignment. Next it requests the CBF primary interface⁶ to set up “array1” with the list of receptors to subscribe to. The CBF primary interface is used for high level configuration and lifecycle management of CBF arrays. It creates a secondary KATCP interface for “array1”. The **data1** proxy connects to this interface and exposes it the higher layers. **subarray1** then requests **data1** to activate the requested CBF products. CBF now assigns and programs FPGA resources to produce the requested products for “array1”. **subarray1** configures SP to receive the CBF data product in a similar way.

subarray1 enters the active state, and the LO is notified. She delegates control to another user, making him the CA for **subarray1**; **katportal** will now relay all CA requests to **subarray1**. The CA puts the **subarray1** schedule in queue

mode. **subarray1** relays this to **sched**. **sched** selects SB1 from the **subarray1** schedule and begins to activate it. It requests **katpool** to assign resources from “pool1” to SB1. **katpool** verifies SB1’s resource requirements against those available in “pool1”. If insufficient resources are available, the CA is notified, otherwise they are assigned to SB1.

Once resources are assigned, **sched** invites **katexecutor** to execute SB1, and informs **subarray1** that SB1 is now active. **katexecutor** examines SB1’s instruction set to determine which observation script to run and the appropriate script parameters. It then launches the SB1 observation script in a subprocess. The observation script uses standard CAM Python library *katcorelib* to connect to **subarray1**; at startup the observation script has no knowledge of the telescope besides the address of **subarray1** and its SB ID code. Once connected, the script identifies itself as SB1. **subarray1** verifies that SB1 is indeed active, and replies with a datastructure describing the telescope resources assigned to SB1. This is passed to *katcorelib* which creates KATCP connections to the resources as required. The script is given a standard telescope object that exposes each KATCP resource (i.e. proxy connection) as a separate client object which exposes KATCP requests as function calls⁷ and KATCP sensors as objects that can be polled, subscribed to, or monitored for a specific trigger value. Resource group objects allow all assigned receptors to be pointed to the same target with a single call, or the same sensor to be monitored across all the receptors. The observation script can now control its assigned resources until SB1 completes. Data products produced by the CBF are captured and processed by SP. SB1’s metadata is also sent to SP so that the captured data can be accurately classified and archived.

Once SB1 completes, **sched** ensures via **katexecutor** that the script has terminated (ensuring that all SB1’s KATCP connections are also closed), updates SB1’s status to completed, and requests **katpool** to free the resources that were assigned to SB1. **sched** selects the next SB from the **subarray1** schedule, and repeats the process with the new SB. At the end of the observations, the CA or LO can request **subarray1** to be freed. The CBF is instructed to deprogram “array1”, freeing up its FPGA resources, and **katpool** frees resources allocated to **subarray1** by moving them from “pool1” to the free pool.

MONITORING AND INTERVENTION

Figure 2 shows the main component interactions for telescope monitoring and interventions and is a logical overlay for Figure 1 – the monitoring connections are always open, whether an observation is active or not.

A number of **katmonitor** instances⁸ make KATCP connections to all CAM proxies and all CAM controller com-

⁴ CAM could support more subarrays, but limitations in other subsystems, the design of human factors in the control room, and the number of receptors in the telescope limit the useful number of subarrays to four.

⁵ For scheduling, observations are broken up into several indivisible SBs.

⁶ Interactions with SP are not shown, but follow a similar pattern to CBF.

⁷ *katcorelib* only exposes functionality that the observation script should have access to by pruning the telescope object. Scripts could easily bypass this mechanism, but they are vetted by CAM beforehand. A future implementation might introduce an intermediate CAM component to limit access.

⁸ Multiple instances allow multi-process scaling.

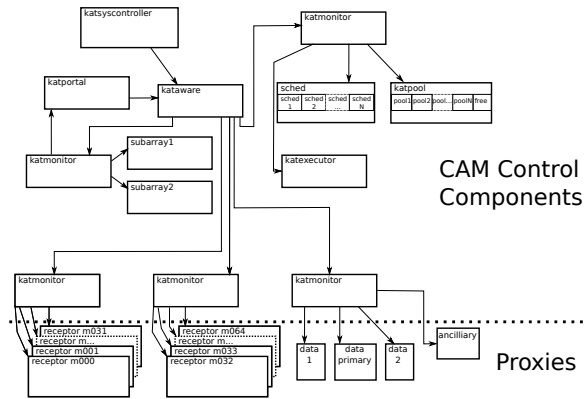

Figure 2: CAM Monitoring and Control Intervention.

ponents, and subscribe to every sensor by setting sensor strategies. **katmonitor** performs two functions on the received sensor samples: They are buffered in memory for the CAM sensor store [6], [7], and aggregation rules are applied in real time. Aggregation rules are defined in **katconfig** e.g. True if all the receivers on all receptors⁹ are cold. The result of the rule is exposed as a new KATCP sensor on the **katmonitor** interface.

A single **kataware** instance observes all the **kataware** instances and applies alarm logic to the aggregate sensors. Alarm rules are read from **katconfig**. Each alarm has a rule for triggering an alarm level (e.g. WARN or ERROR), and an optional alarm action. **katportal** and **katsyscontroller** observe the **kataware** alarm sensors. **katportal** notifies logged in LO and CA users as appropriate; SMS, internet relay chat (IRC) or email notifications may also be configured. **katsyscontroller** implements the actions defined for the alarm and is responsible for taking telescope-wide action to ensure safe and reliable operation. It can make KATCP connections (not shown in Figure 2) to any proxies or CAM components needed to execute an action. Actions can be predefined (e.g. stow all receptor antennas due to high wind), or an arbitrary script file may be executed.

DISCUSSION AND SCALING ANALYSIS

MeerKAT CAM avoids the need for dynamic device discovery since all the nodes in the system are described in **katconfig** (see [1] for more details). This works well since MeerKAT is fairly static in terms of physical configuration; receptors are fixed in place, and have space for a limited number of receivers. While MeerKAT may potentially be expanded with more receptors, receptors are fairly homogeneous in configuration. Only a limited amount of unique calibration data is required per unit, making it almost trivial to add more receptors to **katconfig**.

⁹ A **katmonitor** instance can only apply aggregate rules to the subset of proxies it is connected to. A multi-level **katmonitor** design is planned that will remove this limitation.

Direct TCP connections between components avoid the complication and overhead of message-bus middleware. All critical CAM operations are idempotent, so the combination of TCP and KATCP's request / response or timeout paradigm has been found to provide sufficient reliability. Some messaging middleware provide message multicast features that might improve efficiency for sensors with multiple listeners. Analysis of the MeerKAT design shows that the **katmonitor** components are the only high-bandwidth consumers of sensor data, implying that sensor multicast would not save much traffic.

From the CAM perspective, scaling a radio telescope essentially implies managing a larger number of receptors and associated sensor data. The CAM proxies are inherently scalable, since a separate proxy process is used per receptor and no state is shared. **katmonitor** is similarly scalable. The CAM sensor store and **katportal** GUI are already designed for performance scalability [6], [5]; **katportal** might need some redesign due to human factors. Most of the CAM control components (**sched**, **katpool**, **subarray1...N** and **katexecutor**) have very low transaction rates or are not directly exposed to the number of receptors.

A potential bottleneck is the observation scripts since they need to address every receptor. However, only a handful of receptor interactions are required per SB (continuous antenna pointing is handled by the receptor proxies), so this approach should suffice even for thousands of receptors. A similar concern applies to **kataware**. The addition of a multi-process receptor instruction repeater component would address this bottleneck should it ever become a limiting factor.

Abstract

The Percival Collaboration is developing a high-speed, low X-ray energy detector capable of detecting single photons while maintaining a large dynamic range of sensitivity.

The increased brilliance of state-of-the-art Synchrotron radiation sources and Free Electron Lasers require imaging detectors capable of taking advantage of these light source facilities. The PERCIVAL ("Pixelated Energy Resolving CMOS Imager, Versatile and Large") detector is being developed in collaboration between DESY, Elettra Sincrotrone Trieste, Diamond Light Source and Pohang Accelerator Laboratory.

It is a CMOS detector targeting soft X-rays < 1 KeV, with a high resolution of up to 13 M pixels reading out at 120 Hz, producing a challenging data rate of 6 GiB/s.

The controls and data acquisition system will include a Software Development Kit to allow integration with third party control systems like Tango and DOOCS; an EPICS [1] areaDetector [2] driver will be included by default. It will make use of parallel readout to keep pace with the data rate, distributing the data over multiple nodes to create a single virtual dataset using the HDF5 file format for its speed advantages in high volumes of regular data.

This development project will culminate in a control and DAQ system capable of dealing with very high data rates while providing easy integration with site-specific control systems.

This report presents the design of the control system software for the Percival detector, an update of the current state of the implementation carried out by Diamond Light Source.

INTRODUCTION

The PERCIVAL detector is designed for high-speed and low noise detection of soft X-rays. The Percival CMOS chip is a large pixel array of ~ 13 mega-pixels with 15 bits per pixel (packed in 16 bit words) which encodes a substantially higher dynamic range of the sensor as described below [3]. This leads to 25 MiB per frame. For each data frame the detector

will also produce a reset frame of the same dimension, so the total data produced is 50 MiB per frame. There will also be a ~ 2 mega-pixels version [4]. For the designed frame-rate of 120 Hz this leads to an overall data rate of ~ 6 GiB/s [5].

The Detector

The detector pixel is an adaptive gain design [4], allowing single photon discrimination at low flux while still being capable of high flux measurements at the cost of increased noise. It comprises a diode and three capacitors, each of increasing capacitance, to collect charge depending on whether the next smallest capacitance component has been filled; thus "adaptive-gain". As there are four "collectors" per pixel, there are four possible gain values also. A pixel array feeds scrambled data to a pair of "mezzanine" cards, each with an FPGA to perform a certain amount of low level unscrambling and formatting the data into UDP packets for transfer to the processing nodes. These nodes are a Linux cluster of 8 commodity servers, as recommended by an earlier feasibility study [3] in order to handle the processing of the expected data rate.

CONTROL SYSTEM ARCHITECTURE

Shown in Fig. 1 is an overview of the proposed Percival software architecture, where the green single direction arrows represent the flow of data and purple bidirectional arrows represent control links. The top half represents the data acquisition system, with the sensor board having its data collected by the carriers boards via LVDS lines and transferred to the mezzanine boards before it is sent through the deep buffer switch and onto the Linux cluster.

Each FPGA of the mezzanine board has four 10 GBps links to the deep buffer switch, one for control and three for transmitting data. Since there is a chance of UDP packet loss, and the goal for maximum packet loss is less than 1 in 10^6 , a lightweight retry protocol will be used to ensure this aim.

The Linux cluster software stack and user workstation software suite comprise the control software that is being

The first processing step is to decode the integer coarse, fine and gain codes from the packed 16-bit integer. The coarse and fine codes are converted to a floating point number representing the intensity measured by each pixel. This is called the ADU calibration, and requires a static array of offset and gain values for each of the seven coarse and fine ADCs.

Multiplying the ADU calibrated float by the pixel gain is the next step, the gain is one of four values encoded by the two gain bits of the now unpacked 16-bit integer. The gain values depend on which of the capacitors or the diode is read out from the pixel to the ADC, and depends on which pixel is read out (as the capacitances of the pixel components are not completely uniform over all the pixels).

Next, if the gain corresponds to the photo-diode of the pixel, i.e. the highest gain value, then the reset frame that has also undergone the previous processing steps must be subtracted from the sample frame. This is called the Correlated Double Sampling (CDS) subtraction step, reducing systematic errors in the signal.

Finally, dark image subtraction is performed by removing a constant frame from the result.

The coarse and fine offsets and gains, as well as the pixel gains and the dark frame are all intrinsic to the detector, acquired before measurements are taken and stored in static arrays available in memory for the processing steps to use.

In developing and optimising this library [6], the primary goal is achieving the fastest processing time, indicated by the bandwidth, i.e. the amount of data processed per unit time for both the sample and reset frames. Profiling tools were used to identify the most significant contributions to processing time and potential bottlenecks, and the library was developed as a processing chain so as to swap in and out different versions of the processing steps within the profiling and optimisation framework. Much of the tuning applied here is specific to the hardware and micro-architecture of the system.

- The first step taken to optimise the library was reducing the computation time in the first processing step by changing the floating point division to a multiplication of the denominator's inverse.
- The GCC compiler offers three levels of optimisation, and various techniques offered by the C++ language were employed.
- Parallelisation is employed using Intel Threading Building Blocks (TBB) in order to spread the processing of one node over multiple threads. It was found that the optimal number of logical threads was to use the number of physical threads, although some subtleties were encountered.
- Vectorising the operations such that calculations are performed on multiple pixels at the same offers further improvement in processing bandwidth, using the AVX (Advanced Vector eXtensions) instruction set that is enabled on Intel Ivybridge and Sandybridge architectures.

- Alignment of the data with the available vector sizes also improved throughput, requiring that the multiples of 7 pixels (due to the detector chip having 7 ADCs each with which to read out rows of pixel data) be padded with an empty slot.

Figure 2: Optimisation steps versus processing bandwidth, with comparisons to the baseline [6].

The results of the various optimisation steps and the impacts on bandwidth are shown in Fig. 2. Improvements were optimal when parallelisation, compiler optimisation, replacement with bitwise operations and the AVX with a particular template better suited to large bandwidths is used.

Figure 3 shows the linear dependence of processing bandwidth with up to roughly 10 threads, after which there appears to be a saturation at ~2.5 GiB/s. The result shown is using a grain size, or chunk of data to process from the cache at one time, to be a factor of the number of pixels in the frame. The grain size is optimised to be a multiple of 7 (to match the number of ADCs, and the number of pixels rows is a multiple of 7), and is optimised to fill as much of the memory cache of the server node without saturating it. A grain size of 3528 was used for the result measured in Fig. 3.

Figure 3: Processing bandwidth versus the number of threads [6].

Overall, the optimised library is found to run stably on a single node at $(2.5 \pm 10\%)$ GiB/s, which is $59\times$ the baseline bandwidth, and more than $3\times$ the required bandwidth to achieve the required data processing bandwidth.

Compression

Compression of data before writing to file has been investigated, with optimised parallel compression of interest in particular, to exploit the Linux cluster multi-core architecture. The “blosc” compressor tool [7] was used as it specialises in fast compression and decompression, use of multi-threading capabilities, and it can be applied to HDF5 data when writing to or reading from a disk. Initial and very basic measurement has yielded encouraging results but require further tests and development.

Live Viewer Stream

The live viewer requirement is only a reduced data-rate, sacrificing combinations of frame-rate, resolution and/or region-of-interest. Components for streaming the live data after processing on the Linux cluster already exist so will be incorporated into the Linux cluster software. This is also true for the live viewer; making use of an in-house developed version of an areaDetector plug-in that utilises the ffmpeg libraries to stream live data.

File Writing

File Writing is performed by an in-house developed file writer based on the HDF5 format. The HDF5 group is implementing support ¹ for Single Write Multiple Read (SWMR) to the HDF5 libraries, allowing for live viewing of the data while the detector is capturing, processing and writing images [8]. This is an essential feature for long measurements, to inspect the data early throughout the data acquisition.

Also implemented is direct chunk writing ². This direct chunk write feature is also key in allowing us to do high-performance (i.e. outside of the HDF5 library) compression with something like blosc.

As each node of the Linux cluster will receive one complete frame in turn, and it has been found that parallel writing to one file is not as efficient as writing to multiple files. This will be addressed by adding Virtual DataSet (VDS) support to the HDF5 library. DLS, DESY and the Percival collaboration have jointly contracted the HDF5 group for this feature also. The HDF5 VDS will present data stored in several HDF5 datasets and files as a single HDF5 dataset and to access the data via HDF5 APIs without rewriting and rearranging the data [9].

CONCLUSION

The controls and data acquisition software for the Percival detector under development at DLS already has a design for the system architecture, and has achieved a number of significant milestones.

¹ contracted by DLS and Dectris

² funded by Dectris

The Frame Receiver software can successfully receive data frames over a network switch, with a basic prototype working with the current mezzanine firmware. Live control and region-of-interest support is being developed.

Components developed at DLS for the live streaming and live viewing of processed data are ready to be used within the control framework for the Percival detector.

With the direct chunk write and SWMR feature, tests have shown acceptable performance writing to a parallelised file system.

A prototype of the scripting and CLI for detector control has been tested operating with emulated hardware.

A library written in C containing the live processing algorithms has been developed and extensively optimised to not only meet but substantially exceed the bandwidth requirements for processing data on each cluster node. Testing has shown it is capable of processing at a rate of $(2.5 \pm 10\%)$ GiB/s on one of the Linux cluster nodes.

An interface for EPICS and areaDetector will be included in the developed controls software, and will allow use with other control systems such as TANGO and DOOCS. The SDK also allows for the implementation of a GUI with the controls software.

SODIUM LASER GUIDE STAR EMULATION

I. Price, RSAA, Australian National University, Australia
R. Conan, GMTO Corporation, Pasadena, CA 91101, USA

Abstract

In the era of extremely large telescopes (ELT) an adaptive optics (AO) system with artificial guide stars is an essential part of the optics between the source and the scientific instrument. In the case of the Giant Magellan Telescope these guide stars are formed by stimulating emission from Sodium atoms in the upper atmosphere with lasers launched from the side of the telescope. Moreover, they are resolved by the adaptive optics system so Shack-Hartmann wavefront sensors record elongated spots. Cost effective proof-of-concept systems for investigating control algorithms must be built for deployment in optics labs or on small telescopes. We present a hardware and software system that mimics the propagation of a single laser guide star (LGS) through the Earth's atmosphere and the optics of the Giant Magellan Telescope, using source motion and brightness modulation to simulate the source extension. A service oriented architecture allows adaptive optics scientists to construct images from different LGS asterisms and build non-real-time closed-loop control systems in high-level languages.

SODIUM LASER GUIDE STARS

A Sodium Laser Guide Star (LGS) is an artificial source created from Sodium atoms in the upper atmosphere and used for wavefront sensing as part of Adaptive Optics systems. Laser light at the 589 nm Sodium D2 line wavelength is propagated upward from a small telescope located alongside the main telescope. The photons from the laser interact with a naturally occurring population of Sodium atoms at an altitude of around 90-100km, exciting a shell electron. When the electron returns to its original energy level it emits a photon. Although the Sodium atoms are stimulated by a laser the process is dominated by spontaneous emission events. Ideally all of the energy from the outgoing laser beam would be delivered to atoms at a single altitude. In practice photons are absorbed all along the path through the Sodium layer, based on the remaining laser energy and the Sodium density. This results in a column of point sources that radiate some light back towards the main telescope, forming a laser guide star. Adaptive Optics systems use a wavelength filter to optically separate light from the laser guide star from the sources of scientific interest and natural guide star(s), and feed it to a laser guide star wavefront sensor (LGS WFS).

Shack-Hartmann wavefront sensors are based on lenslet arrays and imaging detectors such as CCDs. In essence, the pupil of the main telescope is divided into small patches, typically 100 to 200mm across. Each lenslet transforms the tip and tilt of the wavefront over the patch into a spot on the detector. Deviations in the spot positions gives an absolute measurement of the local tip and tilt of the wavefront. All lenslets in the WFS are observing the same LGS, but they

each have a slightly different point of view, as illustrated in Figure 1. In the era of extremely large telescopes the size of the primary mirror is significant compared to a 15km long source 90km away. For a 25m diameter telescope, the spot elongation for the lenslet the furthest from the laser launch location will be 9.5". In contrast, a natural guide star spot has a typical size of 1".

Figure 1: Column structure of the laser guide star source in the atmosphere and the variation of the angular size of the source with position in the telescope pupil.

Lenslets that sample the pupil far from the location of the laser launch telescope resolve the vertical structure of the LGS producing an elongated spot on the WFS detector, as shown in Figure 2. This distributes the signal from the LGS over more pixels than would be the case for an unresolved spot, increasing the error in spot position measurements and limiting the range of tip and tilt that can be measured without clipping of the input. Clearly the elongation of the spots has implications for the algorithms applied to WFS data for wavefront correction.

Figure 2: A distorted wavefront incident on the lenslet array of a Shack-Hartmann wavefront sensor (left) and the elongated spots in the image plane resulting from a laser launch telescope effectively located near the top edge of the pupil (right).

EMULATING ELONGATION

In order to emulate laser guide stars in a lab, an optical system must be designed that scales the telescope-atmosphere system down to fit on an optical table and match the physical pixel size of available detectors. The telescope in this case is the Giant Magellan Telescope (GMT). The details of the optical design are not presented here, but suffice it to say a 10km LGS column maps to a small fraction of a millimeter in the lab. While no lab light source has the intrinsic physical structure required, an effective source can be generated by moving a point source during an exposure. For the range of travel and precision required a laser LED fed fibre is mounted on a precision piezo XYZ-stage. The position is set by an analogue input voltage for each of the stage axes. As well as moving the stage, the intensity profile of the source can also be controlled by modulation of the laser diode drive current. Many COTS laser LED controllers support current modulation via analogue input voltage signals. This scheme was used as it consolidated the LGS control scheme into four analogue voltages.

The point of adaptive optics is to correct wavefront errors introduced by atmospheric turbulence. The time variation in this turbulence is dominated by movement of layers of the atmosphere, driven by winds. In a lab experiment turbulence is usually introduced by movement of phase plates. These optical elements have specifically structured optical aberrations. In the GMT emulation system three separate phase plates are used, each mounted on a rotary stage. Suitable placement of the stage along the optical axis sets the equivalent altitude of the turbulent layer. The rate of rotation of the stage sets the windspeed.

An adaptive optics system for the GMT will need to have a control loop rate of at least 500Hz. With an emulated LGS the loop rate is limited to about 1Hz. In each cycle an exposure is taken for each LGS. During the exposure the position of the source and the source intensity are varied to emulate a LGS. When the exposure is complete the source is moved to the starting point of another LGS. At the end of each cycle the phase plates are rotated through the small angle corresponding to the wind speed and the control loop rate under test. This changes the wavefront at the WFS which affects the location of the spots on the image detector. The images recorded at each cycle are processed to compute the wavefront error and ultimately drive wavefront correction for closed loop control.

ARCHITECTURE

The LGS emulation system is one part of a general optomechanical control system. The primary user requirements driving the software design were to enable simple integration with AO algorithms written in high-level languages, have the flexibility to redeploy the components for other experiments, and to be able to operate the system remotely. This naturally leads to a layered service-oriented architecture with minimal coupling between components at the low layers. It was also highly desirable to implement the lower-level control soft-

ware for the Linux OS and utilize open source components. This guided selection of the hardware that interfaces with the lower layer control computer(s). An overview of the architecture is given in Figure 3.

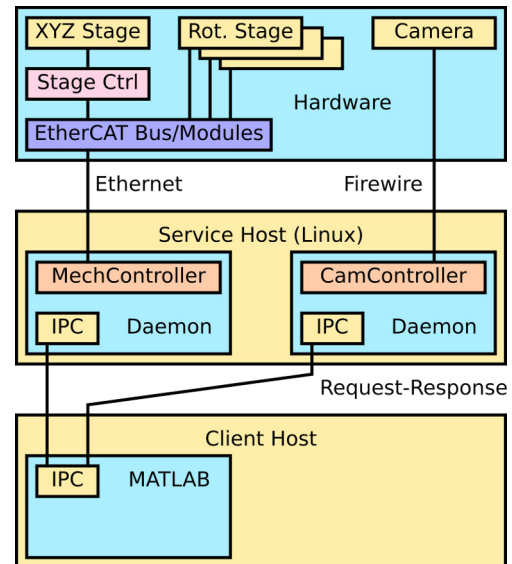

Figure 3: An overview of the hardware and software architecture of the control system.

System

From a control perspective, the rotary stages carrying phase plates are simply bipolar stepper motors and a home position indicator. Similarly, generation of an LGS profile amounts to generation of a four channel analogue output voltage signal. The EtherCAT fieldbus technology was chosen to implement all of these hardware controls, with all modules connected to a single bus coupler. This allows utilization of the open source Etherlabs IgH EtherCAT master and low level control from a Linux host. A digital output module was also included to allow the exposure of multiple cameras to be synchronized via the external trigger mechanism, and to implement laser safety interlocks.

The imaging devices at the core of the LGS WFS, and at other places in the optics, were selected based on pixel size, array size, readout noise, the maximum exposure time and cost. Although many camera interfaces are supported under Linux, cameras from Point-Gray Research with firewire interfaces were chosen. The open source dc1394 library was utilized to control and acquire data with these cameras.

Software

The software architecture follows object oriented design principles within the service and hardware interfacing layers. Each significant hardware component is encapsulated into a single service. All services utilize a common architectural framework. The service level is structured around a multi-channel request-response communication pattern. Each channel services requests sequentially and blocks while a request is being serviced, but the channels themselves are

independent and operate asynchronously. The framework requires each service be classified as a specific type of abstract controller, derived from the pure virtual Controller base class. Image devices are classified as CameraControllers and the LGS and phases plates are bundled together as a MechanismController. Communication channels accept request messages, parse them, and instantiate concrete classes derived from the Request class. The double-dispatch mechanism underpinning the *Visitor* design pattern [1] is used to deliver specific requests to specific controllers. The controller services the request and delivers a concrete instance derived from the Response class back to the communication channel. Responses are loosely coupled to the request type but strongly coupled to the nature of the data that needs to be delivered back to the client. The Request, Controller and Response class hierarchies and the communication channels provide the software infrastructure of each service. Each of the abstract controller classes declare a virtual interface that has a one-to-one mapping to a subset of the concrete request types. The request types encapsulate a single logical operation applicable to the hardware involved. For example, the camera controller has methods that commence an exposure, retrieve the image data from a completed exposure and attempt to abort an active exposure. The mechanism controller class is more generic. Its interface supports homing and positioning stepper motors and analogue signals.

A concrete class derived from one of the daughter classes of Controller is implemented for each type of hardware interface. It is at this layer in the software that thread-safe access to hardware is implemented. For example, the firewire cameras are all supported by the Dc1394Controller class via the dc1394 API, with pthread primitives utilized to ensure asynchronous requests from different channel have well defined behaviour. A simplified class diagram for the core classes and concrete classes utilised for LGS emulation are given in Figure 4.

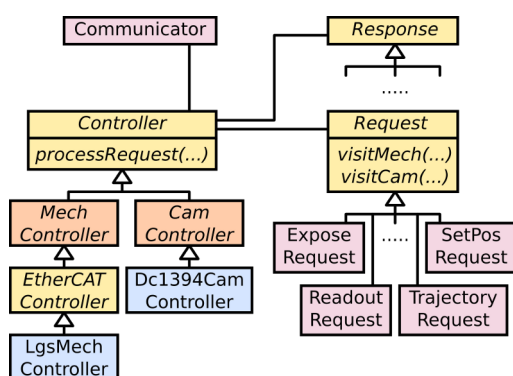

Figure 4: A compact class diagram for the laser guide star emulation services. Concrete classes from the framework are shaded in pink. The hardware specific classes that apply to a single service are shaded in blue.

Each service is implemented as a traditional unix daemon, instantiating a single concrete controller class and a single multi-channel communication class. The communication class provides the client-server support that facilitates remote

operation. A simple message protocol has been implemented on top of the 0MQ (ZeroMQ) API and its REQ-REP pattern. A unique port number is used for each communication channel.

Integration of one or more services into high level languages is based on a thin client C-API and the ZeroMQ library. Each function in the C-API constructs a request message, sends this to the appropriate service, and decodes the response. The interface for MATLAB is based on the MEX function mechanism and is built on the C-API. The MEX interface was utilized from the outset for alignment of the optical system, calibration and general instrument commissioning. An example WFS image verifying the instrument and control system has the capabilities required to emulate a laser guide star is shown in Figure 5.

Figure 5: Data obtained from a WFS camera showing elongated spots as a result of moving the source and modulating its intensity during the exposure.

CONCLUSION

A modular service-oriented control system has been designed and developed to emulate the physical properties of laser guide stars. The hardware interfacing layer runs on the Linux operating system and leverages COTS hardware and open source software. A thin-client request-response communication model facilitates integration into high-level applications with a single third-party library, the only added dependency for the client. Initial results from a Shack-Hartmann wavefront sensor demonstrate that the extended physical structure of a laser guide in the upper atmosphere can be successfully emulated in the lab.

HOT CHECKOUT FOR 12 GeV AT JEFFERSON LAB*

R. Slominski, JLab, Newport News, VA 23606, USA

T. Larrieu, JLab, Newport News, VA 23606, USA

Abstract

A new hot checkout process was implemented at Jefferson Lab for the upgraded 12 GeV accelerator. The previous process proved insufficient in the fall of 2011 when a fire broke out in a septa magnet along the beam line due to a lack of communication about the status of systems. The improved process provides rigorous verification of system readiness thus protecting property while minimizing program delays. To achieve these goals, a database and web application were created to maintain an accurate list of machine components and coordinate and record verification checks by each responsible group. The process requires groups to publish checklists detailing each system check to encourage good work practice. Within groups, the process encourages two independent checks of each component: the first by a technician, and a second by the group leader. Finally, the application provides a dashboard display of checkout progress for each system and beam destination of the machine allowing for informed management decisions. Successful deployment of the new process has led to safe and efficient machine commissioning.

to obtain verbal confirmation from the multiple group leaders of the readiness of their systems. This approach was appropriate for shorter downs where few changes were made to the machine as the RECO did not have the authority or resources to ensure the groups responsible for the machine were meticulously verifying component status. A committee was formed to address the shortcomings of the RECO and produce a more stringent process and associated software tool [2].

Figure 1: Septa magnet MYR7S03 fire damage.

INTRODUCTION

Hot checkout (HCO) is the process by which all required accelerator hardware and software systems are tested for safe and effective accelerator operation prior to beam startup. Checks are performed while the machine is locked up and energized. The goal of HCO is to reduce program interruptions due to faulty or misconfigured hardware and software and to minimize the likelihood of a failure that damages equipment. Such an event occurred at Jefferson Lab (JLab) on October 14 2011 after a small number of preliminary 12 GeV upgrade changes had been put into place. Two septa magnets overheated and ignited a fire causing both program delays and property damage (Fig. 1). The low conductivity water valves for the magnets were closed and the thermal switches on the box supply that normally would trip on an over-temperature fault failed because the switch was disabled via a jumper. The root cause was determined to be inadequate communication of machine readiness and poor work control practices [1].

More extensive changes to the machine, and thus more complicated hot checkouts during the upcoming 12 GeV era were going to need strict oversight. At the time of the magnet fire there was no formally documented procedure for HCO. The previous approach relied on a single individual, the so-called Restoration Coordinator (RECO)

PROCESS OVERVIEW

The new HCO process can be organized into three stages: setup, upkeep, and signoff. The initial setup stage involves documenting components and their properties and only has to occur once. The upkeep stage is on-going and ensures the data put in place during setup remains up-to-date. Upkeep tasks often coincide with accelerator maintenance periods and include preparation for each signoff period. The signoff stage entails checking component readiness and occurs immediately before resuming beam operations after an extended accelerator maintenance period. In practice the signoff stage is usually done twice a year: once before the fall run and again before the spring run.

Scope

The rigorous HCO is reserved for use following extended maintenance periods of a week or more. The HCO process is not used during machine running to track downtime as the HCO process is not designed to be a repair log. There is a separate process and tool for tracking downtime at JLab during machine operation [3]. The HCO process is analogous to an aircraft pre-flight checklist process: once the plane is in the air the checklist is no longer useful.

*Authored by Jefferson Science Associates, LLC under U.S. DOE Contract No. DE-AC05-06OR23177

Furthermore, the HCO process focusses primarily on protecting equipment and reducing operational downtime; it coexists with the personnel safety system (PSS) certification process which remains the primary means for protecting people.

Setup

During setup all of the components in the machine that require checkout must be identified and classified. Components are organized into collections labeled as systems. Systems are further organized into a hierarchical tree of categories based on type (Fig. 2).

Components are placed together in a system if they are of a common type, share the same set of responsible groups, and use the same verification checklist. Placing components into systems helps responsible groups search and filter the large list of components, allows tracking of checkout progress based on systems, and avoids explicitly assigning an often redundant set of responsible groups to each component.

Two other properties of each component are established during setup: the region the component is located in and the set of beam destinations the component participates in. Both of these properties provide additional filters for searching for components and tracking progress. Providing the ability to determine readiness based on beam destination is particularly important since one or more of the experimental halls are often not included in the program and therefore are not needed to be ready for operations when other halls are.

Every group must publish a checklist for each system of components that it is responsible for. The checklist documents how the group determines that each component in the system is ready for beam operations. The checklists are web-accessible by all staff members.

Upkeep

One of the biggest upkeep tasks is ensuring that signoffs are downgraded when needed. Downgrades can occur at any time during the hot checkout process and by any staff member. When one group downgrades a component, the action will cascade to subsequent groups and require them to re-validate their prior checkout. Downgrades are also done administratively during maintenance periods when components are replaced, moved, or repaired. The JLab task tracking system, ATLis, is reviewed by management prior to a signoff period to determine what needs to be downgraded and re-checked.

On-going upkeep of component lists, component beam destination participation, responsible group assignments, checklists, and system and category organization is also necessary. Responsible groups must notify administrators if components are added, removed, or modified. Geographic integrators also play an important role in ensuring the list of components and their attributes is up to-date.

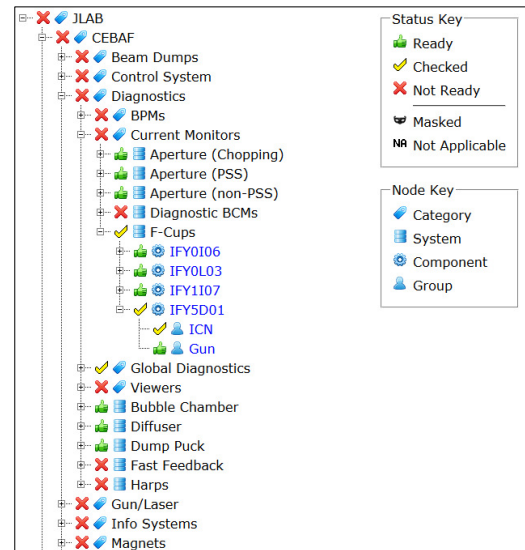

Figure 2: The component hierarchy as viewed from the HCO web application.

Signoff

Signoffs are done by responsible groups and require at least two checks per group. Each group indicates whether a component is ready, checked, or not ready. The typical flow is for a technician to verify a component and mark it as checked. A group leader then only marks a component as ready after conferring with the technician or after putting a second set of hands on the component. Only a group leader is authorized to mark a component as ready. Signoffs are recorded with a digital signature, timestamp, and optional user comment. Any user can make a comment without changing the signoff status. The history of all signoffs is recorded in the database and exposed via a web-interface for easy auditing.

Category readiness is determined by aggregating the readiness of the systems and components it contains. A component is ready once all responsible groups have signed off on the component as being ready. A system is ready once all of the components which it contains are ready. A category is ready only once all of the systems which it contains are ready. Given ready = 1, Checked = 2, and Not Ready = 3; the status calculation can be generalized as the following recursive algorithm: the status of a given node in the tree is the maximum status of its child nodes and in the base case of a component leaf node the status is set by the maximum of the responsible group signoffs. This hierarchical status roll-up allows users to quickly drill down to components which are not ready. Component attributes can be used to filter readiness for a particular beam destination, region, or responsible group.

There are two special signoff statuses: masked and not applicable (N/A). The operations director is given the administrative authority to mark as masked certain components which are not needed for safe machine operation. This is useful for example when a diagnostic that is not required for the upcoming run is non-

functional. The N/A signoff is used in situations where subsets of components in a system belong to different responsible groups. The non-responsible group signs N/A on the components it does not check. Masked components and N/A signoffs are ignored when computing the system/category status roll-up.

DATABASE

The new HCO process relies on readiness information stored in a centralized relational database. The initial list of component names was obtained from the JLab CEBAF Element Database (CED) [4]. The CED contains approximately 86% of the HCO components (7,403 of 8,644 as of September 2015). The remaining 14% (1,241) of components were obtained by soliciting group leaders and geographic integrators to verify the list of components and fill in any gaps. The components which require checkout, but are not in the CED include items that are not part of the EPICS control system, such as HVAC and other facilities items. Scripts were written to keep the databases in sync and are run periodically, especially before a checkout period.

WEB APPLICATION

The HCO web application provides a readiness dashboard for operators, management, and responsible groups to track checkout progress. The components in the machine are presented using a hierarchical tree widget that allows filtering by beam destination, region, and responsible group.

The application also provides graphical reports, a checklist repository, and a form for groups to sign off on individual components or collections of components. The

application requires a published checklist for every system from each responsible group. The software will not permit a group to signoff components until the checklist for the systems is published. Further, the application maintains a list of group leaders and enforces that only they are authorized to signoff as ready.

A setup page provides forms for administrators to add, remove, and edit components and their properties, as well as manage beam destinations, regions, group leaders, and systems/categories.

INITIAL USAGE

The HCO process and software were utilized for the first time in September 2013 with the commencement of the 12 GeV upgrade commissioning. Figure 3 illustrates how as the HCO process progressed and new regions of the machine were verified as ready, project milestones were rapidly achieved. In fact, the accelerator division program goals for 2014 were completed five months ahead of schedule [5].

PROCESS PARTICIPATION

The HCO process has been a demonstrated success at involving a wide swathe of the lab personnel in a cooperative effort. To date, there have been 19,789 signoffs by 132 users across 43 groups. A common goal of achieving 12 GeV upgrade project milestones coupled with the recent collective memory of the YR magnet fire helped imbue staff with an early sense of common purpose. The early involvement of as many people as possible in the process design helped in creating buy-in and cooperation. Encouraging continuous feedback and improvement kept everyone engaged and has led to a better process.

Figure 3: 12 GeV Commissioning Run I and II Progression. The yellow and green areas trace progress of verifying each component as checked and then ready. (Illustration reproduced with permission courtesy of A. Freyberger).

SUPPORTING PROJECTS

Several supporting projects were developed in parallel with the hot checkout process. The JLab wireless network infrastructure was upgraded to cover nearly the entire underground tunnel and a half dozen tablet computers were made available for technician use. The mobile computers allow technicians to view checklists and sign off on components while standing directly in front of the component in question. The Accelerator Bypassed-Interlocks Log (ABIL) project helps operators and technicians communicate bypassed component status using a digital log of bypassed components and physical tags placed directly on bypassed components.

CONCLUSION

We have developed a systematic method of checking, recording, and sharing machine readiness. The new process and software tool guides communication among operators, technicians, group leaders, geographic integrators, and management decision makers. The web-based tool provides a dashboard with real-time status reporting. The new process and tool contributed to a smooth 12 GeV upgrade project commissioning.

ACKNOWLEDGMENT

The JLab hot checkout committee is led by K. Baggett and comprised of T. Larrieu, R. Lauze, R. Michaud, R. Slominski, and P. Vasilauskis.

DRIFT CONTROL ENGINES STABILIZE TOP-UP OPERATION AT BESSY II*

T. Birke[†], F. Falkenstern, R. Müller, A. Schällicke

Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany

Abstract

Full stability of orbit and bunch-by-bunch-feedback controlled top-up operation becomes available to the experimental users only if the remaining slow drifts of essential operational parameters are properly compensated. At the light source BESSY II these are the transversal tunes as well as the path length and energy. These compensations are realized using feedback control loops together with supervising state machines. Key to the tune control is a multi source tune determination algorithm. For the path length correction, maintenance of beam energy and reduction of orbit deviations empirical findings are utilized.

INTRODUCTION

At light sources, capabilities for user experiments rely on source point position, pointing stability as well as stable beam size and shape. These parameters transform to electron beam orbit and tune stability, typically controlled by slow (SOFB) and fast (FOFB) orbit correction feedback installations and by insertion device (ID) focusing feedforward compensations.

The intrinsic stability of the storage ring is greatly enhanced by the thermal equilibrium provided by top-up operation. In consequence correction amplitudes of beam guiding and shaping systems are drastically reduced, and beam quality can be better maintained by the described means.

Nevertheless, new constraints are imposed by the top-up injection permission, the technical solution implemented for FOFB and the stability requirement for efficiency of the Bunch by Bunch FeedBack (BBFB) [1] and for the amplitude of the resonantly excited bunch used for pseudo single bunch pulse picking. At BESSY II, additional control tools are needed to keep tunes, orbit and energy stable within required limits.

MOTIVATION

The ID-tune-feedforward system compensates the baseline tune shifts produced by gap and shift movements of any ID. This feedforward system interpolates empirically produced tables generated and iterated during measurements in dedicated ID-commissioning runs. Nevertheless imperfections and multiple IDs moving gaps and shifts at the same time would still cause significant tunes-shifts if not taken care of.

The purity of the camshaft bunch in the ion-clearing gap is controlled by a vertical knock out kicker. The resonant

vertical beam excitation pulse during the gap around the camshaft bunch (see range marked blue in Figure 1) has to be very short to minimize perturbation of the camshaft bunch. So the kicker is active only for a few damping times at the injection shot. It has to be very efficient to prevent accumulation of charge in bunches to be cleared: If accumulated charge is cleared later when exact resonance condition is reestablished this might result in a shot injection efficiency below the allowed limits. Thus perfect matching of the excitation frequency and the vertical tune is needed to ensure excellent knockout efficiency.

Damping capability of the BBFB systems and the appropriate operational safety margin are well guaranteed as long as the tunes are constant.

Frequency and amplitude of the incoherent excitation for Pulse Picking by Resonant Excitation (PPRE) [2] have to match a specific frequency at the slope of the horizontal tune synchrotron sideband. Even tune shifts of about 500 Hz have severe impact on excitation effectiveness and stability of the PPRE bunch (see Figure 2).

Path length drifts were compensated by the slow orbit feedback (SOFB) by integrating the RF frequency into the horizontal response matrix and minimizing average horizontal corrector strength in the SVD calculation at each step. However, a straight forward implementation of this scheme was not possible with the fast orbit feedback system (FOFB).

Figure 1: Fillpattern in standard multi- and single bunch hybrid mode, serving both average and timing mode experiments. A multibunch fill of 300 bunches including 3 bunches for fs-slicing experiments with an ion-clearing gap of 200 ns (100 buckets). A camshaft bunch at a fixed position in the center and a PPRE bunch close to the end of the gap - both for pseudo single bunch experiments. The blue region on both sides of the camshaft bunch is the cleared by resonant RF knockout during every injection shot.

TRANSVERSAL TUNE MEASUREMENT

Input Signals

Beammotion over a wide frequency range up to 1250 kHz is measured at a crossed stripline with a fast ADC/PXI system running LabVIEW. A processed FFT is provided to the control system in 3 partial ranges for each horizontal, ver-

* Work funded by BMBF and Land Berlin

[†] thomas.birke@helmholtz-berlin.de

tical and longitudinal tune with a resolution of 80 Hz. The measurement system delivers a sliding average of FFT data within each partial range of the spectrum, at a 10 Hz rate.

For standard optics as well as low- α optics, the coarse region of interest of the measurement system has to be set up to properly contain the main tune as well as the synchrotron sidebands of the desired transversal tunes.

Figure 2: Typical horizontal tune spectrum - top: without PPRE excitation; center: with PPRE enabled; bottom: from bunch by bunch feedback with PPRE enabled.

The regular tune spectrum (top plot in Figure 2) has a slight asymmetry because the shifted tunes of high current bunches add a tilt to the spectrum.

Besides any possible unwanted distortions of the tune spectrum, there are inevitable additional types of beam motion e.g. due to the horizontal resonant excitation of the PPRE bunch (see Figure 1 and center plot in Figure 2). This excitation can make the actual horizontal tune impossible to determine by only analyzing the measured spectrum.

Tune-finder Strategies

A regular undistorted tune spectrum shows a peak at the mean tune of all bunches as well as two typically smaller peaks of synchrotron sidebands. In many situations, a simple peak finder is sufficient to identify the correct tune, but other non-tune-related beam motion may distort the spectrum and hence make the main tune hard to detect. Narrow-band distortions can easily be eliminated by removing outliers applying a smoothing algorithm to the spectrum. Since the main tune is not guaranteed to be the highest peak in the spectrum, a simple peak-finder often fails to identify the correct tune.

During pseudo single bunch experiments using PPRE, the motion of the excited bunch adds a major peak to the horizontal tune spectrum (see center plot in Figure 2). This may render a successful identification of the correct tune impossible, using the standard mechanism.

The horizontal BBFB system detects the motion of this bunch and delivers a spectrum showing the horizontal tune and sideband frequencies as notches and the excited PPRE bunch as a peak (see bottom plot in Figure 2) as the PPRE bunch is excluded from active damping. Consequently, switching tune-measurement to use the BBFB system as a source provides a stable and reliable determination of the tune during runs with PPRE enabled by performing simple notch-find on the selected region of interest within the horizontal BBFB system.

Depending on the scheduled optics and fillpattern, one of four algorithms is selected for each plane to determine the main transversal tunes from raw tune measurement FFT data. All these tune-finder strategies are working on a configured region of interest of the spectrum (see Figure 3).

Use BBFB peak- or notch-finder Used if spectrum is distorted by active excitation e.g. during PPRE runs.

Simple peak search Finds the maximum value.

Peak search after smoothing While searching for the maximum value, this algorithm eliminates outliers by applying a simple smoothing algorithm with configurable window-width.

Area above threshold A simple pattern search (three equidistant peaks with the center one being the main tune) turned out to be a too simple approach to provide stable results. Instead, finding all identifiable peaks and selecting the one with biggest area below has proven to be a more reliable method. The threshold in this case is a minimum attenuation level att_0 where all relevant peaks are $att > att_0$.

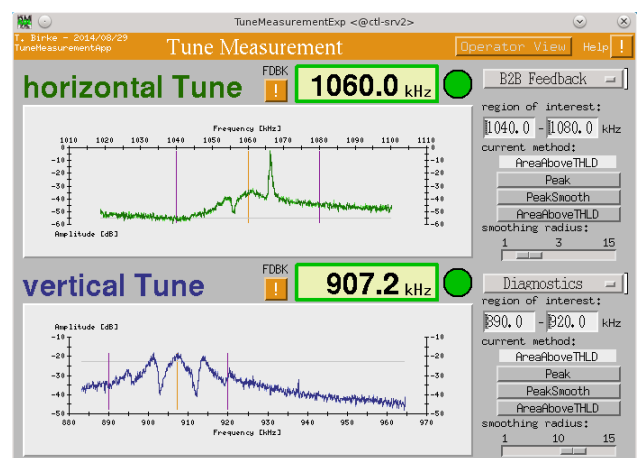

Figure 3: Tune measurement control panel - purple lines mark the regions of interest and a red line marks the identified tune for easy verification by operations staff.

Since injections appear as a major distortion in the measured beam motion, evaluation of FFT data and determination of tune values is paused for a configurable time during and after injections until the distortion is no more present in the smoothed spectrum.

TUNE FEEDBACK

Once a reliably working tune measurement is established, it opens the possibility to setup a feedback system to keep the measured tune at its desired frequency. This way slow thermal drifts as well as residual tune shifts from ID movements can be compensated.

The transversal tune feedbacks are implemented to permanently monitor the motion of the measured tune as well as the difference from the configured target tune. Once, the difference exceeds a defined limit and tune motion is below a certain threshold, a configurable partial correction of the tune is applied. Subsequently, the resulting measured tune is checked for successful correction. If a correction was successful, further partial corrections are applied if necessary until the measured tune matches the target tune (see Figure 4).

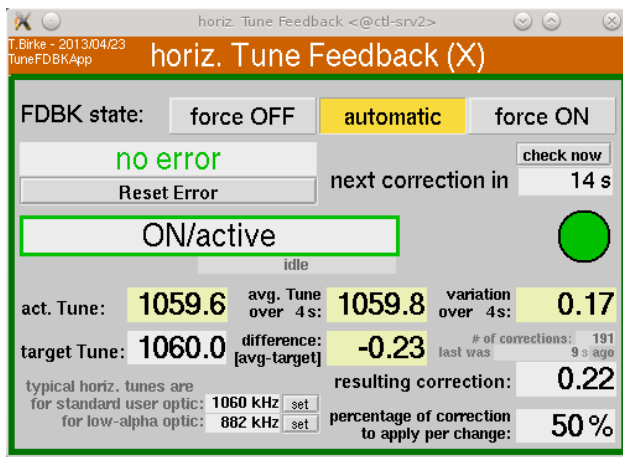

Figure 4: Tune feedback control panel.

User Level Configuration

The basic configuration parameter of the tune feedbacks is the target tune.

Some low-level configuration values control if, when and how any correction steps are performed. Tune corrections are inhibited temporarily

- For a specified time before and after injection shots, to not risk degradation of efficiency by applying a correction during an injection shot.
- When ring current does not exceed a minimum limit.
- If the measured tune varies more than a certain amount within the last few seconds, to not add additional noise.

Also configurable is the time delay between a adjustment step and the check for a successful correction.

To avoid applying additional noise, tune adjustments are performed at a maximum rate and only if a minimum step width is exceeded.

ISBN 978-3-95450-148-9

Error Handling

The following conditions lead to an error and the tune-feedback loop stops processing until error conditions are fixed and the feedback is reset manually. This measure is taken because distortions of the tune spectrum may cause the tune measurement to fail in identifying the correct tune. In this case, excess corrections may move the real tune to areas where subsystems relying on a stable tune won't work properly anymore. The tune may even approach a resonance, which could cause a partial or complete beamloss.

Error conditions are:

- Measured tune identified outside allowed window around target tune triggers a *"too much to correct"* error. The allowed window is small enough to not include the synchrotron sidebands.
- Correction step did not result in tune shift towards target tune causes a *"bad correction"* error.
- Variation of measured tune permanently exceeds a defined limit and hence leads to a *"measurement error"*. The tune determining algorithm could not identify a stable and reliable tune.

All these error conditions cause alarms to be signaled and an appropriate message sent to operators. Manual intervention and re-activation of TuneFDBK is necessary.

PATH LENGTH CORRECTION

Path length drifts are to be compensated by adjusting the RF master oscillator accordingly and hence keep the stored beam energy stable at a desired point.

Since FOFB cannot adjust the master oscillator directly, it instead uses corrector magnets to compensate for path length drifts and to keep the beam centered and stable. Over time excess strength in two corrector families accumulates.

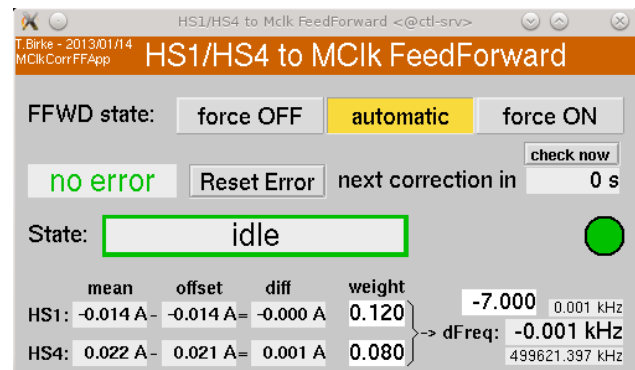

Figure 5: master oscillator FeedForward control panel.

A companion system for FOFB has been implemented, that transfers these excess corrector settings into RF frequency changes according to previously observed relations, and applies these changes "cautiously" (Figure 5). The relation between these corrector settings and the corresponding

Figure 6: Plot of ~400 path length corrections over 5 days after one week of low current low- α operation. Shown are sum of the weighted excess corrector settings and the resulting RF frequency. BPM RMS and mean values are stable within $\sim 1 \mu\text{m}$.

RF change necessary, have been found empirically and is documented in [3, 4].

This companion system is implemented as a feedforward mechanism, that calculates the difference of the average corrector settings per family to a reference offset value. The results are weighted and transformed into a corresponding RF master oscillator change.

As the changes are applied, FOFB takes back the excess corrector settings applied previously.

Besides the influence of slow thermal drifts, driving undulators to small gaps and driving orbit bumps for PPPE experiments have the biggest share on path length changes (Figure 6).

Error Handling

After every adjustment of the master oscillator frequency, the corrector settings are checked. If FOFB did not respond to the RF change by taking back corrector settings, a "bad correction" error is raised, operators are notified by the global alarm handler and further corrections are stopped until manual reactivation.

Run Conditions

Some preconditions have to be met to allow path length corrections to be performed.

- FOFB has to be active and running
- ring current has to exceed 50 mA during multibunch and 11 mA during singlebunch runs
- the last injection shot was more than 3 seconds ago

Cautious application of changes is realized by scaling down the determined necessary frequency change (currently by a factor of 7).

A correction step is initiated as soon as the necessary change of the master oscillator frequency exceeds 1 Hz (RF frequency: 500 MHz). The real window width of ± 7 Hz corresponds to a path length window of $\sim \pm 3.5 \mu\text{m}$.

CONCLUSION

The sketched setup of beam motion measurement, tune identification and tune-drift compensation has reliably stabilized operation at BESSY II. All other systems, that need stable tunes to work properly, benefit from basic beam properties.

Path length corrections have been applied flawlessly since FOFB is in use at BESSY II, and the resulting changes applied to RF master oscillator well reflect e.g. thermal drifts during accelerator startup and the seasonal and weekly changes of the outside temperature.

Performance and stability of top-up operation benefits from both drift control engines, and specialized setups for time resolved experiments heavily depend on these stabilized beam conditions.

EUROPEAN XFEL CAVITIES PIEZOELECTRIC TUNERS CONTROL RANGE OPTIMIZATION

W. Cichalewski, A. Napieralski, LUT-DMCS, Lodz, Poland
J. Branlard, C. Schmidt, DESY, Hamburg, Germany

Abstract

The piezo based control of the superconducting cavity tuning has been under the development over last years. Automated compensation of Lorentz force detuning of FLASH [1] and European XFEL [2] resonators allowed to maintain cavities in resonance operation even for high acceleration gradients (in range of 30 MV/m). It should be emphasized that cavity resonance control consists of two independent subsystems. First of all the slow motor tuner based system can be used for slow, wide range mechanical tuning (range of hundreds of kHz). Additionally the piezo tuning system allows for fine, dynamic compensation in a range of 1 kHz. In mentioned pulse mode experiments (like FLASH), the piezo regulation budget should be preserved for in-pulse detuning control. In order to maintain optimal cavity frequency adjustment capabilities slow motor tuners should automatically act on the static detuning component at the same time. This paper presents work concerning development, implementation and evaluation of automatic superconducting cavity frequency control towards piezo range optimization. FLASH and XFEL dedicated cavities tuning control experiences are also summarized.

INTRODUCTION

Both FLASH and European XFEL are free electron lasers facilities that build up accelerated beam energy using superconducting linacs. Superconducting cavities are or will be operated in pulse mode with 10 Hz repetition range and field gradients up to 30 MV/m. This work conditions causes extensive Lorentz force based reaction on the structure walls [3]. This cause mechanical deformation in range of few micrometers. For around 1 meter long, 1.3GHz resonant frequency, niobium resonator such a length change induces dynamic detuning modification in the range of couple hundreds of hertz. As cavities loaded quality factor is high (range from $3e6$ for FLASH to $4.6e6$ for XFEL) such misalignment results in significant accelerating field gradient drop. This have to be compensated by increase of supplying RF power - in order to maintain constant beam energy level. The other possibility to minimize this effect is external mechanical excitation provided by slow (step motors) and fast (piezo elements) cavity tuners.

MOTIVATION

Since fast tuners are foreseen for precise, in-pulse reaction to cavity dimension deviation their parameters have to be well recognized and adequately used.

Cavity Tuning Components Characterization

The European XFEL linac installation preparation includes also cryo-module testing phase [4]. Among the others also piezoelectric components are being characterized. One of test goal is to determine coefficient that describes relationship between piezo supply voltage and superconducting resonator frequency shift. The same study allows to verify both piezo elements (actuator and sensor) tuning range and voltage polarity (see Figure 1). Other (LLRF related) test

Figure 1: Piezo element tuning range characterization example (XFEL module XM51, cavity 3).

is dedicated to cavity slow motor tuners examination. This devices tuning range is not being verified (about hundreds of kHz). The cavity detuning in function of the motor position change is determined in order to evaluate transfer coefficient (like in previous test). Moreover motor backlash and movement hysteresis is determined. Exemplary measurement results can be found in Figure 2. All measurements results

Figure 2: Slow tuner motor behavior characterization (XFEL module XM51, cavity 3).

are stored in dedicated (PostgreSQL [5] based) database. This data will be used during the XFEL linac commissioning for optimal LLRF system configuration. Additionally this information is also vital for described piezo relaxation algorithm configuration.

Detuning Caused by LFD

Superconducting niobium cavity mechanical deformation can be caused (among the others) by high Lorentz force (LFD) acting on the resonator walls in presence of high accelerating field. In case of short pulse operation of TESLA based structures detuning caused by this phenomenon is often described by linear detuning change during RF pulse flat-top phase. Dependency between cavity field gradient and linear detuning is determined also in the scope of modules characterization (see Figure 3). As it is known the LFD

Figure 3: Static detuning change measured in function of cavity gradient.

is proportional to square of cavity gradient. The proportionality coefficient is determined during this tests. Typically this parameter has value in the range of $-(0.8-0.9)$.

Resonators Tuning Approaches

The cavity detuning is being controlled during RF pulse operation in order to minimize system power consumption. In case of resonator misalignment the accelerating field gradient loss is compensated by the RF power increase. The motor tuner can provide wide range of tuning while its reaction is a time consuming. That is why it can be used for static superconducting structure tuning. The piezo elements provide fast mechanical response (reaction time within RF pulse duration). On the other hand its range is often limited (typically around 1,2kHz). This system can be used both for static and dynamic tuning. Since LFD increases rapidly with accelerating gradient it is highly desired to preserve piezo system frequency shift capabilities to compensate for in-pulse detuning. LFD influence on the cavity operation is minimized by means of piezo components excitation that counteracts resonator dimension change in presence of high accelerating field. In this compensation approach the DC component of piezo voltage excitation is being used for static tuning while AC excitation (sin waveform shape) is used for dynamic misalignment handling. Piezo operation has been automated (for FLASH and AMTF facilities). The algorithm provides both static and dynamic frequency shift reduction

PIEZO RANGE OPTIMIZATION ALGORITHM

The piezo relaxation algorithm main goal is to minimize tuner driver DC stimulus to provide full voltage range for

AC signals (to maximize linear tuning boundaries). This requirement can be fulfilled by combined piezo and motor actions. Main idea of this application has been presented in Figure 4.

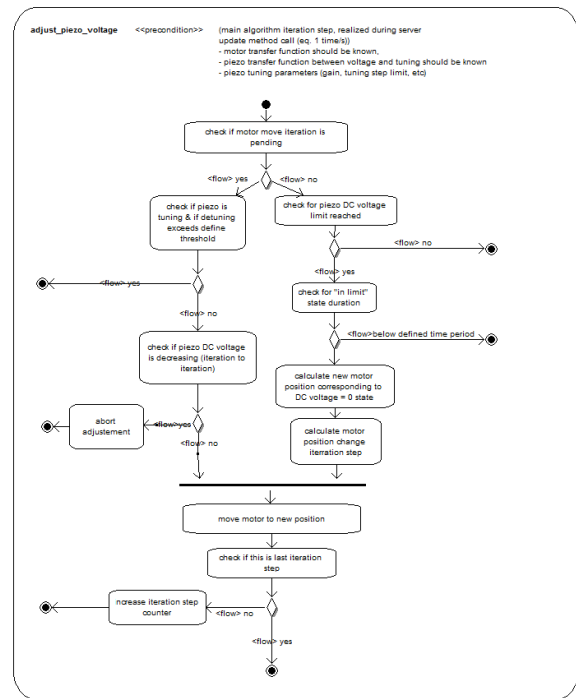

Figure 4: Piezo dynamical range optimization algorithm overview.

In the scope of this application DC voltage level is monitored. In case its value exceeds predefined threshold (near to the driver saturation) required cavity frequency correction is evaluated. Then the motor adequate position change is determined. New slow tuner settings are calculated according to the piezo tuning resolution and motor steps to cavity frequency modification factor (evaluated during module examination). Overall position change is then divided to several steps iterations. Individual iteration size is determined taking into account piezo automation algorithm ability of resonator tuning. One of the application requirement defines maximal deviation from resonance which is acceptable during relaxation actions. Constant monitoring of cavity behaviour allows for algorithm adjustment or termination in case of operation conditions change or exception occurrence. Application concludes after last iteration step execution. Afterwards system continues piezo operation status monitoring and performs range optimization as soon as DC voltage threshold is being exceeded.

ALGORITHM IMPLEMENTATION

The piezo range optimization algorithm has been developed and implemented as DOOCS server [6]. Application has been realized basing on the DOOCS framework. Piezo and motor operations are relatively slow process in comparison to fast LLRF feedback loop. That is why the server

has been prepared as a middle layer process. The server communicates with the LLRF diagnostics server in order to receive cavity detuning calculations readout (see Figure 5). Additionally it connects to the LLRF controller server that provides information about current piezo components drive settings. Since slow motor tuner acts as an actuator in this slow feedback loop also communication with motor management server is provided.

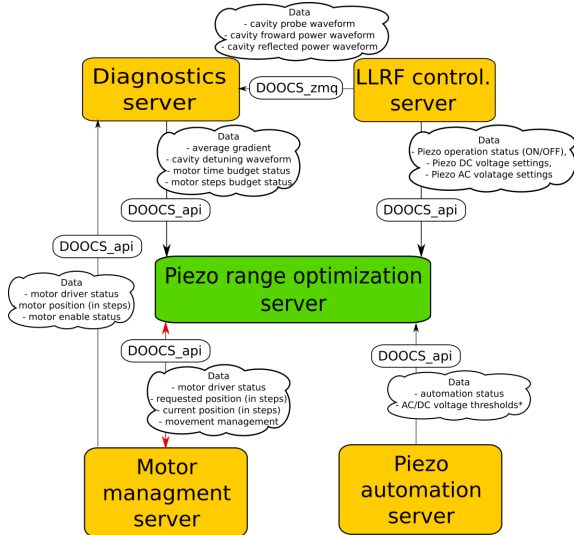

Figure 5: Server interconnections overview.

Server parameters configuration and management has to be performed by RF system users. In order to facilitate server management dedicated GUI (based on JDDD [7]) has been provided (see Figure 6).

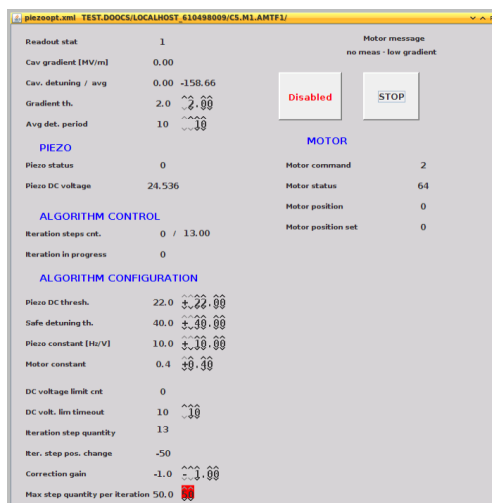

Figure 6: Example of expert GUI.

INITIAL ALGORITHM EVALUATION

Algorithm has been evaluated in the accelerator environment. The FLASH facility is not only FEL research centre but it is also commonly treated as a pilot project to XFEL.

That is why it has been perfect place to conduct study concerning future operation automation software component. First test have been performed for single cavity in accelerating module (ACC3). Initially (before algorithm execution) this resonator has been tuned and operated with gradient of 22 MV/m. The piezo automatic tuning algorithm have had been enabled to maintain resonance conditions. Test began with motor tuner position change which corresponded to 300Hz cavity frequency shift. As automatic tuning process caused piezo driver DC voltage increase and threshold violation the algorithm started motor readjustment. In case of FLASH and AMTF study it was observed that application moved step motor to the position corresponding to minimal DC voltage settings. At the same time boundary detuning deviation (configured by user) had been not violated. At the time of tests the algorithm has been extended by some exception handling mechanisms. The most important were:

- range optimization temporary blocking due to the motor steps budget defined for specific period of time,
- range optimization temporary blocking due to the motor operation time budget defined for specific period of time,

AMTF hosts temporally all cryomodules dedicated for XFEL for components examination. That is why piezo range optimization is integrated with the LLRF systems operating in this facility. Scenario of constant cavities gradient increase (during the quench level studies) is the best candidate for piezo range optimization algorithm usage.

CONCLUSION

Piezo based cavity tuning system is widely used during operation of TESLA cavities in high gradient conditions. Tuner range optimization for Lorentz force detuning suppression is a must in case of variable energy settings for the linac. Presented algorithm optimizes fast tuners dynamic range by means of slow motor system readjustment. Cavities characterization provide necessary data for best application configuration. Initial tests performed in accelerator environment proofs algorithm usefulness. That is why the decision has been taken concerning application integration in overall software framework for automatic tuners systems operation.

CONTROL SYSTEM OF RF STATIONS FOR NICA BOOSTER

G. A. Fatkin, A. M. Batrakov, I. V. Ilyin, M. Yu. Vasilyev, BINP SB RAS, Novosibirsk, Russia
G. A. Fatkin, NSU, Novosibirsk, Russia

Abstract

NICA (Nuclotron based Ion Collider fAcility) is an accelerator complex, which is being built in JINR (Dubna, Russia). The system described in this paper is controlling the RF stations of Booster, the first element of the NICA complex. Control System consists of two devices: Intellectual Controller and Tester module. The first one is designed for precise measurement of magnetic field, generation of the acceleration frequency in accordance with measured field and control of RF power and pre-amplifiers. Intellectual Controller is a real-time feed-forward system with $40 \mu s$ loop time. It is based on ARM microcontroller and bare-metal control programs are used to reach maximum performance. Approaches that were used to achieve maximum performance are elaborated and presented in this paper. The second part of system - Tester is a simulator for tuning and checking the RF stations before start of operations or in absence of real accelerator. The achieved accuracy in chain 'magnetic field' – 'acceleration frequency' is better than $5 \cdot 10^{-5}$. Plans on feedback incorporation to stabilize ion beam behavior via frequency and phase tuning are discussed.

are measured and set, they are presented at table 1. Both RF Controller and Tester modules use telnet over Ethernet interface for interaction.

Table 1: Input and Output Signals of Controller

Signal	Channels	Rate	Resolution
Output signals			
Master frequency	2	25 kHz	24
V cavity	2	25 kHz	12
I anode	2	100 Hz	10
Input signals			
Field sensor	1	25 kHz	18
V cavity	2	25 kHz	12
Phase difference	1	25 kHz	12
Phase bias	1	25 kHz	12
Frequency bias	1	25 kHz	12
V preamplifier	2	100 Hz	12
I anode	4	1 kHz	12
V rectifier	6	1 Hz	12
V filament	2	1Hz	12
Synchronization	7	N/A	N/A

INTRODUCTION

The superconducting accelerator complex NICA (Nuclotron based Ion Collider fAcility) is constructed in JINR, Dubna. Project aims to provide collisions of heavy ion beams in the energy range from 1 to 4.5 GeV/u at the luminosity level of $1 \cdot 10^{27} cm^{-2} \cdot s^{-1}$. The Booster is a cycling accelerator of $197Au^{32+}$ ions and serves as one of the elements in the injection chain. It accepts particles with energy 6.2 MeV/u, accelerates them and extracts with energy 600MeV/u to the next acceleration stage - Nuclotron [1].

RF subsystem of the Booster consists of: two cavities, two RF stations, intellectual controller and tester module. RF stations include power amplification cascades and low-voltage electronics. They provide 10 kV acceleration voltage in required frequency range (0.5-5 MHz) on cavity gaps [2]. Primary function of the controller is to generate master frequency depending on the current value of magnetic field. Inaccuracy of frequency setting must not be worse than $\pm 2 \cdot 10^{-5}$.

RF CONTROL STRUCTURE

RF control structure is shown on Fig. 1. Signals from induction sensor and synchronization pulses are passed through the Tester module to Controller. Tester module allows to substitute real signals with imitated scenario or to through-pass these signals. Frequency, phase and cavity voltages are adjusted according to measured magnetic field and acceleration stage. Other technological parameters

Controller Structure

Observing table 1 one may conclude that controller module must supply 4 fast (25 kHz) output channels and measure 6 signals with the same rate. Most calculations and data conversions will require floating-point arithmetic. It is also necessary to arrange data interchange between several independent measurement and control devices. E.g. to generate master frequency controller must receive data from measuring ADC, convert, correct and integrate the resulting value to attain field value then calculate frequency, apply necessary corrections, then convert it again and finally send this data to DDS. At the same time other signals must be changed and measured: cavity voltages, cathode currents, preamplifier voltages etc.

Probably betatron and synchrotron oscillations damping would be necessary for Booster. It is very hard to predict feedback parameters before Booster starts operation. Therefore we decided to implement feedback later using separate module which will provide frequency and phase bias analog signals.

Nowadays there are two main approaches for creation of such complex high rate systems: FPGA and high-end micro-controllers. Our reasons for choosing micro-controller were following: the need of floating point arithmetic, complex logic with different modes of operation that probably will require expansion and finally the need to provide TCP/IP interface for the interaction with Booster control system. At

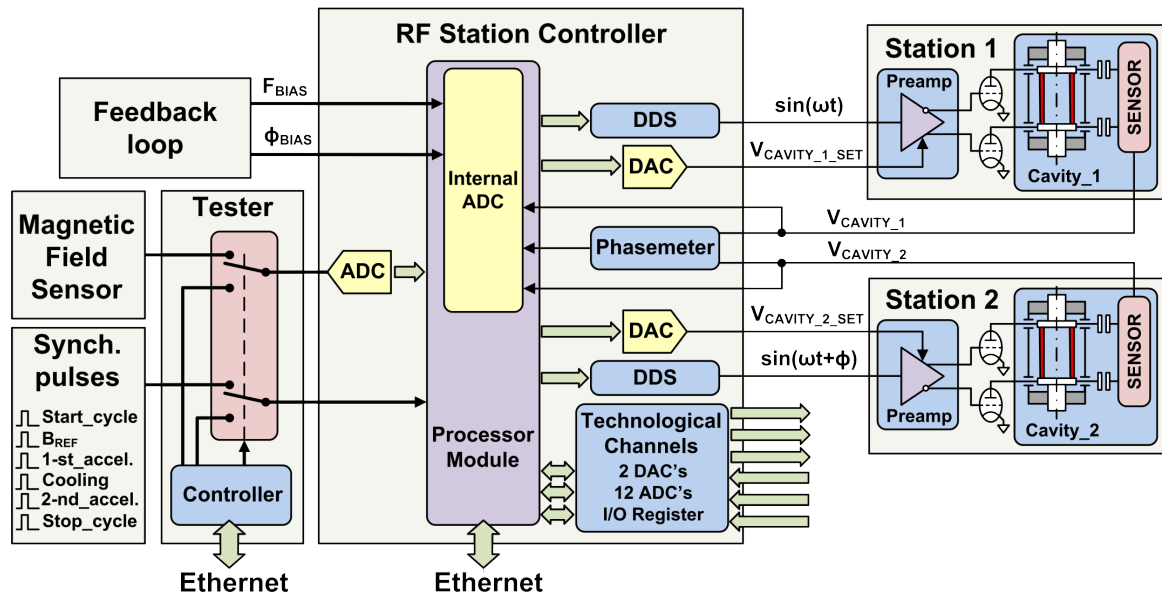

Figure 1: Radio frequency control structure.

the beginning of our work we planned to have Linux with tango-server on-board. Unfortunately we couldn't achieve necessary performance with any variation of Linux, so bare-metal approach was used.

Figure 2: Internal structure of the controller.

Structure of the controller is shown on Fig. 2. We used Atmel SAMA5D31 micro-controller. Availability of on-board 1 MHz 12 bit 8-channel ADC was a significant advantage. Usage of SAMA5D31-CK SO-DIMM board allowed us to simplify PCB design and accelerate production. Availability of different interfaces (I2C, SPI, UART, Ethernet) on this controller was a huge plus. It must be noted though that we had to give up usage of any (even real-time) operational system to provide necessary reaction rate with $40\mu s$ cycle. Apart from such bare-metal approach we had to thoroughly optimize our program code. Resulting algorithm is shown on Fig. 3.

Main cycle is realized using three routines. One of them is called "Fast cycle". It is initiated every $40\mu s$ by high-priority timer IRQ. Signal from inductive sensor is measured, derivative of frequency is calculated and passed to DDS. Fast signals (look at Tab. 1) are measured by ADC and generated by DAC's. Another one is "Synchronization" state machine. This state machine is operated by synchronisation I/O that generates low-priority IRQ. Last one is a "Slow cycle" which

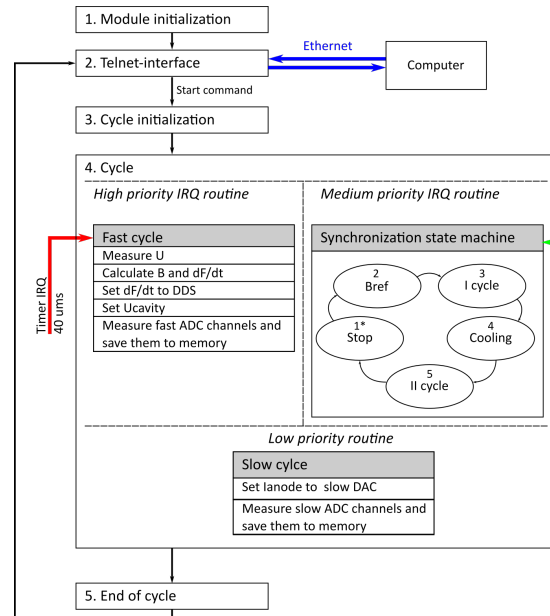

Figure 3: Program structure.

is a loop that measures and generates slow signals. This code works between the other two and thus strict synchronization couldn't be achieved, fortunately it isn't necessary.

Another restriction we had to establish is following: interaction with Booster control system using Ethernet protocol is available only between cycles, while in-cycle Ethernet controller is turned off. Apparently an ideal approach in such case would be the usage of 2-core microcontroller, or SOC with FPGA and ARM kernel e. g. CYCLONE V SOC. But when we started this work, boards like MITYSOM-5CSX on SODIMM were still unavailable. And PCB layout of CYCLONE V SOC is quite problematic in itself and was considered more tedious than program optimization.

Both tester and controller modules are managed over the Ethernet interface using text-based command protocol over telnet. RS-232 interface is provided for reprogramming and debug. Apart from adequate embedded programs, testing software was developed. This software will also serve as a reference for implementation of corresponding modules in NICA Booster control system which is based on TANGO [3].

Low Level Frequency Generation

Main task of the controller is to provide low-level sinusoidal signal with frequency in accordance with the magnetic field. The dependency can be presented in the following form:

$$f(B) = K \frac{aB}{\sqrt{b + CB^2}}, \quad (1)$$

where K - is the harmonic number, B - is magnetic field, and a, b and C are coefficients. We'll use Eq. 1 from now on.

Most common approach for the low-lever RF control systems nowadays is to generate sinusoidal signal using DDS (direct digital synthesis). Both specialized IC's and FPGA with DAC implementations are used. We decided to use latter because our system is based on microcontroller. To alleviate possible difficulties with inter-channel synchronisation two-channel AD9958 chip was chosen.

Actual signal from the inductive sensor is proportional to the change of magnetic flux over time. If the sensor is stationary, then the area is constant and signal U is proportional to the derivative of the magnetic field:

$$U = \frac{1}{\alpha} \frac{dB}{dt}, \quad (2)$$

where $\frac{1}{\alpha}$ is a proportionality constant.

Therefore to calculate B and for Eq. 1, one has to measure the following integral:

$$B(t) = \alpha \int_0^t U dt. \quad (3)$$

We can use several methods to generate master-frequency that varies according to the law Eq. 1. First of them is not to measure integral at all and work by a table instead. Actually if you have perfectly repeatable magnetic field source and perfect synchronisation, you can calculate values of $f(t)$ beforehand, put them in a table and generate them using DDS at appropriate moments of time. We can note that this approach doesn't require measurement of magnetic field at all. The downside of this approach is the complexity of creating sufficiently stable magnet power supply and providing necessary synchronisation accuracy [4].

Rather wide-spread method to measure integral at Eq. 3 is based on the use of voltage to frequency converters (VFC) followed by counter [5].

Other way to determine integral is to measure inductive sensor output voltage (i.e. derivative dB/dt) with the help of fast, precision ADC and then to sum the ADC samples in order to calculate the integral value. This method may be called "direct digital integration" [6]. Usage of the fast

precision ADC allowed us to use a specific method of frequency tuning to achieve higher accuracy. This method is described below.

Our Method of Frequency Tuning

As described previously, one of the approaches is to acquire field value, substitute it to the Eq. 1, integrate it, apply necessary corrections (e.g. feedback signals, etc) and set calculated frequency value to DDS generator. This was the approach that we realized in our first controller prototype.

The main consideration on this approach (besides accuracy of measurement for which appropriate means were taken) is its "stepping" nature, which introduces a quantization error. We can estimate this error in the following way. Highest frequency change rate is 2.25 MHz/sec. With practically achievable cycle time $\Delta T = 40 \mu s$ we get 25 Hz quantization error. That is around $5 \cdot 10^{-5}$ at the starting frequency 500 kHz.

Now we would like to describe the method which allows to simplify calculations, lower quantization error and loosen cycle time requirements. This method relies on the ability of DDS to perform linear sweep of frequency with variable sweep rate over time. This ability is implemented as shown at Fig. 4. Internal down δt counter operates at DDS clock (25 MHz in our case), when it reaches zero a value written in δf register is added to current frequency register and counter is reset to initial value. Current frequency register is used by sinusoidal waveform generator to provide output signal. Essentially this ability means that we are able to provide DDS with frequency derivative $\frac{df}{dt}$ modifying both difference at each step δf and stepping rate δt . If δt is lower than the measurement/integration cycle time ΔT , we get an advantage in precision.

Figure 4: Simplified DDS frequency sweep implementation.

The illustration to this fact is provided on Fig. 5. $U(t)$ is a typical signal from induction sensor, $B(t)$ is an appropriate integral. Let's assume that our cycle period is ΔT , therefore individual readings are taken at moments of time t_0, t_1, \dots, t_i , with $\Delta T = t_i - t_{i-1}$. Graph $f(t)$ represents the approach when on each step we measure $U(t)$, calculate $f(\alpha \int U(t_i))$ and provide DDS with new frequency value. Graph $f_{sweep}(t)$ represents an approach with derivatives which will be described in detail below. Apparently this approach allows to significantly lower quantization error.

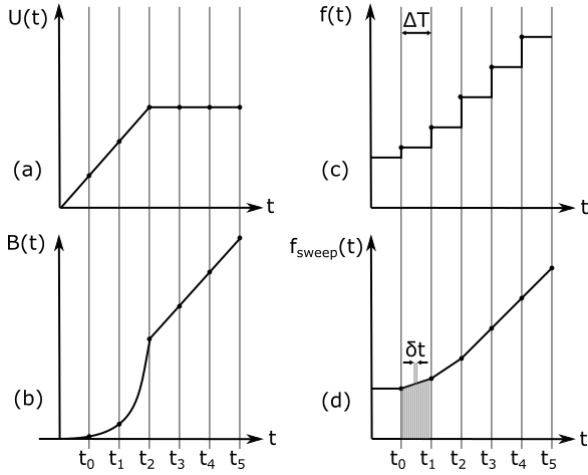

Figure 5: Demonstration of sweep approach superiority. (a) – inductive sensor signal $U(t)$; (b) – magnetic field $B(t)$; (c) – frequency form for “stepping” approach $f(t)$; (d) – frequency form for “sweep” approach.

To calculate $\frac{df}{dB}$ we start from the Eq. 1 and take its derivative over dB :

$$\frac{df}{dB} = \frac{Ka}{\sqrt{b + CB^2}} - \frac{KaCB^2}{(b + CB^2)^{3/2}}, \quad (4)$$

after examination of Eq. 4 taking Equations 1 and 3 into account we get the following:

$$\frac{df}{dt} = \frac{df}{dB} \frac{dB}{dt} = \frac{f}{B} \left(1 - \frac{C}{K^2 a^2} f^2\right) \alpha U. \quad (5)$$

For the actual calculations following discrete form is used:

$$B_i = B_{i-1} + \alpha U \Delta T \quad (6)$$

$$\delta f_i = \frac{f_{i-1}}{B_{i-1}} \left(1 - \frac{C}{a^2 K^2} f_{i-1}^2\right) \quad (7)$$

$$f_i = f_{i-1} + \delta f_i \delta t \quad (8)$$

Notable feature of these equations is the absence of square root operation. Values f_0 and B_0 could be calculated before the start of an acceleration cycle.

Currently we are using the described method with $\delta t = 4\mu s$, therefore achieving theoretical frequency error level of $5 \cdot 10^{-6}$ in the worst case. Error measured using a frequency meter is $1.4 \cdot 10^{-5}$ and is determined by different measurement and synchronisation inaccuracies.

TESTER

Tester Module consists of digital control unit and analog Front-End. Analog Front-End is based on DAC8831 IC with 16 bit resolution. The core of digital control unit is LPC2478 processor, which provides DAC control of analog Front-End, synchronization pulses generation, multiplexer control and Ethernet interface for inter-operation with Booster control system. Particular attention was paid to analog Front-End circuit design. The block diagram of analog

Front-End is shown in Fig. 6. Front-End is a combination of two OPA2277 operational amplifiers. First one provides gain and offset for DAC output signal. Second generates ± 1 V signal on 120 Ohm input resistance of the Controller module. Using offset adjustment circuit, high precision resistors 0.1% with $5ppm/^{\circ}C$ temperature coefficient and precision voltage references (LTC6655) allow to achieve high accuracy of the magnetic field derivative. Resulting noise integral of magnetic field simulation is less than 10^{-5} .

Figure 6: Tester structure.

Ethernet interface for inter-operation with booster control system.

CONCLUSION

Controller and Tester modules were designed manufactured and tested in working conditions with RF stations generating high voltage. Usage of SAMA5D31-CK board allowed to significantly reduce prototyping time. New approach for frequency tuning was devised. Overall measured inaccuracy using frequency meter is better than $1.4 \cdot 10^{-5}$. After NICA Booster commissioning beam feedback module would be produced and incorporated to the LLRF control system. All devices provide simple telnet interface for integration in NICA control system.

TPS BOOSTER TUNE MEASUREMENT SYSTEM

P. C. Chiu, K. H. Hu, H. P. Hsueh, Y. S. Cheng, Demi Lee, K. T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

The Taiwan Photon Source (TPS) is a state-of-the-art synchrotron radiation facility featuring ultra-high photon brightness [1]. Its Booster has 6 FODO cells which include 7 BD dipoles with 1.6 m long and 2 BH dipoles with 0.8 m long in each cell. After magnetization of stainless steel vacuum chamber of the booster were identified and then dismantled, annealed, and re-installed, the electron beam energy of the TPS booster ring has ramped to 3 GeV in a week. The booster tune correction during ramping is one of the main reasons why the booster commissioning progress so fast. This report will be summarized the booster tune monitor system.

INTRODUCTION

The TPS is a state-of-the-art synchrotron radiation facility featuring ultra-high photon brightness with low emittance. The TPS accelerator complex consists of a 150 MeV S-band linac, linac to booster transfer line (LTB), 0.15–3 GeV booster synchrotron, booster to storage ring transfer line (BTS), and 3 GeV storage ring. The booster has 6 FODO cells and its circumference is 496.8 meter; the storage ring's circumference is 518.4 meters with 24 DBA lattice and 6-fold symmetry. The booster and the storage ring share the same tunnel in a concentric fashion. During 4 years of construction period, civil constructions had been completed in early 2013. The accelerator installation then had taken another one year.

At September 2014, booster tune measurement commissioning had committed with beam commissioning. First-turn was easily obtained by beam steering and then multi-turn was also observed after optimization of Linac and transfer line. However, the beam could not be stored. After some hardware improvement such as power supply tuning, chamber and magnet re-alignment, kicker and septum improving and etc., the key setback was finally found on November 12: the pipes had a relative high permeability (ranging from 1.2 to 2.0) induced from the lack of proper annealing process. These un-annealed chambers were uninstalled and treated in vacuum oven up to 1050 °C, and then re-installed. Booster then had stored beam in DC mode and ramped to 3 GeV successfully at December 16 2014 after several times of tune compensation. The tune measurement system provides precise tune measurement to correct tune variation during energy ramping and avoid across the resonant line which would cause a lot of beam loss. This report will summarize the infrastructure of booster tune measurement system measurement results and tune compensation during TPS booster commissioning.

TUNE MONITOR SETUP

Originally during booster commissioning beginning in Sep. 2014, the magnetic shakers where two multi-turn coils are mounted on vacuum chamber in horizontal and vertical plane are applied to excite beam. The kickers with 50Ω terminated load have calibration factor of 3 mG/A and are driven by a 50W amplifiers. Later, the stripline electrodes are adopted to replace magnet shakers on the booster synchrotron considering more power strength to excite beam. The TBT data provided by BPM electronics would be acquired to extract tune by FFT. Agilent arbitrary signal generator would provide band-limited, strength-adjustable excite signal. The functional block diagram of this new tune monitor system is shown in Fig.1. Figure 2 shows the stripline kicker installed in June 2015 to provide more efficient power to excite beam.

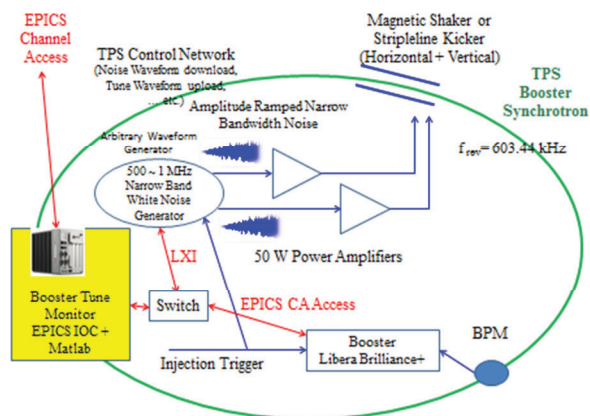

Figure 1: Functional block diagram of the tune monitor for TPS booster.

Figure 2: Stripline kickers installed in June 2015.

Figure 3 shows the booster tune measurement GUI. The spectrogram of the horizontal and vertical of BPM turn-by-turn data could identify tune variation clearly. Peak identification from the spectrogram could extract the

varying tunes during one ramping cycle. Excitation waveform would be generated from white noise with limited bandwidth and strength could be adjusted as energy increased. The generated waveform would be load to signal generator via EPICS channel access.

Besides, the reproduction of ramping power-supplies stability was critical for it could affect the working point and injection efficiency at 150 MeV at the beginning. The real-time injection tune display is also provided for monitoring as Fig. 4 shown.

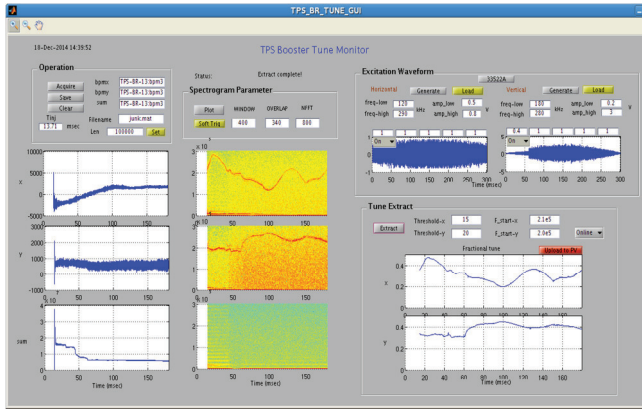

Figure 3: Tune measurement GUI during Booster ramping. Excitation waveform could be set to the proper strength and spectrum.

Figure 4: Injection tune extracted from BPM TBT data at injection time.

TUNE MEASUREMENT AND COMPENSATION DURING BOOSTER COMMISSIONING

After chamber demagnetized, we had a stored beam soon after the RF system was activated. Then the first test of energy ramping at AC mode was found that the beam loss occurred when beam ramping to 2.3 GeV as Fig. 4 shown because the vertical tune across 1/3 the resonance line. After tunes compensation scheme applied during ramping, a 3 GeV beam was attained in two days.

The tune variation was as large as 0.22 for horizontal and 0.1 for vertical as Fig. 6 (a) shown. The working points across the resonance line would cause beam loss and decrease the injection efficiency. It could be inferred that reference waveform generated from the measured I-B table provide by the magnet lab could be deviated from

the actual machine. To improve the injection efficiency, Q1 and Q2 are chosen and measured the tune response for tune compensation. After tune correction, horizontal and vertical tune variations are both reduced to 0.05 as Fig. 6(b) shown.

Figure 5: The beam loss occurred when beam ramping to 2.3 GeV observed on the first day of booster AC mode test.

Figure 6: (a) Tune variation during ramping before tune compensation. Horizontal tune variation was as large as 0.22; vertical tune variation was 0.1. (b) Horizontal and vertical tune variation are both reduced to 0.05 after tune compensation.

BPM TDP AND DDC TBT DATA FOR TUNE MEASUREMENT

DDC (Digital Down Converter) and TDP (Time Domain Processing) Turn-by-turn data are both provided by BPM electronics and the resolution could achieve around 150 μm at 0.5 mA. To use TDP properly, phase offset and mask window should be set correctly [1]. Both of these two TBT data chains could be applied to extract tune. Nevertheless, compared to DDC, TDP could well resolve beam loss status and tune extraction especially in lower beam current or smaller beam motion. It is due to clear and no smear TBT data as Fig. 7 which shows the spectrogram of DDC and TDP data respectively.

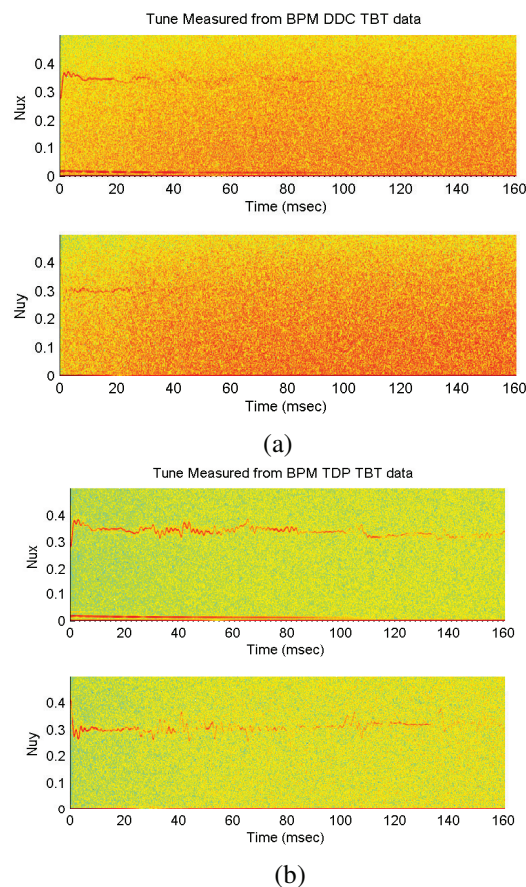

Figure 7: (a) Tune extracted from BPM DDC TBT data during booster ramping (b) Tune extracted from BPM TDP TBT data. TDP had better signal qualities than DDC due to its clear and no smear TBT data.

BOOSTER TUNE STABILITY

Initially, the booster beam current was not stable. It was found that one of the reasons was the stability/reproducibility of booster main power supply not good enough, especially at lower current. Figure 8 shows tune shifts for different injection. At lower energy, the tune reproducibility is worse than high energy. It is because quadrupole to dipole relative err would affect tune and when tune drift to the improper working point, it

would have lower beam current. Figure 8 shows the variations of QF to Dipole err, injection tune and beam current. After stability of power supply improved from 0.5% to 0.2%, stability of beam current was also improved [2].

Figure 8: The tune reproducibility observed from 10 times injection. The reproducibility becomes better as energy increased for the reproducibility of power supply also becomes better as current increased.

Figure 9: The variations of QF to Dipole relative err, tune and beam current.

SUMMARY

In this report, we summarized the TPS booster tune measurement system and perform tune compensation to reduce tune variation and improve injection efficiency.

INTEGRATING THE MEASURING SYSTEM OF VIBRATION AND BEAM POSITION MONITOR TO STUDY THE BEAM STABILITY

C. H. Huang, C.Y. Liao, Y.S. Cheng, P. C. Chiu, K. H. Hu, K. T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

For a low emittance, third-generation light source such as Taiwan Photon Source (TPS), beam orbit motion needs to be controlled within submicron for obtaining a high quality light source. Magnets vibration especially quadruples will be one of the main sources to destroy the beam stability. In order to study the relationship between vibration and beam motion, a synchronous data acquisition system which integrates the measurement of vibration and beam position monitoring system is highly desirable. For a larger vibration such as earthquakes are also deleterious to beam stability or even make the beam trip due to the quench of superconducting RF cavity. A data acquisition system integrated with an earthquake P-wave detector is also quite necessary to show and archive the data on the control system. First, the data acquisition systems of vibration and earthquake measurement system are summarized in this report. The preliminary study of the relationship between the beam motion and magnets vibration will also be presented here.

INTRODUCTION

For a low emittance, third-generation light source such as TPS, it imposes a stringent requirement for the orbit stability. To obtain a high quality light source, the beam orbit motion needs to be controlled at least within $0.5 \mu\text{m}$. There are many sources [1] which may destroy the beam stability such as vibration, ill function of power supply, septum/kicker field leakage, etc. The ground vibration and the technical noise such as vacuum pumps and cooling water flow will cause the magnet and vacuum chamber vibration. It leads to the distortion of the close orbit [2]. The dominant effect for the beam motion caused by magnet vibration is produced by the quadrupole and it introduces a kick angle to the beam as the quadrupole has an offset to the beam due to the vibration.

To achieve submicron stability, various efforts and studies should be continuously performed such as power supply performance, RF system performance, cooling water, mechanical vibration, orbit feedback system and bunch-by-bunch feedbacks. Besides, it is also important to identify various sources and to minimize their effects to the beam instability. In this paper, the data acquisition system for measuring the vibration and beam position is introduced first. The setup of beam position monitoring and earthquake monitoring system are described in the third and fourth parts. In the fifth and sixth sections, the preliminary results to identify the vibration caused by

turbo molecular pump (TMP) system and to study the beam stability are shown. Finally is the short summary.

VIBRATION DETECTOR AND DATA ACQUISITION SYSTEM

Low noise three-component seismometers, LE-3Dlite Mark II, with frequency range 1- 100 Hz is used in this study. The data acquisition unit (Data Translation DT8837), which is complied with LXI class C standard, provides Ethernet accesses via SCPI command to acquire data. Multiple DT8837s are synchronized by wired trigger bus (WTB) interface. To extend length limit of WTB cable, an in-house made small interface adapter from RJ-45 to Micro D is installed at the WTB connector of the DT8837 side. It allows unshielded twisted pair (UTP) cables to replace WTB cables and to send the trigger, sync and clock single from the timing system adapter to DT8837 more than 100 m. Coherent data acquisition can also be achieved by the aid of global timing system for long range or by LXI WTB cable for short range application. A Matlab script can be running in the server for the long-term measurement or in the laptop for the short-term measurement, shown in Fig. 1. The synchronous data acquisition between vibration measurement and beam position monitoring system can also be through the timing system.

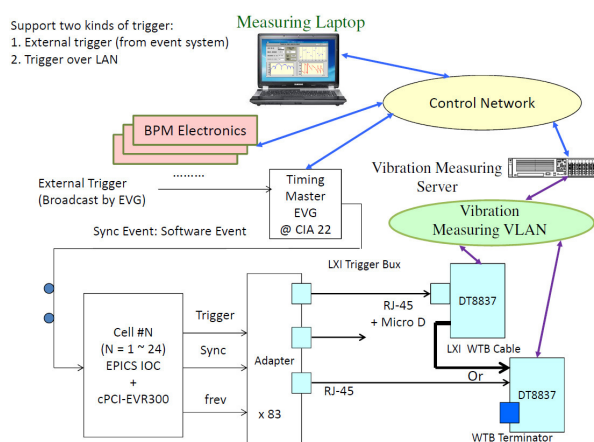

Figure 1: Configuration of vibration measuring system integrated with beam position monitoring system.

BEAM POSITION MONITORING SYSTEM

The TPS storage ring is divided into 24 cells and 7 beam position monitors (BPMs) are installed in each cell.

Another six BPMs are installed at three long straight lines with inserting devices for the local measurement. Two kinds of BPM are installed in the storage ring: one is standard button BPM shape at arc section; the other is primary BPM shape with racetrack at the insertion device straight.

The BPM electronics provide several data types for various application. Analog-to-digital converter (ADC) and turn-by-turn (TBT) data are acquired for first turn and betatron tune analysis; 10 Hz slow acquisition data (SA) is for DC average orbit and 10 kHz fast acquisition data (FA) could be applied for fast orbit feedback application and beam stability analysis. An experimental physics and industrial control system (EPICS) input/output controller (IOC) is embedded in the electronics platform to control, monitor and configure the BPM system in the control network [3]. Here, FA is used to be integrated with vibration measurement system and to study beam stability.

EARTHQUAKE MONITORING SYSTEM

In order to monitor the earthquake information which is happened in NSRRC campus and to study the beam stability as an earthquake is happened, an earthquake P-wave detector which equips with MEMS accelerometers and an ADC with 16-bit output resolution is installed in the TPS building. A complied Matlab program is used to communicate with the earthquake detector through Modbus TCP protocol, and transfer the useful information into the created IOC through the soft process variables (PVs), shown in Fig. 2. The EPICS IOC publish PVs into the TPS control network and earthquake information detected by the detector can be shown on the console on line.

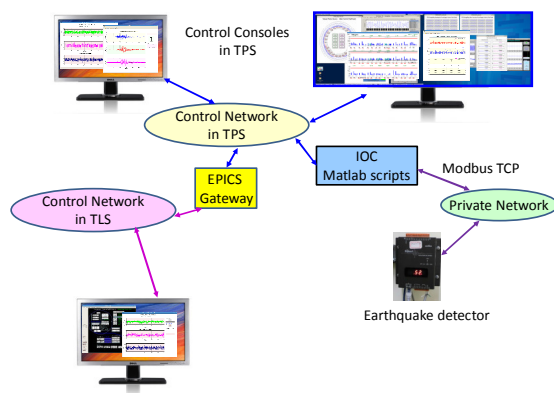

Figure 2: The configuration of the earthquake monitoring system.

As detecting an earthquake, the number of event flag in the data stream will be changed. When the Matlab program detects this flag, the earthquake information with 30 seconds before trigger and 90 seconds after trigger is recorded in the archived file for further analysis. A graphical user interface is used to show the events in the control console, shown in Fig. 3. To show the earthquake information in the Taiwan Light Source (TLS) control

system, an EPICS gateway is used to transfer the earthquake related PVs from TPS control network into the TLS control network. Therefore, the earthquake monitoring system can also be launched in the TLS control system.

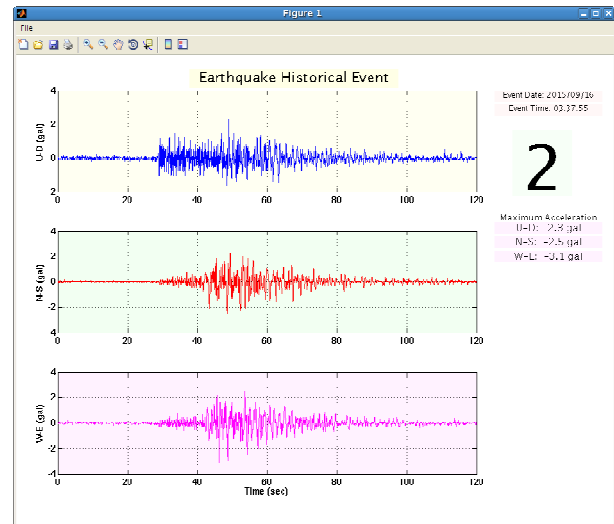

Figure 3: The earthquake historical event loaded from the archived files.

VIBRATION CAUSED BY TURBO MOLECULAR PUMP SYSTEM

In the first phase commissioning during December 2014 to March 2015 [4], an obvious beam motion around 29 Hz is observed. A sharp peak around 29 Hz can also be found in the magnet vibration [5]. As the TMP system, which contains a TMP, a dry pump and a mechanical pump, is turn off, the beam motion and magnets vibration around 29 Hz is highly eliminated. In order to investigate the vibration propagation path, a serious study is performed during the long shutdown from April to August. It was identified that the vibration source is from the mechanical pump, shown in Fig. 4. As a seismometer is put near the mechanical pump, a sharp peak in Fig. 5 can be found in the displacement spectrum.

