The FEL facility in Hamburg, FLASH, at DESY is operated since 2005 as a user facility in SASE mode [1]. Since 2010, an experimental setup for seeding developments has been installed prior to the main SASE undulator of the FLASH1 [12]. At this setup, the direct HHG seeding at 38 nm was demonstrated in 2012 [13]. A limited contrast ratio as well as the fact that the hit rate of the external pulses with the electron bunches was dominated by the relative arrival time variations, which were in the order of the pulse durations, lead to the decision to set the focus of the seeding R&D at FLASH on HGHG and EEHG seeding [14, 15]. Other facilities have demonstrated self-seeding for photon energies above 700 eV [16, 17] and HGHG seeding for wavelength between 4 nm and 80 nm [18]. The EEHG principle has been demonstrated for wavelength down to ≈170 nm [19]. In the following, we will describe the current status of the FEL seeding developments at DESY.

EXPERIMENTAL SETUP

The Seeding Section in FLASH1

Figure 1 shows a schematic layout of the FLASH1 FEL beamline. An overview of the entire FLASH facility can be found in [20]. After the energy collimator, the seeding section starts with two short electro-magnetic wigglers (labeled MOD1 and MOD2) with 5 full periods [21] each followed by a magnetic chicane C1 and C2. Four variable-gap undulators with an effective length of 10 m act as the FEL radiators. The FEL pulses are guided to a photon diagnostics section using a mirror system. The chicane C3 steers the electron beam around the extraction mirrors. The following transverse deflecting structure (TDS) and a dispersive dump section allows to diagnose the longitudinal phase space distribution of the electron bunches.

The Seed Laser

The 266-nm seed pulses are generated by third-harmonic generation (THG) of near-infrared (NIR) Ti:sapphire laser pulses. The UV pulse energy at the interaction region with the electron bunch can be set up to 280 μJ, the Rayleigh length is about 1.4 m. The longitudinal position of the beam waist can be adjusted by changing the NIR focusing into the THG setup. To relax the tolerance of the transverse laser-electron overlap, the waist has been set about 1 m after the end of undulator MOD2. The seed beam position and size is measured before and after MOD2 using fluorescence screens.

Abstract

High quality magnets were designed, fabricated and installed in the Taiwan Photon Source (TPS). The lattice of the storage ring (SR) is based on a double-bend achromat (DBA) structure with an emittance 1.6 nm-rad and a small dispersion in the straight sections. A concentric booster ring (BR) is designed and constructed to share the same tunnel with the SR. The first synchrotron light from the TPS storage ring at 3 GeV was observed on Dec. 31, 2014. This accomplishment indicated that the precision of the profile and the field quality of the magnets as well as the alignment of the girders attained world class. The integral multipole components of the SR-quadrupole and SR-sextupole magnets conform to strict specifications. The maximum offset of the measured mechanical center in the magnets is better than ±0.01 mm after feet-shim. The offset of the magnetic center of the magnets is better than ±0.02 mm, as inspected with a rotating-coil method. The field quality of the BR-dipole and BR-quadrupole magnets were within design errors and proved in the beam commissioning. A study of relative permeability of the vacuum chamber was implemented during testing of the hardware of the booster ring. The magnetic field was distorted by the nonentity relative permeability of the vacuum pipes. This field distortion caused by the vacuum pipe is discussed in this paper.

INTRODUCTION

The Taiwan Photon Source (TPS) is a third-generation synchrotron light source, constructed at the National Synchrotron Radiation Research Center (NSRRC). To accommodate the constraints of the existing building, the magnets of the storage ring (SR) and the booster ring (BR) are constructed in the same tunnel, forming a concentric arrangement. The SR and the BR are composed of 48 SR-dipoles, 240 SR-quadrupoles, 168 SR-sextupoles, 54 BR-dipoles, 84 BR-quadrupoles and 24 BR-sextupole magnets. Buckley System Ltd. (New Zealand) was awarded the main contract to provide 641 magnets for the SR and the BR; Danfysik A/S (Denmark) constructed 255 magnets for transfer lines and corrector magnets. The preliminary magnetic design and engineering of the magnet system began in 2005 [1-3]; the TPS project was approved in 2007. A one-section prototype including 23 magnets was fabricated in 2011. The mass production of magnets was begun in 2012. In total, 641 magnets of the SR and BR were delivered by Oct. 2013. The hardware installation and integration of the accelerator including magnets, vacuum chambers, girders and diagnostic tools completed in mid-August, 2014. The system integration and improvement were completed on Dec. 12, 2014. The first synchrotron light at 3 GeV was observed with no correction applied on Dec. 31, 2014. The design, fabrication and correction of TPS magnets are presented in reports [2, 4-5].

MECHANICAL ERROR AND QUALITY OF THE MAGNETIC FIELD

The precise pole profile of a magnet is manufactured by either a Computer Numerical Control Machine (CNC) or a Wire Electrical Discharge Machine (WEDM). The SR-dipole and long SR-quadrupole magnets are machined with a CNC Machine because of the long yoke length; other magnets are machined by WEDM. Figures 1(a), (b), (c) and (d) display the sketches and labels of pole profile for SR-dipole, BR-dipole, SR-quadrupole and SR-sextupole magnets, respectively. The yoke length of SR-dipole, short SR-quadrupole, long SR-quadrupole, SR-sextupole, BR-dipole (BH/BD) and BR-quadrupole (pure) magnets are labelled as DL_1, SQL, LQL, SL, DL_2 and BQL, respectively. The bore diameter of the BR-quadrupole magnets is labelled as BQd.

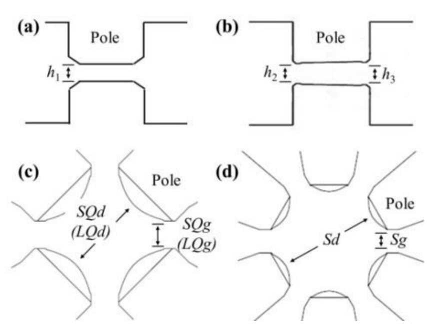

Figure 1: Pole profiles and labels of (a) SR-dipole, (b) BR-dipole, (c) short/long SR-quadrupole and (d) SR-sextupole magnets.

Table 1 lists the mechanical error (mean value±standard deviation) of the SR and BR magnets. The bore diameters of a long SR-quadrupole is counted without a yoke-shim [4]. The discrepancy between the designed and machined value of the bore diameter is better than 0.014 mm. The discrepancy between the designed and machined value of the pole gap of the SR magnet is better than 0.011 mm. The iron yokes of the SR and BR magnets are laminated with 1 and 0.5 mm of 50CS1300 silicon steel, respectively. The deviation of the laminated yoke length was controlled to be smaller than 0.15 % of the yoke length or one thickness of a lamination. The machining

COMPARISON BETWEEN MEASURED AND COMPUTED TEMPERATURES OF THE INTERNAL HIGH ENERGY BEAM DUMP IN THE CERN SPS

G. Steele, F. Pasdeloup, R. Folch, V. Kain, I. V. Leitao, R. Losito, C. Maglioni,
A. Perillo-Marcone, F. Velotti, CERN, Geneva, Switzerland

Abstract

The SPS high energy internal dump (TIDVG) is designed to receive beam dumps from 102.2 to 450 GeV. The absorbing core is composed of 2.5 m graphite, followed by 1.0 m of aluminium, then 0.5 m of copper and 0.3 m of tungsten, all of which is surrounded by a water cooled copper jacket. An inspection during Long Shutdown 1 (LS1) revealed significant beam induced damage to the Al section of the dump block. Temperature sensors were installed to monitor the new dump replacing the damaged one. This paper summarises the correlation between the temperature measured as a function of the energy deposited and the corresponding temperatures computed in a numerical model combining FLUKA and ANSYS simulations. The goal of this study is the assessment of the thermal contact quality between the beam absorbing blocks and the copper jacket, by analysing the cooling times observed from the measurements and from the thermo-mechanical simulations. This paper presents an improved method to estimate the efficiency and long term reliability of the cooling of this type of design, with the view of optimising the performance of future dump versions.

INTRODUCTION

The Target Internal Dump Vertical Graphite (TIDVG) device is used as a high energy (102.2 to 450 GeV) dump for the SPS accelerator. It must withstand the entire range of beams accelerated in the SPS supercycle, including fixed target experiments and injection into the LHC (see Table 1).

Table 1: SPS Run 2 Beam Energies and Intensities

Name	E [GeV]	Bunch Int.	# of Bunches
LHC 25 ns	450	1.2e11	288
LHC 50 ns	450	1.2e11	144
Doublet	450	1.6e11	144
Fixed Target	400	9.52e9	4200

The waveforms of 2 vertical kickers combined with 3 horizontal sweepers in the SPS beam dump system make the whole beam be spread over a relatively large area on the front face of the absorbing core. Since year 2000 three devices have been installed: TIDVG 1 (2000 – 2004), TIDVG 2, (2006 – 2013), TIDVG 3 (installed in 2014). The composition of the three TIDVGs is broadly similar. TIDVG 1 and 2 consist of an absorbing core, encased in a copper jacket surrounded by iron shielding, both containing cooling pipes. The absorbing core is composed of 2.5 m of graphite, 1.0 m of aluminium, 0.5 m of copper and 0.3 m of tungsten. TIDVG3 has a slightly longer (2.7 m) graphite section and a slightly shorter (0.8 m) Al section, because it is the limiting component [1]. During LS1, an endoscopy of TIDVG2 showed significant damage to the Al core section. Energy deposition and thermo-mechanical studies indicated that it did not come from one powerful shot but more likely repetitive dumping of a high power beam. TIDVG2 needed to be replaced by TIDVG3, reusing the iron yoke.

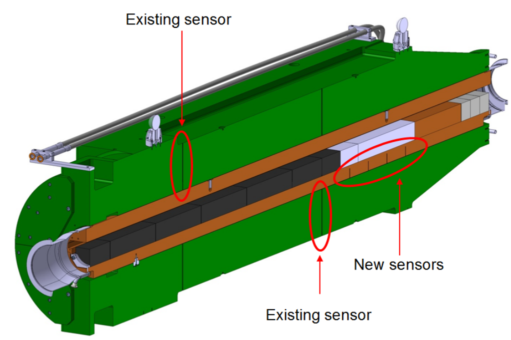

Figure 1: Position of existing and new temperature sensors in the yoke and copper jacket.

Four temperature sensors are installed in the yoke, positioned to give an indication of the temperature on the Cu jacket. Only 2 will be connected due to the number of available connections. Before installation 4 new sensors were inserted into the replacement Cu jacket, positioned to provide sufficient coverage as well as redundancy around the Al section (see Fig. 1). Finally, sensors were installed at the entrance and exit of one cooling circuits, in the Cu jacket.

The extent of the damage prompted several studies to determine the most likely time period when it occurred, and to develop an improved thermo-mechanical model. It serves as a post-mortem tool and to set operational limits for the TIDVG3 for future runs. This paper details the steps taken to improve and verify the simulation model.

SIMULATIONS

Energy Deposition Simulations

FLUKA [2, 3] simulations used a model of the TIDVG3 geometry, and particle density maps from tracking simulations as input (see Fig. 2). Energy density maps for each Run2 beam type are then used as input for the following thermo-mechanical studies. Fig. 3 shows the simulated peak energy deposition along the absorbing core of the TIDVG

Abstract

The European X-ray free electron laser (XFEL) at the Deutsches Elektronen-Synchrotron (DESY), Hamburg Germany is in its construction phase. Approximately a third of the super-conductive cryomodules have been produced and tested. The RF gun is installed since 2013; periods of commissioning are regularly scheduled between installation phases of the rest of the injector. The first linac, L1, consisting of 4 cryomodules powered by one 10 MW klystron is installed and being commissioned. This contribution reports on the installation and preparation work of the low-level radio frequency system (LLRF) to perform the commissioning of the XFEL first components. The commissioning plans, schedule and first results are presented.

INTRODUCTION

An overview of the low level radio frequency (LLRF) system for the European XFEL is given in [1], with a description of the system architecture and the functionality of its main components. Details about the Micro Telecommunication Architecture (MicroTCA.4)-based LLRF system are found in [2] while performance results evaluated in the FLASH accelerator at DESY are given in [3]. Last year, the first component of the XFEL accelerator, the RF gun, was installed in the injector building. A description of its LLRF and the first results of its commissioning are reported in [4]. This contribution reports on the next XFEL milestone, namely, the installation and commissioning of the first linac, corresponding to the first 4 cryomodules installed into the XFEL tunnel (XTL). Results observed with the first beam produced at the XFEL injector are also presented. Figure 1 gives a schematic layout of the accelerator sections of the XFEL (Ax), grouped into injector, linac 1, 2 and 3.

INSTALLATION

Tunnel Installation

All XFEL cryomodules first undergo a series of tests [5,6] performed in the accelerating module test facility (AMTF). The next step consists of installing the waveguide distribution

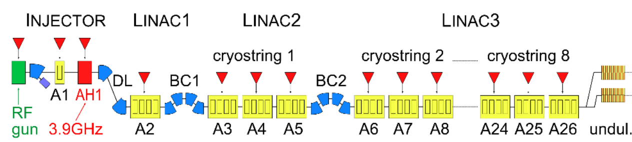

Figure 1: Layout of the XFEL linacs, separated by the dog leg (DL) and the two bunch compressors (BCs).

system, tailored according to each cavity's gradient performance [7]. The complete system (cryomodule + waveguide) is then mounted inside the tunnel, suspended to the ceiling, after which the string connection work can start. The intermodule welding connections are performed and the cryogenic feed- and end-cap at each end of the cryostring are installed. Vacuum connections are performed; the racks containing all electronics can then be placed underneath the modules.

Figure 2: Cryomodule transport into the XFEL tunnel.

The racks require individual water connection for their cooling units, connection to the mains and installation of the concrete radiation shielding, to the side and above the racks. The cabling work can then start (RF, Ethernet, interlock, vacuum, piezo, tuners, optical fiber etc...), from rack to rack and also between racks and cryomodule patch panels. The cabling work requires careful planning and sequential timing;

OPTICS MEASUREMENT AND CORRECTION DURING ACCELERATION WITH BETA-SQUEEZE IN RHIC*

C. Liu†, A. Marusic, M. Minty, Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

In the past, beam optics correction at RHIC has only taken place at injection and at final energy, with interpolation of corrections partially into the acceleration cycle. Recent measurements of the beam optics during acceleration and squeeze have evidenced significant beta-beats that, if corrected, could minimize undesirable emittance dilutions and maximize the spin polarization of polarized proton beams by avoiding the high-order multipole fields sampled by particles within the bunch. We recently demonstrated successful beam optics corrections during acceleration at RHIC. We verified conclusively the superior control of the beam realized via these corrections.

INTRODUCTION

It is desirable to minimize the machine optics (β-functions/phase advances) errors during beam acceleration to improve dynamic aperture for heavy ions and reduce depolarization resonance strengths for polarized proton program. However, it is not practical to pause at step-stones for optics measurement and correction in the simultaneous beam acceleration and beta-squeeze ramp. We demonstrated recently an on-the-fly beam optics measurement during beam acceleration and successfully implemented corrections which substantially suppressed beta-beats on the ramp in RHIC. The method of the measurement and correction is presented in the following sections.

BEAM OPTICS MEASUREMENT DURING BEAM ACCELERATION

Turn-by-turn measurements of the beam position with an applied excitation to the beam has been used at many accelerators to infer fundamental optical parameters such as the tune, the phase advance between BPMs, and with input from the accelerator model, the β-functions. Many different algorithms for data analysis have been successfully applied such as fitting in time domain [1], interpolated FFT technique in frequency domain [2, 3, 4] and statistical techniques (PCA, ICA) [5, 6] finding beam motions in a high dimension data. The interpolated FFT technique was adopted in this report to analyze the machine optics in RHIC.

The acquired turn-by-turn BPM data with the beam kicked by the tune meter kicker multiple times usually oscillates for less than 500 turns because of decoherence for a typical chromaticity setting (∼2 above transition, ∼-2 below transition). The application of interpolated FFT analysis on these BPM data yielded high precision tune, phase advances and β-functions measurement despite the limited data points acquired. This demonstration opens up the possibility of acquiring turn-by-turn BPM data with the tune meter on the ramp for optics measurement [7, 8].

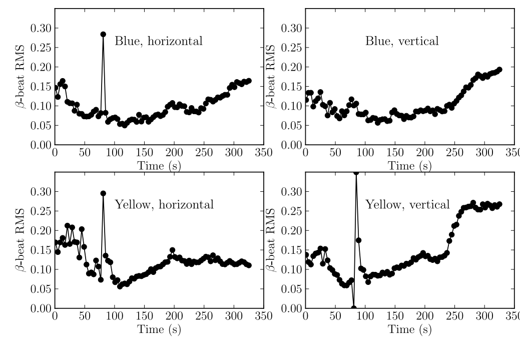

Figure 1: The measured beta-beats during beam acceleration (high energy Au-Au, 2014). Transition crossing occurs at $\sim$ 85 seconds after the start of acceleration.

Measurements of the beam optics were made reproducible by ensuring reproducible beam orbits and betatron tunes using the now standard beam feedback systems during acceleration. While orbit and tune feedback operate independently, the BPM measurements used by orbit feedback and the turn-by-turn BPM measurements share the same networks for data delivery. The timing of the delivery of beam position measurements for these two systems was therefore carefully staggered to avoid data corruption. Orbit feedback operated at its standard 1 Hz rate. We allowed 200 ms corresponding to an upper limit on the time to transmit all (4 planes from both accelerators) the average orbit BPM data well in excess of the 150 ms required based on previous measurements [9]. After delivery of the data for orbit feedback, the beam was excited in one plane followed a short time later by excitation in the other plane, where the spacing between applied excitations was set ($\sim$ 500 turns) to be longer than the decoherence time.

Since the volume of data being acquired is large, we present the deviation of the machine optics in the form of global beta-beat Root-Mean-Square (RMS) during beam acceleration. Figure 1 shows the RMS beta-beats at each time of optics measurement during beam acceleration for the Au-Au physics ramp in 2014.

FINAL COOLING FOR A HIGH-LUMINOSITY HIGH-ENERGY LEPTON COLLIDER

D. Neuffer, Fermilab, Batavia, IL 60532 USA
H. Sayed, BNL, Upton, NY, 11973 USA
T. Hart, D Summers, University of Mississippi, Oxford, MS 38655, USA

Abstract

The final cooling system for a high-energy high-luminosity lepton collider requires reduction of the transverse emittance ε_t by an order of magnitude to ~0.00003 m (rms, N), while allowing longitudinal emittance ε_L to increase to ~0.1m. In the present baseline approach, this is obtained by transverse cooling of low-energy muons within a sequence of high field solenoids with low-frequency rf systems. Recent studies of such systems are presented. Since the final cooling steps are mostly emittance exchange, a variant form of that final system can be obtained by a round to flat transform in x-y, with transverse slicing of the enlarged flat transverse dimension followed by longitudinal recombination of the sliced bunchlets. Other variants are discussed. More explicit emittance exchange can greatly reduce the cost of a final cooling system.

INTRODUCTION

The P5 report stated that "for e^+e^- colliders, the primary goals are improving the accelerating gradient and lowering the power consumptions."[1] Both of these goals are achieved by increasing the mass of the electrons to a level where multiturn acceleration to TeV's is possible, and radiation effects are small. Increasing the mass to 105.66 MeV changes TeV electrons from a radiation source and enables the possibility of multi TeV heavy electron (μ) colliders. Parameters for possible multiTeV Colliders are included in Table 1.

Table 1: High-energy Heavy-lepton Collider Parameters

Parameter	**Higgs (1/8TeV)**	**3TeV**	**6TeV**
Beam energy	0.063	1.5	3
Heavy $e^{-/+}$/ bunch	$2\ 10^{12}$	$2\ 10^{12}$	$2\ 10^{12}$
Circumference (m)	300	2767	6302
Tune	5.16/4.56	20.1/22.2	38.2/40.1
Compaction	0.08	-3E-4	-1.2E-3
Emittance (μ,N)	300	25	25
Collision β_t (cm)	3	0.5	0.25
Energy spread	0.003%	0.1%	0.1%
rep rate	30 Hz	12 Hz	6 Hz
Luminosity (10^{34}cm^{-2}s^{-1})	0.002	4	12

The multi-TeV scenarios require cooling the beam transversely to ε_t ~0.00003m (rms, N (normalized)) while allowing a longitudinal emittance of ε_L ~0.1m (rms, N).[2] The present 6-D cooling systems cool the muons to ~0.0003m transversely and ~0.001m longitudinally.[3] Thus the collider scenarios require a "final cooling" system that reduces ε_t by a factor of ~10 while allowing longitudinal emittance increase. We will discuss several approaches toward obtaining final cooling parameters.

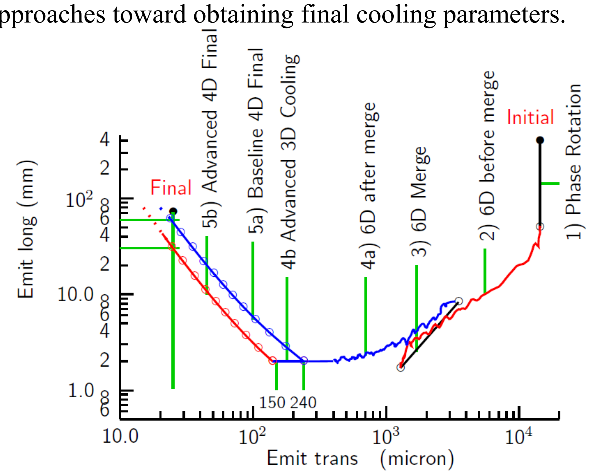

Figure 1: Progression of emittances throughout a collider cooling scenario.

BASELINE FINAL COOLING

A baseline approach to final cooling was developed by Palmer et al. This includes transverse ionization cooling of low-energy muons within high field solenoids, with lower energies and higher fields obtaining smaller ε_t .[4, 5] At low-energies, the variation of momentum loss with energy anti-damps the beam longitudinally, increasing ε_L. Figure 1 shows the progression of emittances throughout a collider cooling scenario, with the "final cooling" portion of that displayed as the lines with transverse emittance decrease and longitudinal emittance increase leading to final values at ε_t = 25μ and ε_L = ~30---60mm.

For final cooling, the beam momentum is reduced initially to 135 MeV/c and only transverse cooling is used. The final cooling system consists of ~a dozen stages. Each stage consist of a high-field small bore magnet with an H_2 absorber within the magnet, followed by an rf and drift system within lower-field to phase-rotate and reaccelerate the muons. From stage to stage, the muon beam energy is reduced (from 66 MeV toward

EFFECTS OF ACCELERATING STRUCTURES ON ON-LINE DFS IN THE MAIN LINAC OF CLIC

J. Pfingstner[1,2,*], E. Adli[1], D. Schulte[2]
[1]University of Oslo, Oslo, Norway, [2]CERN, Geneva, Switzerland

Abstract

Long-term ground motion will create significant dispersion in the time-scale of hours in the main linac of CLIC. To preserve the emittance to an acceptable level, a dispersion correction with on-line dispersion-free steering (DFS) is inevitable. For this on-line technique, the dispersion has to be measured using beam energy variations of only about one per mil in order to not disturb the operation of the accelerator. For such small energy variations, the interaction of the particle beam and the accelerating structures creates large enough additional signals components in the measured dispersion to cause the dispersion correction to not work properly anymore. In this paper, the additional signals are described and their effect on the DFS algorithm is analysed. Finally, methods for the mitigation of the deteriorating signal components are presented and studied via simulations.

INTRODUCTION TO ON-LINE DFS

Linear colliders are very sensitive to element misalignments, due to their ultra-small beam emittances. These misalignments are not only of static nature, but change over time as a result of the impact of ground motion. For time scales below a few minutes, the ground motion induced luminosity loss can be mitigated with orbit feedback systems and mechanical magnet stabilisation systems [1]. Over longer time periods, however, it is not sufficient to correct only the beam orbit. Also the steadily increasing dispersion has to be addressed. For the CLIC main linac, e.g., this dispersion causes an emittance growth in the more critical vertical direction of $\Delta\epsilon_y = 0.75$ nm per hour. This simple empirical law has been found via simulation studies. It assumes ground motion according to the ATL law [2] with a constant A of 10^{-5} μm/s/m.

To avoid this emittance growth, a scheme has been proposed in which the dispersion is corrected during the accelerator operation in a transparent way (similar to an orbit feedback). This scheme, named online dispersion free steering (DFS), is based on the well-known DFS algorithm [3]. The DFS algorithm consists of two steps. Firstly, the dispersion $\eta(s)$, where s is the longitudinal position in the beam line, is determined via the beam orbit change $\Delta x(s)$ of two measurements $x_{E_0}(s)$ and $x_{(1+\delta)E_0}(s)$ due to a change in beam energy of δE_0, where E_0 is the nominal beam energy,

$$\eta(s) = \frac{\Delta x(s)}{\delta} = \frac{x_{(1+\delta)E_0}(s) - x_{E_0}(s)}{\delta}. \tag{1}$$

The dispersion $\eta(s)$ is then used to compute and apply quadrupole magnet misalignments $\theta(s)$ that cancel $\eta(s)$ in a least square sense. Additional constrains can be imposed in the computation of $\theta(s)$, to limit the amplitude of the correction and to not create too large beam orbit excursions [4]. In practice DFS is not applied in one step to the whole linac, but rather in a sequential fashion to overlapping subsection called bins (36 in the case of the CLIC main linac).

The basic form of DFS is intended to be used in the commissioning phase and during performance tuning campaigns. In these cases, large relative energy variations δ (5% to 10%) can be used, since the beams are not used for physics data taking. If DFS should be used on-line, however, only small δ in the order of 1 per mil are acceptable (energy acceptance of the beam delivery system). This results in small orbit variations $\Delta x(s)$, which reduces the measurement quality dramatically, due to the higher relative measurement noise of the beam position monitors (BPM). To recover the necessary measurement quality, an averaging method has been proposed and successfully tested in simulations [5].

Robustness studies have revealed, however, that the online DFS algorithm is sensitive to certain effects due to accelerating structures [6], namely wake fields and structure tilts. In this paper, the influence of these effects on the online DFS algorithm is analysed and modifications to the algorithm are proposed that recover the performance of the dispersion correction. These modifications are tested in simulations and the final emittance growths are reported.

EFFECTS DUE TO ACCELERATING CAVITIES

The sources of dispersion in a particle beam can be traced back to different types of dipole kicks. In linear accelerators without bending magnets, the main sources of dipole kicks are misaligned quadrupole magnets (feed-down effect). The purpose of the DFS algorithm is to cancel this dispersion, by adding new dispersion created by intentionally offsetting quadruple magnets. However, there are also other sources of dipole kicks in linear accelerators that create dispersion. These dipole kicks originate from accelerating structures, either because of imperfect alignment, e.g. tilts, or due to transverse wake fields. In the following, it will be shown that the dispersion due to dipole kicks from accelerating structures create undesirable signals in the dispersion measurement Eq. (1) that deteriorate the performance of the on-line DFS correction. Also strategies to suppress these unwanted signals are presented.

Deteriorating effects of transverse wake fields: An offset of the beam in an acceleration cavity creates transverse wake fields. These transverse wake fields are zero

MEASUREMENT OF THE INCOHERENT DEPTH OF FIELD EFFECT ON HORIZONTAL BEAM SIZE USING A SYNCHROTRON LIGHT INTERFEROMETER

M. J. Boland, AS, Clayton, Victoria, Australia
J. Corbett, SLAC, Menlo Park, CA, USA
T. Mitsuhashi, KEK, Tsukuba, Ibaraki, Japan

Abstract

The electron beam size as measured using synchrotron light in a circular accelerator is influenced by the incoherent depth of field effect. This effect comes about due to the instantaneous opening angle of the emitted synchrotron radiation (SR) and the acceptance angle of the SR light monitor beamline. Measurements were made using a visible light interferometer at the visible light beamlines in three circular accelerators at ATF, SPEAR3 and AS. The first order spatial coherence of the beam was measured and from that the horizontal beam size was calculated. The data is compared with a theory of synchrotron radiation with and without the horizontal incoherent field depth effect.

INTRODUCTION

The work in the paper covers in more detail the horizontal theory presented in Ref. [1]. If we accept the theory of the coherence of SR given in Ref. [2,3], then the highly relativistic motion of electrons in a storage ring results in temporal squeezing at the point of photon emission. From the observers frame of reference, this gives the appearance of a small cusp in the trajectory which – in the visible part of the spectrum – effectively forms a diffraction limited window from which the SR emerges. Each single electrons emits pencil of light having approximately the same opening angle in vertical and horizontal (precisely speaking the vertical distribution has π component so a small difference exists) which is then occupied by a single mode of 1 photon (or vacuum when photon number is zero). The opening angles of the pencils of light are $(\lambda/\rho)^{1/3}$ in both for vertical and horizontal.

The independent electrons in the bunch emit this pencil of light with a probability roughly proportional to the fine structure constant $\alpha = 1/137$. According to quantum physics, a fraction of a photon does not exist, leaving the situation that only one electron in every 137 electrons emits one single photon. The observed intensity downstream is the incoherent summation of these pencils of light. In an light source storage ring there are a lot of electrons in the bunch, so the SR is still very bright. One single photon mode in a pencil of light is coherent, so an interferogram created by a double slit interferometer must have a contrast of exactly 1 for many observations of individual photons emitted by single electrons. So, if this pencils of light illuminate a double slit downstream, as shown in Fig. 1, the following situations emerge in the horizontal case.

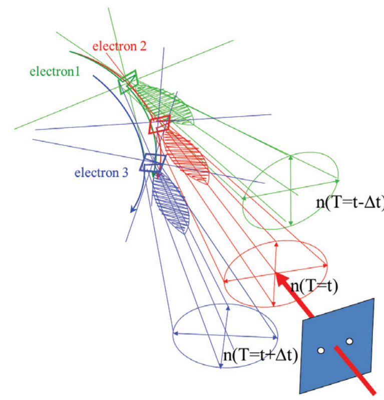

Figure 1: Photon emission from an electron beam in storage ring bending magnet.

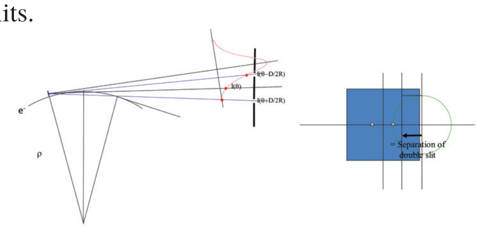
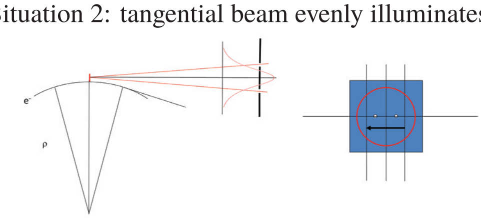
Situation 1: beam upstream of tangent starts to illuminates slits.



Situation 2: tangential beam evenly illuminates slits.



Situation 3: beam downstream of tangent last illumination of slits.

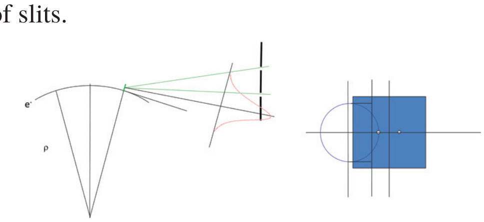


Figure 2: Horizontal sweeping of beam over double slits.

Situation 1 in following figure shown pencil of light start to illuminate the one of double slit, full noon illumination

LAYOUT OPTIONS FOR THE AXXS INJECTOR AND XFEL

M. J. Boland, Y.-R. Tan and D. Zhu, AS, Clayton, Victoria, Australia

Abstract

A new injector is being planned for the Australian Synchrotron that is designed to feed both an upgraded storage ring and an XFEL. The desire to fit the AXXS project on the same site as the existing light source presents several layout difficulties. Several options are studied and simulations are performed to check the impact each choice has on the beam performance.

INTRODUCTION

The Australian X-Band X-Ray Source (AXXS) [1] is part of an effort to use the CLIC [2] x-band technology from CERN to develop a Free Electron Laser (FEL). A research and development collaboration has been formed [3] and a baseline design for the linac has emerged [4]. This paper explores some of the layout options that are specific to the Australian Synchrotron (AS) site in Melbourne, Australia. At this stage it will be attempted to fit the construction of an FEL to be co-located on the same site as the existing storage ring and to use the linac to inject into the new multi bend achromat (MBA) lattice that is being designed to replace the existing storage ring. Including the neighbouring car park on one side and an empty lot on the other side, there is 550 m of land available on the existing AS site (see Fig. 1).

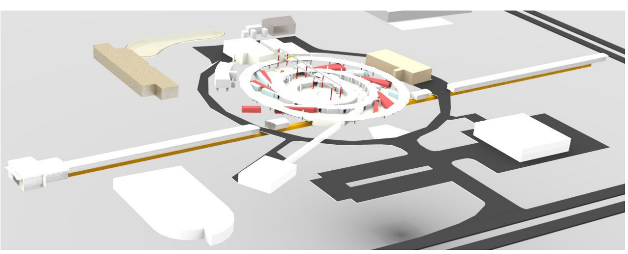

Figure 1: AS site with proposed AXXS FEL overlay.

As explained in Ref. [1], the first phase of any upgrade project is to fill out the remaining beamlines (marked in red on Fig. 1) on the existing storage ring, before replacing the storage ring with a new diffraction limited storage ring (DLSR) [5]. The AXXS linac can then replace the current injection system, necessary to inject into a DLSR which will have a very narrow magnet apertures – approximately 12.5 mm for the present DLSR designs [6] compared to 37.5 mm for the current AS ring [7].

STORAGE RING UPGRADE

The user community of over one thousand users per year is very satisfied with the operation of the current storage ring. There is high demand for beamtime and some beamlines are heavily oversubscribed – up to five times more beamtime is requested than can be provided. The first priority for the facility is to complete the build-out of the available space for beamlines, which amounts to five more insertion devices and several bending magnets. In parallel there is also a very active part of the x-ray user community in Australia who are doing research using FELs, spearheaded by the Centre for Advanced Molecular Imaging [8]. Both these factors in the Australian user community are driving the efforts on the AXXS project.

The first steps towards designing a new storage ring have been taken following the trend in MBA lattice designs [9], see for example the MAX IV facility currently being built [10]. The lattice functions for one cell are shown in Fig. 2 and the constraints that have been used are a) circumference remains 216 m to fit in the same tunnel and b) the beamline source points remain in the same location.

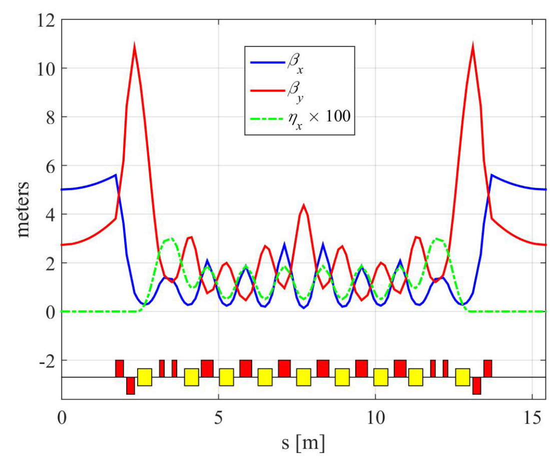

Figure 2: Lattice functions of AS MBA cell.

Some of the parameters for the MBA are listed in Table 1.

Table 1: Selected Machine Parameters for MBA Lattice Compared with Present DBA Lattice

Parameter	DBA	MBA
Beam Energy (GeV)	3.0134	3.0000
Beam Current (mA)	200.0000	200.0000
Horizontal Emittance (nm)	10.3488	0.2023
Vertical Emittance (nm)	0.1035	0.0607
Critical Photon E (keV)	8.1068	6.6371
Energy Spread (%)	0.1021	0.1047
Lin. Energy Acceptance (%)	2.1774	7.4462
α_c (10^{-3})	2.1115	0.1976
Bunch Length (ps)	23.0879	7.1781
Bunch Length (mm)	6.9218	2.1520
Horizontal Tune	13.2900	46.1038
Vertical Tune	5.2160	19.1729

OPERATOR ROLES AT THE AUSTRALIAN SYNCHROTRON

Don McGilvery, Greg LeBlanc, Australian Synchrotron, Clayton, Australia

Abstract

The Accelerator Operators at the Australian Synchrotron undertake a wide variety of critical functions as part of their regular duties. In addition to normal Control Room duties, they play a major Role in Machine Physics, provide after hours support for Users on Beamlines and contribute extensively to the Controls and Database Development across the facility.

OPERATIONS AT THE AUSTRALIAN SYNCHROTRON

The Australian Synchrotron (AS) has been in User Beam Operation for 8 years. It comprises a 3GeV electron storage ring with a full energy injector. Top Up Operation commenced in 2013 and there are currently 10 beamlines. The yearly schedule includes 5000 hours of User Beam and 2000 hours of Machine Development and Physics.

Operator Rostering

Operators are rostered to cover 24 hours a day, 7 days per week. Two Operators are rostered on each shift and work a 12 hour 7 day on, 7 day off , 7 nights on 7 days off rotating roster. The Operators find this particular roster rotation works extremely well. It features minimal shift changes, every second weekend off and sufficient time to prepare for and recover from the night shifts. For 75% of the week the Operators are the only AS staff regularly on site and they play a key role in the delivery of great science.

Diversity of Tasks

Since commencing Top Up Operations and the provision of uninterruptible power to the Storage Ring, RF and the Conventional Facilities, minimal Operator intervention is required to maintain stored beam during User Operations.

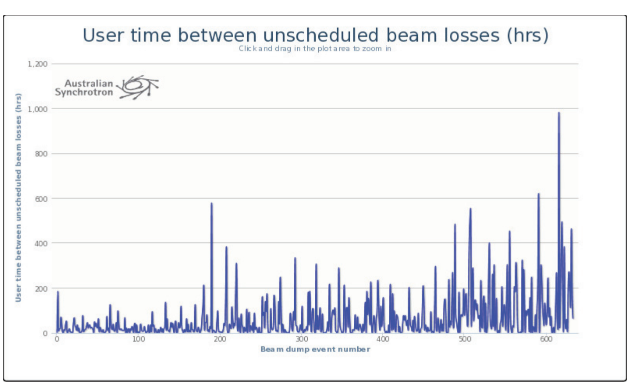

Figure 1: Reliability improvement of operation indicated by the increasing times between unscheduled beam trips.

The reliability of operation of the Australian Synchrotron (see Figure 1) is demonstrated by the recent delivery of 982 hours of User Beam without an unscheduled beam loss event. Some time is still required for dealing with minor trips, tuning, fault diagnosis and recovery but most Operator time is devoted to other activities and projects.

Operator Projects

Some of the Operator Projects include:

- The development of an Electronic Log Book
- Maintaining the Facility Statistics and KPI's.
- EPICS, Database and Web page maintenance
- Design and construction of a Tunnel Robot
- Development of Environmental Monitors
- Improvement to Beam Diagnostics
- Auto-tune Routines for the Accelerators

A key Role the Operators now undertake is to provide "After Hours Support" to Users on Beamlines.

After Hours Support for Users on Beamlines

Beamline Science staff provide support for Users between 8:00 and 18:00 Monday to Friday and are rostered on call weekends and until 22:00 each night. At other times the Operators provide the Ussr support. Furthermore any requests for on call User support is provided through the Control Room. This has been a very successful undertaking with the Operators now handling around 70 User support calls each month.

Operators have been formally trained on a number of beamlines and are able to apply their machine problem solving skills to assist with fault resolution and training on beamlines.

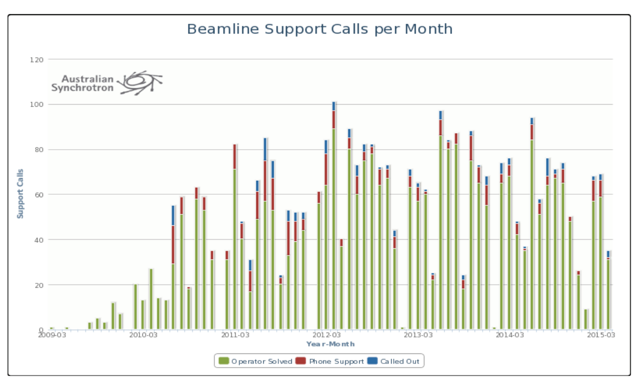

Figure 2: Graph showing the number of beamline support calls per month handled by the Operator.

It can be seen in Figure 2 that the number of support calls handled by the Operators grew over the first couple of

COMPARISON OF BUNCH COMPRESSION SCHEMES FOR THE AXXS FEL

T. K. Charles, D. M. Paganin,
School of Physics and Astronomy, Monash University, Clayton, Australia
A. Aksoy, Ankara University, Golbasi / Ankara, Turkey
M. J. Boland, R. Dowd, Australian Synchrotron, Clayton, Australia
A. Latina, D. Schulte, CERN, Geneva, Switzerland

Abstract

Different types of electron bunch compression schemes are compared for the AXXS FEL design study. The main linac for the proposed machine is based on CLIC x-band structures. This choice leaves several options for the bunch compression schemes which impact the injection system RF band. Both harmonic linearization and phase modulation linearization are considered and their relative strengths and weaknesses compared. Simulations were performed to compare the performance of an s-band injector with a higher harmonic RF linearization to an entirely x-band injector and linearization scheme. One motivation for the study is to optimize the length of the AXXS machine, allowing the linac to fit onto the proposed site and also act as the injector to the existing storage ring at the Australian Synchrotron

AXXS

AXXS (Australian X-band X-ray Source) [1] is strategically planned to incorporate an upgrade of the current Australian Synchrotron storage ring and provide a new high brightness sub-Angstrom wavelength XFEL. The design includes a 6 GeV linac based around the CLIC x-band linac [2, 3].

PHASE MODULATION LINEARIZATION

In attempting to linearize the longitudinal phase space most FELs around the world employ harmonic linearization. When looking to design an all x-band linac, as is the case of AXXS, the high frequency accelerating structures preceding the first bunch compressor make harmonic linearization more difficult to achieve.

Phase modulation linearization is the term introduced in this paper to describe a new method of linearization. Through independently varying the phases of two cavities positioned before the first bunch compressor, 2nd order effects encountered through bunch compression can be minimized. These 2nd order effects refer to both the RF curvature impressed onto the beam during accelerating, plus the second order longitudinal dispersion, T_{566}, of the magnetic chicane.

Implementation of Phase Modulation Linearization is sketched in Fig. 1. To establish an energy chirp, the RF phase of the first section after the injector, ϕ_0, is chosen to be 70°. The two additional cavities required for Phase Modulation Linearization are shown as having the parameters V_1, ϕ_1, V_2 and ϕ_2.

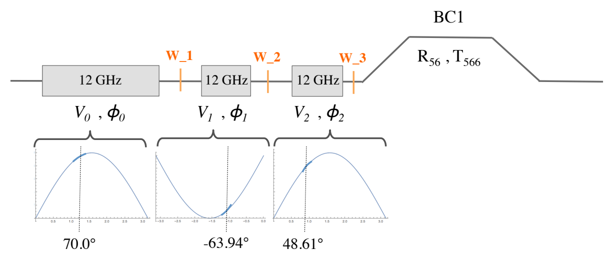

Figure 1: Layout of an x-band FEL accelerator design, up to end of first bunch compressor, which employs Phase Modulation Linearization. Included are markers showing location of longitudinal phase space plots in Fig. 3.

Analytical Approach

The beam energy after passing through the accelerating section leading up to the first bunch compressor is,

$$E_f = E_i + V_0 \cos(\phi_0 + k_x z_0) + V_1 \cos(\phi_1 + k_x z_0) + \ldots \\ + V_2 \cos(\phi_2 + k_x z_0), \quad (1)$$

where V_0, V_1, V_2, represent the RF voltages of the three sections shown in Fig. 1, and ϕ_0, ϕ_1, and ϕ_2, are the RF phases of these sections, where the RF phase is defined to be 90° at the crest of the RF acceleration, and over the interval $0 < \phi < 90°$ defines the negative slope of the RF curve (i.e. the head of the bunch is accelerated less than the tail). z_0 is the position of an electron with respect to the bunch center, and k_x is the wave number of the RF frequency.

The longitudinal position of any electron as it passes through the dispersive region of the chicane is,

$$z_f(\delta) = z_i + R_{56}\delta + T_{566}\delta^2 + U_{5666}\delta^3 + \ldots \quad (2)$$

Taking the Taylor series expansion of Eq. 1, calculating the relative energy deviation and then substituting the result into to the dispersion relation (Eq. 2), the final longitudinal position is,

$$z_f = z_0 + R_{56}(az_0 + bz_0^2) + T_{566}(az_0 + bz_0^2)^2 \\ + \text{higher order terms} \quad (3)$$

$$= z_0(1 + aR_{56}) + (bR_{56} + a^2T_{566})z_0^2 \\ + 2abT_{566}z_0^3 + b^2T_{566}z_0^4 + \text{higher order terms} \quad (4)$$

SIRIUS ACCELERATORS STATUS REPORT

A.R.D. Rodrigues*, F. Arroyo, O.R. Bagnato, J.F. Citadini, R.H.A. Farias, J.G.R.S. Franco, L. Liu, S.R. Marques, R.T. Neuenschwander, C. Rodrigues, R.M. Seraphim, O.H.V. Silva, LNLS, Brazil

Abstract

Sirius is a 3 GeV synchrotron light source that is being built by the Brazilian Synchrotron Light Laboratory (LNLS). The electron storage ring is based on a modified 5BA cell to achieve a bare lattice emittance of 0.27 nm.rad in a 518 m circumference ring that contains 20 straight sections of alternating 6 and 7 meters in length. The 5BA cell accommodates a thin permanent magnet high field (2 T) dipole in the center of the middle bend producing hard X-ray radiation (ε_c=12 keV) with a modest contribution to the total energy loss.

In this paper we discuss the main achievements and issues for Sirius accelerators. Developments in beamlines are not discussed here.

INTRODUCTION

Over the last year the earthwork at the Sirius site was completed and the building foundation work has began just after the groundbreaking ceremony on Dec. 19, 2014. See Fig. 1. The project underwent an overall budget and schedule revision after the detailed engineering design of the building was concluded. Start of machine installations is now scheduled for the end of 2017.

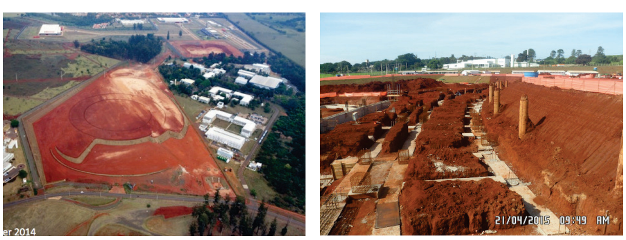

Figure 1: Aerial view taken in October 2014 of the Sirius site with earthwork completed (left) and construction of building foundation as of April 2015 (right).

The storage ring design optics has been upgraded to improve the matching in phase space between the electron beam and photon beam from insertion devices [1]. The main parameters for this new mode are summarized in Table 1. Most of the accelerator subsystems are in R&D and prototyping phase; a few are already under production, such as the booster magnets.

MAGNETIC LATTICE

A few modifications in the magnetic lattice have been implemented to optimize the design and fabrication of the magnets as well as to provide more space in the arc: the quadrupole lengths have been reduced, the slow orbit correctors and skew quadrupoles have been combined into the sextupoles, the different types of dipoles have been segmented into a rectangular unit block, and the horizontal and vertical fast orbit correctors have been combined to minimize the length of special vacuum chambers. The BPMs adjacent to the insertion straight sections have been moved closer to quadrupoles to optimize the beam-based alignment process and the BPM downstream the central dipole has been removed to avoid synchrotron radiation power. The optical properties for the new lattice are described in more detail in ref [1]. The injection straight section has also been optimized for injection with a pulsed multipole magnet. In this case, the conventional four kickers are not necessary and more space is available to optimize the pulsed magnet injection. A single kicker is kept for on-axis injection during commissioning.

Table 1: Sirius Storage Ring Main Parameters

Energy	3.0	GeV
Circumference	518.4	m
Horizontal emittance	0.19 - 0.27	nm.rad
Betatron tunes (H/V)	48.14 / 13.12	
Natural chromaticity (H/V)	-126.1 / -79.4	
Natural energy spread	0.076	%
Natural bunch length	2.3	mm

VACUUM SYSTEM

The vacuum system design for a standard storage ring sector is complete. Prototypes for bellows, BPMs, fast orbit correctors, multipoles and dipole vacuum chambers have been produced and prototypes for crotch absorbers and dipole chambers with narrow antechambers are under production. Pumping for Sirius will be based on NEG coating with in-house deposition. The NEG coating procedure has already been developed and optimized for most chamber geometries; even the 6 mm height narrow dipole antechamber already showed good activation results. For in-situ NEG activation a special 0.4 mm thick heating jacket has been developed by EXA-M. The jacket, which fits in the narrow gap between the vacuum chamber and the magnet poles, includes an external radiation shield to reduce heat transfer to the magnet. Further R&D work is being devoted to the optimization of crotch absorbers, bellows and BPMs.

The booster dipole vacuum chambers have been contracted to a local company (FCA Brasil).

UPGRADED OPTICS FOR SIRIUS WITH IMPROVED MATCHING OF ELECTRON AND PHOTON BEAM EMITTANCES

L. Liu*, F. H. de Sá, N. Milas, A. H. C. Mukai, X. R. Resende, LNLS, Campinas, Brazil

Abstract

A new optics has been designed for Sirius with improved betatron function matching in the 6 meter-long low beta straight sections for insertion devices. Both horizontal and vertical betatron functions are set to 1.5 m in the center of the section, improving the matching of the electron and undulator photon beams. In addition, the horizontal beam stay clear has also been reduced allowing for small horizontal gap devices as well as the conventional small vertical gap ones. The new design optics has been optimized to the same previous performance regarding dynamic aperture and momentum acceptance.

INTRODUCTION

To take advantage of the unprecedented X-ray brightness from insertion device photon sources offered by the 4th generation storage rings, it is important to match the electron and photon beam phase space orientations. It is well known that the effective photon beam distribution in phase space is the convolution between the diffraction-limited radiation emittance and the transverse electron beam emittances [1]. When the electron beam emittance becomes comparable to the diffraction-limited photon emittance, the effective photon beam brightness is greatly affected by the mutual orientations of both beams in phase-space. Matching the orientations will maximize the photon beam brightness. To improve the matching conditions in Sirius, we have reduced the horizontal betatron function at the center of the low β_x straight sections (SSB) from 4 in the previous mode [2] to 1.5 m in the new mode.

This modification also results in a reduction of the horizontal beam-stay-clear (BSC) at the SSB sections, which opens the possibility for small horizontal gap insertion devices in addition to the conventional small vertical gap ones.

DESIGN OPTICS

The Sirius lattice has alternating high and low horizontal betatron function straight sections for insertion devices. A high β_x is desired at the injection straight section and at long or canted undulator sections; and a low β_x optimizes the brightness from short undulator sources. At the high β_x sections (SSA) a quadrupole doublet is used to match the optical functions whereas at the low β_x sections (SSB) a quadrupole triplet is used. The extra quadrupole at SSB reduces the straight section length from 7 to 6 meters.

We have recently upgraded the Sirius design optics to further improve the beam brightness from undulator sources installed in the center of the low beta sectors by reducing the horizontal betatron function from 4 to 1.5 m. This corresponds to the optimum matching for undulators of approximately 4.5 m in length, according to the relation $\beta_{opt} \approx L/\pi$. For Sirius, 2-m long undulators are planned for SSB sections. Although not perfectly matched for this case, an increase of 10 to 25% in brightness, depending on the photon energy, is expected.

The new optics can be implemented preserving the bare lattice emittance of 0.27 nm.rad and without requiring changes to magnets or power supplies. The reduction in horizontal beta leads to an increase in the horizontal tune by two integers while the vertical tune is reduced by one. The dynamic aperture and momentum acceptance for this new operation point in tune space have been optimized to the same values of the previous mode. As a result a similar beam lifetime of approximately 10 hours is achieved for 500 mA with third harmonic cavity, uniform filling, 1% emittance ratio and both chromaticities set to +1.5 to reduce resistive wall growth rates. The optimization process uses the tracking-based multi-objective genetic algorithm MOGA [3] to refine the initial solutions. The new optics has thus been adopted as the official design mode for Sirius.

Further modifications in the lattice have been implemented in connection with the detailed design of the magnets. In particular, the quadrupole lengths have been reduced, the slow orbit correctors and skew quadrupoles have been combined with the sextupoles, the different types of dipoles have been segmented into a rectangular unit block, and the horizontal and vertical fast orbit correctors have been combined to minimize the length of special vacuum chambers. The BPMs adjacent to the insertion straight sections have been moved closer to quadrupoles to optimize the beam-based alignment process and the BPM downstream the central dipole has been removed to avoid synchrotron radiation power. The reduction in quadrupole length and the option for combined sextupoles and orbit correctors opened up significant space in the lattice: the magnets share in the total circumference is reduced from 45% to 39%.