The electric mains frequency in Taiwan is 60 Hz. All of these mechanical pumps are driven by induction motor. There are four poles in this motor so the synchronous speed should be 30 Hz [6]. The slip of rotor and stator makes the revolution frequency less than 30 Hz and the revolution frequency depends on the load of the motor. Therefore, the measured vibration frequencies of magnets in each girder are slightly different. The TMP system is the most pumping efficient for high gas load and was planned to operate during the early commissioning and the first year operation. In order eliminate the destroying of beam stability, all the TMP systems are turned off in the later period of beam commissioning.

The propagating path from the mechanical pump to the TMP is by the vacuum pipe connected between TMP and dry pump. The TMP is combined with the vacuum chamber of the storage ring so vibration of mechanical

pump would also propagate into the vacuum chamber. There are no direct contact between magnets and vacuum chambers so the vibration propagating from the vacuum chambers to the magnets should be through the girder.

Figure 4: The setup of the turbo molecular pump systems.

Figure 5: The displacement spectrum near the mechanical pump.

As comparing the vibration of quadruples in the third cell, it can be observed that the peak around 29 Hz is disappeared as the TMP system is turned off. When the cooling water of magnets and vacuum chamber is turned off, the vibration around 20 - 40 Hz is greatly reduced, shown in Fig. 6. Therefore, the source of vibration around this frequency should be the water flow. However, the measuring results in the magnets is not only corresponding to the amplitude of the vibration sources but also the transform function or resonance frequency of supporting mechanical structures such as the girder so advanced study is necessary to figure out a complete conclusion.

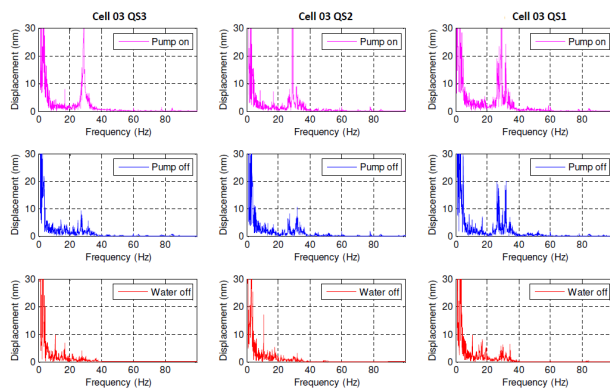

Figure 6: The vertical displacement spectra of the quadruples in the third girder of the cell #3 as TMP is

turned on, TMP is turned off, and cooling water is turned off.

PRELIMINARY ANALYSIS OF BEAM STABILITY

The phase II commissioning with SRF cavities and inserting devices starts at September, 2015. All the TMP systems are turned off. In the beginning of the commissioning, we found there is a 3 Hz oscillation in horizontal axis plane from the 10 Hz BPM data. As the ramping the booster power supply is turned off, the 3 Hz peak is disappear, shown in Fig. 7. From the power spectral density (PSD) of the 4th BPM in the cell #5, the variation contribution is mainly from 20 - 50 Hz in the horizontal axis plane

Figure 7: Power spectral density (PSD) in horizontal axis plane of the 4th BPM in the cell #5 as the ramping power supply (PS) in the boosting ring (BR) is turned on or turned off.

Figure 8: The comparison of vertical beam motion in the 5th BPM of cell #7 as the TMP in the 3rd girder of the cell #7 is turned on and turned off. The beam motion around 29 Hz disappears as TMP is turned off.

In order to test the data acquisition between vibration and BPM system, the TMP system in the 3rd girder of cell #7 is turned on. Comparing with the results as all TMP systems are turned off, a strong beam motion can be observed around 29 Hz in the vertical direction, shown in Fig. 8. Note that the beam motion around 29 Hz could be

observed in all of the BPMs with various amplitudes due to the different beta function and phase advance. As measuring the coherence between the quadruple vibration and beam motion, the coherence around 29 Hz is almost 1 and the coherence in the other frequencies is lower, shown in Fig. 9.

Figure 9: The vertical coherence between the 8th quadruple and 5th BPM in the cell #7.

SUMMARY

The phase II commissioning with SRF cavities and inserting devices is in process. Data acquisition which integrates with the beam position monitoring system and vibration measurement is setup for studying the relationship between beam stability and vibration. The earthquake monitoring system is also setup not only to monitor the earthquake but also try to investigate the relation between the earthquake and beam motion. By the vibration measurement and beam position monitoring system, the source and propagation path of the beam motion around the 29 Hz is identified and the strong coherence is found. However, the beam motion around 20 – 50 Hz is still not low enough. A lot of efforts should be done to increase the beam stability.

CONTROL OF FAST-PULSED POWER CONVERTERS AT CERN USING A FUNCTION GENERATOR CONTROLLER

R. Murillo-Garcia, Q. King, M. Magrans de Abril, CERN, Geneva, Switzerland

Abstract

The electrical power converter group at CERN is responsible for the design of fast-pulsed power converters. These generate a flat-top pulse of the order of a few milliseconds. Control of these power converters is orchestrated by an embedded computer, known as the Function Generator/Controller (FGC). The FGC is the main component in the so-called RegFGC3 chassis, which also houses a variety of purpose-built cards. Ensuring the generation of the pulse at a precise moment, typically when the beam passes, is paramount to the correct behaviour of the accelerator. To that end, the timing distribution and posterior handling by the FGC must be well defined. Also important is the ability to provide operational feedback, and to configure the FGC, the converter, and the pulse characteristics. This paper presents an overview of the system architecture as well as the results obtained during the commissioning of this control solution in CERN's new Linac4.

INTRODUCTION

CERN has nine accelerators, numerous experiments and various test areas. One commonality of such infrastructure is the need of a power system to energize the magnets (dipoles, quadrupoles, septums, etc.) and the various radio frequency cavities. In total, CERN has around 5,600 power converters, accounting for a typical consumption during exploitation of 1.2 TWh per year [1].

From an operational point of view, power converters fall into three categories:

- Cycling: the field, current or voltage reference value can synchronously be modified on a cycle-by-cycle basis. At CERN each cycle is a multiple of a basic period, which has a fixed duration of 1.2 seconds.
- DC: the reference is asynchronously modified as required during operation to reach a desired field, current or voltage.
- Aperiodic: operators trigger aperiodic cycles to ramp the current to maintain the required beam stability. This is the case of the LHC.

Fast-pulsed converters are used with cycling circuits to generate a pulse with a flat-top duration of only a few milliseconds and synchronous to an event such as beam injection or extraction.

This paper describes the use of the third generation of the CERN-designed Function Generator/ Controller embedded platform (FGC3) to control the four types of

fast-pulsed power converters currently being commissioned in CERN's new Linac4 (see Table 1).

The Linac4 beam is 400 μ s long, whilst the flat-top pulse is stable solely during a few milliseconds. As these two events must be synchronized to ensure the correct functioning of the accelerator, the FGC3 must guarantee time accuracy and inter-FGC precision better than 10 μ s.

Table 1: Fast-pulsed Power Converters in Linac4

Name	Peak Power	Pulse	Number*
Mididiscap	30 kW	5 ms	50
Maxidiscap	4 kW	2 ms	48
Modulator	5.5 MW	1.8 ms	14
HMinus	150 kW	1.2 ms	3

FUNCTION GENERATION/CONTROLLER

Most power converters currently being installed at CERN are controlled with FGC3s, shown in Fig. 1. This embedded device includes a mainboard, an Ethernet-based communication card[†] and an analog card with four high precision ADC channels (ADS1274) and two 16-bit DACs (MAX5541) [2]. The mainboard includes a Renesas RX610 microcontroller (running a small footprint real-time operating system called NanOS), a TI TMS320C6727 floating point DSP with a 10 kHz interrupt-driven task and a Xilinx FPGA for glue logic and peripheral handling.

Figure 1: Function Generator Controller: mainboard, Ethernet and analog cards.

The FGC3 is integrated within a CERN-designed chassis called RegFGC3 [3], shown in Fig. 2. A backplane links the FGC3 with a variety of cards dedicated to state control, analog interlock, digital interlock, measurement conditioning, etc. Communication buses over this backplane include:

- SPIVS: serial bus used by the FGC3 to send the reference value in digital form.
- SCIVS: serial bus used by the FGC3 to exchange parameters with the cards.

* Number of converters on completion of Linac4.

[†] The FGC3 can also be fitted with a WorldFIP-based communication card.

- QSPI: a serial bus supporting detailed diagnostics.

Although the number and type of cards connected to a RegFGC3 chassis depends on the needs and specifications of a given power converter, the state control card is always present. It implements the state machine for the particular power converter. It is partially driven by the FGC3 output commands such as power on, power off, reset and timing pulses (described in the section Timing Pulses), and it relays back to the FGC3 status and fault information.

Figure 2: RegFGC3 chassis for the Modulator converter.

CONTROL OF OPERATIONAL POWER CONVERTERS

The three-tier control system of the FGC3-based power converters is illustrated in Figure 3. The equipment tier encompasses the pulsed converter, RegFGC3 crate, Ethernet switches, and sync pulse injectors, whilst the top tier includes the controls applications, alarms service, etc. mainly used by the machine operators. Between the FGC3s and these applications lie the front-end computers known as FGC_Ether gateways. The gateways[‡] is a rack-mounted Linux-based computer with two network interface cards: one connected to the CERN Technical Network for access to the upper control layers and the second connected to a gigabit Ethernet network with enough capacity to manage a cluster of up to 64 FGC3s. Each FGC3 integrates a 100 Mbps LAN chipset to manage the raw Ethernet-based communication.

Control applications can perform three operations on a device: get a property, set a property and subscribe to a property. A property is a device-specific parameter through which the underlying hardware – a power converter in this case – can be configured, controlled and monitored.

Gateways receive these commands over the Technical Network using an in-house distributed communication protocol known as Controls Middleware (CMW) [4]. The commands are reformatted and forwarded to the appropriate FGC3. A task associated with the command is then executed in the FGC3 and a packet with the command response is transmitted upstream through the gateway to the control application.

[‡] In the FGC lingo and by extension in this paper the term ‘gateway’ refers to the front-end computer responsible to forward to and fro commands and responses between the upper control layers and the FGCs, thus acting as a gateway to these messages and hence the name.

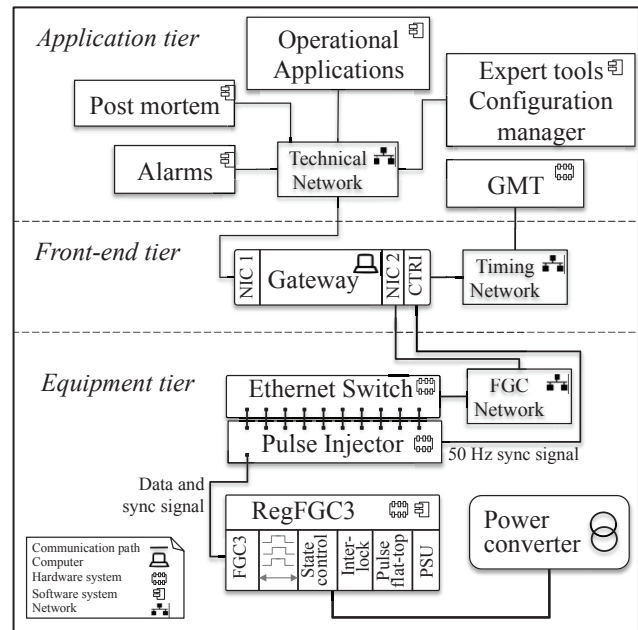

Figure 3: Power converter control.

TIMING DISTRIBUTION

The correct operation of the accelerator depends on the accurate timing of the pulse generation. To this end, the General Machine Timing (GMT) plays a preeminent role by distributing timing events and telegrams over a dedicated communication network to timing receiver cards, driven by a UTC-synchronous 40 MHz clock with small jitter and known delay [5,6]. One such card installed in all the gateways is a PCI variant known as the CTRI. These timing packets provide information on the machine state; post-mortem; the cycle selector of the next cycle within the super-cycle; and the delay in milliseconds of the next event, be it a start of cycle, beam injection or extraction.

In addition, the CTRI cards in all the gateways are configured to generate a 50 Hz synchronization signal on one of its four outputs. This is linked through a coax cable to the first Pulse Injector. This CERN-designed 24-port box injects the sync signal onto a spare pair of wires of the 100 Mbps Ethernet cable. Thus, a single Cat7 cable from the Ethernet switch to the FGC3 device coalesces the data communication link and the synchronization signal (Fig. 3), which saves significantly on cables and connectors. The combination of an Ethernet switch and a Pulse Injector is known as an FGC_Ether star point [7]. Up to three star points can be daisy chained using a backbone of Gigabit Ethernet and a coax cable to enable one gateway to support up to 64 FGC3s.

In the FGC3, the 50 Hz sync signal is utilized to discipline the PI-based Phase Locked Loop (PLL), which synchronizes a 25 MHz Voltage Controlled Crystal Oscillator (VCXO) through a 14-bit DAC. The resulting clock has a jitter below 40 ns and accuracy better than 2.5 μ s [8]. The clock is fanned out to the various integrated circuits in the FGC3 (MCU, DSP, FPGA,

ADCs, and DACs) making the firmware and the interrupt-driven software tasks in the MCU and DSP fully synchronous with the GMT.

FGC3 SOFTWARE

The first software class written for the FGC3 devices provides function generation and regulation [9], property management, event and analog signals logging, ADCs and DACs calibration, monitoring and diagnostics of the converter, and an interface with the interlock system.

This code base has been reused as the foundation for a new class of software used to control fast-pulsed power converters. Function generation and regulation is not needed and thus have been removed. Instead a mechanism to synchronize the converter with the GMT has been developed to achieve the required time constraints. Due to size restrictions, this section only presents two of the features specific to this software.

Timing Pulses

The FGC3 commands the electronics of the fast-pulsed power converter with timing pulses. These control the use of the capacitors stocking the energy needed to generate the current or voltage pulses.

Figure 4 provides a typical sequence of events starting with the GMT transmitting a timing event over the timing network to the CTRI in a gateway. The software running in the gateway formats the event and broadcasts it to all the FGC3s connected to the FGC Ethernet network. This information includes the current UTC and millisecond time, the type of event and the remaining time in milliseconds until the event will occur. The FGC3 retrieves this last value and writes it into the FPGA register `TIME_TILL_EVENT`. This register implements a free-running counter that starts down counting at 1 MHz at the start of the next millisecond. Thus, the exact event time coincides with the register reaching the value zero.

The FPGA also provides a peripheral consisting of a set of GPIOs that can generate timing pulses. Each output channel has two associated registers: `PULSE_ETIME` defines the time of the rising edge of the pulse with respect to the `TIME_TILL_EVENT` and `PULSE_WIDTH` specifies the pulse duration in microseconds.

As represented in the example of Fig. 4, the timing event is received 875 ms in advance. The timing pulse A0 controls the capacitor charging time, which starts 410 ms prior to the arrival of the beam and lasts for 400 ms. The timing pulse A1 controls the capacitor discharging time spanning from 4 ms before the event to 1 ms after the event. Finally, A2 is used to synchronize the acquisition measurement sampled precisely at the event time. This measurement is then made available to the operators.

To complete the above description it should be noted that the Modulator converter, employed to power the radio-frequency klystrons, requires a fourth timing signal to trigger an active bouncer used to stabilize the pulse.

The FPGA registers `PULSE_ETIME` and `PULSE_WIDTH` for each output channel (A0, A1, A2) are initialized from FGC3 properties, which are

Figure 4: Simplified chronogram of timing pulses for fast-pulsed converters.

configured based on the requirements of the fast-pulsed power converter. With this strategy, converters with different topologies can be controlled homogenously.

Pulse State Machine

The main power converter state machine encoded in the FGC3 [10] is driven by external stimuli (inputs, commands, etc.) and accounts for various working modes: direct, cycling, economy, etc. Fast-pulsed converters operate in the cycling state, allowing operators to specify a different pulse reference for each cycle. This state has been extended with a pulse state machine (Fig. 5) to sequence the generation of pulses. The following functionality is implemented within each pulse state:

- Waiting: waits for a timing event.
- Preparing: verifies if the pulse for the current cycle is enabled and latches the reference and timing parameters.
- Setting: configures the timing pulses as described in the previous subsection; sends the reference value to the converter; and if a polarity switch is present and its position does not match the sign of the reference, the output command to change the polarity switch is activated.
- Reporting: gathers the current and voltage measurements and verifies if a fault condition has occurred. This information is published and made available to the operators.
- Fault: logs the error condition.

Some of these states have an associated timeout. If the timeout expires before the onwards transition is asserted, the state machine defaults into the Fault state, where the appropriate information is logged. This is then followed by a transition to the Waiting state to handle the next

timing event. This prevents the state machine from locking up, allowing subsequent timing events to be handled and thus improving the software resilience.

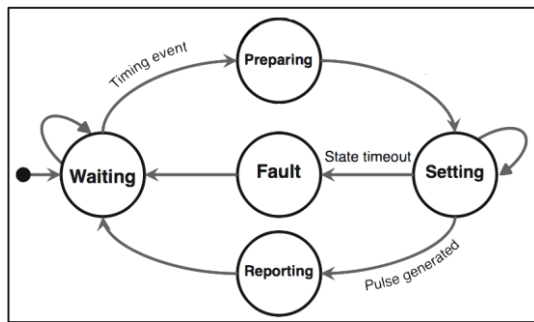

Figure 5: Pulse state machine.

PERFORMANCE

Since the FGC3s are synchronized with the General Machine Timing, the timing pulses and consequently the current or voltage pulses are generated synchronously. This can be observed in Figure 6, which shows pulses with various references sampled from six circuits installed in Linac4. Note how the overlapping flat-top stability is of merely 1.5 millisecond. Longer pulses would require an over-dimensioning of the power system, resulting in higher costs.

Figure 6: Six Maxidiscaps pulsing synchronously.

The FGC3 timing accuracy is demonstrated in Fig. 7, which includes three oscilloscope snapshots. The left and middle ones were taken in the laboratory. The signals probed comprise: the pulse; the exact event time as output by the CTIRI card in the gateway; and the acquisition timing pulse (A2) defining the event time from the FGC3's perspective. It can be observed how the difference between these latter two signals is less than 200 ns, well below the requirement of 10 μ s. The right image shows the acquisition timing pulses (A2) of three different Maxidiscap converters connected to one gateway and a Modulator connected to a different gateway in Linac4. The inter-FGC timing precision among the three Maxidiscaps is negligible whilst between these and the Modulator is only 186 ns, due to differences in cable length. In any case these values are also below the 10 μ s requirement.

FUTURE WORK AND CONCLUSIONS

Two important software features are yet to be developed:

- Fast sampling: the software must be adapted to provide support for a new analog interface which is based on four LTC2378 SAR ADCs sampling at a rate of 500 ksp/s. This will allow acquiring the pulsed signals with a better time resolution.
- Slow regulation: the Modulator converter works in open loop, i.e. the flat-top pulse is not regulated. The FGC3 shall implement an algorithm that trims the reference value on a pulse by pulse basis to minimize the error.

Despite the above, the core functionality of the software is fully operational and has been integrated with the tools in CERN's new Linac4 accelerator to control the currently installed. When complete, there will be 115 circuits in Linac4 controlled by this software.

Working in collaboration with the converter designers has proved essential to successfully reach this goal. Their feedback was crucial to provide an intuitive interface and to correctly parameterize each circuit. In return, an unprecedented level of remote diagnostics and monitoring is now available, which will shorten the intervention times during machine exploitation.

WHITE-RABBIT BASED REVOLUTION FREQUENCY PROGRAM FOR THE LONGITUDINAL BEAM CONTROL OF THE CERN PS

D. Perrelet, Y. Brischetto, H. Damerau, D. Oberson^{*}, M. Sundal[#], A. Villanueva, CERN,
Geneva, Switzerland

Abstract

The measured bending field of the CERN Proton Synchrotron (PS) is received in real-time by the longitudinal beam control system and converted into the revolution frequency used as set-point for beam phase and radial loops. With the renovation of the bending field measurement system the transmission technique is changed from a differential sequence of pulses, the so-called B-train, to a stream of Ethernet frames based on the White Rabbit protocol. The packets contain field, its derivative and auxiliary information. A new frequency program for the conversion of the bending field into the revolution frequency, depending also on parameters like radius of the accelerator and the particle type, has been developed. Instead of storing large conversion tables from field to frequency for fixed parameters, the frequencies are directly calculated in programmable logic (FPGA). To reduce development time and keep flexibility, the conversion is processed in real-time in the FPGA using Xilinx floating-point primitives mapped by a higher level tool, Simulink System Generator. Commissioning with beam of the new frequency program in the PS is progressing.

INTRODUCTION

The CERN PS accelerates protons and ions [1] for fixed target experiments and as part of the LHC injector chain. For protons, its kinetic range covers 1.4 GeV at injection to 26 GeV total energy. The longitudinal beam control system drives in total 25 cavities in a wide frequency range (2.8-10, 20, 40, 80 and 200 MHz). It requires the so-called open-loop revolution frequency to be derived from the bending field of the main dipole magnets which serves as a reference for the feedback loops closed around the beam. In addition to protons from the PS Booster (PSB) the PS accelerates a large variety of heavy and light ions such as $^{208}\text{Pb}^{54+}$ [2,3,4] or $^{40}\text{Ar}^{11+}$ injected from LEIR.

Motivated by the renovation of the present measurement system of the magnetic field, its distribution in the form of asynchronous pulses (so-called B-train) [5, 6] has been upgraded [7] to a stream of Ethernet frames based on the White Rabbit (WR) protocol. The reception of the magnetic field information for the longitudinal beam-control and its conversion into the open-loop revolution frequency has been redeveloped and commissioned with beam.

^{*}HEIA-FR (Haute école d'ingénierie et d'architecture Fribourg)

[#]IST (Instituto Superior Técnico Lisboa)

FIELD MEASUREMENT

The existing system uses a peaking-strip (PKS) marker at 49.8 Gauss as an absolute reference at the start of each cycle. This implies to ramp down to a low field between cycles to reset the integration process, consuming time and power. Moreover, the $B_{\text{up}}/B_{\text{down}}$ pulses distribution scheme triggered by 0.1 G changes in B at a maximum rate of 500 kHz is at the limit for ions in terms of resolution and also in case of flat zones.

In the new system, the measurement setup is referenced at each cycle by a Ferromagnetic Resonance (FMR) tunable marker and integrates a flux coil voltage, meaning the derivative of B . This kind of marker has a working point closer to the injection field, thus reducing the ramp down constraint besides improving the injection accuracy. The regulation done in B , has to cover the range from 600 G to 13000 G with a maximum changing rate of ~ 30 kG/s.

Following the acquisition process, the magnetic field and its derivative are transported via Ethernet frames using the White Rabbit protocol over optical fibres [8]. At the reception side, B is extracted and then converted into the open-loop revolution frequency.

Transmission side:

Figure 1: Overview of the whole system and its connection between reference magnet and longitudinal beam control.

OPEN-LOOP REVOLUTION FREQUENCY

In a synchrotron, the orbit of the particles can be controlled by changing the bending field in the dipole magnets or the RF frequency. A theoretical relationship between magnetic field and revolution frequency can be derived from machine parameters [9,10]. According to

$$f_{\text{rev}}(B, b) = \frac{c}{2\pi R_{\text{nom}}} \frac{1}{\sqrt{1 + \left(\frac{E_0}{b \cdot B \cdot c \cdot \rho_{\text{nom}}} \right)^2}} \quad (1)$$

with the velocity of light in vacuum c , the mean radius R_{nom}

of the vacuum chamber and the bending radius of the bending magnet ρ_{nom} to end with the relation Eq. (1) describing the revolution frequency f_{rev} as a function of the magnetic field B . For ions, a charge-over-mass scaling factor b relative to protons ($b=1.0$) is introduced

$$b = Z_{\text{ion}} \frac{E_{0,\text{proton}}}{E_{0,\text{ion}}} \quad (2)$$

requiring only the charge Z_{ion} of the species and its rest mass energy $E_{0,\text{ion}}$. This scaling factor is then directly applied as a factor to the magnetic field B . Figure 2 shows

Figure 2: Revolution frequency function of B .

frequency swing for different particle accelerated in the PS.

Table 1: $f_{\text{rev}}=f(B_{\text{inj}}, B_{\text{ej}}, \text{particle type})$

Species	Region	B [G]	f_{rev} [kHz]
p^+	Injection	1013	436
	Ejection	12550	477
$^{208}\text{Pb}^{54+}$	Injection	685	178
	Ejection	12550	473
$^{40}\text{Ar}^{11+}$	Injection	685	187
	Ejection	12550	473

Equation (1) shows that the frequency sensitivity is greater for ions than for protons and in particular at low energy.

Table 2: Δf_{rev} and ΔR for a ΔB of 0.1 G at Injection

species	b	Δf [Hz]	ΔR [mm]
p^+	1	7.0	0.32
$^{208}\text{Pb}^{54+}$	0.261571	22.3	0.40
$^{40}\text{Ar}^{11+}$	0.277303	23.1	0.40

The simple theoretical relationship (1) is not sufficiently precise, mainly due to saturation effect in the main magnet and hypothetically due to uncertainties and dispersion in the magnetic length of the magnets, non-linearities and other errors in addition to the fact that the beam over its path sees the integrated B and not exactly the measured B_{ref} at a specific location in the magnet).

Therefore a fit-based frequency model [11] has been implemented for the PS to reduce the action of the radial loop of the beam control. The polynomial coefficients are extracted using beam-based measurements of the radial loop error to perform a fit optimization of the low energy part of (Eq. 1) in order to minimize the radial loop correction. The fit-based revolution frequency model becomes

$$f_{\text{rev}}(x) = \frac{c}{2\pi R_{\text{nom}}} \frac{1}{\sqrt{1 + \frac{N}{P(x)}}} \quad (3)$$

with $x=b \cdot B$ and

$$P = \left(x \left(1 + a_1 x + a_2 x^2 + a_3 x^3 + a_4 x^4 + a_5 x^5 \right) \right)^2 \quad (4)$$

TRANSMISSION/RECEPTION

The WR technology [8] developed at CERN as an extension of the IEEE 1588 protocol, a time precise Ethernet, has been chosen as a transmission standard to distribute the magnetic information in the accelerator complex. There are two ways of using it, the pulse mode where the reference timing is given by the grand master and all slaves align to it allowing generation of grouped precise pulses or simply in Ethernet packet streaming mode, the one currently used.

For this application, a dedicated frame (Fig. 3) with specific type (0x42, ASCII code of 'B' for B_{field} measurement frame) and content has been defined as a standard to transmit magnetic information. The latency of the link is monitored by extracting and differentiating the time included in each frame. To guarantee a transmission rate of the existing B -train, the frame rate is constant and currently set to 250 kHz, with a maximum rate defined by the size of the payload and number of users in a standard Ethernet 1 Gbps network.

Figure 3: Layout of B field frame.

IMPLEMENTATION (CORE)

The new frequency program uses mainly standard hardware as open hardware designs (SPEC and SVEC) [8,12] related to the WR project. New FMC daughter boards hardware designs (ADC, CVORB, SERIAL40M)

[10] and specific firmware to adapt the data format from the WR core to the transmission standard of the RF beam control have been developed. A new approach has been explored and validated for the conversion of B to f_{rev} implemented in the FPGA of the SVEC board. The conventional way might have been to pass through the development of a fixed-point implementation and iterative algorithms to perform elaborated mathematics like the reciprocal square root or via huge and static conversions tables present in the existing system to implement Eq. (3). The approach chosen was to calculate the revolution frequency on the fly in floating point algorithms in the FPGA. The calculated f_{rev} digital word is serially Manchester encoded for being finally distributed through the daughter board FMC-DTX-4CHA as a reference revolution frequency to the beam control. This so-called open-loop revolution frequency is then multiplied by the harmonic number. Some corrections such as a frequency steering offset and weighted radial and phase loop errors are applied to finally become the closed loop revolution frequency. The better the frequency program quality, the smaller is the difference between open and closed loop, which translates in a well centered orbit in the machine and less action of the radial loop.

To reduce the floating point development time, Matlab System Generator associated with the ISE Xilinx Primitives library has been used. The library contains optimized versions of advanced mathematic operations whereas the simulation and verification process is convenient and simple. Then the generation process ends up with a mapped and configured netlist directly targeting the project FPGA. These generated files have to be included in the Register Transfer to Logic design entry tools or directly in ISE where it is simply interfaced by port mapping to the main part of the design. This way of designing gives a higher abstraction level to the FPGA and allows to build complex blocks more rapidly. However the commercial tool is vendor specific and requires a license.

The complete project is a versatile assembly of different languages (VHDL2008, Verilog2010 and native C) and philosophy (generic code and use of specific IP cores). In the WR Core, an instantiated LatticeMico32 soft core processor described in Verilog is initialized by a compiled and linked C code. After the compilation and generation processes, a unique file is given to the final tool Xilinx ISE to perform the fitting for the Spartan6 FGPA.

EXPERIMENTAL RESULTS AND COMMISSIONING

The transmission and reception of magnetic bending field frames over WR has been validated and commissioned with beam on operational cycles without a significant or notable difference on the radial loop signal (Fig. 7), confirming as well that the conversion part is fulfilling the requirements. This is a trustable indication about the whole chain validity from this complete new setup. The small difference between both systems is explained by the two independent measurement setups of

the magnetic field which slightly deviate from each other. In both sides of the WR link, relevant signals are directly stored in the DDR memories (Fig. 8-10), remotely available for acquisition and diagnostic. On top of this, drivers and FESA classes have been developed and deployed for the integration in the CERN infrastructure.

Measurements with beam (Fig. 4-7) are made with the operational user for LHC-type beam with 25ns spacing on 4 consecutive cycles with the existing setup and then switched to the new WR system for the 4 next cycles. They shows the existing B-field still measured with the $PKS+B_{up}/B_{down}$ setup available in the samplers, the new Bfield FMR+WR accessed in the DDR memory through the fesa class, the closed loop revolution frequency analogue signal resampled (Fig. 5) and the radial loop with arbitrary units also resampled from the beam analogue signal (Fig. 6) of the LHC beam control. Figure 5 confirms that the cycle is properly accelerated through transition crossing up-to flattop. The only notable difference is during the ejection synchronization process and is visible at the end of the radial loop signal (Fig. 6 and 7). The cycle-to-cycle dependent start of the locking of the loop explain this behavior.

CONCLUSION

New hardware and firmware developments have been completed to adapt the PS frequency program according to this new distribution scheme of the bending field over White Rabbit. Measurements with beam shows a minor difference between the existing and the new WR system (Fig. 5, 6 and 7) essentially because the bending field measurement setups are different and also the regulation is still performed using the existing field measurement setup. The new revolution frequency is real-time processed entirely in the FPGA with a floating-point signal chain giving accurate values.

Furthermore, acceleration of LHC type proton beam has been demonstrated successfully, confirming the functionality and capability of the new system on its own. As a last step, the new system will be put in operation after the completion of its integration in the CERN control system in addition to a dedicated commissioning phase with ions. Finally, some further development work is planned, notably to offer more advanced diagnostics signals in addition to a monitoring of the link status.

ACKNOWLEDGMENT

The authors would like to acknowledge the support of colleagues from the CERN Radio-Frequency, Controls, Magnetic Measurement, and Operation Groups. In particular we thank A. Beaumont, S. Hancock, W. Höfle, M. Jaussi, G. Sterbini and T. Włostowski for their contributions to the project.

INTEGRATION OF THE TRACK BEAM DYNAMICS MODEL TO DECREASE LINAC TUNING TIMES

Christopher E. Peters[#], Clayton Dickerson, Francisco Garcia, Maria A. Power
Argonne National Laboratory, Argonne, IL, USA

Abstract

The Accelerator R&D Group within the Argonne National Laboratory (ANL) Physics Division maintains a beam dynamics model named TRACK. This simulation code has the potential to assist operators in visualizing key performance parameters of the Argonne Tandem Linear Accelerating System (ATLAS). By having real-time access to visual and animated models of the particle beam transverse and longitudinal phase spaces, operators can more quickly iterate to a final machine tune. However, this effort requires a seamless integration into the control system, both to extract initial run-time information from the accelerator, and to present the simulation results back to the users. This paper presents efforts to pre-process, batch execute, and visualize TRACK particle beam physics simulations in real-time via the ATLAS Control System.

INTRODUCTION TO ATLAS AND TRACK

The ATLAS accelerator is located at the United States Department of Energy's Argonne National Laboratory in the suburbs of Chicago, Illinois. It is a National User Facility capable of delivering ions from hydrogen to uranium for low energy nuclear physics research in order to perform analysis of the properties of the nucleus. As a result of the wide variation of beams delivered [1], re-tuning of the entire machine is necessary on a near weekly basis. After a series of upgrades, ATLAS will consist of two possible source lines, a common injection and beam transport line, and 8 different target areas. This wide range of possible machine configurations combined with the thousands of individual devices which support them present a very real challenge to operators to arrive at a final tune quickly.

The TRACK beam simulation program developed at ANL-PHY is available and has been validated during the design of upgrade projects at ATLAS [2]. This code can perform individual particle simulations of a beam traveling through various types of optical and RF fields in order to predict final emittance and beam shape. The resultant plots show an animation in time of beam emittance ellipses, and an overall plot of beam size vs. distance. It should be possible to link the TRACK simulation code to the real-time running parameters of ATLAS in order to give the operators a detailed overview of the tune process. This effort requires that the program be integrated into the control system in a seamless way so

that non-PhD personnel can operate and understand the behavior of the machine. The TRACK program's graphical user interface (GUI) only runs in Windows (Figure 1) while the control system is primarily developed using Vista Control Systems, Inc.'s Vsystem [3].

Figure 1: Existing TRACK GUI and Simulation.

USER INTERFACE & CONFIGURATIONS

In order to fully realize the potential of fast, real-time iterations on tuning time, the interface to TRACK must operate very similarly to the existing control system. Therefore, brand new interface windows were designed using native control system libraries (Figure 2). One important difference between the TRACK application GUI and the control system GUI is the presence of 'configuration' buttons. These are pre-selected input conditions, source/target line selections, and graph views which can be executed more quickly than re-running a full simulation for the entire machine.

Figures 3 and 4 represent a full TRACK simulation from current device settings by the operator. Note the black boxes which indicate corresponding quadrupole devices. By using the same interface as normal, operators can move sliders and immediately see the resultant simulation update.

USE CASES OF TRACK AT ATLAS

There are two main ways in which a pre-processed simulation of the beam could be useful to operators. The first is by importing the real-time settings of each device in the current beamline to give operators an overview of the performance of the machine. The second is by utilizing a database of previous runs to predict which machine configurations have been successful in the past. This second method will be useful before the start of a new experiment to predict future good tunes.

This work was supported by the U.S. Department of Energy, Office of Nuclear Physics, under Contract No. DE-AC02-06CH11357. This research used resources of ANL's ATLAS facility, which is a DOE Office of Science User Facility.

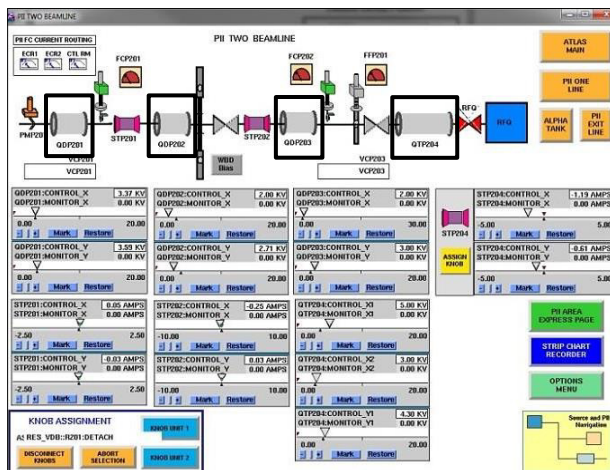

Figure 3: Simulating four quadrupole adjustments via the standard control system interface.

Simulation of Current Real-time Settings

The first integration of a beam dynamics model into the control system provides operators with a full overview of the running experiment's beam quality. In order to simulate the current experiment, device settings are extracted from the running control system and scaled according to scaling parameters stored in the real-time database, specific to each device. These scaled values are then written, along with previously stored constants like device length and radius, to specially crafted input files.

ISBN 978-3-95450-148-9

Figure 4: The four sets of brackets show the simulation results after adjusting the quadrupoles.

These input files are fed to TRACK and the resultant view of the simulation is displayed.

Simulation of Previously Archived Settings

The ATLAS Control System maintains a database of run parameters for all previous tunes [4] which runs continuously and archives relevant parameters every four hours or whenever triggered manually. This second simulation method has been implemented by utilizing a duplicate, offline version of the control system databases.

The historical run parameters are extracted from a SQL database and loaded into a staging SQL database on the real-time control system backup machine. Then the standard “Preload Machine” functionality is used to load all the previous parameters onto the backup machine real-time databases for simulation.

PROGRAM DEVELOPMENT AND FLOW

In order to extract real-time parameters, a series of new methods and programs were developed. The first program named TRACK_VSYS_InputGenerator extracts and formats an ordered device name list from an existing relational database. Depending on which source and target lines are currently selected in the control system, the program executes a series of SQL unions and sorts in order to automatically select each device which is currently in use. Next the program reads this ordered list, and for each device extracts the current set points and scales the control value to a corresponding electrical or magnetic RF field value (Figure 5). It then writes the scaled value to a specially crafted output file containing values and formats used by TRACK.

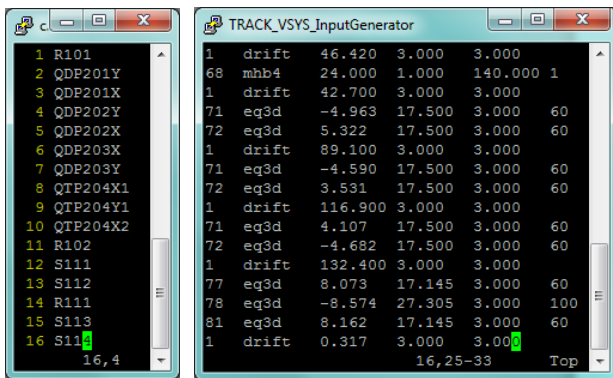

Figure 5: Example of automatically generated device list (left) and associated TRACK input file containing device parameters like radius, length, and field strength (right).

The scaling factors are stored within each database and are used to scale a control system variable, e.g. ‘0 – 10 volts’ into a representative field value, e.g. ‘0 – 2.6 MV/m’. These scalers are either determined from manuals or empirically using equipment like a gauss meter. These scaler values, combined with assumed initial conditions, represent critical factors which influence the accuracy of the overall simulation.

Upon completion of the TRACK simulation, the results are in the form of a large set of text files, which defines the beam state after each device. This file is then parsed by a new program called TRACK_VSYS_Graph, which reads the data and automatically uploads it into the control system for input into the new GUI system.

EFFECT OF INITIAL CONDITIONS

TRACK uses, as part of its input files, a set of parameters which define the starting normalized emittance of the beam. There are two proposed methods to determine these initial conditions, only one of which is

currently in use. The R&D group has developed a PepperPot emittance measurement program [5] written in LabVIEW [6], which can take ‘snapshots’ of the beam projected onto a phosphorescent plate through small holes arranged in a grid layout. The program then automatically calculates the ‘Twiss’ parameters [7] associated with the beam. A second method is to use a beam profile monitor (BPM) and quadrupole combination. By varying the quadrupole field and monitoring the BPM, Twiss parameters can be determined [8]. One result of this work is the ability to test the level of influence beam emittance has on the tune parameters. By varying the initial conditions, it is possible to quickly determine exactly which devices are critical to achieve proper optics (Figure 6).

Figure 6: Effect (top to bottom) of changing only initial beam emittance parameters and keeping devices constant.

RUN TIME AND ITERATIONS

The TRACK program can be configured to perform a simulation of the entire defined beam path, or to continue from a pre-configured saved state from a previously run simulation. This ‘continue’ option can save a large amount of time if the user is only interested in one section of the beam path. These ‘continue’ options are saved as defined configurations within the buttons at the bottom of the TRACK simulation page (Figure 2). If the user pushes one of the partial beam path buttons, iterations of the tune become very rapid between changing a device set point and seeing the results on the screen.

INTERPRETATION OF RESULT PLOTS

Table 1 summarizes the execution time of the current single-threaded server setup, which is not yet optimized for a dedicated simulation machine. Note the decrease in execution time between a full simulation, and a pre-configured partial section of the beam line.

Table 1: Comparison of Full/Partial Execution Time

Program and Action	Time
Extract path info and create Device List	1.0 sec
Generate TRACK input files for devices	6.1 sec
Full Execution of injection line and linac	200 sec
Partial Execution of injection line only	11 sec
Plot & animate results on User Interface	10 sec

The graphs in Figure 7 represent one possible example of an A-B comparison example between beam shapes. In general, the top plot has more variations in beam focus and size, and also hits the beam pipe starting at the 4 meter mark. In comparison, the bottom plot has smoother trends using less focusing, and hits the pipe much less. The TRACK simulation predicts 100% transmission for the bottom plot, while the top plot loses beam at the pipe.

Figure 7: Comparison of good (top) & better (bottom) tunes. Note the bottom plot hits the beam pipe less.

RESULTS AND VALIDATIONS

This program is still in the early stages, and only a few beam line tunes have been simulated in advance of the actual experiment start date. The first time the plots were used, it was shown that operators had over focused the beam in several areas. By decreasing quadrupoles in key areas as suggested by the simulation, beam current immediately increased by ~5%.

Another area of validation of the TRACK simulation against machine performance is in the area of longitudinal beam size during runs with ions with relatively low mass/charge ratios. Beam transmission has historically been poor in these cases, and the simulation shows the potential for over-bunching of the beam. This is due to the configuration of the first buncher having a minimum amplitude level which is greater than the required field to bunch light ions (Figure 8).

FUTURE WORK

One of the greatest areas for improvement in iteration time is on the server which currently runs the applications. The current version runs on a standard desktop PC which is not dedicated to running simulations. A separate multi-core server with additional RAM has been ordered to speed up the simulation times.

There are several other applications going forward where this type of overall simulation can be useful. Pre-processing historical tunes would provide a catalogue of tunes which can be re-used. Operators could scroll through plots of beam sizes and determine which tunes could work for a future run. Additionally, automatic iteration of sequential simulations in order to converge on a full tune could be provided in advance of the tune day.

Figure 8: Top: over bunching of a 'light' beam as a result of required minimum field to run the buncher. Bottom: simulated beam at ideal 1/3 maximum amplitude.

REAL-TIME BEAM LOADING COMPENSATION FOR SINGLE SRF CAVITY LLRF REGULATION

I. Rutkowski, M. Grzegorzówka WUT, Warsaw, Poland
 Ł. Butkowski, C. Schmidt, DESY, Hamburg, Germany
 M. Kuntzsch, HZDR, Dresden, Germany

Abstract

Stable and reproducible generation of a photon beam at Free Electron Lasers (FELs) necessitates a low energy spread of the electron beam. A low level radio frequency (LLRF) control system stabilizes the RF field inside accelerating modules. An electron beam passing through the cavity induces a voltage proportional to the charge and the cavity shunt impedance. The feedback loop tries to compensate for the perturbation after the accelerating gradient drops. The delay and high gain result in an overshoot or oscillations during transients. A feed forward signal can be applied to act on the plant simultaneously with the RF feedback. It can be generated off-line based on system characteristics and beam parameters or on-line using information obtained from the beam diagnostic systems. In the latter scheme fluctuations of the beam current are accounted for in real-time using an open-loop (feedforward) controller. The bunch charge detection scheme and its implementation is described. This paper describes results of the tests performed on the ELBE (Electron Linac for beams with high Brilliance and low Emittance) radiation source at the HZDR (Helmholtz-Zentrum Dresden-Rossendorf) facility using a MTCA.4-based LLRF control system.

INTRODUCTION

Stable and reproducible generation of a photon beam at Free Electron Lasers (FELs) necessitates a low energy spread of the electron beam. A low level radio frequency (LLRF) control system stabilizes the RF field inside accelerating modules. An electron beam passing through the cavity induces a voltage proportional to the charge and the cavity shunt impedance. For an SRF cavity with a high loaded quality factor (Q_L) compensation of the beam loading may require more RF power to be provided than is required to sustain the field gradient in the cavity, making it a major source of distortion of the RF field. Waveforms from a MTCA.4-based digital LLRF system using only a PI feedback controller are shown in Fig. 1 (gain in arbitrary units).

The doubling time of the integral controller is significantly longer than the pulse length (4 ms). Increasing the gain decreases the static error during the beam pulse, but results in transient oscillations (see Fig. 2). A feed forward signal can be applied to act on the plant simultaneously. It can be generated off-line based on system characteristics and expected beam parameters or on-line using information obtained from the beam diagnostic systems. It has been demonstrated [1] that real-time beam loading compensation

Figure 1: Response of a LLRF system using only a PI feedback controller to a beam pulse.

Figure 2: Response of a LLRF system using only a PI feedback controller to a beam pulse (zoom in during beam rise).

(BLC) scheme reduces the bunch-to-bunch energy spread compared to control scheme using the PI controller only.

DETECTION HARDWARE

The bunch charge can be detected using various instruments. For real-time operation a non-destructive scheme is necessary. At ELBE facility an Integrating Current Transformer (ICT) is used. The signal at the output of the ICT is broadband and has low amplitude, resulting in low SNR. A high-gain, wideband amplifier is used to condition the signal. Very short rise and fall times make direct sampling of the signal impractical.

For beam-loading compensation only the information about signal's amplitude is necessary. A peak hold detector with a reset circuit can be used to sample the amplitude. The precise timing information is lost, but requirements for an analog-to-digital converter (such as bandwidth, maximum sampling speed, and aperture jitter) are lessened. The block diagram of the circuit used in this project is shown in Fig. 3.

Figure 3: Block diagram of the peak detector.

The input signal charges a capacitor through a fast Schottky diode and a series 50 Ohm resistor which provides matching during signal transients. The voltage in the capacitor is buffered using a low input bias current operational amplifier. A fast bipolar junction transistor discharges the capacitor after the peak value is sampled. The discharge signal is synthesized from the accelerator's reference signal and shifted by appropriate number of cycles. Waveforms of the peak detector's output signal sampled by a high-speed real-time oscilloscope for various bunch charges are presented in Fig. 4.

For charge below 30 pC the signal is disturbed by strong oscillations during the first 15 ns after the rising edge. The transfer function of the system (voltage → bunch charge) was characterized by relating the mean value of the signal (in time period 35 to 45 ns) to the known bunch charge using linear regression (Fig. 5).

The estimated model equals

$$Q = 0.1044 \frac{\text{pC}}{\text{mV}} * (V + 158.13)(\text{mV}) \quad (1)$$

The charged (Q) is lineary proportional to the measured voltage (V) with a roughly 158 mV offset. The maximum

Figure 4: Detector's output signal.

Figure 5: Characteristic of the bunch charge detection subsystem.

estimation error is 0.73 pC and mean absolute estimation error is 0.41 pC. The measurements prove the detection subsystem can be considered linear.

FIRMWARE

The charge detector output signal feeds the MTCA.4-based single cavity LLRF regulation system [2]. This system consist primarily of an Advanced Mezzanine Card digitizer SIS8300-L2¹ and an analog Rear Transition Module DRTM-DWC8VM1².

An outline of the controller's algorithm is given in Fig. 6. First, the RF feedback loop is described. Sampled IF signals from ADCs are fed into delay blocks, allowing coarse time alignment of different channels. In the next step IQ demodulation and calibration are performed. A programmable IIR filter is typically used as a low-pass or band-gap, limiting the detector noise and suppressing undesired spectral components like other pass-band modes of the cavity. The calculated error signal is fed to the feedback controller, the output of which is limited, before being combined with feed-forward signal. The drive signal is then scaled and rotated to compensate the slow drifts of the system, providing the controller with constant operating conditions. Finally, offset compensation is performed.

Raw ADC samples of the bunch charge detector output signal are fed into a block detecting the maximum and mini-

¹ <http://www.struck.de/sis8300-l2.html>

² <http://www.struck.de/dwc8vm1.html>

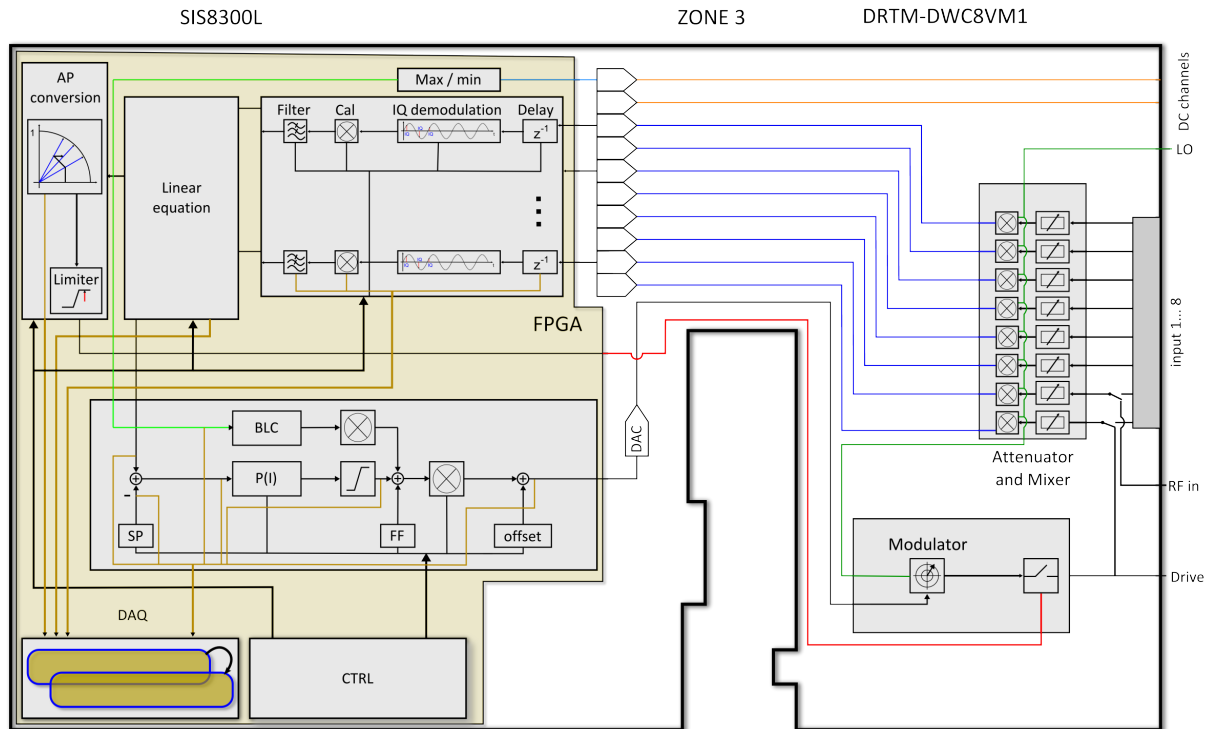

Figure 6: Hardware and firmware block diagram of the LLRF controls.

imum values. The amplitude (difference between max and min values) is multiplied by a gain coefficient. The next step is the rotation on the IQ plane. This signal is combined with feedforward and feedback signals before the output rotation.

TESTS

Measurements of the MTCA.4-based digital LLRF system using a PI feedback controller and the real-time BLC are shown in Fig. 7 (gain in arbitrary units). The beam pulse shape is similar to the one presented in Fig. 1 and 2.

Gain factor and rotation angle were chosen experimentally. The system response to beam rise is smooth, with no visible distortions. After the beam disappears, the RF field oscillates starting with the initial spike independent of the PI controller gain as visible in Fig. 7.

CONCLUSION

The addition of the real-time BLC to the LLRF system improves the system response to beam transients. Further development is needed to improve hardware (offset reduction by using different type of peak detector) and implement new algorithms in software (automated estimation of gain factor and rotation angle). The field oscillation at the end of the beam-body should be reduced.

ARCHITECTURE OF TRANSVERSE MULTI-BUNCH FEEDBACK PROCESSOR AT DIAMOND

M.G. Abbott, G. Rehm, I.S. Uzun, Diamond Light Source, Oxfordshire, UK

Abstract

We describe the detailed internal architecture of the Transverse Multi-Bunch Feedback processor used at Diamond for control of multi-bunch instabilities and measurement of betatron tunes. Bunch by bunch selectable control over feedback filters, gain and excitation allows fine control over feedback, allowing for example the single bunch in a hybrid or camshaft fill pattern to be controlled independently from the bunch train. It is also possible to excite all bunches at a single frequency while simultaneously sweeping the excitation for tune measurement of a few selected bunches. The single frequency excitation has been used for continuous measurement of the beta-function. A simple programmable event sequencer provides support for up to 7 steps of programmable sweeps and changes to feedback and excitation, allowing a variety of complex and precisely timed beam characterisation experiments including grow-damp measurements in unstable conditions and programmed bunch cleaning. Finally input and output compensation filters allow for correction of front end and amplifier phasing at higher frequencies.

INTRODUCTION

At Diamond Light Source (DLS) we have been using a Transverse Multi-Bunch Feedback (TMBF) system based on the Libera hardware platform [1] for nearly a decade [2–5] to control multibunch instabilities. With a new bunch position every 2 ns it is appropriate for the feedback processing to be implemented in an FPGA. The original firmware was based on work done at the ESRF [6], but subsequently the firmware and control system have been rewritten to provide further extensions to the system functionality [7, 8]. This work has extended the lifetime of the original platform and increased its capability, and the DLS TMBF system has now been adopted at ALBA [9] and is being evaluated at the Australian Synchrotron.

In this paper we expand on and update the original IBIC 2013 [7] paper with many system refinements.

OVERVIEW

Figure 1 shows the TMBF processors in context. A 4-button electrode assembly together with an RF hybrid circuit picks up the horizontal and vertical position of each bunch. An RF front end converts this raw 3rd harmonic signal into a 250 MHz bandwidth bunch position signal suitable for processing by TMBF. This signal is digitised at 500 MHz (using four 125 MHz ADCs phased at 2 ns intervals), processed by the FPGA, and then reconverted to drive the striplines.

Figure 1: TMBF system in context. The Transverse Multi-Bunch Feedback system measures the position of each bunch, detects the betatron oscillations of each bunch, and generates a drive signal to suppress the oscillations.

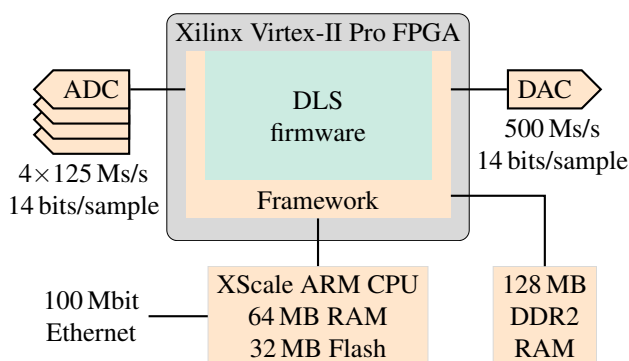

Figure 2: Libera System Platform. The DLS TMBF system is implemented on the Instrumentation Technologies Libera platform with the control system running EPICS on an ARM based embedded Single Board Controller (SBC).

The position of each bunch oscillates at the machine betatron tune, and these oscillations can normally be suppressed by feeding them back with a phase shift of 180° . The TMBF measures the horizontal or vertical position of each bunch, runs a 10-tap FIR filter on each bunch position to compute the appropriate phase adjustment, and outputs a negative feedback signal.

The TMBF processing system consists of analogue to/from digital converters connected to an FPGA for the high speed processing, together with memory for data capture and an embedded Single Board Computer as shown in Fig. 2.

As well as the core feedback function, a number of diagnostic functions are provided, both to enable easy monitoring of the system status, and to support complex experiments on the beam. System status monitoring includes detailed overflow detection and quick measurement of beam movement. Complex experiments are supported by internal oscillators, detectors, and a programmable sequencer, described in more detail below.

Figure 3: This is the core data processing chain in the TMBF processor. Data processing starts by adding a DC offset to each of the four ADC channels to compensate for static ADC errors, followed by a 3-tap filter to compensate for high frequency phase errors in the front end. The minimum and maximum value per bunch of both the ADC and DAC streams is captured for display. A 10-tap filter with programmable gain (in 6 dB steps) is applied in turn to each bunch in the ring. The output multiplexer adds any combination of its three inputs, which is then scaled by a bunch specific gain. Finally an output pre-emphasis filter corrects for amplifier errors and is followed by a delay line to correctly close the loop.

FEEDBACK DATA PROCESSING

The main function of TMBF is to stabilise transverse oscillations of the beam. This is done by running a separate 10-tap FIR on the position of each of the stored bunches. The core data processing chain shown in Fig. 3 combines this feedback with up to two optional Numerically Controlled Oscillator (NCO) outputs.

Note that numerical overflow can occur at any stage in this processing chain. When this is detected, a saturated output is generated and the resulting overflow event is reported to the user through the EPICS interface.

ADC Data In

The Libera platform uses four separate 125 MHz ADCs to sample the 500 MHz bunch position signal, and so the ADC input arrives as four parallel streams of 125 MHz data. The first processing step is to compensate for small DC offsets between the ADCs. These offsets are easily measured and compensated.

The next step is to compensate for gain differences and high frequency phase and gain errors in the front end. This is done by running a channel dependent 3-tap filter on the input data stream.

Finally a “min/max” subunit measures the minimum and maximum compensated value for each bunch; this is read out at 100 ms intervals and used to provide an accessible overview of bunch motion.

FIR Feedback Processing

Next a 10-tap FIR is run on the stream from each bunch. In practice, this means that 936 separate FIRs are run, with a delay of 936 bunches between each tap. The FIR unit can be programmed with four different filters, each of which can be separately selected for each bunch. The filter taps and final output gain are statically configured through the EPICS interface.

The ability to control bunches independently has two main uses: firstly, it can be used to apply a different filter to the isolated bunch in a hybrid fill; secondly, it can be useful as part of detailed machine physics experiments.

Figure 4: Bunch by bunch FIR and output control. The sequencer selects one of four banks to be active, defining basic machine behaviour. Each bank contains bunch configuration information for each of the stored bunches, used to control the feedback filter and the output configuration.

DAC Data Out

Finally the filtered signal is prepared for output. At this point three candidate output signals are selected and summed together: the FIR filtered signal and two internally generate NCO signals. Each of these three signals can be output or set to zero, and this control is per bunch.

Next the summed output is scaled by a bunch specific scaling factor. As this is signed it can be used to reverse the orientation of feedback on a single bunch.

Finally an output pre-emphasis filter is run to compensate for amplifier effects and the output is delayed so that the complete loop delay is a full machine revolution.

In the same way for ADC data, a “min/max” component measures the movement of each output bunch over a measurement interval of 100 ms, providing a quick view of bunch output motion.

Bunch by Bunch Control

As noted above, the FIR filter, the output sum, and the final output gain are selected per bunch. The “Bunch Select” unit, see Fig. 4, stores four arrays (or “banks”) of bunch specific configurations — one configuration is selected by the sequencer unit (described below), and the current bunch configuration advances on each bunch. This configuration can be written through the EPICS interface.

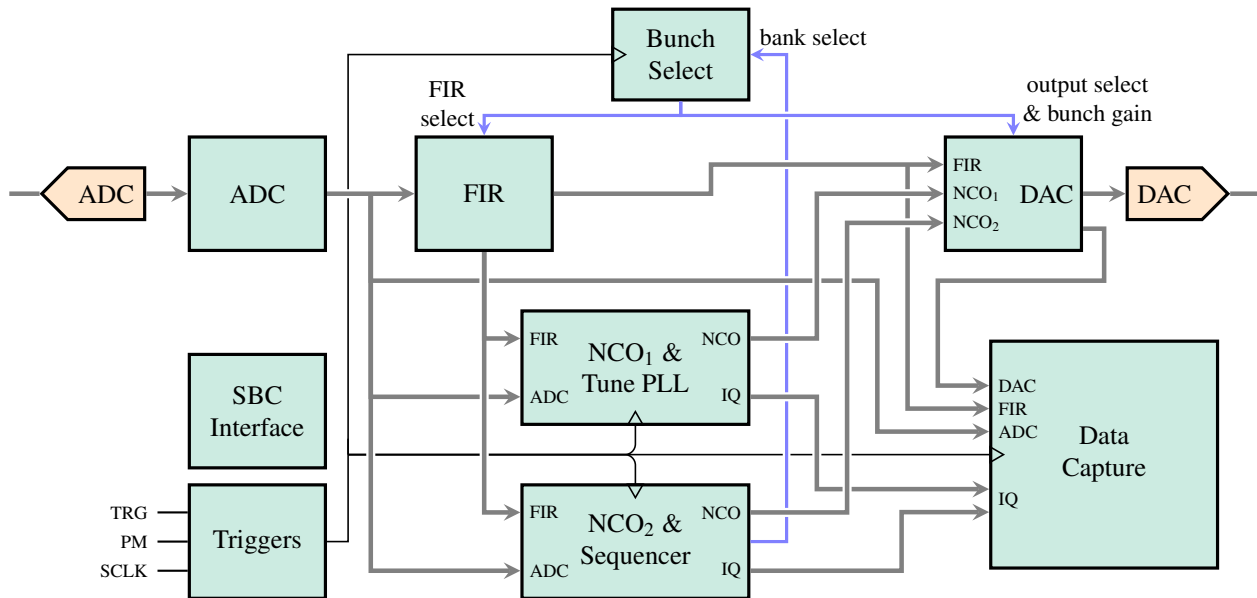

Figure 5: Here we see all of the major blocks of the FPGA system design and their data interconnections. FPGA blocks are shown thus:  and analogue/digital converters thus: . The main data flow is from the ADC, through the FIR with a separate FIR filter selected for each bunch, and out through the DAC with the option of adding up to two internally generated sine waves. The other paths are for control and data capture. The SBC interface controls and communicates with all other components of the system: the EPICS interface is through this component.

EXTRA DIAGNOSTIC DATA PROCESSING

Figure 5 shows the complete DLS TMBF firmware. The ADC-FIR-DAC chain has been described above. The remaining major components are for extra diagnostics and advanced machine experiments.

Data Capture

As already shown, min/max overview data is available for ADC input and DAC output. The Data Capture unit allows more detailed information: up to 4096 bunches of two out of three of DAC/FIR/ADC data streams can be captured, or up to 64 million bunches (more than 65,000 turns) of any one input can be captured. The shorter data capture is to FPGA block memory, the larger to external DDR2 RAM.

An alternative capture source is detector IQ data from either of the two NCO units. In particular, this is used for tune sweeps and more complex machine experiments.

NCO₁ and Tune PLL

Figure 6 shows the first NCO unit together with the tune tracking application (Tune PLL). When tune tracking is inactive the NCO generates a fixed frequency sine wave with programmable gain which can be used to drive selected bunches.

When tune tracking is active the detector (see Fig. 7 for the detector structure) measures the phase response of the beam at the currently driven frequency and runs a simple PI feedback loop to adjust the frequency to keep the

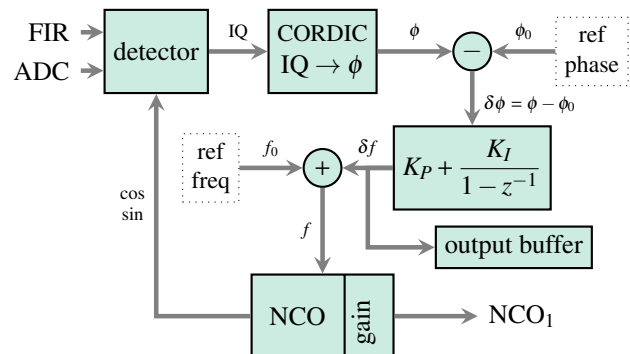

Figure 6: The oscillator NCO₁, can be set to a fixed frequency, or can be used as part of a tune tracking phase locked loop. The tune phase ϕ is measured at the operating frequency f and used to compute a sequence of frequency corrections δf to maintain the phase error $\delta\phi$ at zero. The reference phase and frequency are configured via EPICS.

phase response static. The frequency shift can be read as a continuous stream through the EPICS interface.

This is very useful for measuring rapid changes in the machine betatron frequency, but will only work when the centre frequency and phase are already known to sufficient precision. Measuring this is the primary job of the next unit.

NCO₂ and the Sequencer

Figure 7 shows the second NCO unit together with the sequencer unit and a detailed view of the detector. The detector measures the complex response of the selected input to the driving frequency. The duration of each

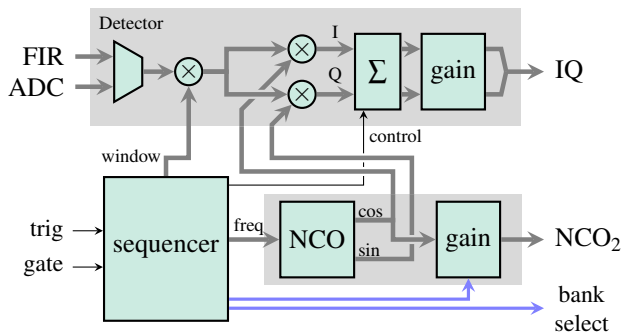

Figure 7: The oscillator NCO_2 is under control of the sequencer, and is only enabled while the sequencer is running a program. The sequencer controls the NCO frequency and gain and performs programmed frequency sweeps. Data from the beam is mixed with the excitation waveform in the detector to measure a complete complex IQ response. Operation of this system produces a waveform of IQ measurements which can be used for measuring betatron tune and other machine parameters.

measurement is controlled by the sequencer. The measured IQ value is scaled to a pair of 16-bit numbers for storage and transferred to the control system.

The TMBF sequencer controls the NCO_2 frequency, the NCO_2 output level, and which bunch bank is currently active. A machine experiment is performed by programming up to seven different control configurations and then triggering the start of the sequencer. The sequencer will then work its way through the programmed states, changing the output configuration as appropriate and capturing the appropriately programmed number of IQ samples, before finishing. Typically the sequencer and the data capture unit are triggered together.

For example, a standard tune sweep is performed using a single sequencer state which configures NCO_2 for output and steps through a preset range of NCO frequencies. Alternatively, a grow-damp experiment requires more states: one to excite the beam for a selected period, one to allow the beam to grow without feedback or excitation for a period, and one to restore feedback.

One final feature of the sequencer is the so-called “super-sequencer”: this repeatedly performs a sequencer programme for a series of base frequencies. This is used to perform a grow-damp experiment on each transverse mode in turn, and allows the transverse mode damping times to be measured for all modes in a fraction of a second [8].

EPICS CONTROL SYSTEM

The control system running on the embedded ARM processor was developed concurrently with the FPGA firmware, and provides access to all settings and readings through around 560 EPICS PVs. A number of supporting scripts were written in Python and Matlab to help configure some of the more complex functions of TMBF.

A complete set of user interface screens built using EDM provides access to every PV published by TMBF. Around 255 PVs are used to configure settings, so the supporting scripts are important for normal operation.

The EPICS control system and the TMBF FPGA system are tightly coupled. Although the ARM processor is low powered and lacks hardware floating point support it is capable of some signal processing if care is taken. In particular, tune measurement is done by first performing a frequency response sweep with the FPGA, and then analysing the resulting IQ response and fitting a multi-pole tune response model. It has been possible to develop quite a sophisticated tune measurement process on this system.

CONCLUSIONS

The upgraded TMBF system described here has been in use at Diamond since late 2013 and is allowing us to perform very complex measurements to characterise the beam behaviour. This development has pushed the 10 year old FPGA technology to its limits, the FPGA now has little or no room for further developments.

Our next step at Diamond is to implement longitudinal bunch-by-bunch feedback in preparation for operation with normally conducting cavities. This will be based on a more modern FPGA on industry standard MicroTCA hardware.

PANDA MOTION PROJECT - A COLLABORATION BETWEEN SOLEIL AND DIAMOND TO UPGRADE THEIR 'POSITION AND ACQUISITION' PROCESSING PLATFORM

I.S. Uzun, T. Cobb, A. Cousins, M. Heron, Diamond Light Source, Oxfordshire, UK
YM. Abiven, J. Bisou, P. Monteiro, G. Renaud, SOLEIL, Gif-sur-Yvette, France

Abstract

Synchrotron SOLEIL and Diamond Light Source are two third generation light sources located respectively in France and the UK. In the past 5 years, both facilities separately developed their own platform permitting encoder processing to synchronize motion systems and acquisition during experiments, SPIETBOX by SOLEIL and ZEBRA by Diamond. New operational requirements for simultaneous and multi-technique scanning, and support of multiple encoder standards have been identified by both institutes. In order to address these a collaborative project has been initiated between SOLEIL and Diamond to realize a new 'Position and Acquisition' processing platform, called Panda. The Panda project addresses current systems' limitations in terms of obsolescence and need for more processing power. Its design is going to be a 1U standalone system powered by a Xilinx Zynq SoC to implement a configurable set of logic functionalities. It will provide a flexible and open solution to interface different third party hardware (detectors and motion Controllers). This paper details the organization of this collaboration, sharing technical leadership between both institutes and the status of the project.

COLLABORATION MANAGEMENT

SPIETBOX [1] and ZEBRA [2] were designed in-house by SOLEIL and Diamond respectively, and both have been integral part of beamline operations, and proven useful for synchronising various equipment and for position capture. One application is to synchronize detectors with optics that select the photon energy of the beam to acquire only useful data, another one is facilitating the use of continuous scanning for faster acquisition in 2014. Both institutes share the same vision for a new motion control and data acquisition architecture. So SOLEIL and Diamond have gone into a collaboration to re-design and improve these platforms with following guidelines:

- Both institutes want to standardize hardware, in order to reduce number of systems which need to be developed and maintained by the support staff.
- Develop a ready to use and complete solution, in order to install quickly and easily all the hardware and software components.

The main goal of the collaboration was to share resources and experiences between both synchrotrons for the development. The first step was to understand existing skills and human resource availability at both institutes and agree on

sharing the responsibilities of each task at design level as shown in Table 1. We decided to manage the work through regular video conference meetings every two weeks, face-to-face meeting every 3 months, as well as sharing minutes and documentation over a private Github repository. Once the organization was set-up, a set of hardware, firmware and software specifications were defined as described in the following sections. It is agreed that the hardware developed during the course of the collaboration would be developed under the CERN Open Hardware (OHW) Licence [3] and released on the public OHW repository following completion of the project. Both parties would also have the option to engage third parties to commercialise the resulting project.

HARDWARE ARCHITECTURE

New applications [4], operational feedback from beamline scientists and from the Flyscan project [5] identified the following requirements to address limitations of existing SPIETBOX and ZEBRA solutions:

- Multi Channel TTL and LVDS I/Os for synchronous triggering and clocking with higher timing resolution.
- 4-Channels of encoder interface I/Os, supporting a wider range of protocols including Incremental, Absolute, EnDat and BiSS.
- 2-Channels of SFP Gigabit Transceiver interface for IpBus, Timing System, Diamond Communication Controller [6] or custom high-speed serial connectivity.

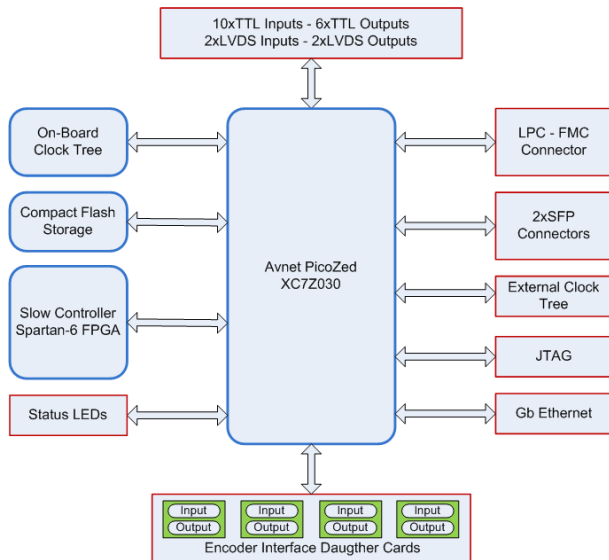

Figure 1: System Architecture.

- A fully compliant Low-Pin Count FMC slot for interfacing to analog and digital off-the-shelf boards or custom I/O modules.
- A Gigabit ethernet connectivity for control systems integration and high-speed data acquisition.
- A capable FPGA-SoC device for significant improvement of existing processing, programmable functionality and tighter system integration.

The proposed hardware architecture in Fig. 1 gives us a platform we can develop specific solutions with simple, reliable and durable tools. The platform is suitable in particular for applications where it is generally necessary to synchronize a range of equipment, which are managed by implementing the process at low level.

At the heart of the system architecture is the PicoZed [7] System-On-Module as shown in Fig 2. The PicoZed module contains Xilinx Zynq-7030 All Programmable (AP) SoC and the common functions required to support most SoC designs, including memory, configuration, ethernet, and clocks. It provides easy access to over 100 user I/O pins through three I/O connectors on the rear of the module.

A modular approach to the hardware design was taken by:

Figure 2: Avnet Picozed SOM.

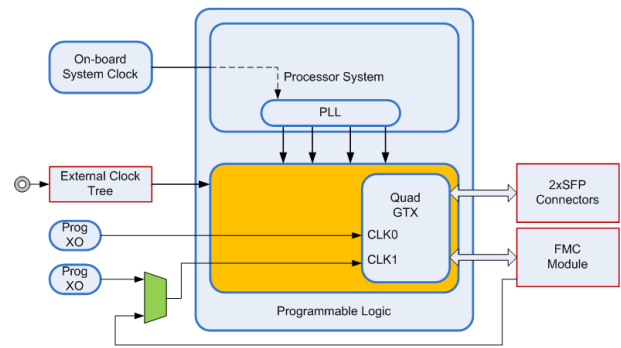

Figure 3: PandA Clocking Scheme.

- Using daughter cards for the encoder interface electronics permitting custom solutions, and to accelerate the development process. The current daughter card has been designed with pin-compatibility with the SOLEIL and Diamond motion controllers.
- Adding an industry standard fully-compliant Low Pin Count (LPC) FPGA Mezzanine Connector (FMC) to the architecture to enable analog I/O capability by using 3rd-party products [8] or custom modules.

In order to achieve the maximum flexibility that PandA can offer in terms of application support, a clocking architecture is built for clocking user programmable logic and Gigabit transceivers as shown in Fig. 3.

One of the drawbacks of modern programmable SoC devices is the limitation in terms of user I/O count. In our case, PicoZed module provides 135 user I/Os which is not enough to cover all the connectivity required by the specifications. To address this limitation, another lower-end FPGA device with multiple user I/Os is used to handle slow control functionality of various on-board devices. The communication between the main XC7Z030 Zynq device and slow control FPGA is achieved using an SPI-like custom interface.

PandA will consists of a 1U metal box, with BNC and LEMO connectors for single ended, differential signals and Gigabit Ethernet on the front panel. 15-way D-type connectors for RS485 encoder signals and power on the back panel.

FIRMWARE CAPABILITIES

PandA firmware functionality was designed to achieve full configuration flexibility and tight control system integration. The firmware implements a list of logical functions, a range of position compare functionality, high-throughput position capturing, multi-gigabit serial interconnections, and Arm processor interface.

Logic Operations and Position Based Blocks

A list of logical functions that had already been implemented by existing solutions was reviewed and following improved blocks were defined for PandA:

- Function generators to implement any 5-input boolean function.

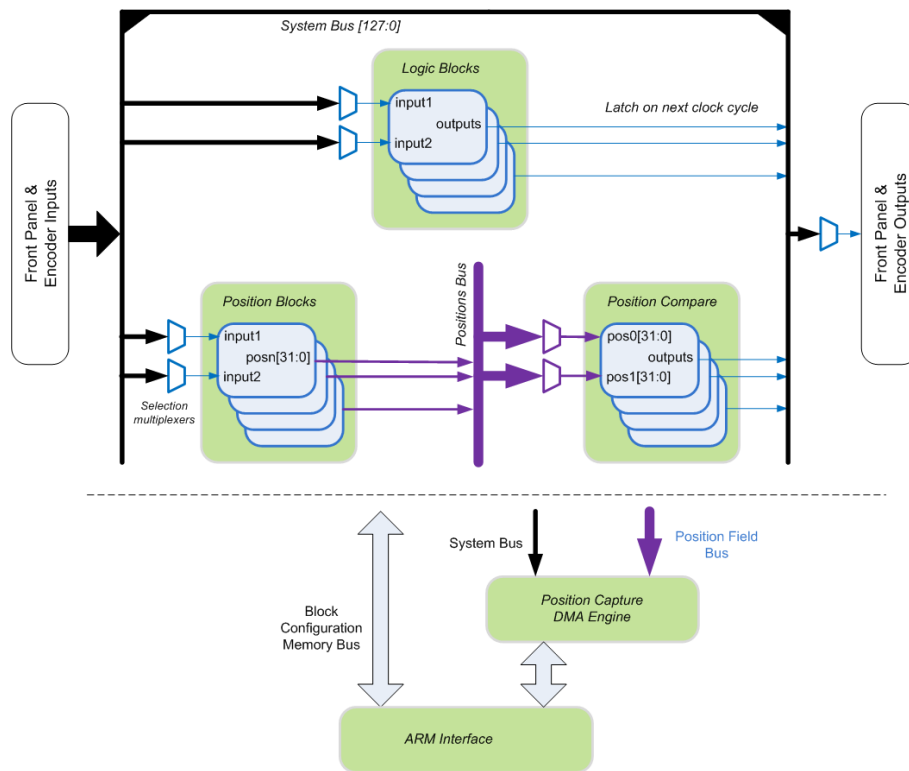

Figure 4: PandA Firmware Architecture.

- Set/Reset Gate blocks with configurable inputs, and an option to force its output independently.
- 32-bit Pulse divider with programmable divisor and two pulse outputs (divided and non-divided).
- Pulse Generator blocks to produce configurable width and delayed pulses triggered by its input and also able to handle pulse trains.
- Sequencer blocks to perform automatic execution of sequenced frames to produce timing signals.
- Programmable clock generators.

Similarly, a wide range of position based blocks are defined:

- Encoder Input/Output blocks supporting multiple encoder protocols.
- Quadrature Input/Output blocks to enable of any discrete signal on the system for quadrature operations.
- Counter/Timer blocks to implement multi-channel 32-bit up/down counters synchronous to system clock.
- Analog input/outputs upto 8-channels through FMC module connectivity.

To achieve connectivity between all design blocks, two internal buses are defined. The System Bus is a 128-bit wide register is composed of concatenating all physical I/Os, and registered discrete outputs from logic and position-based blocks. Similarly, all 32-bit outputs of the position based

blocks are concatenated together to create the 1024-bit wide (32x 32-bit) Position Bus.

By connecting the input of any logic block to the system bus via a 128x1-bit multiplexer, it becomes possible to cascade multiple blocks to achieve the desired functionality. Each physical output is also taken from the system bus in the same way (see Fig. 4). Position Bus feeds all the 32-bit position inputs of all position compare blocks using 32x32-bit multiplexer so that position compare processing can be done on encoder, timer or analog input values.

Position Compare and Capture

The position compare blocks in PandA are designed to be able to generate a stream of trigger pulses, which can be position based, time based, analog input based or externally triggered. A new feature added to the position compare functionality is the ability to use LUT-based arbitrary arrays of position or time points instead of regularly spaced series of values. This facilitates:

- Position based capture – where output pulses are generated when the encoder position reaches a certain value, or series of values.
- Time based capture – where output pulses are generated at regular time intervals, storing the encoder positions as well.
- Analog input based capture – where output pulses are generated when analog input position reaches a certain value, or series of values.

- External trigger capture – where the motion controller stores the encoder position on an external trigger signal.

By cascading multiple position capture blocks, it is possible to mix modes together, such as outputting a time based pulse stream within a series of position based gates.

A central position capture block is responsible for capturing user-defined fields across the design including timestamps, encoder values, analog input values, counters and system status on trigger events. The captured data is DMA transferred into the system memory, and read out via gigabit ethernet interface.

Multi Gigabit Connectivity

The 3-channels of Multi-Gigabit Transceivers (MGTs) on the Zynq device are brought onto the front panel through SFP connectors. Along with the flexible clocking architecture in Fig. 3, these MGTs enable implementation of following interfaces on PandA for wider-level connectivity.

- Diamond Communication Controller: Light weight, low latency and high reliability data distribution.
- IPBUS: Simple, reliable, UDP/IP based protocol for controlling hardware devices.
- Micro-Research Event Receiver: to recover timing events and clocks distributed across the event network.

Processor Interface Logic

The processor interface logic handles communication with the host on Zynq-Arm Processor System for control and data acquisition purposes. The Zynq-Arm will run linux and use a dedicated linux device to tightly integrate with the FPGA logic. This will be through

- A dedicated address space on the host system memory enable direct access to each firmware block's configuration and status registers.
- A Write DMA master engine to transfer position capture data onto the system memory in real-time. Data rates up to 128MB/sec (capturing up to 32 position fields at 1MHz pulse rate) are envisaged.
- A Read DMA master engine for synchronous reading of user-defined arrays for position compare operation. The length of user defined arrays being limited to 1MSamples.

CONTROL SOFTWARE ARCHITECTURE

Figure 5 depicts standalone software architecture for PandA project. The kernel driver provides control and status register access to system blocks, and interface with the DMA engines for synchronous read/write data transfers. It is wrapped by a TCP Server that implements custom protocols over two channels for data and control interfacing. It is our intention that PandA will be integrated either with an EPICS IOC, a webserver interface, or with a separate TANGO server.

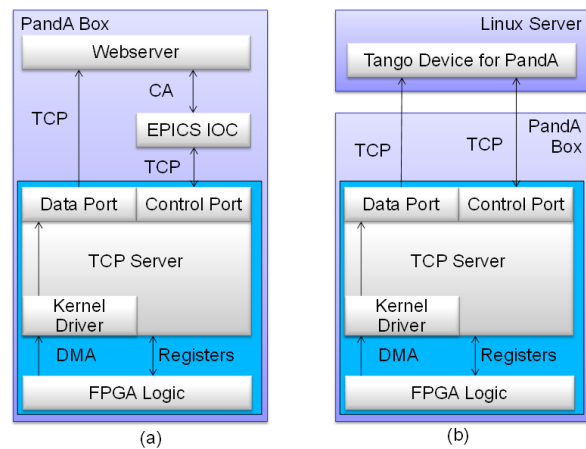

Figure 5: Software Architecture for (a) Diamond, (b) SOLEIL.

SUMMARY

Diamond and SOLEIL share the same vision of motion control architecture and have started collaboration for development of a common platform for Position and Acquisition of encoder sensors (PandA). Following agreement on the hardware, firmware and software specifications, both parties started design work mid-2015. Using commercial products, as much as possible, allows efforts to focus on applications requirements and saving time in development. The initial design and development phase is planned to be completed in the first quarter of 2016, with a provision of having prototype units during mid-2016.

UPGRADED CONTROL SYSTEM FOR LHC BEAM-BASED COLLIMATOR ALIGNMENT

G. Valentino*, G. Baud, M. Gasior, S. Jackson, L. Jensen, J. Olexa, S. Redaelli, J. Wenninger
CERN, Geneva, Switzerland

Abstract

In the Large Hadron Collider (LHC), over 100 movable collimators are connected to a three-tier control system which moves them to the required settings throughout the operational cycle from injection to collision energy. A dedicated control system was developed to align the collimators to the beam during machine commissioning periods and hence determine operational settings for the active run. During Long Shutdown 1, the control system was upgraded to allow beam-based alignments to be performed using embedded beam position monitors in 18 newly installed collimators as well as beam loss monitors. This paper presents the new collimation controls architecture for LHC Run II along with several modifications in the Java-based application layer.

INTRODUCTION

The Large Hadron Collider (LHC) accelerates two counter-rotating beams to an energy of 7 TeV before colliding them in four points where experiment detectors are located [1]. Uncontrolled beam losses can result in quenches of the super-conducting magnets, which can damage the machine. For this reason, a beam collimation system is installed in the LHC, comprising over 100 collimators [2]. It is also designed to protect the LHC in the event of fast failures, which might damage accelerator components.

Each collimator installed for ring cleaning consists of two jaws, made of graphite, tungsten or copper, which have to be positioned around the beam at all times with an accuracy of less than 50 μm . The operational settings of the collimators are defined in order to establish a four-stage hierarchy. They are determined via a beam-based alignment procedure [3] which uses feedback from a Beam Loss Monitoring (BLM) [4] detector positioned downstream from the collimator. From the aligned jaw positions, the measured beam centers and beam sizes can be calculated.

The primary collimators (TCP) are positioned closest to the beam, followed by the secondary collimators (TCSG), tertiary collimators (TCT) and absorbers (TCLA). Most of the collimators are installed in Insertion Region (IR) 3 and 7 for off-momentum and betatron cleaning respectively. The TCTs are installed upstream of the experiment detectors (IR1, 2, 5 and 8), and a TCSG is installed in the dump region (IR6).

The software architecture for the LHC collimation sys-

tem respects the standards of the LHC Software Architecture (LSA) [5], which consists of a 3-tier structure. For the collimators, the bottom layer is composed of a double PXI system that is used to control and read out stepping motors, sensors and measurement devices. The collimator jaw positions can be positioned with an accuracy of 5 μm , i.e. less than 2% of the 1σ beam size at the primary collimators at 7 TeV. The maximum jaw movement rate is 2 mm/s.

Application servers that host databases and operational files make up the middle layer, on top of which Graphical User Interface (GUI) console applications run. The collimator positions can be set from a remote location in the CERN Control Centre (CCC) and synchronized with the operation of the LHC cycle. The software applications interact with the hardware via the Common Middleware (CMW) [6] and Front-End Software Architecture (FESA) [7] infrastructures.

During Long Shutdown 1 (LS1), all 16 TCTs and the 2 TCSGs in IR6 were replaced by a new design, in which Beam Position Monitor (BPM) pick-ups are embedded in the upstream and downstream corner of each collimator jaw [8, 9]. The LHC installation followed a successful validation of a prototype with beam in the Super Proton Synchrotron (SPS) [10]. This required an upgrade of the beam-based alignment control system to acquire and use both the BLM and the BPM data for the alignment.

ALIGNMENT PROCEDURES

BLM-based Alignment

A four-stage procedure is used to align the collimators with feedback from the BLMs. Both jaws of a reference collimator are moved towards the beam in steps of 5-20 μm (1) until they reach the beam halo on either side, which is established when an appropriate loss pattern is observed in a downstream BLM. Then, the collimator for which the beam center and beam size need to be measured is aligned (2). The center is given as the average of the two aligned jaw positions. The reference collimator is then re-aligned (3), and the beam size at the previous collimator is given as the ratio of its gap in mm when aligned to the average of the cut in units of beam σ . The final step is to open the collimator to the new operational positions (4). This procedure is performed at very small gaps of $< 4\sigma$.

One of the main drawbacks of this procedure is that it causes losses of a fraction of the circulating beam and therefore can only be carried out with safe beam intensities. Collimator alignment can therefore not be performed dur-

* gianluca.valentino@cern.ch

ing standard operation. Due to the time needed to complete an alignment of the full system (~ 4 hours), which needs to be repeated for different subsets of collimators at different points in the machine cycle, the system performance relies on machine and collimator setting stability and reproducibility from fill to fill.

BPM-based Alignment

The beam position between two BPM electrodes can be calculated using a well-known linear technique. In a simple 2D approximation of a BPM arrangement, which consists of a circular beam-pipe and two point-like electrodes located 180° apart on a horizontal axis, the approximate position of a charged particle, denoted as X_{bpm} , is calculated from the distance between the opposite BPM electrodes B and the induced potential V_1 and V_2 on opposite BPM electrodes:

$$X_{bpm} = \frac{B}{4} \frac{V_1 - V_2}{V_1 + V_2} \quad (1)$$

The objective of the alignment is to minimize X_{bpm} . A successive approximation algorithm was developed to automatically align the collimator jaws around the beam axis from any starting jaw gap and beam offset [11]. The left and right jaws are moved towards and away from the beam respectively, or vice-versa, depending on the sign of the beam offset. Several iterations are needed due to non-linearities inherent in the BPM geometry. Contrary to the BLM-based method, where the jaws touch a reference halo, this technique does not provide a measurement of the beam size at the collimator. However, the measured beam sizes are only used to calculate the operational settings at injection, as the error introduced by the β -beat tends to be more than the alignment error due to the jaw step size, while at top energy the nominal beam sizes are used as the beam sizes shrink. BPM-based alignment is more useful at top energy in terms of machine commissioning efficiency, as the majority of the machine configuration changes throughout the run take place there.

ALIGNMENT SOFTWARE ARCHITECTURE

LHC Run 1 Architecture

During Run 1, all collimators were aligned using the BLM-based technique as the embedded BPM collimators were not installed. BLM data was transmitted at 12.5 Hz from the crates in the tunnel via UDP to a Linux server, which swallowed or forwarded the packets depending on whether a Java client GUI subscribed to the data. The header of each UDP packet contained the IR and the position within the IR (left, right, center) of the BLM crate. The payload consisted of the data arranged in a 16×16 2D array. The data are in integer format, and were then converted to units of Gy/s. The collimator jaw positions

were set and read out via a FESA class called *LHCCollimator* [12]. A feedback loop was implemented in the Java GUI, which stopped the jaw movement when the losses exceeded a pre-defined threshold in Gy/s [13].

A prototype collimator with embedded BPMs was installed in the SPS in Run 1 for beam tests. This architecture was re-used for the BPM data acquisition, which is provided by electronics based on compensated diode detectors (called DOROS) [14]. By taking measurements over thousands of turns, sub-micrometer resolution is achieved. The BPM-based alignment algorithm was implemented in the Java GUI to make it easier to modify during the beam tests.

LHC Run 2 Architecture

In LS1, the Run 1 control system was upgraded to allow both BLM-based and BPM-based collimator alignment to be performed in the same software module. The new software architecture is shown in Fig. 1. The functionality previously present in two separate Java applications was moved to a new FESA class (called *LHCCollAlign*) running on a Front-End Computer (FEC). The Run 1 UDP packet format was reused to allow the BLM crates to send the 12.5 Hz data to the FEC. *LHCCollAlign* acts as a BLM concentrator and combines the 12.5 Hz data from all 27 BLM crates for logging purposes.

The DOROS electronics was upgraded from the SPS beam tests with automatic gain control to ensure that the signals remain within a fixed range independently of the BPM aperture and beam intensity in the LHC. In addition, asymmetries between two opposite BPM pick-up channels are corrected online by means of a switching mechanism, in which the signals A and B from two opposite electrodes are connected to respective channels A and B or to channels B and A. An averaged, calibrated beam position measurement is then provided at 1 Hz by a second FESA class (*BPMCOL*), which receives the data from the DOROS boxes via UDP and send back control messages to the DOROS boxes (therefore acting as a DOROS controller). The beam positions (X_{bpm}) at each collimator are calculated based on the electrode signals and the BPM aperture. The aperture is calculated by *LHCCollAlign* from the upstream and downstream jaw positions of the 18 BPM-equipped collimators, and a constant offset which is the retraction of the BPM pick-up button with respect to the jaw surface. This is then sent to *BPMCOL* at 1 Hz, which is the readout rate from *LHCCollimator*. All collimators can be concurrently aligned using either of the two techniques.

The BLM-based feedback loop is always active, meaning that should high losses occur during the BPM-based alignment, when the collimator is supposed to be far from the beam, the jaw movement is stopped. The software architecture is designed to be easily extensible should further collimators be equipped with BPMs in future LHC runs. Once sufficient experience is gained with the system, the existing collimation hierarchy margins in the TCSPs and TCTPs (placed to account for beam orbit drifts) can be re-

TCTPH.4L8.B1		●	
		●	

Figure 2: Subview of the monitoring display showing the up and downstream beam positions at one collimator.

USER INTERFACES

limit. The non-linearities inherent in the BPMs can be corrected for by performing a 2D polynomial fit to a series of measured beam positions at different collimator gaps and offsets [11]. The fit coefficients can be sent to *BPMCOL* via a dedicated GUI.

ALIGNMENT RESULTS

The software architecture was tested during a SPS beam test and in the LHC during the beam commissioning period at the start of Run 2. An example of a BPM-based collimator alignment is shown in Fig. 3. A total of 12 iterations were needed to complete the alignment. Initially, both jaw corners are moved in parallel until the upstream electrode signals are equalized. Then, a tilt is gradually introduced in the jaws until the downstream electrode signals are also equalized. All collimators were aligned simultaneously in 15-25 seconds, which is a remarkable speed-up over the ~ 1.5 hours required to align the same collimators with the BLM-based technique.

Figure 3: BPM-based collimator alignment.

CONCLUSION

Beam-based alignment of the LHC collimators is used to determine the jaw settings needed for operation. During Run 1, all collimators were aligned with a beam loss feedback algorithm, which ensured that the jaws stopped moving when the beam halo was reached. This was performed using a Java GUI application. The replacement of 20% of the system with embedded BPM collimators required a controls software upgrade. A new middleware layer was developed in FESA to ensure that the BLM and BPM data acquisition could be performed reliably for the given real-time constraints, and the separate alignment techniques could be performed in the same software module. The next steps will involve a thorough fill-to-fill analysis of the BPM data to determine whether the present collimation hierarchy margins to account for orbit drifts can be removed, and orbit interlocks could instead be put in place. This would allow to reduce the β^* and therefore extend the luminosity reach of the LHC.

HIGH LEVEL CONTROLS FOR THE EUROPEAN XFEL

Lars Fröhlich, Bolko Beutner, Winfried Decking, Olaf Hensler, Raimund Kammering,
Torsten Limberg, Sascha Meykopff, Josef Wilgen, DESY, Hamburg, Germany

Abstract

The European X-Ray Free-Electron Laser (XFEL) will generate extremely short and intense X-ray flashes from the electron beam of a 2.1 km long superconducting linear accelerator. Due to the complexity of the facility and the sheer number of subsystems and components, special emphasis needs to be placed on the automatization of procedures, on the abstraction of machine parameters, and on the development of user-friendly high-level software for the operation of the accelerator. The paper gives an overview of the ongoing work and highlights several new tools and concepts.

INTRODUCTION

The European X-ray Free-Electron Laser (XFEL) is a research facility currently under construction in close collaboration between the European XFEL Facility GmbH¹ and DESY² in Hamburg, Germany [1–3]. It consists of a superconducting linear accelerator delivering an electron beam with particle energies up to 17.5 GeV and a total beam power up to ~600 kW, several long undulator sections enabling the generation of extremely brilliant X-ray pulses at wavelengths down to 0.05 nm, beamlines and setups for photon science experiments, and the associated infrastructure. An overview of the control system architecture is given in [4].

Compared to other accelerator facilities operated by DESY, the XFEL presents itself as a system of unprecedented complexity. It will generate ~600 μ s long *macropulses* of up to ~3000 bunches at a repetition rate of 10 Hz. Individual bunches out of these trains will then be distributed to several undulator beamlines and beam dumps using a system of fast intra-train kickers. Even the sheer number of subsystems and components—more than 1400 electromagnets for beam guidance and focusing, more than 450 beam position monitors, to pick two popular examples—makes it clear that a high degree of automatization will be needed to operate the machine efficiently. Control software should offer high level abstractions for all important machine parameters rather than forcing operators to work at the level of individual technical subsystems.

We have formed an interdisciplinary team of physicists, engineers, and computer scientists from multiple DESY groups with the goal of establishing the best possible operability for the machine. The scope of this *high level controls* (HLC) effort is a deliberately broad one. It includes the preparation of user friendly tools for various physical or technical tasks in the control room as well as the development of feedbacks and of middle layer servers. A lot of work is invested to

improve the entire software stack of libraries, toolkits, and network services. This paper gives an overview of the various projects and activities, starting at the infrastructure level and closing with a discussion of stand-alone tools. For obvious reasons, we limit ourselves to the description of a few selected examples for each category.

PROTOCOLS AND INFRASTRUCTURE

Three main control system protocols are used at the XFEL: DOOCS [5, 6], Karabo [7], and TINE [8, 9]. Much work has been invested to improve the interoperability of these protocols [10], so that the problem of network communication across protocol boundaries is mostly solved. For HLC applications, efforts have concentrated on the development and improvement of interfaces for Matlab [11] and Python.

A *configuration database* has been set up as a central network service using DESY's Oracle 12c database system. It stores a complete list of beamline components and associated information such as calibration data. In this way, inconsistencies in the configuration of distributed servers can be minimized [12].

Finally, a *virtual accelerator* has been created by duplicating most of the middle layer and data acquisition software of the XFEL and exchanging the real front-end servers with dummies generating simulated data. This virtual XFEL has proven invaluable for the testing of high level software [13].

LIBRARIES AND TOOLBOXES

A multitude of libraries has been created to support the development of middle layer servers in C++. These projects include generic class libraries for access to various accelerator components, collections of algorithms for numerical tasks and fitting routines, classes for image analysis and conversion, an easy-to-use interface for retrieving information from the central configuration database, and various utility functions.

Matlab has traditionally been the main high-level interpreted language for physics applications at DESY. A broad assortment of utility functions is therefore available and actively maintained; a report on the DataGUI library for the design of advanced graphical user interfaces is found in [14]. We are currently focusing on the implementation of Matlab classes for access to specific accelerator components.

Recently, Python has been introduced as a second high-level language. Its main application at the moment is the rapid development of graphical user interfaces using the QT framework. Toolkit and library support is still fragmentary, but expanding continuously.

In general, we are encouraging the use of modern language standards where possible. For example, big parts of our C++

¹ European X-Ray Free-Electron Laser Facility GmbH, Albert-Einstein-Ring 19, 22761 Hamburg, Germany

² Deutsches Elektronen-Synchrotron DESY, Notkestraße 85, 22607 Hamburg, Germany

library code use C++11 and all of our Python developments are based on version 3.4 of the language.

MIDDLE LAYER SERVERS

The XFEL is equipped with lots of front-end servers that are distributed all over the accelerator, undulator, experimental, and infrastructure buildings. These front-ends establish the interface between hardware components and the controls network, fulfilling functions such as data acquisition from ADCs, communication with field buses, controlling actuators and the like.

Above this level, another system of servers pre-processes data and offers advanced functionality. In contrast to the distributed front-ends, these *middle layer servers* are running on only a few powerful computers in central locations. Among other considerations, this approach allows data to be streamed and processed via a powerful shared memory based data acquisition (DAQ) system in a fully synchronous manner [15]. A major part of the HLC effort is focused on the development of such middle layer servers, with the following goals:

More physics: We are continuously integrating more physical models directly at the server level. For example, magnets can not only be controlled via their power supply current, but also through the setting of deflection angles or fields under automatic tracking of hysteresis effects. Radiofrequency (RF) stations can not only be controlled via amplitude and phase, but also by specifying a desired energy chirp on the electron bunch. Even a complete optics model with matching capabilities is provided by an optics middle layer server [16].

More automatization: Time-consuming and complex procedures should be automatized wherever possible. For example, state machine based middle layer servers handle the startup, restart, and shutdown of RF stations along with the conditioning of couplers. Another server can perform a phase scan of the RF gun and determine the optimal phase for operation.

More online measurements: The implementation of measurement procedures at the server level makes it possible to provide a bunch-synchronous measurement of beam parameters like energy, slice emittance, or bunch length.

More uniformity: Some subsystems consist of device families with quite different interfaces. Middle layer servers present a uniform interface for all devices with a specific functionality—for example, the beam profile server can measure bunch profiles using scintillating screens or wire scanners, and the charge server will integrate readings from toroids and from beam position monitors (BPMs).

Less load: Because applications retrieve their data from the middle layer, there is less network and CPU load on the front-end side where infrastructure and computing resources are costly.

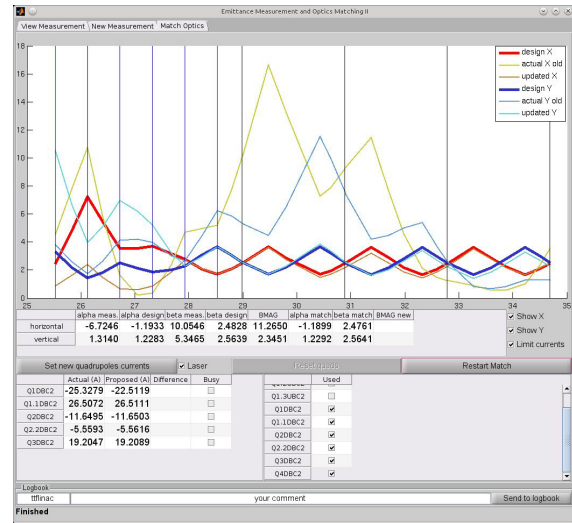

Figure 1: Screenshot of the *Emittance & Matching* tool while matching the beam optics to a periodic lattice.

More jddd: The Java DOOCS Data Display *jddd* [17, 18] is the main user interface builder used for constructing control system panels at DESY. It allows the deployment of standardized, powerful graphical interfaces with a minimum of effort. A lot of functionality that would traditionally have to be implemented as a full graphical application can therefore be integrated at the server level and use *jddd* as a user interface.

Feedbacks

Feedbacks are of enormous importance for the stability of the machine. Apart from a few very fast regulation loops acting within a single macropulse (at time scales of tens of microseconds), almost all beam-based feedbacks are implemented as middle layer software: Trajectory, bunch compression, charge, energy, and more parameters are stabilized by DAQ-based servers. Apart from the stabilization aspect, feedbacks are also important because they enable direct control of the quantity of interest—beam positions are adjusted instead of correction coil currents, beam energies instead of RF amplitudes, and so on.

APPLICATIONS

As mentioned before, a powerful platform for the rapid deployment of graphical control system interfaces, *jddd*, is available for the operation of the XFEL. *jddd* panels cover the vast majority of use cases for applications in the control room, both at the operator and at the expert level. A few cases nonetheless require the development of specialized stand-alone software—when the functionality is too complex or too seldomly used to be implemented in a server, when very specific graphical user interfaces are needed, or when the implementation in a high-level language offers other advantages such as the availability of skilled developers.

While almost all middle layer servers are written in C++ and deployed on Linux systems, applications should gener-

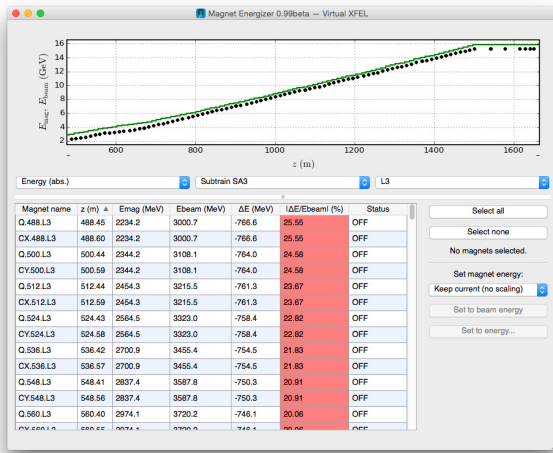

Figure 2: Screenshot of the *Magnet Energizer* tool for the scaling (setting of nominal particle energies) of magnets.

ally run on all of our three supported desktop platforms—MacOS, Windows, and Linux. Therefore, platform-independent development in high-level interpreted languages such as Matlab or Python is preferred. Java Web Start plays an important role in the platform-independent launching of such tools, and many low-level control system utilities are implemented directly in Java. Like the jddd panels, most high level applications rely heavily on the services of the middle layer server system.

The range of applications available and under development is quite broad and very similar to those used at other high gain free-electron laser facilities: To name only a few examples, an *Emittance & Matching* tool supports the measurement of the beam emittance with the 3-/4-screen method, calculates the optical functions and matches them to the design optics (Fig. 1); the *Magnet Energizer* compares the measured beam energy with the settings of magnets and adjusts them accordingly (Fig. 2); *RF Tweak* functions as a graphical frontend to a fast tracking code and can calculate longitudinal bunch profiles from RF settings and optimize bunch compression settings, taking into account radiative, wakefield, and space charge effects (Fig. 3).

CONCLUSION AND OUTLOOK

The European XFEL is a machine of considerable complexity, not only due to its sheer size and number of single components, but also because of the intricacies of its pulsed mode of operation, of its beam distribution system, and of many subsystems. To ensure the best possible operability of the entire accelerator, we are advancing high level controls developments from multiple sides:

- through the preparation of libraries, toolkits and configuration databases (at the infrastructure level)
- by providing more physical values and more automatized procedures in the control system (at the server level)

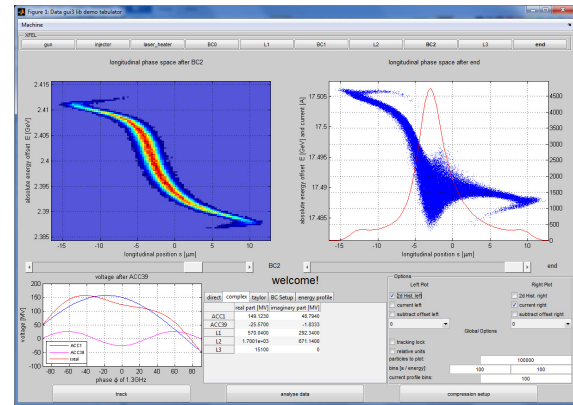

Figure 3: Screenshot of the *RF Tweak* tool for the calculation of longitudinal bunch profiles from RF settings.

- by providing powerful and easy-to-use graphical user interfaces for tasks in the control room (at the application level).

A big part of our software could be tested in the *Virtual XFEL* environment, and as many developments as possible were ported back to the FLASH [19–21] user facility, which is in many ways the predecessor of the XFEL. Experience has also been gained from the first operation of the XFEL gun with beam in February 2015. All of this makes us look forward to the injector commissioning at the end of this year with confidence.

Abstract

NA62 is a fixed target experiment to measure very rare decays of Kaons at CERN Super Proton Synchrotron accelerator. The NA62 experiment line comprises several large detectors installed inside a vacuum vessel with a length of 250 m and an internal diameter of up to 2.8 m.

The vacuum installation consists of 170 remote controlled pumps, valves and gauges. The operational specifications of NA62 require a complex vacuum control system: tight interaction between vacuum controllers and detector controllers, including pumping or venting vetoes, and detector start-stop interlocks; most of the valves are interlocked, including the large vacuum sector gate valves; the vacuum devices are driven by 20 logic processes.

The vacuum control system is based on commercial Programmable Logical Controllers (Siemens PLC: S7-300 series) and a Supervisory Control And Data Acquisition application (Siemens SCADA: WINCC OA). The control software is built upon the standard framework used in CERN accelerators vacuum, with some specific developments. We describe the control architecture, and report on the particular requirements and the solutions implemented.

INTRODUCTION

At CERN, the European Organization for Nuclear Research, the NA62 experiment analyses the outcomes of collisions of proton beams from the SPS (Super Proton Synchrotron) against a fixed target. The rare decays of Kaons are detected along a vacuum vessel of the 250 m. This large vacuum installation is broken down into 7 volumes, called vacuum sectors, separated either by sector valves or by windows. The use of sectors reduces mechanical intervention impact and sector valves, interlocked on pressure rise, avoid the propagation of leaks. The vacuum pressure specification for sectors 1 and 2 is lower than 10^{-2} mbar; it is achieved using 5 primary pumping groups. The vacuum pressure specification for sectors 3 to 7 is lower than 10^{-5} mbar; it is achieved using 8 turbo-molecular pumping groups and 7 large cryogenic pumping groups.

The control software for NA62 Beam Vacuum is based on the same framework as the vacuum control of the LHC (Large Hardon Collider) and its injectors [1].

The huge NA62 vacuum vessels require very large cryogenic pumping stations that offer very high pumping speed. In addition, usual turbo-molecular pumping is installed. The large detectors of NA62 are installed inside the beam vacuum vessels and require a complex hardware

and software alarm system between vacuum and detector controls. Performant diagnostic tools are required to improve interventions and reduce costly beam interruptions.

New control device types and new control functionalities have been especially developed in 2014 for the NA62 Experiment. The software architecture is a two-layer system. The lower one, or automation layer, comprises a set of functions and data blocks, running in a Siemens Simatic S7TM PLC. The higher one, or supervisory layer (SCADA), was developed using the Siemens WINCC OATM application; it consists of a set of routines and processes for monitoring, diagnostics and archiving, together with the graphical user interface.

DATABASE

The database structure, generically called Vac-DB, was developed in collaboration with IHEP for the vacuum control of the LHC and its injectors. This structure is also used for NA62.

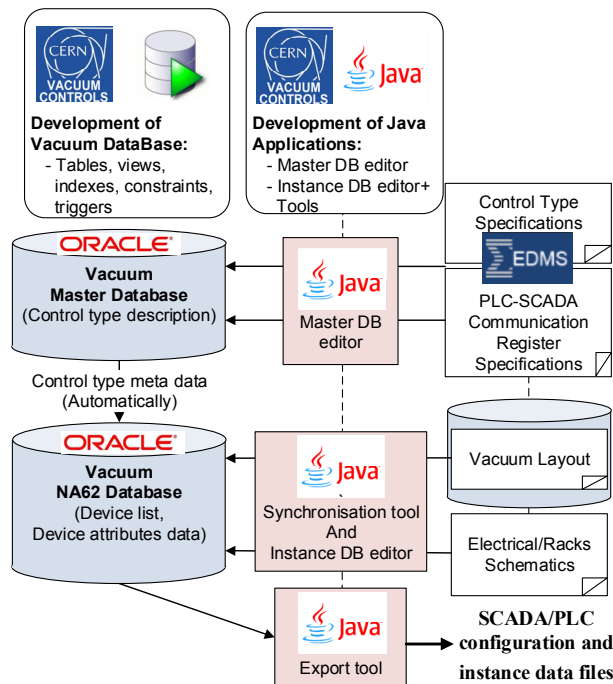

Figure 1: Vacuum database and applications.

Vacuum devices are classified into control types. The control type is identified by the family, type and sub-type of the device; it represents field devices (valves, mechanical pumps, active gauges, passive gauges, etc.) or virtual devices (pumping group process, gas injection process, software interlock, etc.).

A first Oracle database called “Vacuum Master Database” contains the definitions of control types. The definitions include the Data-Point structures for the SCADA application, the description of SCADA-PLC communication registers, and the list of attributes for every control type.

A second Oracle database, the “Machine Instance Database”, contains all device instances and all attribute values. The “Vacuum Database Editor” is a Java application used to insert user’s inputs and to synchronise attribute values with the CERN central Layout Database. Then the Java application automatically produces SCADA/PLC configuration and instance data files, from database views of the NA62 Vacuum instance database.

PLC SOFTWARE

Simatic Step7 PLC functions have been developed by the vacuum control team. The Baseline of the software is composed of organisation blocks (OBs), diagnostic functions and control type functions. Both the baseline and the PLC hardware configuration of NA62 are archived in a versioning repository (SVN) and then deployed to PLC projects; the instance data is generated by the Java export tool from Vac-DB.

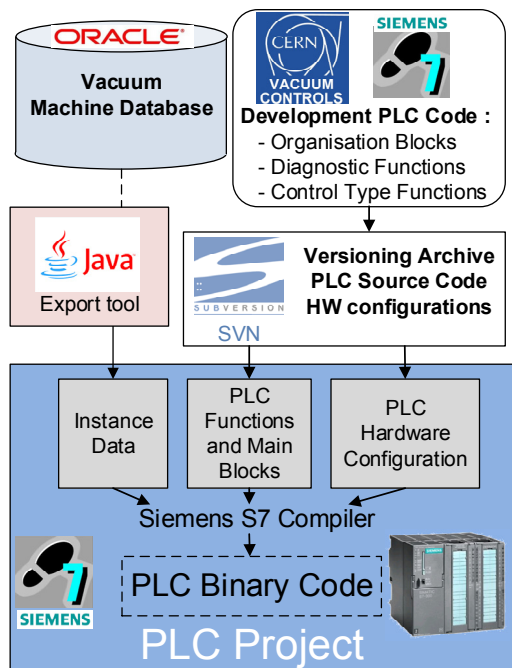

Figure 2: PLC software production.

The PLC binary code is generated by compiling the hardware configuration, the baseline and the instance data. The process of development, archiving and production of PLC code is illustrated by Fig. 2.

Two different software standards run in each PLC CPU. Before 2011, control types were developed using assembly language for PLC functions [2]. Since 2011, all new control types are developed in structured text language, within a novel standard.

Legacy control types that required new functionalities (primary and turbo-molecular pumps, valves and active gauges) were migrated to the new standard. Nevertheless, a significant number of legacy control types remained unchanged.

Legacy Assembly PLC Functions

A set of PLC functions and data blocks was created in 2001 for the vacuum controls of the SPS, then deployed in the LHC and later in PS-Complex and experimental areas. The functions were developed in Statement List Siemens (STL), similar to assembly language. The main organization block (OB) polls throughout a device list and handles one device per PLC cycle. The control type for a device is taken from device Data Block (DB) and the associated device type function (FC) is called with the device DB number as a parameter. Each control type has a dedicated FC; a complete set of FCs covers devices such as ion pumps, sector valves, passive gauges, etc.

Each device has its own device DB, containing all the variables needed by the function; the DB structure depends on device control type. Functions access and update DB variables, global variables and Write and Read Registers.

New Structured Text PLC Function Blocks

A set of new PLC Function Blocks (FB) were developed to incorporate new functionalities for existing control types, and to integrate new control. It has become the standard in vacuum controls PLC software, for all new developments since 2011. Not all of the previously created control types have been migrated to this standard yet; hence, both VACCIN and PSL system coexist in same PLC CPU.

The new standard has the following specifications:

- SIEMENS-SCL Language: textual high-level language; used for complex algorithms.
- FBs: functions with instance DBs.
- Process driven by a phase sequencer: sequence of actions with conditions and time dependencies.

There is one PLC FB per control type, who manages the behaviour of the device taking into account its sub-type. The typical structure of an FB is: get orders and parameters (from communication registers), read physical inputs, manage software interlocks, calculate and update maintenance variables, manage errors and warnings, manage behaviour according to the logic (which can be sub-type dependant), write outputs, update statuses (communication registers). Each device has a DB instantiated by the respective control type FB. This instance DB is composed of: header variables (name, control type, sub-type, machine...), common variables (auto request, manual request, interlock request, on status, off status, error status, object status, mode status...), control type specific variables (input/output addresses, valid range, unit conversion variables, maintenance variables...).

PLC-SCADA Communications

Both PLC programming standards have the same PLC-SCADA communications schema. Devices statuses, orders and parameters are stored in a set of communication DBs. The SCADA application writes orders and parameters into the Write Register DB, from which the PLC function gets the data during initialisation phase. At the end of the PLC function, statuses are updated in the Read Register DB. Vacuum systems are slow processes, allowing 1s as polling period of the Registers by the SCADA. Orders and parameters are transmitted to the PLC Write Register immediately after operator request. The PLC time is synchronized with Network Time Protocol servers, and some device data are time stamped with the accuracy of the PLC cycle time.

SCADA SOFTWARE

The supervisory layer of the NA62 vacuum controls is based on Siemens WINCC OA™ application. The SCADA framework [3] developed in collaboration with IHEP, for the vacuum control of the LHC and its injectors, has been reused for NA62. The schema of development, archiving and production of SCADA code is illustrated by Fig. 3.

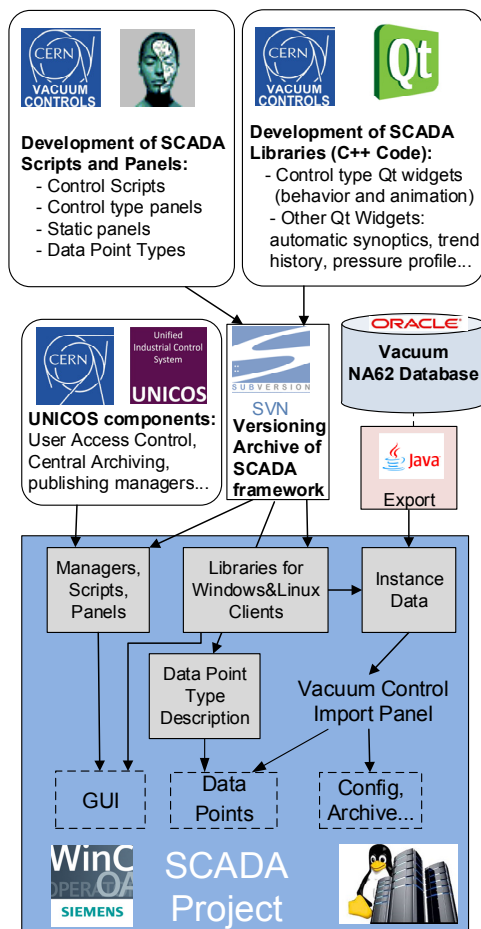

Figure 3: SCADA software production.

Graphical User Interface (GUI)

Devices are represented in the GUI using external widget objects. Symbols, animations and behaviours are defined by QT/C++ code and are control type dependant. Automatic synoptic, trend history and pressure profile are generated by QT/C++ libraries.

In the synoptic panel, main orders are directly accessible with a right click on the device symbol. A double click on this symbol opens the details panel of the corresponding control type. This details panel is graphically developed with the WinCC OA Graphical Editor.

Other functionalities, common to different panels, are developed in QT/C++ libraries.

NA62 NEW CONTROL TYPES AND FUNCTIONALITIES

Several control types and functionalities have been especially developed for NA62 and are currently only deployed in this experiment.

Pumping Group Logic

The high vacuum in sectors 3 to 7 is produced with turbo-molecular pumping groups. The control hardware for pumping groups has been improved [4] with an automatic venting in case of power cut, thus avoiding oil contamination from the primary pump to the turbo-molecular rotor. In addition, the logic disables the venting in case the valves to the vessels are not closed, to prevent accidental venting of the sector vessels.

The vacuum control system is linked to the NA62 detectors control system through several alarms.

Alarms to DCS

Three kinds of alarms are provided to the Detector Control System (DCS).

First, pressure level alarms: free potential relay contacts from the vacuum gauge controllers are hardwired to the DCS. The contact is triggered by the controller following a hysteresis comparison of the pressure measurement against pre-programmed thresholds. The pressure measurement can be low-pass filtered at 16, 160 or 1 600 ms; the thresholds can be remotely setup from the SCADA, through the PLC and Profibus network.

Second, vacuum process alarms: PLC output relay modules are hardwired to the DCS. They deliver vetoes to the detectors, according to the status of the vacuum sectors. These alarms are calculated by complex algorithms according to the vacuum process states. They are parameterized in the vacuum database, from which is defined the PLC instance data block, the type of logic and the reference to the source devices.

Finally, high level notification alarms: the SCADA application publishes the statuses of gauges and valves to

CMW¹ for the NA62 experiment operators. These alarms are not critical and used for information only.

Alarms from DCS

In the opposite direction the DCS provides 2 types of hardwired alarms to the vacuum PLC.

First, pump enable alarms: if the detector is not ready for pumping, these alarms prevent any associated pumping valves to be opened. During operation, in the event of a detector window rupture, H₂ would be released in the vacuum vessel; the pumping and so the compression of a large quantity of H₂ being highly explosive. In case of window rupture detected, the process will automatically close pumping valves.

Second, vent veto alarms: the venting of some sectors may be required during a mechanical intervention. The venting is performed in-situ using a manual valve. Local notifications, using flashing LED, remind to the vacuum operator if venting is allowed or not.

PLC and SCADA developments for these new alarm types have been added to the vacuum control framework. These alarms allow a strong interaction between Detector and Vacuum Control Systems; they provide effective diagnostic information to both vacuum and detector operators.

Pulsed-command Valves and Pumps

In most of the accelerator vacuum systems, the fail-safe position of sector valves is closed, to avoid propagation of any unexpected leak. In the NA62 experiment, due to beam physics transparency requirement, very large valves have been installed with a specific mechanism. As any valve movement produces a leak, a new control type has been developed to cope with this behaviour. The same kind of control type for pumps has also been developed, to drive primary pumps with similar specifications. For both valves and pumps the last order requested is thus maintained in case of power failure.

Gauges with Profibus Interface

Gauges with embedded controller and Profibus interface have been installed in NA62 for the first time at CERN's accelerators vacuum. These gauges may reduce significantly the cost of controls. A new control type has been developed to integrate them in the vacuum controls framework. The new control type offers some extra functionalities as compared with standard one, like the possibility to act individually on each sensor of the full-range pair.

HSRTM Cryogenic Pumping Group

Seven very large cryogenic pumps have been installed in the Decay tubes vacuum sector (135 m long and 2.8 m diameter vessels with decay tubes detectors inside). These are the largest cryogenic pumps installed at CERN, if not

counting the pumping effect of the superconducting magnets in the LHC. They are provided by HSRTM together with their dedicated controller.

For turbo-molecular pumping groups, the PLC manages the logic, which can be found in several control types (one per field device type, and another for the process).

For the HSRTM cryogenic pumping groups, it is slightly different: the group is controlled as a whole by the vacuum PLC, while the process is managed by the HSRTM controller. A first control type is dedicated to the cryogenics cold head, its sensors and the back valves. A second control type is dedicated to the large valve with same behaviour as standard vacuum valves. Both send global orders and get field device statuses from the HSRTM controller via a RS-232 interface. Some vacuum framework functionalities required upgrading; e.g. the trend history originally developed for one analogue value per device has been extended to integrate all the analogue values and bit statuses of the cryogenic pump control type: 2 pressure analogue values, 2 temperature analogue values, 4 bit statuses for the fore valve (V1) and purge valve (V5).

CONCLUSION

The vacuum control framework has shown a high level of flexibility, while being used to build the core of the NA62 vacuum control system. New device types and particular user specifications required custom developments. Thanks to the well-organized structure of the vacuum control framework, the new control types and functionalities have been easily developed and deployed. The result is a very effective control system well adapted to NA62 experiment layout and operational specifications.

THE UPGRADE OF CONTROL HARDWARE OF THE CERN NA62 BEAM VACUUM

F. Mateo, F. Antoniotti, S. Blanchard, R. Ferreira,
P. Gomes, A. Gutierrez, B. Jenninger, H. Pereira
CERN, Geneva, Switzerland

Abstract

NA62 is the follow-up of the NA48 experiment, in the SPS North Area of CERN, and reuses a large fraction of its detectors and beam line equipment. Still, there are many new vacuum devices in the beam line (including pumps, valves & gauges), which required a thorough modification of the control system and a large number of new controllers, many of which were custom-made.

The NA62 vacuum control system is based on the use of PLCs (Programmable Logic Controllers) and SCADA (Supervisory Control and Data Acquisition). The controllers and signal conditioning electronics are accessed from the PLC via a field bus (Profibus); optical fibre is used between surface racks and the underground gallery.

The control hardware was completely commissioned during 2014. The nominal pressure levels were attained in all sectors of the experiment. The remote control of all devices and the interlocks were successfully tested.

This paper summarizes the architecture of the vacuum control system of NA62, the types of instruments to control, the communication networks, the hardware alarms and the supervisory interface.

INTRODUCTION

NA62 will study the rare decay $K^+ \rightarrow \pi^+ \nu \bar{\nu}$ at the CERN SPS. NA62 is built to improve the current experimental precision by measuring kaon decays-in-flight with calorimetry to veto extra particles, very light mass trackers to reconstruct the momenta of the K^+ and the π^+ and full particle identification capability [1].

To reach the required sensitivity and acceptance, the vacuum in the decay area needed to be improved by at least two orders of magnitude compared to NA48. Many detectors that would normally be outside the vacuum chamber are now part of the vacuum system leading to a significant increase of the gas load to be pumped. A particularity of NA62 is the distribution of detectors along 250 m (Figure 1).

The NA62 experiment went through a complete refurbishment with the introduction of new detectors filled with gas. Their operation requires a vacuum system, based on turbo molecular and cryogenic pumps. The beam line is divided into 7 sectors, each having specific vacuum requirements. The vacuum equipment in each sector will be described in the next section.

Figure 1: Layout of the NA62 experiment

VACUUM EQUIPMENT

The upgrade of NA62 beam vacuum comprises more than 200 new instruments (including different types of pumps, valves and gauges) along the beam line. In addition, a large amount of cabling had to be designed, installed and commissioned.

This was a challenging work, as the NA62 beam line measures roughly 270 m from the SPS T10 target to the NA62 beam dump, with also some equipment in a surface building.

In sectors 1 and 2 only passive equipment is used due to the high level of radiation. In sectors 3 and 4, radiation-tolerant active vacuum gauges may be used but not instruments with embedded Profibus interface. Sectors 5 to 7 are radiation-free and allow the installation of controllers and PLCs close to the instruments. The distribution of vacuum devices is shown in Figure 2.

Vacuum Pumps

Vacuum pumps are the basic elements needed to achieve high vacuum in accelerators and experiments. Most of the time, several types are combined and assembled together in pumping groups to pump down from atmospheric pressure down to high vacuum. Three types of pumps are used in NA62 (Table 1):

- **Primary or roughing pumps (VPR)** are used to evacuate from 1 bar down to 10^{-3} mbar; they are also used as a backing pump for Turbo Molecular pumps.
- **Turbo molecular pumps (VPT)**, are effective in the range 10^{-3} to 10^{-10} mbar, therefore requiring rough vacuum achieved by a primary pump. A VPR and a VPT are often assembled and controlled together as a turbo molecular pumping group (VPG).

- **Cryogenic pumps (VPC)** are used to achieve very high pumping speeds at low pressures. They only need rough pumping during regeneration, but not during operation. In NA62, a pumping speed of more than 100 000 l/s is required to reach the low 10^{-6} mbar pressure range, with the particularly high gas load (Ar, CO₂) from permeation from the straw detectors. This is accomplished by 2-stage Gifford-McMahon cryo-coolers, using gaseous helium closed circuits and cryosorbers on the second stage. A cryogenic pumping group (VPGC) includes heaters, gauges and valves.

Table 1: Summary of vacuum pumps in NA62

Type	Units
VPR	7 (5 rotary vane primary @220V, 2 combined dry screw/roots @400V)
VPT	8 (7 DN 100 for normal operation, 1 DN 250 mainly for leak detection)
VPC	7

Vacuum Valves

Apart from the standard electro-pneumatic or electro-magnetic (angle or gate) valves commonly used in accelerators, two special types can be found in NA62.

A fast shutter valve (VVQ) closes within 20 ms, in case of rupture of the thin window that separates the CEDAR detector from vacuum, thus protecting fragile equipment downstream.

The aluminium-sheet valve upstream of the liquid Kr calorimeter must not move unnecessarily, to avoid air-inrush. Its bi-stable actuator does not lose position under a loss of power or compressed air. Also, together with the associated gauges, the controller is powered by an UPS.

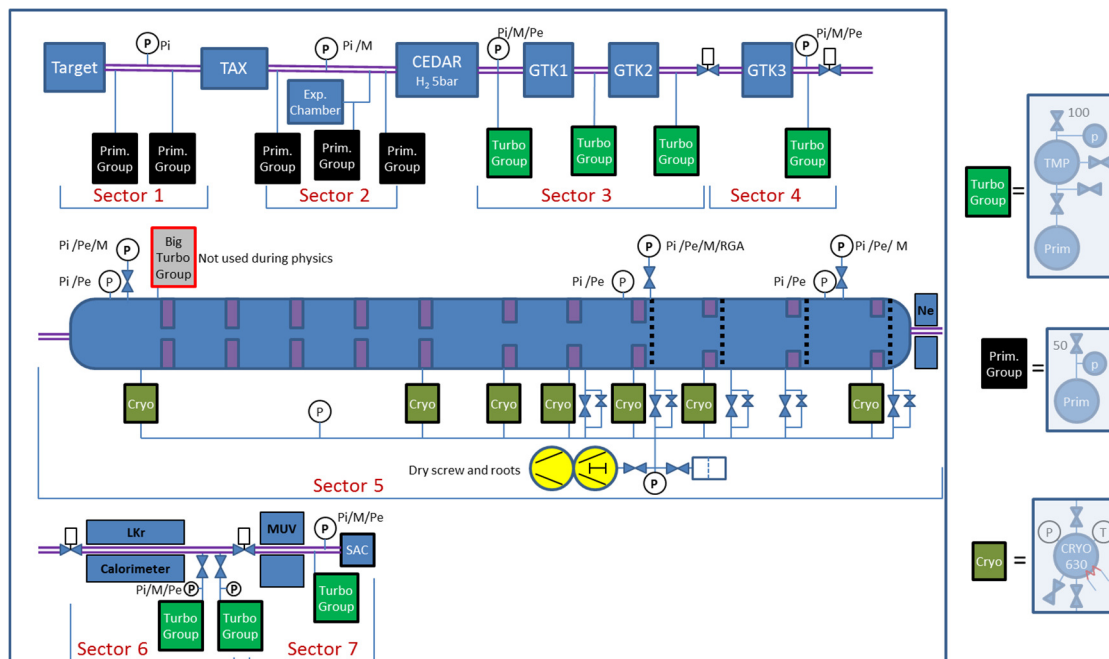

Figure 2: Vacuum equipment layout in NA62 experiment

Vacuum Gauges

Several types of vacuum gauges are used in NA62 depending on the range of vacuum to be measured. Both passive and active electronics gauges are used depending on the radiation levels. In the NA62 experiment, the following types of gauges can be found:

- Passive Pirani gauges (VGR)
- Passive Penning gauges (VGP)
- Active Membrane gauges (VGM)
- Active Full Range gauge-pairs (VGF)
- Active Profibus interfaced gauges (VGF, VGM)

CONTROL SYSTEM

NA62 follows the same controls architecture of the LHC [2]. This means that the vacuum controllers are managed using a PLC-based architecture, using the Siemens™ S7-300 series. The human-machine interface is a SCADA (Supervisory Control And Data Acquisition), built with Siemens WinCC OA®, formerly PVSS®.

The PLC architecture of NA62 is based on a master-slave topology. There is one master PLC, 8 slave PLC for the pumping group control and 5 remote I/O stations that have specific functionality and connectivity, depending on the instruments to interface.

Specific control crates are used for each type of instrument. Some of them have been designed, manufactured and tested at CERN while others are commercial. The controllers have been distributed in six racks in a radiation-safe area of the underground gallery, and two racks in the surface building, where the Master PLC is located. Tables 2 and 3 summarize the controller types used in NA62. The VAT VP-3 valve controllers needed an additional UPS to ensure protection of the LKr in case of power cut.

Table 2: Custom-made controller crates for NA62

Name	Description	Units
VRLMS	Master PLC	1
VRLRG	PLC Remote I/O station	5
VRPGMF	VPT controller	8
VRJTB	VPT patch panel	5
VRPPH	VPR controller	2

Table 3: Commercial controllers at NA62

Name	Description	Units
VRPP	Primary pump local crate	5
VRVRC	VAT VF-2 fast valve controller	1
VRGPT300	Pfeiffer-Balzars TPG 300 gauge controller	5
VAT_VP	VAT VP-3 dual-acting valve controller	2
VRPYA	HSR PCA700C VPC controller	7

The installation and commissioning of all control crates took place during spring and summer of 2014.

COMMUNICATION

For the connexion of all instruments to the respective controllers, a cabling campaign was carried out during spring 2014.

As some equipment (including the Master PLC, one remote I/O station and other controllers) are in a surface building, about 100 m away from the beam line, an optical link was devised to provide fast and reliable communication.

The communication between controllers and PLC is made via Profibus-DP, where there is no radiation hardness (Sectors 5 to 7). Otherwise the communication relies on dedicated individual cables. Three separate Profibus-DP networks have been devised for each specific purpose:

- **Profibus Alarms network (I):** Links the equipment that are source of some type of Alarm. The alarms will actually be generated by the Master PLC that will send them to the Detector Control System (DCS) [3].
- **Profibus VPT network (T):** Establishes the communication between the VPT controllers and the Master PLC.
- **Profibus All-purpose network (A):** Provides the communication interface for Profibus instruments that do not belong to the aforementioned groups (i. e. Profibus gauges).

The interface between the optical and copper Profibus networks is made using Siemens™ Optical Link Modules (OLM).

The management of the VPC controllers was carried out by a remote I/O station using a specific communication protocol based on a Profibus to RS-232 gateway, to interface with the master cryo-controller, which periodically polls the rest of cryo-controllers using a token ring topology [4].

As in other experiments and accelerators at CERN, the Master PLC is connected to the SCADA server via a dedicated Ethernet Technical Network.

The communication networks between vacuum instruments and controllers are summarized in Figure 3.

SUPERVISORY APPLICATION

The supervisory application of NA62 acts as a user interface that can be accessed from the NA62 control room to monitor the status, history and, depending on the user privileges, act on the control of the vacuum devices. It was developed in WinCC® OA and its main screen is illustrated in Figure 4. All the vacuum devices have been modelled and all the relevant attributes are retrieved from a SCADA database. The pumping groups have also been modelled in detail, showing the status of all the devices in the group, as well as the hardware alarms status and history.

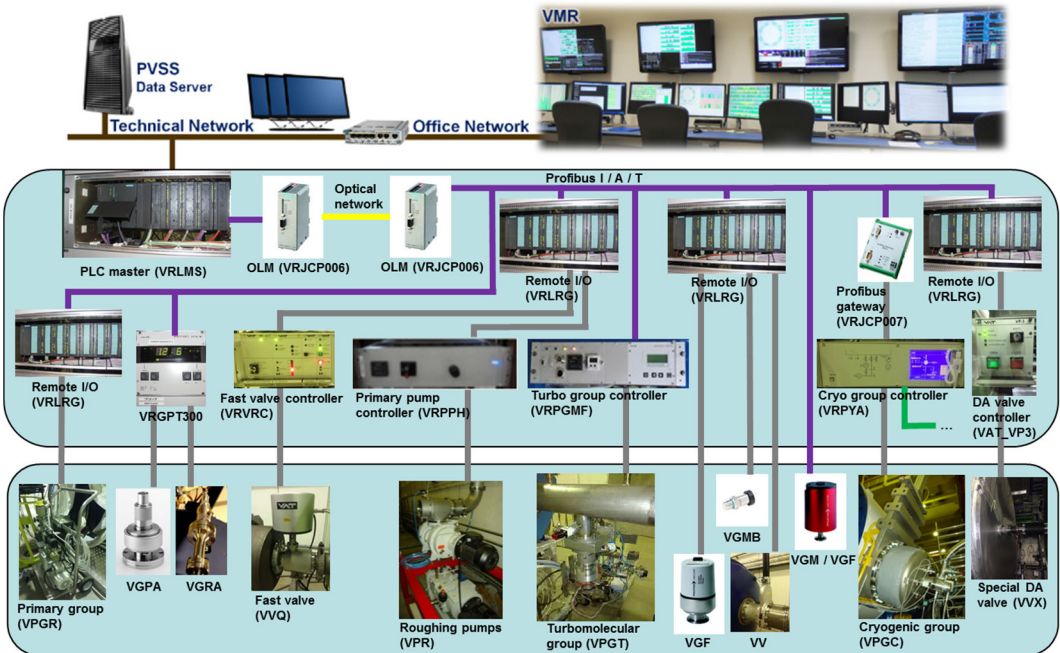

Figure 3: Schematic view of the vacuum controls architecture and communication of NA62.

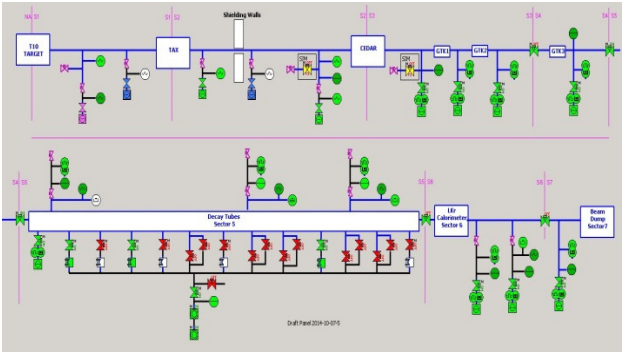

Figure 4: Supervisory application main screen.

HARDWARE ALARMS

For a safe operation of the experiment, the relevant alarms had to be implemented to prevent damage of equipment in case of hypothetical operation failures. The hardware alarms of NA62 are described in Table 4, indicating if it is an output or an input to the vacuum system. The alarms are hard-wired with a dedicated cable from the master PLC crate to the Detector Control System. The alarms were successfully tested during autumn 2014.

CONCLUSION

The NA62 control hardware upgrade was a complex task that required the active participation and effort of several groups at CERN, including engineers, technicians, external workshops and industrial partners. The cabling and control equipment deployment took place in spring 2014. The full system was commissioned during summer 2014. The measured pressure levels meet the nominal specifications [5] in every sector. The alarms are fully operational.

Table 4: Hardware alarms in NA62 vacuum

Output	Enable Inside CEDAR pumping (Sectors 2 and 3 are under vacuum)
Output	Enable GTK cooling (Sectors 3 and 4 are under vacuum)
Output	Enable High Voltage on LAV (Sector 5 atmosphere or under high vacuum)
Output	Enable Inside RICH pumping (Sector 5 is under vacuum)
Output	Enable High Voltage on SAC (Sector 7 atmosphere or under high vacuum)
Input	Pumping Enable for Sector 2 and 3 (CEDAR Window No Rupture)

Abstract

For two years (Spring 2013 – Spring 2015), the LHC went through its first long shutdown (LS1) [1]. It was mainly motivated by the consolidation of magnet interconnects, to allow operation with 6.5 TeV proton beams. Moreover, around the accelerator complex, many other systems were repaired, consolidated or upgraded, and several new installations came to life.

The standardization of vacuum controls has progressed in the injectors, with the renovation of most of their obsolete equipment.

In the LHC, many new instruments were added, the signal transmission integrity was improved, and the exposure to radiation was reduced in critical places. Several developments were needed for new equipment types or new operational requirements.

INJECTORS & LHC CONSOLIDATIONS

Complex PS

The LS1 was an opportunity to extend the standardization of vacuum controls to the Proton Synchrotron ring (PS), the Antiproton Decelerator (AD), and the nTOF experiment. The legacy controls were updated to the same PLC/SCADA-based architecture as in the other machines. Only the pumping groups of the PS complex remain to be upgraded, during the following years. [2]

The existing controllers were either upgraded, or replaced by newer generations, connecting to the PLC directly through Profibus or via remote-IO stations. This involved 500 cables and 700 instruments.

Above all, a large effort was put in the production of complete and up-to-date documentation on the control system layout and on its components technical details.

Linac2, at the head of the proton acceleration chain, received a new set of six pumping groups. These were especially developed to compensate for the dying old ion pumps, helping it to survive until replaced by Linac4.

SPS

In the SPS, controls renovation was applied to its injection line, the interfaces for the Beam Interlock System, and COLDEX.

Several new gauges and valves were added, for a few new sectors. Furthermore, all racks and cables were prepared for the new re-sectorization of all the ARCs.

Campaigns for replacement of aged cables were performed in several places. In total, some 300 cables were replaced, and 200 other were newly installed, mainly for some 80 new instruments.

LHC

About 600 cables and 400 gauges, valves, and pumps, were newly installed in the LHC, together with the corresponding interlocks. Some of them required specific controls developments, treated in detail further down.

The signal integrity has been revised and improved, for the gauges in the ARCs and for the bypass-valves. To mitigate radiation effects in Point7, 27 racks full of equipment were dismantled and relocated into a less exposed zone, while 400 cables had to be extended. These subjects are treated in another paper [3].

During the second half of 2014, six teams of two people were full-time involved in the commissioning of all controls and instrumentation of the LHC. All instrument chains were fully tested; and calibrated when necessary. Documentation was updated about racks layout and interlocks cabling.

During the LHC global check-out, systematic tests were performed on all interlocks, to every sector valve, and to the beam interlock system, automatically from SCADA.

All in all

In total, more than 2 900 cables and 1 500 instruments were commissioned in the accelerators consolidations and new projects. The controls team had to be reinforced by 50%, mainly with engineers from collaborating Institutes, trainees, and technicians from industrial support. The main challenges were the coordination of field activities with access restrictions and other teams' tasks, and having each machine commissioned and ready in time for beam.

DEVELOPMENTS FOR PUMPS

NEG Pumps

A Non-Evaporable Getter (NEG) is a highly reactive and porous material; it needs to be activated, by heating under vacuum, with a suitable temperature and duration. The recommended activation temperature is around 475 °C, corresponding to 6A under 16V, for 1 h.

To increase pumping speed in critical equipment in the LSSs of the LHC, NEG cartridges (Capacitorr D400 2 from

SAES™) were installed, with their activation cycle remotely controlled.

The DELTA™ SM6000 power supply (300V x 20A) is interfaced to the PLC via Profibus. It would feed up to 18 cartridges in series, if it were not for the voltage drop on the long cables. In practice, less than 10 are installed.

Several series of cartridges can be activated from the same supply, but at different times; a multiplexer crate steers the power to one of the series at time, via relays operated from PLC digital outputs.

Through Profibus, the PLC sets the required current on the power supply, which automatically adjusts the necessary voltage. The PLC will only set the power ON if the pressure is below 1e-3 mbar. Several operation modes, parameters, errors and warnings are implemented.

Sublimation Pumps

A Titanium sublimation pump consists of two Ti filaments in a cylindrical stainless steel vacuum chamber. A power supply, custom-designed in 1994, heats one of the filaments to the temperature of sublimation of Ti, in order to coat the inner surface of the chamber, which can then start to absorb the residual gases.

As the pumping efficiency reduces with time, the sublimation process must be repeated periodically. The power supply has two modes of operation: degassing, where both filaments are powered with a given current, for cleaning; and the actual sublimation of one filament, for a given time. It is hardware interlocked on Penning gauge, preventing any powering above 1e-7 mbar.

Remote access through PLC has now been implemented for PS, AD, and will later be extended to the LHC. The PLC sends binary commands and analog set-points, and receives binary status and analog feedback, through ET200™ remote-IO stations; each station can handle 8 devices. From the SCADA, the operator can define the set-points and the duration of the sublimation periods; recipes are available for repetition cycles, for one or several pumps.

Gas Injection in LHC

A prototype of the Beam Gas Vertex (BGV) detector has been installed in the LHC-LSS4L during LS1. This is a non-invasive beam size measurement instrument. It requires a gas injection system for neon or argon.

The control system for this gas injection is similar to the one used for the two Beam Gas Ionization (BGI) detectors, previously installed on both sides of Point4. Neon gas is injected into the BGI vacuum chamber and then ionized to measure beam emittance on LHC.

For both BGI and BGV applications, the gas injection system is composed of a standard pumping group [4], an analogue valve connected to the gas bottle, and an on-off injection valve connected to the beam pipe. The injection process is handled by a sequencer and operation modes. This PLC-based control achieves a safe and automatic gas injection without the need of a specialist in vacuum and injection techniques.

Gas Injection in Linac4

In 2014, LINAC4 had a new system to inject H₂ gas in the Low Energy Beam Transport vessel, for the measurement of the beam current and size. It uses a commercial fine-dosing thermo-valve and its control unit, a primary pump and two on-off valves. They are all connected to a S7-300 PLC, which runs a sequencer and operation modes. The process starts with an isolated mode, to avoid accidental large gas flow that would damage vacuum and beam instrumentation. Then the process can run either in tuning mode (pressure set-point defined in vacuum SCADA) or nominal mode (pressure set point defined by the beam transfer controls).

Cryogenic Pumps

In NA62, seven large and fast Cryogenic pumps are used to reach 1e-6 mbar, by pumping at 100 000 l/s. The process is managed by a proprietary controller (PCA700C from HSR™). Unfortunately, no Profibus interface is available; one controller connects to the PLC via RS-232 and a Profibus gateway; the other controllers are chained with that one, on a token-ring network.

At first, this communication did not work due to a bug in the firmware; it was eventually fixed by the manufacturer, although with some delay for the project.

DEVELOPMENTS FOR GAUGES

Full-Range Gauges

In radiation-free zones of NA62 and HIE-ISOLDE, Pfeiffer™ MPT200 full-range gauges have the signal conditioning and Profibus interface integrated; this reduces cabling costs and offers increased functionality, such as status information and commands directly available on the PLC, without passing through dedicated IOs. The MPT200 comprises a Pirani and a Penning gauge to cover 1e3 to 5e-9 mbar, and switches automatically between the gauges.

After some issues with the evolution of the connector types for Profibus and for power, the gauges performed well. There are two operational modes which, while changeable during the configuration of the device on the Profibus network, cannot be modified during operation.

Thermocouples

800 E-type thermocouple channels have been installed around the machine, for warm magnets and collimators. The measurement covers -40 to +750 °C, with absolute accuracy of +/-2 °C, and is shown with 0.1 °C precision.

Specific 16-input analog modules in Siemens ET200 remote IO-stations, convert the thermocouple voltage into temperature, before sending it to the PLC, who makes them available on the SCADA.

A new instrument-type was defined in Vacuum-DB and developed in the PLC, together with a SCADA panel grouping the 16 channels of each analog input module. There are no commands or interlocks associated to them.

Passive Gauge Controller (TPG)

The TPG300™ gauge controllers are remotely managed by a PLC function created in 2003, never updated since 2007. With the rising number of devices in the system, up to 40 per PLC, some limitations emerged; these are mainly due to the slow polling rate of SCADA to PLC, together with the increasingly slow scheduling of TPG access from PLC.

To visualize on the SCADA all parameters and status of a single TPG, it may take up to 4 minutes, as each value is individually requested to the PLC, and then to the TPG; idem for parameter changes.

In order to keep track of parameter changes by the operators, a daily script gathers the information of all TPGs in each accelerator. This is now taking more than 10 h, and may fail in at some occasions.

A new PLC function was developed and is under test in one of the LHC points. Each PLC cyclically requests all the parameters and statuses of all TPGs connected to its Profibus network; all data is read and logged by the SCADA, and is fully refreshed in the background every 1 to 5 minutes. The historical follow-up of TPG parameters and statuses will thus be directly and immediately available in the SCADA's archives, with no need for heavy daily extraction by an external script.

Cryo-Maintain Interlock to Sector Valves

A temperature increase in one superconducting magnet of the LHC may lead to a pressure rise, propagating into neighboring vacuum sectors. The sector valves around magnets in critical zones have been software-interlocked on the cryogenic conditions. In this way, the loss of "Cryo-Maintain" status will isolate the corresponding sector, avoiding the propagation of the pressure rise.

The cryogenic status for the concerned zones is read directly by the vacuum PLCs in dedicated data-blocks of the cryo-PLCs. An incremental watch-dog is used to assure data validity. Of course, this interlock is not treated by the valves controller if the beam is present.

PROJECTS

COLDEX

In the SPS, the Cold Bore Experiment studies the beam pipe coating with amorphous carbon, under cryogenic conditions. Installed in a by-pass line, on top of two sliding platforms, it is moved into the beam line during experimental periods, and out of the beam for normal SPS operation [5]. The two old step-motors were replaced by new ones, and the old controls gave way to a Siemens S7-300 PLC, integrated in the SPS vacuum control system.

Operation can be manual or automatic, with check and compensation of differences in the advancement of each motor. Each platform provides feedback on the analog position and on the two end-switches.

To move into the beam line, the vacuum sector valves around the experiment must be closed, and the neighboring bumper magnets must be off. For improved security, the operation cannot be done remotely, and requires a physical

key on the controller to enable it and to assure the magnets are not powered. A portable touch-panel provides interface to the system from the tunnel, near the experiment. The renovation of the motor control system was extended to the experiment's vacuum instruments. All can be remotely monitored on the SPS SCADA, and statuses are available for other systems.

Given the importance of amorphous carbon coating for the project HL-LHC, the COLDEX experiment and its controls will continue to evolve in the near future.

SUBU

This Chemical Polishing machine for the surface treatment of superconducting RF cavities was developed in 1989. It was based on Siemens S5 PLCs and a custom HMI, running on Win-3.11. With time, the S5 product line had been discontinued, the HMI hardware was failing and not repairable, the HMI software was running on an obsolete OS, and the PLC code was un-documented. [6]

The challenge of this project was the nearly non-existing documentation, which led to a complete reverse-engineering of the machine: consulting with the operator to understand the process and the plant hardware; visual inspection of the sensors, actuators, and wiring; and re-writing the process description and all electrical diagrams.

The status of the field devices (valves, pumps, sensors, containers) was evaluated and, as it was judged satisfactory after minor reparations, left in operation.

The old control system was completely decommissioned and the new one was developed from scratch, targeting Siemens S7-300 PLCs and WinCC-OA SCADA, under the UNICOS framework, like done before for the ISOLDE complex. As chemical Polishing is a continuous process, the functionalities provided by the UNICOS-CPC are perfectly suited.

Furthermore, because the development in UNICOS is a well-standardized practice, maintenance work and eventual changes can be performed more easily by third parties; also, the development methodology forces the developer document the work thoroughly, resulting in quality documentation that always proves useful.

NA62, AD, LINAC4, HIE-ISOLDE

In NA62, the beam vacuum and the associated controls were completely renovated, and then commissioned during 2014. The new controls architecture follows the framework already used in the LHC and Injectors. It also incorporates a few novelties, which required specific developments in the PLC and SCADA. The hardware is described in [7] and the software in [8].

In AD, many consolidations were completed during LS1: gauges, valves, and ion pumps. The experiments racks were already moved to free space for ELENA installation.

The controls of Linac4 and HIE-Isolde have both been evolving, as new sectors and their instrumentation are added and commissioned. In parallel, the respective test-stands require maintenance and development.

FROM LS1 TO LS2

The next long shutdown (LS2) foreseen for 2019-20 will be dedicated to: Injectors upgrade; LHC maintenance and consolidation; HL-LHC activities anticipated from LS3. Some tasks will use the next three Year-End Stops.

In parallel, several new installations are under way too, like Awake, Elena, etc.; HIE-Isolde will have more cryo-modules; Isolde controls will be consolidated.

In AD, the final consolidations will be: the integration of cryo-compressors for the RF cavities, together with the temperature of their cold heads; the replacement of the old gas injection system by a new one, similar to LHC-BGI; and the implementation of functions like remote-reset and opening of fast valves.

Important developments, to be considered or started, are: wireless communication for mobile equipment (fieldbus vs. 4G+); industrial ion pump controllers vs. upgrade of old ones; new rad-tol electronics for gauges in the arcs; improved design of sector valve controllers.

Also during LS2: support to vacuum mechanical activities and bake-out; calibration, alarm setting, interlock checks; test and commissioning of all instruments. The workload will require substantial manpower reinforcement, expected to be higher than for LS1.

Injectors

Around the complex PS, during the 3 years before LS2, the pumping groups, ion pumps, and their controllers, will be replaced or upgraded. Linac4 will have a full Sector Test in 2016. During LS2, the connection of Linac4 to the PSB, replacing Linac2, will induce layout modifications.

The SPS ARC re-sectorization should be accomplished before LS2. LSS6 will receive a test station for crab cavities, as part of the studies for High Luminosity LHC. There will be modifications in the layout of several zones, with associated cabling campaigns. The grounding of ion pumps will be consolidated. The racks layout will be reorganized, as it was done in BA4 during LS1.

LHC

In the LSS, the turbo pumping groups and their controllers will be progressively renovated until LS2; the controllers in the ARCs will be changed during LS2. Additional turbo pumps will be installed on the beam kickers.

The controllers for mobile pumping groups must be upgraded, due to obsolescence of the PLCs. The control system of VELO will be renovated, possibly before LS2.

In general, important layout modifications will occur in almost all the LSS, leading to large cabling and connection campaigns, and significant modifications in the racks.

Controls Framework

Following the effort of standardizing the naming of all vacuum controls equipment, the instruments will be next. The implementation of both these naming conventions will involve considerable work on the electrical and mechanical diagrams, databases, and SCADA.

During LS1, a large volume of information was collected, about the layout of vacuum controls and the

assets installed in the machines. The organization and formatting of this data is in progress, to later be uploaded into the CERN Layout and Asset-Management databases.

The controls issue-tracker (VTL), together with the handling of vacuum intervention work-orders, is being integrated in Infor-EAM, the CERN asset management system. The tracking of software issues and developments will use Atlassian JIRA. SVN™, used since 2012 for the versioning of SCADA applications, has been extended to the PLC.

SCADA archiving in Oracle (RDB) has been introduced; until the depth of one year is reached, the old archiving system will run in parallel. Some SCADA new features will next be implemented: dynamic calculation and trending of valve reaction times, improved main synoptic warnings for sector valves, and faster acquisition and display of TPG status and parameters.

A new major version (3.14) of WinCC-OA SCADA will be deployed in 2016; it will include a native user interface for mobile devices, dynamic resize of panels, and improved historical data collection.

The UNICOS framework is present in many domains at CERN, who profit from centralized development and support. It is already used for vacuum controls in the Isolde complex and in surface treatment installations.

However, it lacks several vacuum-specific functionalities and field-objects. A convergence project is being established: a minimum set of field objects will be developed and deployed in Isolde complex. In parallel, the SCADA functionalities will be migrated to UNICOS, and progressively integrated. Also, the Time Stamp Push Protocol (TSPP) should soon be implemented.

Linac4 could be a test-bench for the full integration, before global deployment in all accelerators during LS2.

DEVICE CONTROL DATABASE TOOL (DCDB)

Pavel Maslov, Matej Komel, Miroslav Pavleski, Klemen Zagar, Cosylab, Ljubljana, Slovenia

Abstract

We have developed a control system configuration tool, which provides an easy-to-use interface for quick configuration of the entire facility. It uses Microsoft Excel as the front-end application and allows the user to quickly generate and deploy IOC configuration (EPICS start-up scripts, alarms and archive configuration) onto IOCs; start, stop and restart IOCs, alarm servers and archive engines, and more. The DCDB tool utilizes a relational database, which stores information about all the elements of the accelerator. The communication between the client, database and IOCs is realized by a REST server written in Python. The key feature of the DCDB tool is that the user does not need to recompile the source code. It is achieved by using a dynamic library loader [1], which automatically loads and links device support libraries. The DCDB tool is compliant with CODAC (used at ITER and ELI-NP), but can also be used in any other EPICS environment (e.g. it has been customized to work at ESS).

INTRODUCTION

In a physics facility containing numerous instruments, it is advantageous to reduce the effort and repetitiveness needed for changing the control system (CS) configuration: adding new devices, moving instruments from beamline to beamline, etc. We have developed the Device Control Database (DCDB) tool [2], which provides an easy-to-use interface for quick configuration of the control system for the entire facility. The DCDB-tool allows the user to quickly generate and deploy configuration for input/output controllers (IOCs) (EPICS start-up scripts, alarms and archive configuration) onto IOCs; start, stop and restart IOCs, alarm servers and archive engines, and more.

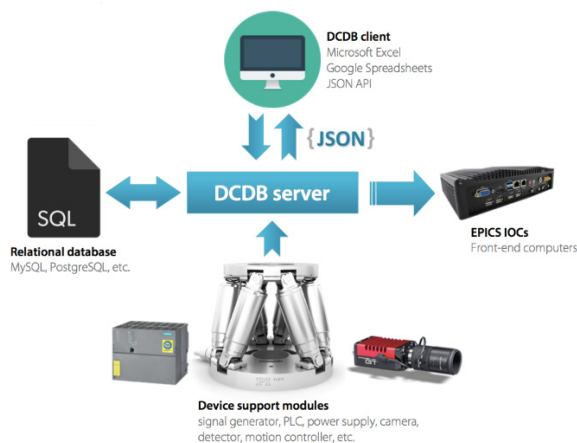

Figure 1: DCDB architecture.

DCDB ARCHITECTURE

The DCDB-tool uses a MySQL relational database. The backend is a typical web-server (Fig. 1), which is realized with a combination of the following Python modules: flask-restful (REST server), sqlalchemy and pymysql (database communication layer), and paramiko (ssh). The front-end is a Microsoft Excel plugin written in C# using .NET technology. IOCs are Linux machines running EPICS and procServ [3]. The client-server communication is based on the exchange of JSON objects (strings).

DEVICE SUPPORT MODULES

To start using the DCDB-tool, simply prepare EPICS device support modules and register them with the DCDB server. In general, device support modules are created in the standard EPICS way. The DCDB-tool introduces the idea of using dynamic macros in the startup scripts. Three additional files, namely: `init.cmd`, `init-pre.cmd` and `init-post.cmd` (Fig. 2) contain macro definitions to be stored in MySQL, and IOC shell commands that register and setup the support module before and after IOC initialization.

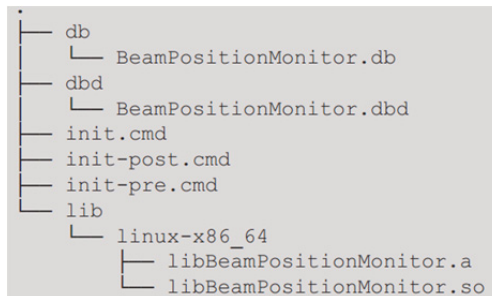

Figure 2: Files to deploy.

The procedure of creating device support modules for ITER using special extensions to the `myv iter` plugin was described in [4]. In the latest version we have tailored DCDB to work in the new EPICS environment developed at ESS [5], since they have a similar approach to using dynamic library loading, and in addition to our setup support dependency resolution and have a simpler unit development workflow. The latter is achieved by creating a Makefile, adding source files and running make. If you want to locally install the module, run the shell command: **`sudo make install`**. In order to register the module with the DCDB tool, run **`make dcdm.import`**. To delete the module from DCDB, run **`make dcdm.delete`**.

The last two commands require two environmental variables `$(DCDB_SERVER)` and `$(DCDB_PORT)` to correspond with the parameters of a running DCDB server.

PLC SUPPORT

While doing EPICS integration of Siemens S7 PLCs, the developer spends a lot of time grouping PVs and calculating offsets in order to match EPICS PV types with STEP7 variable types. We have decided to simplify and

automate this process using Excel and introduce this feature into the DCDB-tool. There are now sheets in the Excel file where you configure the hardware, generate UDTs and assemble DB blocks. As a result, the DCDB-tool generates an EPICS start-up script and two PLC configuration files to be deployed on the PLC.

-	pb1	ioc1	plc2	pyrobreaker
-	pb2	ioc1	plc2	pyrobreaker
-	pb3	ioc1	plc2	pyrobreaker

Figure 4: Microsoft Excel client. PLC blocks configuration.

FRONT-END

The user communicates with the REST server via an HMI, which is realized as an Excel add-in (ribbon). It provides a set of buttons with which you can easily edit your support modules' configuration (Fig. 3), configure IOCs (Fig. 5), PLCs (Fig. 4); start/stop/restart IOCs, and more.

As a free alternative to Microsoft Excel, the DCDB-tool also has a Google Spreadsheets client (Fig. 5), which has been published to the Chrome webstore (Fig. 6). The client is written in HTML/Javascript and fully supports the functionality provided by the JSON API.

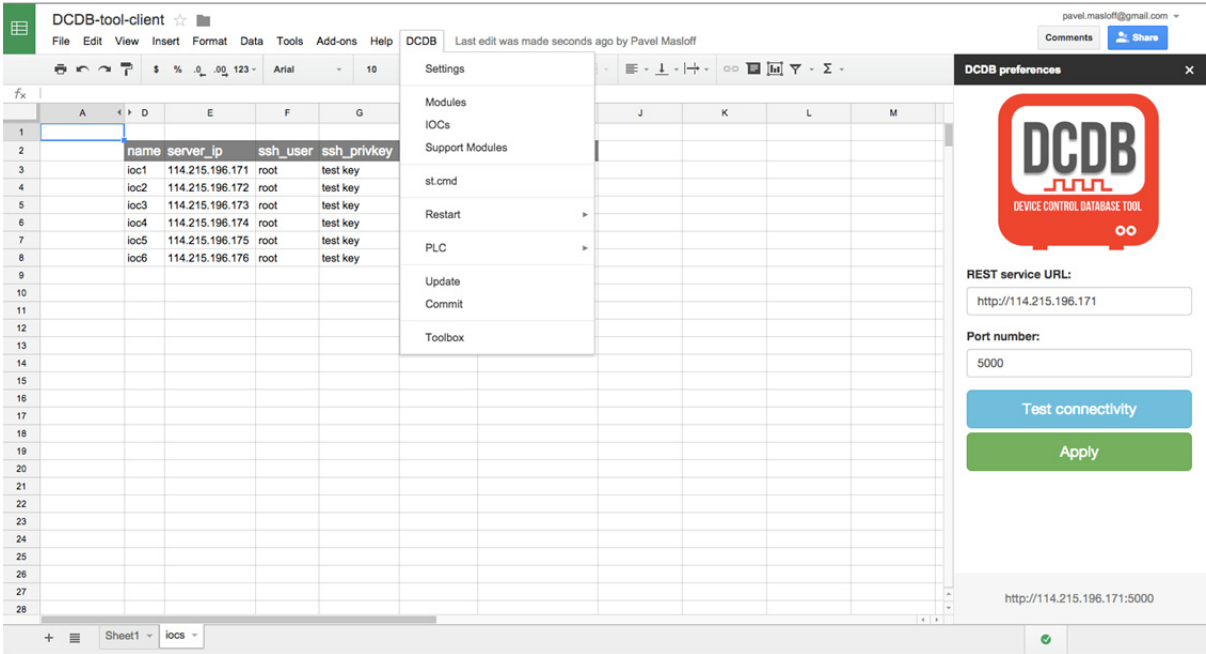

Figure 5: Google Spreadsheets client. IOC configuration sheet.

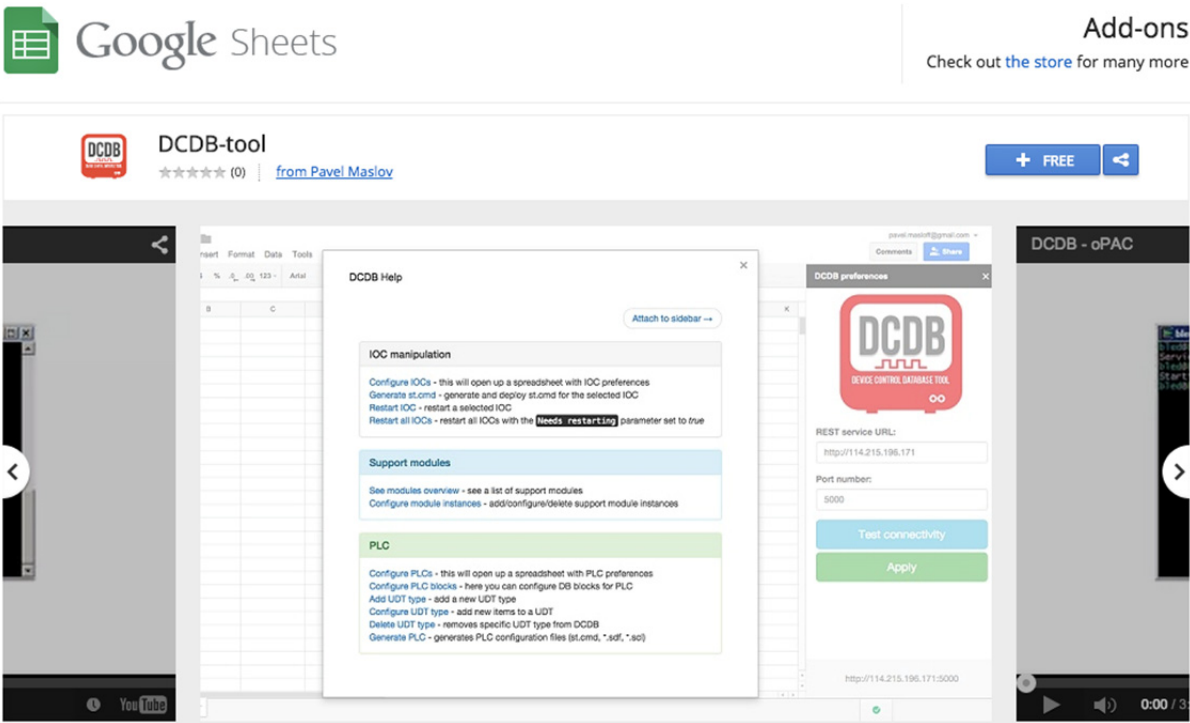

Figure 6: Google Spreadsheets client in the Chrome webstore.

SUMMARY

The DCDB-tool is a powerful control system configuration tool that reduces integration effort and thus, time. It was tested on different platforms including RHEL, Ubuntu, Scientific Linux, Mac OS X and Windows. It is developed with the best practices from the EPICS community, compliant with the CODAC Core System (used at ITER, ELI-NP), but can also be used in any other EPICS environment (i.e. ESS).

ACKNOWLEDGEMENT

This project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement no 289485.

DESIGN STRATEGIES IN THE DEVELOPMENT OF THE ITALIAN SINGLE-DISH CONTROL SYSTEM

A. Orlati, M. Bartolini, S. Righini, INAF-IRA, Bologna, Italy
M. Buttu, A. Fara, C. Migoni, S. Poppi, INAF-OAC, Cagliari, Italy

Abstract

The Italian National Institute for Astrophysics (INAF) manages three radio telescopes: the Medicina and Noto dishes and the newly-built SRT. In order to make their capabilities more valuable to the scientific community, we started the DISCOS (Development of the Italian Single-dish Control System) project. DISCOS is implemented according to a distributed Component-Container model and hides to the users the differences among the telescopes by presenting the same user interface and the same data format. The complexity of coping with three heterogeneous instruments was handled designing a software development infrastructure with a wide monolithic codebase (libraries, components and generic interfaces), which is completely shared among the three product lines. This design permits to produce new software components with a minimum effort and to set up the same test suites for all the environments, thus leading to an affordable development and maintenance process. In this paper we illustrate the design strategies and the development techniques used to realize and optimize this common control software. We also provide a description of the project status and future plans.

INTRODUCTION

The National Institute for Astrophysics (INAF) manages three radio telescopes in Italy: The Sardinia Radio Telescope (SRT) [1] and the Medicina and Noto 32-m dishes. The newly-built SRT, located in the Sardinia island, was inaugurated in 2013. Since the early stages of the project, staff from all the three telescopes has been involved in the development of the SRT control software. This forced us to cope with both the development of a brand-new system and the maintenance of the already existing telescopes, compelling the involved personnel to learn and enhance their competence in distinct and heterogeneous systems based on completely different technologies. Developing a control software to be installed at all the telescopes was the natural and straightforward approach to this problem.

This idea was formalized with the creation of the Development of Italian Single-dish Control System

(DISCOS). The project aims to provide all three Italian radiotelescopes with a common infrastructure that increases their capabilities and the usability for the scientific community and, at the same time, optimizing the efforts made by the technical staff for its development and maintenance.

DISCOS is based on ALMA Common Software (ACS) developed at ESO for the ALMA project [2]. ACS implements a Component-Container model via CORBA (Common Object Request Broker Architecture). It provides a set of tools, libraries and development patterns that hide the complexity of CORBA. This approach permits to reduce the time required for coding and development. The framework also supports both real and non-real time platforms for C++, Python and Java.

The core of the project was completed during the main development stage. The SRT and Medicina installations are now fully operational and supervise all the telescope operations. The Noto antenna is also equipped with a preliminary version, which is going to be finalized in a few months.

In this paper we describe the salient design choices that allowed us to reuse the most part of the code for all the production lines and to hide the instrument complexity under a common infrastructure. We also illustrate the maintenance and development workflows, as they are fundamental part of the DISCOS design.

THE TELESCOPES

The INAF radiotelescopes share some common aspects but are in general different from one another. Medicina and Noto have passed through years of development and updates, while SRT is the result of an organic employment of state-of-the-art technologies. Table 1 recaps the main characteristics and the differences, listing all the major sections – servo systems, front-ends, back-ends. All the telescopes are presently participating in the VLBI network. Medicina and Noto are also offered to the scientific community as single-dish facilities (SRT will very soon be, as well).

A COMMON STRATEGY

Broad categories like development, operations and maintenance are very demanding, especially when highly qualified expertise is required. Our common infrastructure enhances the quality and throughput of our work.

Operations

Operations are immediately affected by this strategy; as operators can now manoeuvre the three telescopes facing very slight differences in the user interface, their require a single training. Similarly, astronomers are presented with

the same observing modes and the same data format at every telescope. Operation manuals and documentation are written with a common effort, sharing most of the information among the infrastructures.

Maintenance

Maintenance consists in code debugging, configuration changes or even complete replacements of software components. Since regular telescope activities require to minimize the time devoted to maintenance, the relative work must be carried out with proper planning and efficiency. This is eased by the use of the same ticketing

system to track software bugs and to monitor the antenna status. A common workflow, involving every collaborator, is employed to fix malfunctions. As the needed tests can be performed at any telescope, we can choose the one providing an adequate scheduling to test patch releases.

Development

The development of new software features is a time-consuming activity that also requires testing time. The DISCOS common platform highly reduces these needs. New components can be deployed indifferently at all the antenna systems, so that separate units can independently carry out the development work. Moreover, once a new piece of hardware is commissioned and integrated into the software system of one of the telescopes, it can be replicated at the other telescopes with little effort.

DESIGN

The design of the DISCOS control software highly relies on the ACS patterns and services. In the ACS model, the basic unit performing a task is a component. It either controls a simple device or executes astronomical computations. Each component exposes an interface or list of capabilities and is individually configured to determine its exact behaviour inside the system. In our project the components are organized into subsystems or packages according to their functional affinity, thus forming system segments that are independent and capable to run as stand-alone groups. During the early development efforts this configuration turned out to be very valuable for our geographically-spread team. Each developer, in fact, could focus on one single subsystem, internal milestone or scheduled test, without being concerned by the delays in the development of the other packages.

Supporting three different telescopes is of course the most challenging goal of the project. This can be reached by expanding the common code, the part of our project that can be reused and deployed at all sites, as much as possible. The station-specific modules, then, consist essentially in the low-level and no-logic control of the devices and of the telescope hardware. According to this approach, a careful design was crucial to ensure that all the peculiarities of the telescopes fitted with the business logic at a higher level and with the common parts of the control software. The Italian telescopes differ in various features (see Table 1), which can be grouped into two categories:

- A given telescope functionality is implemented via different hardware devices at the three radiotelescopes: they could differ in vendor, working mode and communication protocol. The main servo systems of our antennas are an excellent example of this case; in our software implementation such devices were modelled according to an ideal or generic interface that defines the minimal set of attributes and methods required by the control logic. Every other

component handles the device adopting this interface.

- An apparatus is installed at one or two telescopes, but it does not apply to other antennas. For example, the SRT and Noto antennas are equipped with an active surface, while the Medicina one is not. These categories are handled through configuration files describing the available components and functionalities; the system is then capable of detecting if an operation is allowed under the present configuration. If the operation is not fundamental for the running observation, no error is raised.

Development Workflow

In recent years we have tried to formalize the development workflow of new components, resulting in clearer and more maintainable code. As a first step we decided to add the ability to run components by simulating the hardware layer whenever possible. This led us to split the component development into:

- Development of a hardware simulation server
- Development of a standalone hardware communication library
- Development of the ACS component exploiting the library

The immediate benefit of this procedure is to have a simulated hardware environment that permits to run our tests automatically. We consequently adopted integration tests to validate component interfaces and regression tests when fixing bugs in the system. Furthermore, we set up an infrastructure - both Python and C++ are supported - that generates a testing skeleton for new components and runs unit tests collecting xUnit-formatted results.

A new approach was adopted also in the configuration of the software environment. The full stack deployment was formalized via code, resulting into the AZDORA project [3]. It uses virtualization and provisioning technologies in order to setup and run a fully configured DISCOS environment, which can be used both for development and production workstations. This uniformity among development, testing and production environments is crucial in assessing the software stability as much as possible before the on-field production installation.

The just-described features have made it possible to adopt Continuous Integration practices in the development process. A Jenkins server [4] is used in this case. At present we run nightly builds of the trunk branch of each telescope and of every still-maintained release. The proper developer is alerted in case problems are detected; occasional build or integration errors are fed into our bug-tracking system. Each build target results into a ready-to-install package that can be safely used in production environment. This infrastructure also permits test automation and to collect the results on the whole project. In the near future this will give access to new quality metrics and to the possibility of automatically

running acceptance tests upon every new code subscription.

Maintenance Workflow

System bugs are handled with regression tests: each time a bug is found, the developer writes a test that reproduces the buggy behaviour, then the fix is not committed into the patch release until the test executes correctly.

We also adopt a *major.minor.patch* nomenclature. The major version zero (0.y.z) is for initial development, when anything may change at any time: the public APIs, the operator input commands and the schedule grammar are not to be considered stable. New major versions are issued when non-backward-compatible changes are necessary and are planned way in advance. Minor versions are feature releases, so they add functionality in a backward-compatible manner. We also have non-production ready versions that get an additional qualifier: beta and release candidate (RC). The beta versions are to be tested by advanced users, while the RCs are aimed at being tested by a group of astronomers.

Release notes are written by developers in a user-friendly manner and can be found within our documentation portal [5], while technical release notes are automatically extracted from the bug-tracking and features system used to manage the development process [6].

FUTURE PLANS

The DISCOS user interface is currently mainly composed of unrelated GUI applications showing textual information about the main telescope components via *ncurses* based panels. Every interaction with the control software is performed via a command shell that serially reads telescope commands in a synchronous *Read-Evaluate-Print* loop. A remote access to the interface is offered via VNC connections. This setup is effective for early operations; in view of the telescopes future activities we are designing a user-friendly interface in the form of a web application. This will provide the users with a more homogeneous experience, efficiently enabling remote operations. This approach will likely require other software layers, implementing the authentication and authorization of the users and new parameters-publishing

systems. This will also lead to a possible integration with other telescope management software tools, such as the proposal submissions handling system and the schedule creator. This work could also technologically enable the creation of a centralized operation centre for all the radiotelescopes.

Further development in the near future will involve the adoption of the most recent ACS version, the adoption of new technologies for high-rate data transfer, the extension of test coverage to a bigger portion of the code and the automation of tests during the build process.

CONCLUSIONS

DISCOS is serving the scientific community by enabling observations at the Italian INAF radiotelescopes, and while being still subject to some major changes, it is running and effective. The growth of the project and its dissemination among different sites has forced the adoption of a common development strategy and has led to the adoption of best practices from the software industry such as Test Driven Development and Continuous Integration in order to assess software quality and to ensure the stability of successive software releases. This also enables an effective maintenance process, which is a strong assurance for the coming years of development and operations.

TANGO INTEGRATION OF A SPECIFIC HARDWARE THROUGH HTTP-SERVER

A. Panov, A. Korepanov

The Budker Institute of Nuclear Physics, Novosibirsk, Russia

Abstract

MAX IV are new synchrotron third generation. MAX IV synchrotron consist of 1.5 GeV storage ring, 3.0 GeV storage ring and linac; it is located in Lund, Sweden. Structure of storage rings contains several pulse magnets (kicker and pinger). Control system of pulse power supplies based on LTR crate with several modules (ADC, DAC, input/output registers etc.). LTR crate is a product Russian firm L-CARD. In order to communicate with crate native LTR-server is used. LTR-server is a Windows application based on use of sockets. Control system of MAX IV and Solaris uses TANGO. For integration LTR-crates in final structure, special software gateway is used. This gateway is a set of several specific Windows applications implemented by using Qt5 libraries. Gateway allows communicating TANGO-server with crate through built-in HTTP-server.

SPECIFIC HARDWARE

The MAX IV facility included two storage rings for the production of synchrotron radiation: the 3 GeV and 1.5 GeV storage rings [1]. Both rings will be operated with top-up shots supplied by the 3.5 GeV MAX IV linac acting as a full-energy injector at up to 10 Hz repetition rate. At the commissioning phase, the single dipole kickers will be used for the injection in the both rings. In addition, pulsed vertical kickers (pingers) are needed for performing tests with the stored electron beam.

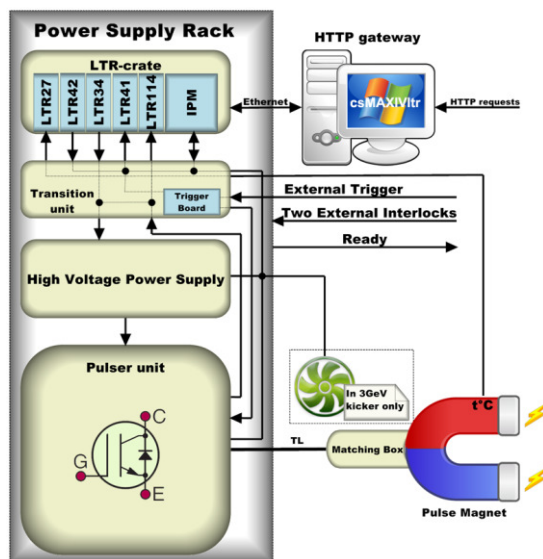

Figure 1: General pulse power supply structure.

Table 1: Pulse Magnet Systems Specifications

	1.5GeV		3GeV	
	kicker	pinger	kicker	pinger
Integrated field, Gm	143	75	450	110
Peak current, A	1060	2050	3600	2600
Pulse length, μ s	0.64	0.64	3.5	3.5
Maximum rep. rate, Hz	10	1	10	1
Pulse to pulse timing, ns	± 5	± 5	± 5	± 5
Pulse to pulse repeatability, %	± 0.1	± 1	± 0.1	± 1

The requirements for the pulse magnet systems are listed in Table 1. Structure of all system (power supply with control electronics and magnet) are illustrated on Fig.1.

Control system of the pulse power supply based on 19" LTR-crate (LTR-EU-16). It is a product of a Russian firm L-CARD (<http://lcard.ru>). Base structure of the LTR-crate are represented on a Fig. 2.

This crate include FPGA Cyclon EP1C3 for

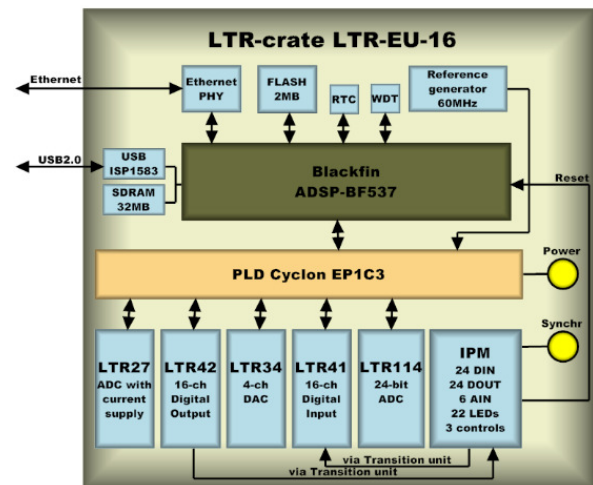

Figure 2: Power supply control system (LTR crate with modules) block diagram.

communication with installed in crate modules via proprietary interface and digital signal processor Blackfin ADSP-BF-537 for preliminary data processing. DSP operates under control of Visual DSP++ Kernel (VDK) [2]. Sources of a DSP firmware in free access and can be modified for individual requirements. Crate can communicate with PC over USB2.0 or Ethernet (TCP/IP) via L-CARD specific protocol.

The following modules are installed in LTR crate:

1. LTR41 (16 channels digital input module);
2. LTR42 (16 channels digital output module);
3. LTR114 (24 digits ADC module);
4. LTR34-4 (4 channels DAC module);
5. LTR27 (thermo ADC);
6. IPM (Interlock Processing Module);

All modules (except IPM) was produced by L-CARD. Interlock Processing Module was made in Budker Institute of Nuclear Physics. It communicate with LTR-crate over digital inputs/outputs by LTR41/42. Brief characteristics of modules and their targets of using are listed below.

LTR41 Digital Input Module

LTR41 is 16-channels input module for TTL/CMOS-signals (with 5 V-logic) and also for current logical signals (up to 25 mA) with per-channel galvanic isolation. It is used to synchronize and to get current states and interlocks values from Interlock Processing Module.

LTR42 Digital Output Module

LTR42 is a 16-channels output module with per-channel galvanic isolation. It is used to send control commands to the interlock processing module and to generate "heartbeat" signal, which is used by the algorithm of checking the status of connection to control PC.

ADC Module LTR114

LTR114 module is a 24-digits ADC with sampling frequency up to 4 kHz, differential input and dynamic commutation to 16 channels. It has software controlled input sub-ranges ± 10 V, ± 2 V, ± 0.4 V independently for each channel. LTR114 is used to measure high voltage and to monitor settings of the HVPS (voltage and current).

DAC Module LTR34-4.

LTR34-4 module is a 4-channel 16-digits DAC with output frequency up to 500 kHz in voltage range from -10 V to +10 V. It is used to set up the HVPS output voltage and current values.

Thermo-ADC LTR27

Unit LTR27 is a mezzanine module with possibility to install up to eight submodules. In current configuration a single submodule H27-R250 for resistances measurement is used. Frequency of data yield is up to 100 Hz. The unit is used to monitor the temperature of the magnet's vacuum chamber by measuring resistance of thermoresistor Pt100.

CONTROL SYSTEM SOFTWARE

L-CARD produce software package for operate with crate and modules. First, this package include LTR-server (for Windows PC) and ltrd daemon (for Linux PC). These applications necessary for initializing operations, obtaining data from crate in uniform format and allocating data according to list of modules. In addition, software package include necessary library (C++/LabView) for implementation individual application for communicate with modules over LTR-server or ltrd. There is utility named UTS for test purposes and there is L-Graph2 application for collecting and visualization data from various ADC.

Set of modules is a low layer control and monitor system of pulse power supply. High layer is a Tango server with appropriate operator screen. Therefore middle layer for communicate Tango server with LTR-crate is necessary. This middle layer was realized in BINP and named csMAXIVltr. Main goal of this software part is be gateway between Tango and LTR. Moreover, csMAXIVltr provide several procedures for normal work of the power supply.

csMAXIVltr consist of four Windows application:

1. Starter, which start and control all other applications;
2. LTR-target – main application, which communicate with LTR-server;
3. HTTP-server – for communicate with Tango server;
4. LTR-server – L-CARD application for communicate with LTR-crate.

Basic structure of the csMAXIVltr are presented at Fig. 3.

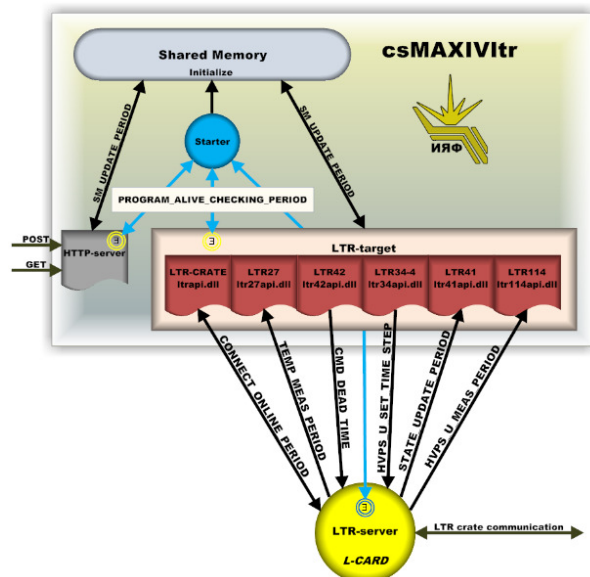

Figure 3: Basic structure of software gateway.

All BINP parts of the csMAXIVltr was realized with Qt5 framework for operate on Windows machine. Starter, LTR-target and http-server interact together over shared memory with specific period (SM_UPDATE_PERIOD) which amount approximately 100 ms. Each module in LTR-target operate in its thread and interact together with QT native SIGNAL/SLOT mechanism.

Http-server

Http-server based on QHttpServer by Nikhil Marathe [3]. This csMAXIVltr part provide access Tango server to main actions (switch on/off, reset), settings (current/voltage), states and interlocks. Procedures for writing and reading of csMAXIVltr internal settings were added in last version.

Http-server ensure the fulfilment of two basic methods: POST and GET. POST method are used for control pulse power supply: switch on/off high voltage power supply, reset interlocks, disable or enable trigger and write voltage and current settings to HVPS. Each POST-request should contains single command. So if it is necessary to send a number of commands to the system then the sequence of POST-requests should be generated. If POST-request contains a few commands then only the first command is processed and other are ignored.

GET method are used for reading various measurements (voltage from divider, feedback levels, temperature), states and interlocks. Moreover, by GET method operator can modify internal csMAXIVltr settings (IP address, timeouts, average size and many other).

Http-server responding with identical answer on POST or GET request. This response consist of two parts: simple html-page (yellow on the Fig. 4) and last line with all required parameters (green on the Fig. 4). "Yellow" part required only for debugging or testing without Tango operator screen. "Green" part are implemented in POST data format – ...&ParameterName=ParameterValue&... This part formatted like comment in html page.

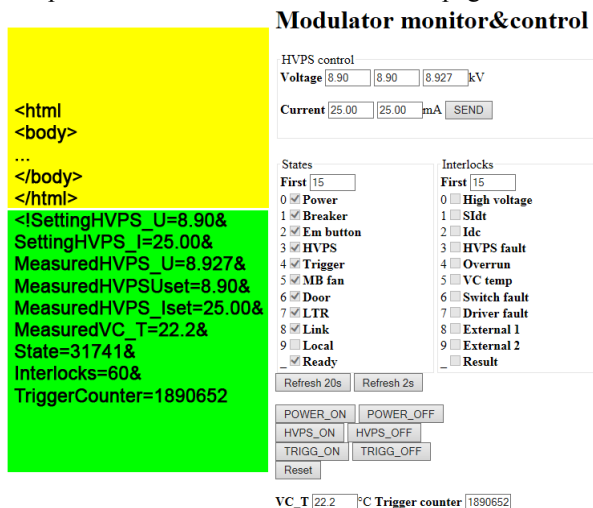

Figure 4: Typical Http-server response.

Read request structure of a csMAXIVltr parameter via GET are look like `http://x.x.x.x/~PATH??`

Write request structure of a csMAXIVltr parameter - `http://x.x.x.x/~PATH=VALUE!` where PATH is variable combined from APPLICATION_NAME and PARAMETER_NAME.

In additional http-server supports authenticate header for security operate with control system. Login and password can be changed by configuring csMAXIVltr.

Tests

Several basic tests was performed for operability checking of the system. Apache Benchmark output are represented at Listing 1.

Listing 1: Apache Benchmark output.

Control test results are represented on a Fig. 5. Histogram corresponds to result of write "action" command tests. Delta is time between operator action (mouse button click on "Reset" button at html page) and actual control system operation (reset interlocks by IPM). This time summarize three large latency: shared memory update time by http-server (≤ 80 ms), read time from shared memory by LTR-target (≤ 80 ms) and send time to IPM over digital output module by using special robust protocol (≤ 160 ms). These times can be decreased by configuring csMAXIVltr, but this action increase CPU load.

Figure 5: Write command test results.

Upstairs graph represent continuous sequence of voltage setpoints from zero to 10 Volts with 300 ms time step.

TANGO VIEW OF PULSE POWER SUPPLY

Tango-server for pulse power supply was realized by Cosylab. It contains 29 attributes for operator display level and additional 35 attributes for expert. Majority of operator view attributes (20) are Boolean which indicate state or interlock.

Power supply control state machine are illustrated at Fig. 6. This diagram not include UNKNOWN and INIT states because they define only internal Tango server implementation. All other state defining from status of the pulse power supply.

Figure 6: Power supply state machine in Tango view.

Figure 7: Basic conditions for Tango state definition.

At the Fig. 7 are represented basic conditions for Tango main states definition. Trigger pulses are external synchro signal for power supply start. FAULT state condition came when high voltage exceed legal level for example.

Software gateway based on the very simple http-server allow to link LTR-crate with Tango approach for successfully control of pulse magnet power supplies.

CERN, Geneva, Switzerland

Abstract

In the LHC beam pipes and cryostats, the pressure measurement covers a wide range, from 1500 mbar down to 10^{-11} mbar and even lower. If vacuum deteriorates, alarm signals are generated and sent to other systems, like cryogenics, accelerating cavities, kicker magnets. In addition, an unacceptable pressure rise in beam pipes generates interlocks to close the adjacent sector valves, thus isolating the sector, so that the pressure rise does not propagate. This pressure interlock is simultaneously forwarded to the beam interlock system.

This paper describes the instrumentation, the interlocks and alarms logic used in the vacuum control system of the LHC. We analyze the possible signal degradation caused by ionizing radiation or due to cable length, shielding and grounding. During the first LHC long shut down, several corrections were applied to mitigate radiation effects and improve signal integrity. The tests performed for the vacuum control commissioning and LHC machine checkout are also presented.

VACUUM MEASUREMENT

Vacuum gauges in accelerators have to cover about 15 decades of pressure. The direct pressure gauges, which measure the force per unit area, are gas-type independent. They cover the rough and medium vacuum ranges. The indirect pressure gauges, which measure a pressure-dependent property of the gas, are gas-type dependent. They can cover a wider range of vacuum, from the rough to the ultra-high vacuum range [1].

The membrane gauge covers the range from 0 to 2 000 mbar. It is composed by a thin silicon crystal layer used as a membrane, whose deformation induces a piezo-resistive effect on the four resistances of a Wheatstone bridge. The resistance variation is a function of the pressure. The signal to be read across the bridge is in the mV range.

The Pirani gauge covers the range from 1 000 to 10^{-4} mbar. The measurement is based on the dependence of the thermal conductivity on the gas pressure. A filament is heated and maintained at a constant temperature. The current needed to maintain this temperature depends on the gas conductivity and therefore is a measure of the pressure. The signal delivered by the amplifier is in the Volt range. Above 1 mbar the measurement becomes non-linear, and depends on the gas species

The Penning gauge covers the range from 10^{-5} down to 10^{-11} mbar; it is also called inverted magnetron cold cathode gauge. It is composed by a thin cylindrical anode rod, surrounded by a cathode. A high voltage (HV)

potential of 3kV creates a high electric field between the two electrodes, which favors the ionization of gas molecules. Around the electrodes, a permanent magnet produces a field that forces the free electrons into spiral paths, thus increasing the probability of ionizing more molecules. The ionization current is a function of the pressure. In the low range of measurement, the current can be as low as the pA; a high quality HV triaxial cable is used for signal transmission.

In the range from 10^{-5} down to 10^{-9} mbar, the Sputter Ion Pump can be used to measure the pressure, in addition to its pumping function. It is composed by several Penning cells, with the particularity of Titanium cathodes and a potential of 7 kV. The principle of vacuum measurement is the same as for the Penning gauge. In the low range of measurement, the current can be as low as 100 nA, and high quality HV triaxial cable is used for signal transmission.

Finally, to measure down to 10^{-12} mbar, the Bayard-Alpert gauge is used. A heated filament emits electrons which are accelerated by the grid potential (+150 V). On their path, these electrons ionize gas molecules, which are gathered by a collector. The collector current is a measure of the ionization and therefore of the gas pressure. It can be as low as 100 fA. High quality triaxial cable is used for this measurement.

INTERLOCKS AND ALARMS

Alarms are binary signals sent to the operators' console, e-mail or SMS, to draw their attention to particular equipment status or situations. There are also alarms directly cabled to other systems, for information or to be used in their control logic.

Interlocks are binary signals used within the vacuum system to prevent entering undesired states. They have a higher priority than the normal process logic or the operator's commands. Apart from the beam permit interlock, the vacuum control system does not interlock any other external systems directly.

The detection of a pressure rise, above a predefined threshold, can be used to produce alarms or interlocks. The gauges used for alarms or interlocks can be the Membrane, Pirani, Penning and Ion Pump [2].

Interlocks for the Vacuum Sector Valves

The beam pipes are divided in "vacuum sectors" that can be isolated by "sector valves" (VVS), to avoid the propagation of leaks over a large volume.

Upon the detection of a pressure rise above a predefined level, these valves will close in 1 to 3 s, depending on the model.

The LHC itself is divided in 8 “machine sectors”. Each one consists of a curved section (ARC + DS) of about 2.8 km where all magnets are cryogenic and kept at 1.9 K in a continuous cryostat. At each side of the continuous cryostat, there is a long straight section (LSS) of some 300 m. Here, a sequence of cryogenic stand-alone magnets (SAM) alternates with sectors of bare beam pipe at room temperature, before arriving to the experimental or technical caverns.

The continuous cryostat, the room temperature sectors and the SAMs have vacuum sector valves at their extremities. During the recent long shutdown (LS1), one of the targets was to minimize the risk of a pressure wave created in the ARC to propagate and damage the SAMs or other equipment.

The sector valves at the end of the continuous cryostat were improved for a faster closing (less than 1 or 2 s). New Penning gauges were added further upstream (Q12, Q13) of the valves, to interlock them on an early detection of the pressure wave front.

In general, a sector valve is interlocked by several neighboring pressure measurements, either to make it close or to enable its aperture. The pressure thresholds can be set individually for each gauge, but preference is given to an uniformity of values all around the machine. A valve closed by a pressure interlock will also propagate it to its 2 neighbor valves, to further isolate the faulty sector.

Figure 1 shows the typical interlock configuration between two vacuum sectors at room temperature.

Figure 1: VVS interlock configuration.

Table 1 summarizes, for different configurations, the thresholds and the fraction of neighboring gauges needed OK, to allow or keep valve opening. The valves at the end of the continuous cryostat have an additional condition on the 2 new gauges.

Table 1: Thresholds and Logic for the Sector Valve Interlocks

	Rising [mbar]	Falling [mbar]	# to allow open	# to force close
continuous cryostat	$2 \cdot 10^{-6}$	$1 \cdot 10^{-6}$	4 OK / 4 + 2	3 bad / 4 + 2
room temperature	$2 \cdot 10^{-6}$	$1 \cdot 10^{-6}$	4 OK / 4	3bad / 4
SAM	$2 \cdot 10^{-6}$	$1 \cdot 10^{-6}$	3 OK / 3	2 bad / 3
dump lines	$7 \cdot 10^{-5}$	$5 \cdot 10^{-5}$	4 OK / 4	3 bad / 4

Interlocks to the Beam Interlock System (BIS)

As a closed sector valve would be in the beam path, and thus damaged, the beam must be stopped before that may happen. Indeed, the beam can be extracted from the LHC and dumped in less than 300 μ s, which is much faster than any valve closing (1 - 3 s).

Therefore, a pressure interlock triggering a valve closing is simultaneously forwarded to the BIS [3]; and so is the information of any valve losing the open state, due to a neighbor valve closing or for any other reason.

Alarms to the Cryogenic System

If the pressure rises, the thermal isolation degrades and the cryogenic system might need to prevent the start of some cryo-compressors or even to stop them.

Each insulation volume around the cryogenic distribution line (QRL) or the cryo-magnets is equipped with a triplet of gauges (Membrane, Pirani and Penning). The first two are used to generate alarms to the cryogenic system, at 500 and 0.1 mbar, respectively.

Alarms to the RF & ADT Systems

If the vacuum degrades inside a radiofrequency (RF) accelerating cavity, the high electrical field may ionize the residual gas and damage the cavity.

For each of the 8 cavities in each beamline, the RF system has its own Penning gauges, to follow the pressure inside the cavities, and to produce the necessary interlocks. These are not available on the vacuum system.

The pressure in the beam pipes outside of an RF module (group of 4 cavities) is used to produce an alarm, combining one Penning gauge ($1 - 4 \cdot 10^{-7}$ mbar) and two ion pumps ($1 \cdot 10^{-6}$ mbar).

For the transverse dumpers (ADT), located upstream and downstream of the modules, the RF system receives the analog reading and a Penning alarm ($1 - 5 \cdot 10^{-7}$ mbar).

Alarms to the Kickers Systems

The injection kicker magnets (MKI) insert the beam coming from the transfer lines into the LHC orbit; there are 4 MKI tanks at point 2 and 4 other at point 8.

The dilution kicker magnets (MKB) sweep the beam in an ‘e’ shape, distributing it over a wide dump surface; there are 5 MKB tanks on each side of point 6.

As the kicker magnets are powered by high-voltage pulses, if vacuum degrades, galvanic isolation becomes a concern and the kickers may have to be stopped. If pressure rises in the MKI, there cannot be injection into the LHC. If

pressure rises in the MKB, the beam should be dumped before the situation gets worse. Table 2 shows the thresholds and the fraction of neighboring gauges needed to send an alarm to the kicker systems.

Table 2: Vacuum Information Sent to the Kicker Systems

	Rising [mbar]	Falling [mbar]	alarm sources	# to send alarm
MKI (4 tanks / beam)	2.10^{-8}	1.10^{-8}	1 gauge	1 bad /1
MKB (5 tanks / beam)	2.10^{-5}	1.10^{-5}	1 gauge 2 pumps	2 bad /3

Their control systems receive binary alarms and analog pressure readings, from the associated Penning gauges and ion pumps.

RADIATION ENVIRONMENT

Service Areas

The majority of LHC vacuum controls are located in underground service areas, shielded from tunnel radiation. During the next 20 years, as the energy and intensity of the beam will increase, those service areas will see an increase of the High Energy Hadron (HEH) fluence rate by one order of magnitude. The electronics installed in those areas may suffer Single Event Effects (SEE).

Solutions, such as additional shielding, relocation or redundancy of critical vacuum controls must be taken into consideration. For example, due to the level of radiation caused by the collimation system at point 7, all vacuum controls equipment in UJ76 has been moved into the TZ76 gallery, during the LS1. This concerned 27 racks; the associated 280 cables were extended by up to 180 m. In this gallery, the HEH fluence rate will be much lower and the SEEs negligible ($< 10^6 \text{ cm}^{-2}\text{y}^{-1}$) [4].

LHC Tunnel

All the gauges in the LHC tunnel are subject to ionizing radiation. Depending on their location, the levels of radiation may vary: in the ARCs, the Total Ionizing Dose (TID) will be less than 10 Gy/y; but in the LSS it will be much higher than that. The lifetime of the gauges must be better than 10 years.

Gauges in low radiation zones are “active”: the signal-conditioning electronics is incorporated in the gauge head. They are locally powered and send their readings on 0-10V through standard multi twisted-pair cables, over up to 1000 m, to the PLCs in the service areas.

The gauges installed in higher radiation zones are “passive”, with the electronics located in a service area, up to 500 m away. Power and signal are carried by special HV cables, according to the gauge type.

The cables in the tunnel accumulate radiation over the time, which progressively degrades their characteristics, eventually destroying them. Also, transient effects might be observed due to radiation-induced conductivity of the insulation of HV cables. Upcoming tests at CHARM

facility (CERN) will give more information on radiation-induced effects on HV cables.

Irradiation Tests on Active Gauges

Priority has been given to test the gauges and electronics to be installed in the tunnel. This concerns the Membrane, Pirani, and Penning gauges, of which the first two are used to generate alarms for the cryogenic system, and are thus more critical for the machine operation.

Irradiation tests have been carried out in 2002 in the TCC2 facility at CERN, on a set of commercial Pirani/Penning active gauges. This facility provided a mixed field similar to that of the LHC.

The Pirani electronics provided correct readings up to 20 Gy, and saturated under-range at 50 Gy. For the Penning electronics, correct readings were obtained up to 40 Gy, saturating under-range at 60 Gy. Therefore, it was decided to use the commercial Penning electronics and to design a radiation tolerant Pirani electronics.

A set of commercial active Membrane gauges has been irradiated at the cyclotron of the University of Louvain (Belgium), in 2003. The source was a 60 MeV proton beam, with a flux of $8.10^7 \text{ cm}^{-2}\text{s}^{-1}$. The best gauge stood up to 200 Gy, with a good stability.

In 2015, a new irradiation test has been carried out at Fraunhofer Institute. A gamma radiation source of ^{60}Co has been used for 20 days to produce up to 500 Gy, which is higher than 10 years of operations in the arcs. Three samples of commercial Penning and CERN-designed Pirani electronics have been irradiated. One sample of each was placed outside the radioactive field as a reference while vacuum was simulated by resistors.

The worst Penning electronics sample was measuring pressure one decade too high already at 15 Gy, and two decades too high at 20 Gy, before falling quickly under-range. The Pirani electronics re-designed at CERN in 2002 stood up 500 Gy, with slight variations around the reference measurement.

The analysis of these tests are still ongoing and the results will contribute to define the strategy against radiation effects to electronics for future consolidations in the LHC.

SIGNAL INTEGRITY

Vacuum Measurement in the ARCs

The readout electronics for the Penning, Pirani and Membrane gauges in the ARCs are installed in a box placed above some of the dipoles. In one ARC, 28 boxes are installed. They are connected, through multi twisted-pair cables, to one of the two ARC PLCs, installed in service areas.

The Pirani and membrane electronics are locally powered, while the Penning electronics are powered from the PLC digital outputs. The 0-10V analog output of each gauge is routed through a twisted pair directly to the PLC analog input module. Moreover, each PLC analog input module provides an analog ground, isolated from the earth, used mainly by the Penning electronics.

The Penning and Pirani gauges located by the middle of the ARCs, where the cable lengths may reach 1 000 m, often shown malfunctions. Some Penning gauges could not be switched on for measurement. Moreover, by switching on or off a Penning gauge, the nearby Pirani and Penning gauges could be disturbed.

Corrective Actions

During the LS1, an investigation took place. Measurements on the output signal of the concerned Penning gauges showed a strong common mode voltage, unacceptable by the analog input module specifications.

The wire resistance on the shared powering return path was too high; the current consumption of the Penning signal-conditioning electronics brought up a voltage across the wire. As the reference for the Penning electronics is based on the common power lead, isolated from earth, this common-mode voltage was also present at the input of the analog input module of the PLC.

Moreover, the cause of measurement cross-talk between gauges installed at different places was explained by the fact that they shared the same analog ground.

An equivalent circuit has been simulated in PSpice, to understand the behavior of the interconnected analog grounds. The simulations indicated that the analog ground connections between two separated gauge electronics generated a current flowing from one to the other, depending of the status of each gauge. This created an additional DC offset to the measurement, of the order of some mV. In the range of measurement, this might correspond to one order of magnitude in pressure.

The solution finally implemented consisted in adding parallel wires, to decrease the resistance on the return path for the Penning supply. Thus, the common mode voltage has been successfully reduced within the manufacturer specifications and solved the first issue.

On the other hand, the analog ground connections have been removed, to avoid complex ground loops between different channels.