The new lattice configuration is shown in Figure 1 and the main parameters in Table 1. Figure 2 shows the lattice function modifications for the previous and the new design optics.

MIXING AND SPACE-CHARGE EFFECTS IN FREE-ELECTRON LASERS*

E. Peter#, A. Endler, F. B. Rizzato, UFRGS, Porto Alegre, Brazil
A. Serbeto, UFF, Niterói, Brazil

Abstract

This work aims to understand the single pass FEL dynamics with an initially cold beam, through a semi-analytical model, based in a group's previous works in beams [1, 2]. The central point of the model is the compressibility factor, which allows establishing the transition from Compton to Raman regimes. The model is useful also to perform analytical estimates of the elapsed time until the onset of mixing and the saturated amplitude of the radiation field. Semi-analytical and full simulations results are compared, showing a good agreement.

INTRODUCTION

Free-electron lasers are devices that efficiently convert the kinetic energy of a relativistic electron beam into the energy of electromagnetic radiation. An electromagnetic wave (called laser or radiation) copropagates with the electron beam, which passes through a static and periodic magnetic field generated by a wiggler. Due the presence of the laser and wiggler fields, the electrons lose velocity, giving their energy to the laser. This single pass FEL, with initially cold beam, in general, is well explored in literature, both in Compton and Raman regimes [3-5].

In a FEL, there is interaction between the electrons and the ponderomotive well (formed through the superposition of the wiggler and laser electromagnetic fields) and among themselves. The last interaction is called space-charge effect.

When the electric charge is small in the system, the ponderomotive well mainly drive the particle dynamics, and the particles are attracted to the bottom of the well. In this case, electric repulsion is weak, and the particles revolve as a whole around themselves in the particle phase-space. This regime is called Compton.

But, when the charge increases, the mixing process in the phase-space become different (Raman regime). Electric repulsion offers resistance against the ponderomotive well, and the process is similar to the case of magnetically focused charged beams [1,6].

The main target of this work is review the paper [7] using more adequate parameters to FEL operation, establishing a threshold between Compton and Raman regimes. We made it through a semi-analytical approach based on the compressibility factor, whose zeroes indicate the onset of mixing in phase-space. This semi-analytical model can provide an estimative of the time and the position in the ponderomotive well for the onset of mixing and the saturated amplitude of the radiation field.

#peterpeter@uol.com.br

PHYSICAL MODEL

A complete description of FEL dynamics must include laser, electron phase and energy evolutions and space-charge effects, which occurs due a longitudinal electric field. We start with the laser and wiggler (w) fields. They are described by the respective vector potentials (with $\hat{e} = (\hat{x} + i\,\hat{y})/\sqrt{2}$)

$$\frac{e}{mc^2}\vec{\mathcal{A}}_w(z) = a_w(e^{-i\,k_w z} + c.c.)\,\hat{e}\ , \qquad (1)$$

$$\frac{e}{mc^2}\vec{\mathcal{A}}(z) = -i\left[a(z)e^{i(k\,z-\omega\,t)} - c.c.\right]\hat{e}. \qquad (2)$$

The dimensionless laser amplitude $a(z)$ is a slowly varying function of z. As for the space-charge contribution, to satisfy the periodic boundary conditions, we consider a thin electron beam moving at the center of the pipe. An equivalent physical picture is of a beam propagating along the z axis with two grounded plates located at $y = \pm L/2$. Based on a sheet beam model [8], Poisson equation is solved, demanding 2π periodicity for the variable $\theta = k_p z - \omega t$, where $k_p = k + k_w$ is the ponderomotive wave number and θ is the particle phase in the ponderomotive potential. In the limit of large values of L, the electric field generated at θ by one particle of unitary charge located at θ' can be expressed as the following periodic saw-tooth function, which is the dimensionless Green's function for the electric field:

$$E_z{}^G(\theta,\theta') = sign(\theta-\theta')[\pi - Abs(\theta-\theta')]. \qquad (3)$$

Therefore, the total electric field at particle phase θ (where $\eta^2 = \omega_p{}^2/\omega^2$, and ω_p is the plasma frequency)

$$E_z(\theta\,) = \eta^2\langle E_z{}^G(\theta,\theta')\rangle. \qquad (4)$$

From Lorentz equation, we write (where $\gamma = [(1+|a_{TOT}|^2)/(1-v_z{}^2)]^{1/2}$ is the relativistic Lorentz factor and v_z is the longitudinal velocity):

$$\frac{d\gamma_j}{dz} = -\frac{a_w}{2\gamma_j}\left(ae^{i\theta_j} + c.c.\right) + v_{zj}v_pE_z(\theta_j). \qquad (5)$$

50 MeV ELECTRON LINAC WITH A RF GUN AND A THERMOIONIC CATHODE

A. Setty, A.S. Chauchat, D. Fasse, D. Jousse, P. Sirot Thales Communications & Security (TCS), 4 avenue des Louvresses 92 230 Gennevilliers, France

Abstract

The low energy part of our pre injectors is made up of a 90 kV DC thermoionic triode gun, followed by a 500 MHz sub harmonic pre buncher and a 3 GHz pre buncher. We propose a new design for a 50 MeV linac with a RF gun [1]. This study will compare the beam dynamics simulations for the new design and for our previous pre injectors.

RF CAVITY F – 3F

The RF gun F – 3F is integrated in a modulated cavity at sub harmonic frequencies 200 MHz and 600 MHz followed by a drift in order to bunch the beam.

The main difficulty is to adapt the cavity geometry in order to have exactly at harmonic 3: $F_3 = 3 \times F_0$.

Then, in order to be synchronised with the travelling wave section frequency we must obtain: $F_{3GHZ} = 15 \times F_0$.

The electrons emission is produced by a thermoionic cathode implemented inside the RF cavity

The feeding RF power is of 25 kW, the entry accelerating field, at the cathode position, is equal to 1.2 MV/m and the crest field is of 6.5 MV/m.

The grid is modulated at 200 MHz with a pulse length gate of 500 ps, i.e. a phase beam extension equal to 36 degrees. We can then choose the appropriate phase with respect to the RF cavity field.

GENERAL DESCRIPTION OF THE F/3F RF GUN 50 MeV LINAC

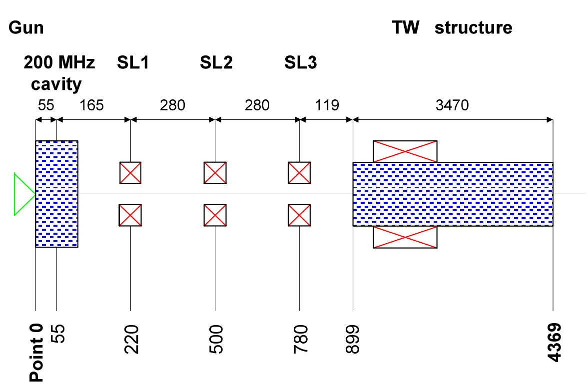

Figure 1: F/3F RF GUN 50 MeV linac (unit in mm).

Figure 1 shows a schematic layout of the F/3F RF gun 50 MeV linac. The subsystems are listed below:

- A RF gun with a thermoionic cathode.
- A 200 MHz/600 MHz cavity.
- Three focusing shielded lenses between the cavity and the accelerating structure.
- A travelling wave accelerating structure.
- A solenoid surrounding the beginning of the structure.

The total length is around 4.4 meters for 50 MeV beam energy. Our previous design for the BESSY II linac at the same energy had a total length of around 8 meters [2].

BEAM DYNAMICS SIMULATIONS

The Gun and the Cavity

The injection line from the gun to the accelerating structure includes the RF cavity with a 25 kW at 200 MHz and a 2.3 kW at 600 MHz.

The drift space between the cavity exit and the RF input of the section is around 900 mm long.

The radial focusing along the drift space is provided by 3 shielded lenses with respectively a magnetic field of 700, 400 and 450 Gauss.

At the cavity exit without space charge, the beam energy varies from 317 keV to 349 keV for a phase extension of 6 degrees at 200 MHz.

Figure 2 shows the phase-energy diagram at 200 MHz cavity exit. For a total charge of 240 pC, the energy varies from 274 keV to 354 keV, an energy spread of 80 keV, for a phase extension of 13 degrees at 200 MHz, i.e. 195 degrees at 3 GHz.

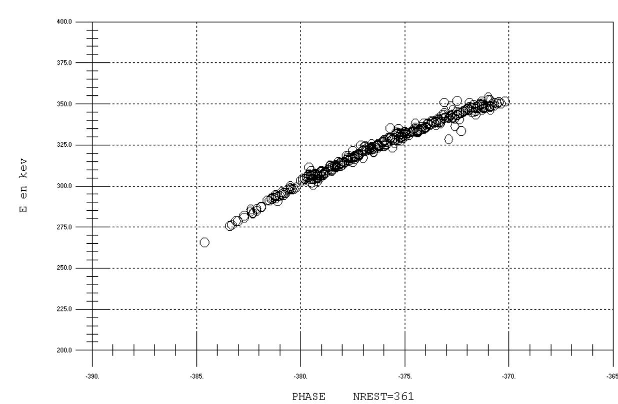

Figure 2: Phase-energy diagram at the cavity exit.

Figure 3 shows the phase-energy diagram at the accelerating structure entry after a drift space of 900 mm. For the phase extension, the same time scale was taken for figures 2 and 3.

After the drift, the phase extension was reduced from 195 degrees to 40 degrees for 91% of the gun charge.

The Accelerating Section

The main accelerating structure is identical to those made for the ALBA and BESSY II pre injectors [3].

Abstract

LUNEX5 (free electron Laser Using a New accelerator for the Exploitation of X-ray radiation of 5th generation) aims at investigating the production of short, intense, coherent Free Electron Laser (FEL) pulses in the 40-4 nm spectral range. It comprises a 400 MeV superconducting Linear Accelerator for high repetition rate operation (10 kHz), multi-FEL lines adapted for studies of advanced FEL schemes, a 0.4 - 1 GeV Laser Wake Field Accelerator (LWFA) for its qualification by a FEL application, a single undulator line enabling advanced seeding and pilot user applications. Different studies and R&D programs have been launched. A test experiment for the demonstration of 180 MeV LWFA based FEL amplification at 200 nm is under preparation, thanks to a proper electron beam manipulation. Specific hardware is also under development such as a cryo-ready 3 m long undulator of 15 mm period.

INTRODUCTION

Since the laser discovery [1] and the first FEL [2] in the infra-red in Stanford on MARK III, followed by the ACO FEL at Orsay [3] in the visible and harmonic generation [4] in the VUV, VUVX light sources are actively developed around the word [5-8]. After the early FEL times, France has remained quite active, with the Super-ACO FEL [9-11] and first user applications [12-14], collaborations on UVSOR [15] and ELETTRA [16]. Besides the CLIO infra-red FEL [17] moved from oscillator to single pass configuration, with a particular interest on seeding schemes (influence of the undulator helicity [18], pulse splitting [19], sidebands [20], seeding with high order harmonics in gas (HHG) [21-23]) and on the transverse properties [24].

The LUNEX5 [25-28] demonstrator (see Fig. 1) aims at exploring several directions for the production of short, intense, and coherent FEL pulses between 40 to 4 nm on the first, third and fifth harmonics.

A 400 MeV superconducting (SC) linac with 2-3 modified XFEL type cryomodules at 1.3 GHz (fed with solid state amplifiers) will enable a CW operation for high repetition rate and multiple users. The qualification of an elementary RF unit with SC cavity, low level RF and solid state amplifier for CW operation is under study. The electron bunch is compressed thanks to a dogleg with sextupoles, enabling phase space linearization and cancellation of the second order dispersion [28]. The gun will be either superconducting [29] or APEX type [30]. In addition, an LWFA [31] based FEL configuration will be explored, requiring a specific beam transfer line able to handle the divergence (1 mrad) and energy spread (1 %) [32-35].

The single FEL line with different cryo-ready undulator segments of 15 and 30 mm period will allow Echo Enable Harmonic Generation (echo) [36] and HHG seeding to be compared for further handling of the spectral and temporal properties. SC linac based FEL calculations anticipate more than 10^{11} photons/pulse and 10^{27}peak brightness on the fundamental wavelength. Two pilot user experiments in gas phase and condensed matter will qualify the FEL performance in the different cases.

After the completion of the LUNEX5 Conceptual design Report at the end of 2011 [25], complementary studies and R&D have been launched.

Figure 1: LUNEX5 sketch: cryomodules (yellow), LWFA laser hutch (grey), undulators (4 radiators and 2 echo modulators) (purple), pilot user experimental sections (green).

SOLEIL STATUS REPORT

A. Nadji, Y.-M. Abiven, N. Béchu, F. Bouvet, P. Brunelle, A. Buteau, L. Cassinari, , M.-E. Couprie, X. Delétoille, C. Herbeaux, N. Hubert, N. Jobert, M. Labat, J.-F. Lamarre, P. Lebasque, A. Lestrade, A. Loulergue, P. Marchand, O. Marcouillé, J.-L. Marlats, L. S. Nadolski, R. Nagaoka, P. Prigent, K. Tavakoli, M.-A. Tordeux, M. Valléau, Synchrotron SOLEIL, Gif-sur-Yvette, France

Abstract

The 2.75 GeV synchrotron light source SOLEIL (France) delivers photons to 27 beamlines and 2 new ones are under construction. The commissioning of the Femtoslicing operation mode involving two beamlines is in progress. The uniform filling pattern is now available to users with a 500 mA stored beam current. The operation of the two canted and long beamlines ANATOMIX and Nanoscopium both using in-vacuum insertion devices (IDs) as a photon source has been raising challenges still under investigation. Upgrades of crucial subsystem equipment like magnet power supplies, storage ring RF input power couplers, and solid state amplifiers are continuing. New user requests for beam stability are under upgrade consideration. Other projects for the storage ring are ongoing such as the design and construction of new insertion devices, new multipole injection kicker, localised small and round photon beam production, as well as R&D on 500 MHz solid-state amplifiers. In parallel first studies for a future upgrade of the machine have been progressing.

OPERATION

Today, 27 beamlines are opened to the users. The last two beamlines ANATOMIX and PUMA, currently under commissioning, will be available to the Users by 2016. Five electron beam filling patterns are routinely delivered during user operation in Top-up injection mode (see Table 1 and Figure 1).

Table 1: Five Different Filling Patterns for SOLEIL Users

Filling pattern	2014 user operation	Achieved ultimate performance
Uniform (416 bunches)	430 mA (one week at 490 mA)	500 mA
Hybrid (312 + 1 bunches)	425 + 5 mA	455 + 5 mA
8 bunches	90 mA	110 mA
1 bunch	16 mA	20 mA
Hybrid Low-Alpha (bunch length/bunch current)	4.7 ps RMS / 65 µA/ bunch	2.5 ps RMS / 10 µA/bunch

In 2014, 6370 hours of beam time have been scheduled shared in 1329 hours for Machine studies and 5041 hours for user operation. A total of 4963 hours were actually issued to the Users which correspond to an availability of the photon beam for the beamlines of 98.5 %.

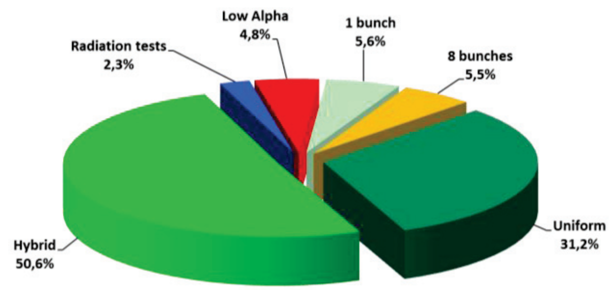

Figure 1: Time distribution of the five filling patterns delivered to Users during 2014.

Over the 35 scheduled weeks, the availability was above 99 % during 21 weeks during 5 of which it was at 100 %. In the very near future, the uniform user operation mode will be delivered with a current of 500 mA.

Operation in this mode has been tested successfully for one week at 490 mA in user operation. In addition, beam current in hybrid mode will be upgraded to 450 mA shortly. The distribution of multibunch mode beam time is different from last year [1]. The hybrid filling pattern is most common, closely followed by the uniform mode while the three other modes are almost at the same percentage as shown in Figure 1. Bunch purity is now maintained to a few 10^{-4} level over a full week thanks to the upgrade of the LINAC bunch cleaner.

As has been the case for the last two years, external electrical power drops are the main source of beam interruption. The main cause is the heavy work around the construction of a new university (Paris-Saclay) nearby SOLEIL. This problem represents 35 % of the beam time lost in 2014. The second main source of beam interruption (15 %) was human errors. Fault rates of equipment are reasonably low as can be seen in Figure 2. In particular, the fraction of lost time due to power supply dysfunctions or failures is drastically reduced compared to the previous years. The Mean Time Between Failures (MTBF) has reached a new record of 75 hours and the Mean Time To Recover (MTTR) has reached 1.09 hour.

Five feedbacks (FB) are simultaneously in operation (Slow Orbit FB, Fast Orbit FB, Transverse FB, Tune FB and Coupling FB). Top-up injection allows constant beam current intensity within ± 0.5 %. The long and short term photon beam position stability is reaching the desired performance. Using global orbit feedback systems, the long term position drift (8 h) is below 1 µm RMS and the short term (0.1 Hz – 1 kHz) vertical noise is below 300 nm RMS. Recently, a regularization of the singular values

LINEAR AND NONLINEAR OPTIMIZATIONS FOR THE ESRF UPGRADE LATTICE

N. Carmignani, L. Farvacque, S. M. Liuzzo, B. Nash, T. Perron,
P. Raimondi, R. Versteegen, S. White, ESRF, Grenoble, France

Abstract

The ESRF storage ring will be replaced in 2020 by a new hybrid multi bend achromat lattice with 134 pm · rad equilibrium horizontal emittance. To determine the best working point, large scans of tunes and chromaticities have been performed, computing Touschek lifetime and dynamic aperture. From different working points, the multi-objective genetic algorithm NSGA-II has been used to optimize the nonlinear magnets values and some linear optics parameters. The analysis have been carried out on lattices with errors and corrections. The optimizations have produced lattices with longer lifetime and larger dynamic aperture for different working points with positive chromaticities.

INTRODUCTION

The ESRF upgrade storage ring will provide x-rays with a 40 times higher brilliance than the present machine, with 5 % coherence at 1 keV [1]. The optics functions of the hybrid multi bend achromat lattice cell are shown in figure 1. The 32-fold symmetry of the lattice is broken at the injection straight section, where the horizontal β function is increased to 18 m, to allow off-axis injection. Touschek lifetime and dynamic aperture are two crucial parameters for lattice design: the first for beam stability and limited losses around the ring [2], the second to increase injection efficiency. The reduced beam size of the upgrade lattice is detrimental for the Touschek lifetime: the scattering rate increases due to the higher bunch density. The dynamic aperture, even if larger in terms of beam size compared to the current machine, is only 10 mm with errors at the injection (8 mm is the minimum required).

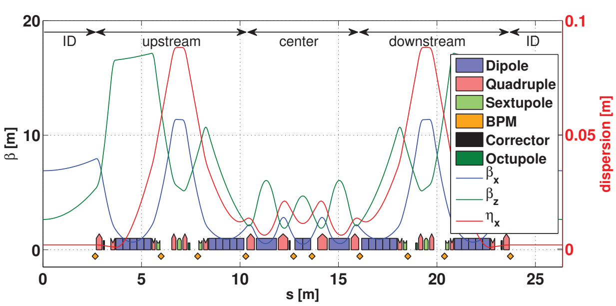

Figure 1: Twiss functions of the ESRF upgrade lattice.

This paper reports the various methods used to optimize the linear and non-linear optics in order to improve the Touschek lifetime and the dynamic aperture. A deterministic technique to partially cancel the effect of the injection cell symmetry breaking will also be addressed.

Simulations

Beam dynamics simulations are done with the Matlab Accelerator Toolbox (AT) [3] [4] [5] and they are designed to exploit the ESRF computer cluster (768, 2GHz cores).

The Touschek lifetime is computed with the Piwinski formula [6], assuming a current per bunch of 0.23 mA. The momentum acceptance computation is limited to four lattice cells, with a loss of only 5% in the accuracy compared to the computation with 32 cells.

Linear optics matching

The linear optics of the cell is obtained putting constraints on the following parameters: the β functions and the dispersion at the focusing sextupoles, in the straight sections and in the middle of the cell, the phase advances between the sextupoles and the total tune of the cell. The target values of this parameters are optimized to improve the properties of the lattice. Nevertheless these modifications have impact on the non-linear optics, demanding for an iterative process of optimization.

LATTICE OPTIMIZATIONS

Working point scan

To determine the optimal tune working point we vary the horizontal and vertical tune over various units and compute the Touschek lifetime and the dynamic aperture, as shown in figure 2.

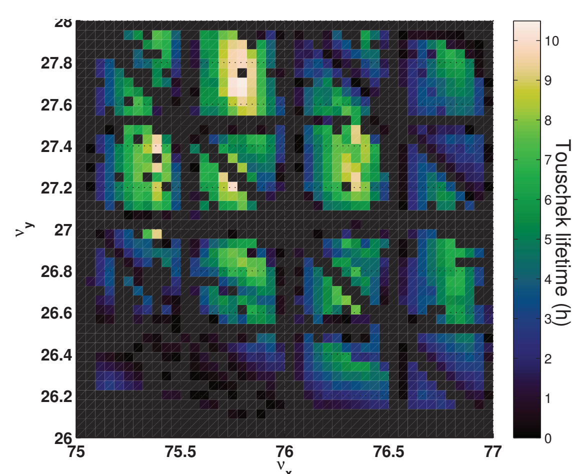

Figure 2: Touschek lifetime for different tunes values.

Keeping the same error seed for the whole scan, at each working point a complete commissioning-like procedure is performed: search for the closed orbit, corrections of orbit, linear optics and coupling [7]. The sextupoles are not

INFLUENCE OF ERRORS ON THE ESRF UPGRADE LATTICE

S.M. Liuzzo, J.C. Biasci, N. Carmignani, L. Farvacque, G. Gatta, G. Le Bec, D. Martin, B. Nash, T. Perron, P. Raimondi, R. Versteegen, S. White, ESRF, Grenoble, France

Abstract

To determine the tolerable alignment and magnetic errors for the ESRF upgrade, we study their influence on Touschek lifetime and dynamic aperture. The correction of each set of errors studied is performed with a commissioning-like procedure, from the search for a closed orbit to the correction of resonance driving terms. Each kind of error is studied independently for each relevant family of magnets. The tolerable values deduced from the analysis are within the practical limits. The impact of the measured and simulated survey errors is also considered, defining the position of the currently installed lattice as the one of least impact for the realignment of X-ray beamlines.

INTRODUCTION

The ESRF Phase II Upgrade storage ring will replace the present light source in 2020, increasing the X-rays brilliance by a factor 40 providing 5% of coherence (at 1 keV) [1]. The chosen lattice for the upgrade is a Hybrid Multi Bend Achromat (HMBA) lattice, with theoretical equilibrium horizontal emittance of 134 pmrad. This lattice is depicted in Fig.1 and features a 32 fold symmetry. The symmetry is broken at the injection straight section to allow for higher beta-functions at the injection point. This insertion has effects on lifetime and dynamic aperture shown in [2]. The sextupoles are located in high dispersion and beta regions (dispersion bumps) and with an almost perfect -I transformation between the first three and last three sextupoles. This allows to cancel the second order sextupolar effects [3]. To enforce this condition in the limited space of the cell, two families of high gradient (91 T/m) focusing quadrupoles (QF6/8) are included together with combined function dipoles (DQ) [4]. To achieve these large fields a smaller bore radius is required and the vertical apertures in the central region of the lattice are reduced to 6.5 mm (10 mm in the rest of the cell). This small aperture and the phase space distortion between the sextupoles lead to strong error sensitivity in this region, mitigated by the smaller equilibrium beam size. To optimize the emittance of the lattice, the first and last two dipoles used in the cell have a longitudinal gradient (DL). In addition one family of octupoles is used to adjust the horizontal detuning with amplitude.

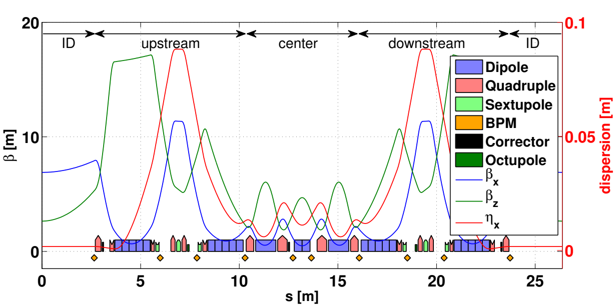

Figure 1: ESRF upgrade unit lattice cell (HMBA).

In this paper we look at the influence of alignment and field errors on lifetime, dynamic aperture and injection efficiency for all the magnets (version S28).

Errors Modeling

The coordinate system used in this document follows the trajectory of the reference orbit. The errors studied for dipoles, quadrupoles, sextupoles, octupoles and girders (support of magnet groups) are:

- transverse displacements Δx (radial) and Δy (vertical)
- longitudinal displacements Δs
- rotation about the beam direction $\Delta\psi$
- integral field errors $\frac{\Delta K_0}{K_0}$, $\frac{\Delta K_1}{K_1}$, $\frac{\Delta K_2}{K_2}$, $\frac{\Delta K_3}{K_3}$
- multipole errors (random and systematic)
- survey errors (random and systematic)

The DL dipoles and DQ dipoles are modeled in the lattice using several separated dipoles. The errors set in these magnets take in account this modeling choice and move the DLs and DQs slices as single magnets. Girder displacements are simulated by systematic movements of all magnets on the same girder. Beam position monitors (BPM) are displaced following the girders. Rotations of the dipoles are included as errors and do not affect the reference orbit.

Lattice Tuning and Correction

Simulations are done using the Accelerator Toolbox [5]. The errors are set for the desired magnet and the correction is performed with all the available correctors in the lattice: three dedicated correctors and six sextupoles with coils for horizontal and vertical steering and skew quadrupole correction. After the application of a procedure to find the closed orbit, the correction is performed following the techniques used in operation for the present accelerator: correction of tunes, orbit, normal and skew quadrupole resonance driving terms [6] and finally chromaticities. The procedure is iterated until convergence. Additional sextupole and octupole corrections are under investigation, together with many other algorithms, to be able to exploit all the available tuning knobs. The final parameters after correction are: rms orbits of ~ 100 µm, rms dispersion < 1 mm in the horizontal plane and ~ 200 µm in the vertical plane, < 1 % β-beating in both planes and the an emittance ratio of ~ 0.1 %. The required correctors strengths are within the power supply limits.

IMPACT OF ERRORS

The conditions to be achieved for a lattice with errors are:

- at least 8 mm of dynamic aperture towards the inner

MODELING OF BEAM LOSSES AT ESRF

R. Versteegen*, P. Berkvens, N. Carmignani, J. Chavanne, L. Farvacque, S.M. Liuzzo, B. Nash, T. Perron, P. Raimondi, K.B. Scheidt, S. White, ESRF, Grenoble, France

Abstract

As the ESRF enters the second phase of its upgrade towards ultra low emittance, the knowledge of the beam loss pattern around the storage ring is needed for radiation safety calculations and for the new machine design optimisation. A model has been developed to simulate the Touschek scattering and the scattering of electrons on residual gas nuclei in view of producing a detailed loss map of the machine. Results of simulation for the ESRF are presented and compared with real beam measurements.

INTRODUCTION

Mapping of the electron beam losses in synchrotron light sources is needed as the beam parameters are pushed and the beam lifetime is reduced to optimise the machine performance for the users. It is necessary to anticipate the protection of various machine equipment and insertion devices from radiation damage. It is also requested from the radiation safety point of view to ensure easy access to the accelerator for maintenance. The tool developed to produce such a detailed description of beam losses, providing the electron loss locations as well as their transverse coordinates and energy when they reach the vacuum chamber aperture, is described in the first part of this paper. Simulations are then compared with experimental data taken on the ESRF storage ring. Finally, the experimental proof of principle of the foreseen collimation scheme for the machine upgrade is presented.

LOSSES FROM RANDOM PROCESSES

Three random interactions are simulated independently: elastic scattering within the bunches (Touschek losses), elastic and inelastic scattering between electrons and residual gas nuclei (Coulomb scattering and Bremsstrahlung).

Touschek losses

The Touschek effect is a large angle Coulomb scattering between two electrons inside a bunch. The transverse momentum is transferred to the longitudinal plane, which leads to the loss of one or both particles because of the limited energy acceptance of the machine [1].

The random particle generation has been developed in Matlab [2], within the Accelerator Toolbox (AT) [3]. In order to save computing resources, the lattice momentum acceptance $\Delta E/E$ is computed beforehand at each longitudinal step ds. Only particles out of the acceptance are generated and tracked to their loss point. Consequently all six coordinates are stored when the particles reach the aperture. The number of particles $N_{p,lost}$ to be generated over the full bunch population N_{tot} is calculated using the theoretical loss rate $1/\tau_T$ as implemented in AT (Piwinski formula [4]):

$$N_{p,lost}(s) = \frac{N_{tot}\mathrm{d}s}{\mathrm{c}}\frac{1}{\tau_T(s)} \tag{1}$$

The initial coordinates of the particles to track $[x\ x'\ y\ y'\ z\ \delta]_{1,2}$ are randomly generated using the 6D beam matrix depending on the position along the lattice and imposing $x_1 = x_2$, $y_1 = y_2$, $z_1 = z_2$. They are selected if the energy deviation resulting from the scattering process exceeds the momentum acceptance. The scattering angle χ and hence the longitudinal momentum kick $\pm\Delta\delta = \pm\gamma v/2|\cos\chi|$ for a colliding pair of electrons are computed according to the Møller differential cross section:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}u} = \frac{8\pi \mathrm{r}_0^2}{(v/\mathrm{c})^4}\frac{u^2-2}{u^3} \tag{2}$$

with $u = \cos\chi$, $v = x_1' - x_2'$ is the relative velocity of the scattering electron pair (neglecting vertical contribution), and r_0 is the classical electron radius.

The random particle generation is repeated until $N_{p,lost}(s)$ is reached. The loss locations are recorded independently from the scattering points to get the full ring loss map.

Vacuum losses

Following the same philosophy as for Touschek losses, collisions of electrons and the residual gas nuclei are simulated randomly in order to accumulate the corresponding contribution to the beam lifetime [5]. Special care was taken to be able to define a varying pressure along the lattice, and to be able to modify the gas composition and pressure locally.

Bremsstrahlung The Bremsstrahlung process is described by the Beithe-Heitler differential cross section:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}|\delta|} = \frac{4\mathrm{r}_0^2 Z^2}{137}\frac{1}{|\delta|}F(|\delta|) \tag{3}$$

with $F(\delta) = \left(\frac{4}{3}(1-|\delta|)+\delta^2\right)\ln\frac{183}{Z^{1/3}}$, Z being the atomic number of the scattering nucleus.

The negative side of the momentum acceptance δ_m is used to compute the number of particles to track by integrating the loss probability for $|\delta| > |\delta_m|$, summing over the gas composition (α_{ij} is the number of nucleus j per molecule i constituting the gas and p_i its partial pressure):

$$\frac{N_{p,lost}}{N_{tot}} = \frac{4\mathrm{r}_0^2\mathrm{d}s}{137}\left(\frac{4}{3}\ln\frac{1}{|\delta_m|}-\frac{5}{6}\right)\sum_j \mathrm{Z}_j^2\ln\frac{183}{\mathrm{Z}_j^{1/3}}\sum_i \alpha_{ij}\frac{\mathrm{p}_i}{\mathrm{kT}} \tag{4}$$

COLLIMATION SCHEME FOR THE ESRF UPGRADE

R. Versteegen*, P. Berkvens, N. Carmignani, L. Farvacque, S.M. Liuzzo, B. Nash, T. Perron, P. Raimondi, S. White, ESRF, Grenoble, France

Abstract

The ultra low emittance foreseen for the ESRF Upgrade will translate into a limited Touschek lifetime, increasing substantially the loss rate around the ring compared to the present machine. Consequently it becomes crucial to know the distribution of electron beam losses to optimize the radiation shielding and to protect the insertion devices from radiation damage. Such loss maps of the storage ring can be produced thanks to the simulation of the Touschek scattering process along the lattice. It is shown that about 80 % of the beam losses can be collimated in a few chosen locations only, keeping the resulting lifetime reduction smaller than 10 %.

INTRODUCTION

The multi-bend achromat lattice of the ESRF upgrade will allow for a reduction of the horizontal emittance down to less than 150 pm.rad [1]. Assuming the same vacuum conditions as today, the beam losses will be dominated by the intra-beam Touschek scattering, implying a reduction of the lifetime by a factor ~ 3 compared to the present machine [2]. A detailed map of beam losses around the ring is necessary to protect the insertion devices and the various machine equipment from radiation damage, as well as to anticipate a proper shielding to guarantee a radiation free zone outside of the accelerator tunnel. For that purpose Touschek scattering has been simulated for the ESRF upgrade lattice using the simulation tool described in [3]. Concentrating most of the losses in a few locations only using scrapers would be highly desirable for radiation handling. The model and simulation results for the new lattice are introduced in the first part of this paper, before describing the collimation scheme. Detailed 6D coordinates of lost electrons on the machine physical aperture are available thanks to the tracking of scattered particles. As shown in the last part, these are valuable input for the collimators' shape optimization regarding the resulting radiation shower.

ESRF UPGRADE BEAM LOSSES

The ESRF upgrade lattice is made of thirty-two cells. The strict periodicity is broken first by the two non standard injection cells where the optics is optimised to allow off-axis injection, and second by the RF cavities, located in three distinct straight sections (cells 5, 7, 25). The physical aperture considered in the model is simplified to three regions plus the injection straight section (see Fig. 1). They correspond to the high betatron functions (β) regions on both sides of the regular cells, the central part with low β (a smaller bore radius is necessary for the high gradient quadrupoles), and the straight sections where the aperture is defined by the Insertion Devices (IDs). To figure the presence of in-vacuum undulators, some parts of the straight sections have a vertical aperture as small as ±3 mm. The main horizontal aperture restriction is at the septum location on the inside of the ring. The model contains either rectangular or elliptical aperture depending on the location.

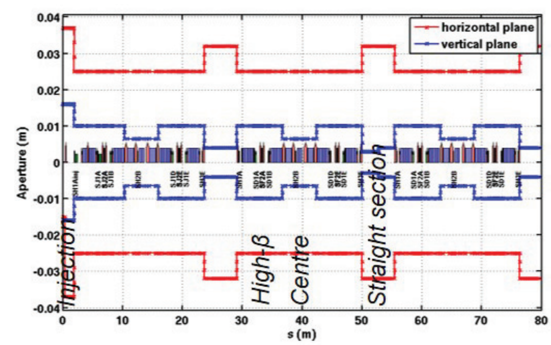

Figure 1: Physical aperture limits of the ESRF upgrade lattice cells. Dipoles, quadrupoles and sextupoles are figured by blue, magenta and green rectangles respectively.

The simulated Touschek loss map is shown in Fig. 2 for the lattice without errors, starting from the injection point. It assumes a vertical emittance of 5 pm.rad and 0.23 mA per bunch, leading to a Touschek lifetime of about 45 h. Each peak corresponds to a physical element of maximum 0.5 m length (including drift spaces).

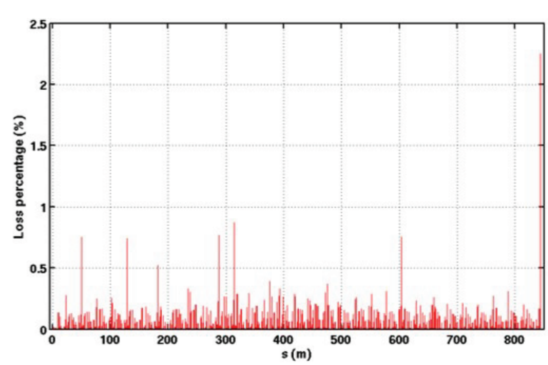

Figure 2: Touschek losses along the lattice without errors.

The highest peaks correspond to the in-vacuum IDs locations, except the last one at s ≈844 m corresponding to the septum blade. Apart from these specific locations arising because of a smaller physical aperture, the effect of the periodicity breaking of the lattice functions is not so strong thanks to the careful nonlinear optics matching [2]. In Fig. 3 the losses of all cells are stacked over one machine period,

PROGRESS REPORT OF THE BERLIN ENERGY RECOVERY PROJECT bERLinPro*

M. Abo-Bakr#, W. Anders, A. Burrill, A. Büchel, K. Bürkmann-Gehrlein, P. Echevarria, A. Frahm, H.-W. Glock, A. Jankowiak, C. Kalus, T. Kamps, G. Klemz, J. Knobloch, J. Kolbe, J. Kühn, O. Kugeler, B. Völker, Helmholtz-Zentrum Berlin, Berlin, Germany.

Abstract

The Helmholtz Zentrum Berlin is constructing the Energy Recovery Linac Project bERLinPro on its site in Berlin Adlershof. The project is intended to expand the required accelerator physics and technology knowledge mandatory for the design, construction and operation of future synchrotron light sources. The project goal is the generation of a high current (100 mA), high brilliance (normalized emittance below 1 mm mrad) cw electron beam at 2 ps rms bunch duration or below.

The planning phase of the project is completed and the design phase of most of the components is finished. Many of them have already been ordered. After some delay the construction of the building has started in February 2015. The status of the various subprojects as well as a summary of current and future activities will be given. Major project milestones and details of the project time line will be finally introduced.

INTRODUCTION

In 2008 the Helmholtz-Zentrum Berlin (HZB) submitted a proposal to build an ERL test facility to investigate its potential as accelerator technology for "Next Generation Multi User Synchrotron Light Sources". In October 2010 the Helmholtz Association approved the proposal, the official project started in the beginning of 2011.

The bERLinPro [1] layout as a single-pass ERL is shown in Fig. 2, together with the project's basic set of parameters. The 6.5 MeV bERLinPro injector consists of a 1.3 GHz, 1.4 cell SRF gun, followed by a booster module containing three 2-cell-cavities. The beam is merged into the main linac via a dogleg merger and accelerated by three 7-cell sc cavities to 50 MeV. Following recirculation via a racetrack, the decelerated beam is dumped in a 650 kW, 6.5 MeV beam dump. Space is provided in the return arc to install future experiments or insertion devices to demonstrate the potential of ERLs for user applications.

A staged installation of bERLinPro is planned, initially focused on the development and successful operation of a high current SRF gun. Depending on the availability of the 100 mA, full current Gun-2 in this first installation phase, called "banana", a medium to full current from the gun will be accelerated in the booster, characterized and optimized and finally sent to the dumpline. The maximum kinetic energy is 6.5 MeV, since the linac is not yet installed at this time. For the second "recirculation" stage the main linac and the recirculator will be installed and commissioned to demonstrate efficient energy recovery of the full current, 50 MeV beam.

In the next sections progress of the various subproject groups within the last 12 months will be presented together with an updated project time line.

PHOTOCATHODE R&D

As quantum efficiency, intrinsic emittance, temporal response and operational lifetime of the photocathode are key issues for the bERLinPro photoinjector a cathode preparation and characterization test lab has been established at HZB, where various kinds of cathodes can be produced and tested (see Fig. 1). A promising candidate to fulfil the requirements for an electron source is the bi-alkali antimonide CsK_2Sb [2]. An in-situ preparation and surface analysis system for CsK_2Sb photocathodes was commissioned at HZB since October 2014 and first samples have been very recently prepared with the sequential growth procedure. The lab operates two chambers: the preparation chamber, equipped with an effusion cell for Sb and with SAES alkali metal dispensers for K and Cs and the surface analysis chamber, equipped with a SPECS PHOIBOS 100 electron analyzer. An X-ray source for XPS and He ion source for LEIS are also attached to the analysis chamber, as well as an additional port for

A CANTED DOUBLE UNDULATOR SYSTEM WITH A WIDE ENERGY RANGE FOR EMIL

J. Bahrdt, H.-J. Bäcker, W. Frentrup, C. Rethfeldt, M. Scheer, B. Schulz, S. Gottschlich
Helmholtz-Zentrum Berlin, Germany

Abstract

At BESSY II a canted double undulator system for the Energy Materials In-situ Laboratory EMIL is under construction. The energy regime is covered with two undulators, an APPLE II undulator for the soft and a cryogenic permanent magnet undulator CPMU-17 for the hard photons. The layout and the performance of the undulators are presented in detail. The minimum of the vertical betatron function is shifted to the center of the CPMU-17. The neighboring quadrupoles and an additional quadrupole between the undulators control the vertical betatron function. Prior to the undulator installation a testing chamber with four movable vertical scrapers has been implemented at the CPMU-17 location. Utilizing the scrapers the new asymmetric lattice optics will be tested and optimized.

INTRODUCTION

EMIL, the Energy Material in-situ Laboratory at BESSY II, is under construction. The facility offers the tools for in-situ and in-system X-ray analysis of materials and devices for photovoltaic applications and for (photo-) catalytic processes. Spectroscopic methods such as PES, PEEM, HAXPES, XES, XAS, XRF, XRD are well suited for the investigation of sample structures with arbitrary depth information between a few nanometer and the micrometer regime. The EMIL laboratory is described in detail in [1]. Two canted undulators deliver photons over a wide energy regime: An APPLE II undulator for soft X-rays (80 eV- 2.2 keV) and a planar CPMU for hard X-rays up to 8 keV. Two beamlines including a double crystal monochromator (hard photons) and a collimated plane grating monochromator with variable deflection angle (soft photons) distribute the light to various end stations. The short period small-gap undulator CPMU-17 will be operated in a mini-beta section to mitigate deleterious effects to the storage ring performance and to avoid beam scraping with the magnets.

MINI-BETA-SECTION

The implementation of short-period small-gap undulators into low energy storage rings requires specific lattice modifications to maintain the beam lifetime at the reduced vertical aperture. Small-gap undulators installed in dedicated mini-beta section are in operation at the NSLS X-ray ring for many years [2]. At BESSY II it was decided to shift the waist of the vertical betatron function to the center of the cryogenic undulator. Asymmetric detuning of the neighbouring quads and an additional quad between the undulators permit a minimum aperture of 5 mm. The lattice modification and the asymmetric re-wiring of the adjacent multipoles are described in detail in [3] [4]. The modified optics without the central quad was already tested with beam. Meanwhile, the central quad and a testing chamber at the location of the CPMU-17 are installed. The chamber is equipped with four vertical scrapers for the detection of the vertical aperture at two locations which gives information about the size and the gradient of the vertical betatron function. The undulators are canted by an angle of 2 mrad which is accomplished with an electromagnetic coil integrated into the central quad. Space for a replacement with permanent magnet 1-mrad-steerers at a later time is foreseen. The 1-mrad kicks are generated from the steerer coils integrated in the neighbouring sextupoles.

UE-48 APPLE II UNDULATOR

The UE-48 is an APPLE II undulator with full polarization control (see Fig. 3). The low photon energy device is designed to cover the range between 80 eV (including the Si L II/III-edge at 99eV) and 2.2 keV (including the Si-K- edge at 1839eV) with the harmonics 1-7. The parameters are listed in Table 1.

Table 1: Parameters of the UE-48

Period length	48 mm
Number of periods	29, symmetric endpoles
Minimum magnetic gap	15 mm nominal
Gap between mag. rows	0.8 mm
Operational modes	Elliptical, inclined, universal
Magnets	$Nd_2Fe_{14}B$, transversally pressed in a dye
A-magnet (long. magn.)	1.28 T / 1670 kA/m
B-magnet (vert. magn.)	1.33 T / 1275 kA/m
B_{eff} (hor. lin. / hel. / vert. lin. / inclined 45°)	0.791 T / 0.626 T / 0.535 T / 0.443 T

The magnets were sorted with respect to systematic production errors, glued to pairs (one A- and one B-magnet) and finally machined before magnetization. The pairs were magnetized in a 45° oriented magnetic field where the easy orientations of the individual magnets determined the individual block magnetization orientation. This procedure will be described in detail in a separate publication.

BNL ATF II BEAMLINES DESIGN *

M.Fedurin[#]*, Y. Jing, D. Stratakis, C. Swinson, BNL, Upton, NY, 11973, USA*

Abstract

The Brookhaven National Laboratory. Accelerator Test Facility (BNL ATF) is currently undergoing a major upgrade (ATF-II). Together with a new location and much improved facilities, the ATF will see an upgrade in its major capabilities: electron beam energy and quality and CO_2 laser power. The electron beam energy will be increased in stages, first to 100-150 MeV followed by a further increase to 500 MeV. Combined with the planned increase in CO_2 laser power (from 1-100 TW), the ATF-II will be a powerful tool for Advanced Accelerator research. A high-brightness electron beam, produced by a photocathode gun, will be accelerated and optionally delivered to multiple beamlines. Besides the energy range (up to a possible 500 MeV in the final stage) the electron beam can be tailored to each experiment with options such as: small transverse beam size (<10 um), short bunch length (<100 fsec) and, combined short and small bunch options. This report gives a detailed overview of the ATF-II capabilities and beamlines configuration.

UPGRADE TO ATF II

The Accelerator Test Facility was established over a quarter of a century ago [1]. For more than two decades it has served national and international accelerator scientists, through a proposal-driven, program committee reviewed process that makes beams available to a broad community of users from Academia, U.S. National Laboratories, Accelerator Facilities and Small Businesses. The ATF offers the state-of-the-art tools that are required by its user community, including sources of high-brightness electron beams and synchronized high-power laser beams [2]. While making these available for accelerator science R&D, the ATF continuously upgrades, reinvents and revamps these tools.

The current experiment program has e-beam only (Wake Field Acceleration in Quasi Non-linear Plasma and Dielectrics [3,4], THz radiation in dielectrics [5]),

Table 1: Projected Beam Parameters

Parameter	Expected Value
Energy	0-150 MeV
Maximum charge	3 nC
Normaliazed emittance	1 mm-mrad
Bunch current	100 A
Compressed bunch	1700 A
Compressed bunch length	10 fsec

combined laser and e-beam (Inverse FEL acceleration and X-ray generation from non-linear Inverse Compton Source [6,7]) and laser only experiments (Ion Acceleration [8]).

The ATF upgrade is focused on three principal components: electron accelerator, CO_2 laser, and experiment area. The plan for the CO_2 laser is to increase power from the present 1 TW to 100 TW and the experiment hall area will increase to seven times it's the size of that available at the current ATF. A detailed description of the electron accelerator upgrade will be discussed here, with specific focus on beamline configuration.

GENERAL BEAMLINE DESIGN

The ATF II electron accelerator will succeed the present ATF electron beam generation technology. The electron source will continue to be a photocathode electron gun (pioneered at the ATF). The fourth harmonic of an Nd:YAG laser, incident on a copper cathode, yields 5E-3 e^-/γ at the present ATF. This gives a high-brightness electron beam with peak current of 100 A and 1 μm

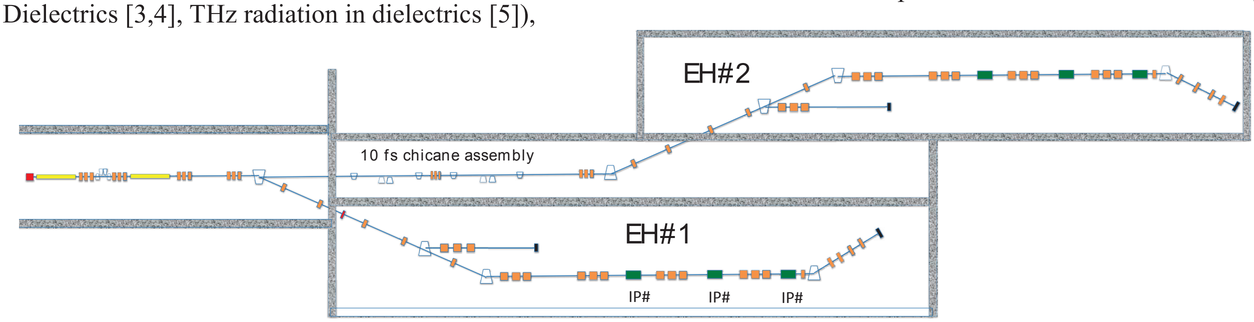

Figure 1: Schematic view of ATF II beamline configurations.

A NEW METHOD TO GENERATE ULTRASHORT AND COHERENT PULSES OF SHORT-WAVELENGTH SYNCHROTRON RADIATION*

S. Khan†, Center for Synchrotron Radiation (DELTA), TU Dortmund University, 44227 Dortmund, Germany

Abstract

A laser-based method to generate ultrashort pulses of synchrotron radiation in electron storage rings is coherent harmonic generation (CHG) using two undulators to produce coherent radiation at harmonics of the initial laser wavelength by microbunching. The bunching factor and thus the pulse intensity, however, decreases exponentially with increasing harmonic order. Echo-enabled harmonic generation (EEHG), proposed in 2009 as FEL seeding scheme, can be used to produce short synchrotron radiation pulses at higher harmonics, but requires three undulators in a straight section. In this paper, a less space-consuming method based on seeding with intensity-modulated laser pulses is introduced, which also has the potential of significant bunching factors at high harmonics.

INTRODUCTION

The advent of linac-based free-electron lasers (FELs) with extremely intense and ultrashort pulses in the femtosecond range has opened up new opportunities for time-resolved studies of ultrafast atomic phenomena. However, only four FELs with sub-visible wavelengths have yet been commissioned and they are essentially single-user facilities with 5-120 bunches (or bunch trains) per second [1–4]. On the other hand, synchrotron light sources based on electron storage rings serve many users simultaneously with a typical bunch rate of 500 MHz and very stable beams, but the pulse duration is 30-100 ps (FWHM). With more than 50 synchrotron light sources in operation worldwide [5], it is worthwhile to investigate methods to extend their capabilities towards shorter pulse duration and higher peak intensity.

In an electron storage ring, the synchrotron motion translates a natural energy spread of typically $\sigma_E \approx 10^{-3}E$ (rms) into a bunch length, depending on the radiofrequency (RF) voltage and momentum compaction factor $\alpha \approx (\Delta L/L)/(\Delta E/E)$. A strong reduction of α at the expense of bunch charge and beam emittance is used at several synchrotron light sources to shorten the bunches to a few picoseconds, see e.g. [6].

SHORT-PULSE GENERATION

Rather than shortening the bunches further, the femtosecond regime is more easily accessible by extracting synchrotron light from a short fraction, a "slice", of the bunch. A femtosecond laser pulse co-propagating with an electron bunch through an undulator (the "modulator") tuned to the laser wavelength causes a sinusoidal modulation of the electron energy within the bunch slice. Femtosecond laser pulses are typically generated by Ti:sapphire lasers at a wavelength of 800 nm (photon energy $E_\mathrm{P} = 1.55$ eV). With a pulse energy E_L in the mJ range ($\approx 10^{16}$ eV) and a pulse duration around $\sigma_\mathrm{L} \approx 20$ fs (rms), the modulation amplitude [7]

$$\Delta E \approx 0.2\,\sqrt{E_\mathrm{L} E_\mathrm{P}}\,\sqrt{M_\mathrm{U}/M_\mathrm{L}} \qquad (1)$$

will exceed the natural energy spread of the electron beam. The expression is valid as long as the number of undulator periods M_U is smaller than the number of optical cycles $M_\mathrm{L} = 2\sqrt{2\ln 2}\,c\,\sigma_\mathrm{L}/\lambda_\mathrm{L}$ per FWHM pulse length.

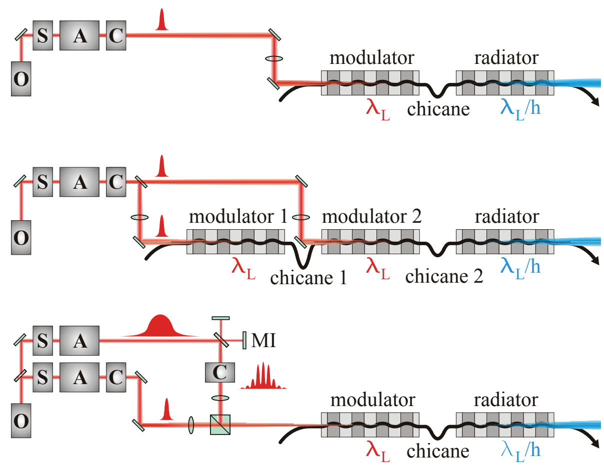

Figure 1: Top: Coherent harmonic generation (CHG) using a laser-induced electron energy modulation in an undulator ('modulator'), converted to a density modulation in a chicane and coherent radiation in a second undulator ('radiator'). Center: Echo-enabled harmonic generation (EEHG) based on laser-electron interaction in two modulators. Bottom: New method with laser-electron interaction at different times in the same modulator. Also shown: laser oscillator (O), stretcher (S), amplifier (A), compressor (C), and Michelson interferometer (MI).