LHC COMMISSIONING

The commissioning of all vacuum measurement, alarm and interlock channels was carried out during the last months of the LS1. Each element of the chain has been tested with and without simulators. The vacuum sector valves were actuated and their status checked.

The signal transmission from the vacuum control system to the BIS has been checked in all points of the LHC. The interlocks and alarms have been triggered and checked for each system (vacuum sector valves, BIC, cryogenics, RF cavities, ADT, MKI and MKB).

The equipment involved in vacuum interlocks and alarms amounts to: 300 sector valves, 230 pairs of gauges, 590 Penning gauges, 350 ion pumps [5].

Machine Checkout

The systematic verification of interlocks and alarms has been performed during the LHC machine checkout phase

[6]. The goal was to check all the interlock sources for the vacuum valves, and confirm that their status were sent correctly to the BIS, for dumping the beam.

An automated test sequence was written in the vacuum SCADA, and its results stored in xml files.

After all the vacuum valves have been opened to set the vacuum interlock to true in the corresponding BIS, each of the N (3 or 4) devices are switched off (and back on) one by one, to see if the valve open-enable is lost (and recovered).

Then, N-1 devices (3 or 2) are switched off to see if the corresponding valve closing-interlock is triggered. The time stamps are stored for: the valve closing-interlock; the loss of valve open-status; the reaching of the valve close-status; the vacuum user permit event, when the BIS receives the interlock from the vacuum. For each valve, the right sequence of all time-stamps is verified, as well as the valve travelling time, from opened to closed.

The test checks also if the corresponding alarms for Penning gauges, ion pumps, and sector valves are present in the LHC Alarm Service (LASER).

CONCLUSIONS

The vacuum measurement chains, alarms and interlocks must be reliable and are crucial to insure the good operation of the LHC. The effects of ionizing radiation and the issues with signal integrity must be understood and minimized, to improve the system reliability. Attention must be paid to the calibration, settings and tests of every measurement chain.

During the LS1, important actions have been performed in this direction: racks relocation against radiation effects; grounding and cabling modifications for signal integrity improvements; systematic test of each interlock and alarm, from front-end hardware to the SCADA. Additionally, some cabling and Database errors were found and corrected. The vacuum interlocks are part of the LHC machine protection; during machine checkout, they were fully verified up to the BIS.

CONTROLS AND INTERLOCKS FOR THE NEW ELETTRA SUPER CONDUCTING WIGGLER

L. Pivetta, F. Giacuzzo, G. Scalamera, D. Vittor,
Elettra Sincrotrone Trieste, Trieste, Italy

Abstract

During the last two years, triggered by the construction of the XRD2 beamline, and to comply with the topup operations, a complete refurbishment of the Elettra Super Conducting Wiggler (SCW) has been carried out. Alongside with the mechanical, cryogenic and electrical components, also the electronics, the control and interlock systems have been upgraded. The MVME5110 PowerPC single board computer, which is a standard in the Elettra control system, has been adopted, as well as RS232 communication modules, analog to digital converters and digital I/O lines. To cope with the high output power of the SCW, up to 18 KW, the interlock system, protecting both the wiggler and the beamline frontend, has been completely redesigned. The control system software has been rewritten from scratch using the TANGO software framework. The complete system has been tested during the second half of 2014 and is now fully operational.

INTRODUCTION

A 3.5 T superconducting wiggler, designed and built by the Budker Institute of Nuclear Physics (BINP), has been installed in the Elettra storage ring as a photon source for the X-ray diffraction beamline XRD2 in 2002 [1, 2]. Due to the lack of funding for the beamline construction, the SCW didn't come in operation in the subsequent years. Then, in 2011, a collaboration agreement between the Indian government and Elettra Sincrotrone Trieste provided the funds required for the beamline construction and the SCW refurbishment. During 2012 and the first months of 2013, at the BINP laboratory in Novosibirsk, the SCW has been provided with a new cryostat aimed at decreasing the helium consumption and increasing the reliability. Then, in July 2013, after successful site acceptance tests, the SCW has been installed in the Elettra storage ring [3]. A picture of the installed wiggler is shown in Fig. 1.

Simplifying, the main components of the SCW are the chassis, the cryostat, the liner and the superconducting coils; the principle of operation of the SCW consists in keeping the cryostat temperature near to the 4.5 K, using liquid helium, and feeding the superconducting coils with the appropriate currents in order to reach the desired magnetic field.

ELECTRONICS

The original Danfysik MPS883 power supplies, powering the central and the side superconducting coils, after being revised have been kept in operation, as well as the four existing Leybold Coolpack 6000 compressors, provided with new Coolpower cooling heads. A new junction

Figure 1: The refurbished super conducting wiggler installed in the Elettra storage ring.

box, shown in Fig. 2, has been designed by BINP to replace both the old cabled box and the VME-based signal conditioning and acquisition board. The new junction box, based on an Atmel ATmega128 microprocessor, acquires the signals coming from the temperature and pressure sensors installed into the cryostat and implements the quench interlock logics. If a quench occurs the junction box turns off the power supplies that feed the superconducting coils driving their external interlock input. A RS232 serial line is available for remote control and supervision.

Figure 2: The new Junction Box.

Ion pumps, powered by the DUAL high voltage power supplies manufactured by Varian, are also installed to provide the requested vacuum levels. A pirani vacuum gauge allows to monitor the pressure in the vessel insulation, whilst some penning gauges are used in the front-end vacuum chamber; they are all powered with two TPG300 power supplies.

CONTROLS

In conjunction with the refurbishment of the cryostat the SCW control system has also been updated. The legacy control system, based on a VME crate and a Motorola 68K microprocessor single board computer running VxWorks, provided by BINP as a turnkey system, has been dismantled. Also, the ELTEC BAB40 single board computer, run-

ning Microware OS-9, which acted as gateway to the legacy RPC based control system has been removed.

Hardware

A new dedicated front-end computer, based on the Artesyn MVME5110 VME single board computer, which is a standard for the Elettra control system, has been installed in a VME64x crate. A number of RS232 serial lines are requested to interface the two Danfysik MPS883 power supplies, the four compressors, the junction box and the vacuum power supplies. Two TIP866 industry pack mezzanine cards, each providing 8 RS232 serial lines, are installed on a TVME220 VME carrier board. An in-house developed signal conditioning board, compliant to the VME64x rear I/O board specification, provides the opto-insulation on the serial lines. To acquire some additional analog signals, such as the current monitor of the MPS883, a TIP501 ADC industry pack mezzanine card is used. Also, a new peripheral of the machine interlock system has been installed to interface signals mandatory for the machine protection.

Software

All the control software has been moved to the TANGO Controls framework [4]. More in detail, one TANGO device server for each family of devices to be interfaced has been developed:

- Danfysik MPS883 power supplies;
- Leybold Coolpack 6000 compressors powering cryo-cooler models 4.2 GM and 10 MD;
- junction box.

The TANGO device servers for the DUAL and TPG300 high voltage power supplies of the FERMI vacuum subsystem have been reused.

In charge of the overall SCW supervision, one more TANGO device server, that interacts with the junction box device server and the power supply device servers, has been developed. Dedicated additional threads are in charge of:

- ramp the magnetic field;
- monitor the junction box status and:
 - ramp the SCW magnetic field to zero in case of helium level warning or temperature warning;
 - stop any magnetic field ramp whenever a quench, or other alarm, are detected;
- monitor the power supplies and compute the actual magnetic field from the currents; this thread is also in charge of pushing the reading events to the clients.

In order to follow a precise trajectory, a look-up table is used to compute the power supplies currents corresponding to the requested magnetic field, using linear interpolation. The look-up table also specifies the speed of the current ramps, in A/s, for a number of predefined magnetic field ranges: different intensities require different speeds. The power supply currents versus the magnetic field are plotted in Fig. 3.

Moreover, even when ramping up or down the field different speeds have to be used. The thread driving the ramps also checks that the actual magnetic field value moves along

Figure 3: Side coil [blue] and central coil [red] power supplies currents versus magnetic field.

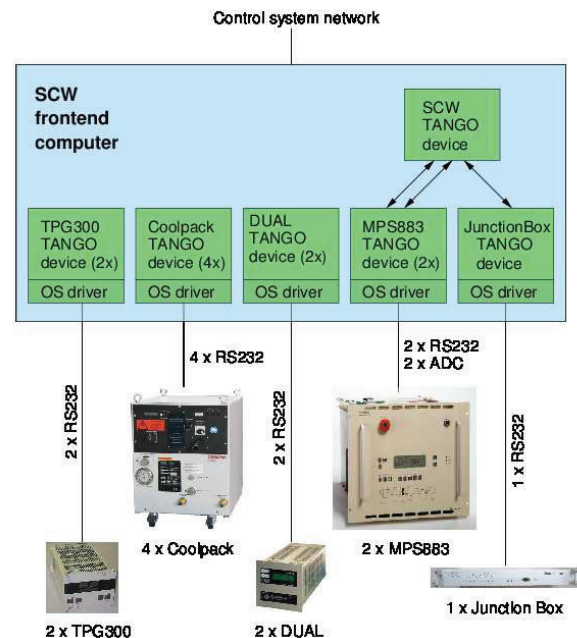

Figure 4: TANGO device servers layout on SCW front-end computer.

the predefined trajectory; if the tolerance is exceeded the current ramps are stopped and a new one started to move to an allowed value on the calibrated trajectory, following the shortest path.

The status of the MPS883 power supplies is also monitored and, should a fault occur, the magnetic field ramp

stopped. The structure of the control software deployed on the SCW front-end computer is shown in Fig. 4.

All the relevant parameters of the SCW are continuously monitored and stored into the historical database of the accelerator, using the HDB++ archiving system, on both variation and periodic basis. A large number of values are stored during the magnetic field ramps, in fact at each setting of the power supplies currents; when the wiggler is not ramping just a few values are stored on a periodic basis.

Graphical User Interface

A graphical user interface, to be used by the control room operators and the insertion devices specialists, has been developed with Qtango and the Qt graphics library. All the parameters and the readings, such as temperatures, power supplies status and currents, helium level, junction box and compressors status and, last but not least, wiggler magnetic field are shown over a synoptic image of the SCW. In addition the pressure levels and the temperatures of the front-end are also displayed. Moreover, the operator can input the desired magnetic field value and start the ramp. A screenshot of the current SCW GUI is shown in Fig. 5.

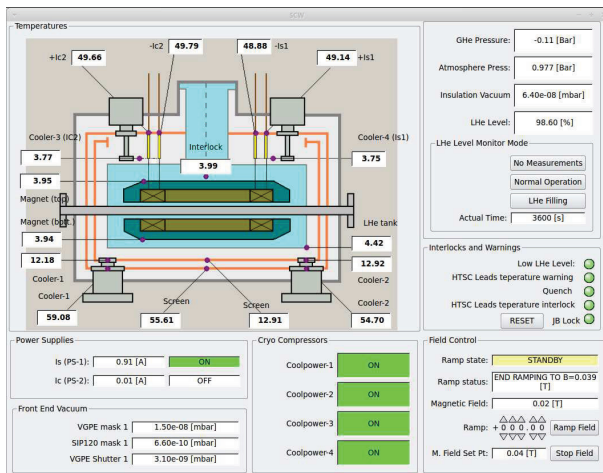

Figure 5: The SCW graphical user interface.

INTERLOCKS

The high output power of the 3.5 T superconducting wiggler introduced a novel issue on the accelerator light exit as well as the beamline front-end.

The machine protection interlock system of the Elettra storage ring is based on Siemens S7 programmable logic controllers (PLC). The interlock PLC, though operating independently, is connected to the control system via Ethernet and a dedicated TANGO device server provides all the process variables to the supervisory system, which is also based on TANGO.

A vacuum valve, protected by a beam shutter, usually separates the Elettra storage ring vacuum chamber from the beamline front-end vacuum. In case of increasing pressure on the beamline, the interlock PLC, in protection of the storage ring vacuum, closes the valve and, to protect the valve

from the beam, the corresponding shutter. However, the standard beam shutter used at Elettra can not cope with the full SCW power. On the other hand, a 18 KW capable shutter is large and expensive, and an additional one is required for the beamline photon shutter. Therefore, the decision has been taken to install a new photon shutter, capable of holding 18 KW photon beam power and to implement a mechanism to protect the existing exit valve/shutter. Consequently, the storage ring interlock system for the XRD2 beamline has been completely redesigned to include the vacuum, the valve/shutter and the front-end protection. A new peripheral of the interlock system, connected via PROFIBUS to the nearest S7 CPU, acquires the SCW power supply currents by means of two dedicated DCCT converters, as well as a number of thermocouples, flowmeters and vacuum gauges, installed on the front-end. To define the operating status of the wiggler two thresholds have been introduced:

- beam shutter protection threshold;
- fast orbit interlock threshold.

The first one, usually set at 1.0 T, enables the interlock protection of the beam shutter/vacuum valve: if the valve is closed, hence the shutter, and the SCW magnetic field is higher than the threshold the electron beam is dumped. The second, usually set at 0.42 T, tells the fast orbit interlock system that the SCW is operating and the tolerance on permissible orbit distortion has to be lowered.

A large displacement of the superconducting coils power supplies currents from the reference trajectory values, possibly due to control software or hardware failure, can lead to heavy orbit distortion and, considered the big output power, to the damage of the vacuum chamber. The PLC monitors the actual power supply currents by means of two DCCTs; the values are compared to the theoretic values, computed from the current magnetic field by a reverse calculation, and, if the tolerance is exceeded, the electron beam is dumped.

The status of all the interlocks related to the SCW operation is summarized on a dedicated GUI, shown in Fig. 6.

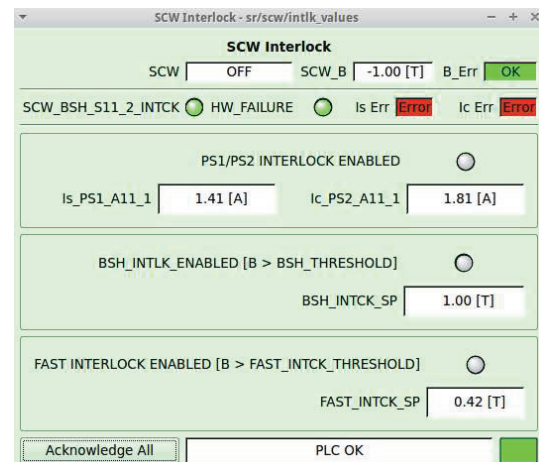

Figure 6: The SCW interlock GUI.

Thermocouples, flow meters and vacuum gauges installed on the front-end are also monitored and the appropriate interlock logics implemented. Currently, in case of low flow the electron beam is immediately dumped. Conversely, a two step mechanism is in place for the front-end temperatures and pressures. First, some alarms have been set up in the TANGO alarm system to alert the operator of possible problems with the temperatures or the vacuum. In case of increasing front-end temperatures, for instance, the operator can ramp down the SCW magnetic field decreasing the output power. Should the operator miss the action, the second step belongs to the interlock PLC that dumps the electron beam.

CONCLUSION

The control system for the new SCW is in operation since autumn 2014. Also the interlock system, updated in two

steps, is now fully operational. A number of alarms are already in place to help the machine operator to supervise and operate the SCW at the best condition and, because of the need of electron beam dump in plight, to prevent possible issues.

CONTROLS INTERFACE INTO THE LOW-LEVEL RF SYSTEM IN THE ARIEL e-LINAC AT TRIUMF

J.J. Pon, K. Ezawa, R. Keitel, R.B. Nussbaumer, J.E. Richards, M.A. Rowe, P.J. Yogendran
TRIUMF, Vancouver, BC, Canada

Abstract

Phase I of TRIUMF Advanced Rare Isotope Laboratory (ARIEL) was completed in September 2014. At phase I, the Low-Level RF (LLRF) system of ARIEL's electron linear accelerator (e-Linac) consists of a buncher and a deflector, one single-cavity injector cryomodule and the first cavity of two dual-cavity accelerating cryomodules. The model for the e-Linac LLRF system is largely based on the experience gained from the fully-commissioned TRIUMF ISAC-II linear accelerator (linac). Similarly, the EPICS-based Controls for the e-Linac LLRF builds on the lessons learned with the linac LLRF Controls. This paper describes the interface between the ARIEL Control System (ACS) and the e-Linac LLRF using EPICS ASYN/StreamDevice and a SCPI-like protocol. Also discussed are the ACS EDM displays and future plans for LLRF Controls.

INTRODUCTION

The Advanced Rare Isotope Laboratory (ARIEL) is the latest project in the Rare Isotope Beam (RIB) program at TRIUMF. In conjunction with ISAC and ISAC-II, ARIEL is designed to triple RIB production and expand the range of exotic isotopes “for Nuclear Physics and Astrophysics, Nuclear Medicine and Materials Science” [1].

In September 2014, phase I of ARIEL was completed with the delivery of a 300KeV DC thermionic gun, a buncher and a deflector, a single-cavity injector cryomodule (ICM), and the first cavity of a dual-cavity accelerating cryomodule (ACM). These components constitute the first half of ARIEL's superconducting electron linear accelerator (e-Linac). The second half of the e-Linac is presently under way and comprises the second cavity of the first ACM, and a second dual-cavity ACM, for a total of five cavities in three superconducting cryomodules.

The design of the Low-Level RF (LLRF) system for ARIEL's e-Linac borrowed extensively from the model used in ISAC-II superconducting linear accelerator (linac) [2] – TRIUMF's first fully-commissioned linac. It was natural then, that the new ARIEL Control System (ACS) interface into the e-Linac LLRF also followed the model used in ISAC-II linac Controls. However, as in any new project, LLRF Controls of ARIEL's e-Linac presented an opportunity to improve on some of the unexpected drawbacks encountered in ISAC-II Controls.

INTERFACE

LLRF-ACS Interface

The overall framework used in ISAC-II LLRF Controls has been carried over into the LLRF-ACS interface. At one end, the LLRF system exchanges information with Controls via an EPICS IOC. At the other end, the IOC makes LLRF data available to EPICS clients in the form of process variables (PV). While this model has worked well at TRIUMF, the way it was implemented in ISAC-II LLRF Controls uncovered some drawbacks that were addressed in the LLRF-ACS interface.

In ISAC-II, the LLRF system interfaced with the Controls EPICS IOC using a shared memory model [3]. The implementation of this method brought in a number of firm constraints. First, inter-process communication via shared memory implies a high degree of coupling. The LLRF system and ISAC-II Controls had to adhere to a strict memory mapping scheme, was not very portable, and carried a moderate amount of complexity to maintain.

Another implication on the use of shared memory is that the IOC needs to run in the same LLRF system computer. The host machine is owned and maintained by the LLRF group. For simplicity and security reasons, LLRF computers are stand-alone machines and are not connected to the site's network. If Controls wanted to perform diagnosis or maintenance of the IOC it was necessary to inconvenience the LLRF group for physical access to the host computer. Even simple actions like viewing IOC log messages or machine crash dumps required local access to the machine.

Furthermore, the IOC had to be built to run on Microsoft Windows. But Controls have had limited experience developing for the Windows environment. Only one Controls programmer gained enough knowledge to build a heavily-customized Windows IOC based on the EPICS Portable Channel Access Server framework and make available to LLRF engineers a C++ API to read/write the shared memory. Plus, the programming was done in Visual Studio and involved the use of WIN32 DLLs [4], these development tools were also unfamiliar to Controls.

During the early stages of ARIEL phase I an alternative implementation for the LLRF-ACS interface was put forward. After some consultation with the relevant groups one of the main conclusions was to not proceed with the shared memory model. Instead, the ACS would use the EPICS ASYN/StreamDevice method of communication with LLRF. The Controls group is familiar with

ASYN/StreamDevice. It has been used in previous occasions to interface with various kinds of peripheral equipment at TRIUMF so the knowledge and experience is well spread among Controls personnel.

In addition, the decision to not use shared memory gave Controls more freedom to choose where to run the EPICS IOC. Whereas in ISAC-II the Controls IOC was required to be hosted in the LLRF system computer, in ARIEL the IOC moved into a computer in the ACS domain. This setup gives Controls personnel freer access, without unnecessary inconvenience to LLRF staff, to peruse the logs and system messages for diagnosis, maintenance, and updates. Not to mention that there is a clearer separation of responsibilities. For example, in ISAC-II, the LLRF group was responsible for updating the Controls IOC database. Not so in ARIEL where the IOC database is out of the hands of LLRF and into ACS.

Another benefit of hosting on an ACS computer is that the EPICS IOC runs on a Linux machine. Controls have ample expertise on Linux - the standard operating system in the group [5]. And Controls is also very familiar with building, maintaining, and debugging EPICS IOCs on Linux. The additional knowledge in Windows shared memory, Visual Studio, or WIN32 DLLs is no longer required.

For its part, the ARIEL LLRF group committed to building a server application to respond to commands and queries from the ACS over a network connection. To preserve the security of LLRF computers, the ACS connection is done over a private network, shielded from the outside world. The LLRF system and ACS agreed to follow the guidelines for Standard Commands for Programmable Instruments (SCPI) for the structure of commands and queries [6]. However, our model does not fully adhere to the complete SCPI (pronounced “skippy”) specification. The intention was not to degrade the standard but to make it as simple as possible to meet our needs at the time. For example, the SCPI specification for command concatenation was deemed unnecessary and thus, not implemented. Similarly, command abbreviation was also not implemented. The set of allowed SCPI-like commands and queries was documented in a table on an internal TRIUMF web page [7] to facilitate separate implementations in both groups. Figure 1 shows the various protocols used and the separation of responsibilities in the model for the LLRF-ACS interface.

Figure 1: LLRF-ACS Interface.

Controls GUI

The ACS graphical displays did not see any major changes from those used in ISAC-I and ISAC-II Controls. In fact, the idea was to borrow or re-use as much as possible from earlier projects [5]. Development of the displays was done using the EPICS Extensible Display Manager (EDM). Colour schemes, size of objects, fonts, etc. followed the same established site guidelines. To preserve the same look-and-feel of ISAC-I and ISAC-II displays the placement of buttons, sliders, labels, etc. was also emulated in the ACS. Figure 2 shows a screenshot of the display for the e-Linac ICM LLRF Controls. Figure 3 shows the expert display, which is used mainly by the LLRF group for more detailed diagnostics.

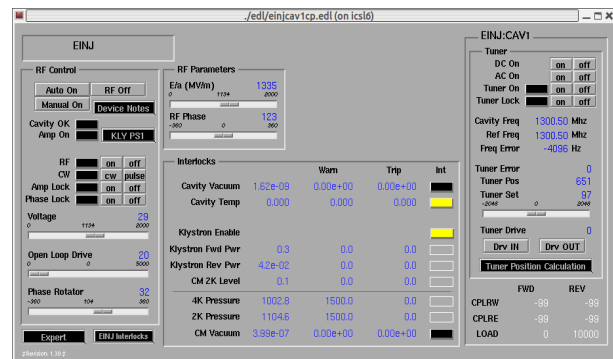

Figure 2: ACS Display of the ICM LLRF.

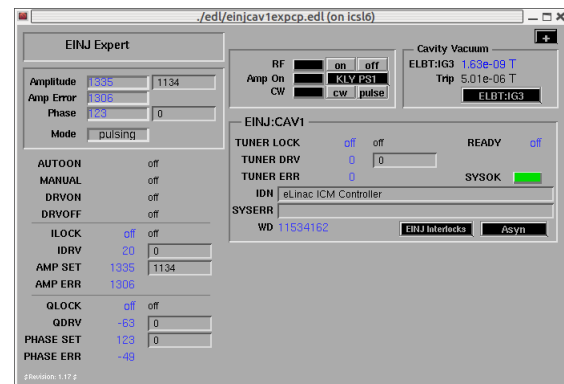

Figure 3: ACS Expert Display of the ICM LLRF.

One notable feature is the addition of a delay on fast, successive commands. In ISAC-II, there were cases when operating on an EDM slider object made the LLRF system unresponsive to remote commands and only a reboot of the LLRF computer would fix it. So far, this issue has not been resolved but we speculate that the fast storm of setpoint commands from the slider overwhelmed the LLRF system and sent it into a funny state. In the ACS, the IOC communicates changes in setpoint values to the LLRF SCPI server at 500ms intervals. Changes in setpoints in between this period are discarded. In other words, the IOC throttles the number of commands to

change setpoints to avoid overwhelming the SCPI server. Granted, this feature is implemented at the IOC level but it directly addresses a potential issue with the setpoint objects of the ACS displays.

FUTURE PLANS

After the implementation of the LLRF-ACS interface was completed in ARIEL phase I, the Operations group anticipated that the improvements would be backfitted to earlier projects. As of this writing, a retrofit of ISAC-II LLRF Controls is being commissioned. The changes have been transparent to Operations because the bulk of the modifications is at the IOC-LLRF interface level, whereas EPICS displays remain largely unchanged. It is hoped that issues like the slider control problem will not re-appear. There are also plans to apply these improvements to ISAC-I LLRF Controls.

It is also worth noting that the shared memory model was applied, to a minor degree, in specific sub-systems in the Laser Control System and Beam Diagnostics System [3]. There are plans to retrofit these sub-systems too but due to constraints in time and resources this may not occur in the immediate future.

SUMMARY

The model for ARIEL's LLRF-ACS interface is heavily based on the design of ISAC-II LLRF Controls. Although the overall framework is maintained, there are notable improvements from an implementation point of view. The decision to replace the shared memory model with ASYN/StreamDevice interface reduced the number of restrictive implementation constraints and allowed for a clearer division of responsibilities. As for the ACS GUI displays, the same guidelines and same look-and-feel of earlier projects were closely followed. ISAC-II operators would be hard pressed to notice much difference in the ACS displays from what they are used to seeing.

In conclusion, the improvements to the LLRF-ACS interface described in this paper have been well received and so far there are no major issues to contend. In fact, there are plans to apply these changes to existing

Controls-related projects where the shared memory model is still in use.

ACKNOWLEDGEMENT

The authors would like to acknowledge the contribution of time and expertise from the SRF/RF group: Ken Fong, Mike Lavery for unraveling the requirements for LLRF Controls. Philipp Kolb, Zhongyuan Yao, Qiwen Zheng for spending endless hours testing the Controls interface.

Also, many thanks to all members of the Controls group for their support and guidance. In particular, Shawn Rapaz for helping setup the Controls hardware and Evgeniy Tikhomolov for sharing his experience of ISAC-II LLRF Controls development.

LABVIEW AS A NEW SUPERVISION SOLUTION FOR INDUSTRIAL CONTROL SYSTEMS

O.O Andreassen, F. Augrandjean, E. Blanco Vinuela, D. Abalo Miron, M. F. Gomez De La Cruz, A. Rijllart, CERN, Geneva, Switzerland

Abstract

To shorten the development time of industrial control applications, CERN has developed the Unified Industrial Control System (UNICOS) framework, which standardizes the programming of the front-ends and the configuration of the Supervisory Control and Data Acquisition (SCADA) layer. At CERN the SCADA system of choice is WinCC OA, but for some specific projects (small or initial prototypes not connected to accelerator operation or not located at CERN) a more customisable supervision using LabVIEW is an attractive alternative. Therefore, a system called UNICOS in LabVIEW (UiL), has been implemented. It provides a set of highly customisable re-usable components, devices and utilities. Because LabVIEW uses different programming methods than WinCC OA, the tools for automatic instantiation of devices on the supervision layer had to be re-developed, but the configuration files of the devices can be reused. This paper reports how the implementation was done, it describes the first project implemented in UiL and an outlook to other possible applications.

INTRODUCTION

The CERN Unified Industrial Control System (UNICOS) project proposes a standardized architecture for both, supervision and control layers. It also defines a set of tools for automatic instantiation of devices, in the two mentioned layers, employing re-usable components, devices and utilities.

However, for smaller lab-size solutions e.g. systems which are only expected to exist for a short time or when users do not have the time and resources to invest in a complete SCADA as WinCC Open Architecture (WinCC OA), a LabVIEW based solution would fill this gap [1][2].

UNICOS in LabVIEW (UiL) gives the user much of the same look & feel and functionality of WinCC OA as Human Machine Interface (HMI).

UiL generates automatically the supervision objects from the same configuration file provided by UNICOS Application Builder (UAB), which was developed to generate the code and configuration files of the different components of the UNICOS project (e.g. WinCC OA, Siemens PLCs etc.) [3][4]. These objects are the counterpart instances of the control objects deployed in the PLCs in the control layer.

Once the objects are instantiated in the UiL application, they can be used in the application synoptic by means of widgets, a reduced but still meaningful vision of its status, and faceplates, a full view of the object status and the

place where the operator will interact with the control system.

In addition to the widgets and faceplates, UiL provides a trending tool, an alarm and an event list. All the components, widgets and user interaction in UiL are designed to resemble the UNICOS look and feel as much as possible; making sure that the transition from one SCADA tool to the other is effortless.

UNICOS

UNICOS was initially developed in 1998 as a need to develop the LHC cryogenics control system, but became a CERN de facto standard for industrial control systems. As shown in the figure 1, the framework connects, instantiates and interacts with both the supervision and control layers with commercial industrial components [1][5].

Figure 1: UNICOS architecture.

Currently UNICOS uses WinCC OA as a commercial SCADA system and both Siemens, Schneider, as Programmable Logic Controllers (PLC) [1][6]. A third possibility using Codesys extends the usage to industrial computers (IPC)

The possibilities and the application of the UNICOS framework extend to monitoring and supervision applications (e.g. Magnets alignment, Collimators, Quench protection systems...) where the control layer could be not based on UNICOS.

The UNICOS framework is based on an object oriented concept consisting of standard object classes featuring process control objects, controllers, valves, pumps, heaters, inputs, outputs etc. It also establishes how these objects interact and formalizes the control unit definition together with the way the specific control logic is implemented.

UNICOS IN LABVIEW

Although deploying a UNICOS/WinCC OA SCADA solution is easier than starting from scratch with WinCC OA, for some applications this solution can still be too difficult, and/or too costly in terms of needed expertise knowledge. In some cases, the developers lack the time, knowledge, manpower and/or resources to invest in a complete SCADA as WinCC OA. Many times the developers are already familiar with LabVIEW as well. These are the basic justifications for the UNICOS in LabVIEW (UiL) project [1][7].

The objective of the UiL project is to offer a simple and affordable solution including most of the core functionality and tools found in UNICOS. The combination of a simplified UNICOS functionality and LabVIEW's graphical programming interface, makes it more suited for lab-size and prototype applications with a substantial reduction on engineering costs (Figure 2). In addition, the site-licensing scheme adopted at CERN for LabVIEW reduces the cost of ownership for smaller SCADA systems.

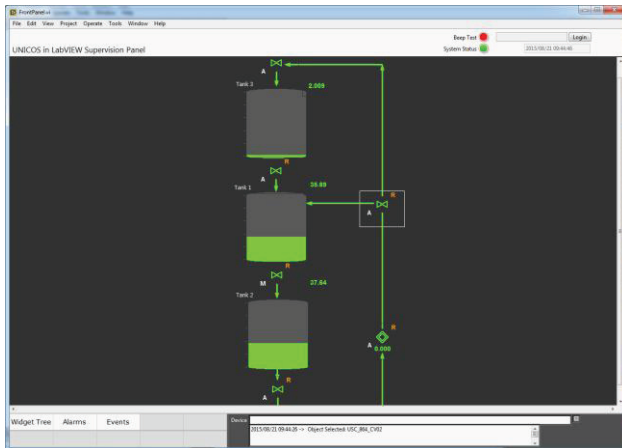

Figure 2: UiL example application

Architecture and Components

UiL is implemented using several commercial off-the-shelf components as LabVIEW, LabVIEW Datalogging and Supervisory Control Module (DSC) and a third party Python bindings application interface to MongoDB, an open-source document database designed to ease the development and scaling [8].

The general module architecture can be seen in Figure 3. The application revolves around a client, which subscribes, caches and re-serves data throughout the application using LabVIEW's internal notifiers and queues. The most recent updates are stored and broadcasted through an internal notifier, which can be read (by reference) in any sub module of the application. The larger data sets (arrays and vectors for trends and graphs) are stored in an internal queue, and indexed by object type identifiers.

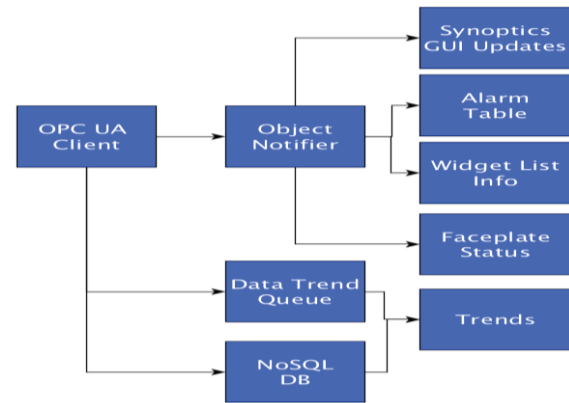

Figure 3: UiL modules.

Communication

The communication between UiL and the UNICOS based PLC's is based on OPC UA. OPC UA is a platform-independent, service-oriented architecture specification that allows the exchange of data in the industrial automation space [9]. The UNICOS based PLCs targeted are Siemens and Schneider. S7 and Modbus over Ethernet are used by those PLCs respectively. Moreover, they implement a CERN in-house protocol, the so-called Time Stamp Push Protocol (TSPP). This protocol is an event-based protocol; data is transmitted towards the supervision layer once it changes and it is sent together with the source time stamp [10].

A dedicated OPC UA server, encapsulating the TSPP protocol, has been developed at CERN. Having such server, any OPC UA client can connect to it and get the PLC data out, as it is the case of UiL, which includes an OPC UA client. This solution is very convenient as it simplifies the communication having only a single mechanism independent of the PLC (Figure 4).

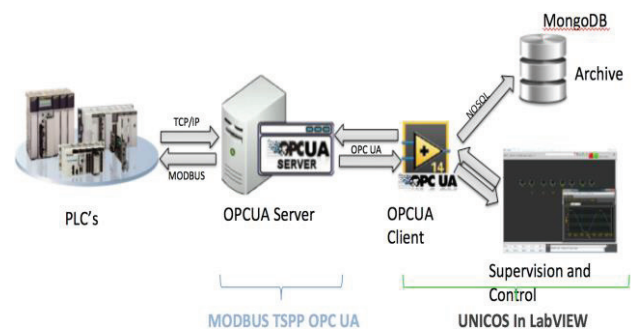

Figure 4: UiL communication.

Data Flow

Data in UiL is primarily stored and accessed through the use of internal LabVIEW notifiers. For trends, the data is queued, in order to accurately display all data from the PLC without losing data points in the graph. The

trends and events also access the NoSQL database for the viewing of historical data (Figure 4).

Archiving

UiL has the capability to archive all live data and settings. When the user selects this option in the UNICOS specification file for a particular device, the data is automatically cached and stored. UiL archives its data in MongoDB, a cross-platform document-oriented database. Classified as a NoSQL database. MongoDB eschews the traditional table-based relational database structure in favour of JSON-like documents with dynamic schemas, making the integration of data in applications such as UiL easier and faster [1][4]. The method used to archive data is class based and intended to support multiple sinks through class overrides in the future. This would make data retrieval possible directly from a WinCC OA archive, hence facilitating integration in between these to supervisors.

WORKFLOW AND DEVELOPMENT

The starting point for UiL configuration is the UAB generated configuration file [3][4]. This file contains the front-end, typically a PLC, parameters and the devices to instantiate. The user navigates to the file, selects a project name and location where to save the project (Figure 5). The IP address or hostname of the PLC is retrieved from the configuration file when the program runs after creation. The user can also manually set this if one wishes to connect to a simulated device.

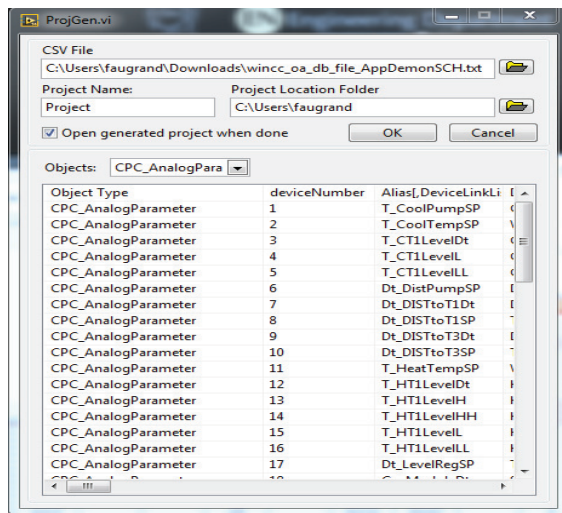

Figure 5: UiL Project generator.

Building the synoptic for a UiL application is drag and drop based. In the LabVIEW Project window, the 'Widgets' folder contains all object types as well as other graphical indicators and decorations. During the generation of the widgets, all items have been given a type identifier, which is used internally by the UiL's scripting engine. This facilitates all animations and user interactions with the widget.

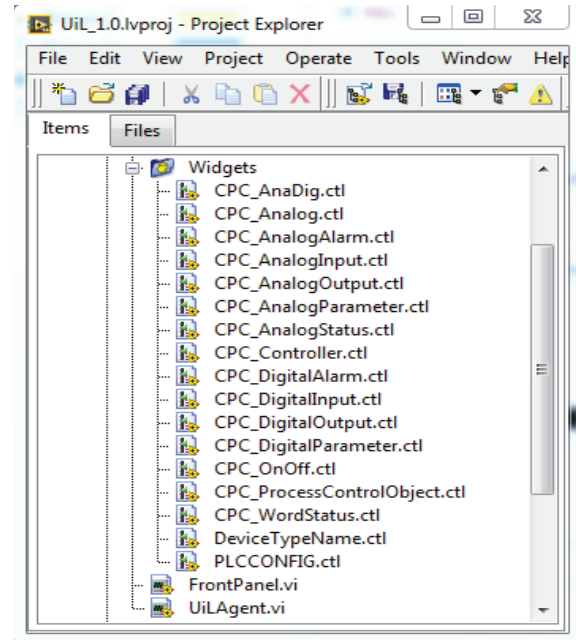

Figure 6: LabVIEW UiL project window.

To place specific devices into a synoptic, the user drag-and-drops a widget (Figure 6) onto the Front Panel which triggers a window where the user can select the object the widget must be linked to, choose an icon representation, and what device reference to connect to. Once configured, the widget is animated on the applications front panel.

VALIDATION

The UiL development has been initially tested in terms of connectivity with two OPC UA servers, interfacing with one PLC and one virtual device and up to three hundred channels. The test machine was a standard HP Compaq 8000 elite with 4Gb of RAM running Windows 7 64bit. The UiL LabVIEW instance was running in 32bit mode. The test bench had 200 active channels to the two servers and all the data was logged to its MongoDB archive. No significant increase in CPU (was at 30% when starting and stayed at 35% after the application ran) or Memory (used 200MB at start and had 350 Mb after 48H run) was noticed while running the test. The test provoked a random alarm every 30 minutes on random channels, and stored all the data while running. The update frequency was set to 1 point every half second, fixed.

The results in terms of animation were also very satisfactory having several dozens of devices in the same synoptic refreshing continuously. Interaction with the devices (via dedicated buttons) in the faceplates associated to the widgets was also smooth and efficient.

The current OPC UA implementation only communicates with one PLC, and some of the status indicators and alarms rely on live data from the OPC-UA server. This can cause confusion in case of communication loss by not having a proper diagnostic in the proposed architecture.

The current UiL release only supports a single database archive per application instance. This limits the cross application interaction although this will be addressed in next releases.

FUTURE PLANS

A consolidation phase is the first step to make the UiL a solid and deployable solution. Up to now all the concepts have been validated during the development and test phases. The plans include the development of a full palette of widgets and faceplates for the different sensors, actuators and control devices. The alarm and event managers will incorporate filtering capabilities and the diagnostics of the front-ends will be properly interpreted and shown to the user.

Support of multiple connections to PLCs will be added, but we still have to decide if this will be done at the OPC-UA server level or with the UiL client connecting to multiple servers.

Cross communication between different instances of UiL backends will be implemented in the next release.

CERN services will be included in future releases, these comprise the interface with LASER, the CERN central alarm system, the DB Logging, the CERN long term database and the CERN middleware (CMW) to exchange data from the UiL to a third party applications.

With the current class based data subscription model and in combination with the RADE framework, this could be done without much effort [7][11].

CONCLUSION

UiL has been successfully developed and is being used for prototypes at CERN. The combination of LabVIEW's intuitive drag and drop-based interaction, together with the similar look and feel of WinCC OA makes UiL a good choice for small to medium sized UNICOS applications as a cost effective supervisor. UNICOS is a widely used and supported standard for industrial control systems at CERN. Using UNICOS instead of a custom solution will benefit CERN users, as it will speed up development time and their support is ensured.

UiL has most of the core UNICOS features, such as the generator, widgets, faceplates, contextual buttons, the alarm and event list, the trend tool and panel navigation tools.

OPC UA has been chosen as the communication layer between LabVIEW and the PLCs. Our tests show that both the Siemens and Schneider PLCs communicate well using the OPC UA interface and scales well with UiL [2][5]. This is accomplished without needing to do any changes to the UiL OPC UA client.

Our performance tests show that UiL can handle several hundred widgets running simultaneously without any significant load to the CPU.

THE CONTROL SYSTEM FOR TRIM-COIL RELAY-SELECTORS IN J-PARC MR

K. C. Sato*, S. Igarashi, N. Kamikubota, N. Yamamoto,
J-PARC, KEK & JAEA, Ibaraki-ken, Japan

S. Yoshida, Kanto Information Service (KIS), Accelerator Group, Ibaraki, Japan

Abstract

In J-PARC main ring, each of the main magnets (Bending, Quadrupole and Sextupole) has a trim-coil. The primary aim of trim-coil is to correct small deviation of each magnetic field. In addition, we use them for other purposes such as: (1) In Beam-Based-Alignment studies, (2) as flux monitors, and (3) to make a short-circuit to reduce ripples of magnetic field. At a moment, each trim-coil can be used for only one purpose. We developed a relay-selector system which enables selection of connection to equipment depending on purpose. When we switch the connection, we have to change 1,200 on-site relays manually, distributed in three buildings. Thus, a control system for trim-coil relay-selectors have been developed in 2014-2015. EPICS tools and environment are used to develop the system. The system comprises PLC I/O modules with a controller running EPICS on Linux. Its operation begun in April, 2015. By using the system, we expect much easier switching of relay-selectors and reduce overheads than before.

INTRODUCTION

J-PARC (Japan Proton Accelerator Research Complex) is a high-intensity proton accelerator facility. It has been operated collaboratively by Japan Atomic Energy Agency (JAEA) and High Energy Accelerator Research Organization (KEK). It consists of three accelerators: a linear accelerator (LINAC), a Rapid Cycling Synchrotron (RCS), and a Main Ring (MR). MR started beam operation in 2008 [1]. MR is an accelerator with circumference of about 1570 meter. This paper aim to main magnets accelerator components.

There are 3 types in the MR main magnets: bending magnet (BM), quadrupole magnet (QM) and sextupole magnet (SM). The number of BM (QM, SM) is 96 (216, 72). They are arranged with a 3-fold symmetry in the MR tunnel. The main power supplies are installed in the MR power-supply buildings. As an example, the cabling layout of a typical family “QFN” is shown in figure 1. The power supply for QFN is located in the second power-supply building, and QFN magnets are wired clockwise. Each of these magnets has an independent trim-coil.

The trim-coil can be connected to four different equipment such as:

- “Harmonic” - to correct small deviation of each magnetic field.
- “BBA” - in Beam-Based-Alignment studies.

Figure 1: The layout of QFN power supply cabling.

- “Flux” - as magnetic flux monitors.
- “Short” - to make a short-circuit to reduce ripples of magnetic field [2].

In 2014-2015, we have developed the relay-selector system. Before the relay-selector system is installed, we have to switch connections between a trim-coil and a corresponding equipment by hands. All trim-coil connectors are placed in MR three power-supply buildings. So we need a lot of time to change connections. This relay-selectors system can reduce these overhead time since need not to switch the connection by hands.

By the way, the relay-selector system is applies to trim-coils of QM and SM. Since the BM trim-coils are used only for the “Short” purpose, it is independent from the system.

TRIM-COIL RELAY-SERECTORS SYSTEM

Each trim-coil need 4 relays. As shown in Figure 2 and 3, a relay-unit has 8 relays for 2 trim-coils. An aggregation-unit gathers cables from 8 relay-units. A control panel with buttons and fault indications is mounted in a rack. A relay-selector system, which consists of three rack, has 6 aggregation-units. Thus, a relay-selector system has to control 384 relays. J-PARC MR have three power-supply buildings, and each building has one relay-selector system. In total, this control system need to switch 1152 relays (equal to 288 trim-coils x4).

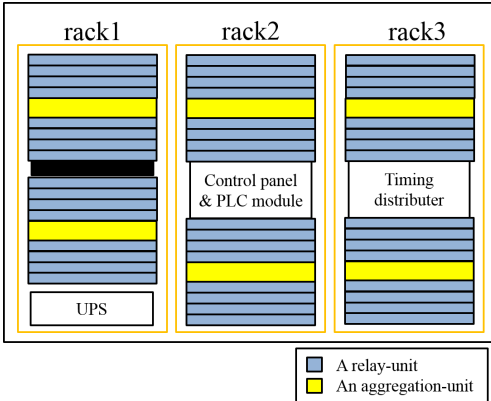

Figure 3: The layout of relay-selector.

EPICS PV CONFIGURATION

PLC Controller and I/O Modules

In J-PARC, we have been using an EPICS-based control system for the accelerator equipment [3] [4]. In J-PARC MR, a PLC-type CPU module running embedded Linux and PLC I/O modules (Yokogawa FA-M3 series) [5] [6] are standard for general I/O purposes. Relay-selectors are connected to PLC I/O via their aggregation-units. The buttons and fault indications of a panel are connected also to PLC I/O modules. Module cabling layout is shown in Figure 4.

Figure 4: The layout of PLC modules and cabling.

Design of EPICS PVs

Created PVs (Process Variables, a signal unit defined in EPICS) and numbers of them per one relay-selector system are shown in Table 1. The lower part of Table 1 concerns bit-oriented relay-output controls. Relationships of control PVs are shown in Figure 5.

Table 1: The Number of EPICS PVs of a Relay-Selector System

PVs	EPICS-type	number	explanation
Status	bi	5	system power, trigger
Interlock	bi	12	temperature, fan
Operation	bo	6	power and remote
Test switch	bo	7	test sw, trigger disable
Relay output	mbboDirect	24	see Figure 5
Extract	calc	96	see Figure 5
Set relay	seq	384	see Figure 5
Reset relay	seq	96	clear all

One “relay-output” PV, which is a 16-bit signal, contains 4 purpose of 4 trim-coils. The 4-bits are extracted as the “extract” PV, corresponds to one of four trim-coils. This PV shows the status of the selected purpose of the trim-coil. Before changing a trim-coil purpose, four relays are cleared by the “reset relay” PV. The reason is to avoid multi-bit-on status. Then, one of four relays, corresponds to the target purpose, are set by “set relay” PV.

GUI DEVELOPMENT

The total system, consists of three relay-selector systems, has 1152 relays. We have developed a top screen and four screens correspond to four purposes.

Figure 6 shows a top screen for total control. Using this screen, main power-switches are controllable. The status of remote-enable switches and fault indicators (temperature

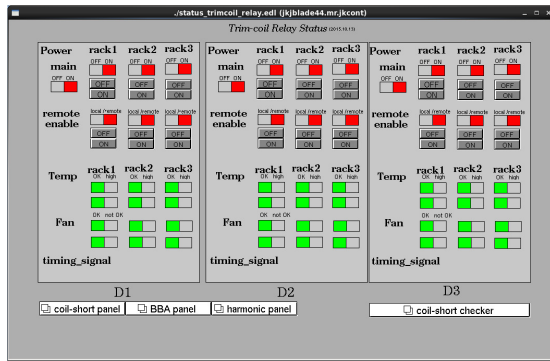

Figure 6: Top screen for the total control.

and fan) can be checked. Moreover, the screen has “open-new display” buttons.

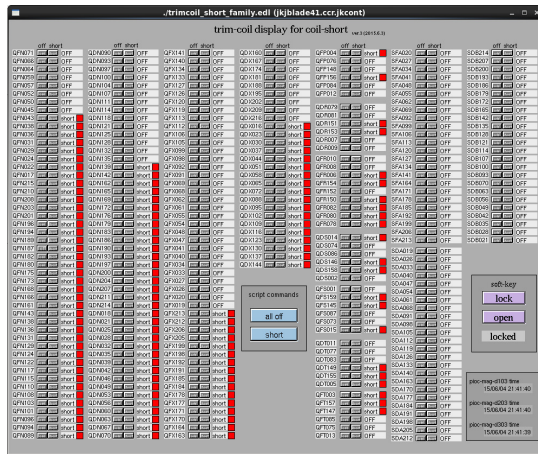

Figure 7: The control screen for switching to “short”.

In the following, two screens of four purposes are shown. Figure 7 is the “Short” screen. As the distance from the power supply increases, ripples of magnetic field also increase. Thus, the trim-coils far from the power-supply are often set “Short”. As shown in Figure 7, we can select any combination of “Short” trim-coils using this screen. The red indication in Figure 7 means that “Short” is selected.

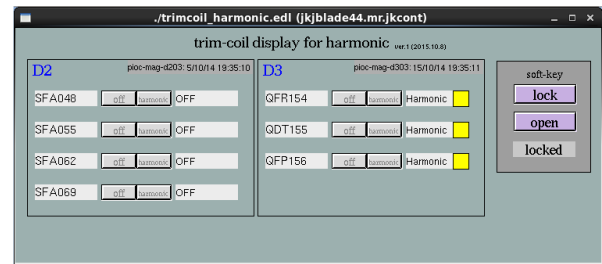

Figure 8: The control screen for switching to “harmonic”.

Figure 8 is the “Harmonic” screen. The “Harmonic” purpose needs only 7 trim-coils. Set and reset of each trim-coil is possible. The yellow indication in the Figure 8 means that “Harmonic” is selected.

CONCLUSION

The three setups of the control system for the trim-coil relay-selector were developed. Operation started in April 2015. By using the system, we reduce the overhead time to change relay connections considerably than before.

DESIGN AND DEVELOPMENT OF THE ECR ION SOURCE CONTROL SYSTEM

Hyungjoo Son, Sangil Lee, Chang Wook Son, Hyojae Jang, IBS, Daejeon, S.Korea

Abstract

The Rare Isotope Science Project at the Institute for Basic Science constructs a heavy ion accelerator (RAON) facility in South Korea. The stable ion beam for the RAON accelerator could be generated by ECR ion source system. Therefore, it is necessary to build an ECR ion source control system that could be integrated into an accelerator control system easily. The vacuum control system is divided several parts because of one vacuum chamber among three different voltage stages (ground, 50 kV, and 80 kV). In this report, we will present the preliminary design and implementation of vacuum control system for the ECR ion source. We plan to use a Programmable Logic Controller (PLC) in order to control the vacuum system through interlock logic program. The PLC system has two major components: a digital I/O module that provides power to each component and standard RS-232 modules to connect the gauge and pump controllers. In addition, we will discuss its extension plan to integrate the vacuum control system into the RAON accelerator control system based on the EPICS framework.

SYSTEM CONFIGURATION

The driver linac injector of the RAON consists of a 28-GHz superconducting Electron Cyclotron Radiation (ECR) ion source, the LEBT (low energy beam transport), the 500-keV/u RFQ (radio-frequency quadrupole) and the MEBT (medium energy beam transport). For the ECR ion source, superconducting magnets and dual high power RF sources of 28 GHz and 18 GHz are used to improve its performance [1]. The high voltage ion sources could get from two different high voltage platforms (50kV and 80kV). The Vacuum control system for the ECR ion source is consisted of Allen-Bradley PLC (AB PLC) modules. The AB PLC chassis consists of four chassis and are installed each of the electrical potentials racks. Each vacuum control devices are connected with AB PLC modules to control turbo pumps and to read pressure of the vacuum chamber. Vacuum gauge controller (XGS-600) is used to read pressure and to communicate with AB PLC through serial cable using RS232 protocol. Similarly, OSAKA turbo pump controller and LAYBOLD turbo pump controller are used to operate turbo pumps with AB PLC through serial cable. In order to construct the network system for connection among multi-voltage stages, we used remote IO modules 1756-AN2TR and 1734-AENTR of AB PLC. 1756-AN2TR and 1734-AENTR modules are used to connect each of two racks on ground state through LAN cable by MOXA switch. And 1783-ETAP2F modules has used to connect among one rack of ground state and two racks installed on high voltage stages (50 kV and 80 kV) directly through optical fibers because communication

failure occurred when LAN cable is used. The basic configuration of the control system is indicated by the network diagram shown in Fig. 1. Dashed lines are optical fibers and solid lines are LAN cables. Each chassis are installed at each platform as below Fig. 2. Internet Protocol (IP) address is assigned to two areas 192.168.1.* (area A) and 100.100.100.* (area B) according to voltage platforms level to reduce the risks from high voltage difference. The area 'A' is connected to total network of the test facility that included the ECR ion source facility. The area 'B' is local network that connects between remote IO modules of the AB PLC only. Because the IP address is not enough when configure the total network system of the test facility. The control system performs the interlocks for the vacuum system of the ECR ion source. And this system will be integrated with the Experimental Physics and Industrial Control System (EPICS) to operate the system record the parameter values by EPICS Input Output Controller (IOC) using "process variables" in real-time.

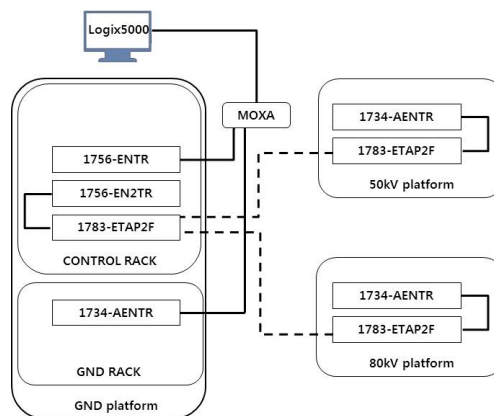

Figure 1: Diagram of network system for ECR ion source control system. 1783-ETAP2F modules for optical communication are used to connect between the high voltage platform and the control module that installed on ground platform.

VACUUM CONTROL SYSTEM

Vacuum control system of the ECR ion source consists of several turbo molecular pumps and controllers. They are installed at each voltage platforms. TC 353 turbo pump controller is installed at the ground platform and TC 2403 is installed at the 50kV platform. Both are made by OSAKA vacuum. TD 20 manufactured by LAYBOLD vacuum company is installed at 80kV platform. Each controller communicates with serial communication module (1734-232ASC) of AB PLC through serial cable. An AB PLC CPU 1756-L71 is used to control entire system of the ECR ion source and is installed at ground platform control rack of area 'A'

Figure 2: Installed chassis on each platform to configure the vacuum interlock system of the ECR ion source.

Figure 3: Preliminary test setup for confirming the network and I/O wiring. Left dashed box in figure is area ‘A’, Right solid box is area ‘B’.

(Fig. 3). As can be seen from the Fig. 3, four slots of the control rack are emptied to install MODBUS communication module to integrate on the EPICS framework after local control test. We performed communication test among the AB PLC and the OSAKA turbo pump controller (TC353) as non-handshake method, the vacuum gauge controller (XGS600). TC353 comes with local and remote capabilities but we can't select these modes at the same time during the serial communication mode. TC353 and XGS600 are coupled with each other to control the vacuum system. We used Logix5000 software to send the command message and to receive the return message with each controller through RS-232 protocol. We completed communication test successfully to

set each value of the parameters and to operate vacuum device. The electric wiring with vacuum components for IO control is proceeding after communication test. Presently, PLC modules are installed at each rack as shown in Table 1. The ladder logic programming for sequence control of the PLC is developed with Logix5000 software using Window based PC. The RSLinx software is used for setting network environment of the AB PLC. The ladder logic program will be designed independently to protect vacuum devices of the ECR ion source. The interlock program designed by PLC could perform protection for the vacuum system even when upper control system is shut down as system fail.

We configured demo vacuum control system like the vacuum system of the ECR ion source to test serial communication for turbo pump controller and vacuum gauge controller as Fig. 4. Because ECR experiment group are performing test for developing the ECR ion source manually. We performed communication test among AB PLC and the OSAKA turbo pump controller (TC353) as non-handshake method, the vacuum gauge controller (XGS600). TC353 comes with local and remote capabilities but we can't select these modes at the same time during the serial communication mode. TC353 and XGS600 are coupled with each other to control the vacuum system. We used Logix5000 software to send the command message and to receive the return message with each controller through RS-232 protocol. We completed communication test successfully to set each value of the parameters and to operate vacuum device.

Figure 4: Demo vacuum control system with turbo pump and several vacuum gauges.

SUMMARY

We completed control test to operate vacuum pump and gauges through demo vacuum control system for the ECR ion source vacuum control. We will modify the vacuum control system of the ECR ion source to operate the system automatically through hard wiring between devices and PLC modules that are operated currently manually.

The system will be integrated with EPICS framework through Modbus TCP/IP module or Ether-IP module of the AB PLC. We are developing the EPICS IOC to control the vacuum system in real-time using EPICS drivers. The User Interface (UI) for monitoring and operating the system will be developed by the Control System Studio (CSS) software to provide easy control environment for the users. The vacuum control system of the ECR ion source is finally designed by the ladder logic program to perform the interlock checks continuously without data from the EPICS IOC so that the PLC can perform its protection functions even when the IOC is shut down [2].

ACKNOWLEDGMENT

This work is supported by the Rare Isotope Science Project funded by Ministry of Science, ICT and Future Planning(MISP) and National Research Foundation(NRF) of Korea(Project No. 2011-0032011).

CAN OVER ETHERNET GATEWAYS - A CONVENIENT AND FLEXIBLE SOLUTION TO ACCESS LOW LEVEL CONTROL DEVICES

G.Thomas, D.Davids, CERN, Geneva, Switzerland
O.Holme, ETH Zurich, Switzerland

Abstract

CAN bus is a recommended fieldbus at CERN. It is widely used in the control systems of the experiments to control and monitor large amounts of equipment (IO devices, front-end electronics, power supplies). CAN nodes are distributed over buses that are interfaced to the computers via PCI or USB CAN interfaces. These interfaces limit the possible evolution of the Detector Control Systems (DCS). For instance, PCI cards are not compatible with all computer hardware and new requirements for virtualization and redundancy require dynamic reallocation of CAN bus interfaces to different computers. Additionally, these interfaces cannot be installed at a different location than the front-end computers. Ethernet based CAN interfaces resolve these issues, providing network access to the field buses. The Ethernet-CAN gateways from Analytica (GmbH) were evaluated to determine if they meet the hardware and software specifications of CERN. This paper presents the evaluation methodology and results as well as highlighting the benefits of using such gateways in experiment production environments. Preliminary experience with the Analytica interfaces in the DCS of the CMS experiment is presented.

INTRODUCTION

The control systems of CERN require the monitoring and control of a wide range of front-end equipment, much of which is installed in technically challenging locations with exposure to ionising radiation, strong magnetic fields and significant sources of electrical noise. A range of fieldbuses, including CAN bus [1], have been evaluated and selected by CERN to enable robust communication with the front-end hardware, leading to their widespread adoption in the LHC accelerator and experiments. As the readout computers and corresponding bus interfaces must be located outside of the hostile environment, the field buses are often more than 100 metres in length.

In the case of CAN bus, the communication on the bus is commonly driven by an OPC Data Access (OPC DA) server that runs on a computer and exposes the monitored hardware process variables and commands via the standard OPC interface protocol. The OPC server enables any OPC compliant client to connect and access the front-end data, independently of the details of the low level protocol used on the CAN bus for each type of hardware. A standard CERN solution for building the supervisory control system layer is to use the commercial SIMATIC WinCC Open Architecture (WinCC OA) [2] control system toolkit which natively supports OPC communication.

CURRENT STATUS AND LIMITATIONS

At the time of the construction of the LHC accelerator and experiment control systems, the connection between the control system computers and CAN buses was typically provided by internal PCI or PCIe cards or standalone USB connected interfaces. These CAN readout systems worked reliably throughout the first running period of LHC.

Changes in the computers running the control system software have been a significant motivating factor to re-evaluate the choice of CAN interface. For instance, the use of blade servers offers opportunities to minimize the rack space used by control system computers. The most compact blade servers do not provide the possibility to add PCIe expansion cards and therefore the PCIe-CAN interfaces are no longer a viable option in this context.

Due to the ubiquity of USB interfaces on modern computer hardware, the USB-CAN interfaces continue to provide a method of connecting CAN buses to any server. However, the limitation of maximum USB cabling length means that the computer and USB-CAN interface are typically installed either in the same rack or closely neighbouring racks. So with both PCIe and USB interfaces, the server and CAN bus interface must be co-located requiring that the control software servers are installed in or near to the racks where the CAN buses currently terminate. This imposes strong limitations on the possible re-organisation of rack hardware. With the current USB or PCIe interfaces, any significant change of server location would involve the costly installation of new CAN cabling.

Furthermore, there is increased interest in the use of redundancy at the control server level and the use of server virtualisation. Using the redundancy mechanism offered by WinCC OA, each control application runs on two computers. For robustness against power failures and network issues, it is beneficial to locate the two servers in different physical locations. As both computers need to access the front-end hardware, each server must be able to connect to the CAN bus interface, which makes it impossible to rely on the existing PCIe CAN or USB CAN devices used previously. Likewise, in the case of server virtualisation, the physical location of the server that runs the control software is not necessarily known in advance so it is essential to have a CAN interface which can be contacted from any location, independently of the distance between the server and interface hardware.

Offering network access to the CAN interface by Ethernet delivers a solution to these issues. This concept was demonstrated at CERN in the TOTEM and CMS experiments by coupling existing USB-CAN interfaces to Ethernet connected USB hubs. Using this approach the

CMS DCS was able to relocate and reduce the server rack space and to implement control server redundancy, without needing to change the existing CAN cabling. From operational experience it became apparent that, while providing the required functionality, the readout chain with both the Ethernet-USB and USB-CAN conversions was complex and difficult to debug in case of problems. For this reason, CERN initiated an evaluation to find a direct Ethernet-CAN interface that would meet the existing and future requirements of the organisation.

The evaluation identified the Anagate Ethernet-CAN Gateway family of devices from Analytica GmbH [3] as a candidate for a standard CERN Ethernet-CAN interface. These devices are based on Linux running on ARM CPUs and are currently available in two generations of hardware, the first being based on a CAN controller chip from Microchip and the second using an FPGA to drive the CAN buses. The first generation hardware is available in models with 1, 2 and 4 CAN ports, packaged in stand-alone boxes. Additionally there is a 1U rack mountable unit which can contain up to three 4-port devices, giving a maximum of 12 CAN ports. The second generation hardware is DIN rail mountable and is offered in 2, 4 and 8 CAN port variants.

INTERFACE EVALUATION METHODS

It is essential to have stable CAN interface hardware in any production environment because any failure will prevent communication between the front-end hardware and the control system software. This can generate downtime of the experiments and creates frustration amongst the support teams. To minimise the issues and purchase the best hardware that would meet the end user's requirements, the following methods were used to evaluate the Anagate Ethernet-CAN gateways.

Defining CAN Interface Test Specifications

The first priority was to define a test specification list describing the objectives, procedures and pass/fail criteria to check that the Ethernet-CAN interface met the user requirements. The tests were grouped into 4 categories; namely Functionality, Usability, Performance and Stress. Only Performance and Stress test categories are described here in detail. The primary goal of this exercise was to define a unit test for each category that specified its objective, a testing procedure and the pass condition. This test case catalogue could then be used to evaluate the hardware and to report the test results.

- **Performance Testing Objectives**

One of the first questions when evaluating a new hardware is inevitably going to be: "How does it perform?" Alternative questions might be: What maximum throughput can it sustain? Can it handle high load? How fast does it respond? There are many different ways to ask the question but all of them refer to the performance of a product. In order to be able to answer these questions and to determine how effectively it can perform under our environmental conditions and constraints, a unit test

specification was defined per performance test criteria. These unit tests included: throughput, endurance and latency. Throughput unit tests were devised to measure the maximum number of CAN frames per second the interface could handle per CAN bus before CAN frames started to be discarded by the interface. Tests were performed for each possible baud rate. Endurance unit tests involved running the interface with a significant load over a long duration to ensure that the throughput and response time did not degrade with long-term sustained load. Latency unit tests were designed to characterise the delay associated with sending CAN data through the interface hardware.

- **Stress (resilience) Testing Objectives**

It is also important to know how well the hardware behaves and recovers beyond its normal operation conditions. As the CAN interface is a key element in the readout chain, it is essential that it can recover quickly and automatically from failure conditions. It should not require a physical human intervention to act on the interface, since the hardware is distributed over distances of several kilometres and located in areas that are not always fully accessible during the operation of the experiment.

Stress testing involved putting the CAN hardware under exaggerated levels of stress to evaluate its stability in the non-ideal conditions encountered in the production environment. Three types of major failures were identified in order to assess the robustness of the interface and check how well it was able to recover.

Power failure unit tests involved powering off and on the interface via hardware and or software reboot during periods of active CAN communication and then analysing how the interface recovered from this state.

LAN failures tests consisted of making a physical disconnection of the network equipment (i.e. Ethernet cabling, Network switch, etc...) for varying durations during operation and analysing the recovery mechanism.

CAN network failure tests aimed at acting on the CAN bus to simulate errors such as putting a CAN port into BUS OFF and verifying that the interface could reset the CAN port without any negative impact on the system.

Writing of Software Tools

As described earlier, the control and monitoring data of the devices on the CAN buses is handled by WinCC OA, which communicates via a native OPC client to a vendor specific OPC server. This OPC server then communicates over CAN with the physical device concerned. The OPC servers were originally written for a CERN defined set of CAN interfaces, mostly from Kvaser AB [4], making use of the vendor specific hardware APIs.

To be able to use and evaluate the Anagate Ethernet-CAN gateways within the CERN control context, it was necessary to write a wrapper DLL that would map between the original vendor (Vendor 1) API used in the OPC server and the new hardware API from Analytica (Vendor 2). This is illustrated in Fig. 1. From the OPC server point of view, the wrapper DLL behaves in exactly the same way as the

Vendor 1 API, avoiding the need to rewrite parts of the OPC server when changing CAN interface hardware.

The wrapper DLL was implemented in C as a re-entrant multi-threaded library.

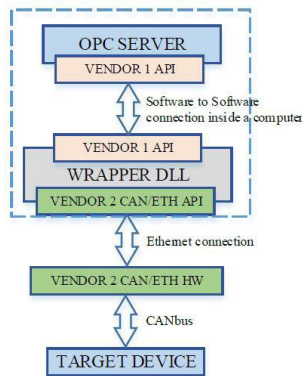

Figure 1: OPC-wrapper-CAN API software layout.

As the Vendor 1 API accesses the hardware via the CAN-port number and has no notion of how to access the Anagate hardware over the Ethernet network, a static configuration file is needed to associate hardware CAN-port numbers with the Anagate IP-addresses and IP-port numbers. To overcome the three types of major failures described in the stress testing section, a complex recovery mechanism was implemented in the wrapper DLL such that those problems become transparent for the OPC servers.

To facilitate the unit testing, a wide-ranging application for interactive testing was written in C. The test application was developed using the Kvaser API and can therefore use the wrapper DLLs to adapt to other CAN interfaces. The test tool can be called from batch scripts, enabling the automation of the required performance and stress tests. Additionally a set of PERL scripts were implemented to assist with the analysis of data generated during the tests.

The test application allows the execution of individual commands or scenarios of consecutive commands. For each CAN port, it is possible to instantiate independent sending and receiving threads. The traffic pattern of the sending thread can be controlled via three parameters: the number of CAN frames per burst, the time between bursts and the duration of the test in terms of the total number of bursts as shown in Fig. 2.

Figure 2: CAN frames transmit pattern.

An additional feature of the test application is that it can uniquely label CAN frames and record the delay between sending and receiving a given frame. By sending data on one CAN port and receiving it on a second port, it is possible to measure the latency of the round trip to the CAN bus and back, passing twice through the software and

hardware interface layers. The latency statistics are written to file in the form of a frequency distribution of the delays.

TESTING AND RESULTS

The testing of the Anagate Ethernet-CAN gateway lasted for several months, with the aim of evaluating a maximum number of software and hardware aspects. Firstly, this involved checking the quality of the interface in terms of hardware parts (i.e. quality of CAN connectors, interface housing, etc...) and software elements (i.e. ease of installation, API readability, quality of documentation, etc...). Secondly, the unit tests described in the test specification document were carried out. Thirdly, the interfaces were installed in an experiment production environment to evaluate the stability and scalability over a period of several weeks with hundreds of CAN nodes distributed over several CAN buses. Throughout the testing period, the quality and responsiveness of the support from the vendor were evaluated.

Hardware and Software Product Inspection

After purchasing, the Anagate gateways were installed in the lab and the following criteria were evaluated:

- The quality of the housing and the integrated connectors (CAN ports, internet and powering) indicated that the hardware was robust.
- The ease and rapid installation and configuration of the interface demonstrated a documentation and software of good quality
- Testing of the native API methods could be rapidly evaluated with little programming effort.

Performance Measurements

Knowing the maximum throughput the interface could handle in receiving and transmitting CAN frames (before CAN frames were discarded) was the first performance criteria to be measured.

To achieve this, we used two Windows 64-bit computers and 3 Anagate CAN Quattro gateways mounted in a 1U case. We installed the hardware in a rack and connected two of the four CAN ports of the first Quattro gateway (which was the device under test) to each of the other two Quattro gateways. For each CAN baud rate (10kb/sec up to 1Mbit/sec) both receive and transmit CAN traffic was generated and passed through the device under test in order to determine the maximum CAN load before frames started to be discarded. The results are shown in Fig. 3.

The findings correspond to tests with a duration of five minutes. The maximum load percentages are the thresholds at which no frames are discarded. When those thresholds are exceeded, frames may be discarded by the Anagate hardware. As can be seen, the maximum load percentage diminishes for high CAN baud rates and when all CAN buses are used. These limitations correspond to the maximum throughput of the Anagate gateway that is consistent with data provided by Analytica.

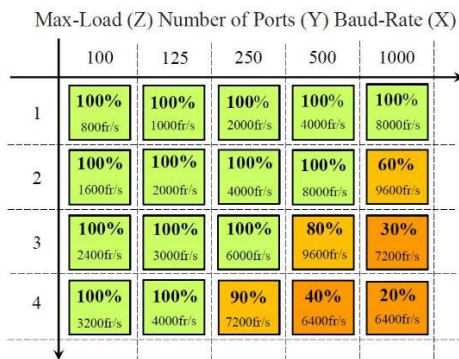

Figure 3: Throughput measurement results.

Latency Measurements

Several tests under different network topologies (with routers and switches) were performed to quantify the latency introduced by the Anagate hardware. The latency measured includes the time it takes to send and read back a CAN frame across the various layers (software, hardware and LAN).

The results in Figure 4 show the distribution of latency introduced by the Anagate hardware in comparison to a USB-CAN interface, when operating with low load. The average latency of the Anagate interface is slightly higher, but more significantly, the latency distribution is wider, with a long tail including longer delays.

Figure 4: Latency measurements results.

Stress Testing Results

The Anagate interfaces were evaluated against several failure types that are encountered in a production environment. With recovery features included in the wrapper DLL, the Anagate interfaces automatically recovered from different type of failures such as power cut, network disconnection and CAN bus errors.

CMS Production Environment Tests

To test the Anagate hardware in a production environment, the Analytica interfaces were installed in CMS and integrated into the DCS in place of the previous USB-CAN interfaces. Tests covered the main types of CAN-based hardware to be controlled in CMS, namely power supplies and VME crates from WIENER Plein & Baus GmbH [5] and Embedded Local Monitor Boards (ELMBs) [6] designed by a collaboration between CERN, NIKHEF and PNPI. Large CMS CAN installations were

selected to test the Analytica interfaces in the most demanding applications. Each test in Table 1 was executed for one week to evaluate performance and stability.

Table 1: CMS CAN Bus Test Applications

Hardware type	Devices	Bus	Baud rate
Wiener VME Crate	88	8	500 kb/s
Wiener Power Supply	136	10	100 kb/s
ELMB	104	8	125 kb/s

Initially, the Wiener OPC server encountered problems due to the additional latency of the Ethernet-CAN interface. The extra latency caused delays in the hardware response to OPC server requests, exceeding the expected round trip time and causing OPC item data to be marked as invalid. After discussion with Wiener, the problem was solved by modifying the OPC server to tolerate a user configurable additional latency in the readout chain.

The week long tests ran smoothly, indicating that the Anagate interface can be successfully integrated as a reliable component in the CMS DCS. An additional long term test was performed where the Wiener VME crate system ran for four months without any negative impact on the control system, in which time, more than 54 billion CAN frames were processed by the interface.

CONCLUSION

The Anagate Ethernet-CAN gateways from Analytica passed the unit tests including those which evaluated the functional, performance and robustness criteria. Furthermore, the tests in CMS demonstrated that the CAN interface could operate robustly in a production environment and that it provided the required quality of service for the experiment control system.

Throughout the testing period most of the issues reported to Analytica were analysed and fixed within a period of few weeks which demonstrated a very satisfactory level of collaboration and support.

The Anagate gateways offer a viable alternative to PCI and USB interface types, which enables the evolution of the CERN control systems towards virtualization and redundancy. There are ongoing studies for the integration of this interface into future OPC Unified Architecture based CERN control systems.

STRIPPING FOIL DISPLACEMENT UNIT CONTROL FOR H⁻ INJECTION IN PSB AT CERN

P. Van Trappen*, R. Noulivos, W.J.M. Weterings, CERN, Geneva, Switzerland

Abstract

For CERN's Linac4 (L4) Proton Synchrotron Booster (PSB) injection scheme, slices of the 160 MeV H⁻ beam will be distributed to the 4 superposed synchrotron rings of the PSB. The beam will then be injected horizontally into the PSB by means of an H⁻ charge-exchange injection system using a graphite stripping foil to strip the electrons from the H⁻ ions. The foil and its positioning mechanism will be housed under vacuum inside a stripping foil unit, containing a set of six foils that can be mechanically rotated into the beam aperture. The band with mounted foils is controlled by a stepping motor while a resolver, micro-switches and a membrane potentiometer provide foil position feedback. The vicinity of the ionizing beam and vacuum requirements have constrained the selection of the above mentioned control system parts. The positioning and interlocking logic is implemented in an industrial Programmable Logic Controller (PLC). This paper describes the design of the stripping foil unit electronics and controls and presents the first results obtained from a test bench unit which will be installed in the Linac4 transfer line by the end of the 2015 for foil tests with beam.

INTRODUCTION

As part of the LHC Injectors Upgrade (LIU), CERN has planned the replacement of the current Linac2 by the Linac4 as injector to the PSB. This new linear accelerator (linac) is expected to increase the beam brightness of the PSB by a factor of 2, making a Large Hadron Collider (LHC) injectors' upgrade possible for higher intensity and eventually a luminosity increase [1]. A combination of bending, kicker and septum magnets will distribute the 160 MeV H⁻ ions to the four superposed PSB synchrotron rings. The beam will subsequently be injected horizontally into the PSB using the stripping foil. The orbit of the circulating beam is displaced by ~81 mm, using two independent closed orbit bump systems, to meet the incoming beam [2]. The first injection bump uses four pulsed dipole magnets (BSW) magnets while a series of 4 horizontal kicker magnets (KSW), located in the PSB circulating orbit, will produce an additional closed orbit dump with varying amplitude to accomplish transverse phase space painting to the required emittance. This is illustrated in Fig. 1 [3]. The injected beam will be stripped by a H⁻ charge exchange injection system (i.e. stripping foil) where the ions will be converted to protons. Partially stripped H⁻ and ~1% H⁻ missing the foil will be directed to an internal dump.

In order to reduce machine downtime it will be possible to remotely interchange the carbon foil (~1 µm thick) when

deemed necessary, e.g. in case of rupture or decreased performance. For that reason a foil interchange mechanism (FIM) has been designed, incorporating a rotating band with six interchangeable foils. This paper discusses the electronic actuators, sensors and control system that make a foil exchange possible.

Figure 1: PSB injection region.

SENSORS & ACTUATORS

The FIM consists of a band, inside a vacuum chamber, that rotates over two pulleys so to displace a foil into the beam aperture. This will allow for a perpetual rotation so that each of the six foils can be reselected. Each foil is attached to a frame that has two important positions: *foil in* and *foil out*. Each of these positions allow for a 4 mm fine-tuning in order to find an optimum position for operation.

A retractable beam observation TV monitor (BTV) screen for beam position measurements on the selected foil is installed at the other side of the vacuum chamber, as shown in Fig. 2. When inserted it will be parallel next to *foil in* frame. To prevent BTV screen and FIM frame collisions, no FIM movement will be allowed when the BTV screen is in and at the same time any BTV movement is interlocked when the frame is not in the above mentioned positions. It is important to emphasise that a collision would result in major downtime because machine access and vacuum breakage will be required to replace the FIM. It is thus vital to know at all times the absolute position of the frame close to the beam aperture.

The choice of sensors is driven by obtaining that exact frame position and furthermore deal with the stringent vacuum pressure and radiation dose constraints. Furthermore the requested positioning reproducibility of 200 µm from the specification has to be taken into account.

Component Selection

The below electrical components are used to displace the band of ~50 cm so that one of the six foil frames is positioned into the injected beam aperture. The motor is the

The arrow indicates the beam direction.

sole actioning component, the other components are used for position readout.

Motor and Resolver The band pulley with a radius of 12 mm has its shaft connected to a mechanical vacuum feed-through. Outside of the vacuum chamber the feed-through is connected to a stepping motor through a 10:1 worm and wheel gearbox. Although some commercial off-the-shelf (COTS) stepping motors are made for operation inside the vacuum, placing the motor inside the chamber would endanger vacuum acceptance tests and complicate signal integrity and motor replacement.

The 1.8° stepping motor is microstepping driven which yields a higher positioning resolution and smoother frame movement. A microstepping factor of 8 steps per full-step has been chosen taking into account the microstepping disadvantages of torque variation and resulting loss of positioning accuracy. Taken all numbers into account the step resolution yields:

$$R = \frac{2 \times 12 \times 10^3 \mu\text{m} \times \pi}{200 \text{ steps} \times 8 \text{ microstepping} \times 10 \text{ gearbox}} = 4.7 \mu\text{m/step} \quad (1)$$

This is well below the required 200 μm positioning accuracy and hence allows for several missed motor steps before the frame will be considered mispositioned. Although a stepping motor can function without feedback, i.e. open-loop control, a resolver has been added to provide command feedback. When the control system detects a difference between the motor command (i.e. the requested amount of steps) and the actual movement seen by the resolver, one can consider missed steps (steps loss). In this application the main cause of steps loss is mechanical friction that cannot be overcome by the motor's torque. Detecting this is crucial because it will result in mispositioning. Furthermore the small step resolution versus required accuracy is important because the asynchronous behaviour of the motor drive and resolver readout module means that several missed steps during positioning should be allowed, as it will be explained later.

For this application a resolver was chosen over an encoder because the elevated radiation doses don't allow for the electronics that are implemented in all but mechanical encoders. Mechanical encoders don't provide the required resolution for this application. Although a final motor has not been chosen yet, several suppliers offer motor-resolver combinations that are radiation hardened.

Microswitch The use of microswitches has several advantages because of their simple construction and operation. Several COTS switches, mainly for use in space, are made to minimize vacuum outgassing and resist radiation. Furthermore the open/close contacts accept a wide range of voltages and can be interpreted by any control system. From a mechanical point of view it is more challenging to implement these switches in the limited space of the vacuum chamber and route the cables through an electrical vacuum feed-through. The production of dedicated frame and microswitch supports has allowed us to detect the *foil in* and *foil out* positions over the 4 mm range. A microswitch is also used for calibration as explained later. After lengthy research, the Honeywell 17HM6 has been selected and successfully tested for outgassing. For each position two switches have been installed for redundancy. Figure 3 shows the two switches that indicate the *foil in* position.

Potentiometer While the closed-loop stepping motor and microswitches are able to provide frame position information, it was seen necessary to include an additional position measurement for reasons of reliability. Furthermore the stepping motor needs to be calibrated and while the calibration can be done using a microswitch, that method doesn't allow for actual position verification. Also microswitch degradation, caused by radiation, could displace its triggering point, hence altering the calibration point. Several sensors such as inductive and capacitive position sensors were evaluated but either they were not vacuum compatible

Figure 3: Front view with (a) microswitches and (b) (c) membrane potentiometers.

or they could not be physically fitted in the limited vacuum chamber space.

Because of the particular band movement it is clear that any linear position measurement won't cover the full range. However with a potentiometer that measures a single frame, preferably the one closest to the beam aperture, and with frame counter mechanism (see further in **Calibration**) an absolute position can be deduced. One has to take into account the limited chamber space and the fact that the frame closest to the beam aperture makes a rotational movement. These considerations have led to the choice of a membrane potentiometer. If the potentiometer consists of Kapton®, a polyimide film, and conductive ink it will experience limited outgassing and furthermore it can be bent around the pulley to follow the frame's movement. Germany-based Hoffmann+Krippner has produced a membrane potentiometer to our design. Figure 3 shows two of these potentiometers on the first test stand unit. The thicker line is the 20kΩ resistance while the smaller line makes up the conductor. Each frame has small wipers that short a certain part of the resistance with the conductor line. The measured resistance can then be translated to an absolute foil position.

Radiation Levels

The vicinity of the beam dump, mentioned in the introduction, is the main source of elevated levels or radiation. FLUKA [4] calculations show that some components can accumulate doses up to 10MGy which is why the microswitches and potentiometers will be sent to Fraunhofer INT for radiation tests. It is important to understand the degrading of the components as this might negatively impact the calibration which relies on for instance the potentiometer's linearity. The test results will also allow us to implement preventive replacement of the components when required. The foils themselves will become activated [5] so any unnecessary or unplanned intervention is to be avoided. The stepping motor and resolver are further away from the dump and can be commercially purchased to be radiation hardened so they will not undergo additional radiation testing.

Vacuum Cabling

For vacuum chamber cabling, no plastic-insulated cables will be used because the outgassing property of polymers cannot be accepted in the PSB vacuum. PEEK and Kapton® are to be avoided so all the cabling will be done by pure, uninsulated copper wire. The amount of microswitches and potentiometers result in a high number of cables that need to be insulated from each other. For this purpose COTS ceramic beads and tubes are used. All electrical contacts are passed through an electrical 26 pin High Density (HD) D-Sub vacuum feed-through.

CONTROL SYSTEM

The discussed components are all wired to the control system that is responsible for positioning the foils by actuating the stepping motor and reading the microswitches, potentiometer and resolver. There is no need for fast control so a PLC was chosen as main controller. PLCs, in general, provide out of the box axis control for positioning but due to the specific nature of the stripping foil this could not be used, as described below.

Hardware

The functional logic is implemented in a Siemens 1515F CPU with decentralised Inputs/Outputs (I/O) over PROFINET. For the final PSB installation there will be one master crate with the CPU and local touchscreen while each PSB ring will have a dedicated control crate with the I/Os. A safety PLC was chosen taking into account the machine downtime that a collision between a BTV screen and stripping foil could cause and not because of risk of human life which is normally the main reason. The implemented safety functions are surveilling the non-equivalent microswitch contacts and will open a contactor to open the motor phases in case of a detected discrepancy. Dedicated modules, for the resolver readout and stepping motor control & drive, have been integrated in the control chassis.

Positioning Algorithm

Calibration Positioning of the foil frames with a 200 μm precision relies mainly on the calibration of the band. Calibrating means finding a point on the band, the zero-point, which is considered to have the absolute position of 0 μm and from where all other positions are referenced. In case of a full turn the absolute position will set to zero again at that point. We know from Eq. 1 that the step resolution is small enough for accurate positioning, as long as the zero-point is found with an accuracy of better than 200 μm. The zero-point calibration error is however added to the existing calibration error with each full turn. Tests have shown that this accumulative error will result in exceeding the required precision after a few band turns. For reasons of consistency it was chosen to recalibrate with each full turn which only takes an additional few seconds. This is acceptable because of the band's slow motion, chosen so not to damage the fragile carbon foils.

Calibration Methods Three different calibration methods have been selected for evaluation, the most accurate two will be kept for reasons of redundancy. All three methods rely on detecting the zero-point at nominal speed, returning a small distance and moving forward with reduced speed for a more precise zero-point calibration.

The first method uses an additional microswitch that can only be triggered by one of the six frames, called the zero-frame, because of a special support on that frame. The second method uses the same microswitch for indicating the zero-frame but it will then use one of the two potentiometers to calibrate the system at a fixed resistance value. Finally the third method uses a linear actuator to mechanically block the band and relies on the resolver to detect missed steps. This method is the least favourite because it requires the motor's torque to be high enough to make the band turn, but low enough so that a blocked band is detected as quick as possible to have an accurate zero-point calibration. A stepping motor's torque can easily be controlled by limiting the current through the stator phases but this is a trial-and-error method and because of slight mechanical construction and friction differences this is expected to be different for every unit constructed.

Absolute Reference Axis A PLC or stepper driver has a certain functionality to allow for automated positioning and axis control. In order to use that functionality however the system assumes certain basic configurations and a band that allows full band turns and recalibration is not one of them. That's why for this project the motor driver is used in relative positioning mode and an algorithm to allow for absolute positioning has been developed for the PLC. A well-known methodology called *finite state machine* has been used to have precise control over the (re)calibration and positioning methods and asynchronous commands to the motor driver. The algorithm also deals with the asynchronous command and readout of the motor drive and resolver modules, as these operations are not synchronous with the PLC program cycle. This asynchronous behaviour imposes that during movement a certain discrepancy between the motor command and resolver position needs to be allowed. The small step resolution ensures that even in this situation the required positioning accuracy is within specification.

Test Results

The implemented positioning algorithm and the positioning accuracy, based on the zero-point recalibration, needs statistical validation so a test-run functionality has been implemented in the PLC. A laser distance sensor with a resolution of 20 μm and linearity of 100 μm has been purchased for position measurement and verification of the potentiometer's linearity in the test bench.

During a test-run the system will position itself to a configurable amount of positions on which all sensor's data is written to an comma-separated values (csv) file. That file

can be read in by spreadsheet software for statistical analysis and graphical representation. A test-run that requested 500 successive 100 μm positions has been used to evaluate the potentiometer's linearity, as can be seen in Fig. 4. At the moment of writing several test runs are being made to evaluate the three calibration methods and currently a standard deviation of 250 μm has been compiled from the data. The reason for that high positioning error has been found due to the mechanical axis feed-through, which allows for a small amount of slack, which is amplified by the pulley's diameter connecting the axis to the band. Work is ongoing to reduce this mechanical slack.

Figure 4: Potentiometer linearity test result, displacement (x) versus voltage (y).

STATUS AND FUTURE

The first unit will be installed at the end of the Linac4 Tunnel (L4T) for stripping foil performance tests. Currently that unit is being prepared for commissioning by the end of 2015 and is actually used as a test bench for the final validation of the mechanical and electrical system. As part of the Linac4 injection scheme for the PSB, the stripping foil exchange units need to be ready by the end of 2016 for an installation during LS2 (Long Shutdown 2) at the latest. The installation of two units, a definite one in the (L4T) and a temporary one as part of the half-sector test [6] scheduled in 2016, will provide us with useful experience that might require some improvements.

A FAST INTERLOCK DETECTION SYSTEM FOR HIGH-POWER SWITCH PROTECTION

P. Van Trappen*, E. Carlier, S. Uyttenhove, CERN, Geneva, Switzerland

Abstract

Fast pulsed kicker magnet systems are powered by high-voltage and high-current pulse generators with adjustable pulse length and amplitude. To deliver this power, fast high-voltage switches such as thyratrons and GTOs are used to control the fast discharge of pre-stored energy. To protect the machine and the generator itself against internal failures of these switches several types of fast interlocks systems are used at TE-ABT (CERN Technology department, Accelerator Beam Transfer). To get rid of this heterogeneous situation, a modular digital Fast Interlock Detection System (FIDS) has been developed in order to replace the existing fast interlocks systems. In addition to the existing functionality, the FIDS system will offer new functionalities such as extended flexibility, improved modularity, increased surveillance and diagnostics, contemporary communication protocols and automated card parametrization. A Xilinx Zynq®-7000 SoC has been selected for implementation of the required functionalities so that the FPGA (Field Programmable Gate Array) can hold the fast detection and interlocking logic while the ARM® processors allow for a flexible integration in CERN's Front-End Software Architecture (FESA) [1] framework, advanced diagnostics and automated self-parametrization.

PRINCIPLE

In Fig. 1 a simplified schematic of a kicker system is shown. In general one can assume a system with matched impedances. A typical operation consists of charging the Pulse Forming Network or Line (PFN/PFL) to a voltage V by a Direct Current or Resonant Current Power Supply (DCPS/RCPS). When the main switch closes, a pulse of magnitude $V/2$ (if matched) propagates through the transmission line to the magnet. The pulse's energy is dissipated in the terminating resistor and full-field is established in the kicker magnet once the pulse reaches this resistor. Note that the magnet termination can also be a short-circuit, which doubles the magnet current because of reflection but also doubles the required fill-time of the magnet [2]. The pulse length in the magnet can be controlled by adjusting the timing of the dump switch relative to the main switch. When a sharp falling edge of the magnetic field is required for systems using a PFN, a clipper switch to ground is added between the PFN and the main switch. Typical values are 50 kV and 10 kA that traverse the magnet with pulse lengths between 500 ns and 600 μ s.

During operation the system might be interlocked because of malfunctioning of one of the High Voltage (HV) switches. These malfunctioning causes are called *fast interlocks*, which

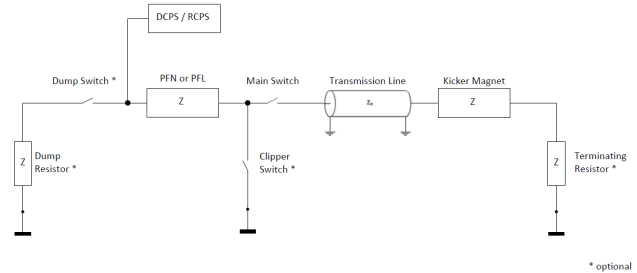

Figure 1: Simplified kicker system.

are detected over a large range of PFN voltages (i.e. the system's dynamic range). In addition to interlocking, they have often also a corrective action such as pulsing other magnets in order to fully deflect the beam and to avoid beam losses, i.e. to protect the machine. The following list gives a basic overview of the different types of fast interlock events:

- **Normal conduction** is not a fast interlock per se but for statistical reason it is useful to count the normal conduction cases.
- **Missing conduction** is registered when a trigger occurs but the switch is not pulsed. Lack of current in a HV switch or a missing load current after a certain amount of time after the trigger will result in a missing detection.
- **Erratic conduction** is the spontaneous conduction of an HV switch caused by tube or semiconductor malfunctioning as opposed to conduction following the normal triggering action. The FIDS mechanism registers an erratic when the switch conducts with no corresponding trigger pulse present.
- **Short-circuits** might happen at several locations, starting from the PFN up to a Terminating Resistor (TR). Depending on the magnet configuration several detection techniques exist, e.g. for short-circuited magnets one can compare the delay between the forward Main Switch (MS) pulse and the Dump Switch (DS) inverse current which, for normal operation, should represent the two-way transmission delay through the cable and magnet plus the single-way delay through the PFN.
- **No dump switch forward current** is the case when, for short-circuited magnets or systems with a Clipper Switch (CS) only, the short-circuit will reflect the travelling wave and the DS will have to withstand an inverse current (i.e. current from cathode to anode). In case of hollow-anode thyatron types, it is vital for the lifetime of the thyatron that it will first conduct forward current (i.e. anode to cathode) before the arrival of the inverse current.

* CERN TE-ABT-EC, pieter.van.trappen@cern.ch

A generator has several pick-up probes installed for analysis of the current and/or voltage. Resistive and capacitive voltage dividers are used as well as current transformers. The idea behind the FIDS is to sample these analog signals and their related trigger signals and perform an analysis to detect as fast as possible one of the above mentioned events. In case of an erratic conduction for example, we often need to pulse other magnets within 500 ns to reduce beam losses. After a certain amount of occurrences we would want to stop, i.e. interlock, the generator for expert intervention. Important in the analog signal sampling is a high signal-to-noise ratio (SNR), especially because many kicker generators have a wide dynamic range. In a simplified view the FIDS thus generates pulse outputs based on the relative timing of its input signals and communicates events to the upper-layer control system.

PROTOTYPE

A wide variety of electronic modules had been produced in the past and the FIDS principle of operation is based on an existing module, called Thyatron Protection Unit (TPU), by moving most of the functionality from analog discrete components to digital logic in an FPGA. This digitization will allow for more flexibility and an automated parametrization while adding improved communication possibilities. A prototype has been designed to verify the principle of operation and to perform several tests on dedicated installations available for development and testing. An FPGA was a logical choice to implement most of the digital logic because of the required reaction time (<500 ns) and the flexibility for designing hardware logic that differs per installation.

Figure 2 shows a block diagram that explains the prototype's functionality and the chosen hardware. All analog input signals need to be converted to digital values so that pulse edges and pulse lengths can easily be compared in time to detect a fast-interlock event. A possible method is to sample all signals with an Analog-to-Digital Converter (ADC) and use digital bit vectors inside the logic. Because of the high bandwidth of the pick-up signals (100 MHz) however a different approach was chosen. Analog comparators will be used to produce a 1-bit signal that indicate the presence of a current or voltage. This simplification will not limit the FIDS' performance because the signal amplitude itself is generally of no importance. It is important however that the SNR is taken into account for the full dynamic range of the input signals. This can be done by having the comparator reference follow the PFN's amplitude to control the comparators switching level at low PFN voltages. An additional advantage of the comparator-based approach is that additional latency due to ADC conversion and communication is avoided.

To implement the variable comparator reference the bipolar PFN voltage is sampled by an ADC after passing through an instrumentation amplifier and low-pass filter. Charging a PFN takes a considerable amount of time so a 10 kHz low-pass filters out transients and harmonics before digitalisation.

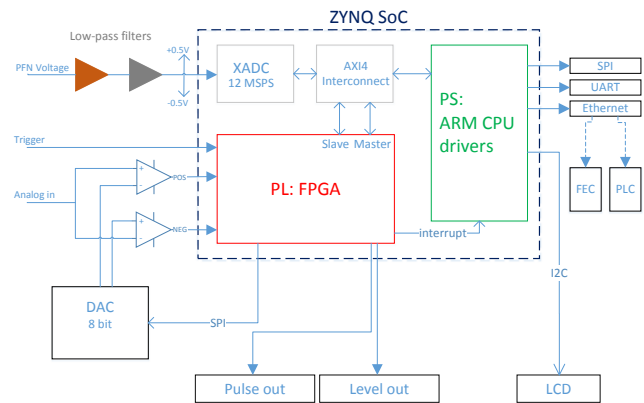

Figure 2: Prototype block diagram.

The digitalised value is used to set the comparator reference after applying a factor multiplication and offset addition. This factor and offset are user-selectable and depend on the kicker installation. A Digital-to-Analog Converter (DAC) translates the calculated value to an analog output that is used as comparator reference. Each bipolar analog input signal passes through two comparators so that a positive and negative amplitude can be detected, as often the case for the DS.

Hardware

Several FPGA evaluation boards were considered to reduce prototyping time. Taking into account the lifetime of the FIDS a recent FPGA family is preferred. Historically Xilinx® has been used in TE-ABT and conveniently their relatively new 7 Series FPGA family has two ADCs (12 MSPS) included - an ideal fit for sampling the PFN voltage. Furthermore a rather recent FPGA manufacturer direction is a System on a Chip (SoC) where an FPGA, ARM® cores and Input/Output (I/O) peripherals, such as I²C and Gigabit Ethernet are included in one package. An internal interconnecting Advanced eXtensible Interface (AXI) bus can be used to link all components together - supported by the CPU cores as well. For the FIDS the Xilinx® Zynq®-7000 is an ideal fit for the prototype because the SoC can lead to significant development time gains. Finally the MicroZed™ low-cost development board was chosen. It includes the XC7Z010 SoC and several peripherals.

Software

The development time gain is mainly achieved by running a bare metal application on the CPU that allows to interact with the FPGA without much effort. The bare metal application is written in Embedded C and can easily access memory-mapped registers in the designed FIDS Intellectual Property (IP) core through the AXI4-Lite protocol. Thanks to the SoC implemented UART peripheral, user I/O is as easy as using printf() and getchar() functions. In the case of a fast-interlock event the IP core will trigger a CPU in-

interrupt which will put all data on the serial UART, such as the acquired PFN voltage and calculated comparator references. Thanks to the implemented I²C peripheral driver and C library it was no problem to quickly add a 2x16 character LCD to let the prototype run for days without needing a laptop for FIDS output visualisation using the UART.

In a second stage the SoC is used by deploying an Embedded GNU/Linux distribution, crafted together by using the Xilinx®PetaLinux tools. The main reason for doing so was to use the kernel's TCP IP stack to easily interface the integrated MAC controller. The idea is to integrate the FIDS seamlessly in CERN's control topology by running a FESA class on the Embedded GNU/Linux distribution. Currently FESA is not available for the ARM® architecture and a port has yet to be studied and/or implemented. At the moment of writing the FIDS prototype has a user-space program that uses a free software library to communicate with Siemens PLCs over Ethernet. This is a future implementation that will often be the case for a kicker installation. Implementing GNU/Linux allows for more flexibility and better control but to properly register the FIDS IP core's interrupts and memory a kernel driver had to be written. Hence additional design time has to be taken into account for the implementation and configuration of Das U-Boot bootloader, the rootfs and the device tree.

Gateway

The gateway for the FPGA is written in VHDL-2008, allowing for more generic packages and modules, and has two main functionalities:

- Interface with the XADC (Xilinx ADC), use of a linear formula to calculate the comparator reference and send it over SPI to the DAC.
- Detect the digitalised (single bit) pulse signals and generate fast-interlock events based on their relative timing and pulse length.

The implemented functionality was tested using a VHDL test bench with additional verification using the Property Specification Language (PSL) which is now part of the VHDL-2008 standard and supported by ModelSim.

Inside the design multiple clock-domains are used and to boost pulse measurement precision and pulse output latency, DSP48 slices have been used to clock the pulse length counters with a 250 MHz frequency. In a later stage the precision should be improved to 1 ns for which a more performant Zynq® SoC needs to be used so we can clock the ISERDES2 primitive at 1 GHz.

Preliminary Test Results

After successful lab tests, the prototype has been tested on two different types of dedicated test installations: the 50kV SPS Beam Dump System (SBDS) and the -60kV Transfer Kicker (TK). These installations are installed in different accelerators and have different PFN lengths and charging methodologies (DCPS versus RCPS). Also the magnet configuration is different because the TK has a terminated magnet with MS and DS configuration while the SBDS has a

MS that consists of a parallel combination of a thyatron with series ignitrons.

Figure 3: SBDS tests scope image; Ch1 (yellow): trigger, Ch2 (blue): comparator output, Ch3 (magenta): comparator reference, Ch4 (green): switch pick-up.

On Fig. 3 the oscilloscope waveforms of the SBDS thyatron switch are shown after a few hours of operation with infinite waveform persistence activated. The operating principle of the FIDS is clearly visible in this image because the installation was operated over its full dynamic range, i.e. from 5 kV to 45 kV. This PFN voltage, measured as a 0 to 2 V voltage from a resistive divider, is sampled by the XADC and used as comparator reference (Ch3 in magenta). When the PFN voltage increases, so does the reference according to the user parameters set by an FPGA register. In this example the linear formula used is $y=1x+5$ where the offset is controllable with 23 mV steps. A higher PFN voltage will result in an increased current through the thyatron (Ch4 in green). The comparator output, a digital signal, hence reflects the length of the current through the thyatron switch. This pulse is then used with reference to the trigger signal (Ch1 in yellow) to distinguish the fast-interlock event.

FULL DESIGN

After successful concept verification, a strategy to develop a board, suitable for every existing and future installation, had to be found. Taking into account the projected lifetime it is important not to select technologies or protocols that will soon become obsolete. The form factor and scalability are equally important because of the variable size of kicker installations with single to tens of HV switches. Finally after thoroughly analysing all requirements and multiple discussions with other groups at CERN, the FPGA Mezzanine Card (FMC) approach was chosen. This ANSI/VITA 57.1 standard specifies an I/O mezzanine module that works in conjunction with an FPGA processing device. The focus is to obtain mezzanine modules that minimize the handling and formatting of the transceived data while conveniently not forcing interface protocols [3]. This allows for example to route the comparator outputs with low-latency differential

signals directly to the FPGA while at the same time using a different subset of pins for DAC serial communication. The two main advantages of the use of the FMC standard for the FIDS are

- **Flexibility:** as mentioned before, kicker installations are complex and use several switches per generator and multiple generators per installation. Using a carrier with FMCs approach allows for adding functionality by simply plugging in an existing FMC.
- **Independency:** at the moment it is unclear what will be CERN's future CPU-bus and once chosen it is certain that this will change again, following the technology trends of the moment. Implementing the core functionality on a mezzanine allows for independency since it is easy to adapt to a new CPU bus by using the according carrier card.