One way to exploit the energy modulation in a second undulator (the "radiator") is to transversely displace the off-energy electrons in dipole magnets, providing a spatial separation between the short radiation component from the slice and the long component from the rest of the bunch [8–11]. Another method making use of the laser-induced energy modulation is known as coherent harmonic generation (CHG) [12–15], see Fig. 1 (top). Here, a density modulation (microbunching) is created by energy-dependent path length differences in a magnetic chicane, allowing to generate coherent radiation at harmonics of λ_L in the radiator. The

CHARACTERIZATION AND OPTIMIZATION OF ULTRASHORT AND COHERENT VUV PULSES AT THE DELTA STORAGE RING*

S. Khan†, F. H. Bahnsen, M. Bolsinger, S. Hilbrich, M. Höner, M. Huck, C. Mai,
A. Meyer auf der Heide, R. Molo, H. Rast, G. Shayeganrad, P. Ungelenk,
Center for Synchrotron Radiation (DELTA), TU Dortmund University, 44227 Dortmund, Germany
H. Huck, Deutsches Elektronen-Synchrotron Zeuthen, 15738 Zeuthen, Germany

Abstract

At DELTA, a 1.5-GeV synchrotron light source operated by the TU Dortmund University, a source for coherent and ultrashort vacuum-ultraviolet (VUV) and terahertz (THz) pulses is now in operation. The VUV source is based on a laser-induced energy modulation and coherent harmonic generation (CHG). A subsequently developing dip in the longitudinal electron distribution gives rise to coherent THz radiation. Recent results regarding the optimization of the laser-electron interaction and characterization of the CHG pulses are presented.

INTRODUCTION

Synchrotron radiation with short wavelengths is the standard tool to study the structure of matter on the atomic level. However, synchrotron radiation pulses with a duration of 30 to 100 ps (FWHM) are too long to study dynamic processes such as chemical reactions, phase transitions, fast magnetic changes, etc. which take place on the sub-picosecond scale. The femtosecond regime, on the other hand, has been made available by mode-locked lasers at near-visible wavelengths which are not suitable to probe inner atomic shells or to provide spatial resolution on the atomic scale.

The need for radiation with short wavelength *and* short pulse duration has prompted new developments such as the free-electron laser (FEL) providing extremely brilliant short-wavelength radiation with femtosecond pulse duration. To date, four linac-based FEL facilities at short wavelengths are in single-user operation (FLASH, LCLS, SACLA, and FERMI) while more than 50 synchrotron light sources worldwide [1] supply multiple beamlines simultaneously with brilliant and tunable radiation. It is therefore worthwhile to study methods which allow to generate shorter pulses at conventional synchrotron light sources.

SHORT-PULSE GENERATION

Some methods to generate sub-ps radiation pulses at storage rings are borrowed from FEL seeding schemes using a femtosecond laser pulse to modulate the energy of electrons within a short "slice" at the center of a long electron bunch. In a subsequent undulator, a short radiation pulse is emitted from the slice together with a long pulse from the rest of the bunch. Off-energy electrons are either transversely displaced in order to separate the short and long components of incoherent undulator radiation spatially ("femtoslicing" [2]) or a magnetic chicane may convert the energy modulation into a density modulation (microbunching) giving rise to a short pulse of coherent radiation at harmonics of the laser wavelength [3]. As long as the signal-to-background ratio

$$\frac{P_{\text{short}}}{P_{\text{long}}} = \frac{n_{\text{short}}^2\, b_h^2}{n_{\text{long}}} = f^2\, n_{\text{long}}\, b_h^2 \quad \text{with} \quad f \equiv \frac{n_{\text{short}}}{n_{\text{long}}} \qquad (1)$$

is tolerable, no geometric separation is required. Here, $f \approx 10^{-3}$ is the ratio between the number of electrons in the slice and in the bunch, and b_h is the bunching factor for harmonic number h. With $n_{\text{long}} = 10^{10}$, as an example, $b_h = 0.1$ would yield an excellent signal-to-background ratio of 10^2. This scheme is known as coherent harmonic generation (Fig. 1 a). Here, the bunching factor decreases with increasing harmonics as $b_h \sim \exp(-h^2)$. In contrast to that, echo-enabled harmonic generation (EEHG, Fig. 1 b) [4] involving a two-fold energy modulation is able to generate higher harmonics according to $b_h \sim h^{-1/3}$.

Further downstream along the storage ring, the energy-dependent electron path length leads to a dip in the longitudinal electron distribution giving rise to coherent THz radiation [5].

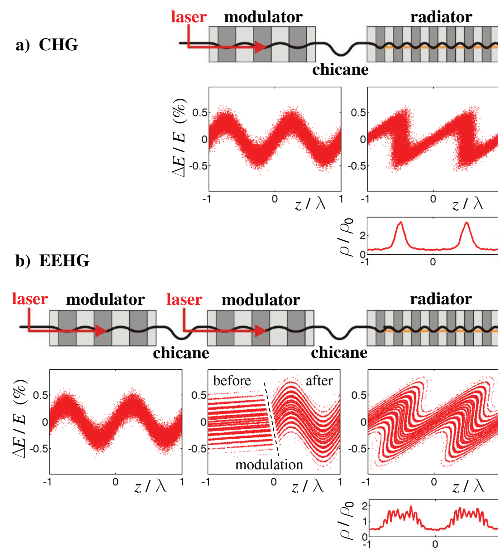

Figure 1: Short-pulse schemes a) CHG and b) EEHG with respective electron distributions in phase space (relative energy deviation $\Delta E/E$ versus longitudinal coordinate z in units of the laser wavelength λ) and electron density $\rho(z/\lambda)$.

A STEP CLOSER TO THE CW HIGH BRILLIANT BEAM WITH THE ELBE SRF GUN-II

R. Xiang#, A. Arnold, P. Michel, P. Murcek, J. Teichert, HZDR, 01328 Dresden, Germany
P. Lu, H. Vennekate, TU Dresden & HZDR, 01328 Dresden, Germany

Abstract

In order to achieve the CW electron beam with a high average current up to 1 mA and a very low emittance of 1 µm, an improved superconducting photo-injector (SRF Gun-II) has been installed and commissioned at HZDR since 2014. This new gun replaces the first 3.5-cell SRF gun (SRF Gun-I) at the SC Linac ELBE. The RF performance of the niobium cavity has been evaluated, the beam parameters for low charge bunches have been measured, and the first beam has been guided into the ELBE beam line. The results agree with the simulation very well. The photocathode transfer system has been installed for the first high current beam test planned in 2015. However, the unexpected strong degradation on the cavity and also on the photocathode was found soon after the first photocathode exchange. In this contribution the results of the SRF Gun-II commissioning and the latest experiment will be presented in detail.

MOTIVATION

The development of top quality photocathode electron guns has become one of the key technologies for modern light sources and large collide facilities based on electron accelerators. There are several successful photo-gun types for various facility requirements [1], like DC guns, rf guns, SRF guns [2] and so on. The Rossendorf SRF Gun-I successfully operated for the radiation source ELBE at HZDR from 2007 to 2014. To achieve higher current and lower beam emittance, a new 3+1/2-cell niobium cavity with a superconducting solenoid and a new 13 MHz laser have been recently developed.

SRF GUN-I

The SRF Gun-I developed within a collaboration of the institutes HZB, DESY, MBI and HZDR has been operated for the supercondctung linac ELBE since 2007 [3] (Fig.1). With the Cs_2Te photocathode driven by a 13 MHz UV laser, the SRF gun produced beams up to 400 µA. The maximum energy of the electron beam reached 3.3 MeV, bunch charge 400 pC and transverse emittance was 3±1 mm mrad with 80 pC bunch charge. In April 2013 the first IR-FEL succeeded in ELBE driven by SRF Gun-I [4].

SRF Gun-I was at the same time a test bench for the SRF gun techniques, CW beam diagnostics and normal conducting photocathode materials:

- The principle concept of SRF cavity with normal conducting photocathode works practically well.
- There is no obvious degradation found in the cavity quality (Fig.2). E_{acc} reached 6.5 MV/m in CW mode, and 8 MV/m in pulsed mode, corresponding to peak field on axis E_{peak} 17.5 MV/m and 22 MV/m, respectively.

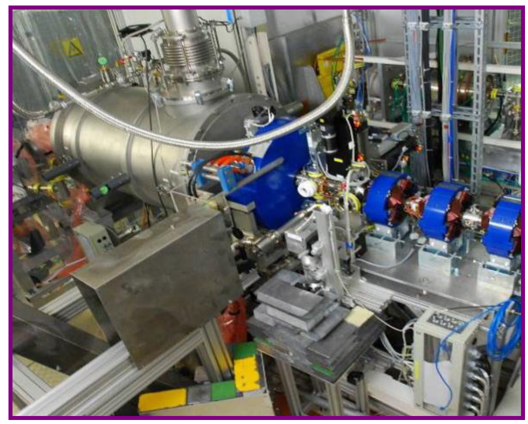

Figure 1: SRF gun-I with the diagnostic beam line.

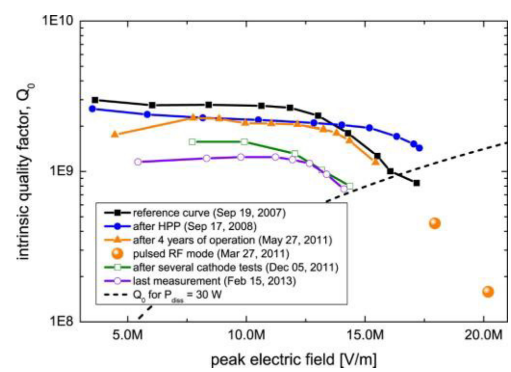

Figure 2: RF measurement result for SRF Gun-I shows that the cavity with cathode inside has the quality factor Q_0 as same as the virgin cavity

- Performance of Gun-I cavity is limited by strong field emission; half-cell is the weak point for the mechanical stability and Lorenz force detuning.
- Multipacting appears mostly in the photocathode area; bias voltage is able to suppress the multipacting.
- LN_2-cooled photocathode works in gun for a long life time; photocathode exchange can be performed in short time without cavity warming up; However, photocathode itself and the exchange process must be particle free.
- RF-focusing, solenoid compensation and proper laser shaping are helpful methods for the emittance compression, but a high acceleration gradient at

BEAM HEAT LOAD ANALYSIS WITH COLDDIAG: A COLD VACUUM CHAMBER FOR DIAGNOSTICS

R. Voutta *, S. Casalbuoni, S. Gerstl, A. W. Grau, T. Holubek, D. Saez de Jauregui, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany
R. Bartolini, M. P. Cox, E. C. Longhi, G. Rehm, J. C. Schouten, R. P. Walker, Diamond Light Source, Oxfordshire, England
M. Migliorati, B. Spataro, INFN/LNF, Frascati, Italy

Abstract

The knowledge of the heat intake from the electron beam is essential to design the cryogenic layout of superconducting insertion devices. With the aim of measuring the beam heat load to a cold bore and understanding the responsible mechanisms, a cold vacuum chamber for diagnostics (COLDDIAG) has been built. The instrumentation comprises temperature sensors, pressure gauges, mass spectrometers and retarding field analyzers, which allow to study the beam heat load and the influence of the cryosorbed gas layer. COLDDIAG was installed in the storage ring of the Diamond Light Source from September 2012 to August 2013. During this time measurements were performed for a wide range of machine conditions, employing the various measuring capabilities of the device. Here we report on the analysis of the measured beam heat load, pressure and gas content, as well as the low energy charged particle flux and spectrum as a function of the electron beam parameters.

INTRODUCTION

Superconducting insertion devices (IDs) can generate higher magnetic fields than permanent magnet IDs with the same gap and period length, increasing the photon flux and the brilliance. The cryogenic design of superconducting IDs requires the knowledge of the beam heat load to the cold vacuum chamber. Potential beam heat load sources are synchrotron radiation, geometric and resistive wall impedance, and electron and/or ion bombardment. To understand the discrepancies between the calculated predictions and the beam heat load observed in several devices [1–3], a cold vacuum chamber for beam heat load diagnostics (COLDDIAG) has been built [4]. After its installation in the Diamond Light Source (DLS) storage ring in September 2012, the beam heat load, pressure and gas content, and the low energy charged particle flux and spectrum have been measured during user operation and in dedicated machine physics sessions until August 2013. A subsequent offline calibration of the beam heat load measurements [5] has been performed in order to remove the contribution of the thermal transitions to the beam heat load from the measurements, which turned out to be about half of the total measured heat load. In the following we present some of the main results from the beam heat load analysis of the data taken with COLDDIAG at the DLS.

* robert.voutta@kit.edu

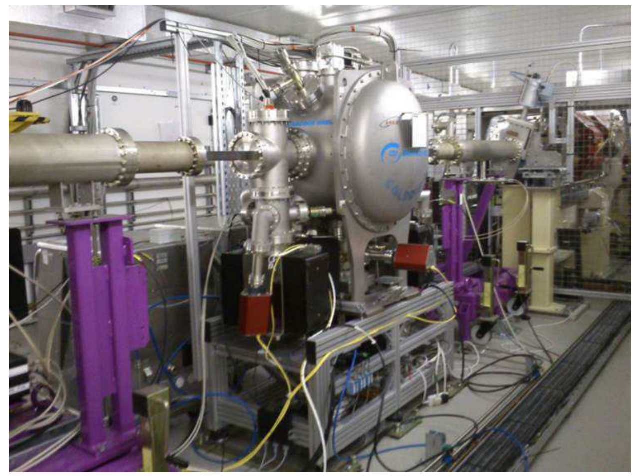

Figure 1: COLDDIAG installed in the DLS storage ring.

EXPERIMENTAL SETUP

COLDDIAG is composed of three sections, an upstream and downstream warm section and a cold section in between. The cold section is cooled down by a Sumitomo RDK-415D cryocooler to a base temperature of about 4 K. Each section is equipped with a diagnostic port, providing a retarding field analyser (RFA), a residual gas analyser (RGA) and a pressure gauge. Eight temperature sensors in each warm section and 24 temperature sensors in the cold section allow to record the temperature distribution along the beam tube (liner) and in the cold UHV chamber. The beam heat load is calibrated using 6 heaters attached to the liner, one in each warm section and four in the cold section. The heaters in the cold section can also be used to regulate the temperature of the cold liner to a specific temperature (usually 20 K) during operation. Two additional heaters, one at each thermal transition to the cold liner, were installed after the removal from the DLS in order to reproduce the temperatures at the thermal transitions during the measurements in an offline calibration. Figure 1 shows COLDDIAG installed in a straight section of the DLS storage ring.

BEAM HEAT LOAD

The beam heat load was measured during user operation and in various machine physics sessions, scanning a wide range of machine parameters. The measurements discussed here were performed with the liner at a fixed temperature

SIMULATION OF OPTICAL TRANSPORT BEAMLINES FOR HIGH-QUALITY OPTICAL BEAMS FOR ACCELERATOR APPLICATIONS*

J. Bödewadt†, N. Ekanayake, DESY, Hamburg, Germany

Abstract

High-quality optical beams play already an important role in the field of particle accelerators which will most probably become even more prominent in the view of laser-driven particle accelerators. Nowadays, optical transport beamlines are needed for particle generation in photo injectors, for particle acceleration in laser-driven plasma wakefield accelerators, for particle beam diagnostics such as synchrotron radiation monitoring systems, or for particle manipulation schemes e.g. for external seeding of free-electron lasers. For the latter case, also the photon beam transport to the user end-stations requires dedicated optical beamlines. The utilized wavelengths range from the hard x-ray up to the far-infrared spectral range. Parameters such as surface quality, polarization effects, in- and out-of-vacuum damage thresholds, mechanical stability, dispersion effect, etc. need to be studied for the variety of applications. Here, we present the simulation results of the optical transport beamline for the seeding experiment at the free-electron laser FLASH and give a comparison to our measurement results.

INTRODUCTION

Designing optical systems for the application in particle accelerators needs to fulfill a variety of different demands. Especially the transport of high-quality laser beams for particle beam production or manipulation required detailed planning and quality control to achieve the desired properties. One example for the application of lasers in particle accelerators is the external seeding of free-electron lasers (FEL). The idea is to use the laser to manipulate the beam properties of an ultra-relativistic electron beam such that it efficiently generates very intense and fully coherent radiation pulses in the soft and hard x-ray spectral ranges. The interaction of the laser and the electron beam takes place in an undulator magnet which deflects the electron beam to an undulatory trajectory leading to a non-zero transverse velocity components. This, in turn, allows the interaction of the electrons with the electric field of the laser beam.

Seeding Experiment

Since 2010 an experimental setup for seeding has been installed at the FEL facility FLASH at DESY [1]. Initially installed for the investigation of direct FEL seeding [2] it also allows for the study of other schemes such as high-gain harmonic generation (HGHG) [3] or echo-enabled harmonic generation (EEHG) [4].

SEED LASER INJECTION SYSTEM

The seed laser utilized in the seeding experiments at FLASH is a commercial, solid-state, Ti:sapphire system based on the chirped-pulse amplification technique (CPA) and consists of a mode-locked oscillator and a flash-lamp-pumped amplifier system (regenerative and booster) [5]. The system is capable of generating ultrashort laser pulses up to 50 mJ with 60 fs (FWHM) duration at a 10-Hz-repetition rate and a center wavelength of 800 nm. In 2012, a new laser transport beamline has been installed to inject ultraviolet (UV) laser pulses at a wavelength of 266 nm [6]. The generation of the UV pulses is done by frequency tripling (THG) of near-infrared Ti:sapphire laser pulses. Currently, the THG setup is located in the accelerator tunnel and placed under vacuum as shown in Figure 1. After UV generation, four mirrors (labeled M1 to M4) are used to steer the UV beam onto the electron beam axis without any refocusing of the UV beam. The longitudinal focus position is controlled by the NIR focusing into the THG setup. A half-wave plate allows for polarization control and a 1-mm-thick crystalline quartz window (QW) divides the ultra-high machine vacuum from the vacuum of the THG setup.

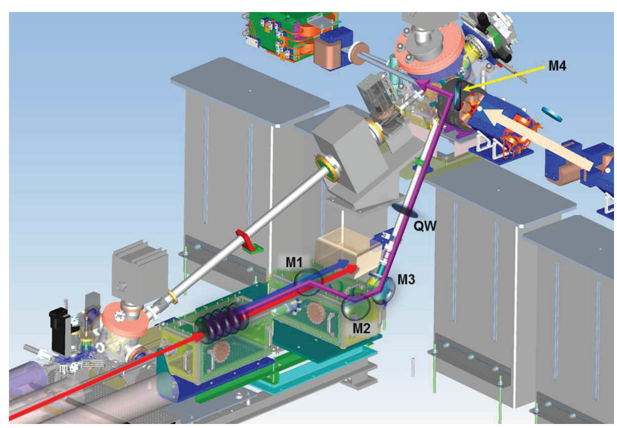

Figure 1: Seed laser injection setup. The NIR pulses arrive at the THG setup located in the accelerator tunnel inside high-vacuum chambers. The generated UV beam is steered with four mirrors onto the electron beam axis. The ultra-high vacuum of the machine is separated by a 1-mm-thick crystalline quartz window (QW).

Beam Polarization

For planar undulators, only the electric field component parallel to the deflection plane of the undulator couples to the electron beam. Therefore, the beam polarization of the

SIMULATION RESULTS OF THE BEAM TRANSPORT OF ULTRA-SHORT ELECTRON BUNCHES IN EXISTING BEAM TRANSFER LINES TO SINBAD

U. Dorda, R. Assmann, K. Floettmann, B. Marchetti, Y. Nie, J. Zhu, DESY, Hamburg, Germany

Abstract

SINBAD, the upcoming accelerator R&D facility at DESY, will host multiple independent experiments on the production and acceleration of ultra-short bunches including plasma wakefield experiments. As a possible later upgrade the option to transport higher energy electrons (up to 800MeV) or positrons (up to 400MeV) from the existing DESY Linac II to the facility is studied. Though existing a possible connection using e.g. a part of the DESY synchrotron as a transfer line and a currently unused transfer-line, these machines were not designed for the desired longitudinal bunch compression and high peak current required by e.g. beam driven plasma wake-field experiments. Simulation results illustrate the modifications to the current layout that would have to be implemented and the corresponding achievable beam parameters.

INTRODUCTION

The SINBAD project [1] aims to set up a dedicated accelerator R&D facility in the former DORIS facility at DESY, Hamburg. This facility will contain multiple independent experiments in the context of advanced, compact acceleration concepts like plasma wake field (PWFA) or dielectric acceleration for ultrafast science. While there will be a dedicated linac for ultra-short bunches, it's energy will be limited to about 200 MeV. The aim of this study is to investigate if the existing Linac II can be used to accelerate electrons to 800 MeV and to subsequently transport them through existing beam lines to SINBAD. Provided that a sufficiently high beam current could be delivered, this would allow to perform e.g. beam driven plasma wake field experiments and FEL seeding studies. Additionally Linac II is capable of producing 400 MeV positrons which is only possible at very few facilities worldwide. While the maximal achievable positron beam current will not be too high, proof of principle experiments of acceleration in a PWFA could be performed as a first step of studying possible future PWFA-based high energy colliders.

Figure 1 shows the existing beam transport system from the electron gun to the SINBAD facility passing through Linac II, the "Positron Intensity Accumulator" (PIA) ring, the "L-weg", the DESY II synchrotron, the "R-Weg" and finally half of the former DORIS arc. As the lines up to including the DESY II, are used as injector chain to the Petra III synchrotron light source, it must be assumed that no significant modifications interfering with the standard operation can be implemented. On the other hand, the R-Weg and the final former DORIS arc serve no other purpose and are free to be modified. Initially it was studied if an existing, empty direct tunnel from the PIA ring to the R-Weg (see dotted line in Figure 1) could be used instead. This option had to be discarded as the dispersion created by the 90 degree dipole of PIA could no be closed and thus the subsequent long straight section would result in a very large linear momentum compaction factor R56 (the 56 element of the linear transfer matrix R). Furthermore, while the tunnel was originally foreseen for beam transport, by now constructional modifications imply that the radiation protection shielding is no longer sufficient.

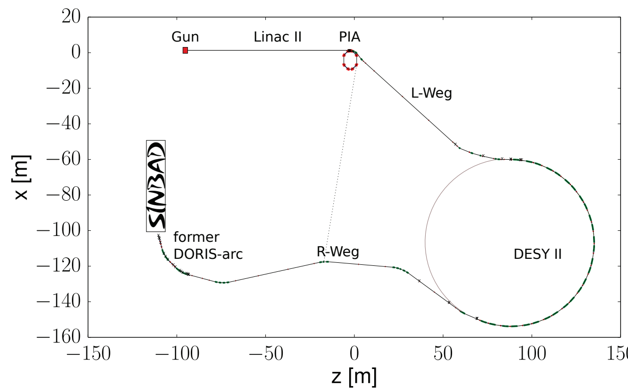

Figure 1: The geometric layout of the beam transport system from the electron gun of Linac II up to the SINBAD facility.

Using an unmodified PIA ring-optics and the corresponding section of the DESY ring-optics as transfer-line, the overall optics from the end of the Linac II to SINBAD would result in the very large R56-transfer matrix element (R56 > 150m). It is therefore obvious that significant changes must be implemented to be able to deliver bunches with a reasonable bunch length.

MODIFIED BEAM OPTICS

In a first step the optics of each part was optimized for a small linear momentum compaction (R56) and only then the second order elements (T566) were accounted for. The R56 element of a transfer line is (mainly) determined by the dispersion D in the dipoles and the dipole strength $1/\rho$ ($R56 \propto D \cdot \rho$). While the arrangement and properties of the dipoles is fixed by machine geometry, altering the beam optics allows to modify the dispersion function and thus the overall R56 element.

Gun & Linac

While the electrons at Linac II were until very recently extracted from an old DC-gun with a subsequent bunching cavity, an upgrade to add a second additional DC-gun has

ARES: ACCELERATOR RESEARCH EXPERIMENT AT SINBAD

B. Marchetti, R. W. Assmann, C. Behrens, R. Brinkmann, U. Dorda, K. Floettmann, J. Grebenyuk, M. Huening, Y. Nie, H. Schlarb, J. Zhu, DESY, Hamburg, Germany

Abstract

ARES is a planned linear accelerator for R&D for production of ultra-short electron bunches. It will be hosted at the SINBAD facility, at DESY in Hamburg [1]. The goal of ARES is to produce low charge (0.2 - 50 pC), ultra-short (from few fs to sub-fs) bunches, with high arrival time stability (less than 10fs) for various applications, such as external injection for Laser Plasma Wake-Field acceleration [2]. The baseline layout of the accelerator foresees an S-band photo-injector which compresses low charge electron bunches via velocity bunching and accelerates them to 100 MeV energy. In the second stage, it is planned to install a third S-band accelerating cavity to reach 200 MeV as well as two X-band cavities: one for the linearization of the longitudinal phase space (subsequently allowing an improved bunch compression) and another one as a Transverse Deflecting Cavity (TDS) for longitudinal beam diagnostics. Moreover a magnetic bunch compressor is envisaged allowing to cut out the central slice of the beam [3] or hybrid bunch compression.

INTRODUCTION

Ultra-short electron bunches, having a RMS length below 1 fs, are of great interest for various applications. First of all they can be used for ultrafast science, for example to generate ultra-short radiation pulses or to run electron diffraction experiments. Moreover they are expected to allow superior performances when injected into novel compact accelerating structures (e.g. based on Plasma Wake-Fields Acceleration). Besides studying novel acceleration techniques aiming to produce high brightness short bunches, the ARD group at DESY is working on the design of a conventional RF accelerator that will be hosted at SINBAD (Short and INnovative Bunches and Accelerators at Desy). ARES (Accelerator Research Experiment at Sinbad) will allow the production of such ultra-short bunches and the direct experimental comparison of the performance achievable by using different compression techniques. At a later stage ARES will be used to inject ultra-short electron bunches into laser driven Plasma Wake-field Accelerator.

Limits for the Bunch Length Compression

The factors limiting the minimum bunch length in the field of linear accelerators are well known. The main limitation is the space charge repulsion among the electrons in the bunch. As the effect scales as γ^{-2} (with γ being the relativistic factor of the beam), it limits the maximum electron densities especially at low energies [4].

The next limitation is set by the sinusoidal shape of the RF fields or the non-linear space charge force causes non-linear distortions of the distribution of the electrons in the longitudinal phase space [5]. Also a magnetic chicane or a dogleg, when present, contains non-linear dispersion terms that increase the longitudinal emittance of the beam. Additionally, when the magnetic compression is considered, Coherent Synchrotron Radiation (CSR) further spoils the longitudinal emittance of the beam [6].

Finally the uncorrelated energy spread of the beam, which is related to the minimum achievable spot size of the laser at the photo-cathode plays also a minor role in the optimization [7].

At ARES we plan to accelerate electron bunches with very low charge (0.2 - 50 pC)[1] to moderate energy levels (100-200 MeV) and to compress them to fs and sub-fs bunch-duration.

The chosen energy range allows to relax the space charge limitation, that characterizes the low energy accelerators (3-5 MeV), while dealing with a considerably more compact and relatively simple accelerator than the high energy (>1 GeV) user facilities.

LAYOUT OF THE ACCELERATOR

The project is foreseen to be realized in several stages. In this paper we will refer to two main stages of the installations. A baseline layout will allow the production of ultra-short bunches thanks to the velocity bunching compression technique [8]. The upgraded layout will allow to compress the beam also with the slit method [3] and by using an hybrid velocity bunching scheme. The introduction of a linearizing cavity is also foreseen.

Baseline Layout

Table 1: Main Accelerator Parameters

Parameter	Baseline Layout	Upgraded Layout
Main RF Frequency	2998 MHz	2998 MHz
Rep. Rate	10 Hz	10 Hz
N. of bunches	1	1
Final e- energy	100 MeV	200 MeV
Bunch charge	0.2 pC - 50 pC	0.2 pC - 1nC
Arrival time stability	<50 fs	<10 fs

The baseline layout of ARES is represented in Fig. 1 while a summary of the main accelerator parameters is presented in Table 1. The electron bunch will be generated by photo-emission from a Cs2Te or metallic cathode embedded in a 1.5 cells, 2.998 GHz frequency, RF gun of the REGAE type [9]. An emittance compensating solenoid having about 0.3 T peak field is placed at the gun exit. The first accelerating

[1] Some of the experiments planned at a later stage in the SINBAD facility would benefit from the use of high charge electron bunches, therefore we plan to make possible the extraction up to ~ 1nC charge from a Cs2Te cathode.

COMPRESSION OF AN ELECTRON-BUNCH BY MEANS OF VELOCITY BUNCHING AT ARES

B. Marchetti, R. W. Assmann, U. Dorda, J. Grebenyuk, J. Zhu, DESY, Hamburg, Germany

Abstract

ARES is a planned linear accelerator for research and development in the field of production of ultra-short electron bunches. The goal of ARES is to produce low charge (0.2 - 50 pC), ultra-short (from few fs to sub-fs) bunches, with improved arrival time stability (less than 10 fs) for various applications, such as external injection for Laser Plasma Wake-Field acceleration. The ARES layout will allow to perform and compare different kind of conventional e-bunch compression techniques, such as pure velocity bunching, hybrid velocity bunching (i.e. velocity bunching plus magnetic compression) and pure magnetic compression with the slit insertion. This flexibility will allow to directly compare the different methods in terms of arrival time stability and local peak current. In this paper we present simulation results for the compression of an electron bunch with 0.5 pC charge. We compare the case of pure velocity bunching compression to the one of a hybrid compression using velocity bunching plus a magnetic compressor.

INTRODUCTION

Ultra-short electron bunches, having a RMS length below 1 fs, are of great interest for various applications. First of all they can be used for ultrafast science, for example to generate ultra-short radiation pulses or to run electron diffraction experiments. Moreover they are expected to allow superior performances when injected into novel compact accelerating structures (e.g. based on Plasma Wake-Fields Acceleration) [1]. Besides studying novel acceleration techniques aiming to produce high brightness short bunches, the ARD group at DESY is working on the design of a conventional RF accelerator that will be hosted at SINBAD (Short and INnovative Bunches and Accelerators at Desy) [2]. ARES (Accelerator Research Experiment at Sinbad) [3] will allow the production of such ultra-short bunches and at a later stage it will be used to inject ultra-short electron bunches into laser driven Plasma Wake-field Accelerator.

One of the characteristics of this accelerator is that it will allow the direct experimental comparison of the performance achievable by using different bunch length compression techniques. In this paper we will focus on the pure velocity bunching and hybrid compression techniques, while we refer the reader to references [4] and [5] for more information about the working points using the magnetic compression and the study of the arrival time stability of the beam.

SIMULATIONS

The elements of ARES which are relevant for the simulations presented in this paper are shown in Fig. 1. In particular we select 4 locations that will be important in the following plots:

- Z1, located at 12.9m and corresponding to the exit of the linac in the baseline layout;
- Z2, located at 18.3m and corresponding to the entrance of the section that matches the beam to the dogleg;
- Z3, located at 21.2m, i.e. the dogleg entrance;
- Z4, located at 30.2m, i.e. the dogleg exit.

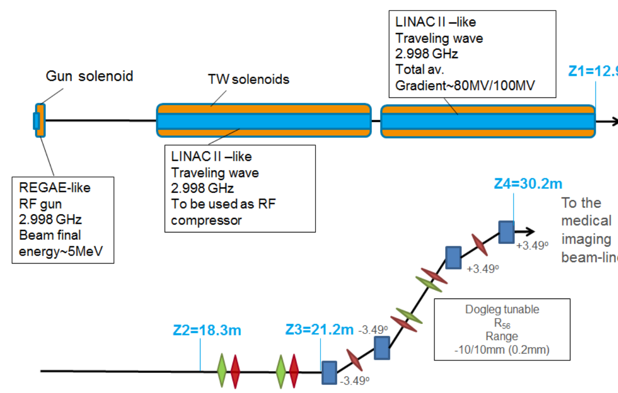

Figure 1: Elements of the ARES beam-line, which are relevant for the simulations described in this paper.

Pure Velocity Bunching

Injecting a not ultra relativistic electron bunch into a RF cavity close to the 0 phase of the electric field, where the head of the bunch sees a lower field amplitude than the tail, the beam is compressed because of the induced velocity chirp. Since the average velocity of the bunch is less than the velocity of the RF field, the first slips along the second, moving towards the crest. In this way it is possible to compress and accelerate an electron bunch at the same time.

In 2010 it has been firstly experimentally shown that it is possible to compress a beam with this technique while controlling the transverse emittance oscillations, through the so-called emittance compensation method [6].

The transverse dynamics of a beam accelerated along a constant focusing channel is described by the envelope equation [7]. Any mismatch between the space charge correlated forces and the external focusing leads to slice envelope oscillations that cause oscillations of the transverse normalized emittance. By properly matching the beam with the focusing channel surrounding the RF compressor it is possible to get close to the invariant envelope beam solution of the envelope equation, that minimizes the transverse emittance growth [8].

COMPRESSION OF TRAIN OF BUNCHES WITH RAMPED INTENSITY PROFILE AT SPARC_LAB

B. Marchetti, DESY, Hamburg, Germany
E. Chiadroni, M. Ferrario, R. Pompili, INFN/LNF, Frascati, Italy
A. Bacci, INFN, Milano, Italy
A. Cianchi, Universitá Tor Vergata, Roma, Italy

Abstract

The production and acceleration of train of bunches with variable spacing in the ps/sub-ps range having ramped intensity profile are interesting to drive a plasma wave in the so-called resonant Plasma Wake-Fields Acceleration (r-PWFA) [1]. At *SPARC_LAB* trains having a constant intensity profile have been produced for the first time by using a shaped photo-cathode laser combined with the use of the velocity bunching compression technique [2–4]. If the sub-bunches have ramped intensity, i.e. they have different charge density, the space charge force affects differently the development of the longitudinal phase space of each one of them during the compression. In this paper we present preliminary simulations for the compression of a ramped train of bunches. The differences between the beam dynamics for a train of bunches having constant intensity profile and the ramped train are underlined. We discuss also the possibility of properly tuning the shaping of the photocathode laser to balance the space charge effect.

INTRODUCTION

Research and Development in the field of Plasma Wakefield Acceleration (PWFA) [5] spread worldwide in the last decades because of the promising results obtained by pioneering experiments such as Ref. [6, 7]. This technique foresees the generation of extremely high (~ GV/m) accelerating gradients having extremely short period (ps or sub-ps) thanks to the creation of a plasma wave in a gas excited by a laser pulse (Laser driven plasma Wake-Field Acceleration - LWFA) or by a particle beam (beam driven Plasma Wake-Field Acceleration).

The use of a train of bunches allows to overcome the main disadvantage of the beam driven acceleration with respect to the laser driven one, i.e. the necessity of a relatively big linac that accelerates the electrons driving the plasma wake-field. Indeed the accelerating field driven by the electron bunch can be increased by resonantly driving the wave through a modulation of the current of the driver.

The transformer ratio of the process is defined as the ratio of the maximum voltage that can be gained by a trailing particle to the voltage lost by a particle in the drive bunch. It can be maximized by using ramped bunch trains as a driver [8].

Nevertheless the beam dynamics of trains of pulses is extremely delicate and the tuning of one parameter (sub-bunch length, sub-bunch transverse emittance, relative spacing) at the entrance of the plasma chamber requires a re-adjustment of the train starting from the photo-cathode.

In this paper we show how it is possible to match a ramped comb driver beam at the exit of the linac by properly shaping the transverse spot size of the different sub-bunches. This method appears to be easy to implement in a realistic experimental setup.

SIMULATIONS

SPARC_LAB Layout

In Fig. 1 the layout of the *SPARC_LAB* facility is shown. The linear accelerator is constituted by a Sband RF gun of the SLAC/UCLA type followed by 3 Sband travelling wave cavities. At the end of the linac is foreseen to be placed a plasma chamber for a beam driven plasma experiment. After the gun there is a short space available for the installation of a linearizing cavity. This element is crucial for obtaining a periodic train spacing after the RF compression. In the following we will include an Xband linearizer located at this position.

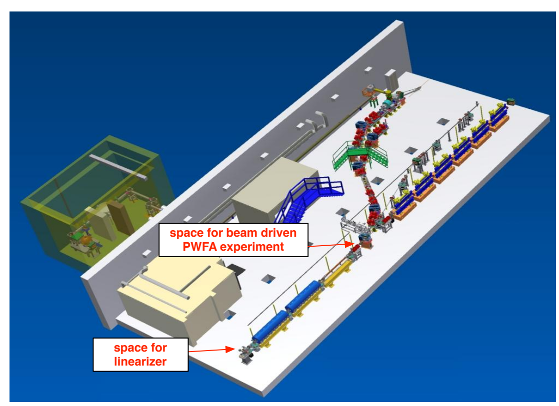

Figure 1: Layout of *SPARC_LAB*.

Compression of a Train of Bunches with Velocity Bunching

At *SPARC_LAB* train of bunches are realized by illuminating the photo-cathode with a longitudinally modulated laser [9–11] , the so-called comb pulse. In this configuration the electrons of each sub-bunch experience a large longitudinal space charge field with a linear correlation along the sub-bunch. The work done by the space charge force produces an energy modulation within the sub-bunch that can be transformed into a density modulation by an RF compressor.

PROGRESS IN THE INJECTOR UPGRADE OF THE LINAC II AT DESY

Y.C. Nie#, M. Hüning, C. Liebig, M. Schmitz, DESY, Hamburg, Germany

Abstract

A new injection system is under development for the LINAC II at DESY to improve the reliability of the machine and mitigate the radiological problem due to electron losses at energy of hundreds of MeV. It consists of a 100 kV triode DC gun, a 2.998 GHz pre-buncher, a novel 2.998 GHz hybrid buncher, and the dedicated beam transport and diagnostic elements. As the key components, the pre-buncher and the hybrid buncher realize a two-stage velocity bunching process including the ballistic bunching and the phase space rotation. Therefore, they produce a certain number of well-bunched 5 MeV micro-bunches from the input 2 ns-50 ns electron pulse for the downstream LINAC II. The overall upgrade plan, developments of the critical components, as well as the latest beam test results will be reported.

OVERALL INJECTOR UPGRADE

The layout of LINAC II at DESY and its injector upgrade are shown in Fig. 1 [1, 2]. LINAC II provides 450 MeV electrons for the light source PETRA III at the moment. Moreover, it has great potential to provide higher energy electron bunches (e.g. 800 MeV) for the Helmholtz distributed ARD facility SINBAD [3]. Within LINAC II, sections 1-3 are surrounded by solenoids with the maximum magnetic field of 0.08 T. The solenoid fields of sections 6 and 7 can reach 0.4 T in the case of positron operation. In addition, there are quadrupoles for the beam transport from the electron gun to PIA.

The new injector of LINAC II has been constructed and is being tested. Its main components are: an 100 kV DC triode gun that delivers 2-50 ns long electron pulses, a 2.998 GHz pre-buncher, a 2.998 GHz hybrid buncher consisting of both standing-wave (SW) and travelling-wave (TW) cells enclosed by a focusing solenoid, a dogleg that serves as an energy filter and delivers the electrons into the old gun beamline, 6 distributed quadrupoles, and a number of diagnostic instruments including 4 toroids, 6 beam position monitors and 4 fluorescent screens with 4 faraday cups inside. The old gun is kept as a reserved electron source. In a long term plan, it might be replaced with a photoinjector to produce ultra-short bunches. To make the coexistence of the two injectors possible, section 2 has been replaced by a beam transport line.

KEY COMPONENTS

For the injector, the critical problem is how to capture the non-relativistic electrons and bunch the ns long pulses into a certain number of micro bunches with high efficiency. Therefore, a two-stage Velocity Bunching (VB) strategy is employed. The first stage, i.e. the ballistic bunching is realized by the one-cell pre-buncher that operates at 90° ahead of the RF crest to introduce a primary velocity modulation. In the second stage, the phase space rotation [4] is used. It is an alternative to the magnetic compressor to provide high brightness ultra-short electron bunches that are required for FELs and some advanced accelerator concepts, such as the bunch-driven plasma wakefield accelerators. In our case, the hybrid buncher is used. The key issue is optimizing the injection phase and controlling the dephasing process that depends on the injection energy. If the injection energy is too low, the beam may transit across the RF crest, and then the de-bunching process occurs. To avoid this case, the one-cell SW section should have sufficient electric field to accelerate the incoming electrons rapidly.

In ASTRA [5] simulations, the wave phase of the hybrid buncher were optimized to make the output bunch length shortest. Here, the wave phase refers to the phase at the time $t = 0$ when the electrons start to be emitted at the cathode, denoted by Φ_0. Figure 2 shows the evolution of the bunch length σ_z versus the longitudinal position at different Φ_0. It can be seen that the optimal wave phase that gives the shortest bunch is -42°. When the bunch is compressed too fast, like in the case of Φ_0 = -60°, the different longitudinal slices can crossover each other, as a result, the bunch length increases again after reaching the minimum value. If the bunch is compressed too slowly, like in the case of Φ_0 = -20°, the bunching will be frozen before having reached the maximum compression due to the acceleration. In the case of Φ_0 = -42°, the bunch is compressed to the minimum length and then the longitudinal waist is frozen, since the beam velocity has become close enough to the RF phase velocity.

Figure 3 shows variations of the momentum gain rate dP_z/dz and the relativistic velocity $\beta = v/c$ along with the longitudinal position for the synchronous electron in the centre of one micro bunch, from the entrance of the pre-buncher to the exit of the hybrid buncher. It can be seen that the synchronous electron has been neither accelerated nor decelerated after the pre-buncher. In contrast, in the hybrid buncher, it is accelerated rapidly by the SW cell from β = 0.54 to 0.75, and to 0.995 at the end of the TW section. The evolution of the momentum gain in the TW section implies that the bunch undergoes a dephasing process while being both accelerated and bunched over the first several cells, and then becomes approaching the crest of the wave mainly for accelerating. Such a combination is ideal to produce well-bunched relativistic electron bunches for the downstream LINAC II. Note that the field distribution in the hybrid buncher is not ideally flat in reality. However, the residual field unflatness after tuning is acceptable in the viewpoint of the beam dynamics performance, as illustrated in [6, 7].

STATUS OF THE SOFT X-RAY FREE ELECTRON LASER FLASH

Mathias Vogt, Bart Faatz, Josef Feldhaus, Katja Honkavaara, Siegfried Schreiber, Rolf Treusch,
DESY, Hamburg, Germany

Abstract

The superconducting free-electron laser FLASH at DESY routinely produces up to several thousand photon pulses per second with wavelengths in the soft X-ray and XUV regime and with energies up to 0.5 mJ per pulse. In 2014 the assembly of a second undulator beamline, FLASH2, was finished. Recommissioning of the FLASH linac and the original FLASH1 beamline was finished already end of 2013 and the commissioning of FLASH2 started in February 2014. Only a few weeks have been reserved for dedicated set up of FLASH2, and most of its commissioning has been performed parasitically during the FLASH1 user run. The first beam was extracted through the septum to the FLASH2 beamline on March 4th, 2014, and the first lasing of FLASH2 at a wavelength of about 40 nm was achieved on August 20th, while FLASH1 was lasing simultaneously with 250 bunches at 13.5 nm. We summarize here the status of the FLASH2 commissioning and the FLASH1 operation during its 5th user period.

INTRODUCTION

The soft X-ray SASE FEL FLASH [1–4] at DESY in Hamburg, Germany is driven by a normal conducting RF photo cathode gun (RF-gun) and a superconducting linac consisting of seven 1.3 GHz accelerating modules with eight TESLA-type 9-cell cavities each. The superconducting modules are capable of producing 800 μs long accelerating flat tops every 100 ms. The UV injector lasers [5] and the Cs_2Te photo cathode [6] are in their standard set up capable of producing 800 μs long pulse bursts of 800 pulses (1 MHz) at 10 Hz. FLASH is therefore ideal for an upgrade to share the long bunch trains between multiple beamlines and thus serve several FEL user experiments simultaneously at 10 Hz burst repetition rate. The accessible wavelength range produced by the FLASH1 undulator is 4.2 nm up to 52 nm. Every year FLASH attracts more users than could possibly be served with only one undulator beam line. A selection of publications based on science at FLASH can be found in [7]. In 2012 and 2013 a new second beam line, FLASH2 [8, 9], was built. Its commissioning started in February 2014. A detailed overview over the history of the FLASH facility can be found in [1]. A schematic layout of the facility with its common parts, i.e. RF-gun, first acceleration stages, two magnetic chicanes (“bunch compressors”), 3rd harmonic compression linearization and the main linac (four acceleration modules), the extraction switch yard and the two beam lines FLASH1 and FLASH2 is shown in Fig. 1. A more detailed description of the layout and a table of typical run parameters can be found in [2].

FLASH1 USER OPERATION AND HIGHLIGHTS OF STUDIES

In 2014 about 4200 h ($\approx$ 50% of the total year) were dedicated to user operation, roughly 3400 h ($\approx$ 40%) for machine development, photon beamline commissioning and general accelerator studies, and approximately 1200 h ($\approx$ 10%) for shutdown mantenance and commissioning. The overall down time over the ca. 7800 h of scheduled operation was $\approx$ 4.5%. Routinely, high SASE energies with up to several hundreds of μJ or alternatively short photon pulses (< 50 fs) were achieved for 10 to 4000 pulses per second. In April 2014 the RF coupler window of the RF-gun was changed because of a developing vacuum leak. The unavoidable reconditioning of the window affected the FEL operation in so far that the initial RF pulse duration did only allow for about 30 bunches per train over the first three weeks and that it took another month to reach 400 bunches [2]. Since June 2014 however, the RF-gun is running very stable with a gradient at the cathode of about 53 MeV/m (corresponds to about 4.8 MW of forward power) and 470 μs flat top.

Using a new third injector laser, capable of producing pulses of only about 1 ps duration, lasing was achieved in single spike mode, i.e. with 3 to 5 fs long photon pulses [10]. The group performing seeding experiments in the FLASH1 e^- beamline has recently achieved HGHG seeding around 38 nm with an energy contrast of about 1000 [11]. Although seeding experiments so far were all performed during dedicated studies, schemes for quasi-parasitic operation parallel to FLASH1 user operation are under preparation [12]. With the increased requirements on beam quality and reproducibility (e.g. for seeding and multi beamline operation) and given the fact that optics perturbations are known to exist in the FLASH injector, it became necessary to start a campaign on optics consolidation [13]. A progress report of the optics studies is given in [14]. Since autumn 2013 accelerator modules are regulated by a sophisticated MTCA.4 based LLRF system [15, 16]. The RF-gun was upgraded to the MTCA.4 in January 2015 [17, 18].

The 5th user period finished in the end of April 2015 and after a short shutdown in May the 6th user period will start in June 2015. The three week shutdown in May is dedicated to complete the radiation shielding in the area between the FLASH1 and FLASH2 tunnels, including survey and realignment of the undulator and photon beamlines.

FLASH2 COMMISSIONING & PARALLEL OPERATION OF TWO BEAMLINES

To preserve as much FLASH1 user time as possible, only very little dedicated FLASH2 commissioning time was allocated. First beam passed the septum on March 4th, 2014 and

STATUS OF THE RECOMMISSIONING OF THE SYNCHROTRON LIGHT SOURCE PETRA III

R. Wanzenberg#, M. Bieler, M. Ebert, L. Fröhlich, J. Keil, J. Klute, G. Kube, G. K. Sahoo,
DESY, Hamburg, Germany

Abstract

At DESY the Synchrotron Light Source PETRA III has been extended in the North and East section of the storage ring to accommodate ten additional beamlines. The PETRA ring was converted into a dedicated synchrotron light source from 2007 to 2009. Regular user operation started in summer 2010 with a very low emittance of 1 nm at a beam energy of 6 GeV and a total beam current of 100 mA. All photon beamlines were installed in one octant of the storage ring. Nine straight sections facilitated the installation of insertion devices for 14 beam lines. Due to the high demand for additional beamlines the lattice of the ring was redesigned to accommodate 10 additional beamlines in the future. In an one year long shut-down two new experimental halls were built. The recommissioning of PETRA III started in February 2015. We are reporting the current status of the synchrotron light source including the performance of the subsystems.

PETRA III

PETRA was originally built as an electron – positron collider and was operated from 1978 to 1986 in this mode. From 1988 to 2007 PETRA was used as a preaccelerator for the HERA lepton hadron collider ring at DESY. After the end of the HERA collider physics program the PETRA ring was converted into a dedicated 3rd generation synchrotron radiation facility, called PETRA III [1]. Beam operation started in 2009 [2] and all 14 beamlines are operational since 2011. Due to the high demand for additional beamlines the lattice of the ring was redesigned to accommodate 10 additional beamlines in the framework of the PETRA III extension project [3, 4, 5]. User operation ended in February 2014 and the short user run of only four weeks can be considered as an extension to the long run period which started back in 2013. It was also the last user operation before a long shut down period of about one year which was started to implement the facility extension project.

General Layout of the PETRA III Extension

Two tunnel sections about 80 m long in the North and the East of the PETRA ring were completely reconstructed and new experimental halls were built to extend the PETRA III synchrotron light facility. In the future more light will be available for users at 10 new beamlines in addition to the already existing 14 beam lines in the Max von Laue experimental hall. The location of the new halls is shown in Fig.1. A detailed layout of the hall North of the PETRA extension is shown in Fig.2. The original plan to reuse the existing accelerator tunnel [3, 4] was not implemented since a new tunnel section is advantageous for the installation of the front end components of the beamlines. The decision to completely reconstruct the tunnel sections was one of the reasons to revise also the project schedule.

Figure 1: Layout of PETRA III. Two new halls in the North and East have been added.

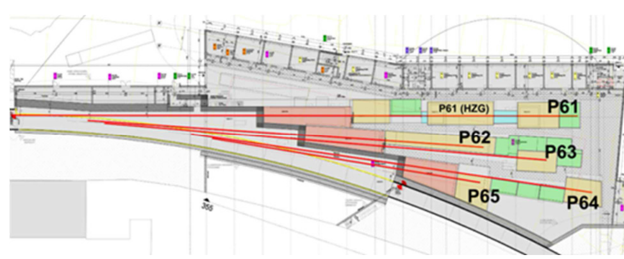

Figure 2: Hall North of the PETRA III extension.

Parameters and Optics

Four beamlines in the North and respectively in the East hall will be fed by four undulators that are installed in two canted DBA like cells that have replaced a part of the FODO lattice. Six 5.3 m long dipoles have been replaced with six shorter dipole magnets (1 m and 0.5 m long). The new lattice configuration is shown in Fig. 3 for the North extension [3,6]. A photo of the section is shown in Fig. 4.

PROGRESS IN OPTICS STUDIES AT FLASH

J. Zemella, T. Hellert, M. Scholz, M. Vogt, DESY, Hamburg, Germany

Abstract

FLASH is the superconducting soft X-ray Free Electron Laser in Hamburg at DESY, Germany. Good control over the beam optics is a key aspect of the operation of a SASE FEL. In 2013 a second beam line, FLASH2, was assembled and the modifications necessary to feed the two beam lines were installed downstream of the FLASH linac. As reported before [1] we started a campaign of optics consolidation. We give an update on the progress of this effort and on results.

INRODUCTION

The superconducting soft X-ray Free Electron Laser in Hamburg (FLASH) [2] at DESY, Germany has recently been upgraded to operate two FEL beam lines, FLASH1 and FLASH2 [3], to potentially serve more users. For optimum FEL performance several several optical criteria have to be met. The most critical ones are the beam waists in the bunch compressors and at he septum of the switchyard (switching the e^- beam between FLASH1 and FLASH2) [4] and matching in the periodic solution of the in the FEL undulators of the two beam lines. In theory it suffices to match the space charge dominated beam from the RF photo cathode gun to the design optics of the linac to meet all the conditions at least for an uncompressed bunch. However it is a well known but not well understood fact that in FLASH the optics is strongly perturbed almost right after the matching point. A campaign of optics consolidation was started in 2013 and described in [1].

THEORY

This section is partial repetition of [1]. Our tools consist of a suite of shell scripts and c–programs utilizing a version of MAD8 which has been extended for linacs [5, 6] as optics engine. The actual machine optics is reconstructed by reading the magnet currents from the control system.