In the following subsections the two basic parts of the system are detailed, being the FIDS FMC DIO 10i 80 module and the FIDS Carrier.

FIDS FMC DIO 10i 80 Module

While adhering to the FMC standard has many advantages, one should not forget the disadvantages of increased design time, small physical size and limited freedom for the Power Distribution Network (PDN). An important advantage however is that at CERN several carriers for different CPU-buses exist and a working FMC can be quickly put in use by using one of these carriers, which are open hardware [4]. FMC is a widely accepted standard and also at CERN different cards with a wide range of functionalities have been developed. In general the additional time spent for fitting a design into the FMC standard pays off if there is enough demand for the card. A high demand, thanks to a general design, could encourage the industry to include it in their catalogue which will yield smaller lead times and lower prices. Also the more users incorporate the card, the faster design mistakes can be found and resolved. Below in Table 1 the card specification is listed and it shows that the analog input stage, including the comparator reference producing DACs, are included. While still a perfect suit for the FIDS, it can easily be used by other users as a general purpose I/O card that offers more user I/O than any other card available today. The card will be made available on the open hardware repository as well [4].

FIDS Carrier

As mentioned before at CERN several carriers such as the Simple VME FMC Carrier (SVEC) exist and the FIDS could make use of one of these to reduce overall design time. It was found however that none of the existing carriers included all of the required functionality so a specific carrier will be designed. The main features are two FMC slots, 6 analog inputs, fail-safe functionality and two Ethernet ports combined with the Zynq SoC. The full specification can be found in Table 2. They will be placed horizontally in a 19" rack and occupy a 1U slot.

Table 1: FIDS FMC DIO 10i 80 Specification

Parameter	Value
Inputs	10 analog comparator
Outputs	8 TTL 1 ns rise time
Number of comparators	20 (2 per input channel)
Comparator reference	20 (1 per comparator)
Comparator input bandwidth	1 GHz
Comparator input levels	$\pm 5V$
Comparators to FPGA	LVDS
FMC to carrier interface	Low Pin Count (LPC) connector
Input impedance	High-Z or 50 Ohm
Programmable threshold	DAC with 5mV precision
DAC resolution	12 bit
DAC Sampling rate	166 kHz

Table 2: FIDS Carrier Specification

Parameter	Value
2 FMC LPC slots	VADJ fixed to 2.5V for slot-1 and 1.8V for slot-2
6 analogue inputs	2 MSPS ADC, 1 MHz BW, 12-bit, lemo-00, $\pm 10V$ input
4 isolated outputs	9-pin D-Sub male connector
4 outputs	TTL level, rise-time < 10 ns
4 high-power outputs	15V, rise-time 20 ns, 1A peak output current
user-button	Momentary NO push-button
reset-button	Momentary NO push-button
8 bi-colour user LEDs	4 FPGA- and 4 CPU-controlled
Serial interface	I2C bus for connecting external LCDs and I/O expanders
JTAG header	Xilinx Platform Cable style
SPI Flash	Bootable, 2x 128 Mbit QSPI
SD card slot	For booting, OS mounting and persistent storage
Fail-safe functionality	FPGA and CPU watchdogs; voltage supervision; pulse output feedback
2 Ethernet RJ45 ports	Ethernet switch; 1 SoC Ethernet MAC; 10/100 Mbps

Abstract

Hadron experimental facility is designed to handle intense slow-extraction proton beam (750kW-15μA) from Main Ring of Japan Proton Accelerator Research Complex (J-PARC). On May 23, 2013, due to malfunction of the slow-extraction system in Main Ring, the production target in Hadron experimental facility was locally damaged because of overheat by absorbing proton beam in extremely short period (5 milliseconds). After the accident we have improved the monitoring system of temperature of the target with 100 milliseconds sampling rate in order to detect damage to the production target as soon as possible. The monitoring system has been operated without failure after the accident. This manuscript reports the upgrades of the temperature measurements at the J-PARC Hadron experimental facility.

INTRODUCTION

The Hadron experimental facility [1] (HD-hall) at Japan Particle Accelerator Complex (J-PARC) shown in Figure 1 is designed to handle intense slow-extraction proton beam from Main Ring (MR). The period of beam extraction from the MR to the HD-hall is 2 seconds and the operation cycle is 6 seconds.

Figure 1: Illustration of the HD-hall.

On May 23th, 2013, 2×10^{13} proton beams were rapidly extracted to the HD-hall in 5 milliseconds due to malfunction of power supply of Extraction Quadrupole magnet in the MR. The production target [2] in the HD-hall was locally damaged because of rapid rise of temperature by beam deposit in extreme short period.

In order to detect the damage to the production target, the requirements of temperature measurement system are as follows.

- Upgrade read-out system of the production target temperature.
 - Hundred milliseconds sampling
 - Synchronization with beam extraction
- Make trend graphs and the waveform spectra of the target temperature as a function of time to tell the operators the state of the production target.

THE PRODUCTION TARGET

The production target at the HD-hall is made of gold and a copper block with coolant stainless pipes. Gold is chosen for high density, high thermal conductivity and good chemical stability. The total size of a gold structure is $15^W \times 6^H \times 66^L$ [mm]. The gold structure was divided into 6 pieces to reduce thermal stress. The water coolant pipes, embedded in the copper block, were made of stainless steel to avoid erosion and corrosion. The gold structure, the copper block and the coolant pipes are bonded by a Hot Isostatic Pressing (HIP) process.

The production target is located in an airtight chamber filled with helium gas. The beam entry and exit are covered with beam windows. Twenty thermocouples were attached at the surface of the gold pieces (12), the copper structure (2), the water and helium gas pipes (4) and the edge of the beam windows (2). The production target is designed to be capable for up to 50-kW proton beams.

MEASUREMENT AND CONTROL DEVICE

Before the accident we had measured the temperatures of the production target with 1-second cycle with a Programmable Logic Controller (PLC). The PLC had consisted of one EPICS-CPU, which is an embedded EPICS IOC on Yokogawa's FA-M3 PLC platform [3], three temperature monitor and one output modules. However, the temperature-measurement cycle of 1 second was too slow to detect the rapid temperature rise of the production target. Therefore we have upgraded the measurement system of the target temperature. Measurements of temperature with 100 milliseconds sampling are controlled with the sequence-CPU. The sampled data are stored in the sequent memory of the sequence-CPU. Then, an EPICS-IOC, running on the adjoining CPU module, installed next to the sequence-CPU, can take data from the sequence CPU via shared memory. Finally, the operators can monitor waveform spectra of the temperature rise on the production target, via the EPICS waveform record.

[#]agari@post.kek.jp

In the sequence-CPU, the temperature data of the production target are continuously compared to the thresholds for each thermocouple. An interlock signal is issued when the temperature exceeds the threshold. The interlock signal is transferred to the accelerator and the next beam extraction is safely stopped.

The start and stop timing of the measurement is synchronized with the beam extraction cycle, using the gate signal synchronized to the accelerator operation. The system of the PLC is shown in Figure 2.

Figure 2: Photograph and illustration of the PLC.

METHOD TO MEASURE TEMPERATURES SYMCHRONIZED WITH BEAM EXTRACTION

We have developed the system of the temperatures synchronized with beam extraction to display the time structure of the target temperature. The way of the system is described in Figure 3 and as follows.

- I The gate signal synchronized with beam extraction (ON-Beam) is detected by the A/D module in the PLC.
- II When the leading edge of the gate signal is detected, the measurement starts with 100 milliseconds sampling rate, and ends after 5.8 seconds. The data are stored in the shared memory on the sequence-CPU.
- III After the completion of each temperature measurement, the sequence-CPU issues the signal to the adjoining CPU module for data-taking.
- IV The adjoining CPU starts to read temperature data via the shared memory, and store data into EPICS waveform records.
- V Finally, the system waits for the timing gate of the next beam extraction after the completion of the temperature measurement.

The EPICS sequencer [4] has been used in order to operate the system synchronized with the beam extraction.

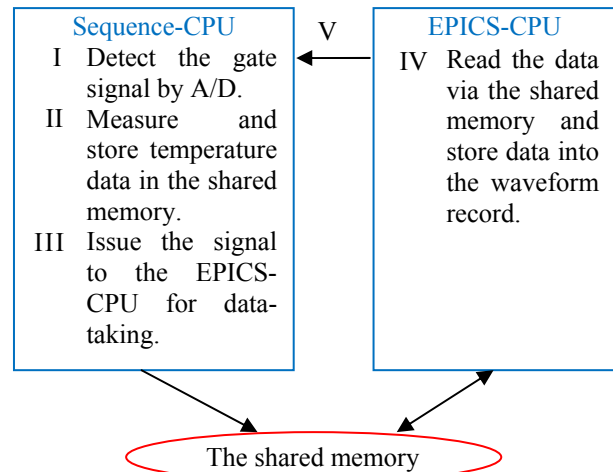

Figure 3: Diagram of how to measure the temperatures synchronized with beam extraction.

INTERLOCK AND ALARM SYSTEM

The interlock signals of the beam line components are used in the Machine Protection System [5] (MPS) in J-PARC. The MPS automatically stops beam operation when the MPS status is broken by the interlock signals from the accelerator and the beam line components. The EPICS Alarm Handler [6] has been introduced to notice the operators the warnings from the equipments. As for the production target, two-step thresholds (“Warning” and “Alert”) for all temperature data are defined, using EPICS ALARM field (HIGH, HIHI, etc.).

The MPS signals from the target system are assigned to be “Alert”.

DISPLAYS

Temperature data synchronized with beam extraction, trend graphs and MPS status are displayed in a control room for the operators. These displays are mentioned as follows.

Temperature Data Synchronized with Beam Extraction

A GUI program for the temperature data synchronized with beam extraction has been developed with wxPython [7]. WxPython is a GUI toolkit for the Python programming language. The operators can monitor the current data via this GUI program and inspect the past data if necessary. Figure 4 shows the typical waveform spectra of the target temperatures during the normal beam operation of 33kW. A smooth temperature rise during the beam extraction is measured from 0.6 to 2.6 seconds. The smooth decrease of temperature continues to 5.8 seconds from the beginning of the measurement. The maximum temperature of the gold pieces was 250.0 degree Celsius at the forth from the front piece. The temperature rises of the copper block and the coolant pipes were not more rapid than that of the gold pieces. The maximum temperatures and the averaged temperatures for last five

shots are displayed on the upper of this graph for beam commissioning.

Figure 4: Display of temperature data synchronized with beam extraction during 33-kW beam operation. Its vertical axis is for the temperature [degree Celsius], and the horizontal axis is for the time [second].

Trend Graphs

The trend of temperature data are displayed by Strip Tool [8] as shown in Figure 5. The target temperature and the thresholds of “Warning” and “Alert” are shown in the same window. Figure 5 shows the typical beam operation continued to operate for 30 minutes without beam stop.

Figure 5: Display of trend graphs. The beam condition of this figure was the same as that of Figure 4. Its vertical axis is for the temperature [degree Celsius], and the horizontal axis is for the time [minute].

The Current Values and the Interlock Status

A GUI program for the current values, thresholds, and the interlock status of temperature has been developed with MEDM [9]. Figure 6 illustrates a top view of the production target. The operator can recognize the current values and the interlock status at a glance.

Figure 6: Display of interlock status.

SUMMARY

- The measurement and interlock system of the target temperature has been developed with the PLC. The temperature data and the interlock signals are handled and controlled with the sequence-CPU module. The EPICS-CPU module can handle the data from the sequence-CPU via the shared memory. The waveform records of temperature as a function of time can be referred on the EPICS-CPU.
- The measuring system operates to synchronize with the beam extraction. The operator can monitor the waveform spectra as a function of time in every beam extraction.
- The trend graphs, the current data of temperature, and the interlock status are shown visually for the operator.
- The two-step alarm system has been introduced for the operators, using ALH.
- The upgraded system has been successfully and stably operated with up to 33-kW proton beams.

THE GENERAL INTERLOCK SYSTEM (GIS) FOR FAIR

F. Ameil, C. Betz, GSI Helmholtz Centre for Heavy Ion Research, Darmstadt, Germany
G. Cuk, I. Verstovsek, Cosylab d.d., Ljubljana, Slovenia

Abstract

The Interlock System for FAIR, called the General Interlock System (GIS), is part of the Machine Protection System which protects the accelerator from damage by mislead beams.

The GIS collects various hardware interlock signals from up to 60 distributed remote I/O stations through PROFINET to a central PLC CPU. Thus a bit-field is built and sent to the interlock processor (PC) via a simple Ethernet point-to-point connection. Additional software Interlock sources can be picked up by the Interlock Processor via UDP/IP protocol.

The Interlock System for FAIR was divided into two development phases [1]:

- Phase A: interlock signal gathering (HW and SW) and a status viewer.
- Phase B: fully functional interlock logic with support for dynamic configuration, interface with Timing System, interlock signal acknowledging, interlock signal masking, archiving and logging.

The realization of the phase A will be presented here.

INTRODUCTION

The Interlock System for FAIR, called the General Interlock System (GIS), is part of the Machine Protection System which protects the accelerator from damage by mislead beams.

The GIS will be used as a slower part of the Machine Protection System for all machines comprising the FAIR accelerator complex. Three components of the Interlock System can be identified [2] (Figure 1):

- the operation layer,
- the processing layer, and
- the signal pickup layer.

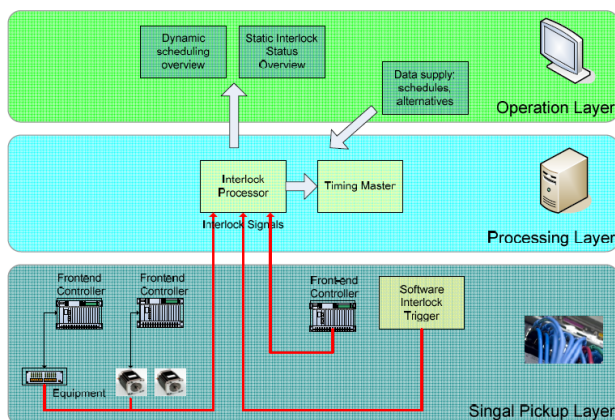

Figure 1: Layers of the interlock system.

The system must be able to collect hardware as well as software interlock signals from up-to 60 remote locations. Each remote station is capable of connecting to between 8 and 192 hardware interlock signals. Interlock transportation and processing must not take more than about 100 ms even when the system is extended to its limits - 4000 interlock signals. Based on these requirements, a combination of a PLC + interlock processor (PC) solution was chosen.

The purpose of Phase A was to confirm the selected architecture and components and to verify that such a solution is scalable and can reach the required performances. The solution will be installed and tested at the CRYRING accelerator in GSI.

The solution was developed by the company Cosylab d.d., Ljubljana, Slovenia, under supervision of the Control System Department at GSI.

SYSTEM DESCRIPTION

The main architecture of the GIS is presented in Figure 2 [3]. PLC Interface Modules (IM) with digital input modules are used to pick up hardware interlock signals. The control system network is used to pick up software interlock signals. After the GIS gathers both hardware and software interlock signals, it calculates summary interlock signals (specifics of this part will be defined and implemented in Phase B).

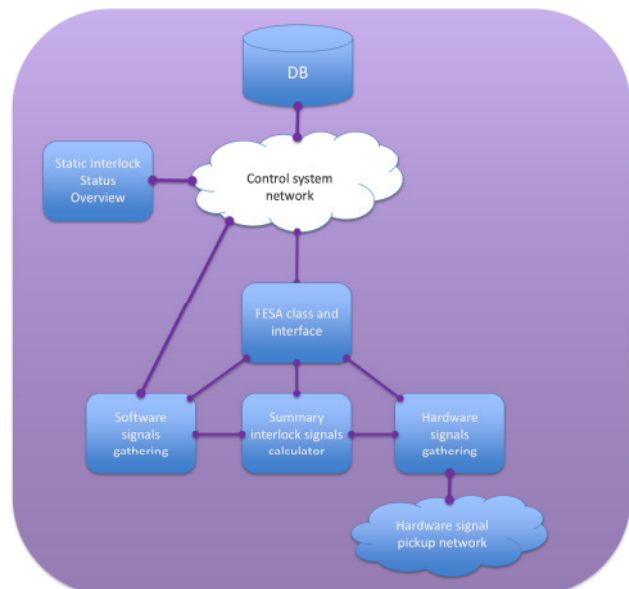

Figure 2: Architectural blocks of the GIS.

All changes of interlock signals are time-stamped. A user can use the GUI of the Static Interlock Status

Overview application to monitor currently active interlock signals. This application obtains information about interlock statuses by connecting to the FESA class interface of the GIS.

Hardware Signals Pick-up

In Phase A, four remote locations were implemented, each hosting an ET200 SP module with a different number of digital input modules for collecting hardware interlock signals (Figure 3). In total 192 hardware interlock signals can be picked-up. If the collection of interlock inputs in some areas is out of operation, these inputs are considered as if they are in an interlock state and the rest of the GIS system remains fully operational.

Figure 3: Hardware interlock signals pickup.

Remote stations are connected to a central CPU (S7 1516-3 PN/DP) via a Profinet network. The CPU runs with a fixed cycle time of 10 ms, thus defining the timestamp resolution. In each cycle, the PLC CPU gathers all hardware interlock signals and send them to Interlock Processor (PC) for further processing.

An extensive diagnostics is implemented to recognize different events and errors on the Profinet network and consequently put the relevant interlock signals into an interlock state. With those diagnostics, one can distinguish signalled interlocks from those caused by error, and furthermore the operator is able to see what kind of problem and in which location/module it occurred.

Software Signals Pick-up

Software Interlocks are collected by the Interlock Processor (PC) using UDP/IP as a communication protocol. For higher reliability, clients (systems sending software interlocks) send redundant datagrams whenever the interlock signal changes. The payload is encoded in such a way that critical bit-errors can be detected.

To make this interface and communication more reliable, the central station maintains a periodical communication (“heartbeat”) with all software interlock sources. An exception to this are interlock sources used for testing, for which the heartbeat functionality is not mandatory.

An interlock source can provide the status of its software interlock signal per Beam Production Chain in the same datagram. Also, if an interlock source provides many interlock signals, all of them can be signalled through a single datagram.

Interlock Status Overview Application

Phase A includes the Static Interlock Status Overview (SISO) application that serves for observing currently active interlock signals (Figure 4). The application connects to a GIS FESA class in order to obtain information about active interlocks, their type (hardware or software) and cause (signal or error) as well as their timestamps. Interlock signals are listed in the table and can be sorted or filtered by its name, type, cause or timestamp.

Source Name	Source Type	Cause	Timestamp

Figure 5: FAT configuration for GIS Phase A.

PERFORMANCE MEASUREMENTS

Two different measurements were done to confirm that the system complies with performance requirements:

- Cycle time measurement, using TIA portal.
- Response time, measured as difference between input and output signal change on two remote stations using an oscilloscope.

Phase A implements only a portion of the whole GIS system (4 out of 60 remote stations), so measuring performance of Phase A system only would not be enough. Therefore, a Profinet network simulator (SIMBA) was used to simulate the missing 56 remote stations with 3808 input signals (i.e. 4000 signals in total with the 4 physical remote stations from phase A).

With the cycle time measurement we want to show that system does not reach saturation even in the most intensive situations like failure of the remote station or even failure of the whole Profinet network. In normal operation, the GIS uses a fixed cycle time of 10 ms. In order to measure the effective cycle time, the fixed cycle time feature was disabled. Figure 6 shows the longest measured cycle time is 4 ms, therefore a fixed cycle of 10 ms has a safe margin.

Figure 6: Cycle time measurement.

Real mitigation actions of the GIS will be implemented only in Phase B. To confirm that interlock transportation and processing takes less than 100 ms, we had to implement an additional feature of driving output signals on remote stations. This testing feature puts an output signal on the selected remote station(s) in a high state for a duration of one cycle each time any interlock signal change is detected. Measuring the time between the interlock signal going from high (OK) to low (NOK) state and the output signal going from low to high, gives the interlock system response time (which includes more than the initial requirement for transportation and processing time).

Different response times were measured because the result depends on when the change of input signal (done manually by opening contacts of the switch) occurs with respect to the start of the next PLC cycle [4]. Figure 7 shows the maximal measured response times (minimal response time was approx. 10 ms shorter). The pink line represents the interlock signal, transitioning from the OK to the NOK state. The yellow line is the response of the

GIS (response was simulated by driving an output signal on each remote station).

These results show that transportation and processing takes far less than 100 ms.

Figure 7: Response time measurement.

CONCLUSION AND OUTLOOK

The GIS for FAIR for Phase A was successfully developed and it fulfils the requirements. A Site Acceptance Test will be performed in the near future at CRYRING@GSI using the system developed for Phase A and operating under real conditions.

Another development is already in progress; its purpose is to include interlock state signals coming from other PLC systems (e.g. Vacuum Control System) using the I-Device functionality. Making use of this functionality avoids physically connecting many signals between two PLC systems; instead of physical signals, “logical” signals are exchanged via Profinet.

The system should be extended further in the next steps of the FAIR accelerator complex construction.

A MODIFIED FUNCTIONAL SAFETY METHOD FOR PREDICTING FALSE BEAM TRIPS AND BLIND FAILURES IN THE DESIGN OF THE ESS BEAM INTERLOCK SYSTEM

R. Andersson^{*1,2}, A. Monera Martinez¹, A. Nordt¹, E. Bargalló¹

¹ European Spallation Source, Lund, Sweden

² University of Oslo, Oslo, Norway

Abstract

As accelerators are becoming increasingly powerful, the requirement of a reliable machine protection system is apparent to avoid beam-induced damage to the equipment. A missed detection of a hazard is undesirable as it could lead to equipment damage on very short time scales. In addition, the number of false beam trips, leading to unnecessary downtime, should be kept at a minimum to achieve user satisfaction. This paper describes a method for predicting and mitigating these faults, based on the architecture of the system. The method is greatly influenced by the IEC61508 standard for functional safety for the industry and implements a Failure Mode, Effects, and Diagnostics Analysis (FMEDA). It is suggested that this method is applied at an early stage in the design phase of a high-power accelerator, so that possible protection and mitigation can be suggested and implemented in the interlock system logic. The method described in this paper is currently applied at the European Spallation Source and the results follow from the analysis on the Beam Interlock System of this facility.

THE BEAM INTERLOCK SYSTEM

The Beam Interlock System (BIS) at the European Spallation Source (ESS) receives around 300 beam permit input signals and needs to stop beam operation in as short as 4-5 μ s for some sections after detection of an error in the proton linear accelerator (linac) [1]. The requirement is based on possible damage from the high proton beam power on the surrounding sensitive equipment. The time scale requirement for the BIS is combined with a need to stop the beam in a reliable way, avoiding both false beam trips (stopping the beam without a hazard) and blind failures (missing to stop the beam when there is a hazard). By meeting these requirements, the BIS can help reaching the reliability goals for ESS and at the same time spare the equipment of any unnecessary damage.

There are four types of modules in the BIS at ESS. Together, they resemble a combined tree and star structure for a reliable transfer of the beam permit signal from the inputs to the actuators. Fig. 1 shows a conceptual flowchart of the BIS, disregarding the actual structure for simplicity. The BIS consists of close to 300 Fast Beam Interlock Driver (FBI_D) and Device Interface (FBI_DIF)

Modules. For redundancy, each input signal goes to two FBI_DIFs. These modules interface with all input signals and transmit a beam permit signal to the BIS. Each signal into the BIS will be propagated through redundant links over the entire signal path. Table 1 displays nominal reaction times for the different modules in the BIS together with an example of the input signal from a Beam Current Monitor (BCM) and the LEBT chopper actuator. The table considers a worst-case scenario in terms of required reaction times. As is seen, if the modules perform as designed, the BIS achieves a total reaction time of less than 3 μ s in the low energy part of the linac.

The rack configuration at ESS contains 24 enclosures with 36 racks each. All the signals from one rack enclosure are grouped into one pair of Master modules (FBI_M), making 48 FBI_M in total. The 48 FBI_Ms connect into two redundant Master of Master modules (MoM) located at the front end of the linac. These two MoMs then connect to three different Actuator Modules (FBI_A) – one for each actuator: Proton Source, LEBT chopper, and MEBT chopper. The FBI_As deliver the final trigger signal to the actuators to stop the beam, by deflecting beam to an absorber by the choppers, and inhibiting the creation of plasma in the proton source [2]. The BIS position in the Machine Protection (MP) conceptual level is seen in red in Fig. 2.

Figure 1: The BIS (red) transmits the input beam permit signals from the monitors and sensors to the actuators, which stop the beam in case of a hazard.

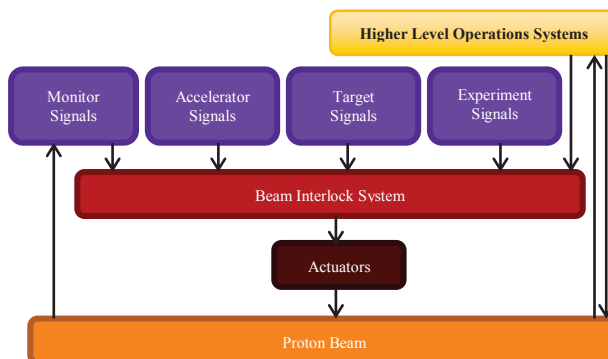

Figure 2: The BIS (red) role in the Machine Protection concept.

* riccard.andersson@ess.se

RELIABILITY ANALYSIS OF THE BIS

The reliability analysis of the BIS was made in two distinct parts. The first part consists of a Failure Mode, Effect, and Diagnostics Analysis (FMEDA) for each BIS module, described below. This part follows to a large extent the approach used for the Large Hadron Collider at CERN [3]. The FMEDA was done using a set of spreadsheets for module and component overview and easy backtracking. The second part uses Reliability Block Diagrams (RBD) on the system level using BlockSim from ReliaSoft [4] to obtain the overall BIS reliability figures.

Table 1: An Example of BIS Detection, Processing, and Reaction Times.

Module	Reaction Time	Accumulated Time
BCM	1 μ s	1.0 μ s
FBI_DIF	500 ns	1.5 μ s
FBI_M	250 ns	1.75 μ s
FBI_A	300 ns	2.05 μ s
MEBT Chopper	300 ns	2.35 μ s

FMEDA

The ESS BIS FMEDA involves (a) identifying the components of the four BIS modules, determine their (b) functionality, (c) failure rates, and (d) failure modes, (e) identify the components' impact on the module as a whole, and (f) find the diagnostic ability to detect the failures. The FMEDA process was launched in the mid 90s as an upgrade of the original Failure Mode and Effect Analysis (FMEA), developed in the 60s and 70s for the US Military Standards. It is a method that has grown increasingly popular in reliability engineering since its introduction.

The (a) components and (b) their functionality are extracted from the design of the circuit boards together with the designer. For the (c) failure rates and (d) modes, the US Department of Defense Military Handbooks 217F and 338B [5] were consulted, which provide failure rates per component and their failure mode allocation, respectively. In the cases where the component manufacturers provided failure rates from accelerated tests, these were used instead. The identification of (e) the components' impact on the module together with (f) the diagnostic abilities of the system is an iterative process together with the system designer in order to reach a satisfactory level of protection. An overview of the inputs and outputs of an FMEDA is seen in Fig. 3. It should be clarified that this process typically brings system flaws into light already at the first iterations and the system design itself is improved continuously throughout the FMEDA steps. Where applicable, the diagnostic coverage

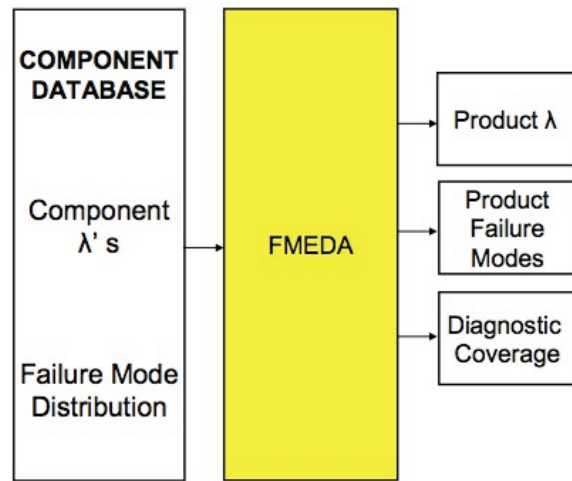

Figure 3: FMEDA inputs and outputs. Source: [6]

of the system can be enhanced in order to foresee and mitigate hazards before they cause the system to fail, as is seen in Fig. 3 where it is displayed as an output of the FMEDA.

From steps (a) through (f) above, the overall failure rates for the four different BIS modules are obtained, and these rates are then used in a system-level analysis using BlockSim. Four failure modes were identified as having impact on the system design and to be dealt with, being (in order of criticality) **Blind**, **Trip**, **Maintenance**, and **Negligible**. **Blind** means a blind failure where the system is unable to mitigate a hazard, **Trip** is a false trip where the beam permit is withdrawn erroneously, **Maintenance** means that the system can continue to operate under marginal protection but the component needs to be maintained “as quickly as possible”, and **Negligible** means that the failure mode has no apparent effect on the system.

The diagnostic ability (f) was also divided into four different modes, being related to the failure modes and using the same color code. This way, one can easily get an overview of a failure mode's ability to be mitigated by the system's design and find possible flaws by quickly scrolling through the FMEDA spreadsheets. The diagnostic abilities are **Test**, **Diagnostics**, **Inspection**, and **Hidden**. Here, the **Test** is an internal test loop that checks the beam permit signal paths for faulty components, **Diagnostics** is the built-in diagnostic feature in the circuits able to detect anomalies in components, **Inspection** means that personnel has to go and inspect the component, and **Hidden** means that the error can not be seen without rigorous demounting and troubleshooting.

Reliability Block Diagrams

BlockSim allows for RBD or Fault Tree Analysis (FTA) approaches to be used for complex systems, in order to analyze reliability measures through both analytical computation and simulation. The BIS was modeled with RBDs to resemble the system behavior. Each module type received its failure rates through the FMEDA described above. As each block in the software

can only represent one failure mode, one system setup was created for each of the four failure modes. By altering the connections and number of input signals per module, it was possible to analyze different designs for optimum performance of the system. The system was analyzed for no redundancy at all, redundant links (as is the current design choice) and for a 2-out-of-3 voting design throughout the system (not included in this paper).

THE ESS AVAILABILITY GOALS

ESS aims for unprecedented beam availability for neutron production, which places high demands on all systems involved. The BIS is the central system in avoiding major damage to the beam pipe and surrounding equipment, which causes long downtimes, and needs to avoid false beam trips, which cause short beam trips and unnecessary downtime. This demands an almost fault-free system that always premieres stopping the beam over a hazard of damaging equipment.

Protection Integrity Levels

The IEC61508 standard [7] includes so-called Safety Integrity Levels (SIL) that define the level of which a certain Safety Function (SF) reduces the probability of a safety hazard. These concepts are both applicable and manageable in the ESS MP work, but as MP only uses the standard to a fractural extent and is mission critical rather than safety critical, the concepts are modified to fit the needs and processes of the MP development work. As MP deals with protection, the Protection Integrity Levels (PIL) are introduced together with Protection Functions (PF) that play the same role as their safety counterparts in the analysis [8].

The PF for avoiding **Blind** failures at ESS needs to reduce the failure rate to 10^{-6} per hour, or the equivalent of once in 114 years. This failure rate has then been allocated to three different major systems: the sensors, the BIS, and the actuators. The sensors are expected to contribute with 35%, the BIS with 15% and the actuators with 50% to the overall PF. That leads to a **Blind** failure rate requirement for the BIS of $1.5 \cdot 10^{-7}$. The BIS then has to be designed to reach this hardware failure rate [1].

As stopping the proton beam does not introduce any potential for damage, the false **Trip** rate is related to the overall ESS reliability and availability requirements [9] and its determination lies outside the scope of this paper. In general, however, one can find that the **Trip** rate is increased as the **Blind** rate is decreased, as the two are opposites in the realm of MP.

ANALYSIS RESULTS

Analysis Assumptions

The analysis was carried out assuming only hardware failures with 12 input signals per rack enclosure and 24 rack enclosures, giving a total of 288 signals and the same number of FBI_D and FBI_DIF. Each enclosure also has one redundant FBI_M pair and there is one redundant pair

of MoMs, adding up to a total of 50 FBI_M. Finally, there are 3 FBI_A, one for each actuator.

Further, it is assumed that all actuators must trigger a beam stop signal and are thus modeled in series. Two prototype designs were considered, named Prototype 0.1 and 0.2. There were two simulations run for each prototype, one without redundant links and one with redundancy.

The component environment is taken to be at 40°C and 45-60% humidity to avoid corrosion, condensation, and static electricity build-up. The components are considered to be mounted in a fixed rack configuration.

Results

Fig. 4 shows the analysis results for the four setups. The bars are explained in the caption of the figure. A non-redundant system does not reach the required failure rate and needs further redesign. In this analysis, a redundant system was considered, which does still not reach the requirement for the initial design, but does so for the second prototype design.

Figure 4: False trip (orange) and blind (red) failure rates for four different BIS designs. From left to right: Prototype 0.1 without redundancy, Prototype 0.2 without redundancy, Prototype 0.1 with redundancy, and Prototype 0.2 with redundancy.

BIS Design Features and Changes

While the current BIS design contains redundant links throughout the system, the option of a 2-out-of-3 voting system was analyzed. However, this also brings a cost issue into the design, as the component costs would increase by 50%. The FBI_Ms also have the ability to mask certain input signals, meaning that specific signals can be completely ignored for a predefined time. While this can increase system reliability in the case of certain components sending spurious signals to remove beam permit, there is also an associated risk with making certain inputs blind that has not yet been analyzed.

The iterative FMEDA process highlighted the weakest links in the BIS layout, being the FBI_A. These modules were a main cause of system-level **Blind** failures and the redesign of the system lead to intra-module redundancy that removed the **Blind** failures. A similar approach was carried out for the FBI_M where the **Blind** failure rate

was drastically decreased. The schematics were also separated into different parts separating for example permit signals from test loops and diagnostics. This gave a better overview of the system as a whole and allowed for more efficient troubleshooting.

It should be clarified that the analysis in this paper only considers hardware failures in the BIS. How surrounding equipment, software and firmware, and configuration failures affect the system are not part of the analysis. The same goes for the potential for failures associated with masking. As testing and fault injection are still to be performed for the BIS, the results described here should be viewed as theoretical on the conceptual design level.

EXTENSION TO OTHER SYSTEMS

The analysis performed in this paper is developed in a generic way and is not system-specific. This way, the FMEDA can be extended to other systems at ESS and at other facilities. The intension is to widen the analysis to include all the systems that feed signals into the BIS (purple boxes in Fig. 1 and 2) and the actuators (brown box in Fig. 1 and 2). This way, one would be able to determine the overall reliability from a signal, e.g. a beam loss, to the action of stopping the beam. This plays a central role in fulfilling the ESS reliability and availability goals and pinpoints the weak links that need to be improved further in the signal chain.

CONCLUSIONS

The development and actualization of the FMEDA together with the system-level RBD analysis of the BIS at ESS described in this paper have allowed for important design improvements throughout the iterative process. These improvements are fundamental to reach the high reliability and availability goals of ESS. It is important to note that these studies should be done at an as early stage as possible in the design process of the system, to avoid expensive and cumbersome changes last minute or even during operation.

The results show how a hardware failure rate of $1.5 \cdot 10^{-7}$ for the BIS can be achieved for **Blind** failures on a system level, at the same time as reliability is kept at a manageable level. By introducing a BIS with redundant links for the entire signal chain, the hardware failure rate requirement is reached without the need to introduce more expensive system designs.

ACKNOWLEDGEMENTS

We would like to thank Christian Hilbes and the Safety Critical Systems Research Team at ZHAW in Zürich,

Switzerland for their contribution in the concept design of the Machine Protection at ESS. The analysis in this paper is greatly influenced by the similar study done at CERN, and therefore we want to thank Benjamin Todd, William Viganò, and the Beam Instrumentation Group there. Lastly, the University of Oslo has been of great support academically and financially for the work described in this paper.

UNDERSTANDING THE FAILURE CHARACTERISTICS OF THE BEAM PERMIT SYSTEM OF RHIC AT BNL*

P. Chitnis[#], T.G. Robertazzi, Stony Brook University, NY, USA
K. A. Brown, Brookhaven National Laboratory, NY, USA

Abstract

The RHIC Beam Permit System (BPS) monitors the anomalies occurring in the collider and restores the machine to a safe state upon fault detection. The reliability of the BPS thus directly impacts RHIC availability. An analytical multistate reliability model of the BPS has been developed to understand the failure development and propagation over store length variation. BPS has a modular structure. The individual modules have joint survival distributions defined by competing risks with exponential lifetimes. Modules differ in functionality and input response. The overall complex behavior of the system is analyzed by first principles for different failure/success states of the system. The model structure changes according to the type of scenario. The analytical model yields the marginal survival distribution for each scenario versus different store lengths. Analysis of structural importance and interdependencies of modules is also examined. A former Monte Carlo model [1] is used for the verification of the analytical model for a certain store length. This work is next step towards building knowledge base for eRHIC design by understanding finer failure characteristics of the BPS.

INTRODUCTION

The Beam Permit System (BPS) of Relativistic Heavy Ion Collider (RHIC) plays a key role in safeguarding against the developing faults in the collider. The energy stored in RHIC is about 2MJ in particle beams and 70 MJ in the form of magnet currents. Any abnormality in the machine can cause an undesirable escape of this energy, which can result into machine damage. BPS senses the onset of failures by monitoring the health inputs from RHIC support systems like power supplies, cryogenics, beam loss monitors, access controls, quench detection, vacuum system etc. In case of anomaly, it directs this energy out the machine for safe disposal.

RHIC reliability is directly dependent on the BPS reliability. Thus it is essential for the BPS to be highly reliable, being a safety critical system. Earlier a Monte Carlo (MC) model [1] was developed to quantify the probability of system level catastrophic events. This model simulated the behavior of modules with exponential competing failures. The module level failures were calculated by a quantitative fault tree analysis [2].

The MC model simulated the failure characteristics of the BPS for a certain store length. Also as the simulation

takes about 17 hours to run 1E9 iterations to generate reproducible results. It generated probabilities of system level failures for a particular store length. This paper is aimed towards developing a model that generates the system failure probabilities as a function of store length. We develop an analytical model of the BPS behavior using stochastic mathematics for this purpose.

RHIC BEAM PERMIT SYSTEM

The BPS has a modular structure that consists of 33 Permit Modules (PM) and 4 Abort Kicker Modules (AKM). These modules are connected by three fiber-optic links that run 10MHz carrier links whose presence signifies that the system is healthy. These links are called the Permit Link (PL), Blue Link (BL) and Yellow Link (YL). The PMs collect support systems' health inputs from the field, called Permit Inputs (PI) and Quench Inputs (QI). The PM takes decision to drop the carrier, indicating a failure. When there is a magnet system failure, QI goes bad, and all the three links are dropped. In case of any other failure PI goes bad and only the permit link is dropped. The carrier drop propagates to all the modules, resulting respectively in magnet power +beam dump and a beam dump only. The AKMs send the beam dump signal to the beam abort system. They have redundancy incorporated. For more details of BPS refer to [3]. Figure 1 shows the BPS configuration.

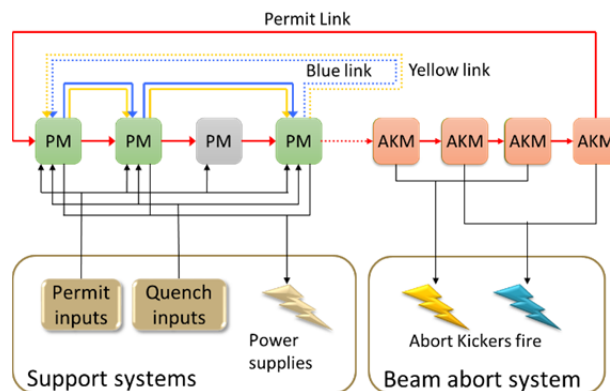

Figure 1: BPS connection diagram.

SURVIVAL DISTRIBUTION

The PMs and AKMs have been analysed for their failure modes in [2]. The top level failure of BPS depends upon the states of the PMs and AKMs. The calculation

*Work supported by Brookhaven Science Associates, LLC under Contract No. DE-SC0012704 with the U.S. Department of Energy.
#prachi.chitnis@stonybrook.edu

showed that the top level failures of the modules have exponential survival distribution, which is characterized by a constant hazard function λ . Modules can have these failure states, False Beam Abort (F), a False Quench (M), Blind (B) and Dirty Dump (D), with failure rates as λ_F , λ_M , λ_B and λ_D resp. The PMs have $\{F, M, B\}$ or $\{F, B\}$ failure modes (green PM and grey PM resp. in Fig. 1). The AKMs have $\{F, M, D\}$. The inputs PI and QI are modelled as Poisson variable with exponential trigger rate as λ_{PI} and λ_{QI} . The initial state is a Good (G) state, where the module performs its intended function properly. The Markov diagrams for states is shown in Fig. 2.

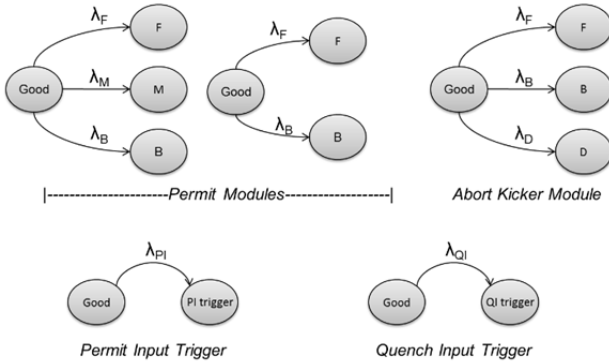

Figure 2: Markov diagrams

A competing risks model with crude lifetimes [1, 4] is implemented here, where multiple risks compete with each other to cause a final failure. Mathematically if a module is subjected to $j = \{1, 2, \dots, k\}$ risks, where $j = \{F, M, B\}$ for PMs, and $j = \{F, B, D\}$ for AKMs. The crude probability distribution function of risk j is given by

$$F_j(t) = \frac{\lambda_j}{\sum_{i=1}^k \lambda_i} \left(1 - e^{-(\sum_{i=1}^k \lambda_i)t}\right); j = \{1, 2, \dots, k\}$$

The marginal hazard rate for j^{th} risk is λ_j and t is the time of observation or the beam store length. The survival function for the module undergoing competing risks is given by

$$S_T(t) = e^{-(\sum_{i=1}^k \lambda_i)t}$$

At any given instant for a module, following expression is always true

$$S_T(t) + \sum_{j=1}^k F_j(t) = 1 \quad (1)$$

ANALYTICAL MODEL

The BPS has a ring configuration. A trigger arrival at a module initiates a carrier failure, which returns back to it after traversing all the modules in the system. The functionality of BPS that affects the reliability is to abort the beams and dump the magnet power upon trigger arrival. We thus cut out this ring configuration to a linear structure, with inputs and outputs. The start of this structure is the master module [3] and the end is the AKMs that abort the beam. We approach the problem of developing math-

ematical equations for system states by looking at the states of each module in this system (Fig. 2). These states are of two kind: trigger state that initiates carrier failure (F, M) and passive state where a module waits in that state for a trigger (B, D, G). PI and QI are also the triggers to the system that initiate a carrier failure. For this reason we always use the failure density function $p(t)$ (instantaneous probability) for triggering state and failure distribution function $P(t)$ (probability that an event has occurred till now) for passive states to derive the expressions for the system level failures. For m^{th} module, and j^{th} triggering state where $j = \{F, M, PI, QI\}$

$$p_j^m(t) = \lambda_j e^{-(\sum_{i=1}^k \lambda_i)t}; P_j^m(t) = \int_0^t p_j^m(t) dt$$

For j^{th} passive failure state where $j = \{B, D\}$

$$P_j^m(t) = \frac{\lambda_j}{\sum_{i=1}^k \lambda_i} (1 - e^{-(\sum_{i=1}^k \lambda_i)t});$$

For passive good state

$$P_G^m(t) = e^{-(\sum_{i=1}^k \lambda_i)t}$$

Similar to Eq. 1, for a module m , at any given instant

$$P_G(t) + \sum_j (P_j^m(t)) = 1$$

Using above equations for modules' states, we further develop the analytical equations for the system states. BPS modules are connected by multiple links and some of the modules do not have blue/yellow link connected to them. We thus simplify the structure of BPS (shown in Fig. 1) for different type of system states. Also because AKM exhibit redundancy, we treat them as a separate entity that receive the signals from rest of the BPS. Consider the following configurations named I, II and III shown in Fig 3. Config. I shows the path of permit link triggers i.e. F and PI. Config. II shows the path of quench link triggers i.e. M and QI. Config. III shows the redundant configuration of the AKMs that signals the beam abort system to dump the beams.

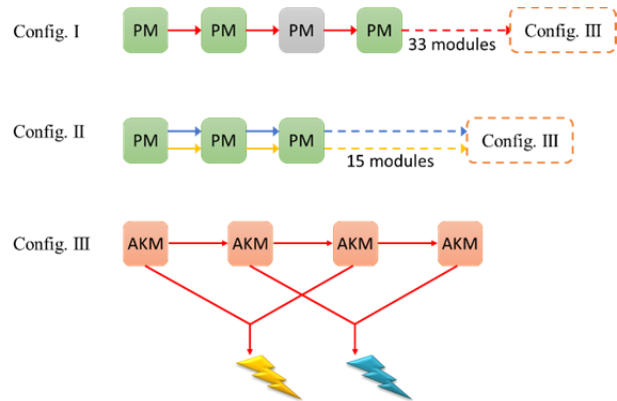

Figure 3: BPS connection diagram

To develop equations for system states, we consider the probability of each module and one by one traverse the path of carrier failure to beam abort system output. Because of the complexity and length of the expressions, we avoid writing them in this paper. However we explain the strategy that we chose to develop them. Following are the system states that can result from combinations of module states.

- ND: No Dump - No trigger generated in I, II and III
- GD: Good Dump - Trigger PI arrives in I, or QI arrives in II. No other triggers are generated anywhere else. Signal goes to the output of III, all modules in the forward path are in G state.
- FD: False Beam Abort Dump - Trigger F arrives in I or III. No other triggers are generated anywhere else. Signal goes to the output of III, all modules in the forward path are in G state.
- MD: False Magnet Quench Dump - Trigger M arrives in II. No other triggers are generated anywhere else. Signal goes to the output of III, all modules in the forward path are in G state.
- BD: Blind Dump - Trigger F/PI arrives in I, or M/QI arrives in II, or trigger F arrives in II. Signal does not to the outputs of III, at least one module in the forward path is in B state.
- DGD: Dirty Good Dump - Trigger PI arrives in I, or QI arrives in II. No other triggers are generated anywhere else. Signal goes the output of III, with at least one output passing through the D state of redundant AKMs.
- DFD: Dirty False Beam Abort Dump - Trigger F arrives in I or III. No other triggers are generated anywhere else. Signal goes the output of III, with at least one output passing through the D state of redundant AKMs.
- DMD: Dirty False Magnet Quench Dump - Trigger M arrives in II. No other triggers are generated anywhere else. Signal goes the output of III, with at least one output passing through the D state of redundant AKMs.

RESULTS

The expressions are solved in Mathematica [5] and the time dependent probabilities functions for each scenario are calculated. These probabilities are verified with the help of Monte Carlo simulation reported in [1]. The failure rates of the modules are obtained from [2]. Some of the module failure rates are very small, especially B and D, which reflect at system level failures. Also due to the AKM redundancy, the DGD, DFD and DMD failure probabilities are much smaller. The Monte Carlo simulation will need a large number of iterations to verify these results. Thus we first assign hypothetical failure rates to all the modules, with specific high failure rates for D mode to overcome the redundancy effect, and get substantial number of DGD, DFD and DMD states for the verification. Also we assume a hypothetical store length $t = 0.232$ hours. The Monte Carlo simulation is run for 2.4E9

iterations and takes about 40 hrs to generate results. The probability is expressed as the number of system scenario generated / total no of system runs. Table 1 compares these hypothetical results from the Monte Carlo and the analytical model (7 digit precision)

Table 1: Verification of the Analytical Model by Monte Carlo Results

Abbr.	Analytical	Monte Carlo
$P_{ND}(t)$	0.0149852	0.0149856
$P_{GD}(t)$	0.0621532	0.0621708
$P_{FD}(t)$	0.3105783	0.3105881
$P_{MD}(t)$	0.2494602	0.2494724
$P_{BD}(t)$	0.2754812	0.2754846
$P_{DGD}(t)$	0.0087564	0.0087507
$P_{DFD}(t)$	0.0406134	0.0406134
$P_{DMD}(t)$	0.0379719	0.0379183
Total (from model)	1.0000000	1.0000000

The individual probabilities of each scenario from the analytical model is very close to the probabilities obtained from the Monte Carlo. The exact sum of all the probabilities from the models is 1 as shown in the table. This verifies that the relative probability expressions for a model considers all possible states in which the BPS can go.

This establishes that the analytical model and the Monte Carlo model both are verified. Next we put the actual failure rates in the analytical model and obtain the actual failure probabilities of the all the system states, with the store length equal to 6 hrs as RHIC average store length.

$$\begin{aligned}
 P_{ND}(t) &= 0.143573 \\
 P_{GD}(t) &= 0.856193 \\
 P_{FD}(t) &= 0.000123713 \\
 P_{MD}(t) &= 0.000101377 \\
 P_{BD}(t) &= 7.74551 E - 6 \\
 P_{DGD}(t) &= 1.39145 E - 6 \\
 P_{DFD}(t) &= 1.99945 E - 10 \\
 P_{DMD}(t) &= 1.64755 E - 10
 \end{aligned}$$

Figure 4: Probability density for FD system failure.

Figures 4, 5 and 6 show the graphs for the probability densities of three important system level failures (FD, MD and BD) plotted as a function of store length. The probability values plotted above are cumulative values and can be calculated as the area under the curve up to a certain store length.

Figure 5: Probability density for MD system failure.

Figure 6: Probability density for BD system failure.

DISCUSSION

There are certain advantages of deducing the mathematical expressions for the probabilities of system level states. It facilitates quicker and easier analysis of the variation in system failure probabilities with change in component failure distributions or PI/QI trigger rates.

We utilize this to analyze the importance and interdependency of individual modules. The importance of the modules is evaluated as a combined effect of their failure rate magnitude and structural position. We analyze the three major system failure states, FD, MD and BD. The procedure is to increase the failure rates of F, M and B modes for each module one by one, and observing the change in the system failure probabilities, which is an

indicator of the importance of the module. To summarize this comprehensive analysis, we can say that a module's importance is highly dependent on its failure rate. Alongside structural placement also plays a key role in determining the importance. The modules which are in the path of propagation of multiple failures have higher importance. The nearer a module is to the abort system output, higher is its importance. This is because probability of it being bypassed in failure propagation is small. The AKMs have lower importance due to the redundancy incorporated. Components that are major contributors to higher failure rate are discussed in [2].

To assess the interdependency between the modules, the modules are ordered according to their importance. After this we increase the failure rate for the subsequent module pairs, and observe the increase in the system level failure probabilities. For no dependency, the system failure should have the same order for importance of modules for pairs [6]. We do not find any inter-dependency in the modules.

CONCLUSION

We develop a mathematical model for understanding the fine failure characteristics of the BPS. After the verification of this mathematical model through a MC model developed earlier, we are able to probe deeply into the failure probability distributions. This provides us with a faster way to analyze the system failures with change in system configuration. This model will provide a vision for the design of protection systems for the upcoming eRHIC project at BNL [7].

INTERLOCK SYSTEM FOR MACHINE PROTECTION AT THOMX ACCELERATOR

N. Elkamchi, P. Gauron, H. Monard, LAL, Orsay, France

Abstract

ThomX is a Compton based photons source. It aims to produce a compact and directional X-rays source, with high performance, high brightness and adjustable energy [1]. The principal application fields are medical sciences, social technology and industry. An interlock system has been implemented for machine protection, especially to protect sensitive and essential equipment (magnets, vacuum system, etc.) during machine operation. It will allow taking appropriate actions to minimize recovery time in case of operation problem. ThomX interlock system is based on Programmable Logic Controller (PLC-Siemens S7-1500) distributed over the machine subsystems, it collects default signals from the different equipment of the machine, up to the central PLC which kills the beam, by stopping the RF or the injection, in case of problem (bad vacuum, magnets overheating, etc.). Actually, the interlock system is under implementation in parallel with the assembly of the machine. It will allow accelerator to work safely, and increase the availability of the machine.

INTRODUCTION

ThomX is a compact light source project where the Compton Effect is used to produce X-rays. A circular accelerator is combined to a high power laser, amplified in an optical cavity, to obtain collisions between an electron beam and the light pulses.

The collision between electrons and photons induces a diffusion of photons in the electrons direction with a high energy gain. Thus, from a few eV photons it is possible to obtain "hard" X-ray (a few tens of keV) using a 50 MeV accelerator. The machine presents the advantage of a compact dimensions (70 m²) and low costs.

Figure 1: ThomX layout

Figure 1 shows the general layout of the machine. It is composed of four main systems: the injector, the storage ring, the laser and the Fabry-Pérot resonator.

The linac includes an electron RF photogun followed by an acceleration structure. The injection line consists of dipoles to steer the beam, quadrupoles and two diagnostic stations for energy spread measurements and beam characterization. The injection is performed by a septum and a fast kicker. [2].

The ring includes dipoles, quadrupoles, and sextupoles for chromatic corrections. An RF cavity is used to bunch the electrons and to perform a longitudinal feedback.

The potential applications of this type of machine are numerous, including medical sciences, social technology and industry. Through collaboration between different French laboratories and industrials, it will be possible to share the technological excellence that will allow ThomX to be one of the most efficient machines in the world.

INTERLOCK SYSTEM DESCRIPTION

Because of the high beam power and energies in accelerator, the risk of beam induced damage is significant [3]. An interlock system is then used to protect the very sensitive and essential equipments (BPMs, vacuum chambers and valves, magnets) during machine operation. The ThomX interlock system is based on industrial programmable logic controller (PLC Siemens S7-1500 [4]). It collects default signals from the different equipment of the machine up to the central PLC which shut down the beam, by stopping the RF or the injection, when some parameters drifts outside specifications (bad vacuum, magnets overheating, etc.).

The interlock system consists of two levels. The first one is a local process, whose role is to monitor the variations of different parameters of the machine equipments, and generates a default signal in case of operation problem. The second level is the central PLC, which gathers and processes all the default signals from subsystems, and stops the RF power in a very short time.

To measure the performance of an interlock machine, we are based on two major parameters: reliability which measures the probability of fulfilling the major design function of the system, continuously and without interruptions, for a predefined period of time. The other parameter is the availability which defines the probability to find the machine fulfilling its major design function, when it is claimed to be in operation [5].

These two parameters describe the aptitude of the interlock system to meet the security requirements and to avoid failures.

ARCHITECTURE OF THOMX INTERLOCK SYSTEM

The interlock system is based on PLC technology (Siemens S7-1500). Low level (process level) modules are distributed around accelerators subsystems (figure 2). They are connected together to the master controller (interlock level) that collects the defaults signal and stops the RF by a redundant wired signal. The PLC of the interlock level is connected via Ethernet to the control interface (Panorama [6]) for default monitoring and signals reset. The architecture of ThomX interlock system is shown in figure2.

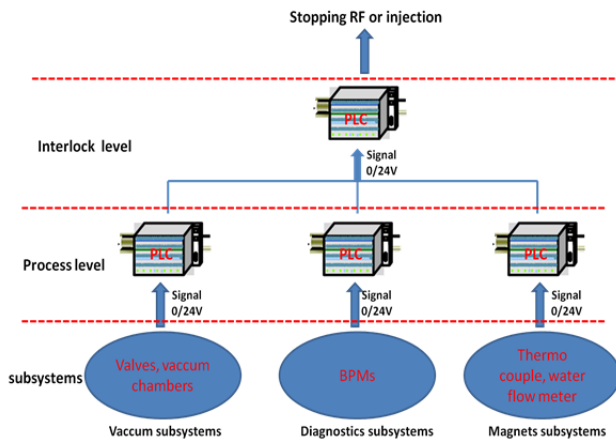

Figure 2: Interlock system architecture

The interlock system is designed basically to protect three sensitive area of the accelerator: magnets, BPMs and vacuum components.

Beam Position Interlock

A beam position monitor (BPM) allows detecting the beam position and assisting to maintain the beam path in beampipe axis. 17 BPM are distributed along the accelerator within 4 cells: storage ring cell 1 (6 BPMs), storage ring cell 2 (6 BPMs), Linac (1 BPM) and the transfer line (4 BPMs). All BPMs are driven by an electronic module (LIBERA [7]) which ensures signal acquisition and processing. Libera modules are connected to the process level PLC, it generate default signal when the parameters of the beam drift from specifications. The interlock signal is set within a millisecond whenever the electron beam position trespasses one of the predefined thresholds. This allows catching up the drift in short duration and avoiding damage to the machine. The BPM interlock is an essential security component that protects with confidence the machine from orbits shifts.

Magnet Interlock

The magnet interlock system (figure3) is designed to protect magnets from overheating in case of failure of powering or cooling systems. It switches off the power supplies in a minimum time, and sends an error message

to the control system to indicate the origin of failure. To ensure short time reaction, the magnet interlock system is a local process, and requires the intervention of a technician to rest the system in case of interlock outbreak.

The magnet security concern 12 dipoles distributed along three subsystems of the accelerator: 8 dipoles in the ring, 4 dipoles in the transfer line and 2 dipoles in the extraction line. To protect the dipoles from overheating, a set of thermocouples and water flow meters are installed in each dipole. when the threshold of the temperature or flow level is reached.

Figure 3: Architecture of magnet interlock

An electronic security box is connected to each dipole; it collects the information of water temperature and outflow and generates a default signal. The security boxes of each group are linked in series (figure 3). In case of problem of temperature or water flow on a magnet, one default signal is sent to stop automatically the power supply of the corresponding group with a maximum delay less than 1 second. However all the security boxes are linked to the interlock PLC to indicate the defective magnet and to stop beam operation if needed.

Vacuum Interlock

The main objective of the vacuum interlock is to protect the machine equipments in case of bad or very bad vacuum. This process stops the beam when the vacuum threshold is reached, and allows also checking the positions of valves before authorizing the beam emission. The accelerator beampipe is divided into several volumes bounded by automatic valves. Multiple ion pumps are installed on each volume. The pumps are connected in series and generate one interlock signal per volume when thresholds are reached for the corresponding volume. The vacuum thresholds are defined as follows: a normal vacuum/bad vacuum threshold around 10^{-7} mbar, and a very bad vacuum threshold corresponding to the disjunction of the ion pump power supply.

The vacuum security process is defined as follow:

- The bad vacuum (BV) threshold stops the beam emission; the operation of the modulator is locked to the threshold (BV) of the ion pump.
- The very bad vacuum (VBV) threshold of all ion pumps (between two valves) upstream and downstream of an automatic valve controls the closing of the valves. The valves can then only be opened after return of good vacuum of the relevant volume, and an open action from the control-command system.

The vacuum interlock system controls 28 default signals from the ion pumps, corresponding to two vacuum thresholds. It controls also the position of 11 automatic valves.

CONCLUSION

In this paper, we presented the operation principle and the architecture of ThomX interlock system, and its importance to avoid equipment damage. The system is actually under implementation in parallel with the assembly of ThomX machine. The future work includes the integration of the interlock system in the supervision interface of ThomX in order to unify the control tool and facilitate the default management. The test phase will start with the commissioning of ThomX, and will include essentially the verification of the response time and the reliability.

BUILDING AN INTERLOCK: COMPARISON OF TECHNOLOGIES FOR CONSTRUCTING SAFETY INTERLOCKS

T. Hakulinen, F. Havart, P. Ninin, F. Valentini
CERN, Geneva, Switzerland

Abstract

Interlocks are an important feature of both personnel and machine protection systems for mitigating risks inherent in operation of dangerous equipment. The purpose of an interlock is to secure specific equipment or entire systems under well defined conditions in order to prevent accidents from happening. Depending on specific requirements for the level of reliability, availability, speed, and cost of the interlock, various technologies are available. We discuss different approaches, in particular in the context of personnel safety systems, which have been built or tested at CERN during the last few years. Technologies discussed include examples of programmable devices, PLCs and FPGAs, as well as wired logic based on relays and special logic cards.

INTRODUCTION

There are three basic types of components in safety systems: *sensors* for collecting data on any measurable conditions important for safety, *actuators* for manipulating equipment important for safety when necessary, and *interlocks*, for computing the safety logic between the two. Sensors and actuators are always particular to the application in question, that is, the conditions to be surveyed and actions to be taken are different in each case. However, an interlock is just a unit for processing of logical information, and the technological choices for its implementation have usually more to do with requirements of overall throughput, reliability, cost, or technological diversity as mandated by principles of safety system design.

Safety interlocks are considered critical components that are subject to careful implementation and certification. International standards, such as IEC 61508 and 61511 for process industry, and IEC 61513 [1] for nuclear industry are often used in the design of entire safety systems, including the interlock. IEC 61508 and 61511 use the concept of safety integrity level (SIL) to quantify the required level of reliability of the safety system in its safety function as well as the ability of the system components to satisfy that requirement.

CERN GS/ASE group is responsible for all personnel safety systems, access control systems, and personnel safety alarm systems at CERN. We have a long experience of designing, building, and operating different personnel safety systems for CERN accelerators and experiments. Over the years, different approaches have been used for building interlocks for these systems, and this

has given us some insight into the relative merits of the various technological choices. The technologies discussed in this paper are programmable logic controllers (PLCs), relay-based logic, wired logic with dedicated logic cards, and field-programmable gate arrays (FPGAs) with the examples based on actual implemented equipment.

PLC

Programmable logic controllers (PLCs) are the mainstay of modern process control applications. A PLC operates in a cyclic manner: during one cycle all inputs are collected, a new system state is computed in the CPU according to the program logic, and all outputs are set correspondingly. Cycle times of PLCs vary normally from a few to hundreds of milliseconds depending on the number of I/Os and the complexity of the program. I/Os are normally handled by separate modules, which can be placed some distance away from the CPU when connected via copper or fiber-optic cabling using a specific fieldbus protocol such as Profibus or Profinet [2]. Modern PLCs are also able to communicate via standard TCP/IP protocols via Ethernet, facilitating long-distance supervision of these systems. Special Supervisory Control and Data Acquisition (SCADA) systems are often used to integrate PLCs into a larger control framework.

Several manufacturers offer safety-related components certified for use in SIL-rated systems [3,4]. As a PLC-based system cannot be certified higher than SIL 3 (according to the standard, no system containing program code can be at SIL 4), that is normally the highest level of certification for the safety-related components as well. Some PLCs are able to integrate safety and non-safety-related programs and components within a single system, making communication between the two parts seamless.

At CERN, various generations of Siemens PLCs (S5, S7) are used in our personnel safety systems: LHC Access Safety System (LASS) [5], PS Access Safety System (PASS) [6], SPS Personnel Protection System, SPS Primary Ion Interlock [7]. This technology is fully mastered at CERN, and Siemens product life cycles are long allowing for a long utilization of installed hardware. Logic modifications and testing of PLC systems is fairly easy thanks largely to an integrated programming environment. Furthermore, PLC safety signatures provide a safeguard against unauthorized modifications of PLC code.

However, there are also drawbacks to PLC technology: For a large system, powerful CPUs are often needed to manage the logic coupled with sophisticated SCADA

systems, which can get quite expensive in hardware and license costs. Also, the entire system environment can get fairly complicated, where considerable expertise is required to manage different generations of hardware, firmware, and software for everything to work correctly together. Upgrading any of the system components, including patching firmware and software even for security reasons can be a complicated and risky affair, which will almost inevitably incur a period of unavailability of the entire system. Furthermore, changing safety system components in any way normally triggers a full suite of validation tests by the responsible safety officer, often requiring days to prepare and carry out, which further limits the usefulness of the otherwise easy programmability of PLC systems in production environments. Figure 1 shows one of PASS PLCs with its I/O modules.

Figure 1: Siemens S7 400 series CPU with ET200 remote I/O modules.

RELAY-BASED LOGIC

Possibly the oldest and still a highly relevant method of building reliable hard-wired logic systems is to use relays. All basic logic gates can be implemented in simple relays with hardwired connections. An example of a relay-based AND-gate is shown in Figure 2.

Implementation of a relay-based interlock is quite straightforward: standard electrical wiring, connectors, and relays are installed in a rack. Special safety relays are often used, which have high MTBFs and known fail-safe states. Generally relay-based systems are quite resistant to external disturbances, with the exception of high magnetic fields in rare cases, which can cause a magnetic relay to misbehave. Also any competent electrician is able to understand, maintain, and modify such a system based on simple circuit diagrams.

Figure 2: A relay-based AND-gate. A and B are the inputs, C is the output, and V is a constant voltage.

However, relay-based systems have several serious drawbacks compared to more modern approaches: Relay-based systems are bulky requiring plenty of rack space even for a small amount of logic, which limits the practical complexity of the application. Safety relays are expensive and implementation of the system is quite labour intensive. If supervision of interlock functions is required, extra logic needs to be implemented. Modifying the interlock logic can also obviously get quite hard.

As a relay-based system is necessarily built and designed in-house, its certification at a specific SIL-rating, if required, could be difficult requiring a calculation based on the individual SIL-rated components. Relays themselves may exhibit wear and tear over time: contact issues due to oxidation, sulphurisation, or arcing may happen. The upside is that in such a case, changing the defective component is relatively easy.

Relays are also not suitable for applications, where the switching frequency is high, since normal mechanical relays are typically only rated for around 1-2 million switches during their lifetime. Also, switching time of a mechanical relay is somewhere between 0.1-10ms and a certain resolution time is in any case required for the state change due to effects like contact bounce. Using solid-state relays could help in these cases, though.

Figure 3: Hardwired relay-based logic using relays. Green LEDs indicate contact states.

For these reasons, relay-based systems are realistically only suitable for fairly straightforward and small-scale logic. At CERN, they have mainly been used to build redundant chains of the most important safety functions of the LHC and PS access safety systems. Figure 3 shows part of the relay logic installed in the PASS cabled loop rack.

DEDICATED LOGIC CARDS

Another way of constructing a hard-wired interlock is by using dedicated electronic logic cards such as HIMA Planar4 series [4]. Logic gates are implemented in standard modular sub-rack-mounted cards and interconnections between these gates are realized by wiring the card inputs and outputs on the sub-rack backplane either by soldering or wrapping. A faulty card can easily be exchanged without having to touch the logic at all.

These kinds of systems can be used to build the highest rated safety systems. Most components of the Planar4 series are certified for use in SIL 4 systems, and consequently, they are often used in people transport systems or for critical process safety at chemical plants, oil rigs, and the like. Various I/O modules based on relays or line-monitored connections are available, and all gates in the sub-rack can be supervised by dedicated communication modules offering Profibus, Modbus, or OPC connectivity to an outside PLC or supervision post. Figure 4 shows the modules of the wired chain of CERN SPS North Area primary ion interlock [7] designed using HIMA Planar4.

Figure 4: Planar4 wired logic in a 19-inch sub-rack. From the left: fuse module, two timing modules, logic modules, and far right a Profibus supervision module.

One of the drawbacks of this technology is that due to a safety-related design and the additional diagnostic functions on each card, switching times are relatively long for active gates (AND, NOT), ranging from 2-15ms depending on the case (see Figure 5). Therefore, complicated logic may introduce a considerable delay of up to tens or hundreds of milliseconds. This may not be a problem in most applications, but should it be necessary to optimize this, careful design is required. For example, by application of De Morgan's theorem it is usually possible to construct the logic by using primarily OR-gates, which incur no internal processing delay. The HIMA wired chain of the SPS North Area primary ion interlock was designed this way [7]. The downside of this approach is that the logic becomes harder to understand from the diagrams.

HIMA provides logic cards for the basic logic operations as well as a variety of I/O options. However, any more complicated logic components, such as latches, flip-flops, etc. would have to be constructed from the basic gates. HIMA also does not provide 2-channel complementary (ambivalent) I/O, for which logic would also have to be custom built, if needed. As the logic programming is carried out with a soldering iron or a wrapper, changing this logic is not straightforward. Even small modifications may require unsoldering of a considerable number of connections to gain access, which is obviously both time consuming and error prone.

Figure 5: HIMA Planar4 AND-gate. E1 and E1 are the inputs and A is the output. The internal design is based on dynamic signaling driven by signal generator G. A simultaneous failure of up to three separate components leads to the output being de-energized. Compared to Figure 2, the added complexity due to safety-related design is clear.

FPGA

Designs requiring very fast logic processing have since long time used Application Specific Integrated Circuits (ASIC) or Field Programmable Gate Arrays (FPGA). An FPGA is an integrated circuit that can be programmed at the gate level to perform desired operations. In contrast to an ASIC, an FPGA can be reprogrammed in field if necessary. Both ASICs and FPGAs can be designed using a specific hardware description language (HDL). FPGA system vendors often also provide block-based graphical programming environments as well as bindings to conventional programming languages, like C. A schematic program is compiled into an array of gates on the circuit, which will realize the desired logic.

The great advantage of FPGAs over general-purpose computers and PLCs is speed. Response times of implemented functions can be in the nanosecond range, obviously depending on their complexity. Testing and modifying logic is as easy as reprogramming a PLC.

FPGAs are normally run within an integrated framework, such as National Instruments cRIO 903x series [8], where the FPGA is controlled by a real-time RT-Linux system, providing connectivity to network and peripherals similar to a normal PC. The FPGA connects directly to its own I/O modules, of which there are many available for different applications. Supervision of the system is easily implemented via the RT-Linux unit.

Table 1: Comparison of Some of the Most Important Metrics Between the Different Interlock Technologies

	Certification	Time scale	Communication	Supervision	Logic changes	Logic implementation	Space requirements	Scalability
PLC	Up to SIL 3	ms	TCP/IP Profibus	SCADA Custom	Easy	Programming	Medium	Good Large scale
Relay logic	None	ms	Wired	Custom	Hard	Manual Hard-wired	High	Limited Small scale
Logic cards	Up to SIL 4	ms	TCP/IP Profibus	SCADA Custom	Hard	Manual Hard-wired	Medium	Limited Medium scale
FPGA	None yet	ns	TCP/IP Profibus	SCADA Custom	Easy	Programming	Small	Good Large scale

The most important drawbacks when considering FPGA-based solutions for safety systems is that they are usually not safety-related by design in the same way as safety PLC systems or HIMA logic cards. While calculations can be made based on the published MTBFs of individual system components, modules explicitly certified for use in SIL-rated systems have not been available. However, this is likely to change in the future, as vendors will be introducing safety-related modules for their systems.

At CERN, a pilot implementation of a small independent safety interlock using a National Instruments FPGA is being studied [9]. One of the aims of this project is to gain experience and confidence in the technology as well as to test the auxiliary functionality provided by the RT-Linux system in running related access control functions, badge readers, touch panels, etc. The test bench FPGA system of this project is shown in Figure 6.

Figure 6: National Instruments cRIO 9030 FPGA controller test bench. The RT-Linux unit is on the left with Ethernet, serial, USB, and video connections. The FPGA unit is on the right with four I/O modules, of which two connected. Each I/O module of this type hosts 32 digital signals.

CONCLUSIONS

We have compared four different technologies for constructing safety interlocks based on our return of experience over years in designing safety systems. The technol-

ogies compared were PLCs, relay-based logic, dedicated logic cards, and FPGAs. All of them have their pros and cons and, indeed, depending on the application, their proper place in the toolbox of an interlock builder: When strictly SIL-certified systems following norms IEC 61508 and 61511 are required, PLCs or dedicated logic cards remain the preferred choices. However, for building diverse and redundant safety systems following norm IEC 61513, relay-based logic and FPGAs can also be very useful. Table 1 presents a synthesis of some of the most important performance metrics potentially affecting the choice of technology for a new interlock system.

DESIGN OF FAST MACHINE PROTECTION SYSTEM FOR THE C-ADS INJECTION I

Fang Liu, Jun Hu, XiaoShan Jiang, Qiang Ye, IHEP, Beijing, China
Guanghua Gong, Tsinghua University, Beijing, China

Abstract

In this paper a new fast machine protection system is proposed. This system is designed for the injection I of C-ADS which fault reaction time requires less than 20 us, and the one minute down time requires less than 7 times in a whole year. The system consist of one highly reliable control network based on a control board and some front IO sub-boards, and one nanosecond precision timing system using white rabbit protocol. The control board and front IO sub-board are redundant separately. The structure of the communication network is a combination structure of star and tree types which using the 2.5 GHz optical fiber links the all nodes. This paper pioneered the use of nanosecond timing system based on the white rabbit protocol to determine the time and sequence of each system failure. Another advantage of the design is that it uses standard FMC and an easy extension structure which made the design is easy to use in a large accelerator.

make a quick decision on the current failure. When a general failure, the system needs to quickly adjust the system without stopping and set the working state to the normal mode. When a serious fault, it is necessary to quickly send out a signal and shutdown the whole system. The system also cans storage the statement before and after the fault. Through the storage of information the staff can quickly rule out the reason of occurrence failure [2].

FAST MACHINE PROTECTION SYSTEM FRAMEWORK

ADS fast protection system is composed of main control board, some front IO sub-boards, supervisory computer and one nanosecond precision timing system. The system framework is shown in Fig. 1.

Front IO sub-board monitors the 24V or 5V switch

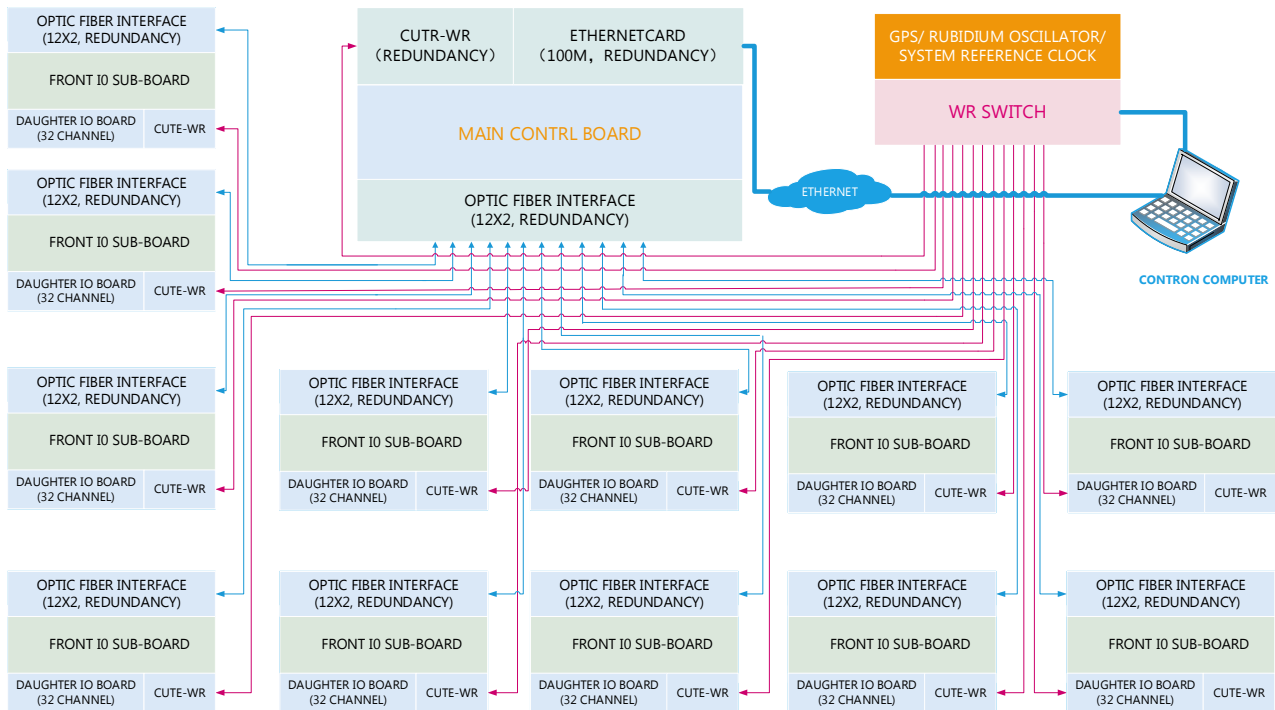

Figure 1: System Framework.

INTRODUCTION

The injection I of ADS (Accelerator Driven Sub-critical System) is being constructed in institute of high energy physics, China [1]. How to ensure the safe and stable operation of the injection, the fast protection system has played a crucial role. The protection system needs to

signal from the LLRF, PS, Vacuum, RFQ and other critical points. When the monitored points occur error, it sends the error signal to the main control board through optical fiber. The signal contains the time information that is labelled by the White Rabbit system. The main control board analyses and judgments the error through the stored fault tree. Then, it issued the processing results to the front IO sub-boards. Meanwhile, the main control board

record the error, process the result and send it to the supervisory computer.

The whole fault reaction time requires less than 20us, including the monitor reaction time, transmission time and processing time.

The framework of the network is a star and tree combination structure. A main control board can control 12 block IO sub-board, and an IO sub-board can manage 32 inputs and 32 outputs separately. It will form a 384 nodes network. The framework shows in Fig. 2. When we need a greater network, we can link tow showed network (Fig.2 showed). It can reach 4068 nodes. If we want to a much bigger one, we can cascade again. So it is very suitable for Multi-node large accelerator. Another advantage of the framework is it save the signal transition time cost in each node. It just need through three nodes from one node to another node.

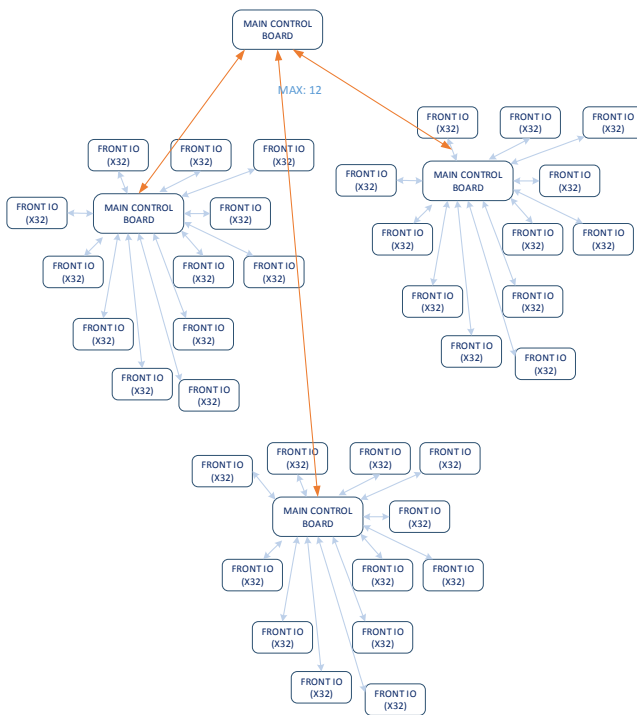

Figure 2: Network framework.

FRONT IO SUB-BOARD

The front IO sub-board use a 2.5 U box, each board can be placed independently. The input voltage is 220V alternating current. The Fig. 3 is a schematic diagram of the front IO sub-board. The front IO sub-board uses the motherboard and daughterboard design. The motherboard is responsible for power processing, logical processing, cache and data transmission. The daughter board is responsible for the acquisition and transmission of the front-end switch quantity.

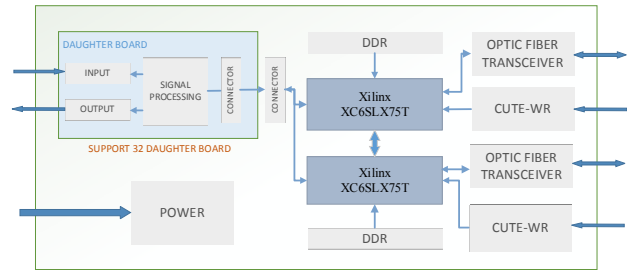

Figure 3: Schematic diagram of the front IO sub-board.

Mother Board

The mother board uses XC6SLX75T-3FGG676I FPGA as the main processor, and communicates with 32 daughterboard through 32 cables. We use the embedded Rocket IO module in FPGA to implement the optic fiber transceiver [3]. The transmission protocol is Aurora 8B/10B. The line rate is 2.5 Gbps. FPGA logic is responsible for the packing and unpacking of parallel data. At the same time, the FMC interface is used to connect the White Rabbit's timing system. And the DDR2 1 GB is used to cache the data.

In order to improve the reliability, the motherboard uses the method of watchdog, redundancy FPGA, DDR and optic fiber transceivers. The reliability of transmission between motherboard and daughterboard is guaranteed by the link showed in Fig. 4. Normal work, the master FPGA on motherboard receive data from 4 and send data to daughterboard from 3, the slave FPGA will also receive the same data from the daughterboard through 7 as a copy one and receive the feedback data from daughterboard through 8 as the verification of the master FPGA send data success. At the same time, the master and slave FPGA will check the work status for each other, and timely send control state to the back-end processing module.

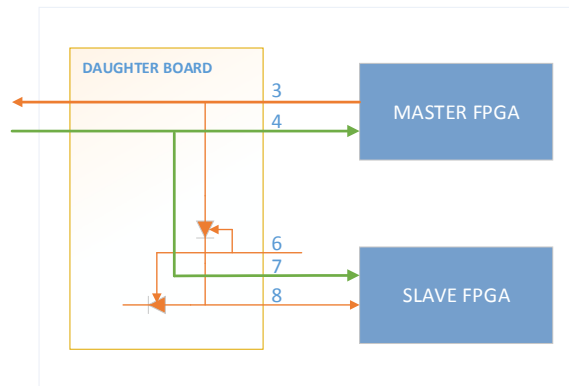

Figure 4: The link between motherboard and daughterboard.

Daughter Board

In order to ensure the link between the fast protection system and monitored system, we design three type boards: 24V optocoupler isolation board, 5V optocoupler isolation board and optical transmission board. The line

rate of each board requires not less than 3Mbps. The board logic is defined as follows:

- **24V optocoupler isolation board:** level greater than 12V as normal, as the error level is less than 5V.
- **5V optocoupler isolation board:** level greater than 3.5V as normal, as the error level is less than 0.8V.
- **Optical transmission board:** according to the optical fiber signal definition "1" as normal, "0" as an error.

The 24V optocoupler isolation board uses TND316S chip as a driver, the 5V optocoupler isolation board uses SN54AC245. The optocoupler chip is FOD8001. The fiber optical transmitter uses HFBR-1414TZ and HFBR-2412TZ. When the signal is transmitted over a long distance or high voltage, the signal will be transmitted through the optical fiber.

MAIN CONTROL BOARD

The main board also use a 2.5U box. The function is receiving data from front IO sub-board, judging and processing the data, sending control command and storing system useful information. The Fig. 5 is a schematic diagram of the main control board.

The main control board uses Xilinx XC6VLX240T FPGA. The board can receives 12 channel signals from the front IO sub-board. It will complete the monitor, analysis, packing and feedback in the FPGA. The status log information will regularly sent to upper computer by a 100Mbps Ethernet sub-card using a FMC interface.

The types of optic fiber transceiver, the transmission protocol, DDR, White Rabbit module are all as same as the front IO sub-board.

In order to improve the reliability, the main control board also uses redundancy design including FPGA, optic fiber transceiver, Ethernet and White Rabbit. The double FPGA will timely check the status of each other. The status includes voltage and temperature information, the current FPGA state and the logic confirm. When we detect the master FPGA in an abnormal mode, the slave FPGA will automatically take over the function of the master FPGA and report the error.

WHITE RABBIT SYSTEM

The White Rabbit timing system is a less than 1ns accuracy, 10ps precision and suitable for long-distance

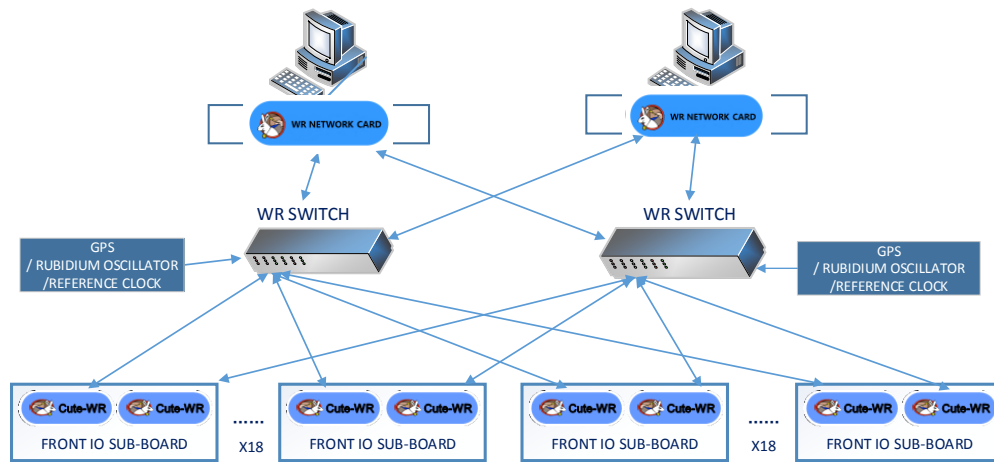

Figure 6: Framework of White Rabbit timing system.

Figure 5: Schematic diagram of the main control board.

transmission timing system. It can receive GPS, rubidium oscillator and reference clock signal [4]. The framework of ADS injection I White Rabbit timing system is shown in Fig. 6.

The network is mainly composed of a white rabbit switch, some front end Cute-WR modules and a white rabbit protocol network card that responsible for the linking to computer. According to the final construction requirement, the switch can choice GPS, rubidium oscillator or the accelerator timing reference clock. The Cute-WR module is the terminal module of the system. It can receive clock and time signal from the switch. A switch can link 18 Cute-WR modules. For this system, we use 13 Cute-WR modules, 12 of which are used in the link of 12 front IO sub-boards, and the other for main control board. The entire WR network uses backup design. It guaranteed the system reliability.

CONCLUSION

According to the reliability and safety requirements, this paper presents a new scheme of accelerator machine protection system. It can make the protection action time less than 20 us and it use sub-nanosecond timing system as the clock and time module, which make it possible to determine the errors occur time and the error sequence. And each node of the system is an independent and easy organized one. It made the system with good integration and scalability.

UPGRADE OF THE TRIGGER SYNCHRONISATION AND DISTRIBUTION SYSTEM OF THE BEAM DUMPING SYSTEM OF THE LARGE HADRON COLLIDER

N. Magnin, A. Antoine, E. Carlier, V. Chareyre, S. Gabourin, A. Patsouli, N. Voumard,
CERN, Geneva, Switzerland

Abstract

Various upgrades were performed on the Large Hadron Collider (LHC) Beam Dumping System (LBDS) during Long Shutdown 1 (LS1) at CERN, in particular to the Trigger Synchronisation and Distribution System (TSDS): A redundant direct connection from the LHC Beam Interlock System to the re-trigger lines of the LBDS was implemented, a fully redundant powering architecture was set up, and new Trigger Synchronisation Unit cards were deployed over two separate crates instead of one. These hardware changes implied the adaptation of the State Control and Surveillance System and an improvement of the monitoring and diagnosis systems, like the various Internal Post Operation Check (IPOC) systems that ensure that, after every beam dump event, the LBDS worked as expected and is ‘as good as new’ for the next LHC beam. This paper summarises the changes performed on the TSDS during LS1, highlights the upgrade of the IPOC systems and presents the problems encountered during the commissioning of TSDS before the LHC Run II.

INTRODUCTION

LHC Beam Dumping System

The Large Hadron Collider (LHC) Beam Dumping System (LBDS) is responsible for the single turn extraction of the beam from LHC rings, after reception of a Dump Request (DR). It is composed, for each beam, of 15 extraction kicker magnets (MKD) followed by 15 extraction septum magnets (MSD) to extract the beam from the ring, followed by 10 dilution kicker magnets (MKB) in the extraction channel to spread the beam over the dump target (TDE) surface [1].

Each MKD and MKB is powered by a High-Voltage Pulsed Generator (HVPG), to produce the fast high current pulse needed to extract and dilute the beam, upon reception of a trigger.

Trigger Synchronisation and Distribution System

Within the LBDS control architecture, the Trigger Synchronisation and Distribution System (TSDS) is responsible for the detection of a DR from various sources, the subsequent generation of a dump trigger synchronised with the beam-free abort gap of the LHC, and the distribution of this Synchronous Beam Dump Trigger (SBDT) to the 25 HVPG of the 15 MKD and 10 MKB [2]. The TSDS is built around a major component, the Trigger Synchronisation Unit (TSU), which detects the DR from sources like the Beam Interlock System (BIS) [3], the State Control and Surveillance System (SCSS) [4], the Beam Loss Monitor Direct Dump

(BLMDD), and issues a dump trigger synchronised with the Beam Revolution Frequency (BRF) signal [5].

The TSDS also includes an asynchronous Re-Triggering System (RTS) to cover the cases where the SBDT is not distributed properly, or when a MKD HVPG self-triggers [2].

During the LHC Run I operation, all beam dump requests were properly detected and distributed. Nevertheless some weaknesses of the TSDS were pointed out during various reviews and discussions, and a consolidation project was planned for Long Shutdown 1 (LS1).

Re-Trigger System Principle

The RTS is entirely passive and is composed of two redundant floating Re-Trigger Lines (RTL). A simplified view of one RTL is shown in Fig. 1. The 25 HVPG are interconnected by a chain of Re-Trigger Boxes (RTB), connected serially using a twisted pair cable. These RTB are composed of simple insulation transformers and decoupling diodes. When an HVPG triggers, five internal pickups in the HVPG will inject pulses in the RTL through five input transformers of the RTB. These pulses are then transmitted to all the other HVPG through two output transformers in each RTB. Thanks to this mechanism, in case of self-trigger of one MKD HVPG, all the other HVPG of LBDS will be triggered automatically as quickly as possible. Only the 15 MKD HVPG will inject pulses in the two RTL, as MKD see the circulating beam, and a self-trigger of one MKD HVPG requires retriggering all LBDS HVPG. The MKB HVPG do not inject pulses in the two RTL, because MKB do not impact the circulating beam, but a self-trigger of MKB HVPG will be detected by the various surveillance systems and a normal SBDT will be issued.

To cover a possible failure of the distribution of the SBDT issued by the TSU, an asynchronous dump trigger is also systematically generated by the TSU at the time it detects a DR. As up to 90 μ s (one beam revolution) may be necessary for the TSU to issue a synchronous dump, the asynchronous dump trigger is delayed by 250 μ s and injected in the RTL using a Trigger Delay Unit of 250 μ s (TDU-250), as can be seen in Fig. 1.

The upgrades performed on the various TSDS subsystems, along with their motivations, are detailed in the following sections.

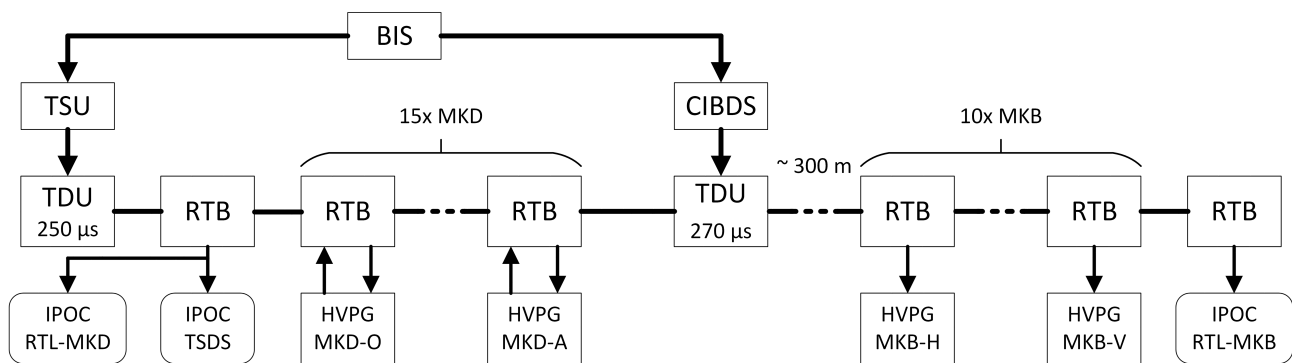

Figure 1: Simplified view of one Re-Trigger Line.

UPGRADES TO TSDS

Improvement of Power Distribution Architecture

During LHC operation in 2012, we faced an unexpected event: One Power Supply Unit (PSU) of one of the Front-End Computers (FEC) located in the control electronics racks of the LBDS failed, causing a short-circuit on its main input. The circuit breaker located in the distribution bar for the electronics rack did not react quickly enough, and the short circuit propagated up to the general circuit breaker in the UPS distribution powering the LBDS. This resulted in eight racks of electronics losing their UPS, which was totally unexpected for such a simple FEC PSU failure. The LBDS nonetheless properly executed a synchronised beam dump, but some of the diagnosis systems were not available for post-operation analysis. An internal review of LBDS powering was conducted later in 2012, when recommendations for a consolidation of power distribution during LS1 were given.

To avoid such a situation in the future, we provided a distribution box to power each crate PSU through an individual circuit breaker, as depicted in Fig. 2.

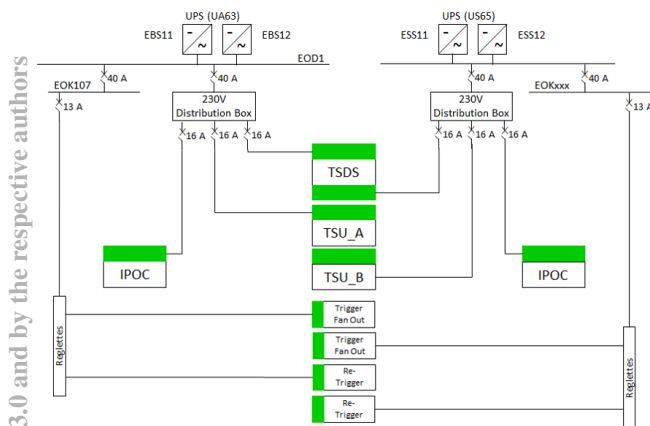

Figure 2: Full redundant electrical distribution.

During LS1, a new dedicated direct connection to a second UPS was also provided for LBDS, so now two independent UPS, one located in UA63, the other in US65, power the various LBDS redundant PSU, see in Fig. 2.

The UPS system was also upgraded during LS1, and a new fully redundant architecture was implemented. As illustrated by Fig. 3, a third 'backup' UPS unit was installed to feed the bypass line of the first two UPS units. Hence, in case of failure of one of the first UPS units, the backup unit guarantees the redundancy of the UPS distribution paths.

Figure 3: Full redundant UPS configuration.

All the FEC housing critical post-operation diagnosis systems were equipped with two redundant PSU, each connected to a different UPS. The monitoring of the state of all the redundant PSU of the LBDS crates is now performed remotely through Ethernet, so a software interlock system can request a beam dump in case a failure is detected in a PSU.

Before the startup of LHC Run I, a simulation of UPS failure was performed for LBDS. Each of the two UPS was disconnected, in two successive tests. Some non-conformities were detected, such as two redundant PSU of a FEC connected to a same UPS. These problems were fixed, but the UPS test proved to be useful and subsequently shall be planned after every intervention on the LBDS power distribution.

New Deployment of TSU Cards

During the LHC Run I operation, a new failure mode of TSDS was identified: Due to the deployment of both TSU cards in the same TSDS VME crate, along with the BRF optical receiver card and the BLMDD interface card, if only the +12V VME power is lost, neither synchronous nor asynchronous triggers are issued. This power failure was not detectable and would have caused the LBDS to not

function, which is totally unacceptable. This failure never occurred, but at the time the failure mode was identified, we immediately requested a beam dump and stopped the LHC operation until a solution was found. The same day, we implemented a surveillance of the +12V power supply of the TSDS VME crate, to inject an asynchronous trigger on the RTL in case a failure is detected.

In order to definitively remove this +12V common failure mode, a new deployment of the two TSU cards was performed during LS1. Each TSU is now installed in its own VME crate with a redundant PSU, and a third TSDS VME crate contains the RF optical receiver card and the BLMD interface card, as can be seen in Fig. 2.

Design of a New TSU Card

Following an external review of the TSU card design performed in 2010 during which recommendations for minor hardware improvements were made, and due to the new deployment of TSU cards over two separate crates, a new TSU card was developed.

A new cabled interconnection between the two boards was implemented to replace the common VME backplane. A surveillance of all internal voltages was added to the TSU card itself, and a DR is issued to the redundant card in case any power supply failure is detected. Additionally, an internal continuous surveillance of the CRC of the TSU programmable logic circuits (FPGA) was implemented, so in case of a Single Event Upset corruption of one of the programmable circuits, an incorrect CRC is detected and a DR is issued to the redundant TSU.

Figure 4: View of some signals captured by IROC-TSDS.

Numerous on-board post-operation diagnosis functionalities have been added, such as the surveillance of the output current of the SBDT signals. Additionally, 32 TSU internal signals are now acquired and analysed by an Internal Post Operational Check (IPOC) system [6], such as all the redundant dump requests from the various clients, which are checked for presence and correct synchronisation after every dump. A view of some signals captured by this IROC-TSDS is shown in Fig. 4. The eXternal Post Operation Check (XPOC) system [7] receives the results of IROC-TSDS analysis after every dump, and will inhibit the injection of beam in LHC in case any problem is detected after the last dump execution.

Direct Connection from the BIS to the RTS

It was noted that the LBDS is very sensitive to any unidentified failure mode of the TSDS. Despite the large redundancy within them, in case of simultaneous failure of both TSU cards, no beam DR would be executed. To reduce this sensitivity, a direct link has been established between the BIS and the RTS of the LBDS [3]. This new link consists of a new electronic board (CIBDS) that follows the same principle as the TSU: It is included in the BIS optical loops, and generates an asynchronous dump trigger when it detects an opening of the beam permit loop. This additional asynchronous trigger is delayed by 270 μ s and injected in the RTL, between the MKD and MKB RTB, using a TDU of 270 μ s (TDU-270), as displayed in Fig. 1.

To assess whether the addition of this new hardware has a significant negative impact on the overall rate of false beam dumps of the LBDS, a reliability study of the CIBDS card and the TDU was carried out, and revealed that the increase in failure rate is almost negligible [8].

Adaptation of the SCSS

First, the SCSS hardware and software were updated to add the functionalities for the surveillance of all the power supplies of TSDS, as explained above. In case a power supply failure is detected, a beam dump is requested before the situation further deteriorates. Secondly, the CIBDS card got a direct redundant connection to the SCSS to inhibit the CIBDS pulses on the re-trigger lines when the LBDS is in local test mode, to make sure that any activity on the BIS does not interfere with LBDS tests. A read-back of the inhibit status of the CIBDS was also implemented, and a beam dump is requested if the CIBDS is not detected as operational [3]. Finally, an improvement to the SCSS was the implementation of a 'spontaneous triggering' test, to make sure that the re-trigger line is working as expected, and that all HVPG are triggered in case one of them triggers spontaneously. The SCSS will send a trigger to all MKD HVPG one after the other on a dedicated line, to simulate a MKD HVPG spontaneous trigger and check that all other HVPG are triggered through the re-trigger line as expected. This system is only active when the LBDS is in local test mode.

Check of Re-Trigger Lines Continuity

The RTL is actually composed of two twisted pairs, one to transmit the re-trigger pulses and the other to allow the SCSS to check that the line is closed using a DC current. During the first tests with CIBDS, we faced an unforeseen problem: The RTL was physically closed and the DC current was normal so the SCSS did not detect any error, but the CIBDS re-trigger pulse was not visible on the IROC-TSDS for one RTL (See Fig. 4). Further investigations showed that a pin was not connected within one of the 110 connectors included in one RTL. We then realised that the DC current loop continuity did not guarantee the continuity of the re-trigger pulse line. Such a fault could not be detected before

LS1, because the IPOC-TSDS picks up the signal on the RTL using a RTB placed at the output of the TDU of the TSU, at the MKD extremity of the line, as shown in Fig. 1. This non-conformity was detected thanks to the addition of the CIBDS, and the check by IPOC-TSDS of the presence of CIBDS re-trigger pulse travelling through the RTB of the 15 MKD. However, with only one IPOC-TSDS system at the MKD extremity of the re-trigger line, we cannot ensure that the re-trigger pulses reach the MKB extremity of the line, so a new IPOC system was added at the MKB extremity of the RTL, to capture and check the presence of the two re-trigger pulses from the TSU and CIBDS cards.