Orbit Response Matrix (ORM) Technique

In a linac the (i, j)-th element of the ORM is defined as the linearized response of a given coordinate (q_i) at the i-th monitor (BPM) to a kick θ_j from the j-th steerer

$$\Delta q_i = \left(\mathbf{R}_{i\leftarrow j}\right)_{q,p} \ \Delta\theta_j \tag{1}$$

where for the moment we neglect inter plane coupling, $\mathbf{R}_{i\leftarrow j}$ is the transport matrix from s_j to s_i [7], and $q, p = 1, 2$ for the horizontal and $q, p = 3, 4$ for the vertical phase plane. In a linac $\mathbf{R}_{i\leftarrow j} \equiv 0$ for $s_i < s_j$. The measured ORM contains calibration errors of both monitors (a_i) and steerers (b_j),

$$\mathbf{R}^{\text{meas}}_{i\leftarrow j} = a_i \, \mathbf{R}^{\text{machine}}_{i\leftarrow j}\{k_1^{(l)} : s_l \in (s_j, s_i)\} \, b_j \tag{2}$$

where the $k_1^{(l)}$ are the quadrupole strengths in-between steerer and monitor. Thus, before non–linear minimization can be applied to identify and/or correct focusing errors, robust estimates of the a_i's and b_j's have to be extracted from the ORM data while fulfilling suitable consistency constraints [8]. Many BPMs in FLASH have been calibrated in a beam based way, relying on the calibration of nearby upstream steerers. This introduces coupling between the a_i's and the b_i's ans is thus an additional complication

MEASUREMENTS

In this section the measurements are presented to investigate the optics perturbation we are expecting at the end of DBC2 section up to the end of ACC2 section. As mentioned before, this has been done by mainly using the ORM technique. Figure 2 shows the relative difference of the measured and theoretical orbit response from UBC2 to DBC3 section for design optics.

The orbit response is calculated by a linear fit to the BPM readings for five steerer kick strengths using the fit function implemented in gnuplot [9] weighted by the rms error of 10 BPM readings for each kick strength. The error for the slope is the error of the fit calculated by gnuplot. A python code performs the fit of the steerer calibrations and BPM gains. In this analysis the measurement data is fitted to the model data. The fit program performs a minimization of the error of the difference ORM weighted by the error of the orbit response using an iterative method based on SVD algorithm.

The ORM measurement in Fig. 2 is representative for a whole set of ORMs taken in the design optics with the injector matched for 0.3 nC. It shows a quite good correspondence between model and measurement up to BPM 11DBC2 for both planes. The fitted steerer calibrations are between 0.9 and 1.15 except H10ACC1 with 0.5. The fitted BPM gains between 0.9 and 1.4 except BPM 9ACC2 with 2.9 in x and 2.4 in y plane and 9ACC3 with 1.6 in x and 1.1 in y plane.

The calibration of BPM UBC2 (1.8 in x and 1.2 in y plane) is far off because it has been calibrated using a nearby steerer whose calibration if far off (H10ACC1). The steerers in UBC2 and DBC2 are of the same type so that in this analysis the mean of the fitted steerer calibrations is used because the steerer calibrations should be almost the same for all these steerers. Whenever the section over which the response was measured intersects with the stretch from approximately BPM 11DBC2 to the steerers in ACC2, the model does not fit the measurements. However the response of the two steerers ACC2 and ACC3 are in good agreement with the theoretical prediction. Thus it is clear that there must be a noticeable optics perturbation located in that section. So far this is not a new result and just reconfirms the findings of many others, e.g. [8]

We have a couple of candidates for causing the perturbation described above, see Fig. 2. Several of them are hidden

POSSIBILITY OF LONGITUDINAL BUNCH COMPRESSION IN PETRA III

I. Agapov *, European XFEL GmbH, Hamburg, Germany,
S. Tomin , NRC Kurchatov Institute, Moscow, Russia,
and European XFEL GmbH, Hamburg, Germany
R. Wanzenberg, DESY, Hamburg, Germany

Abstract

A scheme of short bunch production in storage rings using a longitudinally focusing insertion was presented in [1]. In this work we study the possibility of integrating such insertion into the PetraIII storage ring. In particular, we discuss possible optics solutions to integrate RF stations, chicane-type delay sections, and the undulators into existing ring geometry.

INTRODUCTION

A possibility of short bunch production in storage rings using compression followed by decompression was presented in [1]. There it was also shown that the scheme can be used to operate a high gain FEL in a low emittance storage ring such as Petra III [2]. At Petra III several straight sections are presently available, e.g. one of about 70 m length in the North-West (NW) section (see Fig. 1) The scheme is briefly introduced in first section. Possible solutions in terms of electron optics are discussed in the second section. As part of the compression and decompression, sections with variable R_{56} of opposite signs are required. While a slight modification of an arc provides a section with necessary positive R_{56}, the negative R_{56} requires larger modification to the optics. It turns out that designing such a section is rather challenging due to issues with emittance preservations. A short chicane with rather strong bending magnets could increase the equilibrium emittance significantly and installation of such a chicane for large negative R_{56} does not seem feasible. However, a modification to the scheme where both chicanes have positive R_{56} requires very minor changes to the present machine layout (apart from installing two RF sections) at the cost of slightly more complex longitudinal dynamics.

SCHEME

The scheme proposed in [1] is based on the observation that longitudinal focusing similar to the bunch compression in linac-based FELs could potentially be run in a storage ring. An RF section followed by a section with energy-dependent time delay acts as a 'compressor', and the mirror reflection of this setup acts as a 'decompressor'. The scheme is sketched in Fig. 2. With the peak bunch current thus increased by an order of magnitude and small emittance of a ring such as Petra III operation of a high gain ring FEL could be potentially possible for soft x-rays of energies below approx. 1-2 keV. The longitudinal phase space map for the insertion is

$$M = M_{RF2} \cdot M_{C2} \cdot M_{C1} \cdot M_{RF1} \quad (1)$$

where the magnetic section maps are given by matrices

$$M_{C1,C2} = \begin{pmatrix} 1 & R_{56}^{(1,2)} \\ 0 & 1 \end{pmatrix} \quad (2)$$

and the RF section maps are

$$M_{RF1,RF2} : \begin{pmatrix} t \\ p \end{pmatrix} \rightarrow \begin{pmatrix} t \\ p + V^{(1,2)} \sin(\omega_{RF} \cdot t) \end{pmatrix} \quad (3)$$

Here t and p are longitudinal coordinates usually measured in meters and relative energy units, R_{56} is the standard notation for dispersive time delay, $V^{(1,2)}$ are total RF voltages for the compressor and the decompressor, and ω_{RF}

Table 1: PETRA III beam parameters [2]

Parameter	High charge	Low charge
Beam energy	6 GeV	
Circumference	2304 m	
No. bunches	40	960
Emittance ε_x	$1.2 \cdot 10^{-9}$ m · rad	
Emittance ε_y	$1.2 \cdot 10^{-11}$ m · rad	
Energy spread	10^{-3} (6 MeV)	
Bunch charge	19 nC	0.8 nC
Bunch length	44 ps (rms)	
Peak current	170 A	7 A
Average current	100 mA	100 mA
Long. damping time	8 msec	
Transv. damping time	16 msec

STATISTICAL OPTIMIZATION OF FEL PERFORMANCE

I. Agapov *, G. Geloni, European XFEL GmbH, Hamburg, Germany
I. Zagorodnov, DESY, Hamburg, Germany

Abstract

Modern FEL facilities such as the European XFEL will serve a large number of users, thus understanding and optimizing their performance parameters such as the output power is important. In this work we describe the statistical approach to such optimization under assumption that the possibility of modelling is limited by uncertainties. We present experience of such statistical optimization of SASE radiation power for FLASH and discuss how the results of empirical tuning can be fed back into the model used in simulations.

INTRODUCTION

Experience shows that extensive tuning of an FEL may be required to reach design parameters. The main objective of the present study is to understand methods and design software tools for automatic tuning of FEL parameters. Since many uncertainties are present, we propose to perform such optimization based on empirical methods using very little model information. This roughly mimics what a human operator is doing, only taking advantage of more powerful and faster computations. The possibility of using the model enters into the design of the empirical method. We call such approach statistical. It is described in the first two sections of the paper, including its demonstration at FLASH. The second objective is to try to deduce the model parameters from the measurements so that more realistic calculations can be done. Such problem is typically ill-posed since there is usually much less diagnostics than the potential causes of deviation from design performance. We discuss a possible approach to such model inference in the last section, although its practical feasibility remains to be demonstrated. The statistical tuning software is part of the OCELOT framework ([1, 2]).

EMPIRICAL OPTIMIZATION AT FLASH

Optimization is implemented as an arbitrary sequence of optimization steps, each step maximizing the SASE pulse energy with a certain group of devices. A group of devices can be arbitrary, in practice such groups as all launch steerers, FODO quadrupoles, matching quadrupoles, steerers between undulators etc. are used. Optimization using a group of devices is usually performed with the simplex (Nelder-Mead) method, although other methods can be used too. The objective function used in maximization is proportional to the SASE pulse energy averaged over several bunch trains. Beam losses approaching the alarm threshold are penalized so that in practice the optimization algorithm always avoids beam losses. To better understand the performance of the optimizer response functions of SASE energy to the control parameters can be studied. Examples of such response functions for launch steerers and FODO quadrupoles are shown in Figs. 1 and 2. The scans are done such that starting from some average value the magnet current is first driven up, then down, and then up again. One can see a certain "hysteresis" effect, which is mostly due to the drift in the radiation power. Figure 3 shows such fluctuations when the machine is not interfered with apart from some feedbacks runnning. When present, this drift sets a limit to the optimizer performance. Figure 2 also shows the presence of quadrupole misalignment through the coupling of the quadrupole strength to the orbit, mostly in the vertical direction.

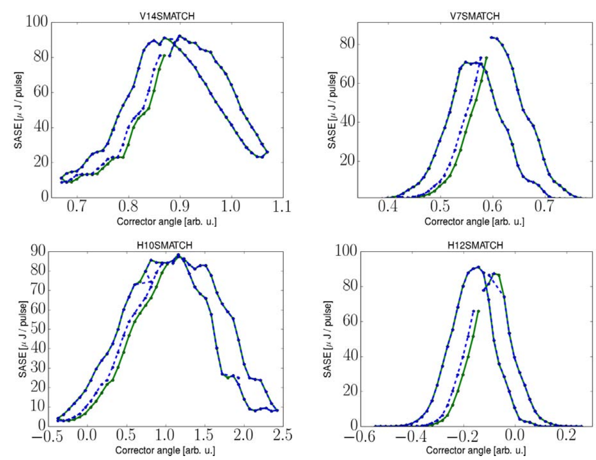

Figure 1: SASE response functions to launch steerers. Green is the set and blue is the read back values.

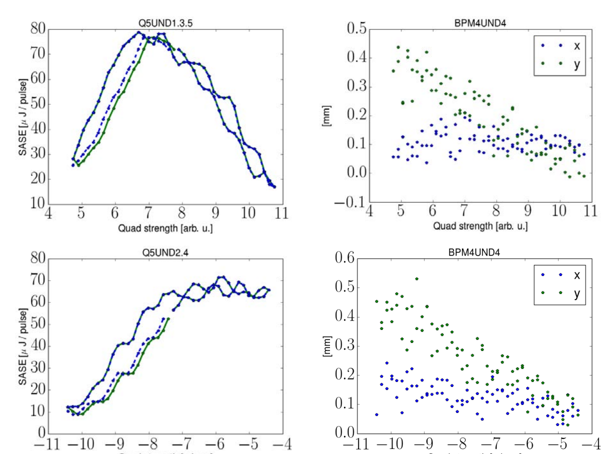

Figure 2: SASE and orbit response functions to FODO quadrupole strength.

OPTICS COMPENSATION FOR VARIABLE-GAP UNDULATOR SYSTEMS AT FLASH

Ph. Amstutz*, C. Lechner, T. Plath, Universität Hamburg, Germany
S. Ackermann, J. Bödewadt, M. Vogt, DESY, Hamburg, Germany

Abstract

Variable-gap undulator systems are widely used in storage rings and linear accelerators to generate soft- and hard x-ray radiation for the photon science community. For cases where the effect of undulator focusing significantly changes the electron beam optics, a compensation is needed in order to keep the optics constant in other parts of the accelerator. Since 2010, the free-electron laser (FEL) facility FLASH is equipped with two undulator sections along the same electron beamline. The first undulator is a variable-gap system used for seeding experiments, the second undulator is a fixed-gap system which serves the user facility with FEL radiation. Varying the gap in the first undulator will change the beam optics such that the FEL process in the second undulator is dramatically disturbed. For the correction of the beam optics an analytical model is used to generate feed forward tables which allows to make part of the beamline indiscernible for the subsequent sections. The method makes use of the implicit function theorem and can be used for any perturbation of the beam optics. Here, we present the method and its implementation as well as measurements performed at FLASH.

INTRODUCTION

The super-conducting linear accelerator FLASH at DESY in Hamburg serves two parallel undulator beamlines, FLASH1 and FLASH2. While FLASH2 is currently being prepared for user operation, FLASH1 has been delivering soft x-ray photons for user experiments since 2005 [1]. As shown in Fig. 1, upstream of the FLASH1 main undulator an experimental setup for FEL seeding (sFLASH) is located. It features two electro-magnetic undulators as well as four variable-gap undulator modules and thus is the ideal testbench for the study of several different seeding schemes [2].

The focusing properties of the seeding undulators in the vertical plane will have an impact on the beam optics at the entrance of the main undulator. At lower beam energies this change can easily be in the order of several tens of percent and thus significantly decreases the FEL performance in the main undulator. Therefore, the disturbance introduced by the seeding radiators has to be corrected for by adjusting the strength parameters of quadrupole magnets in that section to match the optics in the main undulator again.

While most algorithms typically find a suitable correction by numerically solving minimization problems, we present an analytical method. It is based on the implicit function theorem (compare for instance [3]) and allows for the determination of correction parameters as a function of the introduced disturbance. Furthermore, we present measurements confirming the calculations.

THE METHOD

During these calculations the optics will be described employing transverse linear beam optics. We denote the 4×4 transformation matrix describing the effect of the entire section of the beamline as $M(\rho)$, where $\rho \in \mathbb{R}^n$ is a set of all the machine parameters which are needed to fully define the optics, e.g. strength parameters of quadrupole magnets and undulator gaps. We define two machine states ρ and ρ_0 to be equivalent if their matrices are identical

$$M(\rho) = M(\rho_0). \tag{1}$$

The goal of our calculations is to find the disturbed state ρ that is equivalent to the undisturbed case ρ_0 to keep the optical functions after the section constant. For this purpose we split ρ into the parameters that introduce the disturbance σ (here, undulator gaps) and the ones that are used for the correction τ. Under the assumption of uncoupled matrices, $M(\rho)$ consists of two 2×2 block matrices. Since the determinants of both block matrices have to equal unity, Eq. (1) can be reduced to 6 equations of the form

$$\Delta M_{i,j}(\rho, \rho_0) = M_{i,j}(\rho) - M_{i,j}(\rho_0) = 0. \tag{2}$$

By defining a C^1 function $B : \mathbb{R}^n \to \mathbb{R}^6$ to have these six matrix element differences for a given, constant ρ_0 as its components, the set of equations (2) can be written as

$$B(\sigma, \tau) = 0. \tag{3}$$

The implicit function theorem now assures the existence of a unique function $\tau(\sigma)$ around ρ_0, so that

$$B(\sigma, \tau(\sigma)) = 0, \tag{4}$$

if the Jacobian determinant $\det \mathbf{J}_B(\tau)|_{\rho_0} \neq 0$, which we at this point will assume to be true [3]. We see, that B and τ have to be of the same dimension for the correction function to be unique, meaning that the desired compensation can be achieved by adjusting six correction parameters. The derivative of this correction function can be obtained by analytical means from Eq. (4)

$$\frac{\mathrm{d}\tau(\sigma)}{\mathrm{d}\sigma} = -\left(\frac{\partial}{\partial\tau} B(\sigma, \tau(\sigma))\right)^{-1} \cdot \frac{\partial}{\partial\sigma} B(\sigma, \tau(\sigma)). \tag{5}$$

This defines a system of six coupled differential equations. Therefore, by solving this system the sought correction function $\tau(\sigma)$ can be obtained. Due to the complexity of the involved terms it will in general not be possible to find the solution analytically and a numerical approximation is needed.

TRANSVERSE GRADIENT UNDULATOR-BASED HIGH-GAIN-FELS — A PARAMETER STUDY

A. Bernhard*, E. Burkard, V. Afonso Rodríguez, C. Widmann, A.-S. Müller, KIT, Karlsruhe, Germany

Abstract

Transverse gradient undulators (TGU) have recently been discussed as sources for High Gain Free Electron Lasers (FEL) driven by electron beams with an elevated energy spread as for example generated in storage rings or wakefield accelerators. In this contribution we present the results of a parameter study based on the one-dimensional TGU-FEL theory making realistic assumptions on the key parameters achievable for the transverse gradient undulator. We show for which parameter areas LWFA-driven TGU-FELs are virtually technically feasible today and which technical improvements would be required to employ the concept for a laboratory-scale X-Ray FEL.

INTRODUCTION

Is a "table-top" high-gain X-ray free-electron laser driven by a laser wakefield accelerator employing a transverse gradient undulator scheme realistic?

Almost immediately after the experimental demonstration of laser wakefield acceleration (LWFA) of plasma electrons in the highly non-linear regime [1–3] the discussion started how this acceleration scheme could be used to realize compact free-electron lasers fitting into a normal laboratory and delivering laser-radiation in the X-ray regime [4–6] usable e.g. for advanced medical imaging techniques.

The main obstacle on the way to such an admittedly appealing scenario is the comparably large energy spread of the LWF-accelerated electrons (1 % to 10 %). Grüner et al. [6] pointed out that the unfavorable effect of the energy spread could be compensated by the high peak current of the short-bunched LWFA electrons. However, the assumptions the authors made on achievable LWFA beam- as well as undulator parameters have not proved realistic so far.

More recently more elaborated high-gain FEL schemes for electron sources with increased energy spread have been proposed that employ a special preparation of the electron beam phase space distribution by means of magnetic chicanes. Such schemes rely either on bunch decompression [7, 8] or on a transverse spectral dispersion matched to a transversely varying undulator field amplitude. These transverse-gradient undulator high-gain FEL schemes have been discussed both for self amplification of spontaneous emission (SASE) [9, 10] and high-gain harmonic generation (HGHG) [11] scenarios.

In our study we investigated the TGU-SASE case based on the 1-D theory described in [9, 10], searching for optimized and technically feasible TGU parameters for several sets of LWFA beam parameters, moving from beam properties that can be routinely achieved today to beam properties that have been achieved in individual cases to properties that would actually be required.

ACCESSIBLE PARAMETER SPACE

The TGU-FEL scheme implicates modifications of the 1D-FEL equation [10] through the introduction of a modified Pierce parameter

$$\rho_{\mathrm{TGU}} = \rho_{\mathrm{FEL}} \left(1 + \frac{\eta^2 \sigma_\delta^2}{\sigma_x^2}\right)^{-\frac{1}{6}} \tag{1}$$

and an effective energy spread

$$\sigma_{\delta,\mathrm{eff}} = \sigma_\delta \left(1 + \frac{\eta^2 \sigma_\delta^2}{\sigma_x^2}\right)^{-\frac{1}{2}}. \tag{2}$$

Here, ρ_{FEL} is the unmodified Pierce parameter, σ_δ the energy spread, σ_x the transverse beam size (approximated as constant in 1D-theory) and η the dispersion function which is presupposed to be matched to the TGU parameters through the relation

$$\eta = \frac{2 + K_0^2}{\alpha K_0^2}, \tag{3}$$

where K_0 is the undulator parameter at the transverse position for the central beam energy and $\alpha = \frac{1}{K_0} \left.\frac{\partial K}{\partial x}\right|_{x=0} =: \frac{1}{K_0}\alpha_K$ the relative transverse K-gradient, i.e. the linear approximation $K(x) = K_0(1+\alpha x)$ is assumed to be admissible.

The crucial parameters entering into the TGU-FEL equation are therefore the undulator period length λ_u, influencing both the unmodified Pierce parameter and the undulator parameter, the undulator flux density amplitude $\tilde{B}_0 = \tilde{B}(x = 0)$ and the transverse gradient α_K on the one hand, the transverse beam size σ_x on the other hand. In the following, we discuss our considerations on the accessible ranges for these parameters.

TGU Parameters

Technically, transverse gradient undulators are realized by a transverse variation of the undulator gap. Several possible TGU geometries have been discussed in [12, 13] particularly for superconducting TGUs. Among those the TGU geometry consisting of two cylindrically shaped halves provides the highest achievable transverse field gradients. Indeed we consider the statement adequate that the cylindrical superconducting TGU defines the upper limits of the technically achievable crucial TGU parameters for a given gap and period length [14].

To estimate these limits we use the analytic expressions for the field of a cylindrical TGU given in [12], combined with a 2D finite element calculation used to determine the optimum

R. Ischebeck, B. Keil, V. Schlott, L. Stingelin, PSI, Villigen, Switzerland

Abstract

A new compact versatile linear accelerator named FLUTE (Ferninfrarot Linac Und Test Experiment) is currently under construction at the Karlsruhe Institute of Technology (KIT). It will serve as an accelerator test facility and allow conducting a variety of accelerator physics studies. In addition, it will be used to generate intense, ultra-short THz pulses for photon science experiments. FLUTE consists of a ~7 MeV photo-injector gun, a ~41 MeV S-band linac and a D-shaped chicane to compress bunches to a few femtoseconds. This contribution presents an overview of the project status and the accompanying simulation studies.

INTRODUCTION

The objectives of the linear accelerator FLUTE, developed and being constructed at KIT in collaboration with PSI and DESY, range from studying space charge and coherent radiation induced effects to bunch compression studies and systematic comparison of simulation code results with measurements [1]. Furthermore, it will serve as a test bench for advanced diagnostics and instrumentation. The generated intense THz radiation will be used for various experiments for example to study the radiative impact on relevant biomedical tissue. The most important design parameters based on simulations are summarized in Table 1.

Table 1: Main FLUTE Parameters from Simulation

Parameter	**Value**	**Unit**
Final electron energy	~41	MeV
Electron bunch charge	~1–3000	pC
Final electron bunch length (RMS)	~1–300	fs
Pulse repetition rate	10	Hz
Energy / THz pulse	up to ~3	mJ
Power / THz pulse	up to ~5	GW

FLUTE LAYOUT

The design layout is depicted in Fig. 1 showing details of the planned diagnostics components. The main components are: the *electron gun*, pre-accelerating the electrons to an energy of ~7 MeV, including a focusing solenoid; the *low-energy diagnostics section* comprising two screens, beam position monitors (BPM), and an integrating current transformer (ICT) for determining the electron beam current, as well as a spectrometer with a quadrupole for energy measurements; the *linac* accelerating the electrons to an energy of ~41 MeV, followed by the *first high energy diagnostics section* including an electro-optical longitudinal profile monitor (EOM) for determination of the longitudinal bunch profile [2]; a quadrupole triplet, also located in this section to focus the beam appropriately in both transverse directions; the *bunch compressor* consisting of four dipole magnets [3] including some diagnostics in the dispersive section, directly followed by the *THz out-coupling optics*; the *final diagnostics section* including another EOM and a high-energy spectrometer; the Faraday cup used with radiation shielding as *electron dump*.

SIMULATION RESULTS

We use several software programs to optimize the layout of FLUTE. For low charges ASTRA [4] is employed for the entire machine. For charges above ~1 nC comparisons have shown that especially at the end of the chicane, where the electron bunches become very short, coherent synchrotron radiation (CSR) induced effects become dominant [5]. In these cases, CSRtrack [6] was employed in the chicane. For the calculation shown here ASTRA was used, whereas the generated THz spectra und pulse profiles were computed with in-house developed algorithms [7].

Electron Beam

To study the influence of the space between the gun cathode and the linac we performed a set of ASTRA simulation runs with different distances. For this comparison the relevant parameters like RF and laser phase, solenoid and quadrupole triplet focusing strength, chicane dipole fields, and laser spot size and length have been optimized for each case separately. Figures 2 and 3 show first results for a cathode–linac distance of 3 m. This distance allows enough space for the low-energy diagnostics components and later for a buncher cavity. Please note, that in this paper CSR-induced effects have not been studied. This is why we restrict ourselves here to a bunch charge of ≤100 pC where these effects are relatively small.

The transverse RMS beam size plotted in Fig. 2 for both 1 pC and 100 pC bunch charges show that the size after the gun, but before the linac can be kept below 1.4 mm. Furthermore, we reach a small bunch size of ≤105 µm at the end

NON-INTERFEROMETRIC SPECTRAL ANALYSIS OF SYNCHROTRON RADIATION IN THE THz REGIME AT ANKA

J. L. Steinmann*, M. Brosi, E. Bründermann, M. Caselle, E. Hertle, N. Hiller, B. Kehrer, A.-S. Müller, P. Schönfeldt, M. Schuh, P. Schütze, M. Schwarz, KIT, Karlsruhe, Germany
J. Hesler, Virginia Diodes Inc., Charlottesville, VA, USA

Abstract

Interferometry is the quasi-standard for spectral measurements in the THz- and IR-range. The frequency resolution, however, is limited by the travel range of the interferometer mirrors. Therefore, a resolution in the low megahertz range would require interferometer arms of about 100 m. As an alternative, heterodyne measurements provide a resolution in the Hertz range, an improvement of 6 orders of magnitude. Here we present measurements done at ANKA with a VDI WR3.4SAX, a mixer that can be tuned to frequencies from 220 GHz to 330 GHz and we show how the bunch filling pattern influences the amplitude of specific frequencies.

INTRODUCTION

The single particle synchrotron spectrum emitted by an electron in a bending magnet is broad-band and also continuous. In a storage ring where an electron bunch emits synchrotron radiation on every turn, the emitted electric field consists of equally spaced (T_0) series of short pulses. As an approximation we assume a Dirac delta function ($\delta(t)$) as bunch signal which leads to an infinite pulse train, known as Dirac comb or Shah distribution, that can be represented as a Fourier series [1]:

$$f(t) = \sum_{n=-\infty}^{\infty} \delta(t - nT_0) = \frac{1}{T_0} \sum_{n=-\infty}^{\infty} e^{j2\pi n \frac{t}{T_0}} \qquad (1)$$

The importance of this lies in the fact that the Shah distribution is its own Fourier transform which gives us a discretized spectrum

$$\mathcal{F}(\omega) = \omega_0 \sum_{p=-\infty}^{\infty} \delta(\omega - p\omega_0) \qquad (2)$$

The distance between the frequency combs is the revolution frequency ($\omega_0 = 2\pi f_0$, at ANKA: $f_0 = 2.71$ MHz). By having not only one bunch filled, but each RF-bucket (at ANKA: 184), amplified parts with harmonics of the accelerating radio frequency show up. This is because the buckets are not equally filled with electrons, but show some inhomogeneity as illustrated in Fig. 1.

The spectral components of a circulating electron beam have been described by Schott in 1912, long before synchrotrons were being thought of as light sources [2]. However, recent literature does not pay much attention to the spectral lines of synchrotron radiation, as they couldn't be resolved nor exploited by measurements [3, p. 807]. This has changed now.

* johannes.steinmann@kit.edu

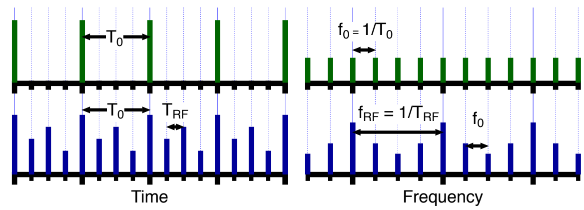

Figure 1: Theoretical spectrum of a series of short pulses as they happen in a storage ring. Each revolution the same pulse is seen, leading to a frequency comb spaced by the revolution frequency (top). By filling all buckets with (slightly) different bunch charges, we see the filling pattern modulated onto the frequency comb, showing extra amplification at the accelerating radio frequency (bottom).

The synchrotron radiation spectrum and the calculation of the frequencies are similar to the signal of a pick-up electrode. Also there, the short signal from the bunch is repeatedly coming by, creating a frequency comb whose analysis is a standard tool for longitudinal diagnostics in synchrotrons and therefore well studied [3, p. 627ff] [4, p. 165ff]. Taking the coherent synchrotron oscillation with frequency ω_s and amplitude $\hat{\tau}$ with bunch current $I = \frac{Ne\omega_0}{2\pi}$ and Gaussian bunch length σ_0 into account, we arrive at [5, p. 264ff]:

$$\mathcal{F}(\omega) = I \sum_{p,m=-\infty}^{\infty} j^{-m} J_m(p\omega_0\hat{\tau})\delta(\Omega) e^{\frac{-(p\omega_0\sigma_0)^2}{2}} \qquad (3)$$

$\Omega = \omega - p\omega_0 + m\omega_s$ leads to the known revolution harmonics. Additionally, every harmonic has satellites spaced by ω_s, where the m-th satellite has a spectral amplitude corresponding to the Bessel function of order m: $J_m(p\omega_0\hat{\tau})$. By having no coherent synchrotron oscillation ($\hat{\tau} = 0$), the satellites vanish. In a multi-bunch fill, due to non-uniform bunch currents, additional amplified harmonics of the bunch spacing appear.

The amplification of the frequencies corresponding to the repetition rate of the emitting particles is called superradiant and has been observed before [6]. Additionally its potential for spectroscopy has been shown recently [7, 8].

In this paper we present a method, how to deal with aliasing when analyzing heterodyne measurements, and how specific superradiant frequencies can be created by adjusting the filling of the bunch train.

MEASUREMENT SETUP

To increase the emitted THz radiation, ANKA is operated in the low-alpha mode, where the momentum com-

TEST ELECTRON SOURCE FOR INCREASED BRIGHTNESS EMISSION BY NEAR BAND GAP PHOTOEMISSION*

S. Friederich†, K. Aulenbacher
Institut für Kernphysik, Johannes Gutenberg-Universität Mainz, D-55128 Mainz, Germany

Abstract

A new photoemissive electron source is being built in order to make use of the reduction of ensemble temperature in near band gap photoemission. It will operate at up to 200 kV bias voltage with NEA GaAs photocathodes. High bunch charges will be investigated in pulsed mode with respect to the conservation of emittances at low energy excitations. High field gradients at the cathode surface will also allow further investigation of the field emission process of these photocathodes.

INTRODUCTION

The temperature of electron ensembles emitted from NEA photocathodes, e. g. GaAs(Cs:O), is reduced if the exciting photon energy approaches the band gap of the semiconductor [1]. This promises to increase the beam brightness $\propto 1/T$. We want to explore if it is possible to exploit this phenomenon for the production of high bunch charges, which may be relevant for applications such as ERL-based light sources. In order to achieve such bunches, a high gradient, high voltage source is needed to cope with the effects of space charge in a vacuum and also internal effects, for instance photovoltage [2]. A particular challenge is that the work function of the material is extremely low (≈ 1.4 eV) - at least if GaAs is chosen as a cathode. A variable field strength in the new source will allow to investigate field emission thresholds for these low work function cathodes.

In respect of that, a new photoemission electron source is under development at the institute for nuclear physics Mainz. The bias voltage will be up to 200 kV and the accelerating field strength will reach up to 5 MV/m. A more detailed view on the design and some simulations are discussed in the following.

SOURCE DESIGN

The design of the Small Thermalized Electron source At Mainz (STEAM) is based on the photoemission electron sources used at MAMI [3] and CEBAF at Jefferson Laboratory [4]. It is illustrated in Fig. 1.

As photoemissive material a p-doped gallium arsenide (GaAs) crystal held by a molybdenum carrier called the "puck" will be used. It is coated with a thin caesium and oxygen layer which forms the negative electron affinity (NEA). The work function is reduced to ≈ 1.4 eV allowing to achieve high quantum efficiencies at low excitation energies. On the other hand, the low work function may provoke field emission if the electric field gets too high.

Inverted Insulator

In order to get a compact source, the cathode electrode holding the photoemissive material is mounted on an R30 "inverted" insulator that points directly into the source chamber. It has three advantages compared to the old insulator tubes: Its size is smaller and allows a compact design, it offers less metallic surfaces that may lead to parasitic field emission and it is cheaper because it is used commercially in the X-ray industry.

Cathode Electrode Design

The cathode electrode is made of low-permeable stainless steel 1.4429 ESU. It is mounted vertically on the insulator and holds the photocathode with the NEA GaAs, which is kept in position due to gravitation.

After exceeding its lifetime, the photocathode needs to be refreshed and for the new preparation it needs to be extracted. Therefore, the source will operate in a load-lock operation: A second chamber for the photocathode preparation will be connected to the source chamber, not affecting its ultra-high vacuum.

Elevator Construction

To provide the mechanical movements needed for cathode exchange, an elevator construction is implemented into the cathode electrode design, see Fig. 2. A rack and pinion gear that is driven by a manipulator levitates the puck inside the cathode electrode so that it can be grabbed by a "fork" mounted on a second manipulator and transferred into the preparation chamber. Using copper in combination with titanium prevents galling and reduces attrition to a minimum [5]. This elevator construction will be tested under ultra-high vacuum conditions after a bake-out procedure at 250 °C at the end of 2015. The manipulator driving the elevator is retracted from the high voltage region during operation.

Anode Design

The shape of the anode is convex in order to keep the outer field strength at the cathode electrode side low while achieving a field strength at the photocathode surface of up to 5 MV/m at a distance of 37 mm between photocathode and anode (200 kV bias). These values were simulated and optimized using CST EM Studio [6] with respect to the goal of keeping the global absolute field strength below 8 MV/m, see Fig. 3. The anode is mounted on a potential-free tube and thereby allows to measure the lost beam and field emission currents emitted from the cathode electrode

FURTHER INVESTIGATIONS ON THE MESA INJECTOR*

R. Heine†, K. Aulenbacher, S. Friederich, C. Matejcek, F. Schlander
Institut für Kernphysik, Johannes Gutenberg-Universität Mainz, Mainz, Germany

Abstract

The MESA ERL (**M**ainz **E**nergy-recovering **S**uper-conducting **A**ccelerator) to be built at Mainz in the next years is a multi turn recirculating linac with beam currents of up to 10 mA. The dynamic range of the beam currents demanded by the experiments is of at least two orders of magnitude. This is a special challenge for the layout design of the injector. In this paper we present the current status of the design of the injector linac called MAMBO (**M**illi**AM**pere **BO**oster).

INTRODUCTION

MESA will be operated in two modes: the first is the external beam (EB) mode; there the beam is dumped after being used with the external fixed target experiment P2. The current required for P2 is 150 μA with polarised electrons at 155 MeV. The second mode is energy recovery (ER). The experiment served in this mode is an (pseudo) internal fixed target experiment named MAGIX. It demands an unpolarised beam of 1 mA at 105 MeV. In a later stage the ER-mode current shall be upgraded to 10 mA.

The concept of MAMBO was presented in [1]. MAMBO consists of a low energy beam transport (LEBT) section preparing a 100 keV beam with a chopper buncher system for capture in the first linac RF-section. The electrons are provided by a 100 keV DC photo gun that is driven by a pulsed laser. Although the laser pulses will last some 200 ps, delayed emission of electrons and dark currents make a chopper system necessary to cut off tails.

The electrons are accelerated by four room temperature RF-sections to 5 MeV. The frequency is determined by the SRF structures of the main linac, which are using TESLA technology at 1.3 GHz. The normal conducting structures are bi-periodic $\pi/2$ standing wave structures. The first section is a graded-β, the 2nd section has a constant $\beta < 1$ and the last two sections are $\beta = 1$. The geometry of the cells is derived from the MAMI injector [2].

BEAM DYNAMICS

The beam dynamics was simulated with PARMELA [3]. To receive more realistic results the space charge mesh was improved to allow for a changing bunch spacing due to energy gain. Especially inside a graded-β section the distance between bunches changes from cell to cell. This was modelled by using the `continue` command followed by a `scheff` line with altered mesh data. Further the number of particles was increased to 300,000 to allow for halo effects to become visible. Also now the 3D space charge functionality of PARMELA is used.

Table 1: Bunch Data at the Start of LEBT (i) and at the Exit of MAMBO (f)

		stage -1		stage - 2
I_b	[mA]	0.15	1	10
$\Delta\phi_i$(100%)	[°]	93.6	93.6	93.6
ΔT_i(100%)	[keV]	0.002	0.13	1.1
$\Delta\phi_f$ (RMS)	[°]	0.14	0.36	1.9
ΔT_f (RMS)	[keV]	0.85	2.2	5
$\Delta T_f/T$ (RMS)	$\times 10^{-4}$	1.7	4.4	10

While arranging focussing elements, now spacial constraints, e.g. positions of flanges, are considered leading to minor alteration in their positions.

The particle distribution now used for simulation has been extracted from CST Particle Studio [4] simulations of the photo source at a given bunch length (see Table 1). The phase spaces achieved with the linac configuration meet the design goals of MAMBO stage-1 ($\Delta\varphi \leq 3°$, $\Delta T/T = O(10^{-4})$) [1]. The parameters of stage-2 will not meet these goals, since space charge forces lead to an energy blow-up right from the gun. The energy spread achieved by MAMBO at 10 mA is 10^{-3}. The most demanding experiment P2 will be satisfied with the results for 150 μA, while MAGIX, which is asking for high currents, can cope with larger energy spread, so stage-2 parameters should be acceptable. This has to be investigated within the design of the main linac.

Space charge calculations also revealed that it is not possible to accelerate 10 mA inside the first RF-section without additional focussing applied over this section. Further an increase of the beam hole diameter in the iris seems to be advantageous.

RF-DESIGN

The MAMI structure has been scaled to 1.3 GHz and some modifications have been made to increase the coupling between cells, this will provide a better field flatness. Compared to the MAMI profile the coupling slots have been moved outside, this increases the area of the slots and therefore the coupling. To close the passband gap, the radius of the coupling cells was reduced. To allow for emittance blow up due to space charge the beam pipe diameter was increased on cost of ca. 10% of shunt impedance. The alterations of MAMBO structure compared to MAMI Ilac are visible in Fig. 1.

Abstract

The Photo Injector Test facility at DESY, Zeuthen site (PITZ), develops, optimizes and characterizes high brightness electron sources for free electron lasers like FLASH and the European XFEL.

In the last year, the PITZ facility was significantly upgraded by the installation of a new normal conducting radio-frequency (RF) gun cavity with its new waveguide system for the RF feed, which should allow stable and reliable gun operation, as required for the European XFEL. Other relevant additions include beamline modifications for improving the electron beam transport through the PITZ accelerator and preparing the installation of a plasma cell. Furthermore, the laser hutch was re-arranged in order to house an additional, new photo cathode drive laser system which will produce 3D ellipsoidal laser pulses to further improve the electron beam quality.

This paper describes the facility upgrades and reports on the first operation experience with the new gun setup.

FACILITY UPGRADE GOALS

In the past, record low emittances at different charge levels were obtained at PITZ [1]. During the last two years, the PITZ facility was then mainly devoted to the preparation of RF guns for their later operation at FLASH and the European XFEL [2], with the main focus on operational stability, which is a critical issue for these user machines.

In view of improving both, beam quality and operation reliability, the PITZ facility was upgraded in summer 2014. The upgrade was realized under three main aspects: preparations for a new laser system for further improvement of the electron beam quality, installation of a new gun cavity together with its new RF feed system for improving the operational stability, and modifications of the PITZ beamline which will be described below.

3D ELLIPSOIDAL LASER SYSTEM

While the low beam emittances reported in [1] were obtained with a flat-top temporal laser profile, the overall brightness of a photo injector can be further improved by using an ideal electron bunch profile which, according to simulations, is ellipsoidal in space and time [3]. Due to the linearization of the space charge forces, homogeneous 3D ellipsoids are the best distributions for high brightness charged beam applications [4].

Quasi-3D ellipsoidal electron bunches can be produced by a laser system delivering 3D ellipsoidal laser pulses. For PITZ, such an advanced laser system was developed at the Institute of Applied Physics in Nizhny Novgorod, in the framework of a joint German-Russian research activity* [5]. Simulations have shown that this photo cathode laser system has the potential to significantly reduce the emittance of the electron bunches generated by the PITZ photo injector, and can also reduce the sensitivity on machine parameter changes [6], thus allowing more stable and reliable operation – key requirements for single-pass FELs like FLASH and the European XFEL.

The installation of the new laser system at PITZ required a major re-arrangement of the laser hutch, which already accommodated the flat-top photo cathode laser system used for a long time at PITZ. In late autumn 2014, the 3D laser system was installed in the re-arranged laser hutch. Meanwhile, first photo electrons have been produced with the 3D ellipsoidal laser system [5]. In the near future, comparative measurements with both photo cathode laser systems (3D ellipsoidal shape vs. cylindrical shape) are planned in terms of beam quality (emittance) and robustness against machine parameter changes (jitter).

BEAMLINE MODIFICATIONS

Extensive beam dynamics simulations have accompanied the development of the 3D ellipsoidal laser

Abstract

A demand on modern high brightness photo injectors required for a successful operation of linac-based free electron lasers is the possibility to generate beams with minimized beam emittance. A major way to optimize this parameter is the operation of photo cathode laser systems generating shaped laser pulses. Up to now flat-top laser pulses have been used at PITZ to achieve this goal.

As a next step in the optimization of photo injectors operated in the space charge dominated regime, the implementation of a photo cathode laser system capable to produce quasi 3-D ellipsoidal laser pulses had been considered as a result of beam dynamics simulations. That show a significant improvement in electron beam emittance compared to conventional cylindrical pulses.

The Institute of Applied Physics (IAP RAS, Nizhny Novgorod, Russia) has developed such a photocathode laser system in collaboration with the Joint Institute of Nuclear Research (JINR, Dubna, Russia) and the Photo Injector Test facility at DESY, Zeuthen site (PITZ). The laser pulse shaping is realized using spatial light modulators. The laser system is capable of pulse train generation. Just recently the delivery of the laser system and the implementation of it into the existing laser beam line at PITZ were finished. First electrons generated by the new laser system have been generated shortly after that. Although emittance measurements have not performed yet, the work presented there is a first significant step towards experimental investigation of the advantages of quasi 3-D ellipsoidal photo cathode laser pulses.

In this contribution the overall setup, working principles and the actual progress of the development as well as first results of electron beam generation will be reported.

INTRODUCTION

Ultrafast spectroscopy in the range of a few femtoseconds or even shorter as an instrument to investigate the behaviour of very fast processes, e.g. thermal excitation of molecules, has become a very popular instrument in various scientific research fields.

Wavelengths in the XUV are necessary for a lot of these experiments [1]. Such beams can be provided by linac-based Free-Electron Lasers (FELs) such as the Free-electron LASer in Hamburg (FLASH) and the European X-ray Free-Electron Laser (European XFEL).

FELs like these two operate on the basis of the Self Amplified Spontaneous Emission (SASE) process [2], which requires an extremely high space charge density of the radiating electron bunches. Therefore, requirements such as high peak current, low energy spread, and small transverse emittance of the electron beam are inevitable. The latter property cannot be improved in the linac and thus the emittance must be minimized in the photo injector.

One of the main possibilities to achieve this requirement is the shaping of the photo cathode laser pulses. By utilizing spatial cylindrical laser pulses with a temporal flat-top instead of Gaussian profile, a significant reduction of the transverse emittance of space charge dominated beams can be achieved.

While at most FELs the Gaussian laser pulse profile is used as the standard, at PITZ a flat-top temporal profile is used by default. Using this shaped laser pulses measurements of the normalized transverse projected beam, emittance between 0.7 and 0.9 mm mrad for electron beams of 1 nC bunch charge have been obtained [3].

To improve this emittance value, simulations with different kinds of laser pulse shapes were performed. As a result it could be shown by several simulations that the next step towards further reduction of the emittance is the use of 3-D ellipsoidal photo cathode laser pulses [4,5].

Laser systems capable of generating such laser pulses for trains of microbunches are currently not available. Therefore, a prototype was developed, constructed and recently installed at PITZ.

BEAM DYNAMICS SIMULATIONS

Beam dynamics simulations have been used to study the influence of different laser beam shapes on the electron beam quality. Therefore, three different types of laser shapes were investigated: 1) spatially cylindrical

RADIATIVE COOLED TARGET FOR THE ILC POLARIZED POSITRON SOURCE*

A. Ushakov,† University of Hamburg, Hamburg, Germany
F. Dietrich, S. Riemann, T. Rublack, DESY, Zeuthen, Germany,
P. Sievers, CERN, Switzerland

Abstract

The target for the polarized positron source of the future International Linear Collider (ILC) is designed as wheel of 1 m diameter spinning with 2000 revolutions per minute to distribute the heat load. The target system is placed in vacuum since exit windows would not stand the load. In the current ILC design, the positron target is assumed to be water-cooled. Here, as an alternative, radiative cooling of the target has been studied. The energy deposition in the target is the input for ANSYS simulations. They include the temperature evolution as well as the corresponding thermo-mechanical stress in the target components. A principal design is suggested for further consideration.

INTRODUCTION

The ILC will provide e^+e^- collisions in the energy range from 250 to 500 GeV, upgradeable to 1 TeV [1]. The positron beam – 3×10^{10} e^+/bunch, 1312 bunches/pulse (2625 for the high luminosity option) and 5 Hz repetition rate – will be produced using the e^- beam which passes a superconducting helical undulator up to 231 meters long to generate circularly polarized photons [2]. The polarized photons hit a Titanium-alloy target located 400 m downstream the undulator to produce polarized positrons [3]. Depending on the undulator parameters, a polarization of about 30% can be achieved for the positron beam which can be enhanced up to 50% using a photon collimator [4]. The corresponding intensity reduction of the positron beam has to be compensated by a longer undulator section.

The typical total average power deposited in the positron target is about 5 kW corresponding to 1.4 MW during the pulse. This power is deposited in the 0.4 radiation length thick Ti6Al4V target ($0.4\,X_0 = 1.48$ cm). In order to distribute the heat load of the photon beam, a target wheel of radius $r = 0.5$ m is proposed. It rotates with 2000 revolutions per minute (rpm) corresponding to a rim velocity of $v = 100$ m/s. The wheel rotates in vacuum since exit windows would not stand the load. Based on first results of running a target wheel prototype [5], it is expected that the proposed water cooling will be a challenge. An alternative could be cooling by thermal radiation: the heat deposited in the Ti alloy target diffuses to a radiator filling the inner part of the wheel. This radiator is rotated and radiates the heat to a stationary cooler. It is also located in the vacuum, opposite of the radiator, and it is water-cooled.

The energy loss calculated with FLUKA Monte Carlo code [6] for the parameter set 500 GeV (high luminosity) and a collimated photon beam with $r = 1$ mm which corresponds to 50% positron polarization. The photon beam hits the target rim with 2625 bunches in a train of 961 μs duration and 5 Hz repetition rate. A photon beam power of about 80 kW is required to achieve a positron beam with 50% polarization and a bunch charge of 3.2 nC. About 4 – 5 kW is deposited in the target. The instantaneous temperature rise per bunch train in the rotating target is roughly 120 K per bunch train since the heat load is distributed on the rotating wheel rim (almost 200 K for the high luminosity option). Only after about 7.4 seconds the beam hits the same place again. The heat dissipation in the target as well as stress and deformation in the target wheel system are calculated with ANSYS [7].

RADIATIVE COOLING

Following the Stefan-Boltzmann radiation law,

$$W = \sigma\epsilon AG(T^4 - T_{\mathrm{cool}}^4)\,, \tag{1}$$

where $\sigma = 5.67 \times 10^{-8}$ W m^{2}K^4 is the Stefan-Boltzmann constant, ϵ the effective surface emissivity, A the surface area and G a geometric form factor, a radiative area $A > 1.6\,\mathrm{m}^2$ is required to remove 5 kW from the positron target assuming $\epsilon = 0.8$, $T = 250\,°$C, $T_{\mathrm{cool}} = 20°$C, $G = 1$.

Temperature Distribution in a Simplified Model

The average energy deposition in the target is 5 kW, the precise value depends on the centre-of-mass energy and the luminosity. As a first ansatz a simple model is considered: The target wheel is a full disk of thickness 1.4 cm. The rim is made of Ti6Al4V and has an emissivity of $\epsilon = 0.25$; the radiative inner part is made of copper with $\epsilon_{\mathrm{radiator}} = 0.7$. The radiation of 5.125 kW is into the environment of $T_{\mathrm{cool}} = 22\,°$C. The resulting stationary radial temperature profile is shown in Fig. 1. The thermal conductivity in Ti alloy is substantially lower than in copper so that the temperature gradient is steep. To avoid temperatures in the target rim above the recommended limits for long-term operation, the contact between target and radiator must be designed accordingly.

ELETTRA STATUS AND FUTURE PROSPECTS

E. Karantzoulis#, A. Carniel and S. Krecic, Elettra – Sincrotrone Trieste, Italy

Abstract

The operational status of the Italian 2.4/2.0 GeV third generation light source Elettra is presented together with possible future upgrades and a vision to its future.

INTRODUCTION

Located on the outskirts of Trieste, Elettra operates for users since 1994 being the first third generation light source for soft x-rays in Europe. During those 20 years many improvements were made in order to keep the machine updated and therefore competitive with the other more recent and modern light sources already designed to operate in top-up. Following the successful set in operation of the full energy injector in 2008, Elettra established top-up operations [1] in spring 2010, although not originally designed for it. Operating in top-up proved to be and still is very beneficial for the machine [2].

Except the above mentioned big upgrades other minor ones added to the smooth and reliable operation of Elettra as reported previously [3]. At the same time studies based on various upgrade scenarios that define the upgrade Phase I are performed. This phase includes plans for upgrading the energy from 2.4 to 2.5 GeV, the possibility of decreasing the emittance [3] (in the present paper the superconducting wiggler currently in operation is taken into consideration), coupling control [4] and mainly rearranging the space for a larger short straight section to be used for additional longer insertion devices.

ELETTRA STATUS

Elettra operates 24 hours/day, seven days a week delivering more than 5000 hours/year of synchrotron light from IR to soft x-rays to 28 beam lines of which 10 are served from dipoles while 2 are in construction/conditioning using light from a superconducting [5] 49 pole 64 mm period 3.5 T wiggler. Many types of insertion devices used such as planar, Figure 8, APPLE II, electromagnetic while one beam line uses a canted set of APPLE II type undulators. The machine consists of a 100 MeV linac a 2.5 GeV booster and a 2/2.4 GeV storage ring. At about 75% of user dedicated time Elettra operates at 2 GeV while for the remaining 25% at 2.4 GeV being the only facility to operate at two energies (both in top-up). The main operating modes are multibunch with a dark gap of 42 ns and hybrid (at 20% of the total user beam time) with a single bunch in the middle of the dark gap. The operating intensities are 310 mA at 2 GeV and 160 mA at 2.4 GeV with a 5 mA single bunch added when in hybrid mode.

In Figure 1, the net availability (blue) is shown during the 3 phases of operations of Elettra; in fact before 2008 the storage ring ramped in energy, whereas after 2008 operates with a full energy injector and since 2010 in top-up. The numbers clearly show that the availability is continuously improving.

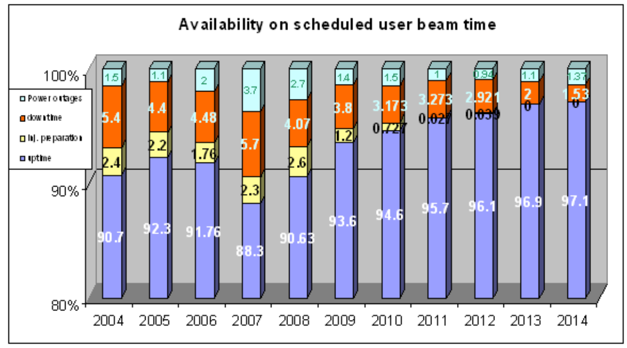

Figure 1: Availability of Elettra. The downtime is shown with red, with yellow the time lost for refilling and with light turquoise the time lost due to external electric power surges.

The downtime distribution amongst the subsystems of Elettra is shown in the next figure 2. As one can observe almost one third of the downtime is due to external electric power surges.

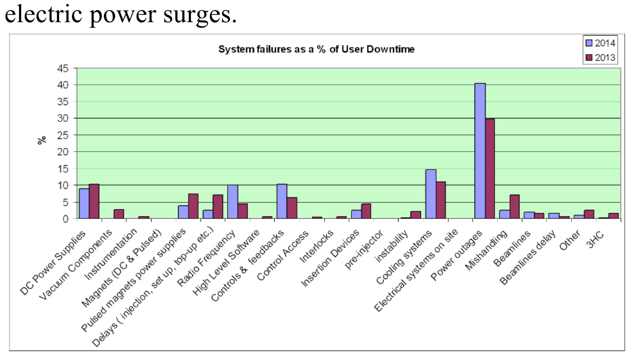

Figure 2: System failures as percent of user downtime for 2014 and 2013.

Another important number indicative of the reliability of a light source is the mean time between failures (MTBF).

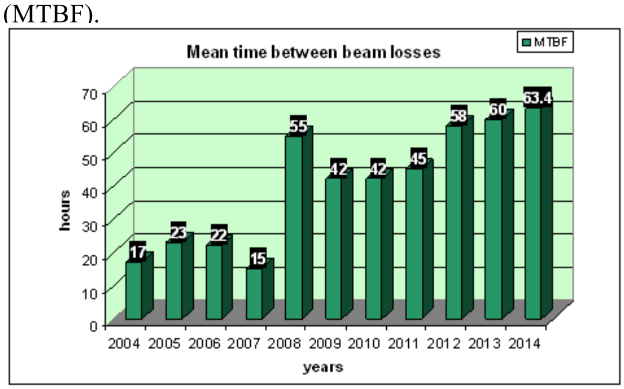

Figure 3: Mean time between beam failures.