Problem of Re-Trigger Lines Absorption

During the re-commissioning of the RTL, we were very surprised to see that the CIBDS re-trigger pulse was not detected by the IPOC-TSDS system when pulsing at energies above 3 TeV. After further investigations, we discovered that the CIBDS pulse underwent an attenuation that increased with both the LBDS energy and the delay between the SBDT and CIBDS pulses. The CIBDS pulse is sometimes so low at the input of the IPOC-TSDS that it is not detectable by its binary digitiser (TTL). We added a new IPOC system at the MKD extremity of the RTL, in parallel with the existing IPOC-TSDS, but with high resolution digitisers, as displayed in Fig. 1.

Figure 5: IPOC-RTL-MKD at 450 GeV and 6.5 TeV.

Figure 5 shows an acquisition of this new IPOC-RTL-MKD for a pulse at 450 GeV, and another at 6.5 TeV. We first see the pulse train injected by the 15 MKD HVPG when they receive the SBDT, then later the TSU re-trigger pulse, and finally, the CIBDS re-trigger pulse, which has an acceptable level at 450 GeV, but a very low level at 6.5 TeV, making its detection very difficult.

This problem of re-trigger pulse attenuation is not yet fully understood. A project was started to simulate the behaviour of the whole RTL in order to understand the phenomenon, and find a way to reduce this attenuation.

Change of TDU Delay

A pulse due to a free-wheel pickup inside the 15 MKD HVPG appears on the RTL when operating above 5 TeV, see Fig. 5. In some cases, this pulse could occlude the TSU

re-trigger pulse, and thus hinder IPOC from checking its presence. This was not an issue during LHC Run I, as the LHC energy was limited to 4 TeV. To avoid this problem, we changed the TDU delay of TSU and CIBDS from respectively 200 and 250 μ s to 250 and 270 μ s.

CONCLUSION

Although the TSDS performed as expected during LHC Run I, some major problems were discovered, and an important number of improvements were implemented during LS1. Many diagnosis systems were added, and already proved to be useful, as they highlighted various issues with the re-trigger lines during the re-commissioning phase. A problem of re-trigger pulses attenuation is still not fully understood, and a full simulation of the re-trigger lines behaviour has been launched in order to address it. The TSDS was successfully commissioned and has been operating flawlessly since the start of LHC Run II.

ADaMS 3: AN ENHANCED ACCESS CONTROL SYSTEM FOR CERN

P. Martel, C. Delamare, G. Godineau, R. Nunes
CERN, Geneva, Switzerland

Abstract

ADaMS is CERN's Access Distribution and Management System. It evaluates access authorisations to more than 400 zones and for more than 35000 persons. Although accesses are granted based on a combination of training courses, administrative authorisations and the radio-protection situation of an individual, the policies and technicalities are constantly evolving along with the laboratory's activities; the current version of ADaMS is based on a 7 year old design, and is starting to show its limits. A version 3 of ADaMS will allow improved synchronization with CERN's scheduling and planning tools (used heavily during technical shutdowns, for instance), will allow CERN's training catalogue to change without impacting access management and will simplify and reduce the administrative workload of granting access. The new version will provide enhanced self-services to end users by focusing on access points (the physical barriers) instead of safety zones. ADaMS 3 will be able to cope better with changing and new requirements, as well as the multiplication of access points. The project requires the cooperation of a dozen services at CERN, and should take 18 months to develop.

INTRODUCTION

ADaMS is a system that centralises and standardises access policies throughout CERN; it is a central management system generating access authorisations for a multitude of different physical access systems. ADaMS has existed since 2007, and was designed for the 30 access zones existing at the time and that were exclusively related to safety, each with a relatively small area and with their access points geographically close to each other.

Figure 1: Evolution of the number of zones managed by ADaMS.

Today, the system is managing more than 400 zones (Fig. 1), not all related to safety, and with some of them concerning non-contiguous areas with access points very far from each other. At the same time, the business logic has changed dramatically both in quantity and quality; where originally only 5 criteria existed to grant or deny access (CERN access card, contractual situation of the person, dosimeter, followed courses and access request), new and more complex criteria have been added following new business requirements; IMPACT – a tool to coordinate the interventions on the accelerator premises during technical stops – now determines if access is granted or not, on top of the original criteria, for dozens of zones, and for around 200000 access authorizations (Fig. 2).

Figure 2: Evolution of the number of granted accesses by ADaMS per cycle.

With time, the changes and improvements to meet new requirements have been implemented on top of the original architecture; this means that even if for the past 8 years all new requirements were met with more or less complex adaptations of the original system, in some circumstances the system is no longer able to automatically justify the granting or revoking of an access right, as by design it does not collect and hold enough data for it. For these reasons, we have decided to build a new version from scratch.

MAJOR CHANGES FROM VERSION 2

Zones and Resources

One of the requirements that ADaMS 3 will have to fulfil is to be able to control access to entities other than "zones". Access to resources such as key cabinets, rooms

and cars are to be managed by ADaMS, using similar business logic to that of zones – namely criteria required to have access, notifications on access revoking, etc.

Access Points vs. Access Zones

Where in the past (with a small number of safety zones) it was easy to remember or deduce the equivalence between “safety zone” and “access point”, currently (with more than 400 zones) this equivalence is difficult to remember or deduce. ADaMS 3 will focus on “access points”, which is a concept closer to the end user, with a known identifier, and keep the “safety zones” concept as hidden from the end user as possible.

Access Profiles

ADaMS 3 will allow the definition of access profiles, a mechanism allowing to request a pre-defined set of access rights for a person, with a single operation. For those cases where each person arriving in a new service (e.g. CERN’s Fire Brigade) is granted access to the same set of zones, the concept of an access profile will greatly simplify the acquisition of all required administrative authorisations as well as training requirements.

Identifiers Associated to Access Points

ADaMS 3 will make a clear distinction between the right to pass by an access point and the ability to do so with the needed identifier. This means that ADaMS will be able to inform the user that even if the authorisation to enter a certain area or take hold of a certain resource is granted, in practical terms, access cannot be done as the person concerned lacks the required device and/or biometric identifier.

Delegation /Simplification of Administrative Authorisations

ADaMS 3 will allow the administrative authorisation criteria for a zone or resource to be fulfilled without the circulation of an electronic document. The usage of an “egroups/roles” tool will allow to administratively allow the access to a resource without any administrative overhead. For instance, automatically authorising the shared access to a key or a room to those persons in a certain administrative unit at CERN, etc. This delegation (on the management of an egroup or role) of the administrative authorisations, even though not applicable to safety zones (where an explicit, personal signature will allow each person to gain access to it) is expected to greatly reduce the circulation of electronic documents concerning access authorisations at CERN.

Training “Ranks” (or levels)

In the beginning, ADaMS only took 3 safety courses into account; when those courses were replaced by other ones, some tweaking was done in the business logic in order to handle it (e.g. the waiving of a course A if course B had been followed, etc.). With the dozens of courses currently taken into account, and the constant changes to CERN’s training catalogue, this way of working (hard-coding the business logic) can no longer be used, if an explanation on an access refusal is to be automatically deduced and a trace of changes in ranks/courses requirements is to exist. ADaMS 3 will interface with CERN’s

new LMS (Learning Management System), and delegate to it the management of “ranks” (or “levels”) and courses. The system works with “ranks”, independently of the course or certificate that grants it.

Better Anticipation of Changes

ADaMS will allow the definition of start and end dates for the criteria required (e.g. a new required rank) for a certain zone or resource, and will allow the evaluation of the impact of that change beforehand, namely in accesses granted or lost. It will also allow notification to those persons affected by the change before the change occurs.

More Systems Managed and Interfaced

ADaMS 3 will have more systems managed/interfaced and will work with more data about each of those systems; ADaMS was created to handle 1 access system for CERN’s infrastructure and one accelerator access system. It was later enlarged and it now interfaces with multiple accelerator access systems (LHC/SPS/PS), 2 generic non-accelerator access systems, as well as SALTO for door locks, TRAKA for key cabinets, Altaïr for car barriers, and RFID reading systems for “kiosk IT”. The interface between ADaMS and these systems is for the time being unidirectional, as all of them fetch data from ADaMS, but supply none, as ADaMS 2 does not work with any data from any physical system. ADaMS 3 will fetch data about the access systems, and will hold data about which systems are used, where, when and with which identifier. By scaling up the new architecture, it will be able to accommodate any new access control systems that may be added (e.g. Indico for room reservation and the SPS Access renovation project).

NEW INTERFACES

ADaMS 3 new graphical user interface will answer to the growing usage of the system by end users (Fig. 3); it will be leaner and more intuitive for the users, proposing more ways to find out if access to a certain location is granted or not; access checks will be proposed by access point name, location code or geographical location (in a map). It will be focused on access points, and not on access zones, and will be able to explain with a simple text, why access has been granted or revoked. It will also allow to easily identify the missing criteria in order to obtain access to a zone or resource.

Figure 3: Evolution of the number logins to ADaMS GUI.

The new system will have functionality providing an overview of all access conditions and situations for the persons in an egroup or organisational unit; this will allow managing the accesses of a series of related persons, in an easy way.

ADaMS 3 will make data available to other systems via the conventional mechanism of database table or view; it will also expose data via RESTful Web Services.

ADaMS will propose simple, visually clear pages to be displayed at access points, with the reasons for an access refusal, at real time.

PERFORMANCE

The new system will perform a full evaluation of all accesses in less than 5 minutes (Fig. 4). This way, we can ensure a high degree of reactivity to any change in the source data used by ADaMS. This period of a refresh cycle will allow any modification to accesses to be propa-

gated to any access point in less than 30 minutes, if desired.

ADaMS 3 will keep a full log of all changes in the source data; this new feature will allow to justify why an access has been lost or granted due to a change in the original system where data is fetched from, without the need to access that system's log mechanism (for those cases where there is one).

Unlike in the past, where for most criteria only the "date" was considered, ADaMS 3 will use the "hours and minutes" for start and end dates; this will allow to have finer access control, and better adapt to other systems such as IMPACT, that use the hours and minutes as well.

ADaMS will have a mechanism that will be able to asynchronously evaluate and make available one person's situation; this feature will be required if ADaMS is to be used as an individual protection equipment validator for access control in the future.

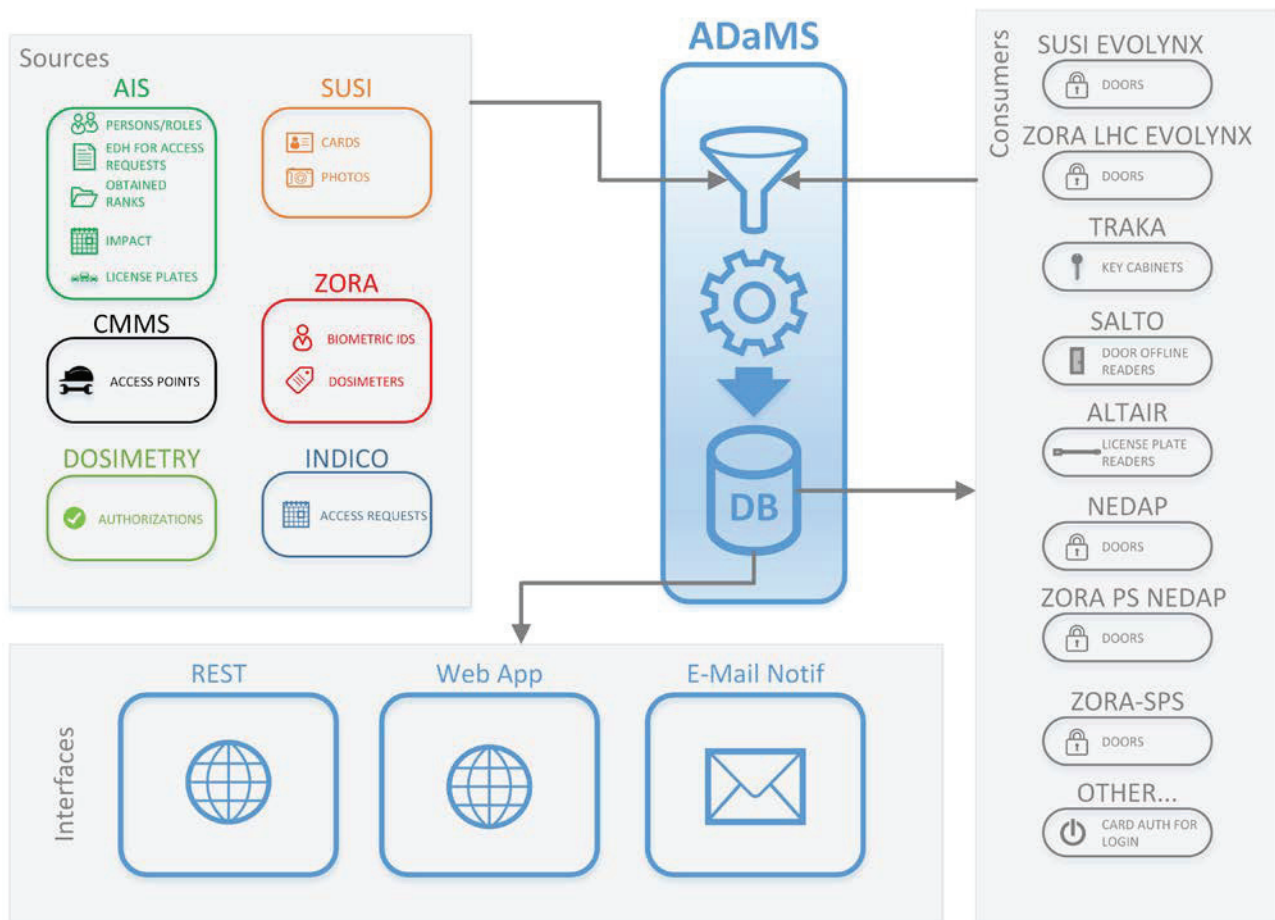

Figure 4: ADaMS 3 refresh mechanism, with its data sources and consumers.

ROLE BASED ACCESS CONTROL

ADaMS 3's interfaces (both GUI and programmable) will have a Role Based Access Control (RBAC) mecha-

nism that will allow (or deny) a certain functionality to be applied to a particular data set; for instance, access to all access data concerning a contract's personnel will be granted to the person defined as the contract's manager.

RBAC will be implemented using CERN's AIS (Advanced Information Services) roles/egroups application, with role types and targets; the logged user is able to perform a certain function on data belonging to a certain person, if he/she is assigned to a role type that may perform the function on a target containing that person.

CONCLUSIONS

Physical access control for an organisation such as CERN is an evolving domain, with new and more complex constraints and devices being introduced constantly. ADaMS has been delivering access data to these systems, in accordance with changing policies since 2007; its original architecture has been stretched to the limit and it is now time to refresh its architecture.

ADaMS will help analyse and allow the modification of our access policies following the observations of the Long Shutdown 1 (LS1) access patterns and problems. It will also facilitate the access process and user experience for accelerator zones, providing new functionalities and interfaces.

ADaMS is also a key element in any access renovation project, as it needs to adapt to new constraints and requirements (e.g. the SPS access renovation project).

ADaMS 3 will allow CERN to continue having a single, centralised system for access management and distribution, adaptable to new requirements and scalable to the new domains where access control is required, while being at the same time, an important link in the safety chain of CERN's accelerators.

INTERLOCK OF BEAM LOSS AT LOW-ENERGY PART OF J-PARC LINAC

Abstract

The output beam power of the J-PARC linac has been improved by increasing the acceleration energy and peak beam current. The beam loss is getting serious along with increasing output beam power; however, the beam loss in the front-end region is difficult to detect because of the low energy of the radioactive emission. An interlock system using the beam current monitors has been developed to prevent significant material activation. In this system, an electrical circuit measures the beam transmission between the two beam current monitors. This study describes the design and performance of this electrical circuit and introduces the system configuration.

INTRODUCTION

The Japan Proton Accelerator Research Complex (J-PARC) linac can provide high intensity beams of peak current 50 mA, beam energy 400 MeV, pulse width 0.5 ms, and repetition rate 25 Hz using a radio frequency quadrupole linac (RFQ), three drift tube linac (DTL) cavities, 16 separation-type DTL (SDTL) cavities, 21 modules of annular coupled structure (ACS) cavities, and two beam transports, which have two ACS-type buncher cavities and debuncher cavities as shown in Fig. 1 [1, 2].

The J-PARC linac has a matching section between the RFQ and the DTLs, where 3-MeV beams are transported and measurements and beam profile matching are performed. An ion chamber-type beam loss detector has been employed for beam loss detection. The beam loss detector has a fast signal response; therefore, we have used this to develop an interlock system to stop beam operation when abnormal beam shots are detected. However, there is no beam loss detector in this section because the energy of radiation generated by 3-MeV beam is not sufficiently high to be detected.

Figure 1: Schematic Layout of Present J-PARC Linac.

An interlock system that uses a new electrical circuit to measure the beam transmission between the two beam

current monitors is proposed because of the large number of beam current monitors in the beam line.

In this study, a procedure for signal processing in the system and for processing waveforms in the processing unit is introduced. The waveforms obtained are also analyzed.

CIRCUIT DESIGN OF BEAM TRANSMISSION MEASUREMENT

The new interlock system, which uses beam current monitors, is named the beam transmission monitor (BTM) because the system compares beam currents detected by two independent beam current monitors. The signal design process is described below.

System Configuration

The schematic configuration of the system that uses the BTM is shown in Fig. 2. The system comprises two beam current monitors, and the signal processing circuit (BTM) shown in gray. Pre-amplifiers are usually used for continual beam operation and they are annually tuned to 0.10 V/mA of the beam current. The buffer amplifier has four channels per module, with two channels connected to the digitizer (one for both waveform outputs, 1 and 2) during operation, and the other two channels used by the BTM. The BTM circuit has six output terminals, as shown in Fig. 2.

Figure 2: System Configuration of the Beam Transmission Measurement.

Process Flow

The signal processing flow in the BTM is shown in Fig. 3. It has two input terminals for the two signals coming from the two beam current monitors. Just after the signal input terminals, gain adjustment knobs amplify the input

[#]akihiko.miura@j-parc.jp

signals independently. These can be tuned by observing the low beam current signals (outputs 1 and 2). To detect small beam losses, the beam current signals are integrated with a gate signal that covers an entire beam pulse. The rise of the gate signal pulse plays a significant role in the trigger of the integration, whereas the flank plays a significant role in the reset of the integration. After integration, which can be observed in outputs 3 and 4, the difference, which should be small, is usually taken by the two integrated inputs. The difference can be observed at the output 5 terminal and it is integrated again into the circuit. The final integrated differential signal can be observed in output 6.

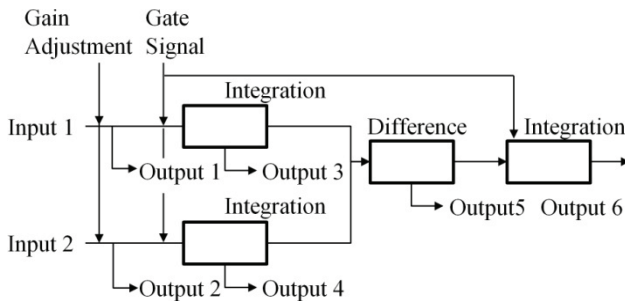

Figure 3: Block Diagram of the signal processing flow in the beam transmission monitor circuit.

Estimated Waveform

Figure 4 shows the estimated waveform at each output terminal. Two rectangular simulated beam input pulses are assumed with different wave heights at inputs 1 and 2. When input 1 is upstream from input 2 and the input gain is adjusted, the wave height of input 2 is smaller than that of input 1. After inputs 1 and 2 are integrated during the gate period, outputs 3 and 4 are obtained. The waveforms of outputs 3 and 4 are proportionally increased between beam-on and beam-off, and the highest peak is held ideally until the reset signal. The integrated signals are subtracted and the result is output 5. Furthermore, this signal proportionally increases in a beam period. The proportional difference is added over time, with the integrated difference being quadratically increased. After the beam has passed, the difference is proportionally increased until the reset signal.

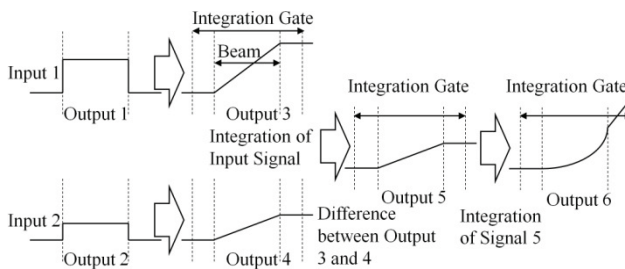

Figure 4: Waveforms during the signal processing.

SYSTEM TEST

Installation

There is a beam transport line between the RFQ and DTL, where the beam energy is 3 MeV, and there are five beam current monitors in this section. We assume that all the beams are lost in the DTL cavity, and we focus on the beam current monitors upstream and downstream of the DTL. Therefore, input 1 is occupied by the beam current signal from the last MEBT1 and input 2 is for the last DTL. In the test operation, we use a 30-mA peak beam current and a 100- μ s pulse length. The integration gate covers the beam pulse preceding 50 μ s from the beam pulse and having a width of 2 ms.

Test Results—Normal Operation

When the beam is operated with tuned beam lines, the beam loss in the DTL is assumed to be small. When the input currents are the same, the trends of inputs 1 and 2 as well as those of outputs 3 and 4 are the same. Therefore, the subtraction of outputs 3 and 4 gives a value of zero for output 5, which will result in no signal in output 6.

For the beam test to use the ideal tuned beam line, inputs 1 and 2 were maintained with the same pulse height by using the gain adjustment knobs for the input signals. The waveforms of output 1 (raw output of input 1), 2 (raw output of input 2), 5 (difference of integration between 3 and 4), and 6 (final integration of the difference 5) are shown in Fig. 5. We used a pulse of 100 μ s with a horizontal axis scale of 20 μ s/div.

Figure 6 shows the waveforms of outputs 3 (integration of input 1), 4 (integration of input 2), 5, and 6 at time ranges of 40 μ s/div along the horizontal axis. Integration of the input pulses, which started from the gate state, shows the same trends for outputs 3 and 4, with the difference between (output 5) of outputs 3 and 4 then being close to zero. Finally, the integration (output 6) of output 5 was shown to be almost zero.

Figure 5: Waveforms of outputs 1, 2, 5, and 6 when pulses with same heights are input. The horizontal axis scale is 20 μ s/division.

Figure 6: Waveforms of outputs 3, 4, 5, and 6. The horizontal axis scale is 40 $\mu\text{s}/\text{div}$.

Test Results—Beam Loss in the DTL Section

We assumed the entire beam to be lost in the DTL section. Input 1 remained; however, input 2 was suspended from producing any signals. Figure 7 show the waveforms of the outputs 1, 3, 5, and 6 at 400 $\mu\text{s}/\text{div}$ along the horizontal axis. Output 3 is proportionally integrated and the difference of output 3 and input 2 (actually no signal input) was also proportionally integrated and the peak value was maintained until the reset signal. While the beam was passing, the proportional difference was integrated quadratically.

Figure 7: Waveforms of outputs 1, 3, 5, and 6 for beam loss in the DTL section. The horizontal axis scale is 400 $\mu\text{s}/\text{div}$.

Figure 8: Waveforms of outputs 3, 4, 5, and 6 with beam loss in the DTL section. The horizontal axis scale is 100 $\mu\text{s}/\text{div}$.

After the beam had passed, the integration of the differential signal was proportionally increased due to the remainder of the peak value. Figure 8 shows the extensions of the waveforms of outputs 3, 4, 5, and 6 around the pulse duration. A quadratic increase of output 6 was observed.

We tested the beam loss detection system in the case of normal operation with beam loss occurring in the front-end section (DTL section). We confirmed that the signal outputs of all the terminals worked as estimated.

Thresholds for the Interlock

We confirmed the performance of the BTM by obtaining the maximum output of the integrated difference. In the interlock level, the worst case is that provides the maximum output from output 6. The reason for using output 6 is that it is sensitive to the small difference between outputs 1 and 2. We decided the threshold value as that which suspends the beam operation alarm. We are now using half of the maximum value, which implies that the alarm is triggered later than halfway through the pulse. The signal rise of output 6 is slow because it increases quadratically in the case of ideal beam loss. We can obtain a quicker response from output 5 than from output 6. Nevertheless, we plan to use both outputs 5 and 6.

This system can also be used for comparing two different signals. In the front-end of the beam line, an RF chopper system is used. As long as the RF chopping error is not sufficiently high to shift the beam away to the beam scraper, the beam remains in a beam line. Because this beam should not be injected into the downstream synchrotron, it is necessary to stop the beam after the chopper error occurs. We have attempted to use the system for detecting chopping errors using a beam current monitor and a beam scraper where the beam was irradiated by the chopper [3].

Operational Use

We continue to use the system for its usual operations. We experienced a triggering of alarm during beam operation when all the magnet setting parameters were lost due to a human error. The system was confirmed to be successful when used in actual beam operations.

SUMMARY

The J-PARC linac has a matching section between the RFQ and DTL, where 3-MeV beams are transported. We usually employ an ion chamber-type beam loss detector for beam loss detection in the linac beam line; however, there is no beam loss detector in the front-end section of the linac because the energy of radiation generated by the 3-MeV beam is not sufficiently high to be detected.

A new interlock system using beam current monitors is proposed. We developed an electrical circuit to measure

the beam transmission using two beam current monitors for the system. We established the new system and tested it using an actual beam in two typical cases. Based on the results obtained in all the cases of beam loss, we obtained the worst signal response, which will be used as a threshold for the interlock. We confirmed the performance of the BTM and its system as designed and decided on the operational threshold. We have been using this system continuously; however, the strategy of the threshold should be more serious if used for alarm timing.

OVERVIEW AND DESIGN STATUS OF THE FAST BEAM INTERLOCK SYSTEM AT ESS

A. Monera Martinez, R. Andersson, A. Nordt, M. Zaera-Sanz, ESS, Lund, Sweden
C Hilbes, ZHAW, Winterthur, Switzerland.

Abstract

The ESS, consisting of a pulsed proton linear accelerator, a rotating spallation target designed for an average beam power of up to 5 MW, and a suite of neutron instruments, requires a large variety of instrumentation, both for controlling as well as protecting the different hardware systems and the beam. The ESS beam power is unprecedented and an uncontrolled release could lead to serious damage of equipment installed along the tunnel and target station within only a few microseconds. Major failures of certain equipment will result in long repair times, because it is delicate and difficult to access and sometimes located in high radiation areas. To optimize the operational efficiency of the facility, accidents should be avoided and interruptions should be rare and limited to a short time. Hence, a sophisticated machine protection system is required. In order to stop efficiently the proton beam production in case of failures, a Fast Beam Interlock (FBI) system with a targeted reaction time of less than 5 microseconds and very high dependability is being designed. The design approach for this FPGA-based interlock system will be presented as well as the status on prototyping.

INTRODUCTION

The team in charge of ESS Machine Protection is facing a great challenge: design, deploy and operate a Beam Interlock System (BIS) needed to protect the machine from beam-induced damage. The unprecedented beam power of 5MW at ESS can lead to severe damage within 10-20 microseconds only and thus beam operation has to be stopped reliably in an even shorter time upon the detection of non-nominal beam conditions. Such non-nominal beam conditions will be detected by several beam instrumentation systems such as the Beam Current Monitoring System, the Beam Loss Monitoring System and the Beam Position Monitoring System. The BIS shall fulfil demanding requirements regarding the hardware failure rate and beam availability as well as the requirements for the very short response time of a few microseconds. There are only four years to develop, test, produce and install the whole system. First commissioning of the ESS linac is planned for the beginning of 2018, and a first version of the BIS has to be ready by then. First protons on target are expected in mid 2019.

In a first step, the possible failure modes of the accelerator systems have been analysed. This analysis has been used to define around 170 different protection functions needed to protect the linac from beam induced

damage, directly or indirectly. For each of these protection functions, an execution time has been defined as well as the required rate of dangerous failures. The highest rate for a function found is of 10^{-6} to 10^{-7} failures per hour with a response time of 5 microseconds (including the detection, processing and execution time) [1].

SYSTEM SPECIFICATIONS

In order to design a Beam Interlock System it is important to understand the system requirements and specifications. The design of the BIS is following the IEC61508 [2] and the IEC61511 [3] standards where applicable. However, since the BIS is a mission critical system and not a safety critical system, it is not needed to be compliant with those standards. Still, the team felt, that it is good to follow the guidelines provided by these standards in order to achieve a good level of protection thanks to the solid framework that the standards offer.

The following selected specifications allow to have a clear picture of what is expected:

Remote Monitoring: The BIS should be able to inform about its status and in case problems occur, operators shall be notified or an alarm shall be raised. For that it is required that the BIS will be connected to the main control system (EPICS) for monitoring and parameterization purposes.

Fast response time: the fast reaction time of the BIS is resulting from a time allocation which is done for a full protection function. A protection function includes time to detect a non-nominal condition of the machine, to process this information, to propagate and inform the BIS, process the information on BIS level and initiate a stop of beam operation. The fastest reaction time found for a protection function is 4-5 microseconds implying a reaction time of the BIS below 2-3 microseconds. This time differs for different beam energies along the linac and is only valid for the low energy part of the linac and can be relaxed for higher beam energies. Hence the Beam Interlock System will be called the Fast Beam Interlock (FBI) System. In order to achieve this reaction time the development of an FPGA-based system is required.

High availability: The FBI System should not interrupt the beam operation unnecessarily. One of the main requirements for the ESS facility is to deliver beam with very high availability. Thus, it is needed to keep downtime and false beam stops due to failures in the FBI System at a minimum. Hence the FBI System should be highly reliable as well as highly available.

Protection: The FBI System shall fulfil the requirement of a dangerous failure rate of 1.5×10^{-7} to 1.5

$\times 10^{-8}$ per hour. This requirement is based on a first risk analysis [1].

Number of Inputs: The number of inputs towards the FBI System will be in the order of a few hundred signals (~300), randomly distributed in a 600m long gallery (where the electronics is located). The final number of inputs is currently under investigation. However, it is not expected that this number will significantly increase.

The Environment

Initially underestimated by many, the environment in which the system is located plays an important role when defining the system's architecture and its distribution. All the electronics needed to operate the accelerator will be installed in the so called Klystron Gallery at ESS. This gallery is very close to the accelerator to keep the cable length at a minimum. Racks will be grouped in two rows of 18 racks each and a group of 36 racks will be housed in an enclosure which is cooled, fulfilling the high temperature stability requirements for the RF system. There will be approximately 24 enclosures for ~800 racks in total. Due to the confinement of these enclosures and requirements for each of them, it could be difficult to distribute cables in and out. It is important to have this factor in mind when defining the location for the different electronics.

Additional non-physical factors like electromagnetic noise impact on the performance level of a system. The FBI System should be designed in a way that this noise doesn't damage the electronics and doesn't impact on the beam availability of the accelerator. Special attention will be given to the selection of cables and connectors, focusing on shielding and good noise immunity but not compromising price and installation cost significantly.

TRADITION VS TECHNOLOGY

Collaboration with many institutes has allowed us to get hold on already developed interlock systems, designed by experienced teams during many years and with proven functionality. The idea of developing a BIS in a short time reinforces the strength of such collaboration and offers the possibility of doing a fast development adapted to ESS needs. On the other hand, new technologies will allow tailor-made solutions for ESS at the cost of lack of reputation and longer time to develop and test.

PROTOTYPES UNDER DEVELOPMENT

Two main ideas are currently being developed, both based on the same principle: Interface modules will allow a wide variety of electronic devices to connect to the FBI System, concentrators will aggregate the signals to simplify and minimize the number of traces and a main master module that will decide if the beam operation has to be interrupted or not.

The FBI System will receive a boolean signal from the Local Protection Systems (LPS) and from Beam

Instrumentation (BI) systems indicating if beam operation should be permitted or not. This boolean signal will be the "Beam Permit" signal. Upon removing this signal, beam operation will be stopped immediately by the FBI System.

Copper-based System

Following the approach that CERN took for their Beam Interlock Systems deployed at LHC [4], LINAC4 and other machines at CERN, ESS will build a similar system following the main design concepts of the CERN Beam Interlock System. This system is based on DC signals, a modular design and very reliable electronics.

Figure 1: CERN Interface Module (CIBU) (left), Beam Interlock Controller (right).

Designed for VME form factor, this system was designed not only to be very robust mechanically and electronically but also to be operated safely in radiation areas [5].

The ESS version of this system will have slight changes in the architecture in order to be accommodated to the ESS Klystron Gallery distribution and the size has been reduced to fit the restricted dimensions without compromising the mechanical strength.

The FBI System will be composed of the following:

The FBI Device Interface (FBI_DIF) will receive the first size reduction and higher integration count, aggregating into a 1U unit up to 8 interfaces without losing availability or protection integrity level. The electronic used will be very similar to the original CERN electronics keeping a wide input range (from 3.3V to 36V) allowing an easy connection, for PLC and FPGA based systems.

The FBI Master (FIB_M) and FBI Master of Masters (FBI_MoM) will undergo major re-design. The form factor will be changed from VME to MicroTCA (or Pizza box) and aggregation from 16 to 32 inputs into a single crate depending of the master location, is foreseen.

The FBI Actuator module (FBI_A) has been designed following ESS requirements. A redundant input and redundant signal path within the actuator are used to avoid dangerous failures. In addition, diagnostics have been implemented to supervise the behaviour together with redundant power supplies and a discrete critical path (no programmable devices on the permit path) ensuring high availability.

An example of the connector chosen and the mechanical redesign is shown in Fig. 2.

Figure 2: Micro D connector cable for the FBI System (left), 3D model for the FBI Interface module (right).

In order to fulfil the required dangerous failure rate, the FBI System will be installed in a redundant configuration. However, due to restrictions on budget and space limitation in the accelerator, the Input devices will not be redundant, only the FBI System will be, offering redundancy from the FBI_DIF up to the Master of Masters. The FBI_A will act as a final, simple but very robust concentrator that will use both permits to turn the actuators on and off when needed.

Furthermore, to avoid single points of failures at the inputs of the FBI System, the Local Protection Systems and Beam Instrumentation systems shall offer a redundant output independently connected from the CPU or FPGA that processes the main protection function.

A small diagram of the system's architecture can be seen in Fig. 3.

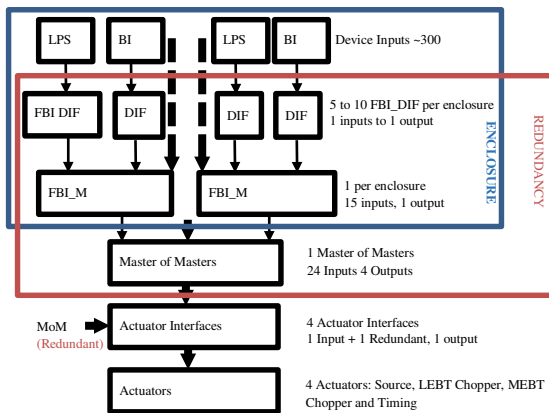

Figure 3: Schematic of the Fast Beam Interlock System based on copper connections.

A recent Failure Mode, Event and Diagnostics Analysis (FMEDA) [6] has been performed for the first engineering model of the FBI System. The results of this analysis show that the system with minimum firmware and redundant channels would offer 1 dangerous failure within 450 years while keeping the false beam trips to less than 3 per month and a reaction time of less than 2 microseconds excluding delays induced by cables.

In addition to the hardware and mechanical modifications made to the CERN System, an extra level of protection has been added to ensure full system functionality and reduce likelihood of blind failures even more.

Self-Testing Functionality

In order to ensure that the FBI System is ready to allow for beam operation, a self-test will be implemented and executed before each beam injection. This test will force the FBI System and input devices to prove their ability to transmit a non-permit command from the protection function to the FBI Master of Masters. Using this self-testing sequence, it would be possible to find dangerous failures on the FBI System itself but also at the input devices.

Due to time restrictions and to minimize the system blindness, this test should be only applied to the FBI System itself and to FPGA-based systems but not to the PLC based systems, which have a slower reaction time.

In addition, this test sequence will be realized on different time scales for each channel. That means, that at all times, only one out of two channels is in test mode.

Additional System Tests

Two additional tests will be used in order to ensure the full functionality of the whole FBI System.

Slow Test: This test will be initiated by the timing system when there is no beam in the machine. The test will virtually generate all the events that can trigger a protection function ensuring the correct behaviour of all elements that form part of every protection function. This test would be scheduled after each technical stop to warranty the protection integrity.

Actuator Test: This test will be executed after the Slow Test but with minimal beam power. During this test the Master of Masters will generate independent triggers that will test all the beam stopping mechanisms (one at the time).

Adding testing and diagnostics functions reduce the dangerous failure rate to below one failure in 1000 years [6].

Optical Fibre Gigabit System

During the analysis of the copper based FBI System it has been found that DC data paths can be easily corrupted due to potential electromagnetic interferences. Using DC signals for transmitting critical information may hide dangerous system failures. An alternative system design that will use gigabit optical links transmitting data packets instead of RS485 links with DC signals, is being evaluated currently.

The FBI System based on optical fibres will use high speed optical links between FPGAs through SFP optical transceivers, allowing for a noise free communication at very high speed. If compared to the copper based system, the gigabit links will always fail into a safe state due to the interruption of the data packs. 10 km transceivers will be chosen for the 600m long Klystron Gallery, allowing a long lifespan of the transceivers and withstand some optical fibre degradation before start failing. It is expected that thanks to the high speed devices, the system will be have a much shorter reaction time.

Furthermore FPGA internal serializers with speeds of up to 6gps, will reduce the number of components and the size of the different boards.

The Beam Permit signals will be transmitted together with the device serial number, supply status and other diagnostics features in data packets allowing not only to know if the beam permit is on or off but also knowing about the health of the interface connected.

While trying to analyse the system, it is clear that the FPGA will become the most critical element in this scheme and thus potentially a weak point due to the higher complexity of the device. At the same time the short lifespan of the fibres may increase the maintenance cost of the system. However, if it is proven that the dangerous failure rate and reliability improves, this increase in maintenance is affordable.

The conceptual idea has been drafted and the design of the first engineering model will start soon.

Optical Fibre System Layout

When designing a system, it is important to consider the integration of the system as well as the installation. In case of ESS, the rack enclosures will heavily impact on the maximum number of cables that can go in and out of each enclosure together with the time required for cable installation.

In order to allow for an easy integration, each enclosure will be equipped with an FBI_Master module combining all the signals from devices located within each rack enclosure into one single permit line. This line will be then connected to the main master or Master of Masters (MoM) located close to the actuators.

Following this strategy allows for the reservation of space for cables and racks within each enclosure ensuring the presence of an FBI_Master module in each enclosure and maintaining low cable installation cost.

under investigation. Future iterations will take the ESS architecture more into account, trying to minimize the total installation cost.

An FMEDA analysis can improve the design significantly, such that weak points in the design can be easily detected. Further improvements will be done for the copper based FBI System, reducing the dangerous failure rate and improving the systems reliability.

CONCLUSIONS

A first prototype based on the copper connections has been developed already but other design concepts are

INTEGRATION OF PLC'S IN TANGO CONTROL SYSTEMS USING PyPLC

S.Rubio-Manrique, M.Broseta, G.Cuní, D.Fernández-Carreiras, A.Rubio,
J.Villanueva, ALBA-CELLS, Cerdanyola del Vallés, Barcelona, Spain

Abstract

The Equipment Protection Systems and Personnel Safety Systems of the ALBA Synchrotron are complex and highly distributed control systems based on PLC's from different vendors. EPS and PSS not only regulate the interlocks of the whole ALBA facility but provide a large network of analog and digital sensors that collect information from all subsystems; as well as its logical states. TANGO is the Control System framework used at ALBA, providing several tools and services (GUI's, Archiving, Alarms) in which EPS and PSS systems must be integrated. PyPLC, a dynamic Tango device, have been developed in python to provide a flexible interface and enable PLC developers to automatically update it. This paper describes how protection systems and the PLC code generation cycle have been fully integrated within TANGO Control System at ALBA.

INTRODUCTION

ALBA[1], member of the Tango Collaboration[2][3], is a third generation Synchrotron in Barcelona, Spain. It provides light since 2012 to users through its 7 beamlines, with 2 more under construction. The ALBA Control Section (ACS) is currently formed by 16 engineers devoted to the development of our Tango-based SCADA frameworks (Taurus[4], Sardana[5][6] and PANIC[7]) and PLC systems.

The ALBA Equipment and Personnel Protection Systems[8][9] (EPS and PSS) are distributed PLC-based systems autonomous from the Tango Control System. Both EPS and PSS are homogeneous systems based on single vendors (B&R and Pilz respectively). While the tasks to be done by the PSS are clearly specified and delimited by the ALBA Safety Group, the EPS PLC's became instead a versatile system that has been adapted for interlock, acquisition and motion control in both accelerators and beamlines.

Although other PLC based systems are used in ALBA to control the RF circulators, bakeout controllers and water or air cooling systems; the EPS is the most complex system managed by PLC's, using 58 B&R CPU's and 110 periphery cabinets to collect more than 7000 signals. In addition to the main purpose of protection, several hundreds of signals distributed across the whole system are acquired for diagnostics and control of pressures, temperatures and movable elements

The integration of the management of an independent system like EPS in the Tango Control System required of several phases, starting from the collection of cables from the Cabling Database to the final auto-generation of GUI's for both EPS Expert GUI and operator users (Taurus) .

GENERATION OF CODE VARIABLES

The Cabling and Controls Database

Every cable and equipment installed in the ALBA Synchrotron is registered in our Cabling and Controls Database (CCDB). Developed in 2007[10] by our Management and Information Software section (MIS) using MySQL and web technologies, it was the main support tool for the design and construction phase and now it is still kept updated as the main repository of equipments and configurations in our Accelerators and Beamlines. As of 2015 it lists 385 racks with 7131 equipments of different 874 equipment types. These equipments are connected using 20053 cables of 487 different cable types with a total length of 172.26 Km.

The CCDB provides, for each of our PLC CPU's or remote peripherals, the full list of connected devices, its equipment types, cable configurations, terminal used and the distribution of hardware in racks, including the routing of cables between hardware and control devices (Fig. 1). It also provides fast access to all available documentation for each type of equipment.

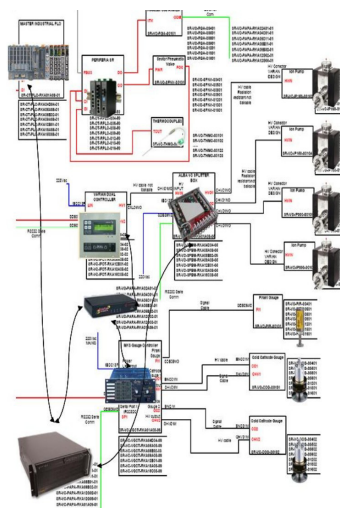

Figure 1: Diagrams of every subsystem have been produced prior to its introduction in our cabling database.

The PLC Auto-Generation Tool

The CCDB python API[11] provides full access to the Cabling Database from our control system tools. The API methods allow to search for equipments and get lists of connections, names and network information. These links are used to enable our Auto-Generation coding tool correlating the information of the equipments from the CCDB with the logics defined for them in the EPS.

To do so, all the common elements of our different Equipment Protection Systems have been standardized in

our EPS_LIBRARY project. This library, later exported to our different CPU sub-projects, provides the standard logic behavior for managing each equipment type connected to the PLC and its remotes. These standard procedures include managing in/out digital signals for valves, alarm/warning ranges for analog values, value conversions for thermocouples, linear correlation for 4-20 mA transducers and standard conversion scales for flowmeters amongst others.

For each CPU of the EPS, the PLC Auto-Generation tool (Fig. 2) extracts exhaustive reports of all equipments connected to the CPU and its remotes, parses the naming of these equipments and its logics depending on the cable and terminal connectors used in both sides (along with notations introduced by the Controls or Electronics engineers). This full cable report is later translated to a full list of the PLC variables with its matching PLC code structures.

Figure 2: PLC Auto-Generation tool.

These steps does not produce the final code of the PLC, but a detailed guide of the structures to be generated. The control engineer then must coordinate logics of individual variables and program the most specific logics of every beamline or accelerators section, being capable of focusing in the most critical parts instead of the tedious and iterative variable naming.

The processes for auto-generation of code variables were originally developed using visual basic, which required manual extraction from database and generated static reports. Migrating these procedures to python allowed to develop tools that can be executed automatically, enabling the automatization of regular code review and error checking.

The final output of the auto-generation process is the variable modbus mapping spreadsheet, commonly known as the EPS CSV. This file will be used later to generate the EPS Expert GUI and the Tango Attributes used by User-Level GUI's.

PLC TANGO DEVICE SERVERS

PLC's at Alba are accessed using two protocols: Fetch & Write for Siemens PLC's (cooling systems) and Modbus (over TCP or RS485) for the rest of systems, including EPS.

Figure 3: Structure of the PyPLC device server.

All Modbus-based PLC's are accessed using the PyPLC[12] device server. This python device server[13] (in use since 2008) have been developed over the Modbus C++ (Fig.3) device class to allow four different types of access:

- Directly executing Modbus commands in the PyPLC device server, direct actions mapped to specific bits (e.g., open Front-End).
- Reading the whole Modbus address space into array attributes, method optimized to get maximum update frequency, used by the Expert GUI.
- Exporting EPS variables as individual Tango attributes, thus enabling Tango features like ranges, alarms, archiving, labels, etc.
- Exporting EPS variables as individual Tango devices, typically valves with its own Open/Close commands.

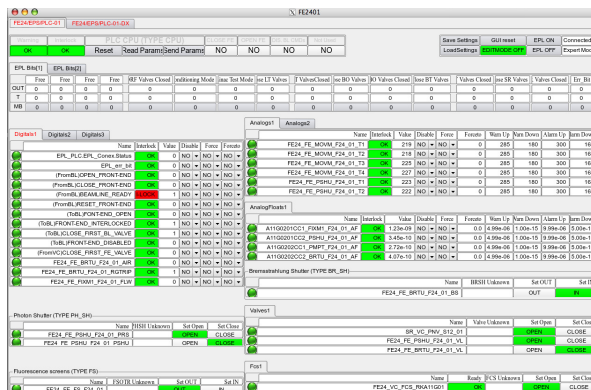

The PyPLC exports the most standard Modbus commands (Read/Write Input/Holding Registers) and PLC variable types (Coil / Flag / Int / Long / Float / Ieee Float). This PyTango device server uses the Fandango Dynamic Attributes [14] template to generate new attributes at runtime based on user-defined formulas (Table 1). These dynamic generation of attributes boosted the initial prototyping of the devices, providing enough functionality for the most elementary systems (temperature controllers, stand-alone PLC's) and allowing to customize the attribute generation done by the EPS Auto-generation tools.

Table 1: PyPLC Attribute Formulas, an Array, a Writable Boolean Flag and Two Commands

```
TEMPERATURES=
    DevVarLongArray(Regs(7800,100))
DIO_01= bool(
    READ and Flag(80,7) or
    WRITE and WriteFlag(81,7,VALUE))
Open_PNV01=(WriteBit(193,2,1),1)[-1]
Close_PNV01=(WriteBit(193,1,1),0)[-1]
```

using them as I/O or experimental data (e.g. temperatures and vacuum pressures). In addition, limited motion control have been implemented using PyPLC and dedicated structures in the EPS_LIBRARY, which allowed direct control from Sardana macros or scans developed by scientists.

A similar approach to higher-level procedures involving several Tango devices are implemented using automated actions from PANIC Alarm System[7]. Those macros allow both scientists and PLC engineers to program automated actions on elements controlled by the EPS (valves, shutters) during experiments. These actions do not bypass the EPS, as it is always kept as an autonomous system ensuring the safe state of the installation, but allow the recovery of the system once all the permits conditions are matched.

This transparent interaction between the Tango and EPS control systems is pushing the need of an standard User-level GUI for the EPS, providing the same information than the Expert GUI but in a way that makes easier to locate and diagnose the causes of an interlock (and the best way to recover). This diagnose feature is being

implemented as a PLC source navigator integrated within our current Vacuum Control Application (VACCA), which has been already extended to manage both Archiving and Alarms services.

CONCLUSION

After 8 years of design, installation, commissioning and operation the EPS has become a mature control system by itself, achieving a high level of consistency and reliability.

Its integration within Tango using PyPLC allowed to integrate the PLC systems in all our Tango services. Not only in “passive” ones like Archiving or Alarms, but also as an active part in our experiment-control framework, Sardana.

The next step is the integration of the current tools in an automated cycle of continuous development and delivery. First steps in this direction have been achieved introducing all the PLC's code in SVN repositories, and later migrating to python all the auto-generation tools.

Now, after several years of operation, the two new beamlines under construction at Alba are bringing an opportunity to put all the recent improvements and develop a clean and optimized solution for them. Learning from the previous experience and aiming to refine the new procedures to be later reapplied to the old beamlines.

The current level of integration between Tango and EPS on older beamlines is still much lower than in the accelerators side. This is due to the bigger number of special cases and exceptions while integrating specific devices in the CCDB catalog or the EPS_LIBRARY. It is expected that the new tools as the Auto-generation and the Source navigator will help the PLC engineers to simplify the logics and naming of the existing systems, but there will be always a big percentage of beamline variables too specific to be standardized.

For those cases, enabling all EPS variables as Tango attributes will allow the users to setup and use their own Labels, while keeping the cabling-based tags as attribute names. This kind of mixed naming schema (attribute for control engineers, label for scientists) should reduce the number of naming conventions exceptions and provide enough consistency to close the auto-generation loop.

ACKNOWLEDGEMENT

Many former ALBA engineers have collaborated in the PLC-related projects in the last 6 years: A.Rubio, R.Ranz, R.Montañó, R.Suñé, M.Niegowski, M.Broseta and J.Villanueva.

The collaboration of Tango core developer, Emmanuel Taurel and former ALBA developer R.Suñé was fundamental in the development of Dynamic Attributes templates and debugging of PyPLC performance.

The work of the Generic Software Group at ALBA in the development of Taurus and the Taurus GUI framework has made possible the evolution of the EPS Graphical User Applications.

Last but not least, none of the elements in the auto-generation cycle would have work without the Cabling and Controls Database, developed by the Management and Information Systems section of ALBA.

UPGRADE OF ABORT TRIGGER SYSTEM FOR SuperKEKB

S. Sasaki[#], A. Akiyama, M. Iwasaki, T. Naito, T. T. Nakamura, KEK, Ibaraki, Japan

Abstract

The beam abort system was installed in KEKB to protect the accelerator equipment and the Belle detector, and for radiation safety, from high current beams. For SuperKEKB, the new abort trigger system has been developed. It collects more than 130 beam abort request signals and issues the beam abort trigger signal to the abort kickers. The request signals are partially aggregated in local control rooms located along the SuperKEKB ring and finally aggregated in central control room. In order to increase the system reliability, the VME-based module and the E/O module was developed, and all the abort signals between the modules are transmitted as optical signals. The system also has the timestamp function to keep track abort signal received time. The timestamps are expected to contribute to identify the cause of the beam abort. Based on the feasibility tests with a prototype module, the new module design has been improved and fixed. This paper describes the details of the new abort trigger system.

INTRODUCTION

SuperKEKB is the upgrade of the KEKB asymmetric energy electron-positron collider in Japan [1]. The designed luminosity is 40 times as high as the peak luminosity of KEKB.

SuperKEKB consist of two storage rings, low-energy ring (LER) and high-energy ring (HER). Each ring has a beam abort system to protect the accelerator equipment and the Belle detector, and for radiation safety, from high current beams. The abort trigger system collects more than 130 beam request signals and issues a beam abort trigger signal to abort kickers.

In KEKB, the modules of the abort trigger system were connected with twisted pair cable to transmit the electrical request signals and low pass filters were inserted to reduce electrical noise. The low pass filters caused time delay and the total system response time was about 100 μ s. For SuperKEKB, the optical request signals are transmitted and the low pass filters have been removed. The response time is improved to be less than 20 μ s.

The new system has the timestamp function to keep track of the abort signal received time. The resolution of the timestamp is 0.1 μ s. It is expected to contribute to identify the cause of beam abort.

This paper describes the design and the status of the new abort trigger system.

[#]shinya.sasaki@kek.jp

SYSTEM DESIGN

Modules

The system is composed of two kinds of modules. First is 2ch E/O module which converts electrical signals from abort request source to optical signals. It can receive 3 kinds of electrical inputs: TTL, RS422, or relay, and can treat the input as active-high or active-low. They are set by slide switches in front panel. Figure 1 shows picture of the 2ch E/O module.

Figure 1: Picture of the 2ch E/O module. Input type and polarity can be set by slide switches (1424).

Second is VME-based 8ch beam abort optical input module (18K15). It gathers 8 optical signals and output an OR optical signal. Since it latches the input signals until reset, pulse input can also be detected and it keeps outputting once request signal is detected. Above functions are processed on FPGA, software is not running on the module. The module can be controlled and monitored via VMEbus. Figure 2 shows picture of the VME-based 8ch beam abort optical input module.

Figure 2: Picture of the VME-based 8ch beam abort optical input module (18K15).

Timestamps

Abort request signals are usually occurred sequentially. Therefore an order of the request signals are important to identify a cause of the beam abort. The new abort trigger system records timestamps when it received the request signal. The timestamps reveal the order of sequential request signal.

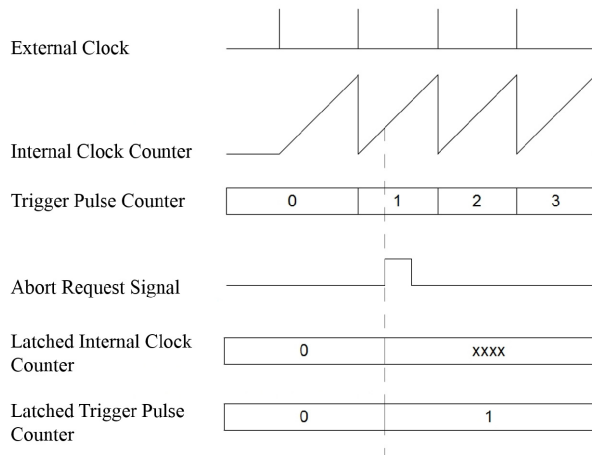

Figure 3: Timing diagram of two counters for timestamps. Internal clock counter counts up at 10 MHz. When the module detects an abort request signal the counters are latched until reset.

The timestamps are generated from two counters, an internal clock counter and a trigger pulse counter, in 18K15. The internal clock counter count up at 10 MHz synchronized to FPGA operation clock. The trigger pulse

counter counts an external clock. Each counter is 32-bit and cleared when the module is reset. The internal clock counter is also cleared when the external clock input is detected. After the module reset, each counter starts to count up after the external clock is detected. The external clock synchronize the counters of the all modules in the system. When the module detects an abort request signal the counters are latched until reset. Figure 3 shows the timing diagram of the counter.

The resolution of the timestamp is 0.1 μ s since the internal clock counter counts up at 10 MHz. We can notice relative time differences from the counters. However absolute time cannot be calculated without software processing. We can calculate absolute time with the time when an external clock source send a signal.

System Configuration

Figure 4 shows entire system configuration. The electrical abort request signals from equipment are converted to optical signals on 1424 E/O modules. The optical signals are partially aggregated in Local Control Rooms (LCR) located along the SuperKEKB ring and finally aggregated in Central Control Room (CCR). The longest distance from LCR to CCR is 2 km and its transmission time is about 10 μ s.

The system needs external clock source to synchronize the timestamp among 18K15s. We use a software trigger system [2] as external clock. It provides the synchronization pulse and/or the interrupt signal to Input/Output Controllers (IOCs) or devices. The time when the software trigger system send a synchronization trigger is recorded on the IOC at CCR.

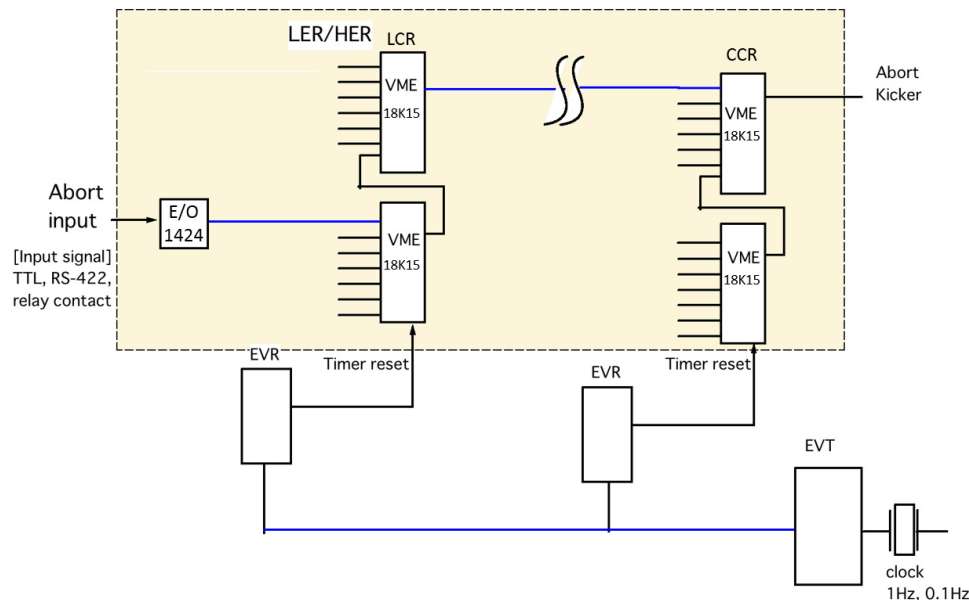

Figure 4: Schematic diagram of the abort trigger system for SuperKEKB. Abort request signals are converted to optical signals on E/O modules and aggregated on VME-based modules. The signals are partially aggregated in LCR and finally aggregated in CCR. The time when EVT (EVEN Transmitter module) send a synchronization trigger is recorded on the IOC at CCR.

PERFORMANCE TESTS

Response time

We have tested the response time of 1424 and 18K15. The setup of the test is shown in figure 5. We have measured TTL outputs of the modules equivalent to optical output. Function generator generates pseudo abort request signal which is 500 ns pulse width.

Figure 6 is result of the test. The system detected 500 ns pulsed request signal. It takes about 150 ns for 18K15 to output after E/O module output. This latency is cable delay and processing time of 18K15. Considering that the longest cable delay from LCR to CCR is 10 μ s, the latency is sufficiently low and the latency of the abort trigger system mainly depends on the cable delay.

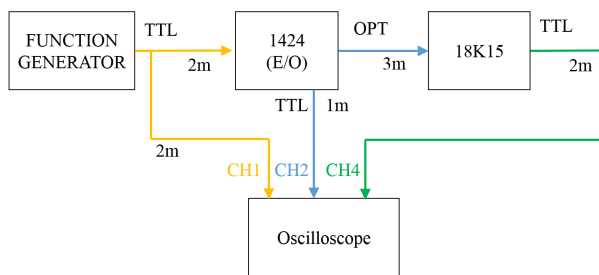

Figure 5: Schematic diagram of the response time measurement.

Figure 6: Response of 1424 and 18K15 to 500 ns pulse request signal input. CH1 is pseudo abort request signal generated from Function Generator. CH2 is TTL output equivalent to output of E/O module. CH4 is gathered output on 18K15.

Module control and timestamp

Since the SuperKEKB control system was based on EPICS [3], we have developed EPICS software to control and monitor 18K15.

We have tested the timestamp function with EPICS control system. Abort request signals were input to 18K15 on arbitrary timing and we confirmed latched counters shown in figure 7. The counters revealed an order of abort request signals.

	TRIG_TIME	ABORT_TIME
CH1	0x20	0x92E8A
CH2	0x23	0xDF10B
CH3	0x2B	0xEF747
CH4	0x2B	0x7DDAA
CH5	0x32	0x5B32C6
CH6	0x2F	0x3207FC

Figure 7: Latched counters of 18K15. TRIG_TIME is the trigger pulse counter and ABORT_TIME is the internal clock counter. The counters show CH1 is the first detected signal.

Figure 8 shows timestamps of time and date format. The timestamps are calculated by software processing based on recorded time which the software trigger system send a synchronization trigger. A relative error among timestamps is several microsecond caused of an error of internal 10 MHz clock on 18K15s and a synchronization error among 18K15s. On the other hand, an absolute error of timestamps is several millisecond caused of an error of the recorded time on IOC at CCR.

CH1	2014/07/16 11:40:51.752964056
CH2	2014/07/16 11:40:54.784157756
CH3	2014/07/16 11:41:02.790870956
CH4	2014/07/16 11:41:02.744340056
CH5	2014/07/16 11:41:10.290467656
CH6	2014/07/16 11:41:07.020674656

Figure 8: Timestamps of time and date format calculated by software processing.

CONCLUSION

We have developed the new abort trigger system for SuperKEKB. The total response time of the system significantly depends on cable delay and it is improved to be less than 20 μ s. The system can record timestamps when it receives abort request signals. Timestamps reveal the order of sequential request signals.

DEVELOPMENT OF A NETWORK-BASED PERSONAL DOSIMETRY SYSTEM, KURAMA-micro

M. Tanigaki, Research Reactor Institute, Kyoto University, Kumatori, Osaka 590-0494, Japan
Y. Nakanishi, Electronics Laboratory, Shikoku Research Institute Inc.,
Takamatsu, Kagawa, 761-0113, Japan

Abstract

KURAMA-micro, a personal dosimetry system with network and positioning capabilities, is developed for the continuous monitoring of radiation exposure of individual in a large group, based on their action histories. Typical target users are the residents returning to their hometown after decontamination, and the workers involved in the decommissioning of the Fukushima Daiichi nuclear power plant. A KURAMA-micro unit consists of a semiconductor dosimeter and a compact DAQ board with a GPS module and a ZigBee module. Each unit records radiation data tagged with their measurement time and locations, and uploads the data to the server over a ZigBee-based network once each unit comes near the access point installed in the area of daily activities of users. Location data are basically obtained by a GPS unit, and an additional radio beacon scheme using ZigBee broadcast protocol is also used for the indoor positioning. A field test of the prototype of KURAMA-micro was performed in Fukushima city, and the radiation trends were successfully observed.

INTRODUCTION

The magnitude-9 earthquake in eastern Japan and the following massive tsunami caused a serious nuclear disaster of Fukushima Daiichi nuclear power plant. Serious contamination was caused by radioactive isotopes in Fukushima and surrounding prefectures. KURAMA [1] and KURAMA-II [2] were developed to overcome the difficulties in radiation surveys and to establish air dose-rate maps during and after the present incident. KURAMA has been successfully applied to various activities in the radiation measurements and the compilation of radiation maps in Fukushima and surrounding areas. KURAMA-II, an advanced version of KURAMA with autonomous operation and pulse height spectra measurement, has been used to establish the continuous monitoring scheme in residential areas in Fukushima prefecture. Fifty local buses and official cars equipped with KURAMA-II have been continuously operated in Fukushima prefecture, and radiation maps have been released to the public on weekly-basis. The results from KURAMA-II also contribute the predictions of air dose rates of the future in Fukushima.

Along with such wide-scale monitoring, the importance of more personalized monitoring intending to track the actual exposure of individual to the radiation are recognized to clarify the dependence of radiation exposures to human activities. For example, it is well known that the indoor radiation exposure becomes lower than outdoors, but the time length of stay indoors/outdoors vary depending on one's

occupation, age, place to live etc. To clarify what kind of activities cause the higher radiation exposure is important to establish effective measures to minimize the radiation exposure. As the recovery from the nuclear accident in Fukushima progresses, strong demands of such personalized monitoring arise for a large group with higher risk of radiation exposure, such as the residents returning to their hometown after decontamination, or the workers involved in the decommissioning of the Fukushima Daiichi nuclear power plant.

For such purpose, personal dosimeters that measure the cumulative radiation dose, such as film badges, electronic pocket dosimeters, have been widely used, but the lack of positioning and time information made difficult to analyze in the view point of the human activities. Additionally, the difficulty in collecting data periodically from a large number of people obstruct the analysis of such data to extract the general tendency of radiation exposure towards human activities.

KURAMA-micro, a personal dosimetry system with network and positioning capability, is developed for such purpose. KURAMA-micro consists of a semiconductor dosimeter and a DAQ board with GPS and ZigBee modules. The data of KURAMA-micro is collected via an ad-hoc ZigBee based network to minimize the troubles of users. The development of a prototype KURAMA-micro is finished and field tests are on the way. In this paper, the outline of KURAMA-micro and the results from a field test in Fukushima are introduced.

SYSTEM OUTLINE OF KURAMA-micro

KURAMA-micro stands on a similar concept as claimed by KURAMA/KURAMA-II, and intends to be the alternative choice of conventional personal dosimeters. Therefore, the system must overcome the difficulties arising from its usage. For example, the unit must be comparable in size to other personal dosimeters, and the operating time should be long comparable to the replacement period of conventional film badges, typically one month. Therefore KURAMA-micro is designed to achieve better performance on power-consumption or sufficient compactness rather than on the detection efficiency or the measurement precision.

KURAMA-micro consists of the radiation detection part and the DAQ part (Fig. 1). The radiation detection part is a conventional accumulated radiation dosimeter with I2C connection to the DAQ part. The DAQ part has an I2C interface for the radiation detection part, a GPS unit for positioning, and a ZigBee unit for the data communication.

This ZigBee unit is also used for a supplemental positioning where the radio waves from GPS satellites are not available.

Figure 1: A prototype KURAMA-micro unit. The board on the right is the DAQ part based on OpenATOMS architecture. The left part shielded by aluminum foil is the radiation detection part. Both are implemented into a box of business card size. The power required for the unit is managed by a 3.7 V rechargeable Li-ion battery.

The radiation detection part of KURAMA-micro consists of a typical semiconductor detector, charge-amplifier, shaping amplifier, and a microprocessor with ADC capability. A conventional photodiode (Hamamatsu S6775) is used as a semiconductor detector. The charge amplifier and shaping amplifier are configured by using Smart Analog series of Renesas Electronics [3]. Smart Analog is a programmable analog IC designed for processing small sensor signals. This IC includes several amplifiers with programmable gain, general-purpose operational amplifiers, high-pass and low-pass filters, and DACs, and those connections and operation modes are programmable. Additionally, Smart Analog has several low power consumption modes, in which the circuits in the IC are operated intermittently or turned off partially upon user's settings. Such low power mode is useful for the devices required for the low-power operation such like KURAMA-micro. Each pulse from the Smart Analog IC is sent to ADC in the microprocessor, then accumulated as a pulse height spectrum. The accumulation period lasts until the request for air dose from DAQ part comes, then the accumulated air dose is calculated from this pulse height spectrum by G(E) function method [4].

The DAQ part of KURAMA-micro is based on OpenATOMS(open Advanced Topological On-demand Monitoring System) [5] developed by Shikoku Research Institute Inc. OpenATOMS is a platform developed for sensor networks in field, especially for the cases that the continuous monitoring is required for a long period under the lack of sufficient power supplies or a reliable network communication. In this platform, each sensing device is connected to a microcomputer board named as NICE(Networked Intelligent Cell). One of the features in NICE is the low power consumption by an advanced power management scheme in which the power of most part in NICE can be switched on/off by the embedded timer. With this feature, a NICE board can be operated for more than a month by a conventional dry cell. Each NICE board joins an ad hoc ZigBee network maintained by a local gateway server connected to a TCP/IP network. All the data are once collected and stored in a local server as an XML based format, then extracted by remote users or data servers upon request. Typical applications of OpenATOMS are the monitoring the ground parameters to detect landslides in mountainous areas, or the condition in hothouses for agricultural products.

These features of OpenATOMS almost satisfy the requirements of KURAMA-micro. The power management system implemented in NICE is quite useful for the minimization of power consumption in KURAMA-micro, and the data management vis the ad hoc network based on ZigBee realizes the data collection without the manipulation of users. But there are still challenges. One of the challenges in the case of KURAMA-micro is that the units do not always join the ZigBee network because each unit always move around the residential area along with the carrier. This results in a large power consumption if the continuous seek of an access point is simply allowed. Therefore, the seeking time of the network is limited based on the activities of the people carrying KURAMA-micro by using the power management capability of NICE. For example, the seeking time is limited to the daytime of weekdays in the case of schoolchildren, expecting the attendance of their classrooms and the connection to the access points placed at the classrooms.

Another challenge in KURAMA-micro is the positioning scheme where the radio waves from GPS satellites are not available, mainly indoors and underpasses. This time, radio beacons using ZigBee broadcast protocol are used as the alternative positioning for this purpose. These ZigBee-based beacons are settled place by place, and the location of the measurement is treated as that of received beacon. This scheme is not only enables the approximated positioning in indoors and underpasses, but also effective to improve the accuracy of the height information in buildings to distinguish the difference of radiation exposure in floor level. The accuracy in height is generally very poor in GPS, poor enough not to distinguish the floor level.

Figure 2: The time-domain trend of air dose rate obtained by KURAMA-micro(upper graph) and that obtained by KURAMA-II(lower graph) for comparison. The measurement period for KURAMA-micro and KURAMA-II are one minute and three seconds, respectively. The air dose rate from KURAMA-micro is described in arbitrary units because the absolute calibration for the unit is not performed at that time.

TEST OPERATION IN FUKUSHIMA

To confirm the concept of KURAMA-micro, a field test of a prototype KURAMA-micro carried by an examinee was performed in the center area of Fukushima city. The purpose of this field test was to examine whether KURAMA-micro actually tracks the radiation exposure to a person under activities of daily living. During the field test, the examinee strolled around the center of Fukushima city, mainly outdoors and occasionally inside the building. The examinee was accompanied by a person measuring the air dose rate by KURAMA-II for comparison. The measurement period of KURAMA-micro was set to 1 minute instead of 10 minutes for detailed analysis of the effect from surrounding condition to the radiation measurement.

The radiation trends of KURAMA-micro and KURAMA-II in time domain is shown in Fig. 2. A moderate correlation was found between the results of both systems. Some differences observed in the trends were caused by "micro hot spots" that were occasionally observed in Fukushima city, such as remaining contamination at hedges along the road. Such small hot spots produce a localized radiation field, which often cause the difference on the air doses of examinee and the accompanied person. Other differences were due to the improper sequence implement in this prototype of KURAMA-micro. DAQ board was programmed not to request the radiation data to the radiation detection part until the positioning had been determined, so the air dose data was often kept accumulated beyond the normal request time period. The positioning by GPS frequently failed due to the buildings along the street, therefore the request period tended to be longer than that was set.

The radiation map generated from the result of KURAMA-micro was compared with that from the result of KURAMA-II units on local buses(Fig. 3). In the central area of Fukushima city, a radiation map with the grid size of $100\text{ m} \times 100\text{ m}$ is generated by KURAMA-II units on local buses on a weekly basis [6]. Through the averaging procedure

of KURAMA-micro data to $100\text{ m} \times 100\text{ m}$ grid, differences caused by "micro hot spots" and intermittent failures of GPS were averaged. These maps are similar except several regions, and these were mainly identified as the effect of measurement points such as inside the building or the underpasses of large roads.

CURRENT STATUS AND FUTURE PROSPECTS

Currently, KURAMA-micro is under development, mainly for the reduction of interference by incoming noise. The reduction of such noise is crucial for the semiconductor detectors since they usually have a high impedance charge amplifier in their front end. As soon as the sufficient noise reduction is achieved, several extended field tests will be performed. Along with the noise reduction, tunings for the power reduction is on the way, such as the optimization in the power management of the GPS module. As for the current prototype KURAMA-micro, the operation time reaches around three weeks with 3.7V 3100 mAh battery.

One of the expected applications of KURAMA-micro is the personal dose monitoring of school children(Fig. 4). In this application, a KURAMA-micro carried by a schoolchild collects the radiation data and positioning data throughout the day. The positioning data is basically collected by a GPS unit in KURAMA-micro, and radio beacon units using ZigBee broadcast protocols are placed in the public buildings in the school district and in houses of school children. Such radio beacons are expected to be placed easier because the area of the activities of school children is mainly in the school district. The frequency of data collection is planned 10 min, to reduce the power consumption and not to disclose the activities of school children too much from the viewpoint of privacy. The data accumulated by each KURAMA-micro unit is collected via the access point in classrooms of their school while schoolchildren stays in their school. The col-

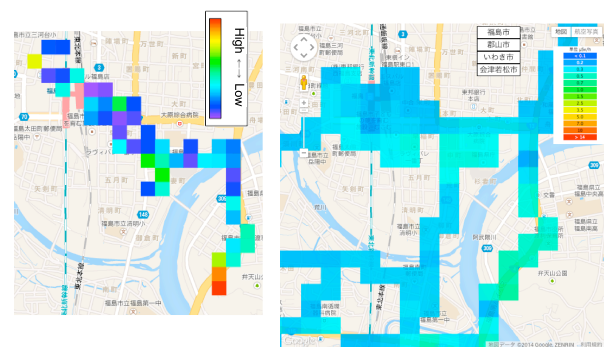

Figure 3: The air dose rate map from the data of KURAMA-micro(left side) and that from KURAMA-II on local buses(right side) at the same measurement period. The values were averaged for every $100\text{ m} \times 100\text{ m}$. The air dose rate from KURAMA-micro is described in arbitrary units because the absolute calibration for the unit is not performed at that time.

Figure 4: An expected operation of KURAMA-micro.

lection time for all the data of schoolchildren in a class is estimated to be several hours by taking into account the transmission speed of ZigBee, almost the same as the average staying time of school children in a classroom. KURAMA-micro units are replaced every month, as that in the case of other conventional dosimeters like film badges.

ACKNOWLEDGEMENTS

Authors are grateful to Mr. Yamasaki, Mr. Ishii, Mr. Takagi at Shikoku Electric Power Co., Inc. for the continuous support on the management of this development project. The author(M. T.) is also grateful to Mr. Matsumoto and Mr.

Dozono at PI system Co., Ltd. for the discussions on the circuit design of the radiation detection part.

INTEGRATION OF HETEROGENEOUS ACCESS CONTROL FUNCTIONALITIES USING THE NEW GENERATION OF NI cRIO 903X CONTROLLERS

F. Valentini, T. Hakulinen, L. Hammouti, P. Ninin
CERN, Geneva, Switzerland

Abstract

Engineering of Personnel Protection Systems (PPS) in large research facilities, such CERN, represents nowadays a major challenge in terms of requirements for safety and access control functionalities. PPS are usually conceived as two separate independent entities: a Safety System dealing with machine interlocks and subject to rigid safety standards (e.g. IEC-61508); and a conventional Access Control System made by integration of different COTS technologies. The latter provides a large palette of functionalities and tools intended either to assist users accessing the controlled areas, either to automate a certain number of control room operator's tasks. In this paper we analyse the benefits in terms of performance, cost and system maintainability of adopting the new generation of NI multipurpose cRIO 903x controllers. These new devices allows an optimal integration of a large set of access control functionalities, namely: automatic control of motorized devices, identification/count of users in zone, implementation of dedicated anti-intrusion algorithms, graphical display of relevant information for local users, and remote control/monitoring for control room operators.

INTRODUCTION

The GS/ASE group is responsible for the realization and the maintenance of Personnel Protection Systems ensuring the safety of personnel accessing to the various accelerator complexes of CERN. The group was responsible for the conception of a new generation of *access points* [3] to gradually replace the traditional rotating gates, some of them aged of few decades.

Even though the different system functionalities were clearly identified and specified since the beginning of the project, the realization strategy favored a construction by the integration of off-the-shelf (COTS) products rather than to privilege any form of custom development. This choice was mainly motivated by the limited internal resources, making it necessary to externalize the activity to a system integrator, and by the fact that the various functionalities to be provided were already present on the market with well-known and robust commercial solutions. Another motivation was the conviction that constructing a new system out of modular simple blocks would be more easy and rapid than to start a development from scratch. However, in our experience, it turned out that dealing with COTS can be quite a risky activity for a wide variety of reasons.

In [1], presented in the *International Conference on Software Engineering* of 1995, Garlan, et al., introduces the term of *architectural mismatch* to explain the different problems inherent in integration of COTS software components. Typically, many problems are caused by incompatibilities between the programming languages, the operating platforms or the database schemas of the products being integrated. The authors argue that at the origin of any architectural mismatch problem there is the fact that COTS components make several assumptions about the system architecture and its operational environment; consequently, when these assumptions conflict or do not match with each other, the simplicity of assembling complex systems from integration of COTS immediately disappears.

The biggest challenge for designing an access point turned out to be the integration of numerous heterogeneous components such as PLCs to command the movements of the motorized doors, *front-end* to deal with the real-time authorization management, *biometry* for authenticating users, *video system* for remote surveillance of the areas, *public address* system for broadcasting of audio messages, and many other devices. In this context our team is constantly seeking new solutions and technologies allowing to minimize the number of CPUs and information that need to be handled and exchanged between the different subsystems.

This paper will especially focus on the impact analysis that a completely COTS oriented realization strategy had on the architecture of the first series of our access points and it highlights the actual interest in the National Instruments technology [5] as a possible solution for the implementation of more rational system architectures.

THE ACCESS POINT CONCEPT

This section describes the ideas and the concepts behind any access point at CERN. Many would claim that an access point is simply made of “*one door, equipped with expensive position sensors, a video camera and a microphone allowing remote connections with guardians or operators*”. However it is much more than that. An access point in a facility like CERN plays a crucial role in defending the installation against intrusions and accesses of people not holding the security requirements. At the same time, it ensures the safety of personnel every-day working inside the potentially dangerous areas.

Figure 1: Standard configuration of an Access Point.

In order to accomplish its double mission, an access point (see Fig. 1) has to provide a certain number of important functionalities:

- **Personnel Access Supervision:** a dedicated device (PAD) is in charge of regulating the entrance of personnel. The device is an air-lock closed by 2 motorized doors and equipped with redundant anti-fraud detection systems dealing with all typical situations of piggybacking and tailgating intrusions.
- **Material Access Supervision:** an additional specific device (MAD) is in charge of controlling the transfer of bulky material to and from the controlled areas. The device is made of two motorized doors that cannot be opened at the same time; the internal volume is then surveilled by two human detection systems based on motion detection and video image analysis algorithms, in order to reduce the possibility for a person to gain easy access to the zone.
- **Dynamic Information Dispatch:** personnel accessing the controlled areas needs to be dynamically informed about the safety conditions inside the zone. The information system is made up of two independent components: a group of LEDs for critical safety warning visualization, directly animated by a PLC; and a standard local screen hosting a graphical user interface. This latter shows information about the operational state of the zone and it drives users through the complete access procedure.
- **User Identification:** in order to access the controlled areas every user must be identified and his access privileges must be checked against the central authorizations database. The identification of users is done via an RFid badge reader and a biometric eyes scanner.
- **Personnel Safety Tokens Distribution:** as additional protection, every accessing user is provided with a safety token that is automatically released by a dis-

tributor. The possession of the token ensures that beam operations cannot be reestablished.

- **Interphone System:** an audio/video communication system allows local users to contact the CERN control room operators.
- **Remote Maintenance:** due to the large number of access points installed all over the CERN complex, the maintenance team needs to be able to perform a certain amount of operations remotely. Extra functionalities were added afterwards in order to power off individuals controllers, access to detailed diagnostic and operational data or to send specific commands to the different electronic devices.

The resulting architecture is the outcome of a process of integration of different hardware and software subsystems, each one basically in charge for realizing a specific well determined function. Just to give an idea, the main subsystems controlling an access point (LHC type) are:

A control unit (UTL) for PAD: the controller, based on a proprietary OS, is in charge of acquiring the RFid badge ids, verifying the users' credentials in a central database and, additionally, for commanding the PAD motorized doors movements.

A Siemens PLC S7-200 for PAD motors: this PLC is provided by the PAD supplier and it is used to directly drive the door motors according to UTL commands.

A control unit (UTL) for the MAD: the controller, based on a proprietary OS, is dedicated uniquely to command the MAD motorized doors.

A microcontroller for MAD motors: this dedicated electronics, Microchip based technology, is provided and programmed by the MAD supplier and it is used to physically drive the door motors according to UTL commands.

Two control units for biometric: one Linux based PC is in charge of the processes related to the eye scanned image, while another dedicated unit simply checks the authorization on the biometric database and communicates the user identified to the PAD's UTL. This info is sent then to the main control front-end that send it back down to the information screen controller for displaying, locally, the name of the user.

A microcontroller for the key distributor: the distributor is an industrial product coming with its own electronic control system to handle all operations on the keys.

A standard Windows PC: another PC is used to run a specific commercial SCADA software that, communicating with a central front-end, displays all live information for local users. Additionally, this PC runs the detection software that is used to analyze the material passed through the MAD.

A Siemens S7-1200 PLC: this was added during the operational phase to perform simple remote maintenance commands. This was the only practicable solution because of the complexity of modifying any of the other existing controllers at this scope.

An I/O remote Ethernet module: the module was added to allow to the MAD video analysis software to acquire

the state of the MAD door, since it was not possible to extract this information from the MAD UTL.

MAIN PROBLEMS ENCOUNTERED FOR THE ACCESS POINT DESIGN

What appears the most shocking in this architecture is that basically every functionality of an access point is realized via one or more industrial controllers. Very frequently these controllers are made by powerful electronics units, equipped with sophisticated microprocessors, modern operating systems and provided with data communication protocols (Ethernet, serials RS 485/422, etc.) as with digital or analog input output interfaces. So, in principle, almost any of the controllers could be programmed to execute the whole set of functions instead of being underutilized and, despite all this, the implementation of some basic functions (as displaying on the local screen the name of last identified user) has turned out to be extremely difficult.

Another critical point is represented by the system maintainability due to the large number of access points actually in operation. Considering a total of 56 units between the LHC and PS with an average of 10 critical controller each, estimating a gross MTBF of 3.4 years for every component, an average time to repair of 3 hours at two technicians: this leads to a total time of **987** working hours per year only for dealing with failures. Additionally to that, extra costs for preventive maintenance (e.g. installation of Windows security patches) have to be considered.

From our point of view many difficulties that are found during the integration of commercial COTS are caused by typical architectural mismatch problems. The attention to a certain number of factors and initial assumptions is essential to avoid a large amount of problems:

1. *Assumptions about the nature of components.*
2. *Evaluation of the communication needs between the different components.*
3. *Flexibility and evolution requirements.*
4. *Maintainability requirements.*

After the return of experience obtained by the design, the construction and the maintenance phases over the past 8 years [3], many efforts have been made in order to find new concepts and methodologies allowing to simplify and homogenize our systems. A second more robust generation of access points have been recently put in operation to regulate all accesses of the PS accelerators complex. Despite that the hardware and software architecture has been entirely reviewed and that the final product presents evident improvements [4], a certain complexity is still affecting the system. The heterogeneity of the various functionalities still requires that a large number of controllers and software products operate together.

CURRENT PRESPECTIVES

Currently, a promising compromise solution between integration of existing components and custom develop-

ment is offered by the *National Instruments* (NI) technology [5]. This especially thanks to the synergy offered by two NI products: the new generation of Compact RIO 903x controllers and LABVIEW as software development environment.

The typical CompactRIO system is a combination of a real-time controller, reconfigurable I/O Modules and an FPGA chip (see Fig. 2). The real-time target includes an Intel microprocessor for implementing network communication, data logging, control algorithms, and it provides support for deterministic execution thanks to the presence of a real-Time OS. The FPGA module, from Xilinx, is integrated in the same chassis of the microprocessor but it is completely independent; it is commonly used to implement high-speed controls, inline data processing, or complex timing and triggering operations, but also to realize interlocks and digital signals logs [2].

Figure 2: NI cRIO RT & FPGA internal schematics.

The new generation of Compact-Rio controllers (903x family) are particularly interesting due to the fact that NI replaced their proprietary OS with a new version based on Linux Real-Time. This adds much more flexibility to the controller; on one side allowing users to run their own software in parallel with the LABVIEW applications; on the other side it offers the possibility to interface the C-Rio with a wide palette of devices such as: USB keyboard, USB mouse, video monitors, smart cameras, etc. as is usually done in any standard Linux machine.

The second element that makes it possible to employ the cRIO controller to a wide palette of application is offered by LABVIEW. It consists of a graphical software development environment allowing one to construct complex software applications by simply composing and connecting together “ready-to-use” blocks. The predefined palette of connectable blocks is very wide and it contains solutions for the most common exigencies of software developers, as: file management, database connections, OPC communications, physical I/O controls, image pro-

cessing, complex vector/matrix manipulation, mathematical analysis, etc.

SOME INITIAL FEEDBACKS

At the present time our team is studying the possibility to drastically reduce the complexity and the amount of electronics required for access point control by adopting the NI cRIO 903x as unique controller. A real scale prototype is under construction, but we have already some feedback on a certain number of core functionalities that were developed in LABVIEW and tested on a cRIO 9030.

Displaying of local information HMI: the new cRIO 903x series is equipped with a HDMI video output port that is perfectly suitable to drive a local screen. Some test GUI applications have been easily realized via LABVIEW in order to test the large palette of graphical components available.

OPC UA data server / remote supervision: the OPC UA server is the solution adopted to make the cRIO communicate with the external world. LABVIEW allowed us to realize a first test application by just connecting a total of 11 predefined blocks to implement an OPC UA server. This sends periodically monitoring data, computed or acquired by the controller, to Technical Infrastructure Monitoring system, that is one of the main SCADA supervision tools for the operators of CERN control room.

Connection to Oracle databases: connections to the authorizations database are performed in order to verify the users' access privileges and to verify a certain number of conditions (e.g. valid activity permit). These functionalities, currently realized by a dedicated electronics (UTL), can be easily programmed in LABVIEW in order to be executed in the cRIO. This is realized thanks to the database toolbox inside the LV *connectivity* package. An interesting possibility to be investigated is the installation, directly on the cRIO Linux real-time target, of a local database instance, anyone suitable for Linux environment (e.g. MySQL). This would allow to store locally a copy of the relevant central database tables so as not to be affected by network cuts or other problems.

Image processing & intrusion detection: the software for video analysis in charge of detecting unauthorized presence of personnel inside the Material Access Device (MAD) has been rewritten in LABVIEW in order to be executed directly on the cRIO real-time target. The exercise was particularly interesting because, thanks to the richness of functionalities offered by the image processing toolboxes, we obtained a very simplified implementation of the software. Contrary to the actual C++ implementation, the LABVIEW version of the software meets much more closely maintenance and evolutionary requirements.

Badge RFid acquisition: Tests to control a STid RF badge reader have been successfully performed using the VISA objects inside the *Data Communication* tool box. The model of RFid reader in use at CERN is of type ISO 15693 (13.56 MHz) and connected via a serial RS485

link. The simple application developed in LABVIEW showed that the control of a standard CERN badge reader was possible and very easy to realize, simply via the connections of a few blocks.

Additional functionalities providing the physical control of PAD and MAD motorized doors, of key distributors and various other devices have to be still implemented, furthermore, performance and robustness tests have to be conducted during several mounts.

CONCLUSIONS

The choice between a fully COTS assembly activity against a more optimized integration, including *in-house* developments, is driven by several evaluation criteria, of which the principals are in relation with:

- Evaluation of available internal resources;
- Time to develop, document and fully qualify certain functionalities;
- Level of complexity of the system in terms of HW/SW components and their interconnections.
- Sustainability of annual maintenance costs.

The REX, gained after several years of system integration, has however highlighted that to gain in maintainability and evolutivity a simple COTS integration may be not sufficient and new concepts or more advanced integration tools needs to be considered. The exigencies for obtaining a system capable of performing heterogeneous functionalities being, at the same time, flexible, capable to host new functional requirements, easy to maintain and to develop prompted us to consider another integration principle, based on National Instruments solutions, for the next generation of access points.

The present prototyping activity showed that the utilization of the CRIO 903x controllers, in combination with LABVIEW development environment, could be suitable for our needs. Although more data is essential to better evaluate performances and robustness of this technology, the first results obtained with NI are encouraging to pursue this investigation.

COMMISSIONING AND DESIGN OF THE MACHINE PROTECTION SYSTEM FOR FERMILAB'S FAST FACILITY*

A. Warner[#], L. Carmichael, R. Neswold, J. Wu, N. Liu and D. Crawford FNAL Batavia, IL 60510, U.S.A

Abstract

The Fermilab Accelerator Science and Technology (FAST) Facility will provide an electron beam with up to 3000 bunches per macro-pulse, 5Hz repetition rate and 300 MeV beam energy. The completed machine will be capable of sustaining an average electron beam power of close to 15kW at the bunch charge of 3.2nC. A robust Machine Protection System (MPS) capable of interrupting the beam within a macro-pulse and that interfaces well with new and existing controls system infrastructure has been developed to mitigate and analyze faults related to this relatively high damage potential. This paper describes the component layers of the MPS system, including a FPGA-based Permit Generator and Laser Pulse Controller, the Beam Loss Monitoring system design as well as the controls and related work done to date.

INTRODUCTION

The FAST Facility comprises an electron injector based on the Advanced Superconducting Test Accelerator (ASTA)[1], a radio frequency quadrupole (RFQ) based proton injector and the Integrable Optics Test Accelerator (IOTA) storage ring. The electron beam is produced by a 1.3 GHz RF photo-injector and then accelerated to ~50 MeV by two 1.3 GHz SRF cryomodels, each containing a single 9-cell cavity. The beam will then be injected into the linear accelerator which consists of a 12-m long, 1.3 GHz 8-cavity superconducting cryomodel (CM2). This is a Tesla type III+ cryomodel[2] driven by a 5 MW klystron. The electron beam energy gain will be approximately 300 MeV at this stage.

Figure 1: Schematic of FAST Facility.

The facility is also being expanded to accommodate further advanced accelerator research and development with the installation of a 2.5 MeV proton/H- RFQ accelerator. This accelerator starts with a 50 kV, 40 mA proton (or H-ion) source coupled to a pulsed 325 MHz RFQ to 2.5 MeV with a 1ms pulse duration for injecting into IOTA. This ring is 39 meters in circumference and will also be capable of storing electrons from 50 MeV to

150 MeV in energy. Figure 1 shows the placement of the ring in the FAST facility layout.

The Machine protection System (MPS) is being developed in stages that are commensurate with the commissioning goals for FAST. The primary objectives from the MPS point of view are to mitigate beam induced damage to the machine components and to provide a comprehensive over-view of the entire accelerator based on the input status of all the relevant subsystems [3].

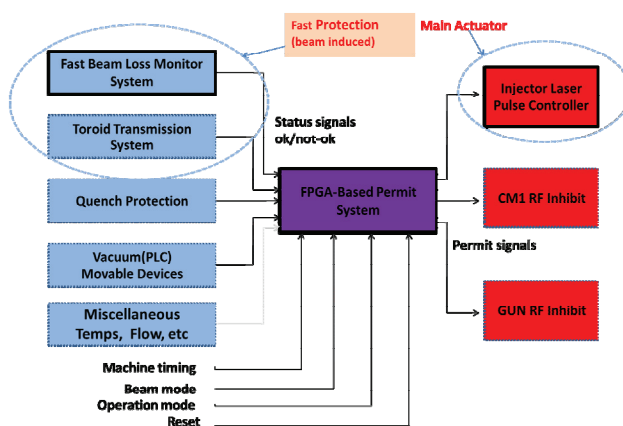

Figure 2: MPS Overview.

Figure 2 illustrates the overall MPS design which is divided into 3 layers; a sensor layer to collect sub-system status, a process layer that utilizes the status to generate the permits and an actuator layer to receive the permits and inhibit the beam. The initial stage of this development involved the design of the Laser Pulse Controller (LPC).

LASER PULSE CONTROLLER

The LPC is designed to be the primary actuator for beam inhibits. Its main function is to provide a gate to the gun laser system via the Pockels cells with a width that corresponds to the total number of 3 MHz pulses allowed without crossing the programmable threshold for losses. The maximum width of the gate is 1 ms which would accommodate a maximum of 3000 bunches. It is designed to inhibit the system within the 1ms macro-pulse window. The response time of the system has been demonstrated to be << 1 microsecond corresponding to less than 3 bunches in the machine. The LPC also provides a number of timing channels to the accelerator complex including a pulse which corresponds with the arrival of the first bunch; so-called first bunch trigger. This is an adjustable trigger delay with < 40 ps of jitter and tuneable to steps of

*Operated by Fermi Research Alliance, LLC, under Contract No. DE-AC0207CH11359 with the United States Department of Energy

[#]warner@fnal.gov

100ps. The laser itself operates continuously at 3 MHz with 200 fs of intrinsic jitter. The LPC is built on a VME platform with a fully programmable general purpose FPGA board. It has inputs for the requested beam modes (intensity limits) defined by the logic layer of the MPS, the operational modes (which defines the beam paths in the machine), the MPS permit signal, the 3 MHz machine timing, and a macro-pulse trigger. It also has ability to control a mechanical shutter used to block laser light from reaching the cathode when it's necessary.

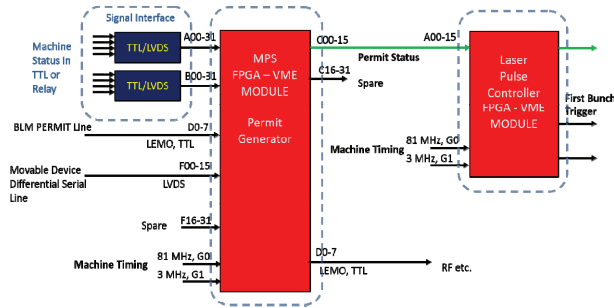

Figure 3: MPS FPGA block diagram.

MPS MAIN PERMIT SYSTEM

The main MPS permit generator board is the central component of the system that serves to collect status (OK/Not-OK) information from the various machine subsystems. The information is used in conjunction with user input such as operational mode and beam mode requests to generate a permit condition. The subsystems interface with the system through several modules that are designed to maintain signal integrity and provide noise immunity by converting input signals to Low Voltage differential signal levels (LVDS).

The permit system is built on a general purpose FPGA board designed to take advantage of its expandability and customizability. The boards can be programmed “on the fly” via VME without any external hardware tools and without disconnecting the boards from the system, and without resetting the system or turning off the crate. A flash memory on the boards stores the programming file.

The boards have been organized into functional blocks to accommodate various input signal types. Machine status signals in slow TTL or relay contact logic levels from vacuum PLCs etc. are converted into LVDS format and sent to ports “A” and “B”. Movable device status is encoded onto a serial differential link and fed into half of port “F” and beam loss monitor status, which is critical for fast protection is fed into “D” port via a 30 MHz carrier pulse train. Output signals to the LPC are received via port “C” and several other TTL output signals are provided via the port “D” for RF inhibits and test monitoring via oscilloscope. In addition to this, several ports allow for future expansion. Individual subsystem and channels can be masked directly at the hardware level or via configuration control software based on modes.

BEAM LOSS MONITOR SYSTEM

The beam loss monitors (BLMs) are the primary protection devices against fast losses and are designed to protect the machine by inhibiting the beam or limiting the beam intensity in response to losses above damage threshold levels. In addition, the same loss monitor signals are also used for beam tuning and diagnostics. The monitors are made of plastic scintillator material coupled to photo-multiplier tubes (PMTs). They deliver a measurement of beam and dark current losses to the control system as well as generate a fast alarm signal when the beam losses exceed user-defined thresholds. The time resolution of the loss measurement provides the ability to distinguish single bunches within each macro pulse. This is achieved at the sampling frequency of 3 MHz (the bunching frequency of the machine) with a repetition rate of 5 Hz. Including cable delays; the interruption signals from the system are generated within 1µs after the loss has occurred during commissioning to the 50 MeV beam dump. Since dark current and beam can only be produced during the RF pulse of the gun and the acceleration modules, it is sufficient to monitor a time window slightly longer than 1 ms per macro-pulse interval; however for alarm generation, continuous monitoring was done to minimize the dependency on time.

Figure 4: BLM Boards.

The front-end signal processing boards used are based on electronics designed by Jefferson Lab for their 12 GeV loss monitor system upgrade [4]. These BLM boards have been modified to meet the specific machine requirement at FAST. The main design change was to process the amplified signals from these boards using faster 125 MHz digitizer boards. The signals are further processed by an on-board FPGA to provide the require threshold levels and protection system shut-down signals.

USER INTERFACE

The user interface is a critical component of the MPS. It provides operators with the tools necessary to find the source of detected trips and provides the following functionality:

- Trip visualization
- Configuration and control
- Post-mortem analysis

A web page, as shown in Figure 5, serves as the entry point to the user interface. This page provides a global view of the permit system, a list of all pertinent applications and has a global log of all critical MPS messages. Trip visualization is provided through several Synoptic displays (Figure 6) which allow users to view the overall trip status and then to drill down to a specific trip.

Configuration control is provided through several Java applications. FAST Facility operators use these applications to select desired beam and operational modes, setup subsystem status masks and set BLM limits. Post-mortem analysis is essential to recovering from a trip. Detected trips are cached on the main MPS board. A background process (Finite State Machine) timestamps all trips and saves them into a repository. A Java application is used to display the logged trip history.

Commissioning was accomplished by manually setting the subsystem status masks and BLM threshold limits. In further runs, as operational knowledge is obtained, the goal is to create a mapping between the modes, masks and BLM limits so that mode changes would allow the correct masks and BLM limits to be automatically downloaded to the permit system.

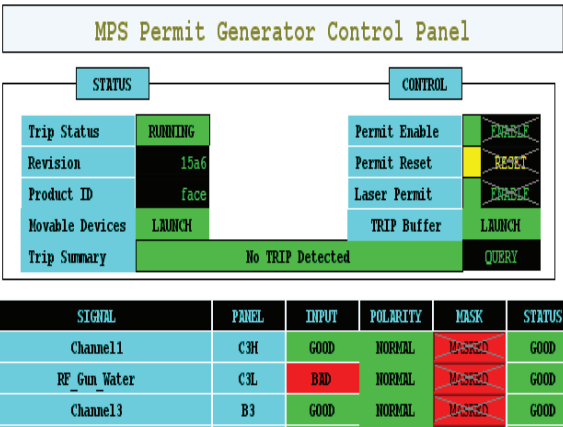

Figure 6: Configuration/Control.

CONCLUSION

The main components for the FAST Machine Protection System have been successfully commissioned. Commissioning began with successfully delivering 20 MeV beam to the low energy 50MeV dump for this first stage. The reaction time of the system is less than 1 us. The loss monitor system is sensitive to losses < 10 pC/bunch. The LPC meets the jitter specifications for tuning and controlling the number of bunches and bunch spacing. The main permit board was successfully interfaced to the control system. Trip visualization, configuration control and post-mortem analysis applications have been successfully developed. For the next phase of commissioning, the system will be expanded to protect the machine from 150MeV injection into IOTA.

SAFETY INTERLOCK SYSTEM FOR A PROTON LINAC ACCELERATOR

Y. Zhao, Q.Ye, Y.Y.Du, J.He, F.Liu

Division of Accelerators, Institute of High Energy Physics, Beijing 100049, China

Abstract

The C-ADS Inject-I test facility is under construction in IHEP. An interlock system based on redundancy PLC is developed for machine protection and personnel safety. Device status, radiation dose, temperature of cavities and chambers are collected for machine state judge and interlock. A MPS(Machine Protection System) are working together with the interlock system in the control loop, and protect the machine in Four levels for different situations.

INTRODUCTION

The C-ADS linac include two Injectors and a main driver linac. Each injector is designed as a spare of another. The injector I proton linac in IHEP is consist of an ECR ion source, a LEBT (low energy beam transport line), a RFQ (radio frequency quadrupole accelerator), a MEBT (medium energy beam transport line) and superconducting spoke cavities[1]. The interlock system is designed and set up to protect personnel and devices from radiation hazards. It also will be a backup protection of MPS (fast Machine Protection System). The interlock system has permission signal, terminate beam signal and state signals collected from front device. Permission signals have the highest priority to access the Personal protection system, a key to the tunnel door will work together with the permission signals for safety. The state signals from Ion source, Power supply, LLRF (Low Level Radio Frequency) control system of RFQ, Vacuum and so on, indicate the corresponding system state or control “on and off”. The terminate beam signals will shut the Ion source down when emergency.

HARDWARE DESIGN

Phoenix RFC (Remote field controller) -460R has been chosen as the main controller for the interlock system. Two RFC can automatically build a high-performance connection to implement redundant through fiber optics for synchronization. Two Profinet interface in the RFC connected the controller into the Profinet ring with RSTP (Rapid Spanning Tree Protocol) to achieve fast ring detection, One LAN interface in the RFC is connected to the control network for. Before each cycle, One RFC which is set as the PRIMARY redundancy role will control the process, and transmits the data to another RFC which is set in Hot Standby mode as BACKUP redundancy role. If one Controller fails, the other will take over immediately [2].

The Axioline modules include bus coupler, I/O modules. The I/O modules complete the function signal in/output are connected to the bus couplers links to the

Profinet ring, it's the most fast I/O system in the world by now[2], the update time for each I/O modules is less than 1μs. The bus couplers has two Profinet interface which support PRL (The Phoenix Redundancy Layer), it will help to adopts valid values from I/O modules to the available Profinet controller.

The power supply of controller and Axioline modules are independent to ensure the reliability. Trio-diode modules are fixed for each two power supply units of the same type connected in parallel on the output side for redundancy. Those two power supply units will be isolated from one another. Figure 1 shows the redundancy diagram and Table 1 shows the signals from devices.

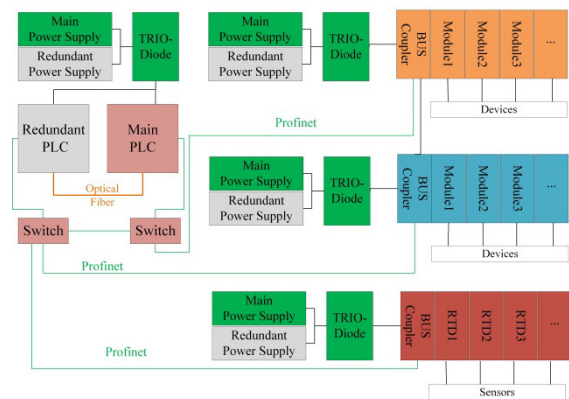

Figure 1: The redundancy diagram of interlock system.

Table 1: The Signals From Devices

Device	Input	Output
Ion Source	1	1
Vacuum	8	1
Personnel Protection	4	3
Power Supply	1	1
RFQ LLRF	1	1
Cryogenic	1	0
Super conductor LLRF	2	2
Bunching LLRF	1	1
MPS	1	6
Temperature	130	4
Flow meter	1	1

The fault tolerance requirements of C-ADS injector I are quite critical. So the reliability of the hardware is also considered. The index R (reliability), MTTF (mean time

to failures) and λ (the failure rate) are always used to measure the reliability of the control system. The MTTF and λ of each component at 25°C are listed in the table in Table 2[2]. As the equipment and cables are located in the stable Power Supply room, the extremely environmental interference can be eliminated.

Table 2: The Reliabilities of the Hardware

No.	Modules	MTTF/h	$\lambda/(10^{-7}h^{-1})$
1	Power Supply/24VDC	500 000	20.00
2	Trio-diode	10 000 000	1.00
3	RFC 460R	281 627	35.5
4	Bus Coupler	3 950 853	2.50
5	Axioline DI	310 104	32.20
6	Axioline DO	310 104	32.20
7	Axioline RTD	310 104	32.20
8	Switch	2 891 123	3.46

PROGRAM DESIGN

The main control system run in the RFC is designed in PC Works 6.20.327(Phoenix contact) and can be download via Profinet. An EPICS IOC has been developed based on the EPICS driver for RFC 460R to complete the control and data-transfer. The driver is embedded in the main file, the so called "send/receive" protocol is adopted to exchange data block between the PLC and the EPICS IOC[3]. User-defined length data can be transferred during each program circle. The data type or other properties can be defined in the IOC. The IOC has been successfully used online. All operation is completed in the console of control room. The control architecture is shown in Figure 2.

Figure 2: Interlock system control architecture.

PROTECTION LOGICAL DESIGN

The interlock system includes four states: stop, running, emergent stop and debug mode.

Stop mode is the safest mode for machine and personnel, the ion source and power source are disabled when the machine runs at stop mode.

Running mode can only be manual switched to when all the device state and temperatures are normal.

Emergent stop include manual emergent stop and interlock emergent stop. Manual emergent stop is the --- protection level, can be switched on the console panel in the central control room. Interlock emergent mode is automatically switched by PLC programme.

Debug is a special mode, because the whole machine is under construction and phase operation, the RFQ, bunching or the spoke cavities system need non-interlock state. The details of logical control is shown in Figure 3.

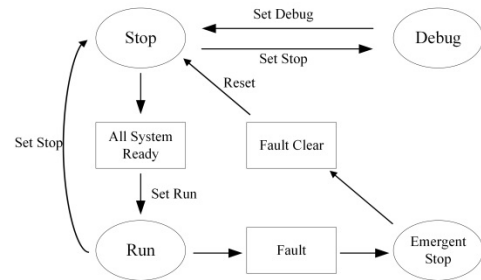

Figure 3: The control logical state.

There are 88 temperature sensors for RFQ water cooling, 12 for bunching cavities, 10 for beam dump, and 20 for vacuum chamber. As the RFQ resonance frequency is nearly linear with the temperature of the cooling water [4], the temperatures are precise to 0.01°C. And if any of the RFQ vanes or the walls temperature is above 28°C, it will trig interlock to stop the power or the beam. The bunching cavities' upper limit is 40°C, the dump and vacuum's upper limit is 60°C. The total state of flow meters for RFQ cooling water is also connected to work together with the temperature sensors.

At present stage, interlock provides 6 protection levels with MPS, for all LLRF state signals are connected to the MPS. According to the different unmoral situations, Interlock will terminate beam or let MPS stop the power source.

The first level - when the RFQ cavities wall, beam dump, vacuum chamber's temperature are higher than the upper limit, the interlock will disable ions source.

The second level - when the RFQ cooling water temperatures are high or the flow meters signal is fault, the interlock will disable the ion source, and let the MPS disable the power source of RFQ.

The third level - when the bunching cavities temperatures are high or the flow meters signal is fault. The interlock will disable the ion source, and let the MPS disable the power source of bunching.

The forth level - when the cryogenic system is not ready, the interlock will disable the ion source, and let the MPS shut the superconductor's power supply and the super conductor cavities' power source.

The fifth level - when the personnel protection system is on alarm, interlock will disable the ion source, and let the MPS shut all power sources.

The sixth level - is used as interlock manual emergent stop. It's the most critical situation, and will shut all the devices once be switched to.

SUMMARY

The interlock system based on the redundant design, combined with the EPICS control platform is more reliable to protect the machine. The different interlock levels ensure the effective protection and avoid unnecessary loss or operation. As the Injector I start to commission, there will be more various complex conditions, both hardware and software will upgrade to meet the actual demand.

REALIZATION OF A CONCEPT FOR SCHEDULING PARALLEL BEAMS IN THE SETTINGS MANAGEMENT SYSTEM FOR FAIR

H. Hüther, J. Fitzek, R. Müller, A. Schaller, GSI, Darmstadt, Germany

Abstract

Approaching the commissioning of CRYRING, the first accelerator to be operated using the new control system for FAIR (Facility for Antiproton and Ion Research), the new settings management system will also be deployed in a production environment for the first time.

A major development effort is ongoing to realize requirements necessary to support accelerator operations at FAIR. The focus is on the pattern concept which allows controlling the whole facility with its different parallel beams in an integrative way. Being able to utilize central parts of the new control system already at CRYRING, before the first FAIR accelerators are commissioned, facilitates an early proof of concept and testing possibilities.

Concurrently, refactorings and enhancements of the commonly used LSA (LHC Software Architecture) framework take place. At CERN, the interface to devices has been redesigned to enhance maintainability and diagnostics capabilities. At GSI, support for polynomials as a native datatype has been implemented, which will be used to represent accelerator settings as well as calibration curves.

Besides functional improvements, quality assurance measures are being taken to increase code quality in prospect of productive use.

COMMISSIONING OF CRYRING AT GSI

At the time of writing, the CRYRING heavy-ion storage ring, a Swedish in-kind contribution to the FAIR project, has been set up at GSI, with only few additional components still to be installed. The machine features an electron cooler, an RFQ linear accelerator and two injectors for different types of ions. See Fig. 1 for an overview of the CRYRING ring section.

Figure 1: Overview of the CRYRING storage ring as setup at GSI (injection lines not shown), W. Geithner, GSI.

From a controls perspective, its commissioning represents a major milestone, as CRYRING will be the first machine

solely operated via the new FAIR control system. Currently, the commissioning group still relies heavily on low-level control, but by the end of the year, they will have shifted their primary work place from the accelerator tunnel to the control room, utilizing the whole control system stack through the high-level applications provided.

TEST-BED FOR THE NEW FAIR CONTROL SYSTEM

Since CRYRING is equipped with its own injector line, it can continue operation even at times when the existing GSI accelerator chain is shut down for necessary FAIR upgrade and civil construction work, making it an ideal test-bed for the new control system. This way, it will contribute to validating concepts and technologies under real-world conditions [1], ensuring that the control system components work properly, individually and as a whole, and that business processes within and between involved parties are effective.

Although operating CRYRING does not imply the same requirements on the settings management system as the future FAIR facility will, core concepts necessary for highly flexible future operation scenarios can nevertheless be tested. As such, the beam-oriented approach to scheduling, designed for parallel beam operation at FAIR, will be utilized at CRYRING for the first time.

PARALLEL BEAM SCHEDULING CONCEPTS FOR FAIR

The designated operation modes of FAIR put demanding requirements on the new control system currently in development. To optimize the number of concurrent research programs, the facility will provide up to five beams in parallel with pulse-to-pulse switching between different particle types. Additionally, great flexibility shall be provided, allowing to change the parallel operation schemes on a daily basis.

Beam production chains and patterns are the central technical concepts within the new LSA-based settings management system to fulfill these requirements. Representing a major change in perspective, beam production chains establish a beam-oriented view on the facility, as compared to the accelerator-oriented view towards settings management dominant at GSI up to this point.

Beam production chains are defined using beam processes as atomic building blocks. Beam processes represent a specific procedure on the beam within one accelerator (e.g. injection, ramp, extraction). Within a beam production chain, the order of all beam processes necessary to provide the settings for producing a certain beam is described, from its

source up to its target, spanning all machines and transfer lines involved.

To be able to coordinate multiple beams traversing the facility in parallel, beam production chains are grouped into patterns. An example of typical parallel operation for the modularized start version of FAIR is given in Fig. 2.

Figure 2: Example for parallel beam operation showing scheduling of beam production chains into patterns. HESR accumulating the anti-protons is omitted.

STATUS OF THE FAIR SETTINGS MANAGEMENT SYSTEM

LSA at GSI has made significant progress since it was first deployed as a test instance in 2008 [2]. In close cooperation with CERN, a structural redesign aimed at modularization led to more efficient handling of change management and release processes while also fostering extensibility [3]. First successful tests with beam at the heavy-ion synchrotron SIS18 were performed in 2010 [4]. More advanced machine experiments were made possible in the subsequent years through implementation of GSI-specific features, like flexible beam process lengths and optics definitions which are relative regarding time [5].

Development is currently focused on CRYRING and implementing the pattern concept. Although still at a prototype state and major features for controlling the entire future FAIR facility to be implemented, LSA now supports all requirements initially needed for CRYRING commissioning. Machine physicists were able to calculate reference settings using the pattern scheduling mechanisms and interface tests using mock-up front-end device controllers are being conducted. Testing data supply with actual devices is expected to start in November.

Two of the most recent enhancements leading to this achievement shall be described in more detail here.

RECENT ENHANCEMENTS OF THE FRAMEWORK

Polynomial Data Types

Developers at GSI implemented a polynomial data type directly in the central value package of the LSA framework. Before polynomials were available, all functions data had to be provided as discrete functions.

There are a lot of benefits to using polynomial data types instead of discrete functions. Polynomials produce continuous values rather than x-y-pairs for potentially millions of steps. Hence less data has to be stored because polynomials are represented as an array of its coefficients only. All polynomials can have an interval describing for which range of x-values they are defined, so it is possible to build sequences of polynomials over different intervals to easily represent complex functions. Consequently, it is possible to provide a more accurate representation of a function than before.

Combining a polynomial with an interval is inevitable for settings management, but it also brings up the problem that it can be interpreted in two different ways: A bounded polynomial can be treated absolute or relative to its interval. Using the absolute interpretation, the polynomial $p[n]$ is evaluated as $p[n].interpolate(x)$ independent of the boundaries, whereas on the relative interpretation the polynomial $p[n]$ is evaluated as $p[n].interpolate(x - b)$, where b is the lower bound. Therefore all polynomials are treated as relative in the current implementation.

The magnet group at GSI provides calibration curves for the magnets in the central component database also as polynomials. Before the polynomials data type was introduced, these polynomials had to be rasterized into discrete functions before they could be used in LSA. Now, calibration curves can be imported in their native, unmodified format as received from the magnet group and handled as polynomials internally as well. The same applies to function settings calculated by LSA, which are sent to the hardware, e.g. the function generator for ramped devices [6], as polynomials.

Data Supply

The LSA subsystem responsible for data supply to devices received a major overhaul in 2014. The project was carried out as a joint effort between CERN and GSI, with one developer from Darmstadt staying in Geneva for several months. The core motivation, equally important for both parties, was to improve diagnostics capabilities of the system.

While data supply results were formerly presented in a flat data structure for the whole supply process, the new hierarchic result classes allow operators to trace errors down to individual parameters, e.g. in case a set value is rejected by a front-end device controller. Navigating the hierarchy level of data supply results is possible in a very convenient way, starting at the beam process that was sent, via device adapters handling value conversion, down to set calls to the middleware, showing exactly where the error occurred. These levels of aggregation can also be identified in the corresponding class diagram shown in Fig. 3.

Figure 3: Class diagram showing the refactored LSA data supply results structure.

The enhanced diagnostics capabilities have already proved beneficial when supplying settings to large numbers of devices. As the need to handle error states can hardly be avoided during commissioning, they will also be a valuable tool for CRYRING.

Furthermore, the subsystem's code, which has been evolving for nearly a decade, received a major refactoring. Coding styles were unified, classes restructured and general maintainability and extensibility enhanced.

QUALITY ASSURANCE MEASURES

Both the implementation of the pattern concept as well as the aforementioned refactoring, being mission-critical core components of LSA, were carried out using a test-driven development approach to facilitate focus, correctness and test coverage. Beyond that, aiming to minimize potential errors within and between LSA components during commissioning of CRYRING, a variety of additional quality assurance measures have been implemented.

The machine model code, written by physicists, is being reviewed both technically by the LSA software development team and content-wise by other accelerator physics experts. During these sessions, to complement the traditional inspection approach, automatically generated reports utilizing a variety of static code analysis tools are consulted to support framework and machine model developers in writing correct and comprehensible code.

Besides methodology and code quality, the third pillar of quality assurance measures currently employed is integration testing. For CRYRING, there are roughly around 15 FESA (Front-End Software Architecture) classes to be run on front-end device controllers, either already implemented or currently under development. Each will be handling at least one, but usually several devices of the same type. To ensure that front-end device controller software works as expected from an LSA perspective, a test suite to perform automated integration testing has been set up. The tests typically operate on mock-up instances of FESA classes, which

mimic the behavior of the actual hardware they are designed to control. At a later stage, tests may also be performed on front-end device controllers connected to real machine components. To maximize efficiency, the underlying testing concept distinguishes and reuses sets of generic tests for all device classes, device-type-specific tests and device-specific tests.

OUTLOOK

As previously mentioned, there are still major features to be implemented in LSA in order to fully support flexible parallel beam operation envisioned for the future FAIR facility. Taking SIS18 booster mode as an example, scheduling a certain beam production chain multiple times as a sub-chain will be necessary to consistently model the successive injections into SIS100. Another challenging task will be to support multiple patterns scheduled at the same time, with one main pattern being executed repeatedly and one or more other patterns serving experiments that require beam on demand only.

In 2016, tests are planned for transferring beams from the storage ring ESR, which is part of the existing GSI facility, to CRYRING. This endeavor requires synchronization between the previous control system still being used at ESR and the new control system used to operate CRYRING. Once LSA has been equipped with additional features specifically targeted at storage ring operation at GSI, most importantly beam manipulation during the cycle for experimentation phases, this will open interesting possibilities e.g. for working with rare isotopes at very low energies at CRYRING [7].

NUCLOTRON AND NICA CONTROL SYSTEM DEVELOPMENT STATUS

Evgeny V. Gorbachev, Vasily Andreev, Alexander Kirichenko, Dmitrii Vladimirovich Monakhov, Sergey Romanov, Tatyana Vladimirovna Rukoyatkina, Georgy Sergeevich Sedykh, Valery Volkov, JINR, Dubna, Russia

Abstract

The Nuclotron is a 6 GeV/n superconducting proton synchrotron operating at JINR, Dubna since 1993. It will be the core of the future accelerating complex NICA which is under construction now. NICA will provide collider experiments with heavy ions at nucleon-nucleon centre-of-mass energies of 4-11 GeV. The TANGO based control system of the accelerating complex is under development now. This paper describes its structure, main features and present status.

INTRODUCTION

NICA complex will consists of heavy-ion and polarized particles sources, RFQ injector, heavy- and light-ion linear accelerators, superconducting booster synchrotron, Nuclotron and two superconducting collider rings [1].

The control system of the NICA complex aims at accomplishing few main tasks:

- Management of large amount of equipment which is distributed on the accelerator complex area.
- Realization of different regimes of the accelerator complex working cycle – colliding or fixed target experiments, various ion types and energy.
- Strict synchronization of accelerators in the chain.
- Comprehensive beam diagnostics during the entire cycle.
- Providing protection and safety measures.

We can specify few important features that the NICA control system has to provide:

- Centralized administration and monitoring of the control system components.
- Reliable operation, quick recovery after possible failures.
- Access to equipment has to be restricted for certain personnel with rights limitation according to user roles.
- Ease of support, modification and scaling during long accelerator complex life-time which will operate until 2045.
- Rapid development and easy deployment of the control system, taking limited time and man-power into account.
- Possibility to integrate third-party control systems as some components of the accelerator complex will be designed and constructed by external organizations.

CONTROL SYSTEM LAYOUT

The control system is distributed network of computers which communicate by means of transport protocol over TCP/IP. The NICA control system uses the TANGO

controls [2] as the middleware providing such communication protocol.

TANGO is the modern distributed control system framework based on CORBA. The fundamental unit of TANGO is a device, which is an abstraction hiding real equipment or program component behind the standard interface. TANGO provides high level client application interface which has necessary programming classes to implement client-server communications - synchronously or asynchronously execute commands, read or write attributes, or use events to acquire the data from the TANGO devices. TANGO incorporates a number of tools to build efficient control system environment including centralized administration and monitoring, access control, logging system, data archiving and code generation for rapid development of the TANGO device servers using C++, Java and Python.

Three layers of the NICA control system components can be distinguished (Figure 1):

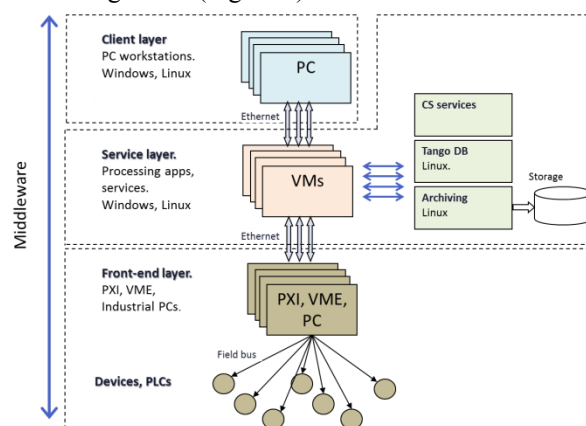

Figure 1: NICA control system layout.

- 1) Front-end layer consists of industrial computers, intellectual controllers, crates that directly control equipment and acquire data from sensors. Front-end computers run low-level TANGO programs that realize data acquisition, equipment handling and hide protocol and connection details from higher layer components.
- 2) Service layer consists of high level TANGO devices representing entire subsystems. They collect data from front-end TANGO devices, process it and realize algorithms to control some large subsystems. Those high-level programs provide standard TANGO interface for entire subsystems allowing client software to execute commands, read and write attributes without knowledge of subsystems structure. Besides, the service layer provides a set of services that are necessary for efficient control

system functioning – administration, control system hardware and software management, monitoring, data archiving, development services.

- 3) Client layer represents the accelerator complex state to operator, visualizes acquired data and allows operator to perform control tasks. We would like to provide global interface to allow operator to access the entire accelerator complex control with possibility to navigate to its components.

Front-end Layer

Primary requirements for the front-end layer hardware are easy and rapid development, good reliability and performance, easy maintenance during the accelerator complex operation. The development and support of custom hardware for the large accelerator complex is a very resource-consuming task. It is decided to use commercial hardware for most of the control systems tasks. The base of the NICA controls front-end layer is National Instruments PXI, which is modular eurocard packaging platform with PCI and PCI express busses with additional synchronization and trigger lines.

PXI platform offers a wide range of modular instruments of many types including digital and analog I/O, industrial interfaces, digitizers and scopes, signal generators and many others. National Instruments provides Windows and Linux drivers for most of the hardware and supports Labview as well as text based languages.

While most of the control system tasks can be implemented by modular instruments, some unique signal generation, processing and synchronization tasks can be realized using programmable logic devices. National Instruments provides few FPGA solutions to implement custom hardware. One of them is FlexRIO product family, which consists of PXI and PXI express modules with Xilinx FPGA, large amount of on-board memory and standard or custom I/O modules that are attached to the front panel of FlexRIO and have access to pins of FPGA. Developer can implement custom FPGA firmware as well as custom input and output signal processing, conditioning and conversion.

Another solution is CompactRIO controller, which is FPGA and processor based platform with standard or custom I/O modules. It is running real-time OS and controlled over Ethernet.

The TANGO device servers for a range of National Instruments hardware performing common acquisition tasks were developed. They include drivers for digitizers and scopes, analog and digital input and output, timers and counters, digital multimeters, temperature sensors acquisition modules.

Software for FPGA based boards consists of two parts: FPGA firmware and FPGA interface program performing data exchange between controller and FPGA. LabVIEW provides rapid firmware development using graphical language and VHDL. Interface programs can be developed as the TANGO devices using FPGA Interface C API. Those TANGO devices are running on PXI or

CompactRIO controllers providing an easy way to integrate FPGA based solutions into the TANGO environment.

Developed drivers allow quick deployment of almost any National Instruments acquisition board. Each driver can perform a single input or output task so it is necessary to run few TANGO devices to realize all features of an acquisition board. The acquisition properties such as sample frequency, samples number, trigger source, and others are configured as the TANGO devices properties.

Client Layer

TANGO provides the set of graphic user interface toolkits for rapid development of graphical client applications in all supported programming languages – C++, Java and Python. There are also LabVIEW TANGO bindings that allow developing full featured TANGO client applications using rich Labview visualization features. Most of the existing desktop client applications for the NICA control system are developed in LabVIEW with the TANGO bindings.

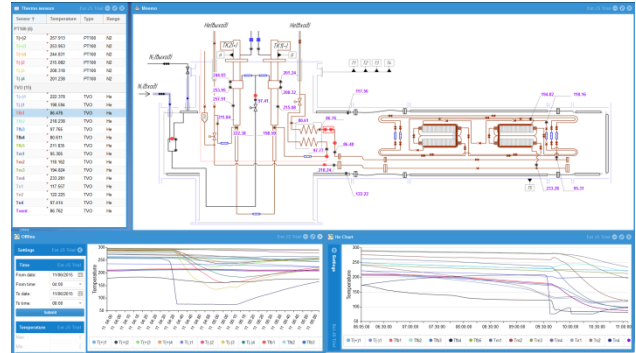

Figure 2: Thermometry web application for the NICA superconducting magnets test bench.

Few auxiliary TANGO devices were developed to simplify creation of web client applications by providing access to TANGO from web browser:

- The TANGO device server RestDS realizes REST protocol to access TANGO devices attributes and commands. It contains embedded http server providing access to TANGO devices attributes and commands at URL combined from host, port, device and attribute names. The reply is JSON string consisting of attribute name, value, timestamp and quality. POST method can be used to execute command with input arguments.
- The TANGO device server WebSocketDS also contains embedded http server and is intended for accessing attributes via WebSocket protocol. The attributes names and the device name are specified in properties, and the data update rate is configured via polling period.
- The TANGO device server TangoWebAuth performs authentication of users to restrict access of web applications to TANGO devices. The access rights are configured in a special database.

The developed auxiliary TANGO servers allow creation of web application in JavaScript without any intermediate application servers. Thermometry web application for the NICA superconducting magnets test bench is shown in Figure 2.

Service Layer

High level applications of the service layer do not interface with any hardware, so they can run in any place of the control system and can be virtualized. Virtualization is an effective way to deploy control system applications providing easier management of virtual machines (VM), better tasks isolation, fine tuning of CPU time or disk space allocation and more efficient usage of hosts resources. Virtualization also makes possible to obtain high availability features – any virtual machine can be quickly restored or migrated from failed physical server to run on a different host.

Proxmox VE is used as a virtualization solution. It is a free server platform for creation and management of virtual infrastructure including virtual machines, local and shared storage and high-availability clusters. It supports both Kernel based Virtual Machines (KVM) and Linux container-based virtualization which provides isolated Linux containers with no performance impact.

Shared storage is the vital part of virtualization to provide high availability of virtual machines. There are few requirements for the shared storage:

- Good performance as we need to run many images on it.
- Redundancy to allow using VM images even if some disks or servers failed.
- Scalability – storage must be expandable without losing performance to provide the data storage for future control system tasks and data acquisition.

The NICA control system uses distributed object storage cluster Ceph [3] as shared storage solution. Ceph storage cluster consists of nodes which communicate with each other via network and distribute and replicate data dynamically. Ceph's RADOS block device (RBD) is an ideal way to store VM images that are stripped and replicated across the entire storage cluster. Ceph RBD is thin provisioned so unused image space can be reclaimed.

It is possible to run Ceph services directly on Proxmox VE nodes, so the same hosts are used to provide both distributed storage and virtualization cluster. The cluster presently consists of four nodes each with dual eight core E5-2600 Intel Xeon processors, 32 GB of RAM, five reliable 15k RPM SAS2 disks and enterprise class solid-state drive (SSD) for operating system and Ceph journal devices. The network equipment includes two 1 Gbit network switches to separate public and Ceph cluster network. One of them will be upgraded to 10 Gbit network switch to provide network capacity suitable for Ceph cluster network.

The high availability of control system is achieved by hardware solutions which include using of uninterruptable power supplies (UPS), redundant power supplies for

servers, enterprise class long-lifetime drives and data redundancy for virtual machines and databases.

All virtual machines run on Proxmox VE cluster with images stored on CEPH storage with replication factor of three. Hard drives failures are handled by Ceph and not affecting the operation of the control system at all. All virtual machines are periodically backed up to external Network File System (NFS) storage located on redundant array of disks (RAID). The uninterruptable power supplies are constantly monitored by using Network UPS Tools (NUT) [4] to ensure proper VMs shutdown on low charge.

The TANGO database is essential for the NICA control system operation. This is a MySQL database that runs in Linux container on fast local SSD for performance reasons. The high-availability of the TANGO database is achieved by means of MySQL replication. Semi-synchronous MySQL replication with two master MySQL servers with fully symmetrical configuration is deployed. Each master MySQL server is a slave of the other MySQL server but only one of them is getting external connections to avoid possible conflicts. A proxy solution for the TCP-based applications HAProxy [5] is used to periodically check health of MySQL servers and route external MySQL traffic to primary or backup MySQL backend server. HAProxy runs on high-available VM to ensure its permanent availability. Periodic dump of the TANGO database from MySQL slave server is used as additional measure to provide hourly TANGO database backups for two weeks of operation.

The storage space scalability is provided by Ceph which retains or improves its characteristics when adding more disks and more nodes.

Storage space and throughput, CPU cores number and amount of RAM can be increased by adding more nodes to the control system cluster. As a result, more data and VM images can be stored and more virtual machines can be run. The only drawback is a short burst of network traffic during data rebalancing to new storage daemons.

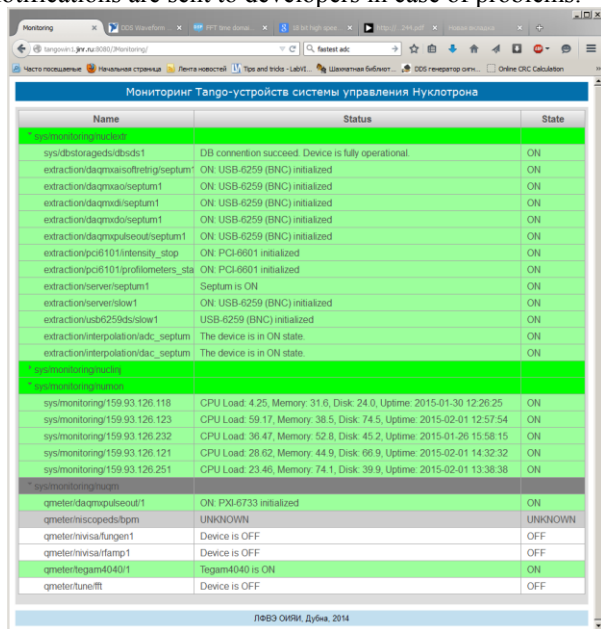

CONTROL SYSTEM ADMINISTRATION

The TANGO device servers are running on many distributed computers, hence the ability to control all the control system components remotely is necessary. TANGO provides a special service Starter which is running on all control system computers. Its main task is to start all necessary TANGO device servers in proper order at system startup and keep them running.

The TANGO manager Astor is used to visualize the state of entire control system and provide tools to start or stop the TANGO device servers remotely, access their logs and settings in the TANGO database. Operator can see if computers and TANGO device servers are running or not. However, a computer can have performance problems or the TANGO device can be in fault state which cannot be seen using Astor.

An additional TANGO monitoring system which consists of two parts was developed. First part is a

TANGO device to monitor computer resources. It runs on each computer of the control system and periodically collects information about the disk, processor and memory usage. Another part is a TANGO device intended for monitoring states of every TANGO device of certain subsystem. The monitoring client application (Figure 3) represents states and statuses of the all TANGO devices and computers of the control system. Alerts and notifications are sent to developers in case of problems.

Figure 3: TANGO monitoring.

Apart from the Tango monitoring, monitoring solution Zabbix [6] is used to monitor network traffic, hypervisors resources, Proxmox VE cluster, UPS devices, TANGO database performance, Ceph cluster performance and health, local and shared storage space.

Another important aspect of control system operation is access control. We want to restrict access to control system software for certain computers and users and give them corresponding rights to perform specific tasks. Network access limitation, including private sub networks for subsystems and proper firewalls configuration is one of the possible measures. Another possibility is Tango AccessControl service that restricts connections to TANGO devices to certain users connecting from certain computers. The access checks are performed on the client side before opening connection to the TANGO device.

Additional server-side authorization service was developed to provide more secure access control and more flexible rights restrictions. It uses additional authorization TANGO device which accepts username/password pair from client application and authenticate the user using Linux Pluggable Authentication Modules (PAM) and information from MySQL database. If authentication is passed, a temporary session is opened for the specific user, IP address and process ID. TANGO device which needs to check the user's rights makes request to authorization server from command execution method with TANGO device name,

command name, client IP and process ID. After that, authorization server checks the IP and process id pair against opened sessions and checks user rights from the database.

It is possible to precisely tune the access rights using MySQL regular expressions. Operator-expert rights separation can also be implemented.

CONTROL SYSTEM MANAGEMENT

The NICA complex consists of few large facilities, such as accelerators and transfer lines. Each of them has a number of subsystems. Every subsystem consists of large number of equipment, TANGO drivers, cables, computers, network equipment which are developed and maintained by certain people.

The NicaControls [7] database was developed to store this information and describe relations between its components. Using these relations one can find documentation for hardware or software, links to source code and executable files, developer name, rack location, computer IP address and other useful information.

Information in the database is added during the control system development. The NicaControls database is also used by other control system components. The TANGO monitoring system periodically queries NicaControls database to include or exclude the TANGO devices from monitoring. The server-side access control also gets access rights information from it.

CONCLUSIONS

Design of the NICA control system infrastructure was presented. It provides rapid development of hardware and software using the TANGO Controls and National Instruments equipment, reliable and scalable operation by using virtualization and Ceph storage cluster, comprehensive administration and monitoring, efficient management of the control system equipment and software by using the NicaControls database.

Several Nuclotron subsystems and prototypes for the future NICA accelerators were developed using the described approach.

IMPROVING SOLEIL COMPUTING OPERATION WITH A SERVICE-ORIENTED APPROACH

A.Buteau, B. Gagey, G.Abeille, Synchrotron SOLEIL, Gif-sur-Yvette, France
JC Fouquet, JCF company, Paris, France

Abstract

SOLEIL Computing division is in charge of managing computing infrastructures and applications on a 24/7 basis for SOLEIL staff and beamlines users.

During the last years SOLEIL accelerators and beamlines have been facing an ever growing dependency on Information Technologies to be able to deliver their service to their respective users. During the same period the Computing division had to manage an increasing number of technologies and software applications while continuously improving IT operation performances.

All this happened in a “classical” scientific environment where having immediate scientific results seems always more urgent than working on enhancing operational activities and minimizing the workload of IT groups.

This context has been the key driver to start the project of optimising our IT operational practices by adopting the ITIL [1] methodology with the following objectives in mind:

- Enhance the quality of IT services delivered
- Decrease the time spent by IT teams in operational activities to be able to keep resources focused on projects and development

The present paper will describe the overall vision of the project “Improving SOLEIL IT operation with a service oriented approach” and the strategy to make the methodology adopted efficiently by all IT groups.

THE MOTIVATIONS TO CHANGE OUR I.T OPERATIONAL PRACTICES

SOLEIL Computing Division Organisation

SOLEIL Computing division is composed of about 40 people organized in 4 groups:

- The ICA group is in charge of software development for Controls and Data Acquisition
- The ECA group is in charge of electronics for controls and data acquisition
- The ISG group is in charge of databases administration and enterprise applications (such as financial ones, technical documents management, etc.)
- The ISI group is in charge of IT infrastructures : networks, servers, file storage , desktops

Operational Practices of IT Groups are Very Different

Depending on their role in SOLEIL organization these 4 groups may have different internal customers:

- ICA and ECA groups are very close to “business” activities as they are working only for Accelerators and beamlines
- ISG is closer to SOLEIL Administration division
- ISI group activities are focused on providing IT infrastructures for all SOLEIL activities from offices to control systems

Moreover these groups are using different operational tools (see Fig. 1) to follow-up their daily activities:

- ICA uses JIRA [2] to manage software changes, users requests and development projects
- ECA, ISI use a CMMS [3] (*Computerized Maintenance Management System*) to track operational activities on the hardware components they are in charge of.
- ISG uses Redmine [4] to follow-up their internal software developments
- The “business” operational groups (*accelerators operators and Experiment Hall coordinators*) also use an ELOG system to track the I.T incidents which occur on the synchrotron facility

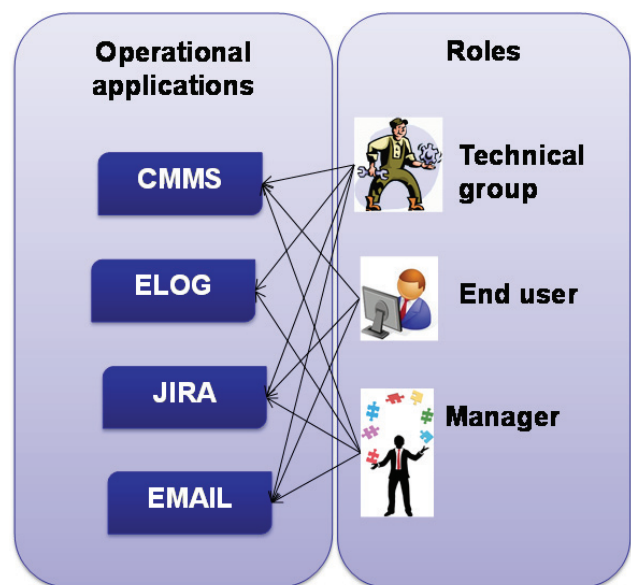

Figure 1: Operational tools used by various support groups.

Last but not least, at the SOLEIL organization level there is no clear definition of business impact of IT incidents/problems that could help all IT people to focus their efforts on the most urgent activities for business.

Be More Efficient and Enhance Services Delivered to End User

Having different operational practices for the 4 IT groups and the “business” operational groups had been possible during the last 10 years but raised daily difficulties that became unsustainable during the last years:

- For an end user the first difficulty is to know to which IT group he must ask for a given service. Then he/she has to choose the right tools (JIRA or CMMS) to post a request
- Then when this request may require actions from various IT groups (*which is more and more common because IT services are always more interconnected*) he/she has to “navigate” between different tools to follow-up this request
- On the other hand, I.T groups have no common vision of the priority/urgency of this request or incident.

This leads to a very chaotic and inefficient treatment chain of the requests/incidents both from the IT resources involved and from the end user perspective.

HOW ITIL CAN HELP US TO IMPROVE OUR IT PRACTICES

Some Reminders on ITIL

ITIL is a set of practices for IT service management that focuses on aligning IT services with the needs of business.

ITIL describes “*processes, procedures, tasks, and checklists which are not organization-specific, but can be applied by an organization for establishing integration with the organization's strategy, delivering value, and maintaining a minimum level of competency*”.

ITIL is focused on operational processes rather than norms and is:

- modular: it can be used for very large but also small organizations
- is a quality oriented methodology allowing better definitions of: objectives, operational processes, responsibilities, and indicators.
- defines a common vocabulary between IT people and “business” people

Our Ambitions for the Beginning are very Modest: Focus our Efforts on a Limited Part of the ITIL Methodology

ITIL aims to define best practices for the whole “Service life cycle”

- ITIL Service Strategy: understands organizational objectives and customer needs
- ITIL Service Design: turns the service strategy into a plan for delivering the business objectives.
- ITIL Service Transition: develops and improves capabilities for introducing new services into supported environments.
- ITIL Service Operation: manages services in supported environments

Nevertheless in a first phase, we decided to concentrate our efforts only on “Service Operation” being conscious that changing operational practices of about 40 people and 350 users is something that needs time!

A Preliminary Study Convinced Us of the Interest of the Methodology

To check ITIL can help us in a pragmatic way we decided to analyze the ICA operational practices to check how ITIL could efficiently help us.

To this aim we examined how ICA group was currently working for each of the ITIL Service Operation and Transition processes.

This analysis document was discussed with various operational managers and inside the ICA group, the conclusion being that definitively following ITIL methodology will help us defining many axes to enhance our current practices.

A FEW INITIAL GUIDELINES

Convince and Not Impose

The decision of adopting ITIL has been left in a first time as an option to the managers of the various IT groups.

The ICA group having initiated the step forward was naturally designated as the pioneer group. Its feedback (*pros and cons*) with ITIL practices should then be useful to convince and help other groups to change their way of working in a second phase and to adopt gradually ITIL operational processes.

Promote the Kaizen Philosophy

The philosophy behind our ITIL project is to promote to the idea of a **continuous improvement** of the I.T services we are delivering. In fact only an active participation of operational people will allow to efficiently track IT defaults but also to gather from IT operational people solutions and enhancements proposals.

Keep Using the JIRA Tool to Manage Operational Requests

It was tempting to use a natively ITIL oriented tool (*such as ServiceNow [5]*) to be driven by the tool when putting in place the methodology. Nevertheless we thought it was too risky in our context to change at the same time the operational practices and

the CMMS/JIRA/ELOG tools SOLEIL operational people used for years.

We accepted the idea of having for a few months a hybrid situation having within JIRA some requests categorized according the ITIL semantics along with “old style” categorization tickets.

OUR FIRST EXPERIENCE OF ITIL: THE ICA GROUP

An Immediate Benefit: ITIL Semantics Helps Categorizing User's Requests

The first benefit we found what that thanks to its very precise semantics and definitions, ITIL helped us to better prioritize and categorize the continuous flow of JIRA requests (around 100 per week).

Nevertheless, we would like to insist that even if words seem easy to understand, it took a couple of months for a team of experienced software developers to integrate in their daily practices the subtle differences between “problems”, “incidents”, “events”, “service requests”.

Second Benefit: Clarification of the Roles of the Various Operational Actors

ITIL definitions helped us to clarify our organizational practices and the “who does what” for the following activities and their operational interfaces with the ICA group.

- **Service Desk Management:** This 24/7 activity is shared between Machine operators and Experiment Hall coordinators who are in charge of the “level 1” support while ICA group is in charge of “level 2”. The role of the service desk has been clarified and ends up now when a workaround has been found to restore the failing service to an operational state.
- **Incident Management :** Incident managers have been designated within the ICA group to make a “root cause” analysis and create the related “problems” JIRA tickets
- **Problem Management:** Problems managers have been designated to follow-up the problem resolution by the development team.
- **Service Requests Management:** This activity is now systematically done by the member of the ICA team who is on call.

Service Transition Processes: ICA Group Proved to Be Quite Mature

Being a group mostly composed of experienced software developers the ICA practices for ITIL transition processes were without surprise well mastered. In particular:

- **Release Management :** Each of the functional service is delivered to users through a software package which regroups software components and is

under the responsibility of an engineer who is in charge of :

- managing the roadmap
- integration of the related software artifacts in the various source code management systems and in SOLEIL Continuous Integration Systems [6]
- Communication with users through Release Notes
- Level 3 expertise on the software package
- **Software Assets Management:** all ICA deliveries are declared and followed in our Continuous Integration Systems. This guarantees that all Control systems software assets are identified, under version control and production versions are correctly identified.

FIRST EXPERIENCE OF ITIL WITH OPERATIONAL GROUPS

Better Manage Incidents: A Win-Win Deal for All Support Groups

As explained in the first paragraphs the various operational groups (IT and business) were using 4 different tools (not including physical contacts and telephones!) to manage daily incidents.

Focusing our efforts to enhance this operational process would be a win-win approach for all support groups.

We organized a workgroup which duty was to define a standard “Incident form” and the lifecycle of an incident.

The JIRA tool was then parametrized to manage numerically the form (see Fig. 2) and the associated workflows.

Figure 2: Incident declaration form.

A First Lesson Learned: “Business” People Must Also Be Trained

One of the difficulties we faced very quickly was the fact that if ICA group was trained to ITIL methodology, our

internal customers were not. This made the communications on first concepts such as “Problems” or “Incidents” much more difficult. We had then to make “Mini ITIL trainings” removing all mentions to IT. This helped to convince Accelerators and Beamlines people the operational processes we were dealing with were also applicable to their operational practices.

THE STEPS FOR THE NEXT 6 MONTHS

Complete and Publish the IT Service Catalog

ITIL promotes the publication to users of the “IT service catalog” which details the full list of services actually provided by Computing division and how to access them and to get help and contact information.

A preliminary version of this catalog (see Fig. 3) has been written by all IT managers. The first step will be in the next weeks to publish this first version to the groups in charge of Level 1 to help them in their daily activities.

Then in a second stage, it will be discussed with SOLEIL “business” representatives to clarify the commitment of all the parties. In particular this approach will oblige to define for each service who is the “Service Owner” on “business” side and which Service Level Agreement (*a.k.a SLA*) there are expecting.

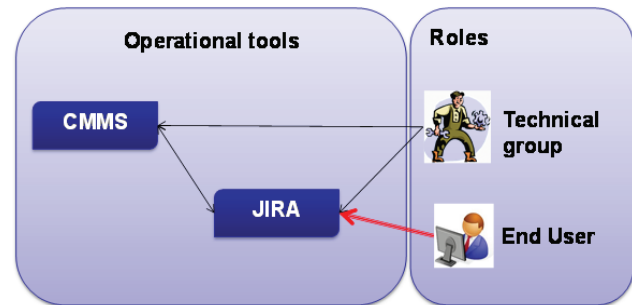

Figure 4: JIRA as the unique entry point.

Put in Place Formal Trainings on ITIL

Formal ITIL trainings will be organized within the next 3 months for all IT and “service desk” people taking into account the experiences gained through the ICA group example and the processes (such as “Incident Management”) already in operation.

OUR VISION FOR THE NEXT 2 YEARS

Enhance Our “Change Management “Processes

A lot of work has to be done in close collaboration with “business” representatives regarding the change management process.

We expect this will be a challenging phase because it will require to clarify the “who decides what” on releases plans, projects priorities, etc.

For IT Division Extend ITIL to Other Processes Such As Service Transition or Service Strategy

The services being currently developed by the computing division such as the FlyScan project [8] are now taking into consideration parts of the recommendations of the “ITIL Service Design and Service Transition” processes.

The definition and follow-up of IT Services Strategy will be directly done under the Director General authority which proves the importance IT has now for all the SOLEIL organization.

[illegible]

Figure 3: IT Services catalog.

A Service Oriented Portal for End Users

The JIRA form used for Incident Management will then be extended:

- to integrate the services identified in the service catalog to be able to directly assign the incident to the IT group in charge of it
- to other users requests such as “ITIL Service Request”

JIRA /CMMS Connection

Groups in charge of managing hardware components use the CMMS system to follow incidents and changes which occurred on each physical device. Keeping the CMMS tool as it is, was then mandatory for these groups.

On the other hand we want to have a unique entry point to IT services from the end user point of view.

We started a technical study on how to interconnect JIRA and our Tribofilm CMMS [7] using the available software interfaces of these tools.

CONCLUSION

ITIL already helped us in improving the service that ICA group delivers to its IT end users. Nevertheless we are also very modest by foreseeing how long the road will be to extend it to all IT groups of SOLEIL. The strategy of a gradual adoption of ITIL and its various operational processes is the only one that can be followed considering the differences in the groups' maturity and cultures.

Another challenge will be in the next years to extend the best practices promoted by ITIL to all "service oriented" activities of SOLEIL.

In fact the quality of the service delivered to the end user scientist can be considered as the result of a chain of services as illustrated by the following schema (see Fig. 5) . If we consider that *"The strength of a chain is the strength of the weakest link"* enhancing only I.T services will not be sufficient to enhance the satisfaction of the end user.

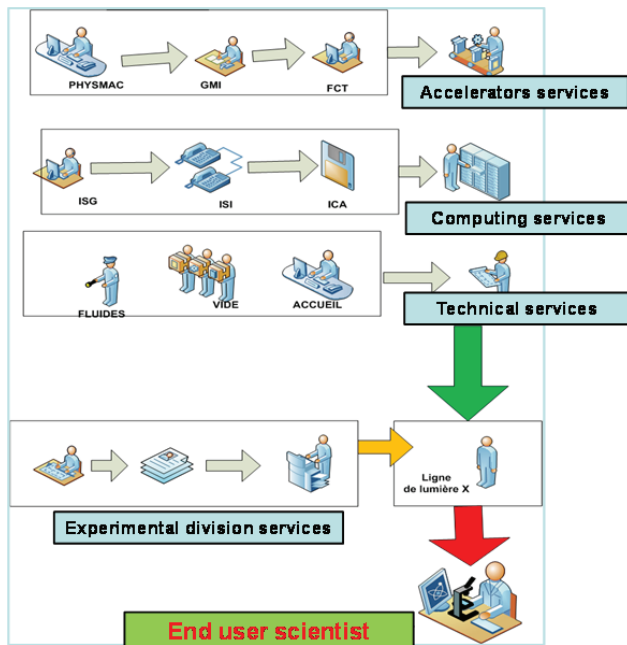

Figure 5: Chain of services to deliver a scientific service to the end user.

To this aim SOLEIL is changing its internal organization and ITIL best practices will be a guide in the next years for all SOLEIL accelerators and technical groups which activities are directly impacting the scientific service delivered to our end users.

BEAM INSTRUMENTATION AND DATA ACQUISITION FOR CRYRING@ESR

T. Hoffmann, H. Bräuning, R. Haseitl, P. Miedzik, T. Milosic, R. Lonsing, A. Petit, A. Reiter
GSI, Darmstadt, Germany

Abstract

At FAIR the re-assembly of the well-known CRYRING accelerator, formerly hosted by Manne Siegbahn Laboratory (MSL) Stockholm, is currently in progress. This compact low energy heavy ion synchrotron and experimental storage ring will be a testing platform for all control system (CS) concepts decided on for FAIR. The CRYRING CS will be based on the system originally developed by CERN which combines the JAVA based application level LSA (LHC Software Architecture), the data acquisition level FESA (Front-End Software Architecture) and the White Rabbit based timing system. All parts have been enhanced with GSI specific functionality. In preparation for the commissioning of CRYRING later in 2015 all required beam instrumentation (BI) equipment including the software is now under development. We present the data acquisition (DAQ) concepts for the various instruments with emphasis on the seamless integration into the overall CS. For standard BI systems, such as digital video imaging, profile and intensity measurement, VME and IndustryPC based DAQ systems are used. For beam position monitoring a new hardware strategy which combines the microTCA and FMC (FPGA mezzanine card) form factors is under evaluation.

INTRODUCTION

The modernized CRYRING accelerator is presently being assembled in Experiment Cave B on the GSI Campus [1]. A schematic overview over site and accelerator design is given in Fig. 1. The accelerator consists of a 108 MHz 300 keV/u RFQ linac with a 50 kV MINIS ion source platform, the ESR injection transfer

GSI experimental storage ring (ESR) will inject cooled, highly-charged heavy ions via fast extraction which can be accelerated up to 14.8 MeV/u in case of U^{92+} or 96 MeV/u protons. All accelerator parts are equipped with original beam instrumentation systems designed at MSL as well as new FAIR type solutions. The original MSL detectors and specialised pre-amps were preserved, but all DAQ systems have to be replaced.

The main intention in operating this accelerator, besides the physics aspects, is to provide a test platform with ion beams for many FAIR relevant systems in both hard- and software. Commissioning of the ion source has already started. The RFQ is ready for operation. The linac and the ring will be commissioned next year.

CONTROL SYSTEM

The control- and data acquisition system for CRYRING operation is based on a three tier architecture with FESA as the front-end level, the ZeroMQ based middleware and the top JAVA application level supported by JAPC (Java API for parameter control) and the LSA settings management [2]. CRYRING will be operated and synchronized with White Rabbit (WR) timing [3]. All BI DAQ systems need to be equipped with dedicated WR timing receivers in stand-alone, VME and PCIe form-factors. All those receivers were developed at GSI.

BEAM INSTRUMENTATION

CRYRING is equipped with a variety of beam instrumentation systems. For all of them new DAQ software has to be provided, which is also suitable for further use at FAIR. Presently the following BI systems are under development:

Intensity

A beam intensity measurement, mainly in the linac part, was realized by using Faraday-cups. The signals are digitized in a VME system by a SIS3302, 8-channel, 100 MSa/s, 16 bit ADC. The current amplifier copes with AC and DC beam and the DAQ calculates the total charge plus mean and maximum currents.

For AC beams automatic determination of the signal's baseline for every bunch is supported. For DC operation, the baseline may be measured on user request when no beam is hitting the cup. In both cases predefined values may be used in case of problems with the online measurement.

The region-of-interest to determine the mean current and total charge can be taken from two dedicated WR machine events indicating "beam on" and "beam off" or via user-defined markers. For offline analysis the raw

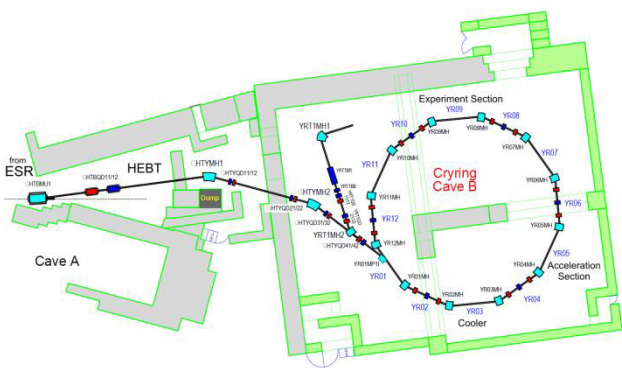

Figure 1: Scheme of CRYRING installation in Cave B.

line and a synchrotron storage ring of 54.18 m circumference including an electron cooler and experiment section. Different singly charged ions in bunched or coasting beam will be provided by the linac. Later, the

data can be stored. Fig. 2 shows a chopped 500 μ s D^+ beam pulse and the correlated intensity in units of Ampere at the linac injector.

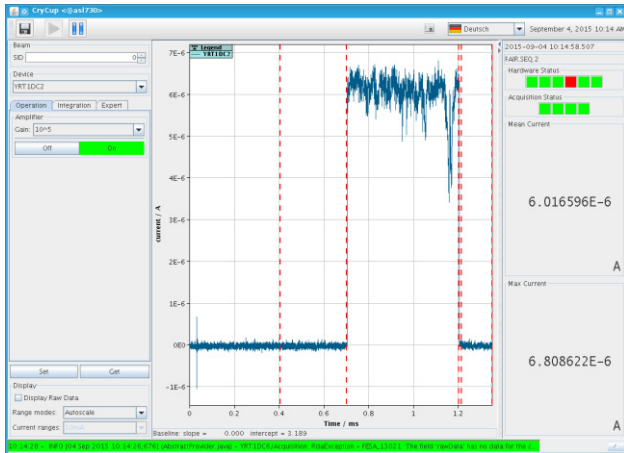

Figure 2: Intensity measurement of a chopped 500 μ s D^+ beam pulse with a Faraday-cup.

For absolute beam intensity measurements in the ring both the Bergoz Integrating Current Transformer (ICT) and Bergoz Parametric Current Transformer (PCT) are used. For relative intensity measurements the IPM count rate is registered. As the bandwidth of the analogue outputs of those devices is below 1 MHz, the signals can be converted by a voltage-to-frequency converter (VFC) and sampled by the VME based GSI LASSIE [4] system, which is based on SIS3820 32 Bit / 32 Ch. multi scalars.

As CRYRING is bakeable to achieve an appropriate vacuum pressure, the transformers need to be protected against overheating. Hence temperature data derived from PT100 sensors is logged in LASSIE. The PT100 measurement is also required for temperature-drift compensation of the PCT. In the same setup Hall sensors are sampled to subtract magnetic field perturbations induced by dipoles and quadrupoles nearby. In addition, all other signals, which can be converted to frequencies such as Hall sensors, and BPM sum signals are fed into LASSIE. They are sampled and displayed on the same time basis for easy correlation.

Linac Energy

Phase and energy determination is realized with 3 capacitive ring pickups by time-of-flight measurements. The DAQ consists of a LeCroy Waverunner 6100A oscilloscope (1 GHz, 5 GSa/s) with 4 channels. As there are 5 signal sources (3 pickups, RF signal, debuncher signal), a Keithley switching matrix (Type 2701/7712 with 2x Dual 1x4, LXI) is used to select four signals for a given measurement. The oscilloscope is read out via LAN by a dedicated FESA class using the LXI protocol. The data is sampled over one thousand and more RF cycles. This allows for efficient noise reduction of the signal and oversampling, thus increasing the time resolution to approx. 5ps [5]. The time-of-flight between two pickups

is determined by cross-correlation of the signals and yields with the known distance the beam energy.

Position and Orbit

CRYRING is equipped in total with 18 either horizontal or vertical oriented Beam Position Monitors (BPM), which will be controlled and read out by a high data bandwidth μ TCA system. As μ TCA, especially PICMG MTCA.4 [6], is an emerging form factor within the physics community, this DAQ system shall contribute in gaining experience on this platform as μ TCA was defined besides VME and IPC as a standard form factor for FAIR beam instrumentation DAQ systems. The DAQ consists of a 12-slot MTCA.4 chassis hosting five AMC Dual FMC Carriers (AFC). Those are equipped with 250 MSa/s, 16 bit, 4 ch. ADC FMC boards. Both AFC and ADC were developed and produced by the Polish company Creotech under the Open Hardware License [7]. Furthermore the system contains a digital I/O FMC board as trigger input and remote control interface of the BPM preamplifiers.

After some incompatibilities and instabilities between different vendors of the main carrier hub (MCH), the module management controller (MMC) firmware of the AFCs is under revision. The setup will be prepared for usage in a Vadatech VT812 chassis with UTC002 MCH and also in a Schroff chassis with NAT MCH. The heart of the BPM DAQ is the trajectory measurement system (TMS), which was developed for measurements at CERN PS [8]. In a first step the system will operate as an oscilloscope type tracker at 125 MSa/s. Later on the system will be enhanced by full CS implementation with closed orbit, tune and bunch tracking features.

The Base Band Tune (Q) measurement system (BBQ) [9], which was invented at CERN and adapted for SIS18 at GSI, will be additionally installed at CRYRING to validate the TMS results. At CRYRING the DAQ is realized in VME also using the SIS3302. The pick-up used for the BBQ can be optionally used for Schottky analysis. This requires an LXI based network analyser (NWA) to investigate longitudinal and transversal beam parameter, such as tune, emittance and chromaticity.

Profile and Imaging

For the beam profile measurements the CUPID [10] system is used, which is already operational at the GSI

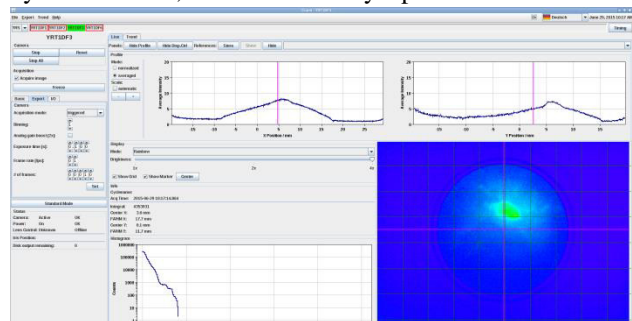

Figure 3: Profile of deuterium beam in the low energy beam transfer (LEBT) during injector commissioning.

transfer lines and fully compliant with the FAIR standards. In total eight fluorescent phosphor screens are observed by GbE μ Eye CMOS cameras, which are concentrated on one 10 GbE HP switch and a 10 GbE uplink to an evaluating Kontron KISS front-end IndustryPC. An additional identical camera provides a direct view into the ion source. The typical presentation of profiles and live view is shown in Fig. 3.

Essential for beam cooling operation within the CRYRING are the non-destructive profile measurements using one horizontal and one vertical ionisation profile monitor (IPM) [11]. Ions produced by ionization of the residual gas are accelerated towards a micro-channel plate (MCP) detector with a position sensitive resistive anode. The time and position pulses of each ion hitting the MCP are amplified and shaped in a CAEN N586 spectroscopy amplifier, which are remote controlled via LAN. A peak-sensing multi-event CAEN ADC V785N digitizes the pulse heights. The interaction vertex of the ion can be reconstructed from the 4 signal amplitudes. The FESA class periodically reads the events stored in the ADC, calculates the position and performs the histogramming of the pulse height and position. It also sends periodically or on request the obtained spectra to interested clients. Insofar the handling of the IPM strongly deviates from the typical, machine event driven arm-trigger-readout cycle of other beam instrumentation like the faraday cups.

High Voltage and Fieldbus

High voltage power supplies (HV) are required for Faraday cups, IPMs, MCPs in front of scintillating screens and electrostatic devices at the RFQ injector beam line. Both commercially available modular HV power supply systems from CAEN and Wiener/ISEG will be used. Fesa classes for the CAEN SY5527 and the Wiener MPOD system have been developed. Special care has been taken to present a unified interface to clients regardless of the differences in the hardware. This allowed us to write a generic GUI for HV control which hides the underlying hardware from the user. However, the unified interface does not prevent future hardware specific extensions should they become necessary.

At CRYRING, the newly developed FAIR standard pneumatic actuators and some other slow-control devices will be operated by Siemens Programmable Logic Controllers (PLC). In order to keep the automation system modular a distributed and decentralized Profinet IO remote system is used. This allows safe hardware control in two different ways: decentralized from the CS and locally, while the machine is in maintenance or shutdown mode. The PLC communicates with the CS through a dedicated Siemens communication processor (CP) and by a FESA class, glued together with a CERN made SILECS (formerly called IEPLC [12]) interfacing software.

The system is accessible via the CS, one mobile and two stationary HMIs, an Android tablet and a PC based visualization running an additional webserver with the capability to archive signal, warning and error messages.

For the purpose of wireless visualization, the Profinet infrastructure has been extended with two iWLAN Access Points operating at 5 GHz.

OUTLOOK

The installation of CRYRING is well on the way. The injector is already under commissioning and first beam instrumentation devices such as screens or Faraday-cups demonstrate very good performance within the new FESA DAQ concepts. It has shown that LXI based systems are a good choice. The LXI protocol can be used from simple function generator and lab oscilloscope readout up to high performance instrumentation such as Schottky NWA readout and linac energy measurements. Learning LXI paves the way to the full digital control room providing reliable remote control and data readout.

The ring itself is being assembled right now and installations are planned to be finalized in 2016. Next steps are setup of the PROFINET field bus infrastructure and improvement of the BPM system.

CURRENT STATUS AND PERSPECTIVES OF THE CRYOGENIC CONTROL SYSTEM OF EAST

Liangbing Hu, Ming Zhuang, Zhiwei Zhou, ASIPP, Hefei, China

Abstract

EAST (Experimental Advanced Superconducting Tokamak) is the first full superconducting experimental Tokamak fusion device in the world which has been carried out ten campaigns since its implementation at the end of 2005. The cryogenic control system for EAST was designed based on DeltaV DCS of Emerson Corporation which has been in operation for the same time period and has been proved to be safe and stable. However, Manny control components have been running beyond the expected lifetime gradually. Many problems from control system have affected the cryogenic system reliability. This paper presents the current status and upgrade solutions of the cryogenic control system of EAST.

INTRODUCTION

EAST (Experimental Advanced Superconducting Tokamak) is the first full superconducting experimental Tokamak fusion device in the world which has been carried out ten campaigns since its implementation at the end of 2005[1]. The cryogenic system is one important subsystem which is to cool down the superconducting magnets and relating components [2]. The total cold mass of EAST is about 250 tons. As shown in Figure.1, the cryogenic system is composed of a helium refrigerator and a helium distribution system. The helium refrigerator is composed of gas management system, compressors station, cold box and 10000 liter Dewar. All heat exchangers, absorbers and four turbine expanders are installed in cold box. The basic design capacity of the refrigerator is 1050 W/3.5K +200W/4.5K +13g/s LHe +12~30kW/80K [3]. To maintain the cryogenic state of the EAST cold components, the helium refrigeration system (HRS) supplies three helium coolants, SHe, liquid helium, and gaseous helium for the SC coils and their feeder lines, current leads, and thermal shield, respectively. The cryogenic distribution system (CDS) has sufficient mass flow to operate each of the SC coils.

Pulsed heat load is the main different factor between the cryogenic system of full superconducting Tokamak system and other large cryogenic systems. The cryogenic system operates in a pulsed heat loads mode requiring the helium refrigerator to remove periodically large heat loads in time. This operation mode must be taken into account for the design of the control system. The EAST cryogenic control system (ECCS) was designed based on DeltaV DCS of Emerson Corporation and has been proved to be safe and stable [4].

However, Manny control components have been running beyond the expected lifetime gradually. Many problems from control system have affected the cryogenic system reliability. This paper presents the current status and upgrade solutions of the cryogenic control system of EAST.

CONTROL SYSTEM OVERVIEW

As shown in figure2, the network of the cryogenic control system is composed of three parts: cryogenic redundant control local area network (LAN), data exchange LAN and main control data server LAN. There is a firewall between the intranet and extranet to ensure the security of the intranet. The cryogenic redundant control LAN employs a three-layer control structure including of the process layer, control layer and supervisory layer. The process layer includes all the field instruments, actuators, sensors and transducers. All the process variables and status information is converted to supervisory by control layer.

The control layer includes two local control cabinets for cold boxes and cryogenic distribution system and a remote control cabinet for compressor station. Local control cabinet includes redundant MD controller, power module and I/O cards. The remote control cabinet includes R5 remote I/O cards and serial card. The remote control system connects to local control by serial cards in terms of MODBUS protocol. New compressors are controlled by PLC and also connect to local control by MODBUS protocol. New PBS turbine is controlled by HEXTR provided by PBS Company and connects to DCS by local bus. New ATEKO turbine is controlled by PLC and as a profibus slave of DCS based on Profibus DP.

The supervisory layer is the interface between the operator and control system, including a professional plus station, four operator stations and an application station as OPC server. In this layer, engineers can configure the program software and manipulate for the cryogenic system.

The data exchange LAN is the auxiliary system of the cryogenic control system. The system includes database server, data acquisition and processing system, web server and FTP server.

The cryogenic data are stored in database server in data exchange LAN connecting to the cryogenic control LAN by application station using OPC protocol. Some important data is sent to the database of the EAST main control system. Some temperature of the magnet coils is acquired by technical diagnosis system. The temperature data are shown in the cryogenic monitor interface. So the process data will be transmitted to the database and

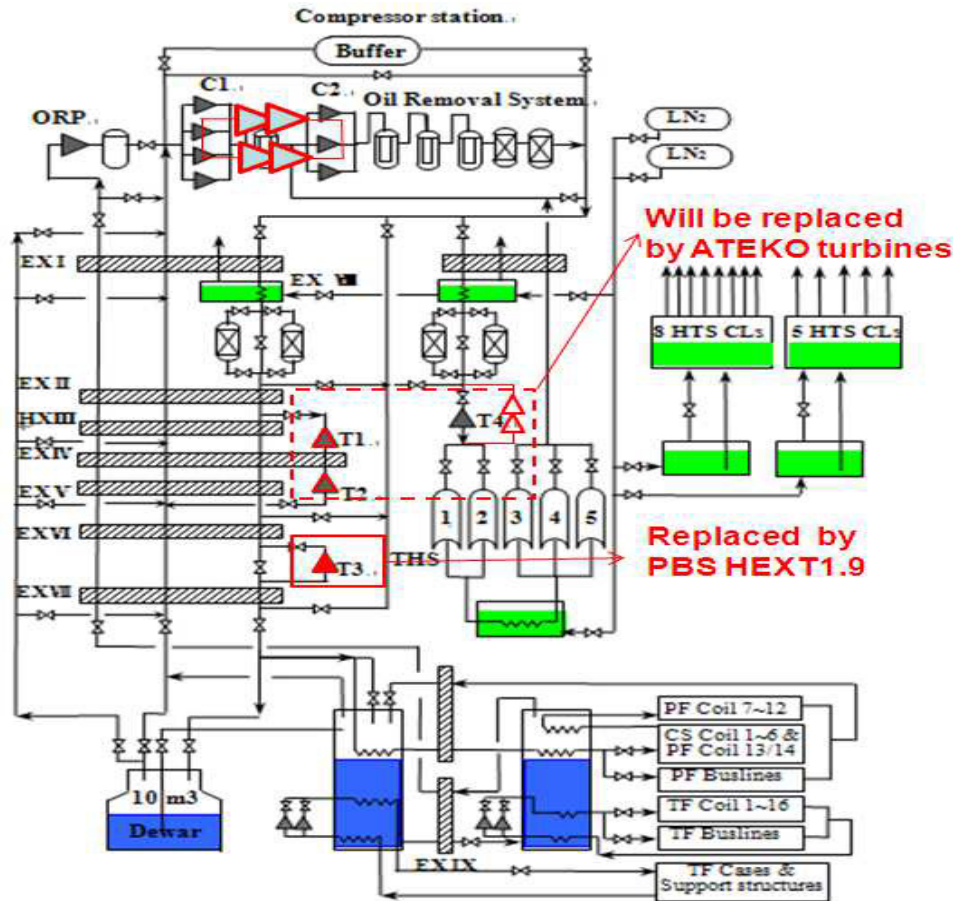

Figure 1 PFD of EAST cryogenic system

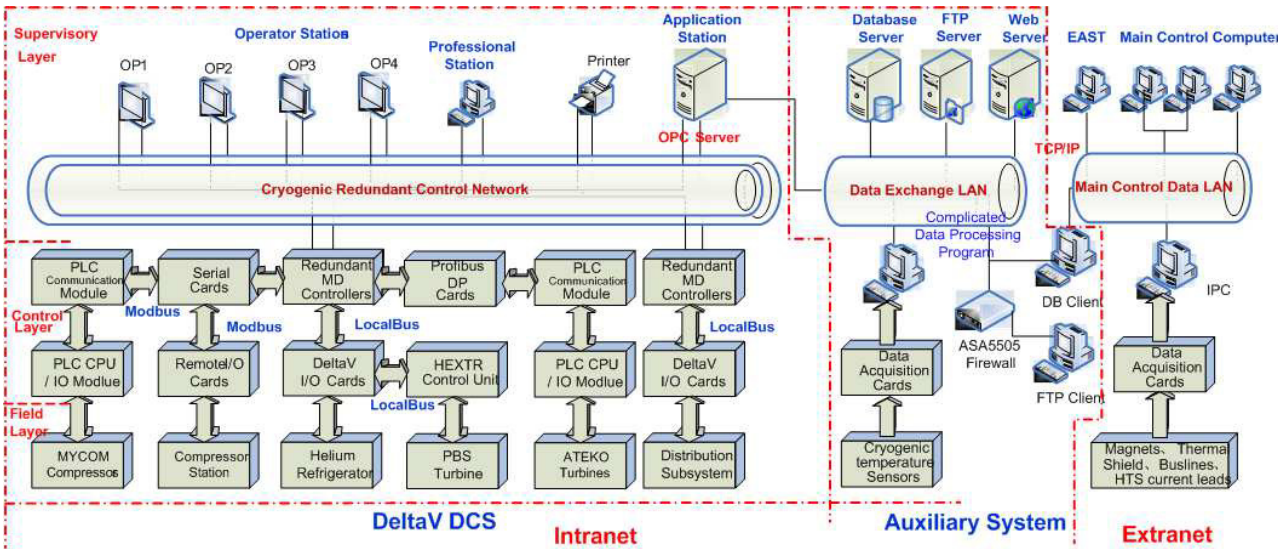

Figure 2 EAST cryogenic control system based on DelatV DCS

exchange system, then send to the DelaV system by OPC protocol.

The data acquisition and processing system has been developed for the temperature and mass flow rate. In order to remotely learn the operation status of the EAST

cryogenic system by internet, the remote control supervisory system has been developed based on the TCP/IP architecture.

CURRENT STATUS AND UPGRADE

The ECCS has been in proved to be safe, stable and expand in operation for many years. However, ECCS is still operating on Windows NT operating system. New hardware may not be introduced because of missing driver support. The manufacture will no longer provide supports for the old DeltaV version. It's very difficult to backup and recover the control system. Once the engineering station or application station fails, the entire cryogenic control system is in danger of paralysis. Many problems caused by the control system have affected the cryogenic systems reliability. At same time, the performance of control system gradually decreases. The memory of MD redundant controller of DCS is only 32M. The load of MD controller is approach to 90% which affects the running speed of the cryogenic control system. Historical data query is slow, resulting in the operation management efficiency decreased. The alarm system function is limited with many nuisance alarm and records query slowly. In addition to, there are some risks in the communication system because the old type 3COM switch has been off production with no supports. The communication efficiency decreased with error rising, occasional packet losing and network clogging. Some new instrumentation and new solutions can not integrate in DCS system. Therefore, it is necessary to maintenance and upgrade EAST cryogenic control system in order to keep the EAST device safe, reliable and stable in operation.

EAST have two campaigns every year and each campaign will last for 3~5 months. So, the upgrade solution can't affect the EAST campaigns. The two solutions have been considered. Upgrade of the DeltaV system is the near term plan to maintain the EAST operation reliability. The DeltaV version will upgrade from V6.3 to V12.3 which operate in Windows 7. PCs and switch will be replaced [5]. System upgrades will improve the performance of the existing device, eliminate hidden faults and enhance the stability of the DCS system which operates into a new life cycle. New Profibus DP will be installed in the DeltaV system for communication with PLC system.

PERSPECTIVE CONTROL DEVELOPMENTS

The upgrades of the commercial control system are very limited because of the fund shortage. The deltaV system upgrades only include the software and PCs not the device of the control layer. There are still potential risks from the hardware of the control layer. The other solution is to upgrade the ECCS based on the EPICS. The central I/O system will be converted to the Profibus field bus. Control System Studio (CSS) will be as the

framework software for the new system. This solution is successful used for the large scale cryogenic control system at DESY [6]. We started the design of new system in this year. The architecture of ECCS based on EPICS is shown in figure 3. Subsequently, we will decide on the specifications for the prototype. The test of the prototype and determination of the specification for the new system will be followed in next year. At last, we intend to introduce the new system based EPICS into operation in parallel with the current system.

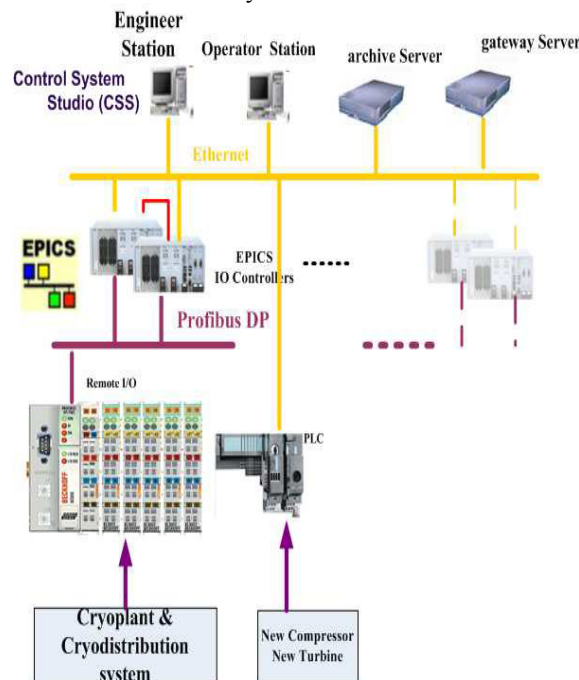

Figure 3: ECCS based on EPICS

CONCLUSION

The upgrades of EAST cryogenic control system have been discussed in this paper. There are one near term and future plan for the upgrades. The DeltaV system upgrades have been implemented on September 2015 and will be tested in the new EAST campaign. In the future, the new EAST cryogenic control system based on EPICS will be designed and implemented.

ACKNOWLEDGMENT

The authors gratefully acknowledge Mr. Matthias Clausen&MKS-2 group in DESY for their advice. We also thank EAST cryogenic group for their expertise of the cryogenic system.

DESIGN AND STATUS FOR THE ELECTRON LENS PROJECT AT THE RELATIVISTIC HEAVY ION COLLIDER*

J.P. Jamilkowski[#], Z. Altinbas, M.R. Costanzo, T. D'Ottavio, X. Gu, M. Harvey, P. Kankiya, R.J. Michnoff, T.A. Miller, S. Nemesure, T.C. Shrey, BNL, Upton, NY 11973, USA

Abstract

The Electron Lens upgrade project at the Relativistic Heavy Ion Collider (RHIC) has reached an operational status, whereby intense, pulsed or DC beams of electrons are generated in order to interact with the RHIC polarized proton beams in both the Blue and Yellow Rings at the 10 o'clock Interaction Region. Interactions between the electrons and protons are utilized to counteract the beam-beam effect that arises from the desired polarized proton collisions, which result in a higher RHIC luminosity. A complex system for operating the e-lens has been developed, including superconducting and non-superconducting magnet controls, instrumentation systems, a COTS-based Machine Protection System, custom Blue and Yellow e-lens timing systems for synchronizing the electron beam with the RHIC timing system, beam alignment software tools for maximizing electron-proton collisions, as well as complex user interfaces to support routine operation of the system. e-lens software and hardware design will be presented, as well as recent updates to the system that were required in order to meet changing system requirements in preparation for the first operational run of the system.

E-LENS GOALS AND DESIGN

The Blue and Yellow e-lenses are installed in the RHIC Ring at Interaction Region 10, in order to partially counteract the head-on beam-beam tune shift effect on the colliding RHIC beams, and thus permit RHIC proton beam operations at higher beam intensities, and therefore higher colliding beam luminosities for the RHIC experiments [1]. First commissioned during the FY2014 run, both electron lenses were successfully operated on a routine basis in a DC mode during the FY2015 RHIC 100 GeV polarized proton run [2].

The main components of each e-lens are the electron gun, electron collector, and superconducting solenoid magnet, though a set of additional systems is required for their routine operation. Beam transport magnets of both superconducting and non-superconducting varieties are controlled through two separate sets of standard VME hardware and software: warm magnets use equipment (PSC, QFG, and PSI) developed for the Injector machines within the Brookhaven National Laboratory (BNL) Collider-Accelerator (C-A) Department, and the cold magnets utilize the RHIC equipment (WFG, MADC) for reference control and readback information. Another system of note is beam instrumentation, which is

primarily comprised of BPMs, current transformers, YAG crystal-based beam profile monitors, pinhole raster scan beam profilers, as well as new electron backscattering detectors [3].

TIMING SYSTEM

The Blue and Yellow e-lenses must be capable of operating in two distinct timing modes: pulsed mode for beam diagnostic measurements and system commissioning, as well as DC mode for routine operations. Activity in pulsed mode must be synchronized with the RHIC Event and Beam Sync Links, such that the timing system is capable of pulsing electron beam from the e-lens as a desired RHIC hadron bunch is passing through the Blue or Yellow Ring in IR10. To achieve these requirements, both e-lenses are dependent on the existing RHIC timing links as shown in Figure 1.

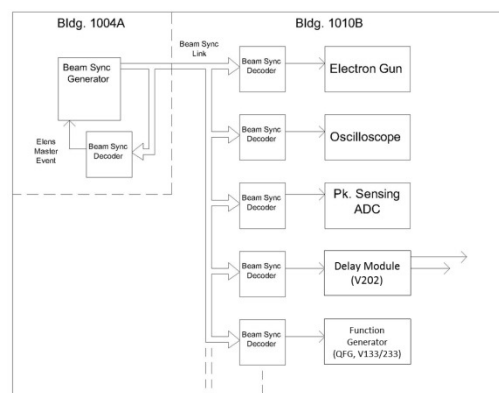

Figure 1: Schematic of the e-lens timing system, including RHIC components (building 1004A) and e-lens-specific components (1010B).

Software Interface

In order to enable the level of system flexibility required to operate the e-lens equipment under many different timing conditions while streamlining the user interface, a server-based ADO program is available to control the system that was written in the Java language. While it was not the first Java server written at the C-A Department, this software interface development project served as an important testbed for use of Java in developing ADO software interfaces rather than the standard C++ option.

[#]jppj@bnl.gov

MACHINE PROTECTION

A total of seven independent e-lens subsystems have been identified that require automated protection from abnormal machine conditions. Thirty-seven quantifiable status conditions serve as inputs to the Machine Protection System (MPS) logic for inhibiting these systems. As the scope of the protection functionality inputs and outputs fits well with the capabilities of the familiar National Instruments cRIO FPGA-based platform, it was selected for the hardware implementation. The response time of the MPS logic in similar configurations was measured to be $\sim 1\mu\text{s}$, though this is dependent on the choice of input modules.

Software integration of the MPS with the Collider-Accelerator Controls System is achieved using the Simple Network Access Protocol (SNAP), which supports bi-directional communication between Accelerator Device Object (ADO) server-based software and LabVIEW software running on the cRIO device that incorporates the MPS logic.

BEAM INSTRUMENTATION

Beam position monitoring of the electron beam is achieved using RHIC-style dual-plane BPM electronics, which incorporate analog/digital integrated front ends (IFE) using 16 bit digitizers in order to achieve a $1\mu\text{m}$ resolution over a $\pm 32\text{mm}$ range [4]. Data from the BPMs has been used for steering optimization of the e-lens electron beam relative to the IR BPM position readings for the hadron beams in the Blue and Yellow Rings.

Initially commissioned during the FY2014 RHIC Au-Au run, electron Backscattering Detectors (eBSDs) have become important diagnostic tools for aligning the electron beam from the e-lenses with the hadron beams in the Blue and Yellow Rings at RHIC [5]. Since the scaler readings from the eBSDs are proportional to the collision angle between the two beams, we have been able to successfully incorporate the new data into the existing RHIC Luminosity and IR Steering (LISA) application shown in Figure 2. This tool allows RHIC machine operators to optimize the impact of the e-lenses on the RHIC luminosity on demand.

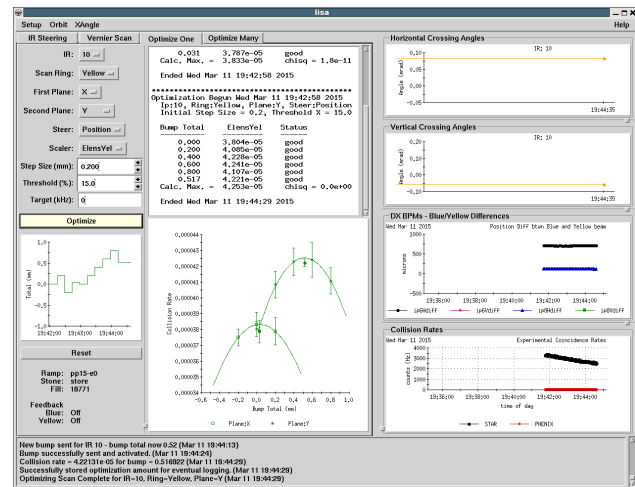

Figure 2: The RHIC Luminosity and IR Steering application (LISA) output after automated optimization of the Yellow e-lens beam alignment using eBSD data.

NEW USER INTERFACE

In addition to the more commonly used user interfaces within the Controls System at the Brookhaven National Laboratory C-A Department, the Syndi editor and display application has been adapted from the original version developed at FermiLab. Due to the compact and complex nature of the electron lenses, synoptic displays created through this toolset have evolved to serve an important role in the operation of the equipment. Figure 3 shows an example of the Blue e-lens Syndi display, which includes statuses of critical sub-systems as well as a select set of control points that are used during routine operations.

Development of the e-lens control pages themselves has migrated since their inception between the Syndi software developers, the project physicist, and ultimately to a member of the RHIC Operations group. While technically capable of embedding complex business logic within each page, we have elected to minimize the amount of such logic within the e-lens pages in favor of server-based software that leverages critical functionality, such as parameter caching. This also reduces the complexity of the page design, and thus improves reliability and maintainability. Our experience during RHIC run FY15 was that such a scheme allowed for maximum flexibility, while adding slightly more complexity over other more commonly used implementations at the BNL C-AD.

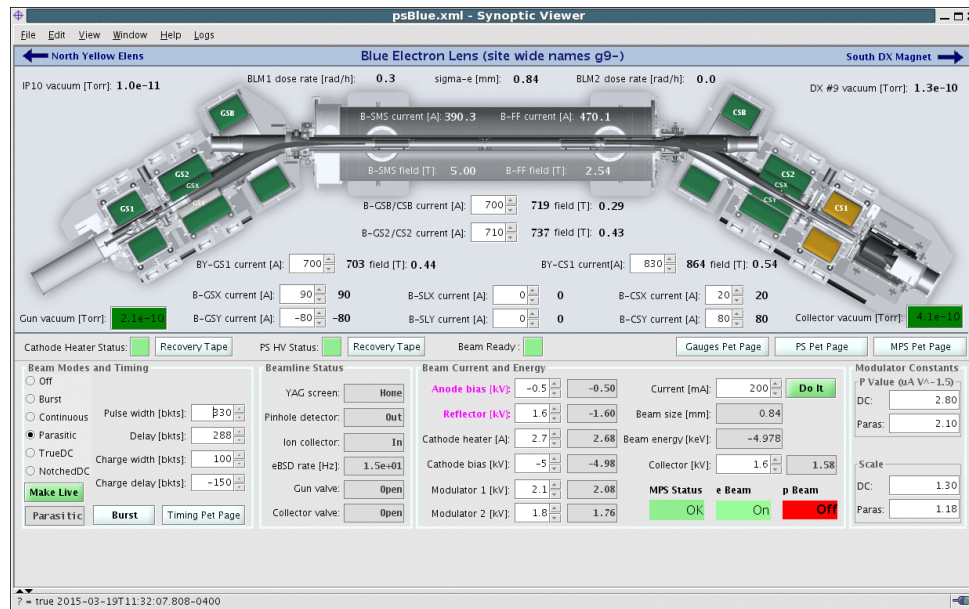

Figure 3: Synoptic user interface for the Blue e-lens created using the Syndi editor.

POWER SUPPLIES

Cryogenic magnet and power supply operations for the e-lenses require coordinated ramping methods, both to avoid unnecessary beam losses and to avoid quenching the superconducting magnets themselves. One method has been developed and exercised during the FY2015 run using ADO server-based software written in C++ that provides such functionality with a streamlined user interface [6] that is capable of controlling RHIC-style Wave Form Generators (WFGs).

CONCLUSION

The complex new Blue and Yellow e-lens systems have been successfully commissioned and operated using a hybrid design of existing controls systems with new equipment and software. COTS hardware is used to good effect as part of the Machine Protection System. Existing software tools, such as LISA, have been adapted to provide novel operating modes that contribute directly to of the new e-lens systems, synoptic interfaces have been developed using the Syndi display editor that have a synergistic relationship with existing interface options. The improvement of the luminosity of the RHIC colliding hadron beams. In order to better visualize the operation

SIRIUS CONTROL SYSTEM: DESIGN, IMPLEMENTATION STRATEGY AND MEASURED PERFORMANCE

J.P.S. Martins, M. Bacchetti, E.P. Coelho, R.F. Curcio, J.G.R.S. Franco, R.P. Lisboa, P.H. Nallin, A.R.D. Rodrigues, L.D.S. Sachinelli, M.E. Silva – LNLS, Campinas, Brazil

Abstract

Sirius is a 3 GeV synchrotron light source that is being built by the Brazilian Synchrotron Light Laboratory (LNLS) [1]. The Control System will connect and operate all the equipment along the whole machine. The main goal of the Sirius Control System is to be distributed and digitally connected in order to avoid analog signal cables. A three-layer topology will be used [2]. The equipment layer uses RS485 serial networks, running from 6 to 12 Mbps, with a light proprietary protocol and CPU boards with proprietary hardware stacked on it, in order to achieve good performance. The middle-layer, interconnecting these serial networks, is based on Beaglebone Black single board computer and commercial switches. Operation layer will be composed of PC's running EPICS client programs. Special topology will be used for Orbit Feedback with a dedicated commercial 10Gbps switch. This paper will discuss the details of the Control System components, the implementation strategy for hardware and software and show some results of the prototypes.

INTRODUCTION

The Sirius Control System is designed to be scalable, distributed and easy to maintain. Currently, we are developing a generic solution for the hardware of the Control System – analog and digital interfaces, and also serial communications interfaces – to provide control features for the most of Sirius systems: vacuum system, pulsed power supplies, magnets power supplies, RF system, etc. The main characteristic of this solution is to be compatible with commercial low cost CPU boards. We achieve this using the SPI standard interface. The very first prototype for the Sirius Control System hardware was a homemade ARM CPU board with analog and digital modules, called PUC (Universal Control Board). Several tests have been done with this board and modules, and some results will be shown in this paper.

Besides the basic input/output, the hardware supports special features for synchronous operations, like curves for energy ramping of the booster and cycling magnets, and a circular buffer for post mortem acquisition.

With this strategy, the Controls Group will provide a low budget generic solution for hardware and software, which is reliable and of good performance in order to meet the requirements of operation of the various systems from Sirius.

HARDWARE IMPLEMENTATIONS

The main goal of the hardware solution provided by the Controls Group is to be easily adaptable to the equipment

being controlled, avoiding the traditional “crate mounting” for a distributed installation, and sometimes inside the own equipment, preventing analog signals to travel over long distances.

Hardware Platform - GESPICON

This platform is under development and aims to be independent of a custom CPU board (like the PUC Base Board). Thus, any commercial CPU board, even the Beaglebone Black, can be used as embedded controller for the interface modules; it just has to have an SPI peripheral and some GPIOs. Figure 1 shows the components of the platform, called GESPICON (Generic SPI Controller). The connection of the stacked boards with the controller is done by a special bus, called SPIxxCON bus. This bus has the traditional SPI pins for serial data interchange, and some GPIOs for configuration of the transactions. It has also the pins for power supply and the optional use of quad-SPI features. The protocol of this bus is capable of addressing 8 module boards with 8 SPI devices in each one. Thus, one CPU controller can manage up to 64 SPI devices attached to it.

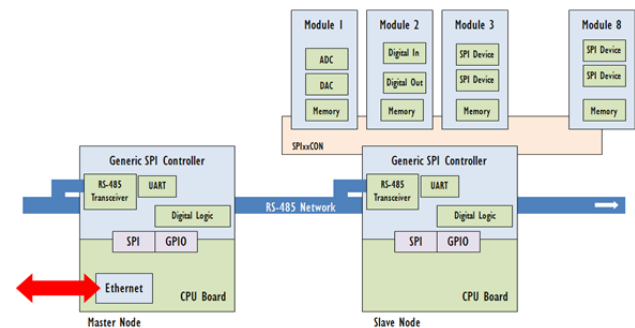

Figure 1: Schematic of the GESPICON hardware platform.

Another important feature of this implementation is the possibility to embed SPI flash memories on the interface modules. Thus, any interface can have static information used by the controller for auto-configuration. At boot time, the CPU module will search for each stacked module memories and download the data on it, which can be:

- Source code (Python or C) for the driver interface of the module;
- EPICS parameters for IOC configuration;
- Any parameter of the module devices;
- BSMP entities description (defined next page);

This system makes the CPU software independent of the interface modules drivers. Any module that would be developed in the future will be compatible with the CPU,

with no need of software upgrades. These features increase the modularity and the flexibility of the whole system.

PUC CPU Module

The PUC (Universal Control Board) was the very first prototype developed by Controls Group. The CPU module (called “base board”) is a homemade device embedded with an ARM Cortex M4 microcontroller, with 256 KB of RAM memory and 2 MB flash memory, running at 180 MHz. The base board also has flash and RAM memories (external from microcontroller), which are used to save waveforms and to hold fast acquisition data. The main communication interface is the RS485 serial, running at 6 Mbps baudrate. Another communication facility is the Ethernet interface. The MAC (Media Access Control) layer is embedded in the microcontroller and the LwIP (Lightweight IP Library) implements the TCP/IP stack.

Analog and Digital Modules

The digital board has 8 digital inputs and 8 digital outputs, TTL level, for digital commands and readings.

The analog board has one ADC (AD7634) and one DAC (AD5781) both with 18 bits resolution, for analog input and output. The working range of the converters is from -10V to +10V. This means that the theoretical resolution is 17 bits for 0 to +10V and 16 bits from 0 to +5V. This module was specially designed due to the fact that these kind of high precision interfaces are unusual to find commercially.

Three basic tests were done with these interfaces: long term stability, linearity and repeatability. The setup for all tests was three PUCs with one analog board module stacked. The analog output was connected to analog input of the same board. The measurements were done by a 2-channel Agilent 34420A 7½ digits multimeter and a HP 34401A 6½ digits multimeter. The multimeters were configured with an integration time of 100 NPLC (Number of power line cycles), and the ADCs with an integration of 20k samples over one second.

Long Term Test was performed setting the analog output once and measuring the multimeters and analog input during 24 hours. Some results are presented in Fig. 2 (analog output) and Fig. 3 (analog input).

Figure 2: Long term of analog outputs from PUC1 and PUC3, fixed on -9V and +9V, respectively, along with temperature (right axis).

Figure 3: Long term of analog input from PUC1 and PUC3 (with temperature).

The result shows that stability is quite adequate. The drift of the voltage references of the converters increases as the output reaches the full-scale value (10V), but stays in a reasonable value.

Linearity Test was performed setting the analog output in 5 ranges of voltages (-9V, -5V, 0V, 5V and +9V), with 512 points around the center values. Table 1 and Table 2 below present some results of analog output module differential non-linearity and integral non-linearity tests, respectively.

Table 1: Analog Output Module Differential Non-linearity

0V	-	0,000	-	0,000	-	0,083
+5V	-	0,257	-	0,157	-	0,263
+9V	-	0,294	-	0,096	-	0,428

The results of INL and DNL of all boards are adequate, staying in ± 0.5 LSB range for the analog outputs, and ± 1.5 LSB range for the analog inputs.

Repeatability Test keeps the same setup. The analog outputs were set repeatedly with the following values:

+9V, +5V, 0, -5V and -9V, during 12 hours, at each update, the multimeters and ADCs were read. No missing steps were found in all measurements. The results of the relative error at the 5 ranges are presented in Fig. 4 below.

Figure 4: Repeatability test of PUC1 analog output (relative errors).

Beaglebone Black

The Beaglebone Black [3] is an open hardware single board computer based on ARM Cortex A8 running at 1 GHz. The rich set of features of this hardware makes it a good solution for an embedded platform:

- 512 MB DDR3 RAM, 4GB on-board eMMC flash storage;
- Linux operating system support;
- Flexibility and modularity;
- Fanless;
- 2X real-time 32 bits microcontrollers (PRU processors);

The Beaglebone Black fits perfectly to be used as a high level platform for communication with the Control System Hardware, and also as a CPU board for the custom analog and digital interfaces of the Control System.

To implement the fast RS485 interface, we designed a cape board for the Beaglebone Black using an external UART (MAX3107), which will reach up to 12 Mbps baudrate. The interface to this component is done by the PRU (Programmable Real-Time Unit), a real-time processor embedded in the ARM CPU of the Beaglebone Black (which has two PRU units). To optimize the software design, we created a C library to interact and manage the PRU firmware. This library has an API for sending and receiving bytes from the external UART, and also for configuration of the device. The result is a high-performance serial device with great processing power and all the facilities of an embedded Linux system.

SOFTWARE IMPLEMENTATIONS

The Sirius Control System will use EPICS middleware, one of the most used frameworks in Particle Accelerators Controls System. For the low level communication, we developed a light proprietary protocol, called BSMP (Basic Small Messages Protocol).

BSMP (Basic Small Messages Protocol)

The BSMP describes two layers of the network model: transport and application. The transport layer transmission unit is the *packet*. Each packet holds a *message*. The packets in a serial network have a well defined format: one byte for destination address, n bytes for the message and one byte for checksum. The addressing can be individual or in multicast groups. The protocol message in the application layer has the first byte for command, two bytes for size and finally n-bytes for the payload. Thus, the whole BSMP packet has only 5 bytes of overhead, for payloads up to 65535 bytes.

Devices using the BSMP protocol manipulate protocol entities, which can be up to four categories: variables, group of variables, curves and functions. To manage and implement the BSMP protocol, a C library (and a Python binding) was developed. The API of the library implements all the routines for data encapsulation, de-encapsulation, entities values attribution and protocol validation. To develop a new hardware and use BSMP, the developer only needs to configure the corresponding entities.

EPICS Device Support

In order to use the EPICS facilities, we developed a Device Support for the PUC prototype. An EPICS Soft IOC for the Beaglebone Black master was configured, because the low level hardware access is done via message based devices. The Device Support driver was created using asynDriver framework [4]. In order to embed the BSMP and PRU Serial libraries on the driver, we developed an Asyn Driver Support, managing the low level communication tasks. Above the driver support, there is an Asyn Port Driver in C++, implementing all the parameters that the hardware could have: analog I/O, digital I/O, waveform I/O and static configurations. The same strategy can be used to develop the EPICS Device Support of the new hardware over the SPIxxBUS. The strategy of message-based devices also permits the use of other software for low level interfaces and data structure, like Redis IO suite [5].

SYNCHRONOUS OPERATIONS

Sirius Control System must support synchronous procedures for many of the machine systems. As a main example, there is the booster energy ramp, performed by the magnet power supplies and RF systems. The Control System hardware supports synchronous operations broadcasting serial messages over the RS485 network, in order to reduce the number of signals and cables from the Timing System. Thus, the triggers only need to reach the single board computers, which will send the broadcast high-priority messages over the serial network, as fast as possible.

To validate this strategy, several tests were performed. The object of measurement is the latency between the reception of the trigger on a single board computer and a flag assertion on a slave node of the RS485 network. The

first test uses a Beaglebone Black with our homemade RS485 cape as the master and three PUCs as slave nodes. The trigger signal was a 3.3Vpp pulse, 5% duty cycle, 5 kHz, produced by a HP 3314A Function generator. As soon as the trigger is detected at the Beaglebone Black GPIO (PRU Unit), the master sends a high priority serial packet over the RS485 network at 6 Mbps baudrate. The flag used to measure the reception of the node is the trigger for the DA converter of an analog interface module. This setup emulates the booster energy ramp. We run the experiment 4 times, acquiring 2 minutes of data in each run. Table 3 shows the average of the obtained values from the 4 runs.

Table 3: Latency Measurement Using Beaglebone Black as Master and PUC as Slave

Latency	Min (us)	Max (us)	Avg (us)	Std. dev (ns)
PUC 1	13.91	14.00	13.94	17.13
PUC 2	13.94	14.00	13.97	14.54
PUC 3	13.95	14.04	13.98	18.45

Other tests were done to evaluate the Beaglebone Black as master and as slave on the RS485 network. In this setup, the trigger signal is generated by the own Beaglebone Black master node, using the PWM peripheral. It's a 3Vpp pulse with 2% duty cycle and 100 Hz. This signal is in a loop back to a GPIO of the PRU processor, which sends the broadcast serial message over the network (at 6 Mbps baudrate). The slave Beaglebone Black PRU detects and decodes the broadcast message, raising a flag when the packet is decoded. The results of the measurements of the reception latency are presented on Table 4.

We also tested the Beaglebone as master and slave but running the software from the ARM core, under Linux environment. The latency increased to hundreds of microseconds and the jitter increased to tens of microseconds, which invalidates this topology.

Table 4: Latency Measurement Using Beaglebone Black as Master and Slave, Running Firmware on PRU Processor

	Run #	Min (us)	Max (us)	Avg (us)	Std. dev (ns)
PRU	1	23.89	23.99	23.94	18.91
(master)	2	23.89	23.99	23.94	18.73
x PRU	3	23.89	23.99	23.94	19.36
(slave)	4	23.89	23.99	23.94	18.97

The repetition rate of the Sirius Booster for top-up operation is 2 Hz. The specification of the ramping curves is about 1000 steps each curve. Thus, for 2 Hz operation, the period of each step is 500 us. The results of the first two tests prove that the system can achieve the necessary

performance for booster operation. Even if the repetition rate increases to 5 Hz, (with 200 us each step) the latency and jitter of the serial broadcast triggers match the requirements. The results can be improved when using 12 Mbps baudrate on the serial network.

Another feature of this topology is the selective interrupt configuration, when the slave nodes respond to specific broadcast messages, allowing more flexibility for the profile of ramping curves. This can be useful for machine operation.

CONCLUSION

The design of the main components of Sirius Control System was presented. The implementation strategy is to provide a robust, modular, flexible and distributed hardware platform for machine operation, in addition to EPICS compatibility on the software side. The analog modules characterization tests are quite reasonable. The synchronous operations support proved to match the specification of the Sirius booster energy ramp. The next designs under development by the Controls Group will increase the performance and flexibility of the whole system.

ARIEL CONTROL SYSTEM AT TRIUMF - STATUS UPDATE

R. Nussbaumer, D. Dale, K. Ezawa, K. Fong, H. Hui, M. Iranmanesh, J. Kavarskas, D. Morris, J.J. Pon, S. Rapaz, J.E. Richards, M. Rowe, T. Tateyama, E. Tikhomolov, G. Waters, P. Yogendran, TRIUMF, Vancouver, Canada

Abstract

The Advanced Rare Isotope & Electron Linac (ARIEL) facility at TRIUMF has now reached completion of the first phase of construction; the Electron Linac. A commissioning control system has been built and used to commission the electron gun and two stages of SRF acceleration. Numerous controls subsystems have been deployed including beamlines, vacuum systems, beamline diagnostics, machine protect system interfaces, LLRF, HPRF, and cryogenics. This paper describes some of the challenges and solutions that were encountered, and describes the scope of the project to date. An evaluation of some techniques that had been proposed and described at ICALEPCS 2013 are included.

SCOPE OF CONTROL SYSTEM

The e-Linac was to include a total of 3 stages consisting of 2 cavities per stage except for the first stage, which has only one, of Superconducting Radio Frequency (SRF) acceleration. The performance of the installed cavities has allowed postponing the third cryomodule. With the installation of the third cavity greater than 30MeV will be achievable. The second accelerator stage is planned for upgrade to 20MeV acceleration in one year from this writing. Deployment of the control system has been performed in subsystems, with the intention to isolate interaction between the subsystems, as well as to dedicate personnel to the various subsystems. Different broad control system technologies are used in each subsystem, and this allows personnel to focus on smaller classes of methodologies.

Figure 1: Scale of the control system at this writing

DEPLOYMENT STRATEGIES

A stated goal of the e-Linac control system was to re-use as much existing design and methodology as possible. The TRIUMF Controls Group has a significant body of work and methodology that was built up from prior projects. This includes a system of tools to build EPICS runtime databases, EPICS Operator Interface (OPI) screens, consistency checking in PLC interlock

programming, and development of a consistent look and feel of control room consoles.

Part of the technology deployed in earlier TRIUMF control systems was based on consistent device styles chosen by other groups, especially vacuum, power supplies, and beam diagnostics groups. Despite the intent to develop no new methods and technologies, the style of control system interfaces used by equipment specialists from other disciplines did not accommodate the controls group strategy, and considerable re-work of existing methods was required. This paper will focus on some details of methods not previously included in control systems deployed at TRIUMF.

CONTROLS SUBSYSTEMS

Vacuum Systems

A new strategy for interface to vacuum systems was required when the vacuum group chose to introduce the concept of portable pumping carts. In this system, a small number portable carts containing turbo pumps, backing pumps, vacuum gauges and related valves was fabricated. These carts are arranged to pump down vacuum spaces at 26 discrete locations along the beamlines, according to stages of commissioning and following maintenance procedures requiring vacuum breakage.