ELETTRA 2.0 - THE NEXT MACHINE

E. Karantzoulis, Elettra – Sincrotrone Trieste, Italy

Abstract

A next generation light source (ULS) to replace Elettra, the third generation Italian light source is presented and discussed.

INTRODUCTION

Located on the outskirts of Trieste, Elettra operates for users since 1994 being the first third generation light source for soft x-rays in Europe. During those 20 years many improvements were made in order to keep the machine updated and competitive with the other more recent and modern light sources. Although Elettra will continue serving the scientific community for some more years, it was felt that the right time has come to prepare her successor and therefore studies were performed on this issue [1].

After the 4th generation light sources came to operation, it became evident that free electron lasers (FEL) cannot replace storage rings (SR) (therefore the term 4th generation is not reflecting the reality since each generation replaces the previous one) but rather are complementary. There are many reasons for that such as the SR high repetition rate and the fact SRs can serve a very large number of experiments whereas FELs serve only few (usually one).

SR light sources clearly cannot compete with FELs on the pulse length (ps against fs) at least at comparable intensities but there is a big margin of improvement on other beam characteristics. Already in the 90's people were speculating on diffraction limited light sources [2, 3] although the times were not yet ripe.

In general a ULS compared to a 3rd generation must have a much higher brilliance (at least one order of magnitude at low photon energies e.g. 1 keV) a high level of coherence in both planes (the 3rd generation has only high vertical coherence) smaller spot size and divergence, higher flux and variety of insertion devices.

Certainly all those beam properties, highly desirable for many experiments, have a great impact on the design and operability of those machines. Reducing the emittance by more than an order of magnitude may result in using higher gradients therefore higher chromaticities, smaller dynamic apertures and stronger non-linear effects. If on this one adds other requirements as for example installing the new machine in the same tunnel in replacement of the old one the degree of complication may increase exponentially.

REQUIREMENTS FOR ELETTRA 2.0

In a previous paper [1] an exhaustive analysis of emittances, beam sizes and free available space for realistic lattices from 4 to 9 bend achromats was made. How Elettra2.0 should be came by merging that analysis with the requirements of the users as expressed during a workshop on the Future of Elettra in April 2014 and summarized below:

- Energy 2 GeV
- Same building, same ring circumference (259-260m)
- Maintain the existing ID beam lines, same position
- Maintain the existing bending magnet beam lines
- Emittance reduction by more than 1 order of magnitude
- Electron horizontal beam size less than 60 um
- Intensity 400 mA, maintain the filling patterns as before (hybrid, single bunch etc.)
- Free space available for IDs not less than that of Elettra
- Use the existing injectors i.e. off-axis injection
- 6+6 months downtime for installation and commissioning

The above user requirements and the analysis made in [1] led us to adopt the 6-bend achromat as best solution.

ELETTRA 2.0 LATTICES

The 6-bend achromat optics, shown in Figure 1 (using OPA [4]), has an emittance of 0.25 nm-rad with WP (33.2, 9.3) and natural chromaticities (-63,-50). The corresponding horizontal beam size at the straight sections is 40 μm for the horizontal and 3 μm for the vertical one at 1% coupling (however higher coupling i.e. towards round beams to avoid resistive wall effects is preferable) and the divergence is 6 μrad. The dipoles have now a field of 0.8 T (compared with 1.2 T at 2 GeV of Elettra) and their maximum quadrupole component is 17 T/m (compared with 2.8 T/m in Elettra). The quadrupoles have a maximum gradient of 53 T/m (compared with 15 T/m in Elettra).

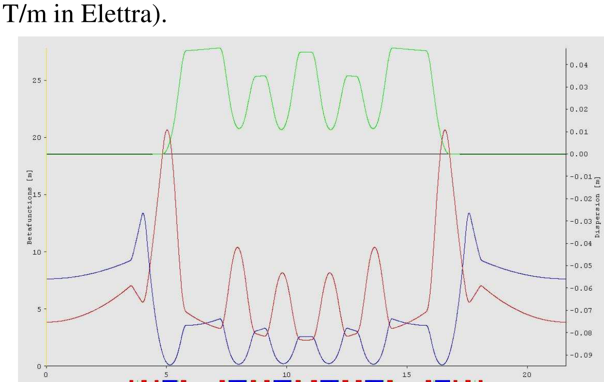

Figure 1: Elettra2.0 lattice 1.

The dispersion in the arcs is low (40 mm compared with 400 mm in Elettra) meaning that also the short straight sections (1.4 m long) situated in the arcs before the outer dipoles can be used for insertion devices with

INFLUENCE OF A NON-UNIFORM LONGITUDINAL HEATING ON HIGH BRIGHTNESS ELECTRON BEAMS FOR FEL

E. Roussel*, E. Allaria, M. B. Danailov, G. De Ninno, S. Di Mitri, E. Ferrari, D. Gauthier, L. Giannessi, G. Penco, Elettra-Sincrotrone Trieste S.C.p.A., Basovizza, Italy

Abstract

Laser-heater systems are essential tools to control and optimize high-gain free electron lasers (FELs), working in the x-ray wavelength range. Indeed, these systems induce a controllable heating of the energy spread of the electron bunch. The heating allows in turn to suppress longitudinal microbunching instabilities limiting the FEL performance. In this communication, we show that a long-wavelength energy modulation of the electron beam induced by the laser heater can persist until the beam entrance in the undulators, affecting the FEL emission process. This non-uniform longitudinal heating can be exploited to investigate the electron-beam microbunching in the linac, as well as to control the FEL spectral properties. Here, we present experimental, analytical and numerical studies carried out at FERMI.

INTRODUCTION

In free electron lasers (FELs), relativistic electron bunches are used to produce intense light from the far infrared to the EUV and X-rays domain [1]. This fourth generation light-source requires electron beams of high quality with very low emittance and high peak current. The control of peak current is achieved by compressing the electron bunch through dispersive magnetic chicane along the accelerator. Many FELs have shown up a longitudinal instability growing up in these chicanes, called microbunching instability which leads to the formation of structures in the electron bunch longitudinal phase-space (in position and energy) [2]. This instability, typically driven by the coherent synchrotron radiation (CSR) and the longitudinal space charge (LSC) effect, increases the electron beam slice energy spread and can limit the FEL emission. The use of the so-called laser heater (LH) is a possible technique to control or even suppress the microbunching instability [3]. This enables to carefully adjust the slice energy spread of the electron beam.

Here we show that a modulated LH pulse can induce a controllable modulation of the slice energy spread of the electron beam, i.e. leading to a non-uniform longitudinal heating. This modulation can be sustained by the microbunching instability in the linac and so, can survive until the entrance of the electron beam in the undulators. This induced modulation allows us to investigate the microbunching instability along the accelerator. Moreover, the FERMI FEL [4, 5] is based on the high gain harmonic generation (HGHG) seeding scheme [6] and the interaction of this modulated electron beam with the seed laser can lead to the emission of multi-color FEL light.

* eleonore.roussel@elettra.eu

MODULATED LASER HEATER

The laser heater system process consists in a resonant laser-electron interaction in an undulator placed after the photoinjector [7] (Fig. 1). The FERMI LH system [8] consists of a short undulator in the middle of a chicane in which the electron beam interacts with a near infrared laser pulse. The electron beam and the laser pulse overlap both transversally and longitudinally. The modulated laser heater pulse is obtained using the chirped pulse beating technique [9]. In this technique, two copies of a chirped laser pulse interferes with one copy delayed with respect to the other. This leads to an output laser pulse with a quasi-sinusoidal modulation whose frequency is proportional to the delay. The main LH parameters are given in Table 1. The delay between the two LH pulses is equal to 28.2 ps which leads to a modulation at a beating wavelength of 32.6 μm (Fig. 2(b)).

Table 1: Main Laser Heater Parameters

Laser heater parameters	
Wavelength	780 nm
Bandwidth (FWHM)	8.4 nm
Pulse duration (FWHM)	12.9 ps
Energy	≤70 μJ
Delay between the 2 pulses	28.2 ps
Beating frequency (wavelength)	9.2 THz (32.6 μm)

NON-UNIFORM HEATING

We apply this modulated LH pulse on the electron beam. Using numerical simulations based on Genesis [10], we checked that a modulation of the energy spread is induced in the LH undulator and survives after the half-chicane of the LH section. The main parameters are given in Table 2. The average power of the laser heater used for the numerical simulation is low (below 1 MW). Indeed, the modulated region of the LH pulse is located in the tail of the main LH pulse (Fig. 2(b)) where the intensity of the LH is weak.

In Figure 3(a), one can see that at the exit of the LH undulator, the electron beam undergoes an energy modulation at the optical wavelength (here, 780 nm) but also an energy spread modulation at the beating wavelength of the LH pulse (here, 32.6 μm). However, the principle of the LH is to induce a controllable increase of the slice energy spread of the beam without modulation of the beam. In that purpose, the half-chicane of the LH is designed to smear out the modulation at 780 nm. By applying the transport matrix R corresponding to the half-chicane, we verified that the energy modulation is suppressed but the energy spread modulation is conserved

Abstract

FERMI is the seeded FEL user facility in Trieste, Italy, producing photons from the VUV to the soft X-rays with a high degree of coherence and spectral stability. Both FEL lines, FEL-1 and FEL-2, are now available for users, down to the shortest wavelength of 4 nm. We will report on the completion of the commissioning of the high energy FEL line, FEL-2, and on the operational experience for users, in particular those requiring specific FEL configurations, like two-colour experiments. We will also give a perspective on the improvements and upgrades which have been triggered by our experience and are aiming to maintain as well as to constantly improve the performance of the facility for our user community.

INTRODUCTION

FERMI [1] has been operating for external users since December 2012, on the VUV to EUV FEL-1 line, covering photon energies between 12 eV and 62 eV [2]. High degree of longitudinal and transverse coherence, tunability, spectral stability with pulses close to the Fourier limit, very low time jitter synchronization to an optical pump laser are among the distinguishing features that make this facility very attractive for the scientific community. The capability of controlling the radiation polarization is another of the unique characteristics of FERMI; a characterization of the degree of polarization in various configurations has recently been reported in [3].

The EUV to soft X-rays photon energy range is covered by the FEL-2 line (62 eV to 310 eV). As a very important milestone, in September 2014 the energy per pulse reached the nominal expected intensity, 10 μJ at 4 nm, the shortest wavelength. The spectral quality and operability characteristics of FEL-2 are similar to those typical of FEL-1, even if an upgrade program has been started to guarantee the same robustness, reliability and flexibility that the user community experiences on FEL-1.

#michele.svandrlik@elettra.eu

Three beamlines, each equipped with an experimental station, are now opened for users: Diffraction and Projection Imaging (DiProI), Elastic and Inelastic Scattering TIMEX (EIS-TIMEX), Low Density Matter (LDM). Three more will be available for users in 2016.

FEL-2 COMMISSIONING RESULTS

In order to efficiently seed the electron beam at short wavelengths, FEL-2 is based on a double stage cascaded HGHG scheme. The external laser seeds the 1st stage that consists of a modulator and a two sections radiator; the photon pulse generated in the 1st stage seeds the 2nd stage, made by a second modulator and a six sections radiator. The magnetic chicane after the 1st stage delays the electron beam with respect to the photon pulse, to shift the seed generated in the 1st stage onto fresh electrons.

First lasing of FEL-2 was successfully demonstrated in October 2012 at 14.4 nm [4]. The performance of FEL-2 was then progressively optimized and extended to shorter wavelengths until in September 2014, finally, nominal operating conditions were attained at the lower edge of the wavelength range of FEL-2, namely 4.0 nm [5]. Main parameters for FEL-2 are listed in Table 1.

Table 1: FEL-2 Main Parameters

Parameter	**Value**
Beam Energy (GeV)	1.0 - 1.5
Peak Current (A)	700 - 800
Repetition Rate (Hz)	10 - 50
Wavelength range (nm)	20 - 4
Polarization	variable
Expected pulse length (fs)	< 100
Energy per pulse (μJ)	up to 100 (~10, 4 nm)
Typical rel. bandwidth % rms	~0.03 (~0.07, 4 nm)
Shot to shot stability % rms	~25% (~ 40%, 4 nm)

This result was achieved after an accurate machine optimization, by setting the peak bunch current to 700 A, the beam energy at 1.5 GeV, keeping the emittance around 1.5 mm mrad for a properly matched beam at the

DAΦNE GAMMA-RAY FACTORY

D. Alesini, S. Guiducci, C. Milardi, A. Variola, M. Zobov (INFN/LNF, Frascati, Rome, Italy);
I. Chaikovska, F. Zomer (LAL, Orsay, France)

Abstract

Gamma ray sources with high flux and spectral densities are the main requirements for new nuclear physics experiments to be performed in several worldwide laboratories with dedicated facilities. The paper is focalized on a proposal of experiment on γ photons production using Compton collisions between the DAΦNE electron beam and a high average power laser pulse, amplified in a Fabry-Pérot optical resonator. The calculations show that the resulting γ beam source has extremely interesting properties in terms of spectral density, energy spread and γ flux comparable (and even better) with the last generation γ sources. The energy of the γ beam depends on the adopted laser wavelength and can be tuned changing the energy of the electron ring. In particular we have analyzed the case of a γ factory tunable in the 2-9 MeV range. The main parameters of this new facility are presented and the perturbation on the transverse and longitudinal electron beam dynamics is discussed. A preliminary accelerator layout to allow experiments with the γ beam is presented with a first design of the accelerator optics.

INTRODUCTION

Many projects worldwide, based on Compton back-scattering between electron bunches and counter propagating laser pulses, are aimed to generate γ photons with high flux and high spectral densities [1-5].

For this purpose it is necessary both to increase the number of electron-photon collisions and to control the electron and laser beam qualities. In normal conducting photo-injectors [6] the maximum repetition rate of the collisions cannot exceed few kHz and also the bunch charge cannot overcome few hundred of pC to preserve good beam quality. On the other hand, due to the very good beam emittance, it is possible to strongly focalize the beam at the interaction point (IP). Then colliding lasers with a high energy per pulse and low repetition rate are required [3-4]. High flux and high spectral densities can be also obtained using storage ring and high rep. rate laser. The aim of the proposal [7] presented in this paper is to create such a source using the DAΦNE stored electron beam colliding with a laser beam amplified in a Fabry-Perot Cavity (FPC) similar to the one designed and fabricated at LAL Orsay, and used in the ATF experiment [8].

DAΦNE is an e+e- collider operating at the energy of Φ-resonance (1.02 GeV c.m.) [9]. Few machine parameters [10,11], are summarized in Table I. As discussed in the paper, the extremely high current storable in the electron ring and the achievable beam emittance, allow reaching excellent γ-beam qualities comparable (and even better) with those of the new generation sources. Moreover, with a proper choice of the machine parameters, the interval between two consecutive collisions of an electron with a photon can be much longer than the damping time of the machine and the beam dynamics is completely dominated by the dynamics of the electron ring without the laser.

Table I: DAΦNE Parameters

Energy	E [MeV]	510
Machine length	L [m]	97.6
Max. stored current	I_{MAX} [A]	2.5 (e- ring)
RF frequency	f_{RF} [MHz]	368.67
Max RF voltage	V_{RF_MAX}[kV]	250
Harmonic number	h_N	120
Min.bunch spacing	T_B[ns]	2.7 (=1/f_{RF})
Hor. emittance	ε_x [mm mrad]	0.250
Coupling	$coupl=\varepsilon_y/\varepsilon_x$ [%]	<0.5
Bunch length	σ_t [ps]	40-60
Energy spread	ΔE/E [%]	0.04-0.06
Long. Damp. time	τ_{damp} [ms]	17

COLLISION SCHEME AND RESULTS

Compton sources can be considered as electron-photon colliders. For a generic γ-source there are four important quantities that characterize the source: the total number of scattered photons per second over the 4π solid angle, the rms source bandwidth (BW), the number of photons per second in the bandwidth and the spectral density. These quantities can be calculated with simple formulas that can be found in [4,7,12-15].

A simple sketch of the interaction region is given in Fig. 1.

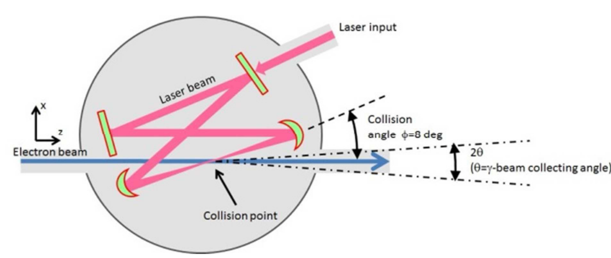

Figure 1: Simple sketch of the interaction region.

Since, in the DAΦNE ring, the coupling can be small (typically <1%) we have considered, at the IP, the case of a flat electron beam and a round laser beam with equal vertical dimensions. It is easy to demonstrate [7] that, to have an equal contribution of the electron beam emittance to the γ final energy spread in both horizontal and vertical planes, the ratio of the β-functions β_y/β_x at the IP has to be equal to the machine coupling. The results of the calculations are given in Fig. 2-3 where few important γ-source parameters have been plotted as a function of the

NEW GUN IMPLEMENTATION AND PERFORMANCE OF THE DAΦNE LINAC

Bruno Buonomo, Luca Gennaro Foggetta, Graziano Piermarini, INFN/LNF, Frascati (Roma), Italy

Abstract

A new electron gun system has been developed for the DAΦNE LINAC, and put into operation since January 2014. Several elements of the system were upgraded, including a new grid pulser, an improved bias voltage system and a renewed cathode socket.

The new LINAC gun has now a wider range of parameters, i.e. the emission pulse length spans from 1.4 ns up to 40 ns, while the better control of the grid and bias voltage allows a maximum peak current of 5 A with a pulse repetition rate of 50 Hz. This paper describes the details of the pulser, the power supply, the socket, all the service components of the upgraded gun and its integration in the main LINAC control system. A report on the performance of the LINAC with the new gun will follow.

INTRODUCTION

The injector of the DAΦNE accelerator complex is an S band (2856 MHz) LINAC that alternately produces and accelerates the electron and positron beams up to the collider operation energy of 510 MeV. Before injection into the Main Rings the beams are stored into the Accumulator ring for phase space damping. The LINAC has been designed, built, and installed by TITAN BETA (USA); the system checking has been done jointly by TITAN BETA and LNF personnel, while the commissioning with both beams has been entirely performed by the LNF staff. The commissioning phase started on April 1996 and was concluded on February 1997.

Since November 2002 the LINAC also delivers beam to Beam Test Facility (BTF)[1] at a maximum repetition rate of 50 Hz: electrons with energy up to 750 MeV, with a typical current of 180 mA/pulse, or positrons with energy up to 510 MeV, with a typical current of 85 mA/pulse. The Beam Test Facility (BTF) is a beam transfer line optimized to produce single electrons and positrons mainly for high-energy detectors calibration in the energy range between 25 MeV and the maximum LINAC energy, and can provide beam in a very wide range of intensities, up to 10^{10} electrons/pulse.

LINAC GUN DESCRIPTION AND PARAMETERS

The electron source consists of a gridded electron gun with replaceable cathode, high voltage deck 150 kV power supply, isolation transformer and sufficient corona shielding to be processed up to full voltage in air.

The deck contains all the necessary electronics to operate the electron gun, and includes fiber optical links to the low level control chassis. Typical operation values are 6 A 120 kV in the positron mode, and 0.5 A 120 kV in the electron one. In normal operation (DAΦNE injection at 510 MeV) the gun is pulsed at 50 Hz with a rectangular waveform of 10 ns.

Up to this date, two different type of cathode grid assembly (HWEG-1227[2] and EIMAC Y796[3]) have been used to provide electron/positron beams during the DAΦNE LINAC operation. The difference between the two types is the size and current capabilities of the planar cathodes. The main specifications of the EIMAC Y796 installed in May 2010 are summarized in Table 1.

Table1: Cathode Grid Assembly Data Sheet

Conflat Size	3-3/8"
Grid-Cathode Spacing (DGK)	170 microns (cold)
Emission, typical	12 A @ Ec=100V
Cathode Area	2.0 cm²
Cathode Heater Voltage	6.0/7.5 V
Cathode Heater Current, typ.	5.8 A @ 6.0 V
Cathode Type	Planar Dispenser

UPGRADE OF ELECTRON GUN

In order to increase the efficiency of the DAΦNE LINAC, a complete upgrade of the electronic control chassis of the electron gun has been performed, starting in January 2014.

A new socket cathode has been installed to obtain the best electrical connection between the high voltage deck and cathode (see Figure 1).

Inside the isolated high voltage station, the old custom TITAN BETA electronics has been replaced, and the new gun electronics (grid pulser and multiple outputs DC Power Supply System) was installed (see Figure 2).

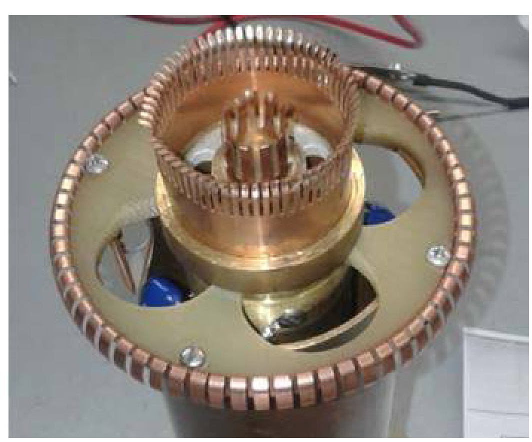

Figure 1: New cathode socket.

DAΦNE LINAC: BEAM DIAGNOSTICS AND OUTLINE OF THE LAST IMPROVEMENTS

Bruno Buonomo, Luca Gennaro Foggetta, INFN/LNF, Frascati (Rome), Italy

Abstract

The LINAC of the DAΦNE complex is in operation since 1996, both as injector of the e^+ e^- Φ-factory, and, since 2003, for the extraction of electron beam to the Beam Test Facility. In the last years, many improvements have been developed in different sub-systems of the LINAC, aiming at a wider, tuneable range of beam parameters, in particular the pulse time width and the pulse charge. A long term measurement campaign has been recently started to characterize the LINAC performance after that many sub-systems has been overhauled and improved, starting from RF power (i.e. klystron substitution, modulator renewal, RF driver layout, SLED tuning) as well as the timing system, magnets, cooling, vacuum, control system and energy/position diagnostics. This work reports the latest results on the optimization of the fully consolidated system.

LINAC DESCRIPTION

The electron-positron LINAC of the DAΦNE collider complex is a ~60 m long, S-band (2856 MHz) linear accelerator, and has been in operation since 1997. It includes a thermionic gun[1], four 45 MW SLEDed klystrons (Thales TH-2128C) and 15, 3 m long travelling-wave accelerating sections[2].

With reference to figure 1, it is possible to see that three of the klystrons have exactly the same configuration consisting of an evacuated rectangular waveguide network with three 3 dB splitters arranged in order to divide the klystron power into four equal parts, feeding each one an accelerating section. The fourth klystron has a different configuration: half the power is sent to the capture section (CS), the first section downstream the positron converter (PC), while the second half is equally divided between two branches feeding the accelerating section P1 the first one, the prebuncher, the buncher and the accelerating section E1 the second one.

All the 15 accelerating sections (E1-E5, CS, P1-P9) are of the same type: the well known 3 m long, 2/3 π travelling wave, constant gradient, SLAC design structures. In our configuration, with 45 MW coming out the klystron, the nominal accelerating component of the electric field is 24 MV/m in the CS and 18 MV/m in the remaining accelerating sections.

The phase adjustments between the sections are performed by means of low power 360° phase shifters upstream the RF amplifiers of each klystron, and by a high power 360° phase shifter that uncouples the CS from E1. The relative phasing between accelerating sections belonging to the same klystron network were regulated once and for all by properly adjusting the rectangular waveguides upstream the section inputs.

The above described configuration allows changing arbitrarily the phase of the CS with respect to E5, and this is an important feature in the positron mode of operation.

The four modulators are able to produce a pulse of 4.5 µs flat top with a repetition rate at 50 Hz, with a HV power supply with resonant circuit charging the pulse forming network (PFN), composed by 9 LC cells up to 50 kV, and a switching thyratron (type EEV CX2168).

The positron converter subsystem is based on the SLAC scheme. The conversion is obtained by interposing to the electron beam a metallic target and collecting the produced positrons by a flux concentrator jointly with DC solenoid magnets, generating a 5 T peak magnetic field. The system allows the choice of three different targets, with thickness varying around 2 radiation lengths, built with an alloy of 75% of tungsten and 25% of rhenium. A remotely controlled actuator permits to extract the target from the beam path during the electron mode of operation.

The focusing system is configured according to the requirements of the interested LINAC portion. An easy way to describe this system is to follow a particle beam from the gun to the LINAC end. The first coil that the beam finds is the bucking coil, used for reducing the presence of magnetic field in the gun cathode region, followed by a 'thin lens' with a solenoid driving the beam to the pre-buncher. The pre-buncher, buncher and the accelerating section E1 are immersed in a solenoidal field produced by 14 Helmholtz coils. A quadrupole doublet between E1 and E2 allows matching between the solenoidal focusing system with the FODO that transports the beam to the positron converter.

The FODO is composed by two quadrupoles per each of the four accelerating sections (E1-E4). A high gradient quadrupole triplet upstream the positron converter is used for focusing the beam into a 1 mm (RMS) radius spot on the converter target. The focusing system on the positron converter area and on the accelerating sections CS and P1 has been already described.

Downstream this part is placed the positron/electron separator which, in the positron mode, separates secondary positrons and electrons in 2 different paths and eliminates the electrons by means of a beam stopper. In the remaining part of the LINAC, from section P2 to P9, a FODO, composed by 26 quadrupoles with steps tapered according to the beam energy, completes the focusing scheme.

A network of vertical and horizontal correctors, in general a couple on each of the accelerating sections, is used for LINAC orbit correction.

Abstract

The SPARC linac at the INFN Frascati Labs is a high brilliance electron source with a wide scientific program including production of THz and Thomson backscattering radiation, FEL studies and plasma wave acceleration experiments. The linac is based on S-band RF and consists in an RF Gun followed by 3 accelerating structures, while an energy upgrade based on 2 C-band accelerating structures is ready to be implemented. Short bunches are ordinarily produced by using the linear RF bunch compression concept. A harmonic RF structure interposed between the Gun and the 1st accelerating structure can be used to optimize the RF compression by a longitudinal phase space pre-correction, allowing to reach shorter bunches, a much more uniform current distribution and in general to control better the whole compression process. Here we report the results of numerical studies on the SPARC bunch compression optimization through the use of a harmonic cavity, and the design of a C-band RF system to implement it. The proposed system consists in a multi-cell SW cavity powered by a moderate portion of the total RF power spilled from the C-band power plant already installed for the linac energy upgrade.

INTRODUCTION

The SPARC_LAB [1,2] linac at the INFN Frascati Lab produces high brightness electron beams by means of the Velocity Bunching (VB) [3], a technique that preserves the low emittance value shown by the beam at the photo-injector GUN exit [4,5,6].

In the last few years the worldwide interest in high brightness electron beams moved towards very low charge ($0.5 - 20\ pC$) ultra-short bunches. This interest is aimed at performing experiments like single spike X-ray Free Electron Laser (XFELs) [7,8], Plasma Wake Field Acceleration (PWFA) [9] and Laser Wake Field Acceleration (LWFA). To satisfy the request of ultra-short, high quality bunches, the VB process can be improved by adding a High Harmonic Cavity (HHC) to pre-correct the bunch Longitudinal Phase Space (LPS) to shorten and flatter the charge distribution. The HHC is also an additional tool to shape the beam in peculiar configurations, such as comb-like distributions [10].

The LPS pre-correction scheme in the Magnetic Bunch Compressors (MBCs) is already well known [11] and the nonlinear term in the beam LPS coming from the curvature (second-order term) of the accelerating RF can be fully compensated by a decelerating HHC. The required correction field to compensate the curvature of the main accelerating RF is given by:

$$V_h \cos\phi_h = -V_{acc} \cos\phi_{acc} / n^2 \quad (1)$$

where V_h, V_{acc} and ϕ_h, ϕ_{acc} are the amplitudes and phases of the harmonic and accelerating voltages respectively, and $n = f_h / f_{acc}$ is the harmonic number. According to Eq. 1 the larger the harmonic number, the lower the beam deceleration required for LPS linearization. At LCLS (SLAC's XFEL), a fourth harmonic of the S-band linac (2.856 GHz) is used, while at the European XFEL and FLASH (Germany) the third harmonic of the main L-band linac (1.3 GHz) is used.

The main difference between MBCs and VB pre-correction schemes is related to the space charge effects, that are negligible for MBCs while are a major issue for the VB that needs to be performed at quite low energies (4-7 MeV). The VB [3] is based on the slippage of not fully relativistic bunches on the accelerating RF wave towards the capture phase, and the bunch distribution in the LPS at the end of the process is affected not only by the RF curvature, but also by space charge effects that are damped by the energy increase but enhanced by compression. The final result is more a distortion than a simple curvature of the LPS, and cannot be easily compensated following the Eq. 1 as for the MBCs case. This difference is crucial; as a matter of fact the correction efficiency is no longer related to the harmonic order as in Eq. 1, but rather to the bunch deceleration before the injection into the first RF accelerating section downstream the Gun where VB takes place, as it is reported in the next paragraph.

SIMULATIONS

To better understand the LPS deformation due to Space Charge (SC) effects we started simulating an ideal VB compression case at SPARC using only the first two S-band accelerating cavities. We considered a large 1nC bunch charge to stress the SC effects, 10ps flat-top (no rise-time) laser pulse, at the cathode, with a uniform transverse profile of 1mm (R_{max}). The Gun was powered at 140 MV/m (6.5 MeV at the exit) and the two TW cavities respectively at 23 MV/m and 33 MV/m. The first

MODELING OF PHOTOEMISSION AND ELECTRON SPIN POLARIZATION FROM NEA GaAs PHOTOCATHODES*

O. Chubenko, A. Afanasev
The George Washington University, Washington, DC 20052, USA

Abstract

Many nuclear-physics and particle-physics scientific laboratories, including Thomas Jefferson National Accelerator Facility, Newport News, VA 23606 (Jefferson Lab) which studies parity violation and nucleon spin structure, require polarized electron sources. At present, photoemission from strained GaAs activated to negative electron affinity (NEA) is a main source of polarized electrons. Future experiments at advanced electron colliders will require highly efficient polarized electron beams, which sets new requirements for photocathodes in terms of high quantum efficiency (QE) ($\gg$ 1%) and spin polarization ($\approx$ 85%). Development of such materials includes modeling and design of photocathodes, material growth, fabrication of photocathodes, and photocathode testing. The purpose of the present work is to develop a semi-phenomenological model, which could predict photoemission and electron spin polarization from NEA GaAs photocathodes. Detailed Monte Carlo simulation and modeling of physical processes in photocathodes is important for optimization of their design in order to achieve high QE and reduce depolarization mechanisms. Electron-phonon interactions near the surface and influence of the presence of quantum heterostructures on the diffusion length are studied in depth. Simulation results will be compared to the experimental results obtained at Jefferson Lab and can be used to optimize the photocathode design and material growth, and thus develop high-polarization high-brightness electron source.

INTRODUCTION

For more than 50 years, photoemission from GaAs and GaAs-based photocathodes has been a main source of polarized electrons for many nuclear-physics and particle-physics facilities. Due to a large direct band gap ($E_g = 1.42eV$) and ability to achieve NEA levels (Fig. 1), GaAs can be used to emit polarized electrons efficiently. The efficiency of photocathodes is described by spin polarization, the degree to which the spin is aligned with a given direction, and QE, the ration of the number of emitted electrons to the number of incident photons.

Band model is used to describe optical transitions between valence and conduction bands (Fig. 2). Near the center of Brillouin zone (Γ point) transitions between s-type conduction band state ($l = 0$) and p-type valence band state ($l = 1$) are possible. Since $|l - s| \leq j \leq l + s$, conduction band state is doubly degenerate ($j = 1/2$; $m_j = -1/2, 1/2$). For the valence band we have a four-fold degenerate state ($j = 3/2$; $m_j = -3/2, -1/2, 1/2, 3/2$), which is separated from a doubly degenerate state ($j = 1/2$; $m_j = -1/2, 1/2$) by an energy distance $\Delta \approx 0.3eV$, spin-orbit splitting.

Taking into account four-hold degeneracy of the $j = 3/2$ state, an effective mass description of the valence band structure is commonly used. It is assumed that the valence band consists of two types of holes, the heavy holes ($m_j = \pm 3/2$) and light holes ($m_j = \pm 1/2$). So the valence band consists of three bands: heavy hole valence band, light hole valence band, and split-off valence band.

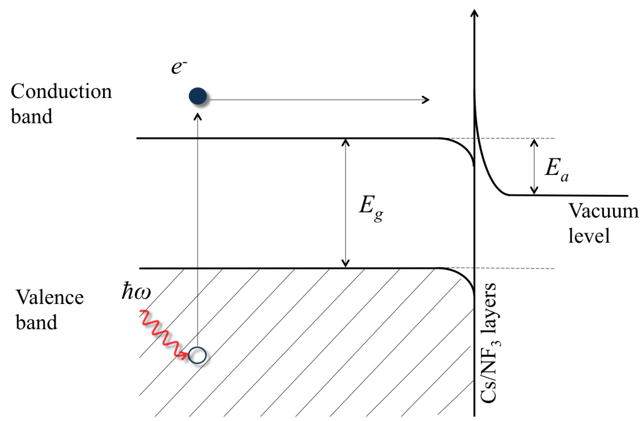

Figure 1: Photoemission from GaAs activated to NEA by putting layers of Cs and NF_3 on the surface of photocathode: photoexcitation of valence electrons into the conduction band; transport of electrons to the surface; emission of electrons into the vacuum.

When unstrained GaAs is illuminated by circularly polarized light (right-polarized, for example), two transitions from $P_{3/2}$ state are allowed, with three times as many electrons in one spin state as in the other spin state (Fig. 3). So theoretically, unstrained GaAs can provide maximum 50% polarization. But because of different depolarizing mechanisms, it is limited at about 35%.

To improve polarization, mechanical strain of GaAs crystals is used. GaAs is grown on a thick substrate, for example GaAsP, whose different lattice constant provides the crystal strain resulting in the valence band degeneracy remove. So excitation by the laser light of certain wavelength allows single transitions from the valence band states, theoretically giving 100% polarization (Fig. 4). But again, depolarizing effects decrease this value to 85%.

Alternating layers of strained GaAs form a Super Lattice (SL) structure (Fig. 5), which helps to improve both polarization and QE.

Abstract

We proposed a torus knot type synchrotron radiation ring in that the beam orbit does not close in one turn but closes after multiple turns around the ring. Currently, we are designing a new ring based on the shape of a (11, 3) torus knot for our future plan 'HiSOR-II.' This ring is mid-low energy light source ring with beam energy of 700 MeV.

Recently some light source rings are achieving very low emittance that reaches a diffraction limited light by adopting a multi-bend scheme to the arc section of the ring. It is not difficult for low-mid energy VUV-SX light source ring because the electron beam less than 10 nmrad can provide the diffraction limited light in the energy less than 10eV. However the multi-bend lattice has many families of the magnets, therefore it is not easy to decide the parameters of the lattice. Especially, it is difficult for the torus knot type SR ring because there is a lot of geometric limitation around the cross points of orbits. We present the details of the designing procedure and the specifications of the ultra-low emittance light source ring having innovatively odd shape.

INTRODUCTION

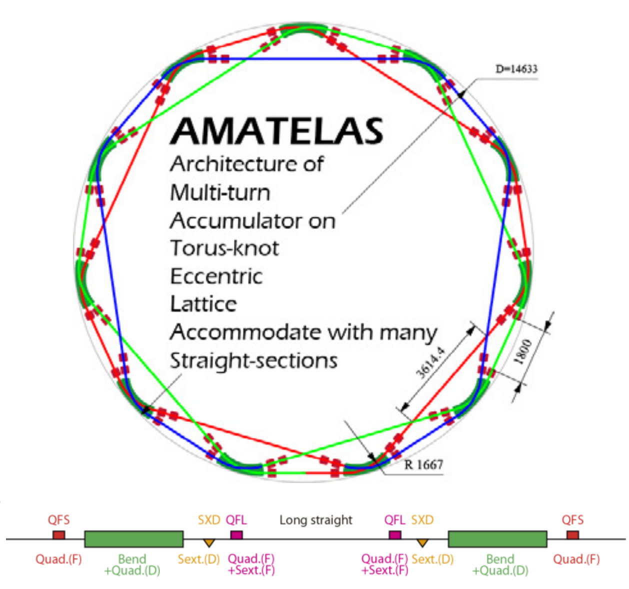

Figure 1: Schematic drawings of (11, 3) AMATELAS designed for HiSOR-II and the lattice of unit cell.

For small light source rings, it is very important to obtain a lot of straight sections in which we can install insertion devices, but it is difficult in reality because they are occupied by various magnets, RF systems or beam monitors. In this context we got a hint from the shape of the torus knot [1], and contrived the ring which had the orbit closed after multiple turns around the ring [2] and named it AMATELAS.

We are planning a new light source ring for our facility [3], therefore we are designing a new ring based on the shape of a (11, 3) torus knot for our future plan 'HiSOR-II' [4]. This ring has 11 long straight sections and we can place insertion devices efficiently by placing the elements such as quadrupole magnets near bending magnet, outside of the orbit crossing section. Furthermore, this ring has about 3 times longer closed orbit in comparison with the conventional ring, the diameter of this ring is as compact as 15 m, but its total orbit length is as long as 130 m. The (11, 3) AMATELAS designed for HiSOR-II storage ring [5] and the lattice of unit cell are shown in Figure 1, and beta or dispersion function of a unit cell is shown in Figure 2.

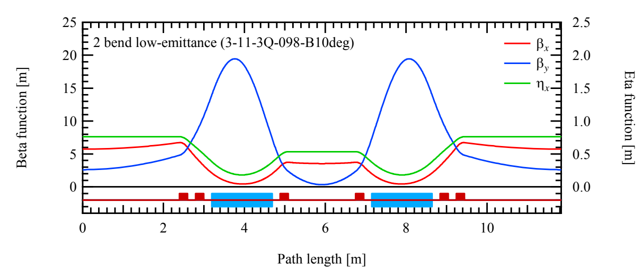

Figure 2: Optical function of (11, 3) AMATELAS for HiSOR-II storage ring.

ULTRA-LOW EMITTANCE RING WITH MULTI-BEND LATTICE

In late years, some compact light source ring achieved ultra-low emittance of several tens of nmrad. For VUV light sources, it means that it obtains the diffraction limited light to achieve such a low emittance beam. Generally, the beam emittance to obtain the diffraction limited light is given as the following.

$$\varepsilon \leq \frac{\lambda}{4\pi}$$

Abstract

Spiral interference patterns between two different harmonic radiations from two tandem-aligned helical undulators were observed by using a scanning fiber multi-channel spectrometer and a UV-CCD camera placed at the beamline of S1 straight section in UVSOR-III storage ring. By a series of measurements, various interference patterns such as single, double, and triple spirals were observed which concur with the theoretical predictions for every mode in the right or left circular polarization. The rotation of an interference pattern by rotating a polarizer was also observed.

INTRODUCTION

A photon beam propagating in the vacuum may carry a quantized orbital angular momentum (OAM) [1, 2]. Based on this fact, many applications in the visible wavelength regime to use light's OAM has been reported such as the manipulation of small particles [3-5], quantum entanglement [6], vector vortex coronagraph for astronomy [7], efficient mode conversion for OAM resolved spectroscopy [8], and so on. On the other hand in the shorter wavelength regime, there have been not many activities on this exotic property due to some difficulties to endow and control such a property. However, after the theoretical prediction that higher harmonic radiation from a helical undulator carries OAM was made [9, 10], this novel property attracts a great deal of attention because it may be used as a new probe for synchrotron radiation science that would be performed in a diffraction limited light source facility such as the MAX-IV, NSLS-II, or APS-II. Although the diffraction limited x-ray source does not yet exist, the first experimental evidence that the second harmonic radiation from a helical undulator carries OAM was presented by Bahrdt, *et al*. at BESSY II [11]. Successive systematic experiments have been done at the UVSOR-III. Here we present experimental results and analyses on OAM properties of undulator harmonic radiation.

EXPERIMENAL SETUP

The 750 MeV UVSOR-III is already a diffraction limited light source in the UV region. In this ring, a tandem-aligned double-APPLE undulator system similar to that in BESSY II is installed for FEL and coherent light source experiments. Using this set-up with a few reduced ring energies, we observed spiral interference patterns between two different harmonic radiations with a scanning fiber multi-channel spectrometer and a CCD camera placed at the end of BL1U Beamline. By these measurements, various interference patterns such as single, double, and triple spirals were observed which concur with the theoretical prediction for every mode in the right or left circular polarization. The rotation of an interference pattern by rotating a polarizer was also observed.

Table 1 shows the total emittance and corresponding diffraction limited wave length at each stored electron energy.

Table 1: Ring Parameters for Experiment

Ring Energy	Emittance	Diffraction Limit. Wave Length
750 MeV	17.5 nm-rad	220 nm (6 eV)
600 MeV	10.9 nm-rad	138 nm (9 eV)
500 MeV	7.6 nm-rad	100 nm (12 eV)
400 MeV	4.8 nm-rad	63 nm (20 eV)

The top view of undulator straight section of UVSOR-III ring is shown in Fig. 1.

GaAs PHOTOCATHODE ACTIVATION WITH CsTe THIN FILM

Masao Kuriki[#1], Yuji Seimiya[#2], Kazuhide Uchida[#3], HU/AdSM, Higashi-Hiroshima, Japan
Shigeru Kashiwagi, Tohoku University, Sendai, Japan

Abstract

GaAs is an unique and advanced photocathode which can generate highly polarized and extremely low emittance electron beam. The photo-emission is possible up to 900nm wavelength. These advantages are due to NEA (Negative Electron Affinity) surface where the conduction band minimum is higher than the vacuum energy state. The NEA surface is artificially made with Cs-O/F evaporation on the cleaned GaAs surface, but the NEA surface is fragile, so that the emission is easily lost by poor vacuum environment and high emission density. NEA activation with any vital material is desirable. We found that the GaAs can be activated by CsTe thin film which is known as a vital photo-cathode material. The photo-electron emission spectrum extends up to 900 nm wavelength which corresponds to the band-gap energy of GaAs. The result strongly suggests that the surface becomes effectively NEA state by the CsTe thin film.

INTRODUCTION

GaAs is a III-V type semiconductor with 1.4 eV direct band gap energy at G point. Valence band electron states which have different angular momentum from -3/2 to 3/2 are degenerated. By employing circularly polarized laser light (+1 or -1 angular momentum) to excite these electron to the conduction band, one of the spin states (-1/2 or +1/2) is enhanced. By introducing special technique as strain and/or super-lattice to break the degeneration, only one spin state can be excited at the conduction band. To extract these spin-polarized electrons in the conduction band to the vacuum state, we need additional energy because the vacuum state is in higher energy state than that of the conduction band minimum in ordinal surface (PEA; Positive Electron Affinity). In contrast, NEA (Negative Electron Affinity) surface where the conduction band minimum energy is higher than that of the vacuum state, makes electron emission possible once they are excited to the conduction band. NEA surface is artificially made on p-type GaAs by adsorption Cs and O/F on the surface. Because the polarized electron excited to the conduction band is in the minimum, the emission is possible only with the NEA surface. NEA surface is however fragile, so it is easily damaged by a poor vacuum quality and particle bombardment. Therefore, the use of the NEA GaAs cathode is currently limited in a DC biased gun and it is not compatible to RF guns.

#1 mkuriki@hiroshima-u.ac.jp
#2 current affiliation is KEK, Japan.
#3 current affiliation is Cosy lab. inc.

If the NEA surface could be made on GaAs surface with a robust thin layer, it could be compatible with RF gun and use of the polarized electron beam would be widen. There was an UPS experiment suggesting that CsTe film on GaAs surface would be NEA[1]. The energy states evaluated from the experiment is shown in Fig. 1. The surface energy state of CsTe on GaAs was 3.1 eV lower than that of bare GaAs according to the experiment[1]. By assuming the work function of bare GaAs is 4.4 eV, the work function of CsTe on GaAs is expected to be 4.1 - 3.1 = 1.3 eV which is lower than the band-gap energy, 1.4 eV. This results strongly suggest that the surface is NEA, because Fermi level of p-GaAs is at the top of the valence band energy.

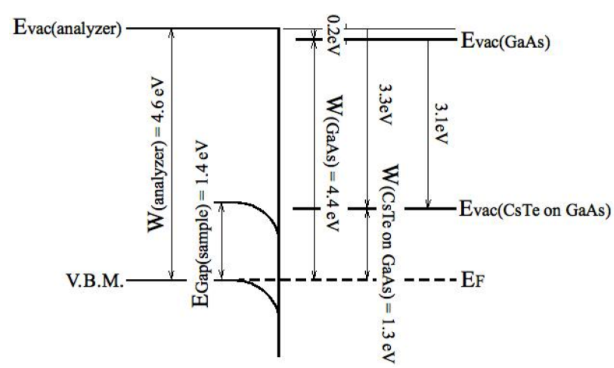

Figure 1: Energy states of CsTe film on GaAs surface. Reprinted from Ref. [1].

The surface state can be understood hetero-junction hypothesis where Fermi energy states for both materials are common. Because Fermi energy of p-GaAs is very close to the top of the valence band energy, the conduction band minimum of GaAs energy becomes higher if the work-function of the surface film f_s is lower than the band-gap energy of GaAs, E_{BG}. The condition for NEA surface is simply expressed as

$$E_{BG} - \varphi_s > 0. \quad (1)$$

In this article, we studied the photo-elelctron emission properties of CsTe-GaAs. Because Cs_2Te is known as one of reliable and robust photo-cathode material[2], NEA activation with CsTe thin film on GaAs could improve the robustness of NEA GaAs photo-cathode.

EXPERIMENT

The experiment was performed in extremely high quality vacuum environment. Zn doped GaAs wafer is placed in a vacuum chamber pumped by ion pump and NEG pump. Typical vacuum pressure during the experiment was $4.0 \times 10^{-9} \sim 2.0 \times 10^{-8}$ Pa. An evaporator

FEL ENHANCEMENT BY MICROBUNCH STRUCTURE MADE WITH PHASE SPACE ROTATION

M. Kuriki#, Yuji Seimiya##, HU/AdSM, Higashi-Hiroshima, Japan
R. Kato##, ISIR, Osaka U., Osaka, Japan
S. Chen, K. Ohmi, J. Urakawa, KEK, Ibaraki, Japan
S. Kashiwagi, Tohoku U., Sendai, Japan

Abstract

FEL is one of the ideal radiation source over the wide range of wavelength region with a high brightness and a high coherence. Many methods to improve FEL gain and quality have been proposed by introducing an active modulation on the bunch charge distribution. The transverse-longitudinal phase-space rotation is one of the promising method to realize the density modulation as the micro-bunch structure. Initially, a beam density modulation in the transverse direction made by mechanical slits, is properly transformed into the density modulation in the longitudinal direction by the phase-space rotation. The micro-bunch structure made with this method has a large tunability by changing the slit geometry, the beam line design, and the beam dynamics tuning. For FEL, energy chirp made by the emittance exchange should be properly corrected. Simulation results and possible applications are discussed.

INTRODUCTION

Laser light is currently widely used for not only to reveal the nature dynamics, but also various applications. Advantages of the laser light over ordinal light source are short duration and coherence. As nature of the laser light, it is almost fully coherent not only in spatial, but also in temporal. In the state of the art technology of the laser, a very short pulse in range of ps to fs is easily obtained by employing mode-lock technique. In various process observed in nature, e.g. electron, nuclear, atomic, and molecular dynamics are in the same range, i.e. from ps to fs. By using these coherence and the short duration, the laser light can be a powerful tool to study these objects. On the other hand, the available energy (wavelength) range by the laser is limited from IR to near-UV. There is a strong demand for tunable, coherent, and short pulse light source. Free Electron Laser (FEL) is one of the solution providing such light. FEL is firstly proposed by J. Madey and now several FEL in X-ray region are in operation[2][3] and construction[4]. SASE FEL is grown from a shot noise and therefore has a large fluctuation, less temporal coherence, and broaden specturm. Seeded FEL as HGHG[5], EEHG[6], etc. which introduce small power laser light to initiate the radiation process have been proposed to improve the FEL performance. More direct density modulation in the bunch intensity is possible by employing the phase-space rotation technique.

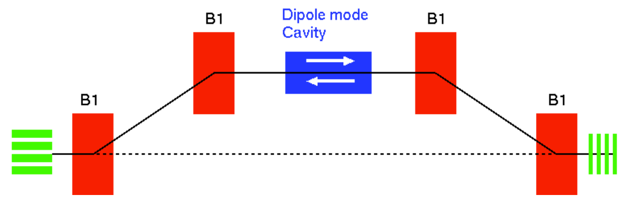

Figure 1: This is a schematic drawing of the beam line for x-z phase-space rotation which consists of one chicane and one dipole mode cavity. It converts the transversely modulated beam to the longitudinally modulated beam.

The schematic view of the beam-line to make the micro-bunch structure by the phase-space rotation is shown in Fig. 1. The beam-line consists from one chicane and one dipole mode RF cavity, such as TM_{110}. The transversely modulated beam generated by mechanical slits is converted to the longitudinally modulated beam. In general, temporal modulation such as micro-bunching can be produced by a photo-cathode with a temporal laser intensity modulation, or laser-beam interaction in undulator like the seeded FEL. It requires a state of the art of technology. On the other hand, the transverse spatial modulation can be made with the mechanical slits and ordinal beam optical components. It is therefore easily obtained. The x-z phase-space rotation give another way to produce the micro-bunching which is applicable for the seeded FEL.

The matrix representation of the beam line M_{EEX} (EEX section) is expressed as

$$M_{EEX} = M_D(\eta,\xi,L)\, M_C\, M_D(\eta,\xi,L)$$

$$= \begin{bmatrix} 0 & 0 & -L/\eta & \eta - L\xi/\eta \\ 0 & 0 & -1/\eta & -\xi/\eta \\ -\xi/\eta & \eta - L\xi/\eta & 0 & 0 \\ -1/\eta & \dfrac{-L}{\eta} & 0 & 0 \end{bmatrix} \quad (1),$$

where M_D and M_C are matrices for the dog-leg and the cavity, h is dispersion, x is momentum compaction, and L is the section length. The matrix is defined in x and z phase-space which is four dimensional in total. Here, the matching condition of the cavity strength parameter k and h given as

$$1 + \eta k = 0 \quad (2),$$

is assumed where k is defined as

STUDY OF INHERENT POTENTIAL FOR EMITTANCE REDUCTION AT THE SPRING-8 STORAGE RING

Yoshito Shimosaki #, JASRI / SPing-8, Hyogo, Japan

Abstract

A design study for an upgrade project of the SPring-8, the SPring-8-II, is in progress, which is a full-scale major lattice modification. Besides the design study for the SPring-8-II, an inherent potential of achieving much higher brilliance than that of the present SPring-8 has been explored for the general evaluation. In this paper, the evaluation of the inherent potential for the SPring-8, not for the SPring-8-II, in terms of increasing the brilliance is discussed.

INTRODUCTION

The SPring-8 storage ring is the third generation type synchrotron radiation facilities with the circumference of 1436 m in Hyogo, Japan. The basic super-period of the ring is 4, and one super-period consists of 9 unit cells, 2 matching cells and a long drift of 30 m (see Figure 1). The natural emittance for the user operation has been reduced from 6.4 nm.rad to 2.4 nm.rad, step by step [1, 2]. The present user-optics with 2.4 nm.rad was opened since 2013, which was optimized for the equilibrium emittance not to be changed drastically by the radiation excitation and the radiation damping due to insertion devices (IDs) in order to provide the stable photon-flux during the user-time [1, 2]. The top-up injection has been utilized to store the electrons of 99.5 mA with the beam energy of 7.976 GeV. The brilliant hard X-ray of the order of 10^{20} photons / sec / mm^2 / mrad^2 / 0.1 % B.W. has been provided.

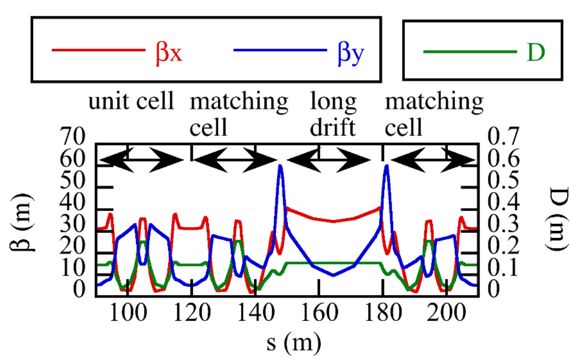

Figure 1: Lattice function of present user optics at the SPring-8 storage ring.

In order to advance promising science and to support industrial innovations, the design study for an upgrade project of the SPring-8, the SPring-8-II, is in progress [3]. In order to increase the brilliance, the electron emittance will be reduced by a multi-bend scheme [4] with a longitudinally varying dipole field [5], by a lower energy operation (6 GeV) than that of the present (8 GeV) and by utilizing a radiation damping by IDs.

Besides the design study for the future SPring-8-II, an inherent potential of achieving much higher brilliance than that of the present user optics has been explored for the SPring-8 storage ring, in order not only to provide brilliant photon beams for "current users" but also to verify a strategy of the lattice design for the SPring-8-II before switching the optics to the SPring-8-II in 2019-2020. Here, the double bend (DB) lattices have theoretically and experimentally been examined at 6 GeV and 8 GeV, and the mixture of both "DB optics" and "double bend achromat (DBA) optics with the damping wigglers" has theoretically been examined. In these designs, it is noted that magnet positions are unchanged and magnetic fields are optimized within the specifications. In this paper, the evaluation of the inherent potential for the SPring-8, not for the SPring-8-II, is presented.

OPTIMIZATION OF DB OPTICS

In general about an optics design, freedoms of the quadrupole and sextupole magnetic fields normalized by beam energy can be expanded by lowering beam energy even within the specifications of the power supplies. From this point of view, DB optics specialized particularly for increasing the brilliance, not the flux density, has been examined at 6 GeV (see Figure 2) in order to explore a potential of the SPring-8 storage ring [6].

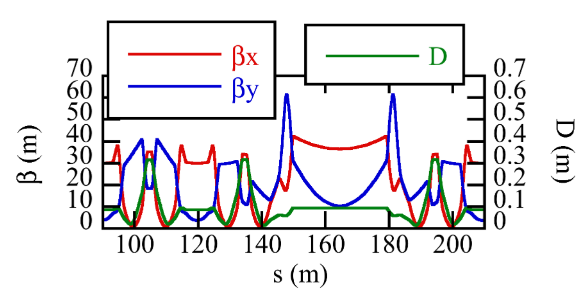

Figure 2: Lattice function of DB optics optimized for 6 GeV at the SPring-8 storage ring.

β_x, β_y and D at the ID positions in Figure 2 are optimized (1) to enhance the emittance damping by IDs, and (2) to decrease the effective photon emittance by matching between the 30 keV photon beam size and the electron beam size at the ID position. The effective photon emittance of 10 keV photon in Figure 2 (6 GeV)

GENERATION OF MULTI-BUNCH BEAM WITH BEAM LOADING COMPENSATION BY USING RF AMPLITUDE MODULATION IN LASER UNDULATOR COMPACT X-RAY (LUCX)

M. Fukuda#, S. Araki, Y. Honda†, N. Terunuma†, J. Urakawa, KEK, Ibaraki, Japan
K. Sakaue, M. Washio, RISE, Tokyo, Japan

Abstract

We have been developing a compact X-ray source based on inverse Compton scattering (ICS) between an electron beam and a laser pulse stacked in an optical cavity at Laser Undulator Compact X-ray (LUCX) accelerator in KEK. The accelerator consists of a 3.6-cell photo-cathode rf-gun, a 12-cell standing wave accelerating structure and a 4-mirror planar optical cavity. Our aim is to obtain a clear X-ray image in a shorter period of times and the target flux of X-ray is $1.7\text{x}10^7$ photons/pulse with 10% bandwidth at present. To achieve this target, it is necessary to increase the intensity of an electron beam to 500 nC/pulse with 1000 bunches at 30 MeV. Presently, we have achieved the generation of 24 MeV beam with total charge of 600 nC in 1000 bunches with the bunch-by-bunch energy difference is within 1.3% peak to peak. The beam-loading has been compensated by injecting the beam before rf power has been filled (ΔT method) and by modulating the amplitude of the rf pulse. We report the results of the multi-bunch beam generation and acceleration in the LUCX accelerator.

INTRODUCTION

X-rays are applied to various area of application, such as medical application, biological science, material science etc. Synchrotron radiation which is generated by GeV order storage rings is commonly used as high brightness X-ray sources. However the rings are generally huge and expensive. On the other hand, an X-ray source based on ICS can be compact and inexpensive compared with its rings because this method can produce X-rays with the same energy by utilizing an electron beam with the lower energy by the rings about two orders of magnitude. However this method requires more development.

In order to develop a compact X-ray source based on ICS for X-ray imaging, we have constructed the LUCX accelerator at KEK. X-rays are generated by ICS between a multi-bunch electron beam with the energy of 24~40 MeV and a laser pulse with the wavelength of 1064 nm in this accelerator.

UPGRADE OF LUCX ACCELERATOR

X-ray imaging experiments have been started here since the autumn of 2011. We have succeeded to take the X-ray image of fish bone [1] so far. However, it took two hours to get this image due to low intensity of X-ray with 10^4 photons/pulse. Therefore we have upgraded this accelerator to increase the intensity of X-rays in 2012. A 3.6-cell rf-gun, a 12-cell booster and a 4-mirror planar optical cavity have been installed and commissioned. The X-ray generation and the X-ray imaging are already started after upgrade [2]. The number of bunches has been extended from 150 bunches to 1000 bunches now. Table 1 shows the present and the design parameters of an electron beam. The target intensity of X-rays is $1.7\text{x}10^7$ photons/pulse 10%b.w. at the energy of 15keV in this upgrade.

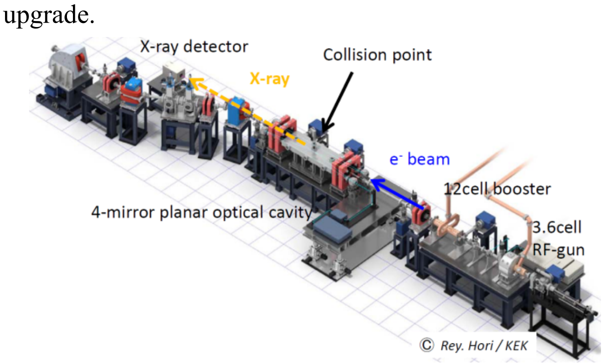

Figure 1: The beamline of the LUCX accelerator.

Table 1: Present and Design Parameters of Electron Beam

	Present	Design
Energy	24MeV	30MeV
Intensity	0.6nC/bunch	0.5nC/bunch
Number of bunch	1000	1000
Beam size (rms)	80μm x 50μm	33μm x 33μm
Pulse length(FWHM)	15ps	15ps

LUCX ACCELERATOR

The the LUCX accelerator is shown in Fig. 1. A 3.6-cell photo-cathode rf-gun generates an electron beam with the energy of 10 MeV and then the beam is accelerated to 30 MeV by a 12-cell booster. After that, the beam is collided with a laser pulse in a 4-mirror planar optical cavity and then X-rays are generated by ICS. The electron beam is separated from the X-ray by a bending magnet and then is dumped to the beam dump. The X-rays are extracted from a beamline through a Be window with the thickness of 300 μm and then detected by either a micro-channel plate (MCP) or an SOI imaging sensor [3].

DEVELOPMENT OF A HIGH AVERAGE POWER LASER FOR HIGH BRIGHTNESS X-RAY SOURCE AND IMAGING AT cERL

A. Kosuge*, A. Akagi, Y. Honda†, S. Araki, J. Urakawa, T. Terunuma†, KEK, Oho, Tsukuba, Ibaraki

Abstract

High brightness X-rays via laser-Compton scattering (LCS) of laser photons stored in an optical cavity by a relativistic electron beam is useful for many scientific and industrial applications such as X-ray imaging. The construction of compact Energy Recovery Linac (cERL) is now in progress at KEK to generate low-emittance and high-current electron beams. In order to demonstrate the generation of high brightness LCS X-rays, it is necessary to develop a high average power injection laser and an optical four-mirror ring cavity with two concave mirrors which is used to produce a small spot laser beam inside the cavity. In this presentation, we will show the result of the development of the high average laser system, the LCS X-rays generation, and the X-ray imaging.

INTRODUCTION

There has been a growing interest in the laser-Compton scattering (LCS) light source. The LCS and a high average power laser with an optical cavity enables generation of monochromatic, bright and tuneable X-rays. Such a photon source is expected to bring breakthrough in fundamental researches [1], medical [2] and industrial applications [3].

The development of the Compact ERL (cERL) is ongoing at KEK to produce low emittance and high-current recirculating electron beams [4]. By combining advanced laser technology with the cERL, a high brightness LCS X-ray beam can be generated. In this paper, we will show the detailed properties of the high average laser used for the LCS X-ray generation at cERL. We will also show the results of the measurement of the LCS X-rays and the X-ray imaging.

PERFORMANCE OF THE SEED LASER SYSTEM AND THE OPTICAL CAVITY

In our experiments, we employ a commercial passively mode-locked diode pumped solid state laser system (ARGOS, Time Bandwidth Products (JDSU)). The oscillator operates at a repetition rate of f_{rep} = 162.5 MHz which has an integer relation with the fundamental RF of the cERL. This laser system delivers an average power of 45 W and pulse duration of 10 ps. The laser beam ejected from the laser system is passed through a mode matching telescope in order to match the laser beam to the cavity mode.

We employ a four-mirror cavity with two concave mirrors to produce a small spot laser beam inside a cavity. Since the LCS X-rays are generated by collision of laser photons and relativistic electrons, the laser beam is required to be well focused at the collision point where the spot size (rms) of the cERL electron beam at the experiment is about 13 - 130 μm (horizontal) and 20 - 25 μm (vertical).

The optical setup of our cavity locking laser system is shown in Fig. 1 (a). The optical cavity consists of two flat mirrors (M1 and M2) and two concave mirrors (M3 and M4). The radius of curvature of the concave mirrors which are manufactured by LMA (Laboratoire des Matériaux Avancés) is 420 mm and the reflectivity is about 99.999 %. The reflectivity of the flat mirror (M2) is 99.99 % and the input coupler mirror (M1) is 99.9 %.

Abstract

In the KEK compact ERL (cERL), machine studies toward higher bunch charge operation is one of the most important issues. From January 2015 to April 2015, we carried out a higher bunch charge operation with an bunch charge of 0.5 pC for the experiment of laser compton scattering. After the study of space charge effect and optics tuning, we succeeded in the recirculation operation with the emittance, which was close to the design value. Moreover, a test operation in the injector section with the bunch charge of 7.7 pC was carried out as a preparation toward the recirculation operation with the average current of 10 mA.

INTRODUCTION

The compact ERL (cERL) is a test accelerator to demonstrate beam performance and high average current operation in an energy recovery linac. It consists of a photocathode DC gun, superconducting RF cavities, a recirculation loop, and a beam dump. The layout of the cERL is shown in Fig. 1. Since commissioning of the injector in April 2013, production and transportation of low-emittance beams have been demonstrated with several tens of fC where the space charge effect can be neglected. In the low bunch charge operation, an energy recovery operation through the recirculation loop with an average current of 6.5 μA was also demonstrated.

One of the most important issues in the cERL operation is to obtain low-emittance and short bunch, high-quality beams under the space charge effect. Since June 2013, we have been studying higher-charge operation with bunch charges of up to 7.7 pC which corresponds to a peak current of 10 mA [1]. To minimize emittance growth due to the space charge effect, we have been developing beam tuning methods.

From January 2015, we increased the maximum average current up to 100 μA [2], and carried out a higher bunch charge operation with the bunch charge of 0.5 pC for the experiment of laser compton scattering (LCS) [3,4]. In this operation, we have to control the space charge effect, because we can not neglect the effect in this bunch charge. Our goal for this operation is to achieve a recirculation without emittance growth. Moreover, we carried out a test operation in the injector section with the bunch charge of 7.7 pC to correct a numerical model for higher-charge and low energy beam. In this paper, we report optics design, tuning methods and our results from higher-charge operations of the injector and the recirculation loop.

* tsukasa@post.kek.jp

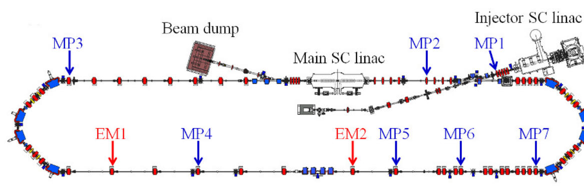

Figure 1: Layout of cERL. MP and EM indicate optics matching point and emittance measurement point, respectively.

RECIRCULATION OPERATION FOR LASER COMPTON SCATTERING

For the LCS operation, the higher bunch charge was required in order to increase the LCS signal power. However, the maximum bunch charge is limited to 77 fC for 1.3 GHz CW operation, in which the maximum average current reaches 100 μA, and it is not enough for the LCS operation. Then, we switched the repetition frequency of the gun excitation laser from 1.3 GHz to 162.5 MHz, and increased the bunch charge to 0.5 pC, in which the average current corresponded to 81μA.

Optics Design

The optics design strategy for the 0.5 pC operation is to use the same RF settings of the injector and main SC linac as the normal operation with several tens of fC to maintain the beam energy, and the same optics parameters at the exit of main SC linac in order to reduce tuning parameters. Under these conditions, we can quickly switch the operation mode from the normal mode to the higher-charge mode. For both operation modes, the beam kinetic energies at the gun, the injector and the main SC linac are 390 keV, 2.4 MeV and 19.4 MeV, respectively, and the distribution of the cathode excitation laser is a gaussian distribution with the rms length of 3 ps.

The optics for the higher-charge operation was designed by the following two steps. In the fist step, we adjusted the strengths of the two solenoid magnets in the injector section to satisfy a condition of emittance compensation. In the second step, based on these solenoid settings, we adjust quadrupole magnets between the injector and the main SC linac to satisfy a optics matching condition at the exit of the main SC linac for recirculation operation, whose values are β_x = 2.67 m, β_y = 2.12 m, α_x = −0.6 and α_y = −0.18. Figure 2 shows the design optics from the gun to the main SC linac for the 0.5 pC recirculation operation. At the exit of the main SC linac, the design horizontal and

SIMULATION STUDY OF BEAM HALO AND LOSS FOR KEK COMPACT ERL

O. Tanaka#, N. Nakamura, M. Shimada, T. Miyajima, S. Sakanaka, High Energy Accelerator Research Organization (KEK), Oho 1-1, Tsukuba, Ibaraki 305-0801, Japan

Abstract

At the KEK Compact ERL (cERL) designed to operate at high-brilliance and high-current electron beams, the maximum averaged current was recorded at about 80 μA for the beam energy 20 MeV on April 2015 and should be increased up to 10 mA in a step-by-step manner in a few years. In order to increase the beam current by reducing the beam loss, we need to know the mechanism of the beam loss. For this purpose we investigate beam halo originated from characteristics and imperfections of an electron gun system, using the tracking code GPT (General Particle Tracer). The beam halo can be lost by the beam-pipe apertures and the collimators in the cERL beam line. In this paper, we will present the measurement and simulation results including the beam halo formation and the beam loss distribution along the beam line.

INTRODICTION

During the last cERL commissioning (January – April, 2015) a high repetition rate (162.5 MHz) electron beams of a 20 MeV energy were produced to test the Laser-Compton scattering (LCS) facility newly installed to the beam line [1] – [2]. Since the average current in the machine is significant (from some pA up to some μA), the beam halo management is extremely important topic for the successful operation.

The beam halo is known to be a collection of particles of any origin and behaviour which lies in the low density region of the beam distribution far away from the core [3]. The beam halo is a key parameter to be improved for any high intensity accelerator. Therefore, experimental measurements and analytical evaluation of the halo distribution are very important to understand the way to minimize the number of particles in the tail region of the beam distribution.

We assume the main reasons of the beam halo in cERL to be:

- Dark current from the gun and from accelerator cavities [4];
- Off-energy beam tails due to mis-steered beam;
- Scattering from residual gas, Touschek scattering [4];
- Beam line elements misalignment, kicks from the couplers, and so on.

The main goal of our research is to understand the beam halo formation processes and to obtain beam halo and corresponding beam loss distribution. Thus, we aim to minimize the radiation damage of the accelerator elements, to avoid emission of secondary electrons, to lower the irradiation outside the machine and nuclear activation of the transport channel, to prevent cavity's quenches, to suppress noise inside detectors, and to reduce the beam loss.

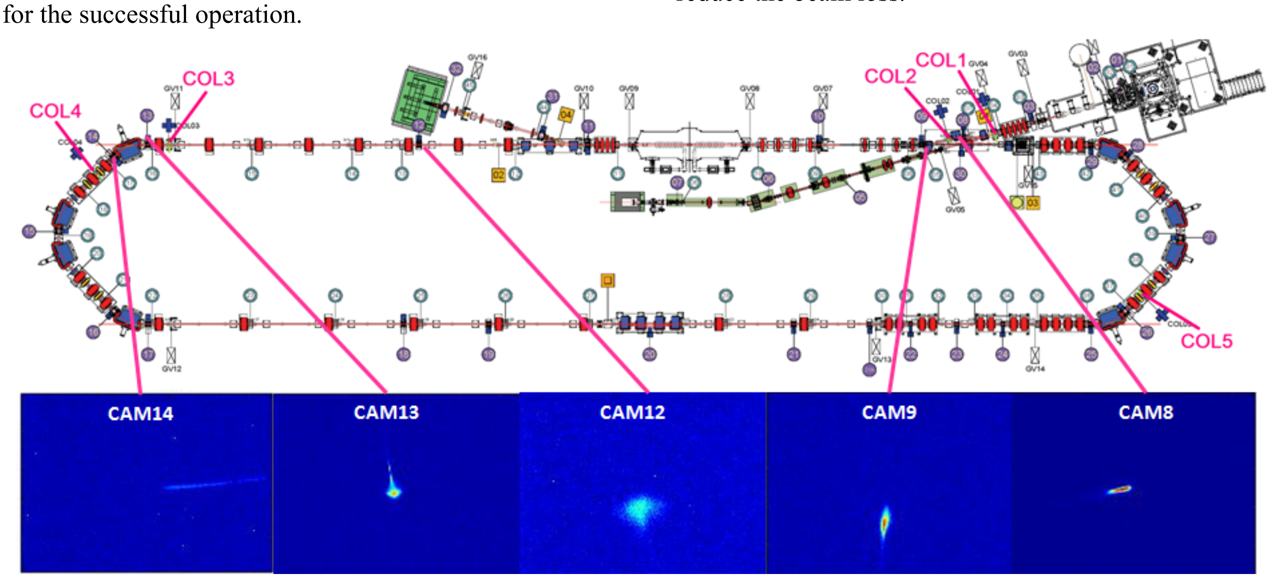

Figure 1: Layout of cERL. Collimators positions and tail profiles screen captures for laser phase +20 deg (42 ps tail).

SIMULATION STUDY ON BUNCH COMPRESSION AND DECOMPRESSION FOR THE COMPACT ERL*

N. Nakamura, M. Shimada, T. Miyajima, K. Harada, O. A. Tanaka, S. Sakanaka,
High Energy Accelerator Research Organization (KEK), Tsukuba, Ibaraki, Japan

Abstract

We study bunch compression and decompression in the Compact Energy Recovery Linac (cERL) at KEK by using simulations to achieve an ultra-short bunch for generation of the THz coherent radiation planned for the near future. In this study, off-crest acceleration in the main superconducting linac and non-zero R_{56} optics in the two arc sections are used and sextupole magnets are introduced into the two arc sections for optimizing T_{566} of the arc sections. The results of the simulation study show that the bunch can be compressed to less than 50 fs and then almost decompressed to the initial bunch length.

INTRODUCTION

The commissioning of the entire cERL was started in December 2013 and the beam recirculation and energy recovery were achieved in February 2014[1]. In 2015, the maximum average current was recorded at about 80 μA and laser-Compton scattering X-rays was successfully generated[2]. In the next step, generation of THz coherent radiation is planned for 2015 - 2016.

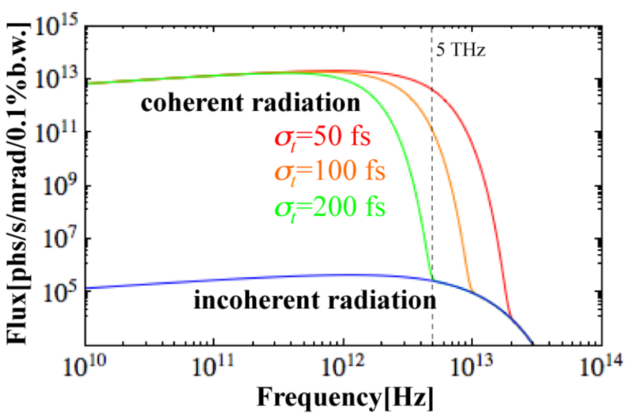

Figure 1: CSR spectra of the 20 MeV cERL for three different bunch lengths of 50, 100 and 200 fs, at the bunch charge of 7.7 pC and the bunch repetition frequency of 130 kHz.

The coherent synchrotron radiation (CSR) spectra generated at a bending magnet of the arc sections are calculated and shown in Fig. 1. An electron bunch less than 100 fs is required for providing intense THz-CSR up to 5 THz to users. We simulate bunch compression and decompression in the cERL by using a tracking code ELEGANT [3] to check the feasibility of generating such an ultra-short bunch. In the bunch compression and decompression simulation, sextupole magnets were added in the two arc sections for optimizing T_{566} of the arc sections. In this paper, we present the simulation results and requirements for the sextupole magnets including their field strengths, number and layout.

LINEAR OPTICS AND SEXTUPOLE MAGNETS OF ARC SECTIONS

Linear Optics

In the bunch compression and decompression scheme of the cERL, the bunch is accelerated off-crest in the main superconducting linac to have a correlation between the energy and longitudinal position and then the bunch length is compressed with a positive R_{56} optics of the 1st arc section. After the bunch compression, the bunch length is decompressed through the 2nd arc section with a negative R_{56} optics and then decelerated off-crest to compress the energy spread to the initial value before the beam enters the dump line. Figure 2 shows the linear optics with three different R_{56} values. The optics with R_{56}=0 is used in the normal operation and the optics with R_{56}=0.15 m and R_{56}=-0.06 m correspond to the 1st and 2nd arc sections in the bunch compression and decompression operation, respectively.

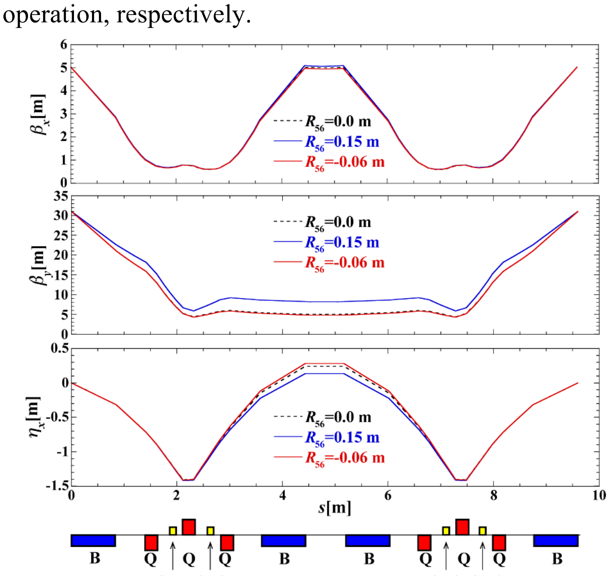

Figure 2: Horizontal and vertical betatron functions (β_x, β_y) and dispersion function (η_x) of the arc sections with three different R_{56} values of 0.0 m (black broken line), 0.15 m (blue solid line) and -0.06 m (red solid line). B, Q and SX1-4 indicate the bending, quadrupole and sextupole magnets, respectively.

CST SIMULATIONS OF THz CHERENKOV SMITH-PURCELL RADIATION FROM CORRUGATED CAPILLARY

K. Lekomtsev[#1,2], N. Terunuma and J. Urakawa, KEK[1], Tsukuba, Japan
A.A. Ponomarenko, A.A. Tishchenko, MEPhI[2], Moscow, Russia
P. Karataev, RHUL, Egham, UK

Abstract

Cherenkov Smith - Purcell radiation (SPR) from a corrugated channel in infinite dielectric material is simulated and compared with a theoretical investigation for such geometry. Dependencies of Cherenkov and SPR intensities on the corrugation depth and the internal radius of the channel are discussed. A corrugated capillary with partial metal coating is also considered in the simulations in order to obtain optimal values of the corrugation depth and the external radius of the capillary.

INTRODUCTION

Terahertz frequency range includes frequencies from 0.3 to 10 THz. This part of electromagnetic spectrum has a variety of potential applications ranging from fundamental, such as studies of physical systems dynamics, to security applications, such as screening of concealed materials [1,2]. Further advances in development of a linac based, tunable and narrow band coherent source of THz radiation are very important. Mechanisms of Cherenkov radiation and SPR may be used for generation of THz radiation via coherent emission [3, 4].

In this report we discuss a hybrid mechanism for generation of coherent THz radiation based on Cherenkov and SPR, produced when a short (100 fs) electron bunch travels through a corrugated channel in dielectric material. The radiation generated by the corrugated channel was simulated using CST (Computer Simulation Technology) Particle Studio (PS) and compared with the theoretical study developed for a corrugated channel in infinite material [5]. LUCX accelerator at High Energy Accelerator Research Organisation (KEK) has been upgraded by introducing a femtosecond Ti:Sapphire laser system and is currently able to generate short, tens to hundreds femtosecond duration electron bunches [6,7]. For a proposed experimental study at LUCX facility at KEK in Japan SPR will be generated in a dielectric capillary with partial metal coating acting as a radiation reflector; the radiation will leave the capillary through the outer boundaries, not covered by the reflector. This geometry allows for generation of narrow-band, coherent SPR in THz region; as well as for more efficient radiation generation, compared, for example, to a flat diffraction grating.

Theoretical Background

Theoretical calculations of the Cherenkov Smith – Purcell radiation from a corrugated channel in infinite dielectric are based on the method of polarization current density (see chapter 4 in [8]). Coulomb field of moving electrons polarizes the material and as a result each elementary volume of the material emits radiation. Electrons in the bunch are distributed with a Gaussian distribution. The polarization currents produce secondary electromagnetic field which then propagates through the material. The spectral - angular distribution of the radiation is given in [5]. The positions of the Cherenkov peak and the SPR peaks satisfy the following dispersion relation:

$$cos\theta = \frac{2\pi m}{kd} + \frac{1}{\beta\sqrt{\varepsilon(\omega)}}; \quad (1)$$

where θ is the polar angle depicted as Theta in Fig. 1; β is the charge speed in terms of the speed of light; k is the wave number in the dielectric; d is the groove period; and m is a diffraction order. The value of $m = 0$ corresponds to the Cherenkov peak, and the values of $m = \pm n; n = 1,2,3 \ldots$ correspond to the peaks of SPR.

SIMULATION GEOMETRY

The simulations are performed using CST PS Particle In Cell (PIC) solver [9]. The simulated geometries are shown in Fig. 1 and in Fig. 2. Figure 1 shows the geometry used for a comparison with the theory; the calculation domain is filled with dielectric in the radial direction, which in combination with open boundary conditions creates a quasi - infinite geometry. An electron bunch propagates through the channel producing Cherenkov and SPR at angles Theta satisfying the dispersion relation (1).

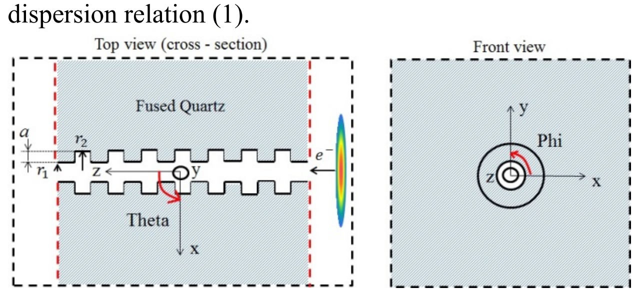

Figure 1: Geometry 1, quasi-infinite in r direction.

Figure 2 depicts the capillary with the reflector. The electron bunch travels with an offset in the capillary in order to generate Smith-Purcell radiation more efficiently. Both in Fig. 1 and Fig. 2 black dashed lines show non-reflective borders (open boundaries) in the calculation domain; and the red dashed lines show reflective borders. Values of the electric field are calculated at each

IMPROVEMENTS OF THE LASER SYSTEM FOR RF-GUN AT SUPERKEKB INJECTOR

R. Zhang*, M. Yoshida, T. Natsui, X. Zhou, Y. Ogawa, KEK, Tsukuba, Japan

Abstract

According to the requirements of SuperKEKB project, the electron beams with a charge of 5 nC and a normalized emittance of 10 µm are expected to be generated at injector linac. In order to meet these demands, an Ytterbium laser system has been being built. For realizing the laser system operating under 25 Hz with double bunch or 50 Hz, improvements of laser system are being done. We obtained 3.0 nC bunch charge by use of Yb:YAG/Cu soldering composite to overcome thermal effect. This demonstration indicates that effective and excellent thermal management can be realized for high repetition laser operation. Cryogenic experiment is also introduced.

INTRODUCTION

Higher luminosity is required in SuperKEKB. The photocathode RF gun with strong electric focusing filed for high-current, low-emittance should be adopted in the injector linac. For generating electron beams with a charge of 5 nC and a normalized emittance of 10 µm in the photocathode RF gun, according to the simulation of emittance due to the space charge effect, the ultraviolet (UV) laser source with a pulse width of several tens of picoseconds (ps) is required [1]. Furthermore, for reducing the energy spread, the laser pulse should be reshaped to rectangle from Gaussian shape [2].

With the aim of achieving the demands on the laser source, a hybrid laser system which includes an ytterbium (Yb) ions doped fiber oscillator, Yb-doped fiber amplifier and thin disk Yb:YAG amplifiers. For 2 Hz repetition rate test, more than 1 mJ UV pulse energy was obtained. As a result, the electron beams with a charge of 5.6 nC were generated. When the laser system was upgrade to 25 Hz, 20 mJ fundamental laser pulse energy and 700 µJ UV pulse energy were obtained and 3.0 nC electron beams were gotten [1, 3].

For the repetition rate of electron beam, the 25 Hz with double bunches and 50 Hz are requested. In order to realize excellent thermal management under high repetition rate operation, the laser system has been being improved.

IMPROVEMENTS OF THE LASER SYSTEM

In the ref [4], 0.8 nC electron beams were obtained by using of Yb laser system. By reforming the laser system configuration, 3.0 nC electron beam was archived under 25 Hz operation.

Figure 1 shows the layout of Yb laser system. The seed laser pulse was generated by an Yb-doped fiber ring oscillator. An electro-optical fiber pulse picker is adopted for decreasing the repetition rate of seed laser to 10.38 MHz. Then laser is amplified by Yb fiber pre-amplifier and chirped to about 30 ps by a transmission grating stretcher. Subsequently, two stages of Yb doped large-mode-area polarizing double-clad photonic crystal fiber are selected as the first and main amplifier to get strong enough pulse energy [5]. Because thin disk laser possesses very favourable thermal management, this configuration is used to obtain the mJ-class pulse energy. A regenerative Yb:YAG thin disk regenerative amplifier and four stages multi-pass amplifiers are employed. UV pulse laser at 259 nm for photocathode is generated by using two frequency-doubling stages and then injected into RF gun.

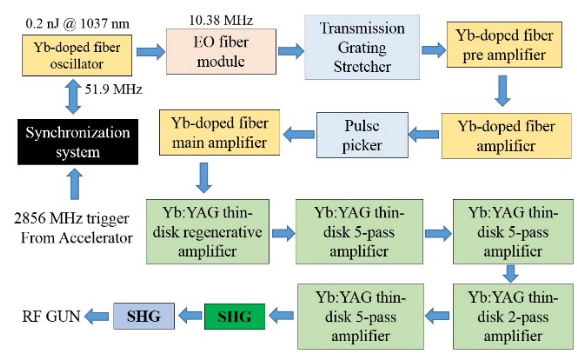

Figure 1: Layout of laser system.

Au-Sn soldering Yb:YAG/Cu Composite for Amplifier

The difficulty in controlling thermomechanical distortions has been one of the most important factors for preserving high beam quality and developing high average power solid-state lasers. By comparing with the 0.8 nC electron beams result we reported in the ref [4], 3.0 nC electron beams were gotten by using of Yb:YAG thin disk and copper plate composite. Waste heat generated in laser active disk can be removed to the copper plate effectively. Due to effective thermal removal in regenerative amplifier and multi-pass amplifiers, the amplified laser pulse became more stable and efficient.

Gold-tin (AuSn) was selected as soldering material for bonding Yb:YAG thin disk and copper plate. It possesses several advantages. Firstly, it has high thermal conductivity and low thermal expansion coefficient, as listed in Table 1. The thermal conductivity is high for AuSn comparing to that of indium-tin (InSn), this is very helpful for waste heat removal. Secondly, the deformation of AuSn is weak on heating because its thermal expansion

COHERENT THOMSON SCATTERING RADIATION GENERATED BY USING PEHG

S. Chen, K. Ohmi, D. Zhou, KEK, 1-1 Oho, Tsukuba 305-0801, Japan
S. Huang, IHIP, Peking University, Beijing 100871, China

Abstract

The density modulation method of the newly proposed PEHG is used to generate ultra-short electron longitudinal structures for the bunch of a 100MeV ERL. Coherent Thomson scattering radiation in EUV range can be emitted by the scattering of such a modulated bunch with a long wavelength laser.

INTRODUCTION

Thomson scattering of an intense laser by relativistic electrons has thus drawn a considerable attention by its possibility of generating short wavelength radiations with relatively lower beam energy. In the recent years, several Thomson scattering light sources have been builted and some new methods of improving the performance of Thomson scattering light sources have been proposed. However, because of the bunch length is usually much longer than the radiation wavelength in these cases, the scattered radiation is mostly incoherent. In order to generate coherent Thomson scattering radiation, electron bunches with ultra-thin longitudinal structures, whose length is compariable or even shorter than the wavelength of scattered radiation, should be obtained first. In order to get such a ultra-thin longitudinal structure in electron bunches, several methods have been proposed previously [1, 2]. In this paper, we are referring a newly proposed bunch longitudinal density modulation method which is called Phase-merging Enhanced Harmonic Generation (PEHG) [3–5] to generate the ultra-thin bunch slices. By colliding with a long wavelength laser pulse generated by ERL beam, coherent and ultra-short pulse radiation is emitted through coherent Thomson scattering.

THOMSON SCATTERING

When a relativistic electron beam collides with an intense laser beam propagates along the inverse direction, the electrons start to oscillate driven by the Lorentz force of the laser electromagnetic field and generate intense and highly concentrated radiation along the direction of electrons propagate. This laser-electron collision process is so called Thomson scattering. The strength of the incident laser is described by the dimensionless vector potential, which can be expressed by the parameters of laser as

$$a_L = \frac{eE_L}{m_e c\omega_L} = 0.85 \times 10^{-9} \lambda_L[\mu m] I_0^{1/2}[W/cm^2] \quad (1)$$

where E_L, ω_L are the electrical field and the angular frequency of the incident laser. The radiation wavelength of Thomson scattering is quite similar to the undulator radiation thus it is also called *laser undulator radiation*. Considering the scenario of backscattering, the radiation wavelength is

$$\lambda_r = \frac{\lambda_L}{4\gamma^2}(1 + \frac{a_L^2}{2} + \gamma^2\theta^2) \quad (2)$$

where θ is the radiation angle and λ_L is the wavelength of the incident laser. Because of λ_L is usually much smaller than the traditional undulator period, one can generate radiation with similar wavelength but much smaller γ.

DENSITY MODULATION BY PEHG

Basic Principle of PEHG

PEHG was first proposed as an alternated harmonic generation method to the traditional HGHG [7, 8]. The performance of traditional HGHG method is restricted by the existence of initial energy spread of the electron bunch. As is shown in Eq. 3,

$$b_n = < e^{-in\theta_j} >= e^{-\frac{1}{2}n^2\sigma_\gamma^2(\frac{d\theta}{d\gamma})^2} J_n(n\Delta\gamma\frac{d\theta}{d\gamma}). \quad (3)$$

where $\frac{d\theta}{d\gamma} = 2\pi R_{56}/\lambda_s\gamma_0$, λ_s is the wavelength of seeding laser, γ_0 is the Lorentz factor of electron beam, σ_γ is the initial energy spread, $\Delta\gamma = \frac{k_s a_u F_B}{\gamma_0} a_s N_u \lambda_u$ with $F_B = J_0(\xi) - J_1(\xi)$ and $\xi = a_u^2/2/(1 + a_u^2/2)$, is the maximum energy modulation. The bunching factor drops exponentially with the harmonic increases due to the none-zero σ_γ in the exponential term. Because the bunching factor is the Fourier expansion of the longitudinal distribution, this also indicates the length of the longitudinal structure in the phase space is restricted.

In PEHG, the traditional modulator undulator is replaced by a *Transverse Gradient Undulator (TGU)* with transverse field gradient α and a dog-leg section is put in the front stream of the TGU to provide a dispersion η. The dog-leg acts a function of transverse-longitudinal coupling to establish a correlation between transverse position with energy. Then the electron bunch passes through the TGU and this correlation alternated to the correlation between electron energy and different undulator parameter. The principle equation inside the TGU is shown in Eq. (4) [3],

$$\frac{\gamma' - \gamma_0'}{\gamma - \gamma_0} = 1 - \frac{2\pi N_u \Delta\gamma}{\gamma_0}(\frac{\alpha\eta K_0{}^2}{K_0^2 + 2} - 1). \quad (4)$$

where γ_0' and γ' are the Lorentz factor of an reference electron and an arbitrary electron which have the same phase at the exit of the dog-leg; γ_0 and γ are the corresponding

Abstract

KEK, Nihon University, and TOYAMA CO., Ltd. have been developing a thin-radiation shielded coherent X-ray source that can cover the X-ray energy range from 3 to 25 keV. The X-ray is the parametric X-ray radiation generated by the high energy electron beam passing through a single crystal. It has a feature that offers quasi-monochromaticity, directivity, and a large divergence angle for the incident beam. These suggest the possibility of application to medical treatments and diagnosis.

Furthermore, reduction of the radiation that is mainly generated at the beam dump will be achieved by the beam energy recovery system. This system consists of the accelerating structure, the decelerating structure, and the beam recovery transport system including four bending magnets. The RF structures are operated under low temperature of 20 K to get a high Q value in the rf recirculation system and a high energy conversion efficiency from the accelerated electron beam to the rf in the decelerating structure. Parametric X-ray radiation is generated from a single crystal that was bombarded with the electron beam accelerated up to 75 MeV. The electrons passing through the crystal is transported into a decelerating structure and then is decelerated to 3 MeV there. Quadrupole magnets are arranged to transport the achromatic beam except for in the arc sections. Simulations have been done on the beam transport, the parametric X-ray radiation intensity and the emittance growth.

INTRODUCTION

Nihon University, KEK, and TOYAMA Co., Ltd. have been developing a coherent X-ray source. This coherent X-ray means parametric X-ray radiation (PXR). This features quasi-monochromaticity, directivity and energy tunability by rotating the target crystal. A coherent X-ray is expected to be useful in a wide range of fields, for example crystal structure analysis, treatment of cancer and X-ray imaging. Nihon University group has been successful in providing PXR to users and has reported X-ray images using PXR in many papers [1, 2].

Most of the light source facilities provide synchrotron radiation to user's experiments as the X-ray sources. Due to the nature of this radiation with continuous spectrum, a monochromator is installed in the beam line to use the X-rays with a specific energy. On the other hand, the PXR X-rays are quasi-monochromatic, the energies of which are tunable with the rotation angle of the target crystal.

In the accelerator design, the decelerating structure has been employed for reducing unwanted radiation at the beam dump. The accelerating and decelerating structures are operated under the low temperature of 20 K in order to get a high efficiency of the energy conversion. Additionally, to get the coherent X-ray, the PXR generation system is used. Calculation and simulation have been carried out on the beam optics, the PXR intensity and the emittance growth. Figure 1 shows the layout of the coherent X-ray source based on the linear accelerator.

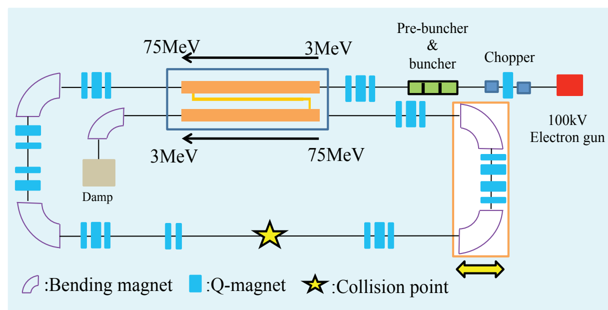

Figure 1: Layout of the coherent X-ray source based on linear accelerator.

PARAMETRIC X-RAY RADIATION

PXR is generated when relativistic charged particles pass through a crystal. This radiation can be interpreted that the virtual photon fields around the electrons are diffracted by the crystal planes. The features of PXR are beam coherence, large divergence angle with respect to the electron beam and PXR energy not affected by electron beam energy. Since the emitted X-rays satisfy the Bragg diffraction condition, the X-ray energy can be controlled by adjusting the angle between the incident beam and the specific crystal plane.

In this accelerator, the electron beam is accelerated to 75 MeV with a pulse duration of 2.5 μs and a repetition rate of 50 Hz. The average beam current is approximately 30 μA. Si or Diamond crystal will be used as the target because these crystals are heat-resistant. Furthermore, Si single crystals are readily available. The thickness of the target must be less than 0.2 mm to avoid too much emittance growth. Under this condition, the number of the PXR photons is expected to be about 10^{-9} photons/e^- [3].

Abstract

Accelerator and laser technologies required for laser Compton scattering (LCS) photon source based on an energy-recovery linac (ERL) have been developed at the Compact ERL (cERL) facility. A high-flux, energy tunable, and monochromatic photon source such as the ERL-based LCS photon source is necessary for nondestructive assay of nuclear materials. For the demonstration of the ERL-based LCS photon generation, a laser enhancement cavity was installed at the recirculation loop of the cERL. The electron beam energy, the laser wavelength, and the collision angle are 20 MeV, 1064 nm, and 18 deg., respectively. The calculated maximum energy of the LCS photons is about 7 keV. A silicon drift detector (SDD) with active area of 17 mm^2 placed 16.6 m from the collision point was used for observation of the LCS photons. As a result of the measurement, the flux on the detector, central energy, and energy width of the LCS photons were obtained as 1200 /s, 6.91 keV, and 81 eV, respectively.

INTRODUCTION

A high-flux and energy tunable photon generation based on laser Compton scattering (LCS) by an electron beam from an energy-recovery linac (ERL) is a key technology for a nondestructive assay (NDA) of nuclear materials. In order to generate such a photon beam, a small-emittance and high-current electron beam as well as a high-power laser are necessary. The ERL is an optimum apparatus to accelerate a high-quality electron beam [1]. The energy of LCS photons can be selected by changing the electron energy, laser wavelength, or collision angle between the electron and laser beams. Furthermore, the energy width of LCS photons can be narrowed by putting a small-diameter collimator which restricts the scattering angle.

Accelerator and laser technologies required for a high-flux LCS photon generation has been developed at the Compact ERL (cERL) facility. The cERL which is a test accelerator for ERL-based light sources has been constructed by collaborative team of High Energy Accelerator Research Organization (KEK), Japan Atomic Energy Agency (JAEA), other Japanese universities, and institutes [2]. In this paper, we present the first result of the LCS photon generation at the cERL.

Table 1: Properties of the Electron Beam

Energy [MeV]	20
Bunch charge [pC]	0.36
Bunch length [ps, rms]	2
Spot size [μm, rms]	30
Emittance [mm mrad, rms]	0.4
Repetition Rate [MHz]	162.5

ELECTRON AND LASER BEAM PROPERTIES

The cERL consists of a photo cathode DC electron gun, a normal conducting buncher cavity, a superconducting injector linac, a three-dipole injection merger, a superconducting main linac, and a recirculating beam transport loop. The electron beam with bunch charge of 0.36 pC and bunch length of 3 ps was generated at repetition rate of 162.5 MHz by the photo cathode electron gun with acceleration voltage of 390 kV. The repetition rate of the electron beam pulse in cERL is originally 1300 MHz, but it was changed to 162.5 MHz which is same as the laser repetition for the demonstration of a LCS photon source. The generated beam was accelerated to 2.9 MeV by the injector linac before merging to the recirculation loop. Then, the electron beam was accelerated to 20 MeV by the main linac and was transported to the collision points with the laser beam. The electron beam was focused to rms size of 30 μm and was bunched to rms bunch length of 2 ps at the collision point. After the collision with the laser beam, the electron beam was injected again to the main linac with a deceleration RF phase. The recirculated beam was decelerated and fed back the energy to the superconducting RF cavity. This recovered RF energy was again used to accelerate subsequent electron beam. The properties of the electron beam at the collision point is summarized Table 1.

Since the cross-section of the Compton scattering is small, efficient recycling of laser photons is important to realize a high-flux LCS photon source. This efficient recycling can be achieved by introducing a laser enhancement cavity. The laser enhancement cavity is a high-finesse Fabry-Pérot optical cavity which stores laser pulses injected from an external mode-locked laser. In the LCS photon source, a 4-mirror cavity is employed to achieve high stability and small waist size [3]. As shown in Fig. 1, two sets of 4-mirror cavities are stacked in the same gimbals but are independently adjustable.

QUASI-TRAVELING WAVE RF GUN AND BEAM COMMISSIONING FOR SUPERKEKB

Takuya Natsui#, Mitsuhiro Yoshida, Xiangyu Zhou, Yujiro Ogawa, KEK, Ibaraki, Japan

Abstract

We are developing a new RF gun for SuperKEKB. High charge low emittance electron and positron beams are required for SuperKEKB. We will generate 7.0 GeV electron beam at 5 nC 20 mm-mrad by J-linac. In this linac, a photo cathode S-band RF gun will be used as the electron beam source. For this reason, we are developing an advanced RF gun which has two side coupled standing wave field. We call it quasi-traveling wave side couple RF gun. This gun has a strong focusing field at the cathode and the acceleration field distribution also has a focusing effect. This RF gun has been installed KEK J-linac. Beam commissioning with the RF gun is in progress.

INTRODUCTION

The upgrade of KEKB to SuperKEKB is going on. Since high luminosity is required in SuperKEKB, improvement of beam emittance and charge is necessary. Table 1 is upgrade parameter of e- and e+ beam.

Table 1: e- and e+ Beam Parameters

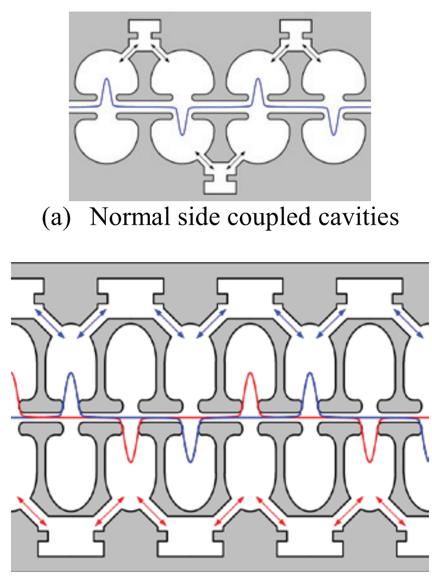
	KEKB (e+/e-)	SuperKEKB (e+/e-)
charge [nC]	1 / 1	4 / 5
Emittance [mm-mrad]	2100 / 300	10 / 20

We are developing a photo cathode S-band RF gun for high charge (5 nC) low emittance (20 mm-mrad) beam generation. A thermionic cathode DC gun was used in KEKB. However it is difficult to make a low emittance beam with the DC gun. Thus RF gun must be installed to realize required electron beam parameter. However the standard on-axis coupled 1.5 cell RF gun is not suitable for this high charge beam, because standard gun is used up to about 1 nC by ordinary. If we obtain 5 nC in the gun, beam size will be too large. We have to consider both beam focus and emittance preservation. Thus it is necessary to make a focusing field against the space charge in the cavities. But in this on-axis coupling cavity, it is difficult to arrange the field freely on the axis. Since beam hole is also the coupling hole. Thus annular coupling is required.

We had tested Disk and Washer (DAW) type RF gun [1]. DAW cavity is an annular coupling cavity. Using this gun, we evaluated the cathode of two types LaB_6 or Ir_5Ce. As a result, we confirm that Ir_5Ce is suitable for photo cathode in terms of quantum efficiency and lifetime. In the DAW type RF gun study, we confirmed that electric field focusing technique is effective for high charge low emittance beam generation. However, focusing is still not enough in this gun, generated beam still has divergence angle. Since 5 nC is maximum output, this gun has no margin. In addition, beam energy is still low (3 MeV). Thus we have to consider the further emittance preservation in beam transport.

We are developing a new advanced RF gun. It has new acceleration scheme, we call it as a quasi-traveling wave. In this method, higher accelerating field and stronger focusing field are expected. It is very efficient acceleration method. This quasi traveling wave cavity is realized by using a two side couple cavities.

Annular coupled cavities as DAW or side coupled cavities are possible to make narrow acceleration gap. The narrow gap makes the focus field. Our DAW RF gun is using this focus field. Side coupled cavity also can be made the narrow gap. However, these cavities have a long drift space as Fig.1 (a) that shown normal side couple cavities. Due to the long drift space, the DAW RF gun generates beam with a divergence angle.



(a) Normal side coupled cavities

(b) Quasi traveling wave side coupled cavities

Figure 1: Structure of the quasi traveling wave cavity.

One solution is to use two standing wave cavities. If two side coupled cavities are arranged staggered, we obtain a double standing wave field as Fig.1 (b). These two standing wave side coupled cavities are independent electromagnetically. If we feed RF power with $\pi/2$ phase difference, acceleration field is similar to traveling wave to accelerated beam. Since two side coupled cavities are possible to place on the same axis, a quasi-traveling wave

NARROW BAND COHERENT EDGE RADIATION AT UVSOR-III

M. Hosaka, D. Oodake, N. Yamamoto ,Y. Takashima, Synchrotron Radiation Research Center, Nagoya University, Nagoya, Japan
H. Zen, Institute of Advanced Energy, Kyoto University, Uji, Japan

Abstract

Edge radiation in the long wavelength region can be an interesting new light source because of its properties of highly collimation and radial polarization. Recently a dedicated beam-line for edge radiation was constructed at UVSOR-III. Coherent radiation from electron bunches after the interaction with the amplitude modulated laser was successfully observed at the beam-line. Intensity of the radiation as functions of the electron beam current and THz wavelength was measured. Spatial distribution of the radiation intensity was also measured. The pattern was not reproduced by a calculation.

INTRODUCTION

Coherent synchrotron radiation (CSR) in THz region can be produced from an electron bunch shorter than the radiation wavelength. Because of high radiation power, being proportional to the square of number of electrons in the bunch, CSR can be a new tool for various applications. However, in typical storage rings, electron bunch length is longer than THz wavelength. But they succeeded in producing CSR by shortening bunch length using special condition of storage rings called low-alpha operation [1]. Laser bunch slicing is another technique for producing CSR by creating mm or sub-mm dip structure in electron bunch [2]. In both cases, broad band CSR with wavelength longer than the bunch length or the dip structure is produced.

At UVSOR storage ring, we demonstrated that, by injecting amplitude modulated laser pulses into the ring, quasi-monochromatic and tuneable terahertz (THz) CSR can be produced [3]. In this method, periodic micro-density structure of THz scale was created on the electron bunch, as the result of the laser-electron interaction in an undulator. In the experiment, the radiation from a bending magnet where electrons are moving along a circular trajectory, is extracted. As a next step we planned to extract the radiation from edges of bending magnets, where electrons experience rapid change of the magnetic field. The radiation is called edge radiation and has distinctive features as compared to normal synchrotron radiation: highly collimation even in long wavelength region, annular radiation pattern and radial polarization [4]. Applying our technique of amplitude modulation laser, intense narrow band edge radiation is expected to be generated. Moreover, radially polarized light can be converted to Z-polarized one by using a high NA lens [5]. Novel new applications of the radiation, such as surface science and solid state physics are expected.

In this article, we describe a new beam-line for edge radiation and some preliminary results from the experiments to characterize narrow band coherent edge radiation.

Abstract

We designed a Pulsed Multipole Magnet (PMM) for Aichi SR storage ring. The design goal is to suppress displacement of stored electron beams smaller than 10 percent of stored beam size. In our past research, we established a technique to compensate magnetic field error. At this time, we estimated effects of magnetic field generated by current leads and of electric field caused by potential differences in the coil. Then, we designed the configuration of current leads to minimize the perturbations to the stored beam. It is expected that the amplitude of electron beam would be suppressed to 4 percent horizontally and 0.08 percent vertically of the beam size.