Each turbo pumping cart is equipped with a small PLC drop that contains sufficient Input/Output support to drive and read the vacuum devices contained on the cart. A central vacuum controls PLC provides the program logic and EPICS interface for supervisory control and display. Asynchronous connection and disconnection of the central PLC is successfully accomplished by exploiting the ability of the Schneider[1] Quantum PLC to perform IO scans. IO scanning allows the PLC program to detect connect events and disconnect events seamlessly, and to map IO registers to beamline location-specific process variables.

The PLC reads dedicated loopback cables at each pumping cart and connection port, in order to permit the location of each connected cart to be tracked. This information is used to allow OPI displays to reflect the connection status of each cart and each beamline connection port in real time.

The ability to seamlessly connect and disconnect field IO at runtime has resulted in estimated saving of CDN \$28000 in PLC hardware by removing the need for redundant dedicated PLC IO hardware. In addition, the reduction in cabling, estimated at 10000 metres, served to relieve the constraint of cable routing space availability to the Electron Hall where the accelerator and beamlines are

located. This strategy is now considered a significant success.

Cryogenics Systems

The SRF accelerator modules rely on the use of liquid helium cryogenics, and sub-atmospheric pumping to establish operation at 2 degrees Kelvin of the accelerating cavities. To accomplish this, a hybrid of commercial and in-house cryogenics system has been developed. Initially, the strategy was to model the prior work in the TRIUMF ISAC-II facility. In this arrangement, a commercial turnkey helium liquefaction plant would be augmented by an in-house cold-distribution system. Air Liquide Advanced Technologies[2] (ALAT) was chosen as the vendor of the helium liquefaction system (cold box). An interface to TRIUMF equipment and signalling was defined, allowing some aspects vital to operation of the cold box, to be provided and installed by TRIUMF, and signals provided to the ALAT PLC.

The cold delivery system and sub-atmospheric pumping system are composed of various valves, pressure, temperature and pressure monitors, as well as four Busch[3] (model here) mechanical pumps. These are controlled by one Schneider Quantum PLC with IO drops at three different geographic locations.

The convention used to deploy control systems heretofore by TRIUMF controls has been a strictly device oriented system. In this arrangement, there is little coupling of device control, except in ways that are well defined where devices provide status information that is used in machine protection interlocks. Automation of processes has been implemented in only very limited ways.

As a departure from this, there is a requirement to provide some level of autonomous behaviour. The intention is to remove or reduce the need for human operator interaction with the cryogenics system, as well as to improve system performance by exploiting the faster response time capability of a PLC. This level of automation is expected to be accomplished as a new layer of logic, which can be used independently of the machine protection and remote control role of the control system. Strategically, this is intended to allow a segmented roll-out and commissioning of the automation portion of the control system. Experts from the Cryogenics Group are collaborating closely with the Controls Group to define what form this will take.

Initially, there was a clear intention to use the ALAT cold box as a turnkey-only package. Due to the dedication and expertise of one PLC expert in the Controls Group, some modifications to the delivered system have been identified and proposed. These include improvements to the way the ALAT system interfaces to two Kaiser Helium compressors, and segmentation of some PLC controls to reflect geographic separation and functional relationships between elements of the ALAT cold box. These enhancements will also facilitate the aforementioned automation efforts, and the interface to the supervisory EPICS controls.

Beam Optics Systems

Beam optics in the e-Linac uses conventional electromagnets for steering and focusing the electron beam. The control system, then, is responsible for control of power supplies. As a departure from prior work at TRIUMF, the magnet power supplies used in the e-Linac are mostly equipped with built-in Ethernet LAN interfaces, and support a SCPI style of command and query language.

These power supplies are controlled directly from EPICS IOCs, using the combination of EPICS asyn and streamDevice support packages. The system of EPICS records used to control power supplies through analog and digital interfaces was duplicated, using the streamDevice over asynDriver/TCP EPICS devices support. This was successful in creating user interfaces and behaviours that closely resembled prior implementations. In addition to the LAN/SCPI interfaces, three power supplies were purchased from BiRa[4] Systems. These are conventional off-the-shelf power supplies that are augmented with a closed loop stability controls system, and are driven by a proprietary EPICS device support layer.

Monitoring of power supply parameters requires continuous polling, which introduces high volumes of network traffic. In order to isolate the effect of the beam optics traffic from the rest of the control system network, dedicated EPICS IOCs with dual Ethernet interfaces were used to control the power supplies. The strategy is to use one Ethernet LAN as a field bus for the power supplies, while the other network interface provides a conventional TCP/IP interface to the IOC host, including the EPICS Channel Access protocol traffic.

For reasons of economics, the power supplies chosen were of a unipolar nature, even though most beamline requirements dictated bipolar operation in order to support magnet degaussing. In-house polarity switches were built, and these are controlled by the EPICS IOCs using VME based digital IO to drive and monitor the state of the polarity switches. EPICS record logic to support these polarity switches has been successfully implemented.

Beam Diagnostics Systems

Several classes of beam diagnostics devices not previously implemented in a TRIUMF control system have been introduced. These include a Fast Wire Scanner (FWS), several viewscreen systems allowing beam physicists to visualize the electron beam, and a non-intercepting RF-Shield used to measure beam current in real time, and in-house designed and fabricated Beam Position Monitors (BPMs).

As well as new device types, the convention previously used to control stepping motors has been changed from the now obsolete Oregon Micro Systems (OMS) VME based motor controllers to Galil[5] controllers. In a previous endeavour at TRIUMF, crafting device support code to augment the EPICS Motor Record interface to the

Galil controllers was found to be unsuccessful by. New motion control for beam diagnostics devices uses streamDevice EPICS support to communicate with the Galil motor controller on a dedicated Ethernet LAN. Control system logic mimicking the function of the EPICS Motor Record was developed, in order to maximize compatibility with prior work, and with a view to later successful implementation of motor record code to support the Galil controller.

There exists in certain instances, the possibility of moving beam diagnostics devices to collide in space within the beamline. A dedicated Schneider PLC has been implemented with the sole purpose of redundant protection against such collisions.

Viewscreens using the EPICS asyn-based Area Detector package were created by a University based partner, and provided to TRIUMF as turnkey packages. These use the same Galil model motor controllers as other beam diagnostics devices. The original delivery provided EPICS IOC hosts that were configured with Ubuntu Linux, and booted from spinning magnetic media. The operating system and filesystem structure for these has been replaced with the diskless booting system that is now a standard in EPICS based controls at TRIUMF. Beam Position Monitors (BPMs) were developed by the Beam Diagnostics group, in collaboration with the Controls Group. Communication with the BPMs is via TCP/IP using EPICS streamDevice to write commands and read query replies.

RF Controls

Low Level RF (LLRF) controls are produced by the LLRF Group at TRIUMF. This permits a system of fast feedback control of the LLRF system, while interfacing to the e-Linac EPICS control system on a supervisory basis. For the e-Linac Control System, a new EPICS interface was developed by the LLRF Group, enabling the use of conventional streamDevice interfacing, and replacing a legacy system that had become inconsistent with current practice.

The SRF cavities receive High Power RF (HPRF) energy from two Ampegon[6] Klystron power supplies. These are turnkey systems containing embedded Siemens[7] PLCs. The principle control system interface to HPRF equipment is via these embedded PLCs, using an in-house EPICS device support package.

HOST SYSTEMS AND NETWORKING

A small variety of EPICS IOC host types have been deployed in the e-Linac Control System. VME based IOCs are used where direct hardware interfaces are required. This strategy is inherited from prior work. Other alternatives were contemplated briefly, however there were too many elements that either required VME, such as the Machine Protect System Long Ion Chamber detector interfaces from Thomas Jefferson Laboratory, or would require replacement of in-house designs that had already been done for the VME form factor.

Other EPICS IOC hosting has been implemented using small form factor commodity PCs equipped with Intel Atom processors and dual ethernet interfaces. Because of the heavy use of EPICS streamDevice over Ethernet TCP/IP, commodity off-the-shelf hosts are deemed suitable, as long as they are capable of running Linux as an Operating System. These are also used to communicate with PLCs, both in-house programmed Schneider PLCs, as well as Siemens PLCs that are embedded in the turnkey cryogenics system as well as two turnkey high power Ampegon Klystron power supplies

Dell server class x86 computers are used as file servers to host all EPICS binaries, runtime databases, configuration files, and to store user data. These are running Debian Linux, which has been adopted as the standard for fileserver and development host applications in the TRIUMF Controls Group.

The front-end IOC hosts use a version of Linux that was tailored in-house for use in EPICS IOC hosts. The OS is booted over the network using the industry standard PXE protocol. Both the Linux kernel and a customized RAM based root filesystem are downloaded from TFTP servers at boot time, and the hosts run disklessly, mounting fileserver NFS shares for non-volatile storage. The custom root filesystem inherits startup arguments from the PXE configuration file, so that specific applications can be centrally assigned to specific hosts.

This system has been updated with some new features since it was reported in ICALEPCS 2011[8]. In addition to scripting that uses kernel arguments to launch specified applications, a system of host-specific (in contrast to application-specific, since multiple EPICS IOC applications can run on a single host) configuration procedures can be launched from the central boot host. This is used for such things as installing iptables based firewall rules that allow the host to provide transparent access to PLCs on the fieldbus network interface, and to launch DHCP servers for many of the controlled devices that use TCP/IP Ethernet interfaces. In addition, a system of shared applications that were chosen not to be included in the RAM based root filesystem can be accessed at runtime for test and diagnostics purposes.

A control room dedicated to the e-Linac has been established, using conventional desktop computers, and running the Debian version 6 Linux, and the KDE desktop framework. A total of five console computers arranged with four monitor and six monitor video configurations is serving the purpose of e-Linac commissioning, and is expected become part of a TRIUMF-wide integrated control room following completion of the ARIEL facility.

Network Structure

The network architecture used in the e-Linac controls system provides for two tiers of Ethernet TCP/IP networks. One is the general purpose Control System network which carries EPICS Channel Access traffic and other TCP/IP traffic such as NFS and SSH communications between the IOC hosts control room consoles, control

system user hosts, and file servers. The other tier is a system field bus oriented networks which are isolated behind IOC hosts. These carry traffic that is only related to the devices under control of the EPICS IOCs. Individual IOC hosts use their respective fieldbus networks to send and receive data between the IOC and each of the devices under control. This strategy is intended to keep overall traffic levels on the principle network low, as well as to allow isolation of any device which may become faulty and disruptive to other control system elements. In addition, it allows conservation of network IP addresses, since the field bus networks are assigned private LAN addresses from the 192.168.0.0 class.

Beyond the standard two tiers of ethernet networks, the PLCs in use in the e-Linac Control System use their own private ethernet networks. These PLC networks carry only Modbus and QEI/O traffic between PLCs and their IO drops, and further segment the overall network infrastructure.

The use of a highly segmented network topology, coupled with fully functioning Linux computers as IOC hosts allows easy network diagnostics, configuration and monitoring of network traffic. Colour coding of ethernet cabling for the respective tiers promotes easier understanding of network connection and topology in the field.

CONTROLS GROUP ECOSYSTEM

In prior control system projects at TRIUMF, a system of tools and methodologies has been developed to allow for high productivity, consistent product output, and low error rates in control system production and deployment. The tools used to perform these tasks include numerous in-house scripts, libraries, and databases, and tools. These are used to generate EPICS OPI screens, EPICS runtime databases, and to generate much of the configuration data that is used in running EPICS IOCs.

Base 3.14.12.3
Alarm Handler
EDM
StripTool
Gateway
TRAR (TRIUMF Archiver)
TDCT (TRIUMF Database Configuration Tool)

Figure 2: EPICS Components.

These tools have been relied upon in roll-out of the e-Linac control system, and have been augmented in a few ways. A web-based application now generates DHCP server configuration files for all EPICS IOCs that use TCP/IP communications with the devices that they control. This allows easy configuration and rollout of field bus oriented networks. EPICS synoptic screens for beam optics and diagnostics devices are now produced by scripts, and configured through the web application and

related database. This simplifies on step of producing these screens, which are dense in content, and have many details that are difficult and time consuming to produce interactively. The e-Linac Control System uses the EPICS components listed in Figure 2.

CONCLUSION

Interfacing with turnkey systems continues to be difficult in some cases. Extremely careful and detailed planning of all aspects of the vendor interface is required for a seamless integration. Much more time is required to perform integration work than is required for basic rollout of an EPICS + PLC slow controls system.

Consistent use of methodologies and tools speed deployment and produces a more consistent control system product. Building tools to produce control system software components takes up-front effort, but pays off quickly through efficiency gains and product quality improvement.

ACKNOWLEDGMENT

The author acknowledges all EPICS collaborators, who are too numerous to mention. Special recognition is given to Mark Rivers for his continued support of the asynDriver[9] package as well as Dirk Zimoch for his development and support of the streamDevice[10] package. Without these two packages, the e-Linac Control System at TRIUMF could not have succeeded. The author acknowledges Jason Abernathy (MSc) of the University of Victoria for his contribution of the viewscreen development.

LANSCCE CONTROL SYSTEM UPGRADE STATUS AND CHALLENGES*

Martin Pieck[#], Dolores Baros, Eric Bjorklund, John Faucett, Jack Gioia, Jeff Hill, Pilar Marroquin, Jerome Paul, James Sedillo, Fred E. Shelley Jr., Heath Watkins
Los Alamos National Laboratory, Los Alamos, NM 87544, USA

Abstract

The Los Alamos Neutron Science Center (LANSCCE) linear accelerator drives five user facilities: Isotope Production, Proton Radiography, Ultra-Cold Neutrons, Weapons Neutron Research, and Neutron Scattering. In 2011, we started an ambitious project to refurbish key elements of the LANSCCE accelerator that have become obsolete or were near end-of-life. The control system went through an upgrade process that affected different areas of LANSCCE. Many improvements have been made but funding challenges and LANSCCE operational commitments have delayed project deliverables. In this paper, we will discuss our upgrade choices, what we have accomplished so far, what we have learned about upgrading the existing control system and what challenges we still face.

INTRODUCTION

The LANSCCE accelerator looks back at almost 45 years of operations. It was one of the first accelerators to use computer technologies to control and monitor its beam line components. It started out with a custom in-house design called RICE (Remote Instrumentation and Control Equipment) which was installed in the early 1970's when the facility was built. Since then, the facility has seen partial upgrades and extensions utilizing CAMAC, VME, and PLCs while introducing EPICS (Experimental Physics and Industrial Control System) in the 1990's as a supervisory software control application.

Figure 1: LANSCCE Control System 1970-2010.

In 2011, LANSCCE started a nine year rolling upgrade project which eventually will result in the complete replacement of the low-level RF system, the timing system, the timed data system, industrial control system, the beam-synchronized data acquisition system (including Beam Phase & Position Monitors (BPPM)), the fast protect reporting system and, wire scanner diagnostic equipment [1].

This upgrade project is primarily focused on ensuring reliable beam operations for a viable user program at the five experimental facilities. It will also benefit Los Alamos National Laboratory's future signature science facility called Matter-Radiation Interactions in Extremes (MaRIE) since, at its core, the 42-keV XFEL will be coupled with the existing LANSCCE accelerator [2].

UPGRADE SCOPE

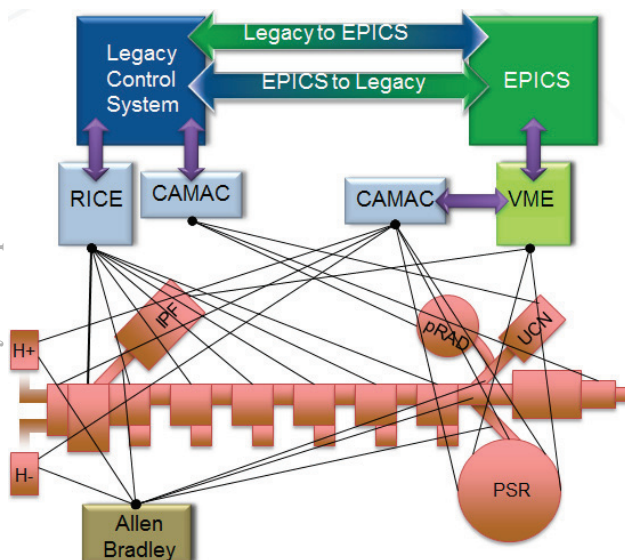

The monumental challenge of upgrading the control system is focused around the need to replace our VAX-based legacy control system which goes hand-in-hand with our RICE system. The VAX system has reached end-of-life and the RICE systems, while a novel invention when it was designed in the late 1960's, is getting harder to maintain, and lacks the flexibility and performance of a modern distributed system with processing power near the front end.

RICE is a star configured control and data acquisition system that supports industrial control and beam-synchronized type of data acquisition. At its heart, the RICE Interface Unit can issue a parallel RICE module read request that provides a transverse snapshot of the accelerator. This implementation resembles the functionality of a timing system which provides trigger gates to distributed data acquisition equipment.

Given the complex functionality, replacing the RICE system is not an easy task and one starts to appreciate the engineer's ingenuity to design such a system about half a century ago.

Industrial Control

The first part of our RICE upgrade project addresses the Industrial Controls (slow control). We chose a Programmable Automated Controller (PAC) built by National Instruments (NI). The controller is called CompactRIO (cRIO) and is a reconfigurable control and data acquisition system which is supported by EPICS [3]. The NI cRIO-9024 embedded real-time controller features an industrial 800 MHz processor and contains, 512 MB DDR2 RAM, and 4GB of non-volatile storage. The removable cRIO controller sits in an NI cRIO-9118

*Work supported by LANL for the U.S. Department of Energy under contract W-7405-ENG-36; #pieck@lanl.gov ; LA-UR-15-27880

chassis with eight accessory slots, and a user programmable Xilinx Virtex-5 LX110 Field Programmable Gate Array (FPGA). The most noticeable advantages are reliability, high performance and hot swappable modules and a high performance FPGA. For our application, the cRIO is hosted in a commercial BiRIO rack-mount chassis which interfaces to commercial BiRIO interface boards that in turn provide interfaces to the device field wiring.

Figure 2: cRIO in BIRO chassis.

National Instruments provides a wide variety of modules that cover most of our needs. Beyond that third-party products complement the NI module product line. If that still doesn't meet the needs, a Module Development Kit (MDK) allows the development of custom modules to meet the unique needs of particular products and applications.

The cRIO is a fast and flexible solution at a reasonable price point. The typical response time is in the μs range vs. msec in Programmable Logic Controllers (PLC). In addition, the cRIO provides more programming flexibility than a PLC. The cRIO FPGA and Real Time Controller (RTC) running VxWorks, are programmed in LabVIEW. The RTC embedded EPICS IOC (with a complete environment - all record types and fields are visible and available) makes this solution a standalone EPICS IOC which communicates with the RTC LabVIEW Real Time code via a shared library. Another advantage is that the independently running FPGA, interfacing directly with the cRIO I/O modules keeps running even though the EPICS IOC is rebooted. This can be helpful if interlock functionality needs to continue even when the IOC has to undergo maintenance. Last, but not least, the whole system maximizes its flexibility through the freedom on how an application is partitioned between the FPGA, LabVIEW RTC, and EPICS database code [4].

Beam-Synchronized Data Acquisition

The second part of the RICE system replacement effort focuses on the beam-synchronized data acquisition. The hardware solution chosen is a cPCI/VPX architecture in one crate allowing the communication between both sides via a PCI Express communication bridge. VPX is an ANSI standard (ANSI/VITA 46.0-2007) that provides VMEbus-based systems with support for switched fabrics over a new high speed connector [5].

Figure 3 provides the front view of our cPCI/VPX chassis. On the left we have three 250W, 3U high plug-in power supplies with an additional power supply expansion slot for redundancy. Located to the right of the

power supplies are the six 3U VPX slots. The picture shows two test cards inserted, one of which is an Ethernet controller providing network connectivity to all VPX slots via the backplane. On the right side of the chassis are eight 6U cPCI slots.

Figure 3: cPCI/VPX Chassis Front View.

This architecture will be used for the BPPM system. On the cPCI side the signals from 4-electrodes (top, left right, bottom) are captured along with the accelerator reference signal. The signals are then conditioned to 201.25 MHz RF waves and then transported to the VPX side where a high speed digitizer captures the data at 4-nanosecond time increments in order to analyse beam position and phase variations that occur throughout the 1 millisecond pulse cycle. Timing for synchronous measurements between BPPMs and beam specific information is provided by an event receiver (connected to the master timer via optical links) on the cPCI side that provides the timing and beam species information prior to submission to the EPICS database. A soft core processor, which resides in FPGA fabric, is used to store the results to the EPICS database for use by beam operators [6].

Figure 4: FMC Carrier Board with Altera Stratix IV FPGA and front end ADC.

The BPPM hardware solution on the VPX side shown in Figure 4 is very adaptable and will be used for our other beam-synchronized data acquisition application needs. It consists of a FPGA interfaced Mezzanine Card (FMC) [7], that hosts an Analog Digital Converter (ADC) and an Altera Stratix IV-GX230 [8]. The latter hosts an

embedded EPICS IOC running the RTEMS operating system on a NIOS-II softcore. The hardware/software solution has numerous advantages:

- Enables buying hardware COTS but still employs high performance hardware design
- FMC enables custom Digital Signal Processing (DSP) solutions in hardware without custom board design
- Ensures an independent and incremental upgrade path for AFE (ADC), DSP, or IOC
- Integrates ADC, digitizer module, signal processing EPICS IOC all into one board
- Highly distributed, therefore increased fault tolerance

Timing System

Essential to beam-synchronized beam operations is the timing system which undergoes a change from a centralized gate generating system to a distributed event-based system where timing gates are generated locally. The new Timing Pattern Generator (TPG) is a dual-redundant system. Each of the redundant TPG's has a VME-64x crate, a MVME-6100 processor, a set of Micro Research Finland (MRF) event-generator modules, and an AC zero-crossing detector and beam-enable logic module (implemented in a cRIO system). The cRIO FPGA-based beam enable logic has been used to implement specific features, such as enabling or disabling a beam from the operator consoles, single-shot mode, single-burst mode, continuous-burst mode, burst of bursts mode, and cycle stealing. The new TPG has performed successfully during the 2014/15 run cycle interfacing to the old (RICE) and new timing distribution system (fibre optics to local Event Receiver). While the TPG work is complete the distributed event-based generating devices (Timing IOCs), some of which are tightly coupled with our Low Level RF system, still need to be installed during future maintenance periods [1].

Wire Scanner

The cRIO platform is also used to upgrade our aging Wire Scanner control and data acquisition system that has been using RICE and CAMAC (Computer Automated Measurement And Control) technology. Beyond the cRIO Industrial Control configuration, the Wire Scanner cRIO chassis has an NI TPC-2206 Touch Panel Computer integrated into the chassis front panel to provide real-time visual display of wire-scanner operation and direct manual control of the wire-scanner actuator [9].

Furthermore, the project took advantage of the cRIO National Instruments MDK to design a specific, commercially unavailable, cRIO AFE module. The design has been built by and is available through National Instrument's Alliance Partner BiRIO. This Analog Front End (AFE) module is a dual channel, transimpedance amplifier with dual summed inputs and true DC coupling to collect the charge signals from the sense wires. It is designed to accommodate comparatively long macro pulses (>1ms) with high repetition rates (>120Hz)

without the need to provide integrator reset signals. The basic AFE bandwidth is flat from true DC to 35 kHz with a well-defined first-order pole at 35 kHz. Numeric integration is utilized in the cRIO FPGA to provide pulse-to-pulse numeric integration of the AFE signal to compute the total charge collected in each macro pulse [10].

Other Controls and Diagnostics Equipment

Beyond what has been described so far we have other systems that need to be upgraded to allow us to retire RICE and the associated Legacy Control System. Among others, this includes the Harp and Emittance diagnostic equipment mostly located along our linac.

For the Harp, a cRIO based system is in production at our 1L target. This design will be leveraged to replace the remaining Harp systems. The current design has three AFE boards and one integrity board outside the cRIO but housed within a BiRIO chassis. Logic signals for beam synchronization and AFE control connect to the cRIO through a single NI-9401TTL logic module. Signals generated by the AFEs are digitized by three NI-9220 ADC modules. Finally, one NI-9475, 60V-source module is incorporated for integrity pulse generation that used is to check continuity of the Harp wires [11].

For the Emittance stations we are still working on our design but we are confident that the cRIO system will meet the requirements and become the platform of choice.

Another system in need of replacement is our CAMAC system that provides timing and data acquisition solutions. For the most part we have been very successful and found cRIO modules with similar functionality of the CAMAC module that needed to be replaced. Other CAMAC module functionalities are not that easily replaceable and we are diligently working on a path forward.

UPGRADE STATUS & CHALLENGES

At the beginning of the project we focused on engineering solutions that would minimize the number of hardware platforms we would need to introduce and still meet all our technical requirements. We believe that our cRIO and cPCI/VPX based platforms meet that objective. The controls upgrade project is only one part of a larger investment to upgrade the LANSCE accelerator. Funding levels have been flat for the project and did not consider the year to year funding needs to execute the project in the most effective fashion. This, combined with some unexpected funding adjustments for other non-controls project scope elements, added a great deal of uncertainty to whether we would be able to do everything we had planned for.

Therefore, after the design phase, we chose to focus the majority of our controls scope elements on the purchase of the equipment vs. purchase & installation. Hoping that if we have all the hardware in hand, we will find the funding to install it either through remaining project funds, one-time funding, and/or through our maintenance budget.

Table 1: Control System Upgrade Project by Numbers; (#) Number of WS Ctrl. & Data Acq. Chassis only.

	RICE to Industrial Controls	RICE to Synchronized Data Acq.	BPPMs	Wire Scanner	CAMAC to cRIO	HARP	Emittance
Total Number of Systems to be upgraded	66	66	34	53	38	32	3
Upgrades Installed / In Production	9	0	0	4	28	1	0
Equipment on Hand but Not Installed	27	31	7	8 (40)	2	0	1
Remaining Systems to be Purchased	30	35	27	41 (9)	8	31	2

This, however, has led to some unintended consequences. Not all of the control subsystems and/or related non-control subsystems designs are at the same maturity level. For example, while the majority of the wire scanner controls equipment (Table 1: #s in brackets) is ready for installation, the associated actuator has not been funded at the level that would allow us to install a completely new system. This in turn, made us explore the possibility of retrofitting our new Wire Scanner controls chassis to the old actuator still in the beam line. Furthermore, our RICE to cRIO (Industrial Control) upgrade has progressed with nine units installed while we don't have a RICE to cPCI/VPX (Synch. Data Acq.) unit in production. This is inefficient since we will need to get back to those systems that have been upgraded to the new cRIO subsystem in order to install the cPCI/VPX subsystem in order to retire a whole RICE unit. So far we still have all of our RICE units in production. However, 9 of them only run the beam-synchronized data acquisition.

Table 1 shows a numerical overview of our controls subsystems that need to be upgraded (row 1); subsystems hardware that have been upgraded (row 2); hardware that has been purchased for a pending upgrade (row 3); and subsystem hardware that still needs to be purchased such that a system can be upgraded (row 4).

Figure 5: LANSCE Control System 2020.

Our progress has been hampered by the funding limitations and uncertainty. Furthermore, all installation work needs to be done during our 4 month maintenance period on top of all other maintenance that needs to be done without additional labor resources. Our ultimate

goal is shown in Figure 5 (compared to Figure 1) with EPICS as a supervisory control system.

CONCLUSION

The cRIO and cPCI/VPX are flexible hardware and software solutions and therefore adaptable to a wide range of control and data acquisition problems. With most of the LANSCE Control System design work complete the project has transitioned to purchasing and installation. Significant work still lies ahead to complete this monumental control system upgrade task by 2020.

MaRIE – INSTRUMENTATION & CONTROL SYSTEM DESIGN STATUS AND OPTIONS*

Martin Pieck[#], Robert W. Garnett, Brian G. Smith, Fred E. Shelley Jr.,
Los Alamos National Laboratory, Los Alamos, NM 87544, USA

Abstract

Los Alamos National Laboratory has defined a new signature science facility, Matter-Radiation Interactions in Extremes (MaRIE) that builds on the existing capabilities of the Los Alamos Neutron Science Center (LANSCE). It will be the first multi-probe materials research center to combine high-energy, high-repetition-rate, coherent x-rays with electron and proton-beam charged-particle imaging to perform in-situ measurements of a sample in extreme environments. At its core, a 42-keV XFEL will be coupled with the LANSCE MW proton accelerator. A pre-conceptual design for MaRIE has been established. Technical risk reduction for the project includes an injector test-stand that is currently being designed. New accelerators are either planned, under construction, or currently in operation around the world, providing opportunities for the MaRIE project to leverage the instrumentation & controls (I&C) efforts of these facilities to minimize non-recurring engineering costs. This paper discusses possible MaRIE I&C system implementation choices and trade-offs, and also provides an overview of the proposed MaRIE facilities and the current design.

BACKGROUND

X-ray imaging is unique, both because of the penetrating power of x-rays in solid matter - as Wilhelm Rontgen discovered in 1895 - and because x-ray wavelengths are short enough to resolve the interatomic spacing in matter via diffraction - Max von Laue's discovery in 1912. Those properties allow scientists to push forward fundamental physical sciences and to find major applications in structural imaging, from new commercial drugs to jet turbine blades [1].

Los Alamos National Laboratory's proposed Matter-Radiation Interactions in Extremes (MaRIE) experimental facility is slated to introduce the world's highest energy hard x-ray free electron laser (XFEL). The MaRIE 42-keV XFEL, with bursts of x-ray pulses at up to gigahertz repetition rates for studying fast dynamic processes, will help accelerate discovery and design of the advanced materials needed to meet 21st-century challenges [2].

MaRIE FACILITY

The MaRIE facility will include a 12-GeV linac to provide a suite of measurements designed to investigate the performance limits of materials in extreme environments. One of MaRIE's most powerful tools will be the ability to multiplex an x-ray FEL, electron, and

proton radiography onto a target material to study dynamic events as they develop. The existing LANSCE proton linac will be used to provide proton radiography (pRad) [3]. The MaRIE electron linac will be built in a new tunnel north (right side in the figure) of the existing LANSCE proton linac tunnel as shown in Fig. 1 [4].

Figure 1: MaRIE Facility Layout.

OTHER XFELS

Besides the planned MaRIE XFEL facility in Los Alamos, New Mexico, USA, next-generation light sources also exist in Europe, Japan and elsewhere in the USA. X-ray facilities are being constructed at LCLS in California, SACLA in Japan, the European XFEL in Germany and the SwissFEL. The operating principles of these facilities are very similar. Electrons are first accelerated to high energies and then made to generate high-intensity x-ray laser light. LCLS and SACLA rely on conventional accelerator technologies. The European XFEL will use superconducting technology [5].

MaRIE BEAM REQUIREMENTS

The MaRIE electron beams consist of micro pulses for an XFEL undulator and micro pulses for electron radiography (eRad). A special feature of the MaRIE facility is the ability to provide unevenly spaced XFEL and eRad micro pulses distributed over a macro pulse of up to 100 μ s. The macro pulse repetition rate is 60 Hz. Each XFEL micro pulse includes up to 0.2 nC of charge. Each 100- μ s-long macro pulse can include up to 30 XFEL micro pulses. Each eRad micro pulse includes up to 2 nC of charge. Each 100 μ s long macro pulse can include up to 10 eRad micro pulses. The spacing between micro pulses is determined by the experimental needs. The minimum spacing for each eRad micro pulse is 25 ns, while the minimum spacing for each XFEL micro pulse is 2.5 ns [4].

*Work supported by LANL for the U.S. Department of Energy under contract W-7405-ENG-36; #pieck@lanl.gov; LA-UR-15-27877

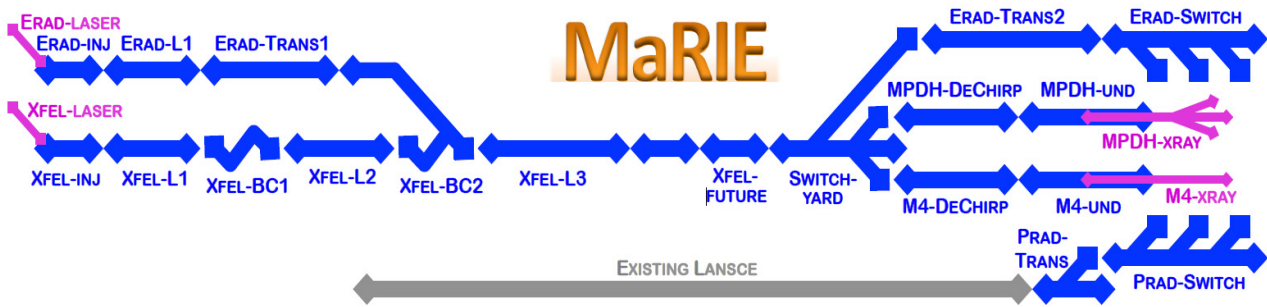

Figure 2: MaRIE Beamline Layout [6].

MaRIE BEAMLINE LAYOUT

The MaRIE XFEL and eRad micro pulses are produced and accelerated by separate injectors and initial injector linac sections. Both injector linac sections include an injector and L1 linac section. The XFEL side includes two bunch compressors and a short L2 linac section. The outputs of these parallel beamlines feed the L3 main linac as shown in Fig. 2. A switchyard at the end of the L3 linac splits the XFEL and eRad beams off to go through undulators or directly to the target [4].

Photo Injector Region

Current plans suggest a 1.3 GHz normal conducting photo injector (PI) for long pulse (100 μ s) operation and a 60 MV/m gradient cathode for both the eRad and XFEL [7]. The photo injector design is similar to the PITZ design used at the Photo Injector Test facility in Zeuthen, also used at FLASH [8] and will be used for the European-XFEL [9]. Following each injector are two superconducting cryo modules (CM1 & CM2) operating at 1.3 GHz for the purpose of capturing the beam from the PI and introducing energy slew for bunch compression BC1. Cryo modules 3 & 4 will operate at 3.9 GHz for the purpose of linearizing the beam energy slew for bunch compressor (BC1). BC1 will provide x20 compression at about 400 MeV. An overview of the injector region is given in Fig. 3 [6].

Figure 3: MaRIE Injector Region Layout.

Linac

The MaRIE linac will use proven RF cavity designs. Four hundred sixty cavities will be of the 1.3 GHz TESLA type used in the FLASH [8], LCLS-II [10] and European XFEL [9] projects. The L2 linac includes 78 of these cavities and the L1 linacs each include 11 of these cavities. Like the International Linear Collider (ILC), the 460 TESLA cavities are run at an average cavity field of 31.5MV/m [11]. The 22 third-harmonic linearizer cavities will be of the 3.9-GHz type used in the FLASH linearizer [8]. Each L1 linac includes 7 of these cavities and the L2

linac includes 8 of these cavities. The average cavity gradient is 20 MV/m [4].

Undulator

The MaRIE facility is expected to have two matching undulator beam lines each leading to a different experimental facility. An undulator line is shown in Fig. 4. The first undulator line will go to the Multi-Probe Diagnostic Hall (MPDH). Each end-station in this hall will receive simultaneously eRad, pRad and XFEL beams. The second experimental facility will be the Making, Measuring, Modelling, Materials (M4) facility with potentially 3 end-stations. The undulator lines will produce greater than 2×10^{10} 42-keV photons in each 33-fs pulse from a bunch length of 10 μ m.

Figure 4: MaRIE Injector Region Layout.

The undulators planned for MaRIE are similar to the SwissFEL U15 undulator. Fourteen alternating focusing and defocusing quadruple lenses forming a FODO magnetic focusing lattice make up each of the undulator lines. Each 0.6 m break between undulator segments will house two gate valves, a beam position monitor, a phase shifter, a permanent magnet FODO quad and an adjustable alignment quad [12].

ACCELERATOR CONTROL SYSTEMS

Requirements

The demands on modern accelerator control systems are increasing from year to year. Today's operator and operations physicist require more and more information in real-time in order to minimize start-up time, maintain optimal beam parameters, predictively intervene to minimize beam down time and to recover quickly from off-normal events.

Given that an accelerator facility lifecycle consists of several different stages, the control system must be modular, scalable, and incrementally upgradeable.

Expansion of the control system to accommodate the installation of the accelerator and beamlines from early testing, through commissioning, and during the life of the facility should not impact the control system performance.

Today's Accelerator Control Systems

Today's accelerator control systems are a combination of a wide variety of commercial/industrial and custom made hardware and software solutions. Early accelerator controls deployed in-house custom solution as this was often the only choice. Over the years this has dramatically changed. Today more and more industrial and commercial based control system solutions are available and have become the first choice for control system engineers. The spectrum of these industrial and commercial products reach from uniquely dedicated hardware products with software configurable solutions for standard implementations to custom software solutions in highly adaptable hardware.

On a related note, over the past decade accelerator control system integration with facility related systems has become more common. Control systems for cryogenics, tunnel cooling and ventilation, etc. monitoring are needed and should be well-integrated because of their tight coupling to accelerator operation. It only recently has been felt there was a need for integrating the water distribution, building heating, etc. as well.

MaRIE CONTROL SYSTEMS

The scope of the MaRIE project likely requires a multilab collaboration with other facilities that have expertise in many of the systems required for MaRIE. Similarities between MaRIE and other XFEL facilities have been pointed out in this text. The expectation is that some of these systems could be delivered as turnkey subsystems (i.e. Cryo Plant System, Cryo Module Systems, High Power and/or Low level Radio Frequency System, Undulator System ...) and later integrated with the overall facility control system. However, past experience has also shown that some of the subsystems and associated equipment were delivered by partner labs or industrial partners without their control system and were equipped in-house later with the control system product of choice. In the following we discuss the pros and cons (pros of a turnkey systems are in most cases closely tied to the cons of the in-house solution and vice versa) for a turnkey system.

Turnkey System vs In-House Solution

A turnkey system is a system that has been customized for a particular application. Turnkey systems include all the hardware and software, installation, start-up assistance, training, etc. for a subsystem with little or no involvement of the host facility (in this case MaRIE) until the system is accepted.

The pros of using a turnkey include:

- One responsible supplier will provide all the project management and become the single interface to the host facility. This frees the host facility from dealing with many individual contractors to achieve the same result.
- Suppliers most likely have already developed a control system solution for a particular subsystem which could save design / engineering costs.
- Turnkey system providers (subject matter experts) often have a better understanding of what is required to make a system work which in turn increases the cost certainty for the project.
- When working with one responsible authority, one would expect to have one warranty to secure the quality and craftsmanship of the subsystems to be delivered.

The cons of using a turnkey system include:

- Having a single responsible supplier usually means a higher management fee for this type of service which could be equivalent to hiring independent consultant(s) or permanent staff.
- Most likely the turnkey system needs to be integrated into one holistic control system which may require extensive integration work.
- In-house personal likely need extensive training due to the lack of being involved during the engineering design phase.
- Higher maintenance cost due to the possible wide variety of hardware and software solutions used across the host facility for different turnkey systems.
- Timely response to pending problems may be difficult due to lack of on-site subject matter experts.
- Reduced opportunity to develop in-house capabilities and knowledge base that could be beneficial for future projects at the host site.

Systems Engineering

A project of the scale of MaRIE will likely take delivery of many turnkey systems. To successfully integrate these systems a strong systems-engineering approach is needed as early as the beginning of the project.

A model should be developed to investigate and determine the required data flow, direction, performance, and need of synchronization between the individual systems.

Prime candidates for a turnkey system may be those that can operate in a stand-alone fashion or those that have limited interaction with the rest of the control system.

Before deciding to work with a turnkey system provider it is necessary to evaluate the technical expertise

available within our organization. For instance, if we have resources that could do the work, it may be better to take advantage of these in-house resources rather than outsource the work to a turnkey provider.

However, once a decision is made in favor of a turnkey system several things should be kept in mind in order to avoid any difficulties down the road.

- Be mindful about changing interface requirements in the future as the facility goes through its lifecycle stages.
- Insist on having access to all system documentation and software. Proprietary implementation may lead to the inability to make required changes in the future.
- Require the use of industry standards whenever practical which will make upgrading and interfacing easier in the future.
- Like the rest of the control system, turnkey systems should be designed with a modular upgrade path in mind.
- Test early, test often. Take advantage of prototypes, simulators, emulators, and any other way to let everyone involved get an early look at the system. Make sure tests prove that the supplier satisfies the requirements.

Integration

Given the range of demands (controls, data acquisition, data management, data analysis, ...) on information technology in an accelerator facility one solution may not fit all needs. Coupled with individual preferences of the controls engineers it is more than likely that extensive integration work will need to be done. Given these facts integration should be planned for accordingly.

MaRIE PROJECT FUTURE

Over the last several years the MaRIE project has gained more and more momentum with the likelihood of gaining official US Department of Energy (DOE) project status soon. The first critical project milestone to be met will be approval of the project mission need, Critical Decision Zero (CD-0). In anticipation of an approved CD-0, the MaRIE project team has developed a project schedule and cost estimate based on the facility layout presented in this paper. Furthermore, independent reviews have validated our scientific and cost/schedule bases.

To further reduce project risk a detailed technology maturation plan has been developed for MaRIE that includes an injector test stand based on an existing Advanced Free Electron Laser test facility at the LANSCE user facility.

CONCLUSION

MaRIE is a promising project that will require a multilab collaboration. In this environment, the control system's ability to be upgradable, scalable, extendable, and allow the integration of many turnkey systems will be essential to the success of the project. Implementing

turnkey solutions is not necessarily always the best choice for a project like MaRIE. To determine whether a turnkey solution is a viable option, there are a number of important considerations to take into account which have been discussed in this text.

 V. Baldini, R. Cirami, A. Marassi, INAF-OATS, Trieste, Italy

Abstract

The Square Kilometer Array (SKA) project aims at building the world's largest radio observatory to observe the radio sky with unprecedented sensitivity and collecting area. In the SKA1 phase of the project, two dish arrays are to be built, one in South Africa (SKA1-Mid) and the other in Western Australia (SKA1-Survey). Each antenna will be provided with a local monitor and control system, enabling remote operations to engineers and to the Telescope Manager system. In this paper we present the current status of the software system being designed to monitor and control the dish subsystem. An overview of the dish instrumentation is reported, along with details concerning the software architecture, functional interfaces, prototyping and the evaluated technologies.

THE SKA DISH ARRAY

The Square Kilometer Array (SKA) project [1] is being designed to carry out radio observations of the sky in the wide frequency range from 50 MHz to 20 GHz with high sensitivity and collecting area to throw light in key areas of astrophysics and cosmology [2].

To this aim three different arrays were planned to be built for SKA Phase I and deployed at two different sites: the SKA1-Mid array at the South Africa's Karoo region hosting 190 dish antennas incorporating the Meerkat precursor telescopes and observing in the 0.35-13.8 GHz domain, the SKA1-Survey array at the Western Australia's Murchison region (MRO) site hosting 60 dishes equipped with phased array feeds (PAFs), incorporating the ASKAP precursor telescopes and observing between 0.65 and 1.67 GHz, and the SKA1-Low at the MRO site hosting 250000 low-frequency antennas.

The SKA design foreseen for Phase 1 was recently updated after a re-baselining process [3] carried out by the SKA Office to constrain the project costs to the established cost ceiling. The major outcomes of such review impacting dish array were a reduction in the SKA1-Mid array to 70% of its original size (190 dishes), equipped with prioritized band 2 (0.95-1.76 GHz), 5 (4.6-13.8 GHz) and 1 (0.35-1.05 GHz) and the deferral of SKA1-Survey array. Antennas (64) from the Meerkat precursor will be integrated in the SKA1-Mid array. The achieved array layout will have a central core component and additional spiral components targeted to deliver baseline lengths of 150 km. In the rest of the paper we will focus on SKA1-Mid antennas only.

* sriggi@oact.inaf.it

DISH INSTRUMENTATION

The general design for a SKA1-Mid antenna, shown schematically in Fig. 1, currently foresees a 15-m offset Gregorian dish with a feed-down configuration equipped with wide-band single pixel feeds (SPFs) for Band 1-2-5. The feed packages are mounted on a fan indexer at the focal position, allowing for changing among the available frequency bands. Only one band will be available for observation at any given time. A RFI-shielded cabinet is present in the antenna pedestal to house digital electronics and hardware for antenna movement and monitoring and control purposes, including the computing equipment supporting the Local Monitoring and Control system. No active cooling will be available for equipments inside the cabinet, only ventilation. Four sub-elements are identified in the SKA-Mid1 dish element: the Dish Structure (DS), the Single Pixel Feed (SPF), the Receiver (Rx) and the Local Monitoring and Control (LMC). Additional details on the first three are reported in the following subsections, while the LMC design is discussed in final sections.

Figure 1: Schematic overview of SKA Dish design and instrumentation.

Dish Structure

The Dish Structure (DS) sub-element is responsible for the design of antenna, including mechanical structure and support, optics, reflectors, indexer as well as for the power distribution to be supplied to all sub-elements and safety systems (i.e. fire/intrusion sensors, limit switches, ...). DS

will supply the servo systems for antenna positioning in both azimuth and elevation comprising servomotors and encoders for precise position reading, connected to the Antenna Control Unit (ACU), placed inside the pedestal compartment. Three different antenna prototypes have been built within the DS consortium and tested against performance requirements derived from scientific goals. A down-selection among the antenna candidates is expected within few months.

Single-Pixel Feed

The Single Pixel Feed (SPF) sub-element will provide the feed packages of the antenna that receives the astronomical radio signals and relative control equipment. Each feed package will include orthomode transducers (OMTs) and low noise amplifiers (LNAs), prototyped for the SKA SPF bands, along with a Gifford McMahon (GM) cryogenic cooler to cool the LNAs, a cryostat assembly sharing a common helium supply system with a single helium compressor located at the antenna yoke, with helium supply lines routed to the indexer. A rotary vane vacuum pump is located on the indexer with vacuum lines to all connected cryostats. A single controller placed in the pedestal interfaces with the SPF feed packages, helium and vacuum systems using a low speed serial protocol over fibre, and allows external monitoring and control operations performed by LMC through a controller application software implemented on an ARM architecture.

Receiver

The Receiver (Rx) sub-element provides the hardware equipment to digitize the RF signal (e.g. the science data) received from each SPF band after a RF-to-optical conversion performed at the indexer. Digitization occurs inside the pedestal enclosure. A number of components are present. The digitiser packetizes and transmits the signal over a high-speed Ethernet link to the central signal processor. A Master Clock timer unit receives time and frequency reference inputs externally (from SKA SaDT element) and generates timing and frequency references where needed, including the control of the calibration noise source that is transmitted over fibre to the feed packages. As for SPF, a central controller is present and acts as a single point of monitoring and control to the LMC sub-element.

THE DISH LMC SYSTEM

The SKA M&C Hierarchy

The monitoring and control of the SKA constitutes a big challenge given the large and heterogeneous number of instrumentation to be remotely managed, including the integration of SKA Meerkat and ASKAP precursors. The overall number of monitoring points is roughly estimated of the order of 10^5 for SKA Phase 1 and larger than 10^6 for SKA2 [4], each antenna contributing with few hundreds parameters for SKA1-Mid and few thousands for SKA1-Survey antennas and PAF receivers. In this context the monitoring and control data flow provided by each SKA dish is expected to be of

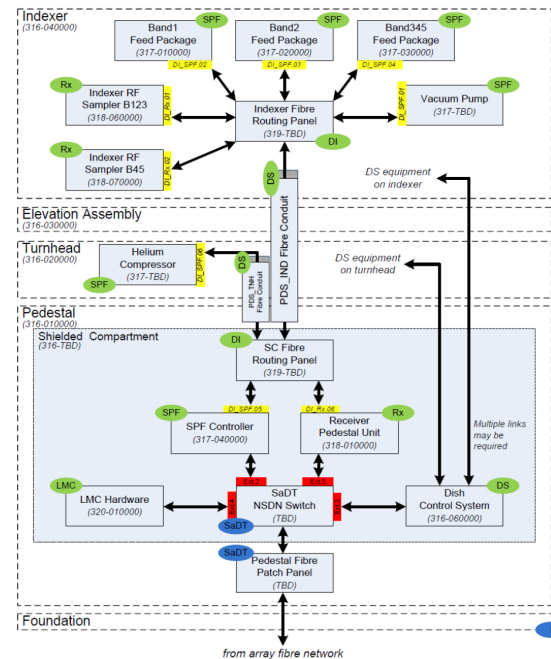

Figure 2: Schema of monitoring and control interfaces among SKA dish sub-elements.

the order of 100-200 kbps for SKA1-Mid and SKA1-Survey antennas and 1 Gbps for SKA1-Survey receiver. To deal with complexity and ease system scalability, a hierarchical architecture of the M&C system was considered. The Telescope Manager (TM) element at the top of the hierarchy orchestrates the scientific observations, centrally coordinating all the involved telescopes and providing control information to them. Further details on TM design and organization will be given at this conference [5]. In order to perform the telescope monitoring and control TM communicates with the Local Monitoring and Control (LMCs) elements of the other SKA subsystems (one per each SKA subsystem, i.e. Dish, Central Signal Processor (CSP), Science Data Processor (DSP), ...). These LMCs perform the direct control and monitoring tasks on their subsystems, fulfilling the following main responsibilities:

- maintain direct and local connectivity to controlled components, specially in case of TM downtimes
- receive and execute control commands (i.e. setup, configuration, calibration, scheduling, life-cycle, ...) from TM involving dish components
- collect and aggregate logging and monitoring information (state/status, monitoring parameters, ...), events and alarms from dish components and report them to TM, after a proper mapping to a SKA common model
- perform diagnostic operations, fast control (<100 ms rate) and safety actions (autonomously or when commanded) on dish components
- perform life-cycle management operations (i.e. remote software/firmware update, power up/down)

- providing drill-down and tunnelling capabilities (i.e. remote access to devices or engineering interfaces, ...) to TM and operators

The M&C interfaces among dish sub-elements are represented in the diagram of Fig. 2. LMC performs M&C operations exclusively via the sub-element controllers, through a local Ethernet link, enabled by a network switch provided by the SKA Signal and Data Transport (SaDT) element, responsible also for the external connectivity of the antenna (e.g. transport of science and M&C data).

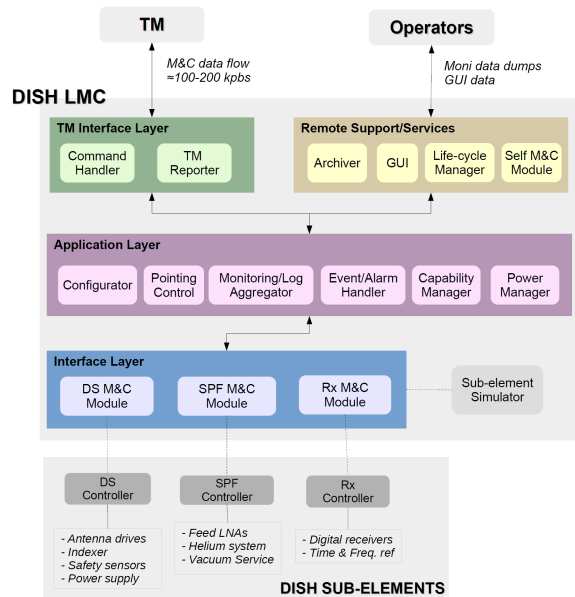

Figure 3: Logical view of Dish LMC software architecture arising from the preliminary design phase.

Preliminary Dish LMC Design

The high-level components of Dish LMC were identified during the preliminary design phase. A logical schema of the LMC architecture for SKA1-Mid antennas is reported in Fig. 3. The LMC software system can be regarded as a collection of modular packages, each providing a set of functionalities (as per SKA LMC requirements), organized in a three-level hierarchical structure. The “Interface” layer comprises a set of interface modules for the DS, SPF and Rx controllers, implementing communication access, control commands and retrieval of monitoring information. At this level a mapping from internal hardware state/status parameters to a global SKA control model (standardized for all SKA LMCs) is also performed. A suite of sub-element simulators is also planned to be developed for early testing of internal interface modules.

The “Application” layer implements built-in high-level functionalities and collective operations on sub-elements. For instance, configuration tasks, such as the configuration of the antenna for observation in a given frequency band or the setup of TM interface reporting, are performed by a *Configurator* component. Aggregation of all monitoring and log

information collected from sub-elements (including pointing meta-data) and from LMC components (self M&C module) is carried out by a *Monitoring/Log Aggregator* component, which is responsible to maintain a rolled-up view of monitoring data inside the antenna and report it to TM. Similarly, events and alarms, particularly those related to safety or emergency situations (i.e. intrusion, emergency stop, ...), are handled by an *Event/Alarm Handler* component, which is responsible to execute recovery actions on failing components, filtering/reporting relevant events to TM (i.e. target lock, stow position, power-cut, ...).

Further, LMCs in SKA are expected to report a global capability information to TM, expressing the ability to deliver certain functionalities, i.e. for the dish the ability to operate the telescope in a band given the internal (health) status of all its constituents. Such functionality is provided by the *Capability Manager* component in the LMC architecture.

Pointing operations, performed by the *Pointing Control* component, requires support for receiving and executing pointing commands from TM interface, including the computing of local pointing correction to be applied before commanding the DS controller servo system.

On top of the hierarchy, a “TM Interface” layer is responsible to execute high-level commands from TM (defined in a standardized TM-LMC interface model), making use of service functionalities implemented in the middle layer. This layer was introduced since TM should not be aware of LMC internal implementation nor should access directly dish sub-element components. Moreover, it is desirable to decouple as much as possible TM interface from LMC internal design, so that a change on the interface side does not severely affect LMC.

An archiving component, comprising a data archive plus archiving services, is also present. It is infact expected that LMC should not permanently store monitoring and log data locally. These data will be delivered to TM which will make them available globally. Only a limited-duration circular queue data archive, covering a 12 h time-window at maximum, is therefore foreseen and LMC shall provide services for creating, managing and downloading the archive.

Finally a set of high-level services are to be delivered to both LMC and engineering operators, such as a monitoring and control GUI, tunnelling services to access sub-element engineering GUIs and utilities to perform life-cycle operations (i.e. software/firmware update).

Implementation Guidelines

Object-oriented design will be extensively adopted for the implementation of the LMC control system, C++ and python being the likely adopted programming languages. LMC components are mostly network-distributed “online” components, designed to be configurable at run-time, exchanging data/events/logs each other over a software channel with different patterns, exposing commands callable by other components. “Offline” components, in turn, provide a utility or support function in the context of online components. All the required communication and M&C features (alarm,

logging, archiving systems, GUI tools, error and exception handling, security, ...) will be provided by a M&C framework and its underlying communication middleware. To minimize efforts and risks LMC will therefore rely on an existing off-the-shelf M&C framework rather than implementing base functionalities from scratch.

Key Technologies

A considerable effort is being made within the SKA Telescope Manager consortium to promote a standardization of adopted technologies, best practise, conventions (i.e. common model for definition of states and modes, ...) and re-utilization of experiences and modules throughout the entire SKA control system. As a consequence the choice of a suitable COTS M&C framework, affecting the development of all SKA elements, resulted from a collaborative effort of representative members from all elements' LMCs and TM groups, as well as from the support of selected experts of the framework candidates and reviews of external accelerator/observatory facilities. A set of about 150 requirements (including performance requirements whenever available for LMCs) has been weighted against all the examined frameworks to drive the best choice for SKA needs, among which:

- Strong alignment with architectural concepts and required LMC functionalities;
- Reliability and scalability to SKA system size;
- Support for industrial standards and custom module development;
- Maturity and long-term support for both framework and middleware;
- Support for hierarchy creation among components, component configuration and command implementation;
- Availability of experiences both within LMCs and SKA precursors;
- Integration and re-use of precursors;
- User-base and strong community support

The following candidates were taken under consideration for evaluation against technical requirements: EPICS v3 [6] and v4 [7], TANGO Control System [8], Alma Common Software (ACS) [9], Meerkat CAM [10]. At last TANGO got the highest scores and was finally selected for prototyping stage after a careful evaluation of pros and cons considering also modern M&C trends (see for instance [11]).

The protocol for communication between LMC and sub-element controllers is still to be defined. A natural choice would be extending TANGO layer down to low-level, but other alternatives for the middleware and data serialization have been evaluated against LMC requirements: ØMQ [12] with MessagePack [13] or Google Protocol Buffer [14] as serializer, ZeroC ICE [15], KaTCP [16]. Sample prototype modules have been developed and benchmark tests carried out on different network links. ØMQ and ICE received higher overall rates in the scoring process. KaTCP and ØMQ were found easier to be integrated with the TANGO layer. TANGO, ICE and ZeroMQ middlewares latency scaling curves were found comparable and allow to fulfil the most

stringent performance requirement. KaTCP significantly deviated from the other middlewares, particularly above few MB transferred. The reason of such discrepancy requires further investigation.

Other technologies are currently under investigation, particularly those related to GUI development and continuous integration. Outcomes of the evaluation will be reported in a future project update.

SUMMARY

The SKA project has recently entered pre-construction phase II. LMC is expected to report a detailed design review of the dish control system. This stage will include definition of commands, monitoring points, state/status for each dish sub-element, consolidation of internal and external interfaces, refinement of the architecture and downselection of technologies to be employed. Development of some of the software components is also foreseen.

ACKNOWLEDGMENT

The author thanks the System Engineering (SE) team of Dish Consortium for their efforts and support in the dish interface modelling.

STATUS OF THE EPICS-BASED CONTROL AND INTERLOCK SYSTEM OF THE BELLE II PXD

M. Ritzert*, Heidelberg University, Germany[†]

Abstract

The Belle II e+e- collider experiment at KEK (Tsukuba, Japan) will include a new pixelated detector (PXD) based on DEPFET technology, providing the two innermost layers around the beam pipe. This detector requires a complex control and readout infrastructure consisting of several on-sensor ASICs and remote FPGA boards. We present the architecture and EPICS-based implementation of the control, alarm, and interlock systems and their interconnectivity to other legacy/heterogeneous subsystems. The interface to the NSM2-based Belle II run-control to orchestrate the PXD startup sequence is also presented. An installation of CSS is used to implement the user interface. The alarm system uses CSS/BEAST, and is designed to robustly minimize spurious alarms. The interlock system consists of two main parts: a hardware-based system that triggers on adverse environmental (temperature, humidity, radiation) conditions, and a software-based system. Strict monitoring including the use of heartbeats ensures permanent protection and fast reaction times. Especially the power supply system is permanently monitored for malfunctions, and all user inputs are verified before they are sent to the hardware. The control system is embedded into a larger slow-control landscape that also incorporates archiving, logging, and reporting in a uniform workflow for the ease of daily operation.

CONTROL SYSTEM

The PXD control system is built on the control framework EPICS¹, which is widely used in high energy physics systems. The Eclipse-based suite Control System Studio (CSS)² is being used as the operator interface framework.

The EPICS system will be deployed in a dedicated physical network segment only accessible via a gateway using the Channel Access (CA) protocol [1] for load reduction on the EPICS Input/Output Controllers (IOCs)³ and access logging. Access control lists (ACLs) enforced within the IOCs will be used to implement various access levels (read only, user, administrator).

In order to achieve a consistent view on operating conditions during the experimental run and for analysis after a failure, a major amount of identified key values have to be recorded and archived centrally in a database. This is to ensure that in normal as well as abnormal situations a consistent and synchronized view on the data and whole system is possible.

The system will be deployed on x86_64 servers running Scientific Linux as the operating system. To allow for fast, repeatable installation and controlled updates, the required software is packaged as RPMs.

The following list details major devices of the system and their means of control via EPICS:

- The data handling engine (DHE) [2, 3] receives the global trigger and timing signals and distributes them to the sensors. The internal FPGAs connect to the outside world via the IPbus protocol. IPbus is based on UDP/IP and can be implemented purely in HDL. An IOC implementing the IPbus protocol in the DHE-specific way has been written.
- The actual DEPFET detectors are controlled and read out via a number of ASICs that are accessible via JTAG from the DHE. The IOC for the DHE and the firmware running on the DHE include code to access the JTAG chain. Actual commands are again transmitted to the DHE via IPbus.
- The power supplies communicate with the control PC via the CHROMOSOME protocol, a fault-tolerant middleware [4] that also includes a heartbeat to quickly detect a lost connection on both sides. Another custom IOC has been written to interface these devices.
- The online selector nodes (ONSEN) receive tracking information from other subdetectors via the data concentrator (DATCON) and high level trigger (HLT) and uses it to filter out events not in proximity to a projected particle crossing in the PXD. The ONSSEN devices are controlled with an IOC running on the embedded Power PC in the FPGA via a memory mapped interface.
- The ATCA and µTCA crates housing the ONSSEN, DHH and DATCON systems are accessible via IPMI.
- Belle II run control communicates via the NSM2 protocol developed at KEK [5, 6]. A bidirectional gateway also developed at KEK is used to interface with the EPICS world.
- The environmental conditions inside the detector volume are monitored via Bragg grating fibres read out with an optical interrogator from Micron Optics. An IOC that reads data from the device at high frequency (several 100 Hz) is under development. The data will be made available to EPICS either as a single data points down-sampled from the raw device rate, or put through an FFT transformation to obtain a frequency spectrum, which is then available as a waveform record. The latter mode is especially useful to analyze the minute movements of the detector.
- The actual slow control of the IBBelle CO₂ cooling plant is implemented in a PLC located within the plant itself. The Modbus protocol is used to monitor its

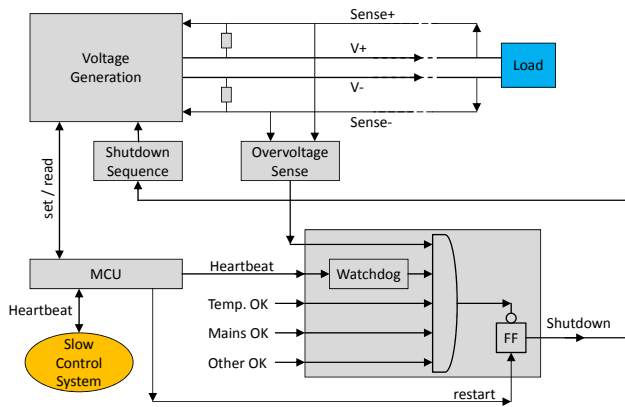

Figure 1: Protection system of the power supplies. All items in gray are inside the power supply.

operation, set the desired operating point, and provide expert access.

A common naming scheme for all PVs ensures that users can quickly decode the meaning of a PV name in any context.

ALARMS AND INTERLOCKS

The Best Ever Alarm System Toolkit (BEAST) [7] integrated into a custom build of CSS is used to visualize the alarms for the operators.

Two alarm levels, major and minor, are defined as “(part of the) detector in-operational, or immediate danger to the detector” and “take action to avoid a major alarm” respectively. A major alarm will typically cancel the current run. Many major alarms also trigger an interlock.

Several soft-interlocks have been applied in order to ensure immediate action during detected potentially dangerous conditions or malfunctions, or to prevent these situations from arising in the first place. Software interlocks are accompanied by hard-wired interlocks that are in any case the last-resort to prevent hardware damages.

Power Supplies

As the only supplier of power into the detector volume, positive control of the power supply (PS) system at all times is of utmost priority. The PS unit is controlled by an internal microcontroller (MCU). To allow for immediate, automatic reaction in case of problems, a sophisticated interlock system is implemented, as shown in Fig. 1. It can command an automatic shutdown of all voltages the power supply provides to the detector. A number of conditions are monitored to compute the shutdown signal. Besides the over-voltage protection and monitors for the mains input voltage and internal temperature of the power supply, a watchdog IC for analog regulators triggers a shutdown when the MCU fails to send a proper heartbeat signal for any reason. An analog principle is used between the MCU and the control IOC. Here, a periodic heartbeat signal is part of the CHROMOSOME protocol. Together, both heartbeats ensure that the output of the power supply can only be enabled when the MCU is operational, and the slow control system is connected. In the

Table 1: Alarm Conditions in the Power Supply System

Enabled	Set V	Actual V	Mode	State
no	1.8 V	0.0 V	CV	OK
no	1.8 V	1.8 V	CV	OV
yes	1.8 V	1.5 V	CV	UV
yes	1.8 V	1.5 V	CC	OC
yes	1.0 V → 1.8 V	1.5 V	CV	OK
yes	1.8 V	2.0 V	CV	OV
yes	1.8 V	1.8 V	CV	OK

IOC, a single PV to shut down all connected power supplies is provided. It is accessible as an “emergency shutdown” button from all power supply- related operator screens, or from other IOCs that implement additional interlock functionalities.

Any emergency shutdown triggers an orderly shutdown sequence that operates independently from the MCU by means of adjustable RC delays. It ensures that the various voltages for the system are brought down in a safe order. In the case of mains failure, a large capacitor provides enough power to complete the shutdown sequence.

Input Validation

All data requests (especially voltage and current set points) towards the power supplies are validated before being sent to the devices. Beyond hard limits set in the corresponding EPICS records, dynamic limits depending on other settings are considered. Typically, this includes a maximum allowed difference between a pair of voltages, or current limits based on the state of the system.

The verification is done purely inside the EPICS database. An example set of PVs implementing the functionality is shown in Fig. 2. In this figure the requested value in (#3) is validated by a dedicated calcout record (#4), which filters malicious values before they reach the ao record (#5) of the device driver. An alarm is triggered and stored in a bo record (#7) if the requested and set values do not match. Note that the behavior is different to just using DRVH and DRVL in the ao record (#5), as invalid values are not clipped to the maximum/minimum allowed, but completely ignored. Additional logic in the record (#2) resets the channel to idle (i.e. 0 V) when the emergency shutdown of the PS has been triggered as recorded in record (#1). A similar but slightly more complex logic is used to introduce dependencies between different values.

Access control lists are used to ensure that the actual set record (#5) is not accessible from outside the IOC, so that the verification cannot be bypassed. Access to the PVs defining the conditions is limited to experts’ accounts.

Readback Monitoring

The provided voltages of the PS are monitored by both the PS itself, and by the external SC system. The EPICS database structure used to implement the monitoring is shown in Fig. 3 and explained in the following: First, the

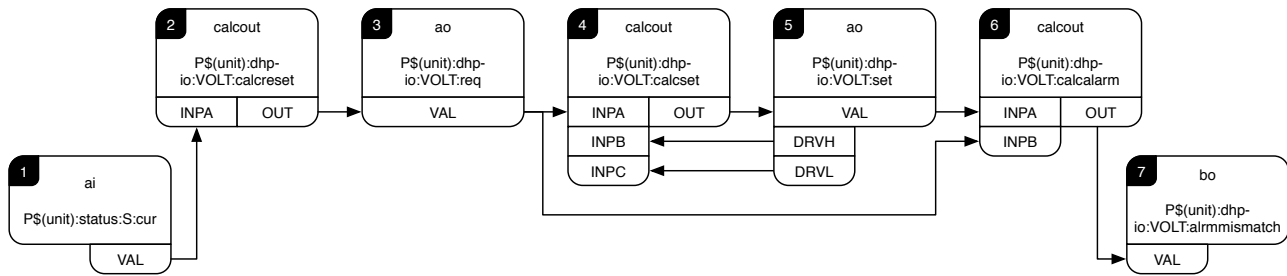

Figure 2: The EPICS database structure implemented to validate input values.

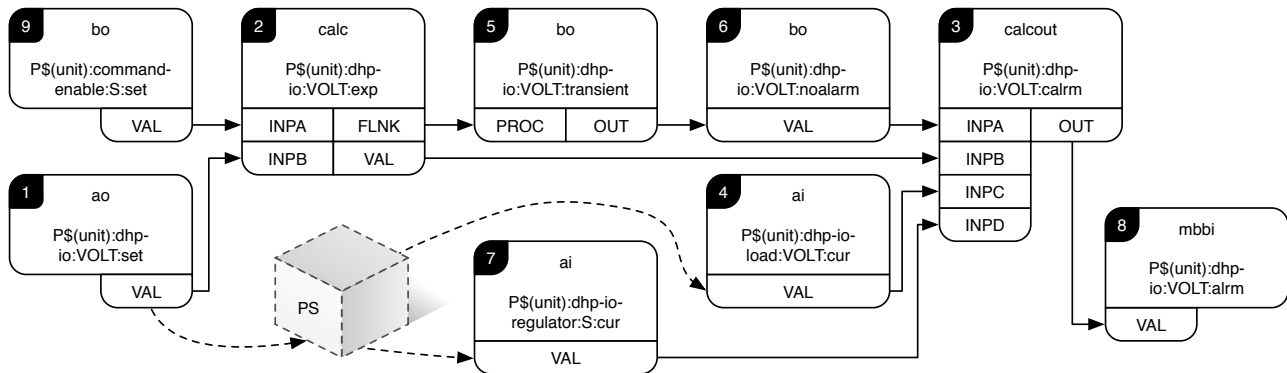

Figure 3: The EPICS database structure implemented to detect error states in the power supply system.

expected voltage at the load (record #2) is computed. It corresponds to the voltage requested by the user (#1), if the PS is enabled, or to 0V otherwise (#9). The (#3) record compares it to the actual voltage (#4), which is read back from the PS device. To avoid spurious alarms during voltage ramping steps, the alarm is suppressed for one second in case of the expected voltage changes. To that end, the bo records (#5) with OMSL closed_loop and (#6) with HIGH 1.0 are used to form a PV that is "on" for one second after a change in record (#2). The signal of this record is then considered in the logic for raising an alarm in case of a voltage mismatch. Also considered is the current regulator state (constant current vs. constant voltage) of the channel available in the record (#7). The effect of the implemented logic for a channel that is supposed to provide a fixed voltage is shown in Table 1. The detected states are OK (no alarm), OV (over-voltage), UV (under-voltage), and OC (over-current). All comparisons take the precision of the voltage readback into account by accepting readback data as matching within a sufficiently wide range around the desired value. Finally, the state is pushed into an mbbi record (#8), where mnemonic names are assigned to the states. This is the record whose state is shown in the GUI.

Radiation Monitoring

The PXD, as the innermost detector of Belle II, is most at risk to receive dangerous doses of radiation. Therefore a set of several radiation monitors are positioned at locations of expected high doses that have been identified from simulations and subsequently used to monitor the actual dose rate at all times. The monitors are controlled via a PLC that

also computes interlock conditions on fast, extremely high rates, and slower but still higher than normal rates. In case of dangerous conditions, an immediate dump of the beams is requested from the SuperKEKB accelerator via a dedicated hard-wired line of communication.

The Modbus protocol is used to communicate with the PLC from the EPICS network. It is used to configure the interlock conditions, and to monitor the rates for display and archiving purposes.

CONFIGURATION DATABASE

The system configuration required to start a run is stored in a configuration database. An XML-like tree structure of configuration variables is efficiently stored in an SQL (currently PostgreSQL is used) database using a wandering tree algorithm to implement revision control system like functionalities. This way several files with multiple revisions per file can be stored in the database, and each entry can be queried for its history (change author, date and commit text). On run start, the desired run type category is used to identify the desired configuration.

The configuration data are made available to the system by means of an IOC that reads the configuration from the database and exports the configured PVs in the EPICS network.

The storage itself is tamper proof: After a commit, a revision cannot be modified in any way, it can only be superseded by a new revision. This is enforced by access controls on the database level and ensures that the active configuration at any point in time can positively be identified only from the configuration id in use at that time.

RUN CONTROL

The run control of the PXD is implemented in a hierarchical way. The desired run state is set either by the user for PXD-only test runs, or received from the Belle II master run control. It is forwarded to all PXD subsystems, which can decide to participate in the automatic run control, or be left out of it for the current run. A new state is only considered as reached, when all dependent subsystems confirm it. The actions during the state transitions are implemented using the sequencer module for EPICS⁴.

The most complex part controls the ASICs on the detector modules and the PS. About 100 steps are required to bring up the digital power for the ASICs, configure them, and finally enable the analog power to the detector. Sanity checks throughout the sequence ensure that the sequence completes successfully. The state machine code is simplified by means of the C preprocessor. After converting it with `snc`, the code is compiled in C++ mode.

On a larger scale, the Belle II detector overall implements its run control and power supply control using the Network Shared Memory system version 2 (NSM2). A bidirectional gateway between NSM2 and EPICS is used to establish the communication.

LOGGING INTEGRATION

A C++ logging library that can interface with JMS2RDB, a connector layer between the Java Message Service and Relational Databases, which is also used for log messages from CSS components, has been written. It forwards log messages to an ActiveMQ server via the STOMP protocol⁵ that is converted by ActiveMQ to be understood by JMS2RDB. IOCs can use this library to implement their own logging. This allows for all messages from the entire system to be combined in the “Message History” view in CSS.

Besides the STOMP implementation, the library features a thread-safe and fast design, and automatic generation of a backtrace in case the application crashes. For the application thread, posting a log message is always $O(1)$, because the message is only put in a queue to be processed by another thread. The implementation is integrated into EPICS in the sense that a DBD file is provided that, when loaded, provides commands on the IOC level that allow the dynamic configuration of logging destinations, changes of the log levels per subsystem or destination, etc. Adjusting log levels via PVs is planned for the next release.

IMPLEMENTATION STATUS AND OUTLOOK

The development of the SC system for the PXD is progressing from the stage where all components are controlled

independently from their respective developers to a more integrated mode of operation. Tests and measurements with several systems in use together are now common and working smoothly.

The next milestone is a test beam with all system components early 2016, when all components of the SC system are expected to be ready. During the commissioning phase of the accelerator, a partial PXD system, installed in the Belle II detector on the beam line, and the final detector in the assembly room have to be supported at the same time. A full setup of the slow control system will be used for both purposes. The hardware used in these setups will be combined for the final installation, so that two parts of each component are available to build a redundant system using pacemaker/drbd that offers the high-availability required in HEP experiment controls.

ACTIVE MAGNETIC BEARINGS SYSTEM UPGRADE FOR LHC CRYOGENIC COLD COMPRESSOR, RADIATIONS MITIGATION PROJECT (R2E)

P. Arpaia, University of Napoli Federico II, Naples, Italy; CERN, Geneva, Switzerland

M. Girone, University of Sannio, Benevento, Italy; CERN, Geneva, Switzerland

M. Hubatka, MECOS AG, Winterthur, Switzerland

M. Pezzetti, CERN, Geneva, Switzerland

Abstract

During the normal operations of the Large Hadron Collider (LHC), the high hadrons flux level induced several Single Event Errors (failure caused by a particle passing through a sensitive device) to the standard electronics installed underground. Such events perturbed LHC normal operation. As a consequence, a mitigation plan to minimise radiation-induced failures and optimise LHC operation was started: Radiation to Electronics (R2E) mitigation project. The full paper will deal with the mitigation problem for LHC/Point 8 equipment and the main improvements for the equipment in LHC/Point 4, with special focus on the controllers for the Active Magnetic Bearings (AMB) used in the IHI-LINDE cold compressors. A proven approach based on frequency response analysis to assess the cold compressor mechanical quality will be presented. The hardware and software design, implemented to increase the global reliability of the system, will be highlighted. A corresponding experiment protocol was developed at CERN in collaboration with the Swiss Company MECOS and the Italian Universities of Sannio and Napoli Federico II. Preliminary experimental results showing the performance of the proposed approach on a case study for the cold compressor stage 1 in Point 4 will be finally reported.

INTRODUCTION

The level of the flux of hadrons with energy in the multi MeV range expected from the collisions at the interaction Points 4 and 8, which are not in the center on the cavern, unlike Point 1,2 or 5, (Fig. 1) will induce Single Event Errors (SEEs) in the standard electronics present in much of the control equipment. Furthermore, a risk of SEEs induced by thermal neutrons cannot be excluded. In the long-term, such events could perturb the LHC operation, possibly leading to critical situations for the machine elements and subsequent important downtime [1].

In particular this paper is focused on the impact on the electronics of MECOS Active Magnetic Bearing controllers. The high-performance bearing are applied in the LHC cryogenic cold compressor equipment in order to satisfy the need of covering vibration, stability and robustness in nominal operation and transition phases. In fact, magnetic bearing-equipped machines are suitable for unlimited, reliable and safe operation even in the presence

of “large” residual unbalance levels [2]. Those high performances requires deeper user understanding of the magnetic bearing technology and a commissioned system cannot be modify so easily. The R2E Mitigation Project foresees shielding or relocating the equipment sensitive to radiation, which is presently installed in these critical areas, into safer areas. The majority of these mitigation activities were performed, in three phases, between (date) in Point 4 and between (date) in point 8. This document reports on these mitigation activities and their associated improvements. It presents the strategy applied, the enhancements on the modification for the new version of AMB used in the IHI-LINDE cold compressors which were needed to be replaced within a longer distance (from 20 m to 45 m).

STRATEGY APPLIED

The first LHC run took place from 2010 to 2013, on 14th February 2013 the Long Shutdown 1 (LS1) started. During the LS1 preventive maintenance, upgrade and necessary repairs were performed.

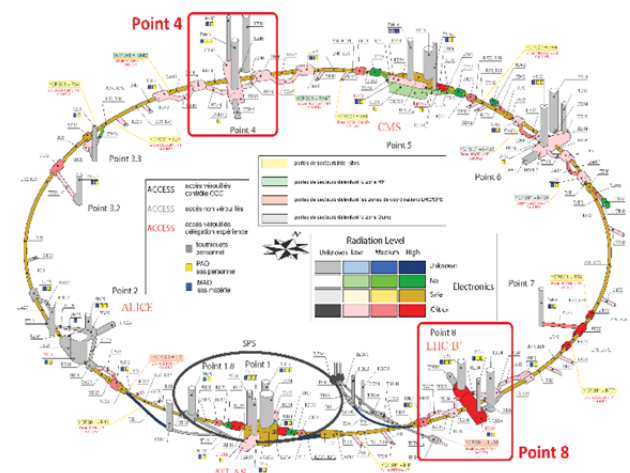

Figure 1: LHC critical areas considered by the R2E Mitigation Project.

A project called Radiation to Electronics (R2E) has been created in 2009 to mitigate the risk of failures due to single events upset (SEU) of the equipment installed in the tunnel and shielded areas. In 2011-2012, due to beam parameters increasing, SEUs had a significant

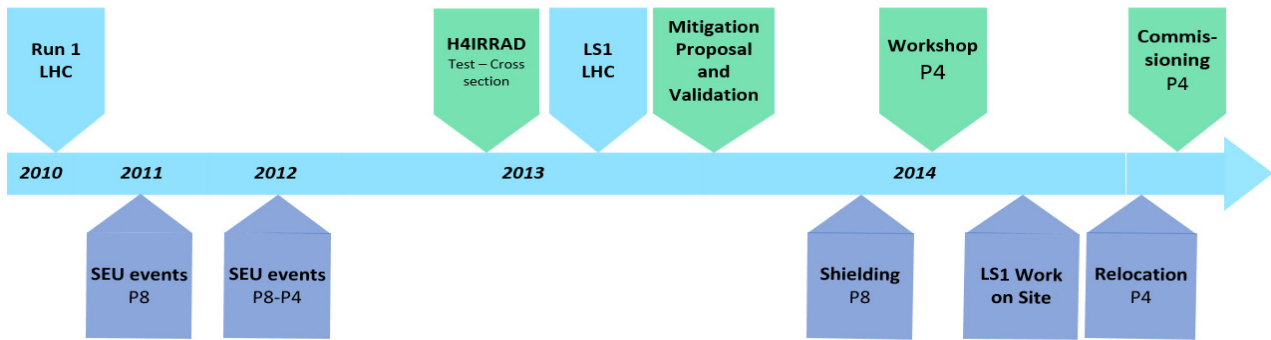

Figure 2: Actions strategy timeline.

impact in P8 and P4. These events caused several equipment failures. On October 2012, in order to determine the failure cross-section due to radiation of specific bulk equipment, a new test area was setup in the H4-beamline of the North Area: H4IRRAD. In this area several tests were conducted and they proved that industrial or commercial equipment are not qualified for radiation and they had to be removed from exposed areas. As a consequence the sensitive equipment located in these areas was relocated to safer areas and protected by new shielding walls (for P8). These mitigation activities were performed mainly during the LS1. Even though the commissioning had very tight constraints it was successfully accomplished.

AMB R&D

In this section, the enhancements on the controlling system for the Active Magnetic Bearings (AMB) used in the IHI-LINDE cold compressors are presented. All the hardware and software improvements were first tested in the CERN control and electricity laboratory, and after several validation tests were implemented in the cold compressor systems in LHC/Point 4. The hardware and the software improvements will be first discussed. At the end the proposed fault detection protocol for the cold compressors will be presented.

Hardware Improvements

Before the installation in the LHC cavern in P4, several tests and measurements on IHI-LINDE spare cold compressors systems (CCS) were performed together with MECOS Company.

Due to the electrical cabinets' relocation, as previously described for R2E project, longer cables (from 20 to 45 m) to connect the cold compressors and the magnetic bearings controllers were needed. Thanks to this project the cabling know-how has been transferred to CERN and the new cables were produced in situ and improved.

In Fig.3 an active magnetic bearing system architecture is schematized and it is possible to notice that two different type of cables are needed for an AMB control system: a cable for position sensors (blue arrow) and another cable (red arrow) for the levitation magnets (actuators).

Figure 3: Active magnetic bearing system architecture.

Major attentions were put on sensors cables, because all the processor calculations are based on the position sensors measurements, and high noise levels could lead to system instabilities. In Fig.4.b a section of the existing sensors cable is showed.

Figure 4: a) New sensors cables; b) Old sensors cables section.

A different configuration was adopted, and in particular, the following cables were chosen (Fig.4.a): IGUS Chainflex CF12 TPE-14 x 2 x 0.5. In these cables the wirings are twisted per pairs and they have a double shield: one shield per pair and a global shield for the entire cable.

In Fig.5.a and 5.b, position sensor test measurements, performed in CERN control and electricity laboratory, are showed. The measurements were carried out with the old controller (MBC150) and with the old and the new cable respectively, both 20 m long.

It is possible to notice that the overall noise level, with the new cable, is decreased. After these encouraging results, several measurements were performed on the new

cables and in particular several lengths were tested: from 25 up to 60 m.

The power supply cables for actuators were also changed (CERN NG18-9 x 2 x 1.0) but no tests were performed on

Figure 5: a) Position measurement with the old cable; b) with the new cable.

them because, as mentioned, they are not as critical as the sensors cables for compressors controls.

Together with the new cables, new connectors (Amphenol MS4102E), for power supply and sensors, were installed on both the cables extremities and on the new MECOS controller to improve the connections robustness.

Several hardware modifications were also implemented inside the AMB controller (MBC-170A). The internal power supply was removed in order to enhance the system reliability. Instead of 4 different power supplies, one per unit, CERN adopted a redundant system: the 4 controllers were supplied by two independent electrical power systems circuits.

In more, the previous MBC generation needed two different software configurations for the four stages: one type could be used only for stage 1-2 and another type for stage 3-4. CERN, together with MECOS, decided to implement the same configurations for all the controllers, thus helping reduce the down-time of the LHC machine by simplifying the maintenance procedure. Moreover it improves the handling of the spare parts by reducing the number of controllers to be kept in stock.

Software Improvements

Together with the hardware enhancements, some software modifications were implemented in the supervision and control system for the cold compressors system in P4.

In case of cold compressors failures, on electrical/electronic or mechanical equipment, the entire 1.8 K cold box, and consequently the entire LHC machine is stopped. To restart the system an operator was required to go to the caver and reset the system manually in the electrical cabinet. In order to reduce the operation time a remote controller RESET was implemented on MBC-170A. Thanks to that the operators in P4 cryogenics control room can easily restart the entire cold box.

Together with the remote RESET, a monitoring interface, integrated in the LHC supervision and control panels, was implemented. In particular the axial rotor position and the radial bearings unbalance levels are monitored. The operators, monitoring the abovementioned trends, can avoid potential failures in a reactive manner.

Another enhancement, aimed to facilitate the control and the supervision system is the implementation of a customized analog output (4-20 mA) to monitor the compressor rotational speed. The maximum current (20 mA) is set according to the maximum compressor speed: 240, 500, 833, and 833 Hz respectively for compressor stages from 1 to 4.

In conclusion, a different control strategy on cold compressor stage 1 (CCS1) was adopted. All the cold compressors installed in the 1.8 K cold boxes are controlled with a SISO type controllers (Fig. 6.a [2]).

Figure 6: a) AMB controller architecture SISO; b) Parallel/conical modes control.

Due to the CCS1 intrinsic physical properties (higher gyroscopic effects due to impeller dimensions, first bending modes close to nominal operational frequency), during the controller parametrization, some difficulties in tuning the different SISO controllers independently were found. For this reason a MIMO strategy was applied (Fig. 6.b [2]). Such a controller, controls the *parallel* (centre of gravity motion on x and y planes) and *conical* (centre of gravity tilting motion on α and β angles) modes.

Cold Compressors Fault Detection

To evaluate the cold compressor mechanical quality a proven technique based on frequency response function analysis (FRF) has been used. A corresponding

experiment protocol was developed at CERN in collaboration with the Swiss Company MECOS and the Italian Universities of Sannio and Napoli Federico II. The proposed method will allow, during the LHC ordinary maintenance stops, to evaluate the mechanical quality of the cold compressors through a proactive fault detection.

Thanks to the nature of the active magnetic bearings, the system FRF $H = Y/X$ can be measured without additional sensors or measurement devices (Fig.7).

Figure 7: Measurement system architecture.

In particular, the system outputs Y are the rotor position measurements, while the inputs X are the sum of the controller signals (X') and an excitation signal X_0 . In Fig.8 a FRF measurement for CCS1, performed in the lab, with the impeller in a vacuum case and in standstill conditions, is reported.

Figure 8: Cold compressor system 1 frequency response function.

During the P4 commissioning phase, FRF measurements were performed on all the cold box stages for both the installations: QURCA and QURCB. In particular, several test campaigns were conducted: a first measurements campaign was conducted for fixed rotational speeds (15, 22, 35 and 45 Hz for CCS1 to CCS4 respectively) at 300 K. Consequently, other measurements were conducted with the same rotational speeds but with the helium temperature was equal to 30 K. Finally a last test campaign was conducted on QURCB speeding up the compressors up to their nominal speed: 240, 500, 833, and 833 Hz respectively for compressors stages from 1 to 4.

During the first two measurements campaign on QURCA, a strange behaviour on CCS1 was detected. A special focus was addressed to the first resonance

frequency peaks because from 300 to 30 K, they moved to lower frequencies (Fig.9).

Since the rotor is considered as rigid body, for lower temperatures, and especially for such a temperature gradient, the peaks were expected to move to higher frequencies. In more the CCS1 FRF presented some unexpected peaks at low frequencies, as it is possible to notice in Fig.9. Based on that, the compressor was replaced and sent back to the manufacturer.

Figure 9: CCS1 installed in P4: frequency response function at 300 K—blue— and 30 K—red—.

The IHI-LINDE confirmed that some mechanical small problems were present. The same test campaign at 300 and 30 K was then performed on the new compressor (Fig.10). As it is possible to notice the behaviour is completely different from the previous compressor.

Figure 10: New CCS1 installed in P4: frequency response function at 300 K—blue— and 30 K—red—.

Thanks to this technique, in a preventive way, a mechanical compressor fault was detected and consequently a potential breakdown was avoided.

CONCLUSION

The work described has enhanced a deep knowledge of the cold compressor process control equipment. Moreover a new improved preventive maintenance plan has been set up based on the cold compressors mechanical quality evaluated by on-line measurement (done through AMB) compared with old one.

Abstract

The Alba Controls Section (ACS) develops and operates a diverse variety of controls software which is shared within international communities of users and developers. This includes: generic frameworks like Sardana [1] and Taurus [2], numerous Tango [3] device servers and applications where, among others, we can find PyAlarm [4] and Panic [5], and specific experiment procedures and hardware controllers. A study has commenced on how to improve the delivery process of our software from the hands of developers to laboratories, by making this process more reliable, predictable and risk-controlled. Automated unit and acceptance tests combined with continuous integration, have been introduced, providing valuable and fast feedback to the developers. In order to renew and automate our legacy packaging and deployment system we have evaluated modern alternatives. The above practices were brought together into a design of the continuous delivery pipelines which were validated on a set of diverse software. This paper presents this study, its results and a proposal of the cost-effective implementation.

INTRODUCTION

The ACS designed, constructed and maintain the control systems required to run the facility. The core software components of the Alba control systems, like for example Tango – the middleware framework for building distributed control systems, Sardana – the scientific SCADA oriented to the experiment control and Taurus – the GUI library, are fruits of a collaborative effort of many institutes including Alba [6]. Peripheral components, like Tango device servers, Sardana controllers and macros or Taurus GUIs were either developed in-house or reused from the public repositories. Most of them are developed in Python.

Previously, the software development processes were mainly organized around one-person projects that made it difficult to conduct design questioning discussions and limited the knowledge flow. The software testing was neither formalized nor tried to be automated. This made the project transfers between the developers more difficult, for example on a developer leave. Newcomers, without the complete knowledge of the project, could not feel confident when introducing a change in the code without a way of testing it at the unit or at the system level. In some extreme cases this lead to development downtime periods, to abandoned projects or simply to buggy releases. Subversion (SVN) was the standard version control system (VCS) which did not encourage

working branch-per-feature mode. Untraceable commit histories were not helping to enter into the project dynamics. The software packaging and deployment were done manually what is neither interesting nor motivating for the engineers. All the above problems and difficulties were not helping in reducing the long lead time – from the scientist request to the successful use of the software in the experiment.

DEVELOPERS COLLABORATION

Almost two years ago the ACS decided to introduce changes in the software development organization. The in-house projects were transformed from the individual to the group-based efforts. Furthermore, in the case of the two core and initially ACS's internal projects Sardana and Taurus (started at Alba in the previous decade) community-driven development and organization models were introduced. This had an impact on the following parts of the software development process.

Code Design

Internally, developers were organized in groups of 4-6 members – the *Scrum* teams [7]. A mixture of senior and junior developers were selected to build each team. The knowledge transfer activities became a second plan and continuous process. Information about the projects, previously restricted to the privileged project owners, quickly equalized among the team. Agile design practices were introduced: avoidance of upfront designs and plans and promotion of iterative and incremental developments. The Scrum activities brought many interesting design discussions that helped to achieve a better quality of the released products.

In parallel, the Sardana and Taurus project development and decision-taking was opened to a community composed mainly by synchrotrons similar to Alba (DESY in Germany, MaxIV in Sweden Solaris in Poland and ESRF in France), as well as by other institutions, companies and individuals (mostly within the Tango collaboration) who are basing their own developments in them. All these entities actively participate in the community activities. The community model requires remote collaboration tools. Sardana and Taurus are hosted on the Souceforge [8] platform and use a number of provided tools (e.g. issue tracker, mailing lists, wikis, etc.) in the code design processes. Discussions about the critical improvements and modifications are organized and formalized around public processes called Sardana Enhancement Proposal (SEP) and Taurus Enhancement

Proposal (TEP) inspired in similar workflows from the Python [9] and Debian [10] projects.

Code Control

Since many developers started contributing to the projects the SVN became a limitation in many ways. Other systems were evaluated having the following reasons in mind: easier branching and merging (necessary in scattered organizations like ours) and easier tools and workflows for the code validation. Git won this competition bringing many other benefits such as its distributed architecture, better performance and the possibility of much cleaner history of commits with less effort. Hence Sardana and Taurus projects were migrated from SVN to Git, and the ACS started using Git for the newly created internal projects.

Sardana and Taurus branching rules were formalized according to *gitflow* [11,12] (Fig. 1). Two main branches and the core for the project are: the *develop* branch – where all the developments take place or get integrated into and the *master* branch – which always represents the latest production-ready state of the project. Each commit to the master branch gets tagged following the *semantic version system* (semver) [13] consisting on three dot-separated fields: major, minor and patch (Fig 1.). Increment in the major field indicates backwards incompatible changes in the API. The minor field increments when new functionality is added in a backwards compatible manner. And finally the patch field increments with the backwards compatible bug fixes. Other supporting branches are: the *feature* branches – where development of the SEPs, TEPs or feature requests take place, the *release* branch – the intermediate branch between the develop and the master states as well as the *hotfix* branches where the critical bugs in the master branch are fixed.

Figure 1: Extract from the Taurus git history demonstrating use of gitflow and semver rules.

Code Review

Together with collaborative software development, systematic code review practices were introduced. They rely on examination and validation of the contribution, usually done before checking it into the repository. In the case of the internal projects, lightweight peer reviews had proven to be a great way of improving the quality of code. Apart from that they help to equalize the technical knowledge within the team and reduce the information silos across the developers. The Sardana and Taurus projects apply more formal code reviews. All the code

contributions are evaluated on the public forum but only the integration managers (representatives of each of the community institutes) are allowed to push the code into the canonical repository. The only tools used in this process are just a few git commands and the developers mailing list. Based on the current experience we can affirm that the quality of these projects has improved thanks to the code reviews. At the same time we can observe that the limited time of the integration managers is a bottleneck for patch integration.

TESTING

No testing strategy existed for the software projects developed and maintained by the ACS. SEP5 [11] established the common testing strategy for Sardana and Taurus. The following best practices are based on its results and more than a year experience with software testing.

Tests should be written before developers start work on the features that they test. Together, these tests form an executable specification of the behaviour of the system, and when they pass, they demonstrate that the functionality required by the users has been implemented correctly. The automated test suite should be run by the continuous integration (CI) service every time a change is made to the application – which means that the suite also serves as a set of regression tests. This strategy applies ideally to new projects, where with prior selection of the testing technology and the CI platform, developers could start writing and applying automatic tests in the process right from the beginning. However mid or legacy projects, like for example Sardana and Taurus, require a certain variation of the approach. The best is to start automating the most common, important, and high-value use cases of the application. Based on this selection, “happy path” tests covering these high-value scenarios should be automated. The rest of the scenarios should initially be tested manually. They should be automated only when one discovers that the same function is tested manually more than a couple of times.

Jenkins [14] was selected as the general CI system for the ACS projects mainly because of its big community of users, a broad and continuously growing set of plugins, and simplicity in setting them up and running.

The main purpose of the CI service is to test the software on each commit, providing fast feedback to the developers. Our use of Jenkins was extended to the unique registry of all the software maintained by the group. Hence even the projects which are not actively developed by the group or the external projects have their corresponding Jenkins jobs. These jobs are not triggered at each commit but their role is to automate the build processes and the integration tests with our control system.

CONTINUOUS DOCUMENTATION

Sardana and Taurus projects use Sphinx [15] to create documentation. Sardana and Taurus documentation was originally hosted on the Alba's internet servers. This setup required manual builds and deployments on every update. Mainly due to the work overheads the documentation update frequency gradually decreased to twice per year, concurring with the biannual releases.

The documentation build processes of both projects were adapted to make them independent of specific libraries e.g. PyTango (Python language binding to Tango). This was achieved via a custom Python modules *mock* generator. Finally, both projects migrated their documentation to the Read The Docs (RTD) [16] platform (Fig. 2), bringing the following benefits:

- Documentation gets built on every commit, early validating its correctness and notifying developers about any errors.
- Maintenance of the servers and the necessary software is outsourced to RTD.
- Several versions of the documentation e.g. *stable* or *latest* are available in a unique place.
- The documentation is available in different formats e.g. html, pdf, epub and is easily searchable.

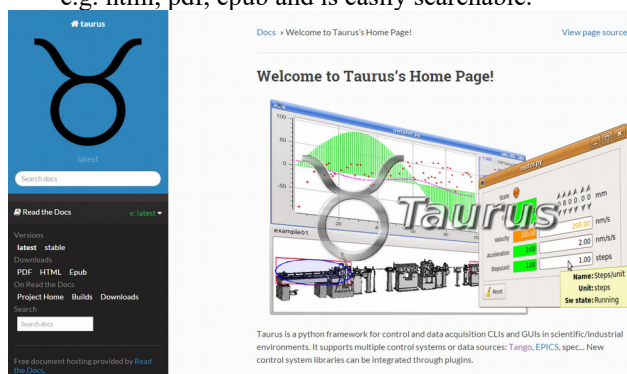

Figure 2: Taurus latest documentation available on RTD.

CONFIGURATION MANAGEMENT

The ACS manages all the software under maintenance with the bliss system [17]. The bliss system, developed by the ESRF, is a rpm-based packaging and Software Configuration Management (SCM) tool. It comprises two applications: the blissbuilder and the blissinstaller, and centralizes information about the packages and the hosts in a mysql database. Its main advantages are: the offline access to hosts' configurations and an intuitive to “non-packaging experts” graphical way of defining and creating packages. While bliss has served very well over its many years of use, it shows limitations when it comes to automatic package creation and deployment. First, all the package definition is spread in the bliss database tables and it is not possible to maintain it in the project code repository. This limits the creation of the project rpm package to the bliss system users only. The automatic package creation is not fully customizable, and requires modification of the package metadata in the database.

However the biggest limitation of bliss comes with the configuration management and the automatic deployments (bliss does not provide a way to configure a group of hosts neither supports the Windows platform). While it seems possible to implement all the missing features in the bliss system (it is written in Python) or develop the complementary scripts, we decided to evaluate alternative public and widely used products.

SCM Tools

Many SCM tools exist, with the most popular choices being Puppet, Chef, Ansible [18] and Salt [19], and all of them are successfully used in many different organizations. In the process of comparison we had in mind the following aspects: precedence was given to free and open source projects, ideally developed in Python – the widest spread programming language in the group. Apart from that the ideal candidate was expected to support both Linux and Windows platforms in the most seamless way possible. Definition of the hosts configuration, and the possibility of applying them to different groups of hosts was also considered as an asset. Finally, the simplicity and the smoother learning curve for the ACS were also considered.

A closer look was given to the two Python based candidates: Salt and Ansible. They give a possibility to use the repository integration modules like the ones for apt, zypper or yum and allow operating system agnostic definitions of the hosts configurations. Salt architecture is based on a single master and distributed minions which exchange messages when necessary. However the use of minions is optional, and Salt could fallback to execute commands via ssh if necessary (a mixture of both solutions in the same system is possible). Ansible and Salt offer very similar features. Salt could eventually bring benefits in the future thanks to its higher scalability and the agent based architecture. In its favour speaks that the Alba IT Systems Section uses Salt for SCM of the High Performance Computing Centre of the Alba Synchrotron.

Packaging

Migration from the bliss system to Salt would eventually require an alternative way of creating software packages. This seems quite simple in case of the Python based projects since the standard packaging modules allow creation of rpm and deb packages for the Linux platform and exe and msi installers for the Windows platform. Sardana and Taurus already use distutils [20], and as a proof of concept creation of the rpm packages was successfully tested. In case of the Windows platform the msi format proved to be a better choice than the exe, since it allows the unattended installations necessary by the SCM. The migration from bliss would also require setting up package repositories where the packages would be uploaded and from where the SCM tool would pull the packages for installation.

CONTINUOUS DELIVERY

Agile software development together with the continuous delivery aims to transform a concept into working software as fast as possible. Continuous delivery is based on fully automated, reliable, repeatable and constantly improving software delivery pipelines. Each change in the project code should trigger the pipeline execution and in case of success deliver a deployment-ready product. The negative result of an intermediate pipeline stage must break the pipeline execution and be immediately reported to developers who should stop the current work and fix the breaking change. Each project actively developed by the ACS could have its continuous delivery pipeline, initially comprising three stages: commit, acceptance and user acceptance. These stages should be executed sequentially only if the previous stage ended successfully. Each stage could be divided into parallel run jobs if necessary.

Based on the experimental implementation of the pipelines for Taurus (Fig. 3) and Sardana the following tools and setups are recommended. Jenkins works as the pipeline orchestrator where each job represents one pipeline stage. Jobs are interconnected and trigger the downstream jobs while the pipeline advances.

Figure 3: A proof-of-concept continuous delivery pipeline of Taurus project.

The commit stage is triggered on each change in the VCS. The commit stage should run the unit tests of the project and execute the static code analysis and in case of success build the software packages. Finally, all the packages get uploaded to the repository. It is very important that from now on, all the subsequent stages always use the same package created in the commit stage.

The acceptance test stage should take place in an environment as similar to production as possible. This stage should start from the package deployment to the acceptance test environment using the SCM, as it would be deployed to production. If the software works in production on various platforms e.g. Windows and Linux, the acceptance tests should also be performed on all of them. Finally the automated acceptance tests should be executed. The acceptance tests may require a specific configuration (also maintained under the VCS) which should be applied to the acceptance test environment

before the tests execution. Preparation and maintenance of the acceptance test environments may be a tedious and error prone job. Execution of the acceptance tests in the Docker [21] containers showed to be a great solution to these problems. Docker is a platform for developing, shipping, and running applications using the container virtualization technology. The idea behind it is to maintain the Docker images for each of the acceptance test environments and spin them up on demand of the pipeline execution. This solution provides lightweight, reliable and isolated testing environments occupying the resources only when needed. Docker integrates well with Jenkins via plugins and one of them allows to seamlessly use Docker containers as the Jenkins slave nodes.