INTRODUCTION

Aichi SR, a 1.2 GeV storage ring light source, is the newest synchrotron light source in Japan. The ring is equipped with four superconducting bending magnet, which can provide hard X-rays to more than 10 beam-lines. The storage ring has been operated with the top-up injection mode since the beginning of the users operation in 2013[1]. The parameters of Aichi SR storage ring are shown in Table 1. So far, the stability of 0.2% for the stored beam current is achieved. In the usual injection scheme, four pulsed kicker magnets create a bump orbit. At the beam-lines in this orbit, synchrotron radiation is lost due to momentary displacement of a stored beam orbit. Because Aichi-SR is relatively small, the local bump lies in about a half of the circumference and there exist many beam-lines. For those reasons, this problem is quite essential.

In order to solve it, we decided to introduce the PMM injection scheme, which enables beam injection without perturbing the stored beam [2,3,4,5]. However, in reality, a PMM didn't completely suppress perturbations to stored beams. The effect of quadrupole field was treated in [3] and the effect of dipole field error and its compensation method was discussed in [5]. In this work, we treat electric field generated by the conductors and magnetic field generated by current leads, which have not been considered in the previous studies, and design a PMM. Our design goal is suppressing the amplitude of the electron beam oscillation less than 10 percent of stored beam size.

Table 1: Parameters of Storage Ring

Electron Energy	1.2 GeV
Circumference	72 m
Current	>300 mA
Natural emittance	52 nm-rad

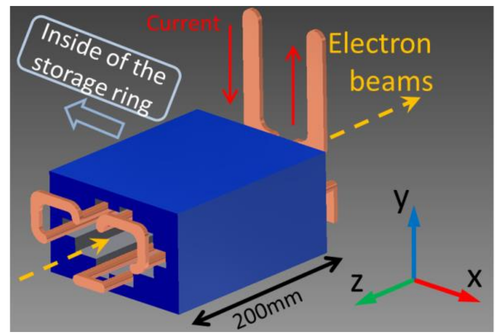

Figure 1: The appearance of the PMM of Aichi SR.

PULSED MULTIPOLE MAGNET

Figure 1 shows the appearance of the PMM of Aichi SR. It consists of a yoke and a single-turn coil. The yoke is painted blue in Fig. 1 and is made of laminated silicon steel. Its height, width and length are 120 mm, 180 mm and 200 mm, respectively. Electron beams pass through this yoke. The coil is painted orange and as a matter of convenience, we divide it to 3 parts. First, we call the part inside of the yoke "main coils." Second, we call the part outside of the yoke in the left side of Fig. 1 "upstream current leads" and similarly, call the opposite side "downstream current leads." Pulsed current runs through the coil to excite the magnetic field. Its waveform is a half-sine pulse whose width is 960 ns. Figure 2 shows the cross-section of the PMM with magnetic field lines. The current runs through 6 conductors in alternate directions and excites sextupole magnet field. Figure 3 shows the magnetic field distribution in the horizontal plane. The stored beam passing at the center is not affected by the magnetic field. On the other hand, the injected beam passing at 20 mm from the center is kicked and captured. The $B_y \cdot L$ component of the magnetic field has to be about 27 $\mathrm{mT} \cdot m$ at the injected beam orbit.

Abstract

A 750 MeV VUV synchrotron light source, UVSOR, has been operational since 1983. After the major upgrade in 2003 and in 2012, the machine UVSOR-III is now routinely operated with small emittance of 17 nm-rad and six undulators, as the beam current is kept at 300mA with top-up injection. New pulsed sextupole magnet for the beam injection has been under testing. New light source development station for FEL, CSR, CHG, LCG etc. was constructed is being developed. Reconstruction of the optical cavity for the resonator FEL has started.

INTRODUCTION

UVSOR was designed and built early in 1980's as a 2nd generation synchrotron light source in the vacuum ultraviolet range with emittance larger than 100 nm-rad and few insertion devices. The most recent parameters of UVSOR are shown in Table 1. The emittance is one of the smallest among the low energy synchrotron light sources below 1GeV. In addition, totally six undulators are operational in this small storage ring. The beam current is kept at 300mA with the top-up injection scheme. In this paper, we briefly review the upgrade history of UVSOR. Then, we describe recent status of the machine and some results from the recent researches and developments on light source technologies.

Table 1: Basic Parameters of UVSOR-III

Beam Energy	750 MeV
Circumference	53.2 m
Cell Structure	Extended DB
Emittance	17 nm-rad
Energy Spread	5.4E-4
Straight Sections for I.D.	4m x 4 1.5m x 2
Beam Current	300 mA (top-up)
Injector	15 MeV Linac 750MeV Synchrotron

30 YEARS OF UVSOR

In Dec. 2013, we celebrated the 30 year anniversary of the UVSOR Facility. The recent view of the storage ring is shown in Fig.1. In this section, we will give an overview of the history of the facility focussing on the accelerator upgrades.

Figure 1: Recent view of UVSOR-III storage ring.

UVSOR-I

We shall call the machine UVSOR-I, in the period from the first light in 1983 to the first major upgrade in 2003. It consisted of 4 DBA cells with four 3-m straight sections [1]. Its emittance was 120 - 160 nm-rad, depending on the operating betatron tunes. It has two undulators and a superconducting wiggler [2]. The operation energy of the storage ring was initially 600 MeV and was soon upgraded to 750 MeV. However, the energy of the injector remained at 600 MeV.

During this period, many beam-lines were constructed and commissioned. On the other hand, the basic performance of the storage ring was not changed drastically. The research on free electron laser started in 1980's. A new optical klystron of variable polarization was installed in 1990's [3] and the lasing in the deep UV range was demonstrated [4]. A study on the low-alpha operation was carried out [5]. The 3rd harmonic RF cavity was installed, which was effective to suppress the longitudinal instabilities and to improve the Touschek lifetime [6]. The accelerator control system was upgraded [7].

UVSOR-II

In 1990's, construction of 3rd generation synchrotron light sources started all around the world, and continued in 2000's. To meet the increasing demands for brighter

MEASUREMENT OF TEMPORAL ELECTRIC FIELD OF ELECTRON BUNCH USING PHOTOCONDUCTIVE ANTENNA

K. Kan[#1], J. Yang, A. Ogata, T. Kondoh, M. Gohdo, I. Nozawa, T. Toigawa, Y. Yoshida[#2]
ISIR, Osaka University, Osaka 567-0047, Japan

Abstract

A temporal electric field profile, which is a radially polarized terahertz (THz) pulse from an electron bunch, was measured by a large-aperture photoconductive antenna (PCA) with micro-structured concentric electrodes for the detection of THz pulses. Photo-induced charge carriers were generated by irradiation of femtosecond laser pulses on semiconductor plane of the electrodes on the PCA. Time-domain measurement of coherent transition radiation (CTR) was conducted by the measurement of electric-field-induced current output from the PCA with sweeping the timing of the laser irradiation. The measurements on femtosecond electron bunches of 32 MeV and >80 pC will be reported.

INTRODUCTION

Short electron bunches with durations of picoseconds to femtoseconds are useful for generation of light in terahertz (THz) range [1] and time-resolved studies of ultrafast phenomena and reactions, including ultrafast electron diffraction (UED) [2] and pulse radiolysis [3,4,5]. Electro-optic sampling [6], which is one of detection techniques of THz light pulse, is used in diagnostics of electron bunches. In EO samplings, the birefringence of EO crystals is induced by the beam electric field, and laser polarization corresponding to the longitudinal electron beam profile is detected [7,8]. EO monitors based on the temporal decoding have revealed the Coulomb field of a root mean square (rms) width of 60 fs from femtosecond electron bunches [8]. Interferometers [9] have been also used for the detection of single mode or multimode THz pulses generated by electron bunches and slow-wave structures [10,11]. Coherent transition radiation (CTR), which is generated by electron bunches crossing a boundary between different media, has been measured by interferometers and grating-type spectrometers [12,13]. Photoconductive antennas (PCAs), which are composed of semi-insulating (SI) semiconductor with electrodes, are widely used for both generation and detection of THz pulses in THz time-domain spectroscopy [14,15,16,17,18]. PCAs could be good candidates for analyzing temporal electric field profiles of electron bunches due to the correlation between electric-field-induced current output and THz electric field strength [17]. Fabrication of a large-aperture PCA is expected to enhance both generation efficiency and detection sensitivity of THz pulses with designed polarization character. Enlarged aperture of PCA and concentric electrode configuration scheme in the present study utilizes the application of PCAs with enhanced sensitivity and radial polarization feature. The application of those PCAs on the detection of THz pulses from electron bunches will be a new methodology for beam diagnostics.

In this paper, analysis of the temporal electric field profile of CTR using a large-aperture PCA with micro-structured concentric electrodes is demonstrated. CTR was emitted by femtosecond electron bunches from a photocathode-based linac. The PCA enabled the detection of radially polarized THz pulses with adequate sensitivity according to the geometry of electrodes. Photo-induced charge carriers were generated by irradiation of a femtosecond laser on the PCA. Electric-field-induced current was obtained as THz electric field strength of CTR at the duration of the laser irradiation.

EXPERIMENTAL SETUP

Generation of Femtosecond Electron Beam

Femtosecond electron bunches were generated by the photocathode-based linac [13,19,20], which consists of a 1.6-cell S-band radio frequency (RF) gun with a copper cathode, a 2-m-long traveling-wave linac, and an arc-type magnetic bunch compressor as shown in Fig. 1. The photocathode of RF gun was excited by 4th harmonic (262 nm) of a picosecond laser with an energy of <180 μJ/pulse and a pulse width of 5 ps FWHM at 10 Hz. The electron bunches were accelerated in the gun and the linac using a 35-MW klystron. In the linac, the electron bunches were accelerated to 32 MeV at a linac phase of 100° for an optimal energy modulation of electron bunches [13]. The accelerated electron bunches were compressed to femtosecond by the magnetic bunch compressor, which was composed of bending magnets (B), quadrupole magnets (Q), and sextupole magnets (S). CTR was generated by the compressed femtosecond electron bunch.

RELOCATION AND IMPROVEMENT STATUS OF THE SCSS TEST ACCELERATOR TO PROVIDE DUAL FEL DRIVERS AT SACLA *

Yuji Otake #, on behalf of the members of XFEL research and development division,
RIKEN, Koto 1-1-1, Sayo-cho, Sayo-gun, Hyogo 679-5148, JAPAN

Abstract

To increase user experiment chances at SACLA, equipping a new beamline and an additional linac as a further FEL driver is effective. For these reasons, the SCSS test accelerator as the prototype of SACLA is reused, because of terminating its role. SCSS with an electron beam energy of 250 MeV generated an extreme ultraviolet laser with 50~60 nm. We relocated SCSS into the SACLA undulator hall and improved its performance. Three newly designed C-band acceleration-structures for the relocated SCSS accelerator with an acceleration gradient of 46 MeV/m at maximum boost an electron beam energy of up to 500 MeV. By FEL simulation, the EUV-FEL with 10~40 nm and 100 μJ are expected by the increased electron energy and 2 undulators with 5 m long each. By taking opportunity of the relocation, performance improvements of instruments, such as an inverter charger for the pulse-forming network (PFN) of a klystron modulator, were also done. The relocation work of the linac with several instrument developments finished in the summer of 2014 and rf conditioning for the units almost finished in the spring of 2015.

INTRODUCTION

Free-electron lasers (FEL) [1] generate fruitful science results [2] and already become important instruments for science. They have attractive features, such as wide wavelength tenability up to an X-ray region, compared with ordinal laser devices. However they are usually expensive, because of a single user machine being not like ring photon sources. In order to increase experiment chances for users, we had plans for constructing another new beamline BL-2, as well as the existing X-ray beamline BL-3, and an additional linac to drive a FEL in the existing beamline BL-1 of SACLA [3]. Light generated by this linac with a 450~500 MeV electron beam and the BL-1 covers lower wavelengths from 10 nm to 40 nm. This wavelength will be extended up to several nm by a future extension plan to increase a beam energy up to 1.4 GeV by adding 9 C-band acceleration units and 2 undulators. In order to realize the linac for the BL-1, we already had a very suitable machine that is the SCSS test accelerator. The roll of the test accelerator to check feasibility of the X-ray free-electron laser (XFEL) already terminated at that point. Therefore, we decided relocation of the test accelerator from the original place to the SACLA undulator hall. However, space for the relocation is not so wide. Furthermore we want to cover further shorter wavelength of the laser for the experiment users. For these reasons, a higher electron-beam energy by high-gradient acceleration was planned for the relocated test accelerator. We developed a 2π/3 mode qusi-constant gradient (CG) accelerating structure with a highly acceleration gradient of 45 ~ 47 MV/m, which is about 10 % bigger than the present SACLA's case. [4]

By taking opportunity of the relocation, performance improvements of instruments, such as an inverter charger for the pulse-forming network (PFN) of a klystron modulator at SACLA, were also done [4], since the performance, such as a trouble rate, of the inverter was not then perfect for us. Furthermore, individual device controllers using programmable logic controllers (PLC) and a low-level rf (LLRF) system for SCSS was different to those of SACLA. They should fit to the present control system for SACLA, because of easily building and easy maintenance. The rf phase and amplitude stability of the LLRF system for the test accelerator, as which temporal drift is over several pico-second, was not sufficient. Hence, we changed the controller and LLRF system from SCSS's one to the standard instruments for SACLA. [5] The permanent magnet-cell arrangement of the SCSS's undulator was different from that of SACLA. The magnetic period of the undulator was adjusted from 15 mm (K=1.5 at the maximum) to 18 mm (K=2.1 at the maximum). [5] Machine construction for this relocation now proceeds and almost finished. In this paper, the construction status of the relocated SCSS test accelerator, which is under high-power rf conditioning, and improvement status of the above-mentioned accelerator instruments are described.

CONSTRUCUTION AND INSTRUMENT IMPROVEMENTS STATUS

Accelerator Feature and Construction

In accordance with the plan to realize the linac mentioned above, the relocation of the SCSS test accelerator was started in 2013. The relocated accelerator is settled in the upstream of the BL-1 in the undulator hall, as shown in Fig. 1. Figure 2 depicts machine configurations before and after the relocation.

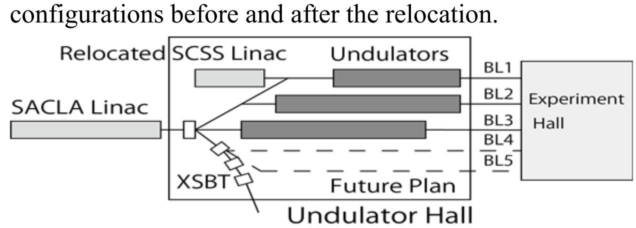

Figure 1: Place to install the relocated SCSS test accelerator (LINAC) in the undulator hall of SACLA.

STUDY ON FREQUENCY MULTIPLIER OF A PULSED LASER REPETITION USING AN OPTICAL CAVITY*

T. Kobayashi†, R. Suzuki, K. Sakaue, M. Washio,
Waseda University, Tokyo, Japan

Abstract

We have been studying a compact electron accelerator based on an S-band Cs-Te photo-cathode rf gun at Waseda University. The system is using S-band rf of 2856MHz. When a repetition of the electron bunch is integral multiple of rf, it enables a lot of electron bunch acceleration for the rf gun. The repetition of the electron bunch generated by a photo-cathode rf gun depends on the oscillating frequency of the pulsed mode-locked laser. We have been developing a mode-locked Yb-doped fiber laser based on Non-Linear Polarization Rotation (NLPR). However, its repetition is limited by the fiber length to produce NLPR. So we have started to develop the external optical cavity which is multiplier of a pulsed laser repetition. It would enable the rf gun to generate high-dose electron beam in a very short time. In this conference, we will report design of the external optical cavity to multiply the pulsed laser repetition, the experimental results of the frequency multiplying of a mode-locked Yb-doped fiber laser, and the future prospects.

INTRODUCTION

At Waseda University, a compact linear accelerator system, based on a 1.6 cell S-band Cs-Te photo-cathode rf electron gun, is applied for the various researches, such as laser Compton scattering (LCS) [1] and pulse radiolysis [2]. When a repetition of the electron bunch is integral multiple of rf, it enables a lot of electron bunch acceleration for the rf gun. The repetition of the electron bunch generated by a photo-cathode rf gun depends on the oscillating frequency of the pulsed mode-locked laser. The Yb-doped fiber laser studied as excitation pulsed laser for Cs-Te photo-cathode rf gun at Waseda University [3] has virtue of allowing high-power by Chirped Pulse Amplification (CPA), and its compactness. However it is necessary to make the repetition frequency higher in some way, because of the difficulty to get repetition rate more than about 100MHz. The repetition frequency is limited by the laser oscillation cavity length. Therefore, we have been developing an optical cavity to multiply frequency of the pulsed laser repetition.

PRINCIPLE OF FREQUENCY MULTIPLIER USING AN OPTICAL CAVITY

In order to multiply the repetition frequency of pulsed laser by an optical cavity, there are roughly two conditions.

The first condition is that an optical cavity length matches with an integral multiple of laser half-wavelength. The condition is shown in Fig. 1.

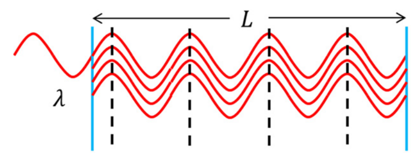

Figure 1: Schematic of storage condition of CW laser.

This is storage condition of continuous wave (CW) laser, and given by:

$$L = n\frac{\lambda}{2} \tag{1}$$

where L, λ, and n are the optical cavity length, laser wavelength and integer, respectively.

The second condition is that an optical cavity length matches with integer part of the laser's going around length. The condition is shown in Fig. 2.

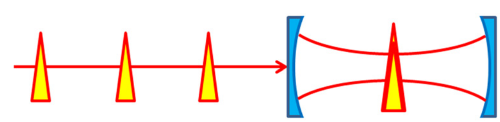

Figure 2: Schematic of overlapping of pulses.

This is overlapping of pulse, frequency multiplying, and given by:

$$L = \frac{L_{laser}}{m} = \frac{c}{mf_{rep}} \tag{2}$$

where L_{laser}, c, f_{rep}, and m are the laser oscillator cavity length, velocity of light, repetition frequency of pulsed laser and integer, respectively.

It is possible to achieve storage of pulsed laser and frequency multiplying of pulsed laser repetition by that consists of an optical cavity to satisfy the above conditions. The repetition frequency of pulsed laser passed this frequency multiplier is $f'_{rep} = mf_{rep}$ (Fig. 3).

STUDY OF Cs-Te PHOTOCATHODE FOR RF ELECTRON GUN*

Shuri Matsuzaki, Mariko Nishida, Kazuyuki Sakaue, Masakazu Washio,
Waseda University, Tokyo, Japan
Hokuto Iijima, Tokyo University of Science, Tokyo, Japan

Abstract

At Waseda University, we have been studying high quality electron beam with an rf electron gun. In recent accelerator study and application researches, high quality electron beam are strongly required. Photocathode is a key component to generate higher quality electron beam, thus we started to develop a Cs-Te photocathode as an electron source since 2007. Cs-Te photocathode shows high quantum efficiency (Q.E.) (~10 %) and has long life time (~several months). From 2013, we built a photocathode evaporation chamber and started photocathode study. In this study, our purpose is to clarify their property and to establish an ideal evaporation recipe. We succeeded in producing high quality Cs-Te photocathode, and electron beam generated by our Cs-Te photocathode shows high charge (4.6 nC/bunch) and high Q.E. (1.74 %) in our rf electron gun. Furthermore, we found a Q.E recovery after Cs deposition process and it causes higher Q.E. than usual due to, we believe, Cs deposition quantity or Cs deposition speed. Thus we are now surveying the optimum Cs evaporation parameters. In this conference, we will report a detail of our photocathode development system, the latest progress of optimization study of Cs-Te photocathode and future plans.

INTRODUCTION

At Waseda University, we have been studying high quality electron beam generation with photocathode rf gun and it was applied for several experiments, such as laser Compton scattering (LCS) [1] and pulse radiolysis [2]. In recent accelerator study and application researches, high quality and high charge electron beam are strongly required. Photocathode is a key component to generate high charge electron beam, thus we started to use a Cs-Te photocathode as an electron source since 2007 and built a photocathode evaporation chamber in 2013. Cs-Te photocathode is widely used because of its property of high quantum efficiency (Q.E.) (~10 %) with UV light and long life time (~several months). In this study, our purpose is to clarify their property and to establish an ideal evaporation recipe. We found a Q.E. recovery after Cs deposition process and started to research its mechanisms because it caused higher Q.E.. In our past study, we have already clarified that Te deposition seemed to not have relationship with it. Carrying out further study, we developed two new devices. The first device is a newly-designed evaporation source holder which enables us to measure Cs deposition quantity and Cs deposition rate. The second device is a substrate heating system. In this paper, we describe our results of optimization study of Cs-Te photocathode preparation by means of substrate temperature in the Cs deposition.

EXPERIMENTAL EQUIPMENTS

Photocathode Evaporation Chamber

We built a photocathode evaporation chamber in 2013. Figure 1 shows the appearance of the chamber. It is required ultrahigh vacuum for preparing Cs-Te photocathode, therefore, the chamber is equipped several vacuum pumps. Its vacuum level can reach 6×10^{-8} Pa after chamber baking (~200 ℃, 24 h).
Since the chamber is independent from our rf gun, we adopted a load-lock system to transfer a photocathode without air exposure.

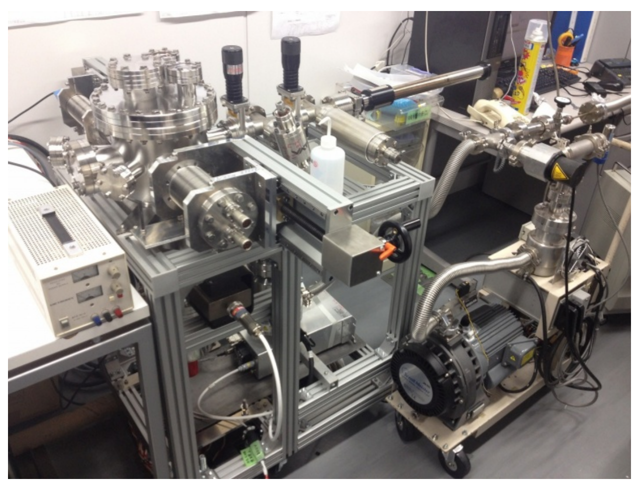

Figure 1: The appearance of the photocathode evaporation chamber.

Evaporation Source Holder

In order to make it possible to measure Cs deposition quantity and Cs deposition rate, we developed a newly-designed evaporation source holder shown in Fig. 2. It can be mounted four kinds of evaporation source (tellurium, antimony, cesium and potassium). Sb and K are in preparation for multi-alkali photocathode study in near future. As shown in Fig. 2, this Evaporation source holder is equipped two Cs dispensers. These dispensers

LASER-COMPTON SCATTERING X-RAY SOURCE BASED ON NORMAL CONDUCTING LINAC AND OPTICAL ENHANCEMENT CAVITY *

K. Sakaue†, WIAS, Waseda University, Tokyo, Japan
M. Washio, RISE, Waseda University, Tokyo, Japan
S. Araki, M. Fukuda, Y. Honda, N. Terunuma, J. Urakawa, KEK, Ibaraki, Japan

Abstract

We have been developing a compact X-ray source via laser-Compton scattering (LCS) at KEK-LUCX (Laser Undulator Compact X-ray source) facility. The LUCX system is based on S-band normal conducting linac with an energy of 30 MeV and optical enhancement cavity for photon target. As a photon target, we invented a burst mode laser pulse storage technique for a normal conducting linac, which enables to store the high power laser pulses at the timing of electron bunches. The peak storage power exceeds to more than 250 kW with 357 MHz repetition. Electron linac is under operation with multi-bunch mode, 1000 bunches/train with 600 pC charge in each bunches. We have succeeded to produce 1000 pulse/train LCS X-ray train. Combining high repetition rate electron linac and burst mode optical enhancement cavity, more than 10^9 ph./sec/10% b.w. flux would be possible. In this conference, the introduction of our test facility LUCX, recent experimental results, and future prospective including normal conducting LCS X-ray source will be presented.

INTRODUCTION

An X-ray generation method based on laser-electron Compton scatterings (LCS) is one feasible technique for a high brightness compact X-ray source. It utilizes a process in which energetic electrons scatter elastically a target laser photons, with an energy transfer from the electrons to the photons. The advantages of LCS are compactness thanks to its short undulation period by laser electric field[1], high brightness caused by the focused electrons and photons, and relatively large divergence angle due to small Lorentz factorγ. For instance, a 30 MeV electron beam with the laser wavelength of ~ 1 μm can produce 15 keV X-rays. This advantage has propelled worldwide laboratories to develop compact LCS X-ray sources with a brightness equivalent to the second generation light sources.

We have been developing a compact X-ray source based on an optical enhancement cavity operated with a burst amplifier[2] and a normal conducting pulsed linac. The pulse X-ray trains were already observed using a multi-bunch electron beam and an optical enhancement cavity[3]. Also, we have already tried to take X-ray images by LCS X-rays[4]. Recently, we have upgraded both accelerator system and enhancement cavity in order to increase the photon flux.

The paper describes the recent status of our accelerator and optical enhancement cavity, especially focused on the burst mode operation of enhancement cavity system, experimental results of LCS X-ray generation and feasibility study of our X-ray source extrapolating our recent results.

EXPERIMENTAL SETUP

In this section, we mention about our LUCX facility, based on normal conducting linac and optical enhancement cavity.

Multibunch Normal Conducting Linac

The LUCX facility is located inside the housing of the KEK Accelerator Test Facility (ATF). Firstly, we show the accelerator layout in Fig.1 The LUCX accelerator is an S-band, normal conducting rf linac operating with 12.5Hz pulsed electron beam. The electron bunches were produced by 3.6cell photo-cathode rf electron gun and accelerated up to 30MeV by 12cell standing wave booster linac. This linac can produce multibunch electron beam by irradiating the UV laser pulses with high repetition rate. Detail of multibunch beam handling is described in [5]. Successful approach of multibunch beam manipulation by rf amplitude/phase modulation allows us to produce 1000 electron bunch with 2.8ns bunch space on one rf pulse. The LCS interaction point is located at the center of optical enhancement cavity. The multibunch electron and optically enhanced laser pulses were interacted with each other inside the optical cavity. After interacting with laser, electron bunches are separated from the LCS X-ray by bending magnet and transported to the beam dump.

PRELIMINARY RESULT OF PHOTON COUNTING ACQUISITION SCHEME FOR LASER PUMP/ X-RAY PROBE EXPERIMENTS*

J. He[1], Y. Zhang[2], Z. H. Gao[2], Y. F. Zhou[2], Y. F. Sui[1],J. H. Yue[1], J. S. Cao[1], Y. Tao[2]
[1]Division for Accelerators, [2]Beijing Synchrotron Radiation Facility, Institute of High Energy Physics, Beijing 100049, China

Abstract

R&D project has been initiated for a proposed ultralow emittance (~50pm.rad) synchrotron light source built in Beijing. The R&D includes the development of high repetition rate laser pump/X-ray probe for ultrafast dynamics detection in future source. In a typical laser pump/X-ray probe measurement, the X-ray pulse follows a laser pulse in adjustable delay. We are interested in the difference between laser on and laser off at different delay, which will snapshot dynamic process. To capture this trivial difference, it requires the acquisition system to single out the signal from this special X-ray pulse at adequate S/N ratio. For the R&D of high repetition rate pump-probe, we have set up a prototype counting acquisition system based on NIM modular electronics, which was tested in Beijing Synchrotron Radiation Facility (BSRF). The laser will be synchronized with a camshaft bunch at 124 kHz, a tenth of the revolution frequency. Avalanche Photo Diode (APD) was used to detect the X-ray pulse from this camshaft bunch due to its nanosecond response. Before the laser is delivered, we mimic the 124 kHz laser- on signal. The signals from APD are separated by power dividers into two Constant Fraction Discriminator (CFD) input channels. The signal in laser-on/off channel is gated out using the 1.24MHz timing signal divided from 499.8 MHz RF signal, while the mimic laser-on signal gated out at 124 kHz. Multiplied by ten times, the mimic laser-on signal counts should be consistent with the laser-on+off counts, if our counting modular works well. We carried out this test at 1W1B wiggler beam line to measure the Fe fluorescence signal. The performance of our system is demonstrated in the good consistency between mimic laser on and laser on+off signals.

INTRODUCTION

Synchrotron radiation characterization technology is developed with the advancement of the accelerator technology. There is a first generations light source Beijing Electron Positron Collider (BEPC) II in Institute of High Energy Physics (IHEP). It can be operated in either of two modes: SR mode for the BSRF (Beijing Synchrotron Radiation Facility) and Colliding mode for BES III (Beijing Spectrometer III) [1]. A third generation light source High Energy Light Source (HEPS) is in a state of pre-research [2]. Table 1 shows the main parameters of BEPCII and HEPS. After the development of different steady state analysis methods, dynamic information study is developed in many synchrotron light sources [3-6], which are called time-resolved detections using a method of Pump-Probe. To use laser excitation (pump) samples and synchrotron light to detected (Probe) the samples. The goal of the experiment is to detect the trivial difference between the ground state and exiting state.

The light source will provide synchronous photons with a special time structure in these experiments, which is called mixed (Hybrid) model, bunches current and bunches gap are not the same. There will be a bunch or some bunches which called camshaft bunch, which have a larger gap and a bigger current than the normal one. In order to make X-rays synchronized with laser spatially and temporally, there are some preliminary study are done for HEPS on BEPCII [7,8].

Synchrotron-based laser pump/x-ray probe experiments on an ns or faster time scale have typically used ultrafast lasers suffering from the limitation of low repetition rates on the order of 1-10 kHz. This severely limits the data collection efficiency, since the x-ray bunches repeat at a much higher rate. This is particularly critical for XAFS experiments, which require very large S/N ratios (~ 10^4 or better) to extract useful EXAFS far above the absorption edge. In order to set up a high frequency laser ultrafast time-resolved beam line on the HEPS, some preliminary test results will be introduced in this article.

Table 1: Main Parameters of BEPCII and HEPS

Parameters	BEPCII Collide mode	BEPCII Synchrotron mode	HEPS [2]

LATTICE DESIGN OF LOW BETA FUNCTION AT INTERACTION POINT FOR TTX-II*

Tenghui Rui, Wenhui Huang
Accelerator Laboratory, Department of Engineering Physics,
Tsinghua University, Beijing 100084, China

Abstract

TTX-II is a storage ring being designed at Accelerator Laboratory in Tsinghua University as the second phase of Tsinghua Thomson scattering x-ray source (TTX), to increase the average photon flux generated. To achieve a small beta function at the interaction point, four pairs of quadrupole magnets, whose focusing strengths are optimized, are added to the baseline. The lattice design is presented in this work.

INTRODUCTION

For a storage ring dedicated to the generation of X-ray by means of Thomson scattering, the transverse beam sizes at the interaction point have great influence on machine performance. The number of scattered photon in a collision between electron beam and laser beam is determined by the beam luminosity and total cross section of Thomson scattering [1].

$$n_\gamma = L\sigma \tag{1}$$

In laboratory frame, the luminosity is described by Eq. 2 [1].

$$L = \frac{n_e n_l / 2\pi}{\sqrt{\sigma_{ye}^2 + \sigma_{yl}^2}\sqrt{\sigma_{xe}^2 + \sigma_{xl}^2 + (\sigma_{se}^2 + \sigma_{sl}^2)\tan^2(\frac{\varphi}{2})}} \tag{2}$$

where $\sigma_{x,y,se}$ and $\sigma_{x,y,sl}$ denote the horizontal, vertical and longitudinal sizes of electron and laser beams at interaction point, $n_{e,l}$ the particle numbers of electrons and photons. The collision plane is horizontal and φ is the collision angle between electron and photon beams.

The transverse beam sizes at a specific location in a storage ring is determined by beam emittance and optical functions.

$$\sigma_{xe} = \sqrt{\epsilon_x \beta_x + \eta_x^2 \delta_p^2} \tag{3}$$

$$\sigma_{ye} = \sqrt{\epsilon_y \beta_y} \tag{4}$$

where ϵ_x and ϵ_y are the horizontal and vertical emittances, δ_p the momentum spread of the electron beam, η_x the dispersion function at IP, and β_x and β_y the horizontal and vertical beta functions at IP.

To reduce the transverse beam sizes at IP, either the betatron function or the emittance should be minimized. In this work, the design of a mini-beta lattice is presented.

MINI-BETA LATTICE

The baseline design of TTX-II and the previous mini-beta lattice design are discussed in [2, 3]. To avoid element intersection and to match the ring revolution frequency with synchronizing system frequency(2856 MHz), the ring circumference has to be changed. Moreover, the layout of the magnets has to be rearranged because the stripline kicker strength is not sufficient enough for beam injection. The layout of the current design is shown in Fig. 1.

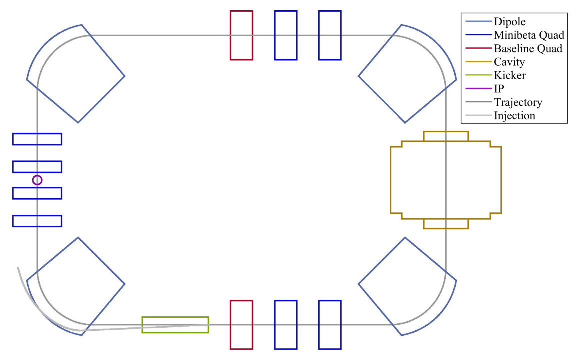

Figure 1: Layout of the mini-beta lattice.

Two pairs of quadrupoles are placed around the interaction point to provide strong focusing of the electron beam. Another two pairs of quadrupoles are placed in the straight sections between the baseline quadrupoles and bending magnets, to help adjust ring parameters such as working point and dispersion.

To find potential configurations for the lattice, all possible settings of quadrupole strengths are scanned and filtered by properties of interest such as betatron tunes and natural chromaticities. The time complexity of this algorithm depends exponentially on the number of variables, so the step size of scanning has to be large and we can only get a rough idea of what can be achieved with the current layout. For further optimization, genetic algorithm technique(GA) is exploited. To speed up convergence, the initial values of optimizing variables are chosen from the scan results. Then a population of possible settings are created and evolved by mimicking natural evolution process such as mutation, crossover and selection. The objective of GA is a function of lattice properties such as betatron tunes, beta functions and dispersion function at IP, natural chromaticities and momentum compaction factor. The program ELEGANT is used in the optimization process [4].

Figure 2 shows the optical functions of the optimized mini-beta lattice.

AN X-BAND LINAC WITH TUNABLE BEAM ENERGY*

Zhang Liang,[1,2,†] Shi Jiaru,[1,2] Wang Ping,[1,2] Zhang Zhe,[1,2] Du Yingchao,[1,2] Jin Qinxiu,[1,2] Tang Chuanxiang,[1,2] Chen Huaibi,[1,2] Han Yuansheng,[3] and Wang Chuanjing[3]

Nuctech Company Limited, Beijing, People's Republic Of China

INTRODUCTION

X-ray system is widely used in medical diagnosis and treatment [1]. In the existing medical imaging systems, the energy lower than 500keV X-ray is normally generated by X-ray tube. And the energy higher than 2MeV X-ray is generally generated by low energy electron linacs, energy between 0.5MeV and 1.5MeV X-ray source remains almost a blank. In the energy range, the ability of the X-ray tube has almost reached the limit. With the improvement of energy, the cost of X-ray tube rapidly rises [2]. Recently, the research of energy adjustable linac is of high interest and various institutions around the world are focusing on this topic [3-6].

In x-ray imaging, appropriate x-ray energy is required for different substances to meet a better sensitivity. The energy varies from several hundreds of keV to several MeV. In the low energy end, x-ray tubes has been well developed. However, tubes with energy higher than 500keV is not easy to obtain. Linacs with energy at MeV levels are also adopted in the industrial for radiographic applications such as non-destructive test and cargo inspection.

An X-band linac has been developed to produce beam with energy from 0.5MeV and 1.5MeV. During the design process, some kinds of software such as PARMELA and SUPERFISH have been used for cell optimization and beam dynamics study. After fabrication by high-precision machines tools, we measured the frequencies and field distribution in the cold test. The results were similar to the precious simulations.

MAIN PRINCIPLE

The tube of the accelerator is separated into two sections which is different from single accelerating tube. By changing the amplitude and phase of the second linac section, it is possible to realize the change of energy continuously.

*Work supported by Tsinghua University Initiative Scientific Research Program No. 20131080112
†zhangliang13@mails.tsinghua.edu.cn

The principle of changing the beam energy is described as follows: The energy of the electron beam is correlate with the acceleration phase. If the accelerating tube is divided into two segments, the first section accelerates the electron energy to E_1, and the second section of the accelerating tube can accelerate the electrons to an Energy of E_2 while the phase is adjustable, so the final energy is (see Eq. 1):

$$E = E_1 + E_2 \cos\varphi . \tag{1}$$

Figure 1 shows the schematic diagram of the system configuration of the X-band linac. The RF power is supplied by one source, which is a magnetron in this design. The power is divided into two parts: one is fed into the first accelerating section directly; the other is fed into the second accelerating section through an attenuator and a phase shifter, which are used to change the amplitude and the phase of the second tube [7].

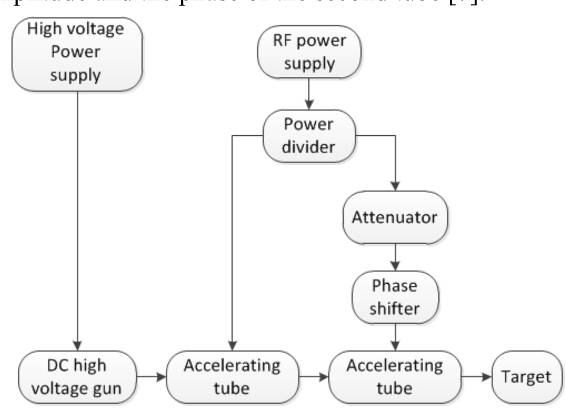

Figure 1: Schematic diagram of the linac system.

Since the electron beam energy is between 0.5MeV to 2MeV, the traditional industrial measurement method can not meet the needs of energy measurement accuracy.

During the measurement of electron beam energy, we can use current-thickness curvilinear to extrapolate the energy. Experiment results show that if we take aluminium as the absorbing material, we can get the database diagram about the current and the thickness of the aluminium plate. The simulation result is shown in Fig.2.

BETA FUNCTION MATCHING AND TUNE COMPENSATION FOR HLS-II INSERTION DEVICES*

Bing Li, Wei Xu, Ke Xuan, J.Y.Li†
National Synchrotron Radiation Laboratory,
University of Science and Technology of China, Hefei, Anhui 230029, China

Abstract

In order to increase its brightness and improve the performance, the Hefei Light Source (HLS) was completely renovated from 2010 to the end of 2014. The magnet lattice of the new storage ring consists of four double bend achromatic (DBA) cells. There are eight straight sections which can be used to install up to 6 insertion devices (IDs). Currently, five insertion devices have been installed in the storage ring. It is known that the dynamics of the electron beam motion in the storage ring would be influenced by the insertion device, depending on its physical properties. In order to keep high performance operation of the storage ring and make the insertion device transparent to the rest of the storage ring, a complex compensation scheme is developed to match the beta functions at both ends of a ID and perform transverse tune compensation. This scheme has been integrated into the EPICS based control system of the HLS-II. The result indicates that the scheme is very effective to compensate the impact of the insertion devices.

INTRODUCTION

The Hefei light source (HLS) at the National Synchrotron Radiation Laboratory (NSRL) was overhauled to increase its brightness and improve the performance. This major upgrade was started in 2010 and finished at the end of 2014. The new light source, named HLS-II, is comprised of an 800 MeV linac, a beam transfer line and an 800 MeV electron storage ring. Some critical parameters of the HLS-II storage ring are listed in Table 1.

Table 1: Main Parameters of the HLS-II Storage Ring [1]

Name	Value
Beam energy (MeV)	800
Circumference (m)	66.13
Magnet lattice	DBA
Beam emittance (nm·rad)	38
ν_x/ν_y	4.414/3.346
Number of IDs installed	5

Four fold double bend achromatic (DBA) cells are adopted as the magnet lattice of the HLS-II storage ring. The storage ring has two types of straight sections, four 4-meter long and four 2-meter long straight sections. One 4-meter long straight section is used to install the injection devices, and one 2-meter long straight section is used to hold the RF cavity. The rest straight sections can be used to install up to 6 insertion devices (IDs) . At present time, five insertion devices have been installed in the storage ring and providing strong narrow band synchrotron radiation for various user experiments. It is known that an insertion device would have strong impact on the optical parameters of the storage ring, depending on the physical properties of the insertion device. In order to keep high performance operation of the storage ring and make the insertion device transparent to other parts of the storage ring, a complex compensation scheme is developed to match the beta functions at both ends of the ID and perform compensation for the transverse tune. This scheme has been implemented in the EPICS based control system of the HLS-II storage ring. The impact of the IDs is automatically compensated by the control system according to the gap between the top and bottom magnetic poles.

As one example, this paper reports the compensation results of one of the HLS-II insertion devices. It first illustrates the fitting for the scheme, and then a beam based calibration of the scheme is reported. The tune shift and orbit distortion after the compensation are also presented in this paper.

REVISIT OF THE COMPACT OF AN UNDULATOR ON THE STORAGE RING OPTICS

Considering a horizontal undulator, the magnetic field is given by [2]

$$B_y = B_0 \cosh k_w y \cos k_w z, \tag{1}$$

where $k_w = 2\pi/\lambda_w$ is the wave number of the undulator, B_0 is the peak value of the magnetic field. The vector potential of the undulator is

$$\vec{A_x} = -\frac{B_0}{k_w} \cosh k_w y \sin k_w z. \tag{2}$$

And the normalized vector potential is

$$\begin{aligned} a_x &= \frac{eA_x}{P_0} = -\frac{eB_0}{\gamma\beta mck_w} \cosh k_w y \sin k_w z \\ &= -\frac{K_w}{\gamma\beta} \cosh k_w y \sin k_w z, \end{aligned} \tag{3}$$

where $K_w = \frac{eB_0}{mck_w} = \frac{eB_0\lambda_w}{2\pi mc}$ is the undulator strength parameter.

In the undulator, the Hamiltonian for the electron motion is given by [2]

$$H \simeq \frac{(p_x - a_x)^2 + p_y^2}{2(1+\delta)}, \tag{4}$$

COHERENT SYNCHROTRON RADIATION FIELD AND THE ENERGY LOSS IN A WAVY BEAM*

Derong Xu†, Hongliang Xu‡, USTC/NSRL, Hefei, Anhui, China

Abstract

The synchrotron radiation will be coherent when the wavelength of the radiation can be compared with the bunch length. There are two approaches to produce Coherent Synchrotron Radiation (CSR) on a storage ring. One is to compress the bunch length, the other one is to produce a wavy beam which has high spatial repetition along the longitudinal direction. The latter one can expand the radiation frequency range of a light source. However, CSR can bring nonlinear effect which brings in extra instability. The Liénard-Wiechert potentials in three-dimensional space may have very complicated forms. The most common way to investigate CSR is numerical method. This paper try to use a simple model to obtain energy loss of the electrons in theory.

PHYSICAL PICTURE

Assuming an electron moves along a fixed circular orbit of radius ρ with a constant speed $|\vec{\beta}| = \beta$. At the present moment, the electron locates at point P. We want to know the fields around point P. Radiation field in the orbit plane is discussed in [1]. To simplify the question, we assume the observation point A just above or below the trajectory. Thus, we get a two dimensional model. The field of point A is emitted at an earlier time when the electron located at point P'. The relations between P,P' and A are as shown in Fig. 1.

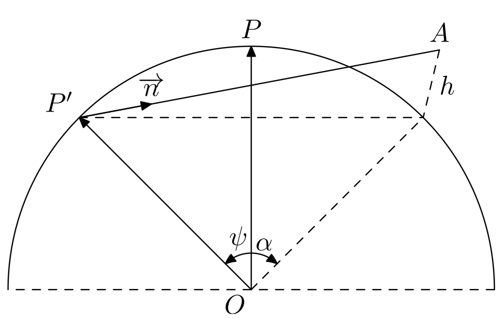

Figure 1: Diagram of the 2D model. ψ is the retarded angle, α is the azimuthal angle between P and P', h is the height of A relative to the orbit plane. Here $h > 0$ means the observation point A is above the orbit plane and $\alpha > 0$ means A is ahead of the electron present position P. ψ is always positive and $-\pi < \alpha < \pi$.

According to the geometric relationship, we can get the retarded equation:

$$\frac{\psi^2}{\beta^2} = (\frac{h}{\rho})^2 + 4\sin^2(\frac{\psi+\alpha}{2}). \tag{1}$$

The retarded equation is nonlinear, so it is generally not possible to obtain an exact answer. However, under some approximations, we can get some meaningful analytic solutions.

SOLUTION OF THE RETARDED EQUATION

Equation (1) shows that the retarded angle ψ depends on the electron's energy γ, the longitudinal azimuthal angle α and the height between the observation point to the orbit plane. In other words: from equation (1), we can get the numerical solution as shown in Fig. 2 and Fig. 3.

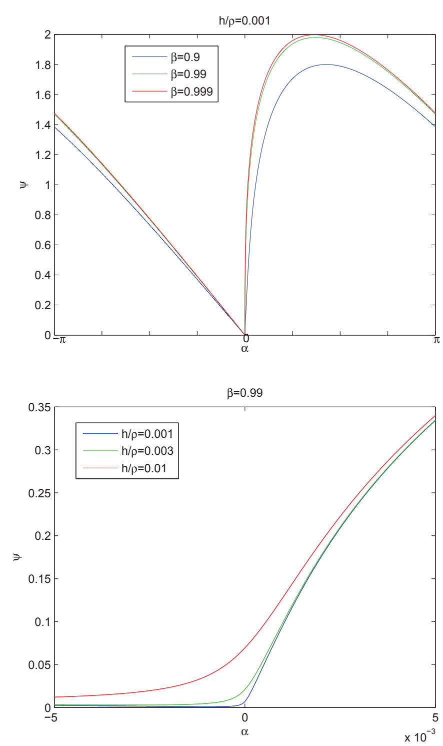

Figure 2: Retarded angle ψ as a function of α. The upper shows how ψ varies with the whole α when $h/\rho = 0.001$ for different β(or γ). And the lower shows small α when $\beta = 0.99$ for different h/ρ.

The conclusions are: (a)$\psi = \alpha_0$ when $\alpha = -\alpha_0$, here $\alpha_0 = h\beta/\rho$; (b)ψ is bounded; (c)ψ grows rapidly when $\alpha > 0$; (d)ψ is weakly related to γ when γ is large enough; (e)$(\psi + \alpha)/2 < 0$ when $\alpha < 0$ and vice verse.

THE GENERATION OF HIGHLY INTENSE THz RADIATION BASED ON SMITH-PURCELL RADIATION *

Yuanfang Xu†, Weiwei Li † ‡, Zhigang He §, Qika Jia, NSRL USTC, HeFei, AnHui 230039, China

Abstract

A photocathode RF gun can generate trains of THz sub-picosecond electron bunches by illuminating the cathode with trains of laser pulses. Let this electron bunches passes close to the surface of a lamellar grating, THz radiation will be emitted, which is the so-called Smith-Purcell Radiation (SPR). If the lamellar grating has a narrow groove, this radiation will be narrow band. By choosing suitable parameters, the SPR frequency can be resonant with the electron bunches frequency, and then generate highly intense, narrow band THz coherent radiation.

COHERENT SMITH-PURCELL RADIATION

When an electron beam passes close to the surface of a periodic structure (such as a metallic grating), radiation is emitted because of the interaction of the particles with the periodic structure, which is the so-called Smith-Purcell radiation (SPR)[1]. The intensity of radiation is proportional to the number of periods of the grating (N_g), hence it is strongly compared to other coherent radiation generation techniques such as synchrotron, transition and diffraction radiation.

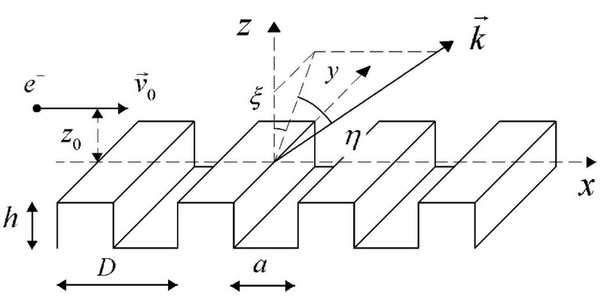

Figure 1: Definition of the geometry. The electron beam moves with constant reduced velocity $v_0 = \beta_0 c$ at a distance $z = z_0$ parallel to the grating surface in x-direction.

According to the theory of di Francia[2], the emission mechanism of SP radiation can be interpreted in analogy to the diffraction of light as the diffraction of the field of the electrons (virtual photons) which pass the grating at a distance z_0 away from its surface by the grating grooves. One characteristic signature of SPR is that it must fulfill the dispersion relation

$$\lambda = \frac{2\pi c}{\omega} = \frac{D}{|n|}\left(\frac{1}{\beta_0} - \sin\eta\right) = \frac{2\pi}{k_0}, \quad (1)$$

where λ is the wavelength of the radiation, n is the spectral order, β_0 is the ratio of the electron velocity to the speed of light c, D is the period of the grating, and k_0 is the wave number. For one electron, the radiated energy density per unit solid angle in direction (η, ξ) of the SPR of order n can be written as[2]

$$\frac{\mathrm{d}W_n}{\mathrm{d}\Omega} = \frac{Le^2}{2D^2\varepsilon_0}\frac{n^2\cos^2\eta\cos^2\xi}{(1/\beta_0 - \sin\eta)^3}|R_n|^2 \exp\left(\frac{-2z_0}{\lambda_e}\right), \quad (2)$$

Where $|R_n|^2$ is radiation factor, $L = N_g D$ is the total length of grating, N_g is the number of grating periods, η and ξ are the emission angles as introduced in Fig. 1, and λ_e is the so-called "evanescent wavelength". For N_e electrons in a bunch, coherent radiation is produced for wavelengths longer than the bunch length. The total energy density becomes

$$\left(\frac{dW_n}{d\Omega}\right)_{N_e} = \frac{dW_n}{d\Omega}(N_e S_{inc} + N_e(N_e - 1)S_{coh}^2), \quad (3)$$

where S_{inc} and S_{coh} are the incoherent and the coherent form factors, respectively.

RADIATION FACTOR: NARROW BAND SMITH-PURCELL RADIATION

To calculate the radiation energy, the key problem is to calculate the radiation factors. Van den Berg model[3, 4] is a rigorous solution under infinitely long and wide grating assumption. The radiated energy is calculated by solving two separated integral equations, each having a periodic Green's function, excited by the charge wake fields. Kesar and co-workers developed EFIE[5] and FDTD[6] model which extend Van den Berg's model for a finite grating size, and the two models agree well with each other. However they are more complex and need a much longer computation time. For the low relativistic elctron energies($\sim KeV$), Van den Berg's model ensures a reasonable agreement with experiments[7, 8]. The experiment at 15 MeV have demonstrated good agreement between measured power and the predictions of the EFIE model[9]. The simulated results at 18 MeV with 20 period length showed that in the plane (x,z), the angular radiation intensity per groove is greater than that of Van den Berg's model and their intensity shapes are close to each other[5]. As the number of periods increases, the simulated radiation intensity will be more and more close to that of Van den Berg's model[5, 6, 10].

ON-AXIS INJECTION SCHEME FOR ULTIMATE STORAGE RING WITH DOUBLE RF SYSTEMS

B. C. Jiang, Z. T. Zhao, S. Q. Tian, M. Z. Zhang, Q. L. Zhang,
Shanghai Institute of Applied Physics, Chinese Academy of Sciences, Shanghai 201800, China

Abstract

An on-axis injection scheme using double RF systems for an ultimate storage ring with very small dynamic aperture is proposed. By altering RF voltages, empty RF buckets can be created which will be used for on-axis injection. After bunches are injected, a reverse voltage altering process is performed and the injected bunches can be longitudinally dumped to the main buckets.

INTRODUCTION

A storage ring using "multi-bend achromat" (MBA) optics to reduce the natural emittance by one or two orders of magnitude down to current synchrotron light source storage rings has been proposed since 1995 [1]. After decades of efforts, this will become reality at MAX IV lab [2]. If the ring circumference is in the 1~2 kilometers range, the emittance of the electron beam will reach the photon diffraction-limited region for hard X-ray, an area that is of great interest to the synchrotron light community that could provide synchrotron radiation with high repetition rates and high brightness holding a large percentage of spatially coherent flux [3, 4]. A storage ring with these characteristics is called an "ultimate storage ring" (USR).

MBA optics employs much more numbers of bending magnets to decrease the bending angle θ of a single magnet and so reduce the natural emittance, which decreases as θ^3. Thus stronger quadrupoles are required to suppress the small dispersions created in the bending magnets, leading inevitably to the large negative native chromaticities in both transverse planes. In order to combat the head-tail instability and avoid large tune shifts of off-momentum particles, the chromaticities are usually corrected to slightly above zero, so strong chromatic sextuples are needed. These nonlinear elements will significantly reduce dynamic apertures presenting a great challenge for USR lattice design [5]. Many of the USR lattices which have been designed to date only provide horizontal dynamic apertures of around 2mm [6, 7, 8], leading to severe difficulties in injection.

One of the on-axis injection schemes, "swap-out injection", has been proposed [9], which uses a fast dipole kicker to inject fresh high charge beam onto the closed orbit while the stored beam is extracted. Swap-out scheme provides a baseline to inject the beam into the storage ring with a rather small dynamic aperture without major technical challenges. Recently, a novel longitudinal on-axis injection scheme was proposed in [10], in which a low frequency RF system is used, the bunch is injected at a phase with large deviation from the synchrotron phase and with energy slightly higher than the stored beam. Then the injected bunch damps to the synchrotron phase. For a storage ring with large energy acceptance this is a compact on-axis injection scheme without significant changing of the hardware.

In this paper, a possible approach for injecting beams into the USR, a new on-axis injection scheme is proposed. By altering the two RF voltages, empty RF buckets can be created which will be taken for on-axis injection. After bunches are injected, the voltage altering process will be reversed and the injected bunches can be longitudinally transferred to the main buckets (where the stored bunches are located). The energy oscillation of the injected bunches in this process can be controlled to less than 1%.

TWIN RF BUCKETS PRODUCTION

Assume that the storage ring has two RF systems, with the main RF system operating at 250MHz and the other one at the 2nd harmonic frequency 500MHz. The time dependence of the RF voltages are given by

$$V_m = \widehat{V_m}(st)cos(\omega_m t) \quad (1)$$

$$V_h = \widehat{V_h}(st)cos(2(\omega_m t - \varphi_s) - \pi/2), \quad (2)$$

$$\varphi_s = arccos(\frac{U_0}{\widehat{V_m}(0)}), \quad (3)$$

Where V_m, V_h are the voltage of the main and 2nd harmonic RF system respectively. The amplitudes of the RF voltages $\widehat{V_m}(st)$, $\widehat{V_h}(st)$ are modulated stepwise in a preset pattern. φ_s is the synchrotron phase of the main RF system, st denotes the modulating step, U_0 is the radiation energy loss per turn, and ω_m is the angular frequency of the main RF system.

If $\widehat{V_h}(st)$ is increased from near zero to its maximum value, while $\widehat{V_m}(st)$ is kept constant, one RF bucket will be split into two (twin) buckets as shown in Fig 1. As the stored bunches are located at synchrotron phases, they will be partitioned into two parts. In order to prevent the already stored bunches from being partitioned, a 'knot' as shown in Fig. 2 should be formed slightly before φ_s. The expression for the voltage of the second RF system should be modified to

$$V_h = \widehat{V_h}(st)cos(2(\omega_m t - \varphi_s) - \frac{\pi}{2} + \Delta\theta). \quad (4)$$

We call $\Delta\theta$ the synchrotron phase deviation and assume $\Delta\theta > 0$.

Figure 2 shows the detailed total voltage evolution process with $\Delta\theta > 0$. The stored bunch marked by the red dot will be pushed backward and the second empty RF

OPERATING CASCADED HIGH-GAIN HARMONIC GENERATION WITH DOUBLE-PULSE ELECTRON BEAMS

Zhen Wang[1], Chao Feng[1], Qiang Gu[1], Lihua Yu[2,*], Zhentang Zhao[1,†]
[1]Shanghai Institute of Applied Physics, Chinese Academy of Sciences, Shanghai 201800, China
[2]National Synchrotron Light Source, Brookhaven National Laboratory, New York 11973, USA

Abstract

Cascading stages of high-gain harmonic generation (HGHG) is a promising candidate for the generation of fully coherent x-ray radiation. However, fluctuation of the output pulse energy is still a critical issue for a realistic facility with cascaded HGHG scheme. In this paper, we proposed using double-pulse electron beams to drive two stages cascaded HGHG, which will be helpful for increasing the stability of the output pulse energy against the arriving timing jitter in the second stage. Methods to generate the required double-pulse electron beams are introduced in the paper and three-dimensional simulations are carried out to show the significantly improvement of the FEL stability comparison with the standard cascaded HGHG by using this technique.

INTRODUCTION

Free electron lasers (FELs) hold great promise for the generation of coherent x-ray radiation with high brightness and ultra-fast time structures which will enable scientists in physics, chemistry, biology and medicine to study nature down to the molecular and atomic level at a time-scale that fits this resolution [1]. For nowadays, self-amplified spontaneous emission (SASE) FEL [2] is still the primary candidate for nanometer and sub-nanometer wavelength FEL generation. As the world's first hard x-ray FEL facilities, the Linac Coherent Light Source (LCLS) and the Spring-8 Angstrom Compact Free Electron Laser (SACLA) have demonstrated x-ray FEL technology in an impressive fashion [3-5]. However, SASE FEL suffers from the limited temporal coherence and large statistical fluctuations as the initial radiation starts from the electron beam shot noise.

To improve the FEL performance, frequency up-conversion schemes, such as high-gain harmonic generation (HGHG) [6,7], echo-enabled harmonic generation (EEHG) [8-10] and phase-merging enhanced harmonic generation (PEHG) [11,12], etc., have been proposed to manipulate the electron beam phase space with external coherent laser sources. In the standard HGHG, coherent micro-bunching is formed in the electron beam after energy modulation and density modulation. The output radiation, which inherits the properties of the seed laser, can have a high degree of temporal coherence and much stable central wavelength and output pulse energy compared to SASE. These properties of HGHG FEL have already been demonstrated in several single-stage HGHG experiments. However, the need to limit the growth of the energy spread prevents the possibility of reaching X-ray wavelength in a single-stage HGHG. To overcome this problem, cascading multiple stages of HGHG with 'fresh-bunch' technology have been proposed [13] and recently realized at FERMI for coherent soft X-ray generation at the wavelength of 20 to 4 nm [14-17]. The experimental results at FERMI show great output stability for the first stage HGHG but large pulse energy fluctuation up to 50-60% (FWHM) in the second stage [18], which may be a quite serious problem for FEL users. Such a critical energy fluctuation may primarily originates from the interplay of timing jitter between the relative arrival times of the electron beam and seed lasers, together with variations of the electron beam of properties along the longitudinal direction: for different shots, seed laser pulses in the modulator of the second stage will interact with parts of electron beam with quite different beam qualities.

In this paper, we propose using double-pulse electron beam to significantly improve the output stability of a two stages HGHG. The two pulses are separately used for producing of high harmonic radiation pulses in two stages. With the first bunch length much longer than the second one, the radiation pulse from the first stage can cover the whole bunch length in the second stage. Thus makes the power output much less sensitive to the small relative arrival timing jitter in the second stage. We first show the simulation results of a standard two stages HGHG. Then, we will introduce methods to generate two-pulse electron beams that fit the requirement. Summaries and conclusions are given in the last.

STANDARD CASCADED HGHG WITH A SINGLE-BUNCH ELECTRON BEAM

The Shanghai Soft x-ray FEL facility (SXFEL) is a test facility based on two-stage cascaded HGHG, as shown in Fig. 1. The linac of SXFEL consists of an injector, a laser heater system, a main accelerator (L1, L2 and L3) and two bunch compressors (BC1 and BC2). The electron beam is generated in a 1.6-cell S-band photocathode RF gun with initial bunch length of 8 ps, bunch change of around 500pC and peak current of 50A. Then the electron beam is boosted to 210MeV in L1 (S-band) and compressed by 5 times in the first bunch compressor (BC1). After that, the beam is boosted again to about 420MeV in L2 (S-band) and compressed twice further in the second bunch compressor (BC2). Finally, L3 (C-band) is used to future accelerate the electron beam to 840 MeV

INTERACTION CHAMBER DESIGN FOR A SUB-MeV LASER-COMPTON GAMMA-RAY SOURCE

Hanghua Xu[#], Jianhui Chen, Gongtao Fan, Dong Wang, Hailong Wu, Benji Xu,
SINAP, Shanghai, China

Abstract

Previously, fixed angle Laser-Compton Scattering (LCS) experiments have been conducted at the terminal of the 100MeV LINAC of the Shanghai Institute of Applied Physics, using SINAP-I [1] and SINAP-II [2] facility. Sub-MeV energy continuously tunable laser-Compton light source device (SINAP-Ⅲ) is an updated facility that will allow the collision angle between the laser and electron beam continuously adjustable from 20° to 160°. This new feature will enable convenient control on the peak energy of the generated X/γ ray, especially when the energy of electrons cannot be momentarily adjusted, e.g. on the storage ring.

Keeping the electron beam and laser beam waist coincident at arbitrary angle is crucial for LCS gamma-ray production, an interaction chamber containing a rotatable bracket that holds a series of plane mirrors and convex lens is presented. This work is a summary of its design.

The simulation of photon production's variation caused by the system errors is performed using a MC code [3]. The accuracies of installation and adjustment of mirrors and lens are given according to the simulation results. The sizes of these optical devices are also optimized to make the chamber as compact as possible due to space limitation.

INTRODUCTION

In the past ten years, with the development of advanced accelerator and laser technology, the new X / γ-ray source based on Compton scattering obtain a rapid development and was rated as one of the most potential in the field of ultra- short pulse light sources. It uses high-power short-pulse laser beam with high brightness relativistic electron beam interaction, Compton scattering to produce high flux, short-pulse, quasi-monochromatic X/γ-rays. Currently, many research institutions such as LLNL [4], BNL [5], SLAC, IAC, MIT, Spring8, JAEA, INFN and ESRF are committed to the construction of the experimental device of LCS. The peak energy of produced X/γ-rays have wide applications in nuclear physics, medicine, energy, defence and industrial applications. The peak energy of the scattered X/γ-ray photon [2] is

$$E_x = E_L \frac{(1-\beta\cos\theta_L)}{1-\beta+\dfrac{E_L}{E_e}(1-\cos\theta_L)}$$

Where β is the electron velocity normalized to the speed of light, E_e and E_L are the energies of the incident electron and laser photon, and θ_L is the incident angle of the laser photon with respect to the direction of the incident electron beam. Traditionally, this value can only be varied by changing E_e (electron's energy) or E_L (the wave length of laser), which is inconvenient.

SINAP-III facility [6] is a sub-MeV gamma-ray source based on Laser Compton scattering. It is constructed on the branch line of SDUV-FEL [7]. The electrons and laser are both imported from the principle line into an interaction chamber. A specially designed laser transport system enables θ_L to be continuously changed from 20° to 160°, scattered photon energy E_x is thus continuously adjustable easily without changing E_e, E_L.

In this paper, we present the optical design of the interaction chamber and the study on the tolerance of mirrors.

LASER TRANSPORT SYSTEM

To achieve the continuously adjustability of the colliding angle of the electron beam and laser beam, a rotatable structure is designed.

Basic Structure

As shown in Fig.1, laser beam would propagate along the path from mirror No.6 to mirror No.0. The green lines in Fig. 1 is the maximum envelope of laser beam that these Optical elements' apertures can hold.

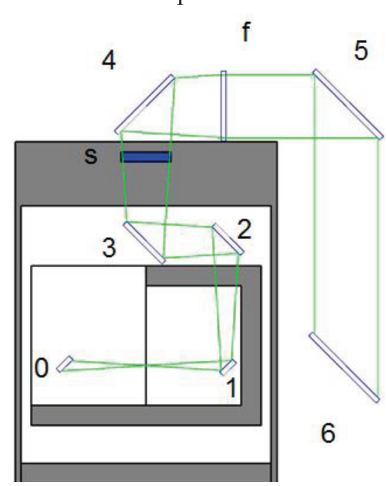

Figure 1: Basic optical structure (side view). The rectangles with number 0-6 represent plane mirrors, the rectangle referring to "f" is a convex lens, and the one with "s" is a transparent glass which covers the chamber.

STUDY ON BEAM DYNAMICS OF A KNOT-APPLE UNDULATOR PROPOSED FOR SSRF

Q.L. Zhang, B.C. Jiang, S.Q. Tian, Q.G. Zhou, Z.T. Zhao
SINAP, Shanghai, 201800, P.R. China

Abstract

A new type of undulator, Knot-APPLE undulator, is proposed for SSRF as a solution to reduce the heat load of on-axis high harmonics without losing its capability of tuning synchrotron polarization. It will be applied for SSRF Photoemission Spectroscopy beamline (PES-beamline) in the near future. Impact of the undulator on the beam dynamics has been studied based on the 3D magnetic field model and kick map analysis. Linear optics can be retained by quadrupole compensation within two adjacent cells. Dynamical aperture (DA) shrinkage has been found in the tracking and optimized with sextupoles. An active correction scheme of current strips is studied to compensate the kick maps, and both the linear and nonlinear effects are suppressed.

INTRODUCTION

Shanghai Synchrotron Radiation Facility (SSRF) is an intermediate energy light source opened to users since 2009 [1]. There are 7 beamlines in operation, 5 of which are from insertion devices including IVUs, wigglers and EPU. Another 6 beamlines are under commissioning, including the 'dreamline' based on a double EPU, two canted beamlines from canted IVUs in one straight section, and some other beamlines from IVUs or bending magnets. In near future, a new type of undulator, Knot-APPLE undulator, will be equipped in SSRF storage ring for PES-beamline [2]. Main parameters of the existing IDs and Knot-APPLE in SSRF are listed in Table 1.

Table 1: Main Parameters of Existing IDs and Knot-APPLE in SSRF

	Type	λ_{ID}	L_{ID}	$B_{y,peak}$
H08U	EPU	10cm	4.2m	0.6T*
H09U58	EPU	5.8cm	4.9m	0.68T*
H09U148	EPU	14.8cm	4.7m	0.67T*
H13W	Wiggler	14cm	1.4m	1.94T
H14W	Wiggler	8cm	1.6m	1.2T
H15U	IVU	2.5cm	2m	0.94T
H17U	IVU	2.5cm	2m	0.94T
H18U	IVU	2.5cm	1.6m	1T
H19U1	IVU	2cm	1.6m	0.84T
H19U2	IVU	2cm	1.6m	0.84T
Knot-APPLE	EPU	20cm	4.4m	0.7T*

* For horizontal polarization mode

In this paper we will firstly give a brief introduction of Knot-APPLE undulator, and then estimate its effects on beam dynamics using kick map analysis. Quadrupole compensation is studied, and the linear optics could be retained. The nonlinear effect, which brings significant reduction of dynamical aperture, was optimized with sextupoles. Furthermore, an active correction scheme of current strips is also considered to compensate the kick maps, so as to suppress both the linear and nonlinear effects. The preliminary simulation gives us an encouraging result that the linear effect would be an order less and the dynamical aperture is tolerable for operation.

KNOT-APPLE UNDULATOR

Knot-APPLE combines the advantages of both the Knot and the APPLE type of structure in EPU fabrication, and could reduce the on-axis heat load without lose its ability to generate variable polarization [2]. With such a complicated structure, Knot-APPLE would significantly impact on beam dynamics. To estimate its effects, the 3D magnetic field model has been established, as shown in Fig. 1.

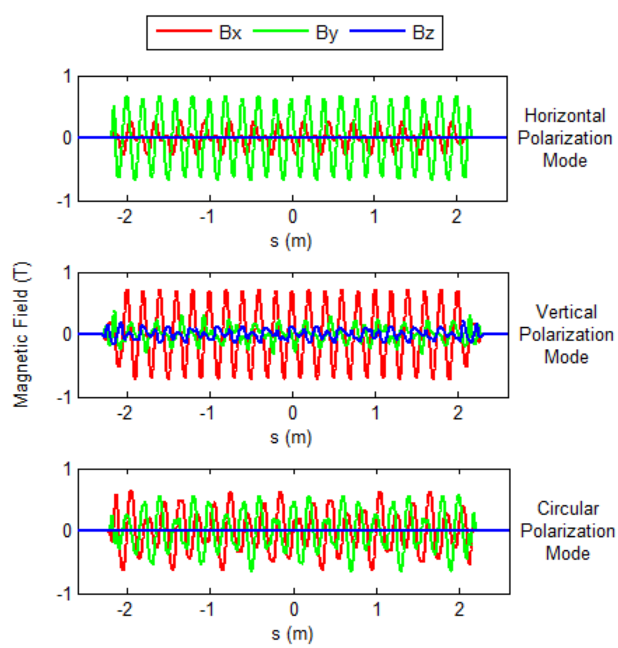

Figure 1: Magnetic field of the Knot-APPLE undulator at minimum gap.

CONSIDERATION ON THE FUTURE MAJOR UPGRADES OF THE SSRF STORAGE RING

Z.T. Zhao, L.X. Yin, Y.B. Leng, B.C. Jiang, S.Q. Tian, M.Z. Zhang for the SSRF team
Shanghai Institute of Applied Physics, Shanghai 201800, P. R. China

Abstract

The SSRF storage ring began its user operation in 2009, currently it is operating at the energy of 3.5GeV, the natural emittance of 3.9 nm-rad and the beam current of 240 mA, serving for 13 beamlines with 9 IDs. Around 2020, there will be close to 40 operational beamlines at SSRF, which demand to further improve the performance of the existing storage ring, such as implementing the new lattice with superbends and installing 18 more new IDs. Looking for the future beyond Phase-II beamline project, a major upgrade towards a diffraction limited storage ring is under consideration. This paper presents the initial proposal on the ultimate storage ring upgrade for SSRF.

INTRODUCTION

The Shanghai Synchrotron Radiation Facility (SSRF) is a third generation light source, consisting of a 150 MeV electron linac, a full energy booster, a 3.5 GeV storage ring with circumference of 432m, and now 13 operational beamlines and 16 experimental stations. It started users' operation in May 2009 and already served more than 10000 users from all over China.

SSRF switched to top up operation [1] for routine user experiments in December 2012, its ring current had been gradually increased from 200mA to 240mA during the last 3 years. The major efforts for increasing the beam current is made on conditioning the superconducting RF cavity and suppressing beam instabilities. At present, the bunch filling pattern is shown in Fig. 1, four 125-bunch-trains separated by 55-empty-bucket gaps. While previous one is a uniform 550-bunch train, followed by a 170-empty-bucket gap. The main reason for such a filling pattern is to reduce the fast ion instability that is caused by high current and the newly installed undulators where the vacuum pressure is higher than the rest part of the ring.

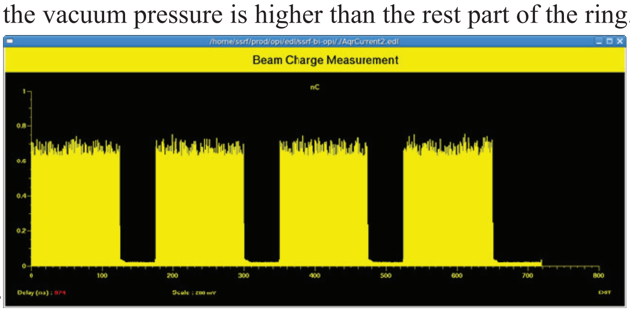

Figure 1: Bunch filling pattern of the SSRF storage ring.

Hybrid filling pattern has also been provided for users. A single bunch of 5 mA which is followed by a bunch train with current of 225 mA has been successfully run for the time resolution experiments. The time gap between single bunch and the bunch train is 110-empty-bucket gap as shown in Fig. 2.

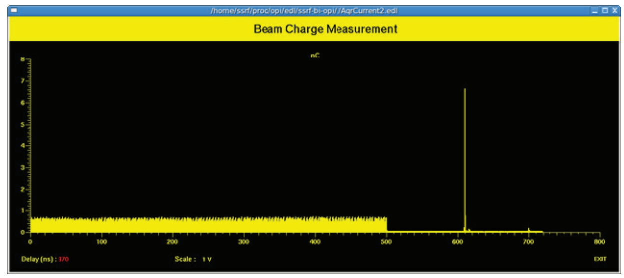

Figure 2: Hybrid bunch filling pattern in the storage ring.

The storage ring fast orbit feedback was successfully commissioned in 2013, and it has been implemented in users' operation since then. The system contains 60 fast correctors and 40 BPMs in each plane working at 10 kHz, controlling the orbit at the both end of straight sections [2]. The effective bandwidth is better than 100 Hz. The fast orbit feedback system works together with the slow orbit feedback system controlling the long term orbit stability to 0.26 μm and 0.25 μm (RMS) in horizontal and vertical planes respectively.

Over the past 3 years, five new insertion devices have been installed in the ring. Three of them are in vacuum undulators and two of which are dual canted with a canted angle 6 mrad. Another one is a double elliptical polarized undulator (DEPU) as shown in Fig. 3. The DEPU holds two undulators with period 58 mm and 148 mm respectively which can be shifted mechanically in horizontal plane to the electron beam orbit. The purpose of such a design is to provide soft X-rays with the photon energy from 20 eV to 2000 eV to one beamline. The additional one is a prototype of cryogenic permanent magnet undulator (CPMU) for performance evaluation. At present the phase error of this CPMU is under calibration and measurement through photon spectrum.

Abstract

Pohang Accelerator Laboratory (PAL) is developing a 0.1 nm SASE based FEL based on 10 GeV S-band linear accelerator named PAL-XFEL. At the first stage, PAL-XFEL needs two undulator lines for photon source. The hard X-ray undulator line requires 18 units of 5 m long hybrid-type conventional planar undulator and soft X-ray line requires 6 units of 5 m long hybrid type planar undulator with additional few EPUs for final polarization control. PAL is developing undulator magnetic structure based on EU-XFEL concepts. The key parameters are min pole gap of 8.3 mm, with period length 26 mm (HXU), 35 mm (SXU), and 5.0 m magnetic length. . In this report, the prototyping, and the development of pole tuning procedure, the impact of the background field error, and the effects of the girder bending on the optical phase error will be presented.

INTRODUCTION

The Pohang Accelerator Laboratory (PAL) has been developing SASE based light sources since 2011. The target wavelength is 0.1nm for hard X-ray SASE radiation, with 10 GeV class S-band linear accelerator. For soft X-ray SASE, 3.0 nm FEL radiation using 3.15 GeV electron beam is assumed. To achieve this target, a few key components like low emittance (0.5 μm) photo cathode RF gun, and EU-XFEL style out vacuum undulator system are being developed [1]. For undulator system, there will be 18 undulators for X-ray line and 6 planar undulators with additional two EPUs (Elliptically Polarized Undulator) are expected. The EPUs will be used for polarization control at the last stages of lasing. The major parameters of the X-ray FEL and undulator line is slightly changed recently and the updated parameters are shown in Table 1. A minor changes were the magnetic gap and period. The gap was changed from old 7.2mm to 8.3 mm resulting period change from 24.4 mm to 26.0 mm maintaining 0.1 nm SASE lasing at 10 GeV electron beam energy. The number of required units for soft X-ray SASE line is estimated to be 6 5 m long planar undulators with 2 additional EPUs. The major parameters of the HXU undulator system is summarized in Table 1. The parameters of the EPUs are under study now, and the magnetic pole gap is 10.0 mm with 44.0 mm magnetic period to match the resonance condition with the conventional hybrid undulator for soft X-ray undulator lines. The horizontal space between magnetic arrays are tuned to 4.0 mm to secure the transverse roll off of Keff within 0.50 mm to 5.0×10^{-4} at helical mode where Kx=Ky. At non-planar mode, Keff is defined by the usual formula $Keff^2 = Kx^2 + Ky^2$. A detailed design and quoting is going on and the final contract is expected to be early 2015.

Among the available five undulator lines in the undulator halls, only two undulator lines will be prepared during the construction period of year 2011-2105: a hard X-ray FEL line (HX1) with 18 undulators and a soft X-ray FEL line (SX1) with 8 undulators are anticipated. HX1 covers the wavelength range of λ=0.06 - 0.6 nm using a 4 to 10-GeV electron beam and uses linear polarization, variable gap, out-vacuum undulators. SX1 covers the wavelength of λ = 1.0 - 4.5 nm using a 3.15-GeV electron beam. In SX1, two EPUs (Elliptically Polarized Undulator) following six planar undulators will be used for polarization control at the last stages of lasing. An enough space is reserved in the undulator halls for the future upgrade to accommodate a total 29 undulators for HX1 and 16 undulators for SX1.

Table 1: Major Parameters of the HXU Undulator

Symbol	Unit	Nominal value
E	GeV	10.000
g	mm	8.30
λ_u	mm	26.0
L_{und}	5	5.0
λ_r	nm	0.100
B_{eff}	Tesla	0.8124
K		1.9727
Optical phase error	degree	Less than 7.0
Total number	EA	18

UNDULATOR SYSTEM

For the PAL-XFEL undulators, the EU-XFEL design and technology [2,3] was adopted and further developed. The EU-XFEL design is a well proven using standardization and optimization for mass serial production and was successfully used for the production of 91 undulators for the EU-XFEL

At PAL a full scale prototype undulator was built. It is based on the EU-XFEL concept with some modification reflecting different magnetic periods and pole gaps. In addition, precision tilt meters were attached to the girders to monitor the tilting and tapering of the undulator. Also the control systems are developed to be used in EPICs environment. A prototype is based on the old magnetic periods of 24.4mm and old magnetic gap of 7.2 mm had

A RESEARCH ON THE REVERSE TAPERING METHOD TO GAIN HIGH POWER POLARIZED PHOTON BEAM WITH FIXED WAVELENGTH

C. H. Shim, I. S. Ko, Pohang University of Science and Technology, Pohang 790-784, Korea
J. -H. Han, Y. W. Parc#, Pohang Accelerator Laboratory, Pohang 790-784, Korea

Abstract

Polarization of soft X-ray photon can be controlled with combination between planar undulators and helical ones. We need to give a reverse tapering to the planar undulators to make microbunching in the electron beam while the linearly polarized radiation power is depressed. In this case, however, resonance wavelengths in each planar undulator are different each other. Therefore, proper initial undulator parameter and tapering strength parameter have to be chosen to obtain high power polarized photon beam with fixed wavelength. In this research, method for deciding suitable reverse tapering is presented using simulation results of PAL-XFEL soft X-ray case with 10 GeV electron beam energy.

INTRODUCTION

In the soft X-ray regime, polarization control is essential for some experiments [1]. Applying the reverse tapering method to planar undulator section, the high degree of polarization of photon beam can be obtained by using only a couple of helical undulators, and this scheme is demonstrated at LCLS. [2,3].

Objective of undulator tapering is generally to obtain high radiation power by maintaining resonance condition according to decreasing electron beam energy [2]. In the reverse tapering case, however, resonance conditions in each planar undulator are different each other, so resonance wavelength is also changed along planar undulators. Therefore, appropriate initial undulator parameter and tapering strength parameter have to be selected to gain high power photon beam with fixed wavelength.

In this research, method for choosing suitable reverse tapering is presented using simulation results of PAL-XFEL soft X-ray case with 10 GeV electron beam energy. All simulations are performed as time-dependent model in GENESIS 1.3 using real beam properties [4].

THEORY

Reverse Tapering Method

In the reverse tapering method, undulator parameter a_w is increased along the undulator length as shown in Fig. 1 [2]. Bunching factor is growing while radiation power is quite suppressed compared with non-tapering case. Tapering strength parameter, β, is defined as

$$\beta = -\frac{\lambda_u}{4\pi\rho^2}\frac{a_w(0)}{1+a_w(0)^2}\frac{da_w}{dz}$$

where λ_u is period of undulator, ρ is FEL parameter,

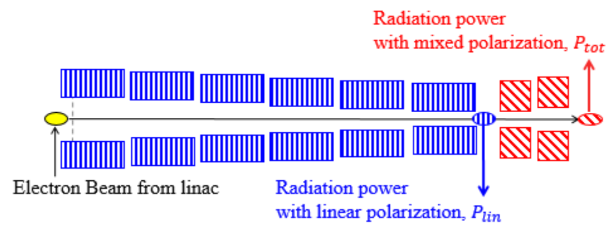

Figure 1: Schematic diagram for reverse tapering method. (Blue Box) Reverse tapered planar undulators (Red Box) Helical undulators.

$a_w(0)$ is initial undulator parameter and da_w/dz is derivative of undulator parameter along undulator length. When the reverse tapering method is applied, β is negative.

Polarization

Electric fields of linearly polarized radiation and circularly polarized radiation are given by the Eq. 1 [5].

$$\vec{E}_{lin} = E_{lin}\cos(kz - \omega t + \phi_{lin})\,\hat{x} \quad (1.a)$$

$$\vec{E}_{cir} = E_{cir}\cos(kz - \omega t + \phi_{cir})\,\hat{x} + E_{cir}\cos(kz - \omega t \pm \pi/2 + \phi_{cir})\,\hat{y} \quad (1.b)$$

The circularly polarized radiation is amplified at the same phase of linearly polarized radiation, so ϕ_{lin} is equal to ϕ_{cir}. Total electric field is given by the combination of two electric field equations and given by

$$\vec{E}_{tot} = \vec{E}_{lin} + \vec{E}_{cir} = (E_{lin} + E_{cir})\cos(kz - \omega t + \phi_{cir} - \theta)\,\hat{x} + E_{cir}\cos(kz - \omega t \pm \pi/2 + \phi_{cir})\,\hat{y} \quad (2)$$

The radiation power can be calculated from the electric field of radiation in Eq. 1 and Eq. 2 as follows [5]:

$$P_{lin} = E_{lin}^2 \quad (3.a)$$

$$P_{cir} = 2E_{cir}^2 \quad (3.b)$$

$$P_{tot} = (E_{lin} + E_{cir})^2 + E_{cir}^2 \quad (3.c)$$

In simulation, only P_{lin} and P_{tot} are obtained as shown in Fig. 1. So P_{cir} is calculated using relations above and it is induced as follows:

$$P_{cir} = P_{tot} - \sqrt{P_{lin}(2P_{tot} - P_{lin})} \quad (4)$$

Stokes parameter is also expressed in terms of P_{lin} and P_{tot} as given by Eq. 5 [5].

$$S_0 = (E_{lin} + E_{cir})^2 + E_{cir}^2 = P_{tot} \quad (5.a)$$

$$S_1 = (E_{lin} + E_{cir})^2 - E_{cir}^2 = \sqrt{P_{lin}(2P_{tot} - P_{lin})} \quad (5.b)$$

$$S_2 = 2(E_{lin} + E_{cir})E_{cir}\cos(\pi/2) = 0 \quad (5.c)$$

$$S_3 = 2(E_{lin} + E_{cir})E_{cir}\sin(\pi/2) = P_{tot} - P_{lin} \quad (5.d)$$

The fraction of circularly polarized radiation, $|S_3/S_0|$, is given by Eq. 6 [6].

$$\left|\frac{S_3}{S_0}\right| = \frac{P_{cir}+\sqrt{2P_{lin}P_{cir}}}{P_{lin}+P_{cir}+\sqrt{2P_{lin}P_{cir}}} = 1 - \frac{P_{lin}}{P_{tot}} \quad (6)$$

A PRELIMINARY REPORT FROM LOUISIANA STATE UNIVERSITY CAMD STORAGE RING OPERATING WITH AN 11 POLE 7.5 TESLA WIGGLER

R. S. Amin, P. Jines, D. Launey, K. Morris, V. P. Suller, Y. Wang,
LSU CAMD, Baton Rouge, LA 70806 USA
N. Mezentsev, S. Khruschev, V. Lev, V. Shkaruba, V. Syrovatin, O. Tarasenko, V. Tsukanov, A. Volkov, A. Zorin,
BINP, Novosibirsk, Russia

Abstract
Louisiana State University installed a 7.5 T superconducting wiggler in May 2013 on the electron storage ring located at the Bennett Johnson, Sr. Center for Advanced Microstructures and Devices (CAMD). The wiggler's influence on betatron tunes and functions, orbit, lifetime, performance, and other relevant beam parameters are described. We further comment on device operations and modifications to ring operations that were necessary to provide light for both wiggler and dipole stations.

INTRODUCTION

Louisiana State University (LSU) operates the CAMD light source at the Center for Advanced Microstructures and Devices. This electron storage ring has been delivering synchrotron radiation (SR) regularly since 1992. The working energy of the storage ring is 1.3 GeV, and injection energy is approximately 180 MeV. CAMD has a circumference of 55.2 meters. There are 4 dispersion free straights and 8 dipoles operating at 1.48 Tesla. Each dipole chamber has two ports delivering SR with a critical photon energy of 1.6 keV. A 7 Tesla superconducting wavelength shifter installed in straight section 2 increased this critical photon wavelength to 7.95 keV for three x-ray beamlines. In 2007, a proposal was made to increase the amount of x-ray radiation being delivered to protein crystallography, x-ray absorption spectroscopy, and tomography experiment stations [1]. In May 2013, a 7.5 Tesla 11-pole multipole wiggler (MPW) with 4 additional fractional field poles was installed in CAMD's third straight section. This device has been delivering light routinely at 5.5 Tesla since October 2014.

The device was built by N. Mezentsev's group at Budker Institute for Nuclear Physics (BINP). Overall the layout is similar in design to SIBERIA-2's superconducting multipole wiggler. However, in terms of physical dimension and stored energy this device is the largest ever fabricated by BINP [2].

*Work supported by … NSF Grant Number: DMR-0923440
Louisiana State University

GENERAL MPW PARAMETERS

The CAMD MPW supplies 3 x-ray beamlines with a critical photon wavelength of 8.53 keV. The 11 main poles are used to generate SR While the two twin outer poles control trajectory by introducing ¼ and ¾ field. Basic parameters are listed in the Table 1.

Table 1: General Parameters

Parameter	Value
Poles	11 full; 2 ¾ field pole; 2 ¼ field pole
Peak Field	7.5 Tesla
Wiggler Pole Period	193.4 mm
Pole Gap	25.2 mm
Beam Aperture	15 mm by 80 mm
Physical Length (Magnet)	1594 mm
Field Energy Stored	≈ 850 kJ
Power Output at 7.5 T	7.38 kW at 100 mA
Superconducting Currents	205 A (central coils), 143 A (side coils)

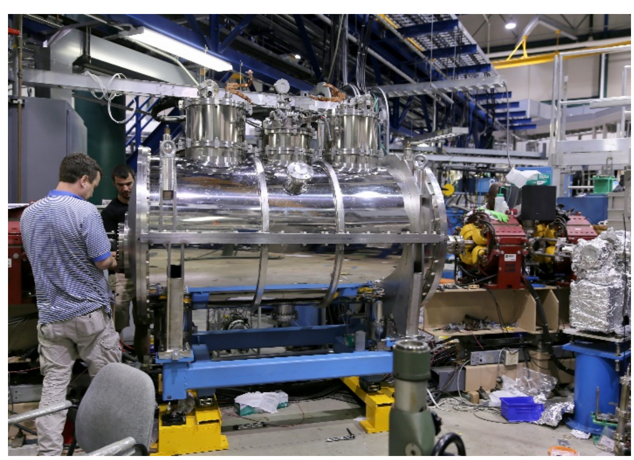

Figure 1: The MPW installed on the CAMD ring.

OPTIMIZATION OF TURN-BY-TURN MEASUREMENTS AT SOLEIL AND ALBA LIGHT SOURCES

M. Carlá, Z. Martí, G. Benedetti, Alba, Cerdanyola del Valles, Spain
L. Nadolski, Soleil, Saint Aubin, France

Abstract

Beam position monitor turn-by-turn measurements paves the way for fast storage ring lattice diagnostics. On the other hand turn by turn technique is by its very nature delicate, requiring an extensive system tuning and understanding. During last year several tests to retrieve linear model informations from turn by turn measurements have been carried out in collaboration between the synchrotron of Soleil and Alba. A routine to extract phase advance and betatron amplitude from turn by turn measurements has been developed. Moreover a first attempt to retrieve quadrupole errors from such observables has been done.

INTRODUCTION

To meet the required performance, modern synchrotron light sources demand a fine control over lattice parameters. Lattice assessment methods, usually employed used at Alba and Soleil, are based on slow orbit acquisition (i.e. LOCO [1–3].) The response of the beam orbit to a change of each dipole corrector is recorded and lattice parameters are then fitted to reproduce the experimental results. The robustness of such method resides in the precise but slow orbit change measurements that have to be repeated for a large number of correctors, until a response matrix is obtained. Turn-by-turn measurements represent a fast way to compare the behavior of the machine lattice with respect to the nominal model, resulting in a good candidate to implement rapid optics correction. To validate the capabilities of the turn-by-turn approach a measurement campaign has been launched in conjunction between the synchrotron of Soleil and Alba.

TURN-BY-TURN SETUP

In order to produce good observations of the transverse dynamics, the beam motion has to be excited coherently and kept coherent as long as possible. The excitation is produced by means of a magnetic pinger, with a characteristic pulse time shorter than the revolution period and a pulse profile as flat as possible [4, 5].

On the other hand the delicate coherent motion of electrons is easily washed out by second order effects jointly with the finite emittance of the beam. Especially the dependence of the transverse tunes on the kick amplitude and electrons energy (chromaticity). Such effect can be minimized by properly tuning the sextupoles in the ring [6].

Soleil

The Soleil storage ring is equipped with 122 beam position monitor (BPM) each of them connected to a Libera electron receiver. Even if such receiver system guarantees a high bandwidth, it is till not enought to discern the beam position sampled at successive turns. This phenomenon is commonly known as turn smearing. To cope with this inconvenience a post processing of the data is required, where the response function of the BPM to a single turn signal is deconvoluted from the recorded signal. The response function can be measured by injecting a short train of electron bunches in the ring and dumping it out after exactly one turn.

Alba

The Alba storage ring is equipped with 120 BPMs equipped with the Libera Brilliance receiver [7]. Such receiver can be reprogrammed with a non-standard firmware (MAF [8]), developed originally under request of ESRF, that is immune to the smearing effect. In MAF the turn mixing is avoided by substituting the narrow band infinite impulse response filter, that causes the smearing, with a finite impulse response filter obtained by means of a fixed time integration window. This different filter design requires a special setup procedure, where the integration window is synchronized with the train of bunches traveling in the ring. The synchronization was adjusted by scanning the delay of the window and looking for the maximum of the sum signal from the four BPM's buttons. The MAF design not only avoids the smearing effect but also ensures a lower noise, being the signal integrated only when the train of bunches transits through the BPM. The reduction of the integration time results thus in less noise entering the BPM's demodulation chain.

TURN-BY-TURN ANALYSIS

Turn-by-turn data have been analyzed using the interpolation approach described in [9], that ensures a very precise reconstruction of amplitude and phases information.

Lattice Jitter

In an ideal system without noise the tune signal measured by each BPM is expected to have the same frequency. The observed agreement between different BPM in the same shot is remarkable ($\sigma = 7.0{\times}10^{-7}$). On the other hand a shot to shot fluctuation of the tune frequency is evident($\sigma = 2.3 \times 10^{-4}$) even if small. A similar behavior, but of smaller entities, has been observed also at Soleil. No correlation between the tune fluctuation and the kick strength is observed, nor a simple trend in time of the tune variation. Most likely the source of such fluctuation resides in the residual line-ripple coming from quadrupoles power supplies. Figure 1 shows the tune jitter spectrum. Two main contributions, at 100 Hz and 300 Hz are clearly visible.

A NEW BENCH CONCEPT FOR MEASURING MAGNETIC FIELDS OF BIG CLOSED STRUCTURES

J. Campmany, F. Becheri, C. Colldelram, J. Marcos, V. Massana*, L. Ribó, J. Nicolás, CELLS-ALBA Synchrotron, 08290 Cerdanyola del Vallès, Barcelona, Catalonia, Spain

Abstract

The measurement of big closed magnetic structures is becoming a challenge of great interest. The main reason is the tendency towards building accelerators with high magnetic fields produced by small gap magnets, as well as the development of cryogenic or superconducting narrow-gap insertion devices. The usual approach, based on side-measurements made with a Hall probe mounted on the tip of a motorized arm mounted on a long granite bench is no more applicable to such closed structures. So, new concepts and approaches have been developed, mainly relying on complex devices that insert a Hall probe inside the magnetic structure maintaining the desired position by closed-loop controls. The main problem of these devices is that they are not general-purpose oriented: they need a special vacuum chamber, require a specific geometry of the magnetic structure, or do not provide 3D field-map measurements. We present in this paper a new bench that has been built at ALBA synchrotron that is simple, multi-purpose and can be a general solution for measuring big closed structures.

INTRODUCTION

The conceptual approach to design this new bench has been presented elsewhere [1],[2]. Basically, it consists in placing a very light Hall probe in the middle of a flexible belt that can be easily introduced inside a magnetic system. The edges of this belt are then attached to an external mechanical bench to position the Hall probe with a high degree of accuracy. Magnetic fieldmaps are recorded operating in on-the-fly mode: that is, acquiring the magnetic field values at the same time the Hall probe is moving along a path. The path is a set of straight lines oriented along the longitudinal direction (Z) that can be independently defined to scan any desired region.

For CELLS standardization reasons, we used step motors controlled via the Icepap motion driver system [3], developed by a collaboration participated by CELLS.

The main challenges that, if not solved, could have jeopardized the feasibility of this concept were:

- Vibrations of the flexible belt.
- Positioning Accuracy of the Hall probe.
- Synchronization between movement and acquisition.
- Alignment of Hall probe with respect to gravity.

The first challenge is related to the vibrational eigenvalues of the mechanical structure; the second to the straightness, linearity and flatness of the bench; the third to the real time control system; and the latter to the methodology used for measurements.

REQUIREMENTS

A general view of the bench is shown in Figure 1.

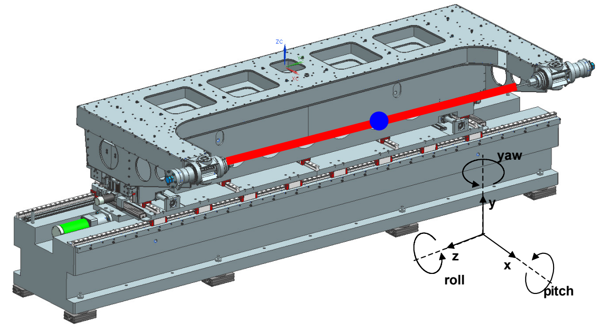

Figure 1: General view of the new Hall probe bench and reference system. Stretched belt is painted red, and Hall probe position is marked with a blue dot.

The specifications of the bench are shown in Table 1.

Table 1: Main Specifications

Magnitudes on top of Hall probe	Values
X positioning tolerance	$\pm 25\cdot 10^{-6}$ m
X stroke	0.2 m
Y positioning tolerance	$\pm 25\cdot 10^{-6}$ m
Y stroke	0.1 m
Z positioning tolerance	$\pm 10\cdot 10^{-6}$ m
Z stroke	1.2 m
Z positioning resolution	$10\cdot 10^{-6}$ m
Pith angle tolerance	$\pm 50\cdot 10^{-6}$ rad
Yaw angle tolerance	$\pm 100\cdot 10^{-6}$ rad
Roll angle tolerance	$\pm 50\cdot 10^{-6}$ rad
Eigenfrequency (Z direction)	> 50 Hz
On-the-fly velocity	$\sim 15\cdot 10^{-3}$ m/s

In order to fulfil the positioning and angular tolerances, the material for the bench basis is granite, and the linear guides and mechanical chain have been designed according to the usual high precision mechanics concepts.

Regarding vibrations, the key point is the fact that the Hall probe is placed on a stretched string, and therefore

MAGNETIC MEASUREMENTS OF THE NSLS-II INSERTION DEVICES

M. Musardo#, D. Harder, C. A. Kitegi and T. Tanabe
National Synchrotron Light Source II, Brookhaven National Laboratory
Upton, New York 11973-5000, USA

Abstract

This paper presents the results and the recent progress in the magnetic measurements of the insertion devices (IDs) for the National Synchrotron Light Source-II (NSLS-II) at Brookhaven National Laboratory (BNL). A detailed analysis of the magnetic measurements is carried out for various IDs with particular attention at the influence of the magnetic field errors on the devices spectral performance. Several specific details of the measurements and the recent results from IDs commissioning are presented.

INTRODUCTION

The NSLS-II is a state-of-the-art electron storage ring of 3 GeV third generation light source at Brookhaven National Laboratory. NSLS-II has been designed and constructed to deliver photons with high average spectral brightness in the 2 keV to 10 keV energy range exceeding 10^{21} ph/s/0.1%bw/mm^2/mrad^2, and high spectral flux exceeding 10^{15} ph/s/0.1%bw. This performance requires the storage ring to support a very high-current electron beam (I = 500 mA) with a very small horizontal (down to 0.5 nm-rad) and vertical (8 pm-rad) emittance. [1].

NSLS-II will be able to accommodate more than 60 beam-lines in the final built-out for a wide-range of scientific programs, with future development of additional beam-lines through canted insertion devices and multiple hutches [2].

At the time of this report 13 insertion devices have been installed into the storage ring and are currently under commissioning and studies [3,4]. All these IDs were procured as a "turn-key" devices from main ID companies (Danfysik, HITACHI and Kyma).

They include 6 damping wigglers (DWs), utilized to achieve a low horizontal beam emittance and as broadband sources of very bright and high flux x-rays superior to conventional bend-magnet sources, 2 Apple-II type undulator with four movable arrays, for full polarization control and 5 In-Vacuum Undulator for hard X-Ray. The basic parameters characterizing the NSLS-II IDs installed so far are listed in Table 1.

MAGNETIC FIELD MEASUREMENTS

All insertion devices mentioned above underwent rigorous magnetic measurements before installation into the storage ring in order to validate the ID performance requirements and confirm the measurement data of vendors. Furthermore some IVUs went through magnetic retuning performed at BNL with vendor technicians in order to improve the magnetic field quality.

Table 1: NSLS-II Insertion Devices Installed

Cell ID	Beam line	Type	Length [mm]	Period [mm]	B_{PEAK} [Tesla]	Gap [mm]

Magnetic Measurement Facility

The magnetic measurement system facility at BNL consists in a 3D Hall probe-mapping bench MMB-6500 for local magnetic field measurement and an Integrated Field Measurement System (IFMS) for first and second field integral measurement [5]. The IFMS is a versatile measurement system as it includes 3 different field integral measurement systems, a stretch wire system, a flipping coil system and a long board. The flipping coil has been used to measure IDs field integral.

A fully integrated SENIS 3-axis ultra-low noise probe, accurately recalibrated [6], is used as Hall sensor in order to measure three independent components of the magnetic field at single location. The Hall sensors arranged along longitudinal axis have a magnetic field sensitive volume of 150 *x* 1 *x* 150 µm, which allows very high-resolution measurements with a linearity error up to 2 T less of 0.15% and a good angular accuracy with an orthogonality error < 2°.

The full control of the measurement system is carried out using a LabView software. Recent developments have allowed the automation of ID gap/phase motions and

IMPACT OF INSERTION DEVICES ON THE MAX IV STORAGE RINGS

S.C. Leemann*, H. Tarawneh, MAX IV Laboratory, Lund University, SE-22100 Lund, Sweden

Abstract

There will be multiple compensations employed for insertion devices in the MAX IV storage rings. Apart from well-known dipole corrections and previously detailed local and global linear optics matching, certain insertion devices in the MAX IV storage rings will also require nonlinear optics adjustments and/or skew quadrupole corrections. The goal of such corrections is ensuring sufficient dynamic aperture as well as low residual emittance coupling. This paper will present a few studies that rely on tracking through kick maps in order to quantify detrimental effects of insertion devices on dynamic aperture and vertical emittance, develop suitable countermeasures, and finally, verify restored storage ring performance.

INTRODUCTION

During the design phase of the MAX IV storage rings several example insertion devices (IDs) were used to develop compensation strategies [1–4]. This resulted in ID compensation schemes where the storage ring optics are matched in a two-stage process both locally and globally to each ID thus making the ID transparent to other users [3,4]. The first step is *local*: the beta functions of the achromats adjacent to the ID are matched to the ID by adjusting quadrupole gradients (implemented as a feedforward table depending on ID gap and phase settings). This is a rather fine adjustment because of the low beta functions in the ID straights. Nevertheless, a small phase advance leading to a tune shift for the entire ring results. This is then corrected in the second matching step: a *global* matching is carried out where quadrupole gradients around the ring are gently adjusted to restore the design working point (implemented in a feedback scheme relying on an online tune measurement). Ideally, the result of these two matching steps is that the ID becomes transparent to the rest of the ring. The beta functions in the sextupoles and octupoles are virtually unchanged and the working point is at its design value. Therefore, the chromatic and amplitude-dependent tune shifts (ADTSs) are restored to their design behavior thus replicating the tune footprint of the design lattice with its large dynamic aperture (DA) and good lifetime.

Already during the design process limits were set for acceptable multipole content in IDs [4] and used for ID specification. In the meantime, RADIA kick maps for the Phase I IDs [5] have been prepared so actual tracking studies can now be performed to verify the proposed compensation scheme leads to acceptable storage ring performance. The kick maps are inserted into the Tracy-3 lattice model and the optics matching is carried out (assuming that all first and second-order ID integrals have been canceled using dedicated dipole correctors at the IDs). The effect on optical functions, tune shifts, and coupling is then assessed and additional nonlinear and/or skew quadrupole matching requirements are derived where necessary. Performance of all optics adjustments combined is again verified using 6D tracking including imperfections (misalignments as well as field and multipole errors) [6] to determine overall resulting DA, lifetime, and coupling. Examples of such studies will be discussed in this paper. It should be pointed out, however, that several effects of IDs on the storage rings are not treated here: firstly, the effect of IDs on emittance, energy spread, bunch length, and lifetime can become severe in the ultralow-emittance lattice of the 3 GeV storage ring [7]; the effect of optics matching and choice of coupling on resulting brightness [8]; and finally, IDs can have many implications for collective behavior and instabilities; this is, however, also beyond the scope of this paper.

Optics Matching in the 3 GeV Storage Ring

In the 3 GeV storage ring local matching (cf. Fig. 1) is achieved by adjusting the quadrupole doublets (QFend/QDend) in the matching cells adjacent to the ID so the beam is over-focussed in the ID [1, 3]. This allows compensating the ID focusing without actually increasing the beam size in the ID. Global matching is then carried out by adjusting all QFend/QDend around the ring coherently by a small amount. Such corrections leave the optical functions in the unit cells virtually unchanged and the working point is exactly restored. Note that this matching does not involve excitation of the pole-face strips (PFSs) that are used to adjust the vertical focusing in the gradient dipoles.

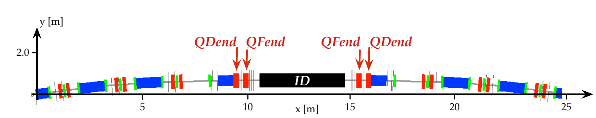

Figure 1: Schematic of an ID installed in a long straight section between two achromats of the 3 GeV storage ring. The two quadrupole families involved in the optics matching are indicated.

Furthermore, the 3 GeV storage ring lattice contains three octupole families that allow direct shaping of the ADTSs [9]. These can be used to counteract amplitude detuning that arises from strong IDs. Finally, all sextupoles and octupoles in the 3 GeV storage ring carry auxiliary coils that can be powered, among other ways, as a skew quadrupole. This opens the possibility for strong local coupling corrections around specific IDs.

Optics Matching in the 1.5 GeV Storage Ring

In the 1.5 GeV storage ring local matching (cf. Fig. 2) is achieved by adjusting the combined quadrupole/sextupole

RECENT RESULTS ON THE PERFORMANCE OF Cs_3Sb PHOTOCATHODES IN THE PHIN RF-GUN

C. Hessler, E. Chevallay, S. Doebert, V. Fedosseev, I. Martini, M. Martyanov, CERN, Switzerland

Abstract

For the CLIC drive beam a photoinjector option is under study at CERN as an alternative to the thermionic electron gun in the CLIC baseline design. The CLIC drive beam requires a high bunch charge of 8.4 nC and 0.14 ms long trains with 2 ns bunch spacing, which is challenging for a photoinjector. In particular the required long and high intensity laser pulses cause a degradation of the beam quality during the frequency conversion process, which generates the ultra-violet laser beam needed for standard Cs_2Te photocathodes. To overcome this issue Cs_3Sb cathodes sensitive to green light have been studied at the high-charge PHIN photoinjector since a few years. In this paper recent measurements of fundamental properties of Cs_3Sb photocathodes such as quantum efficiency, cathode lifetime and dark current from summer 2014 will be presented, and compared with previous measurements and with the performance of Cs_2Te photocathodes.

INTRODUCTION

The Compact Linear Collider (CLIC) is a future e^+e^- collider, which is currently under study by a worldwide collaboration led by CERN [1]. It is based on a novel two-beam acceleration scheme, which requires a high peak and average current drive beam accelerator for generating 12 GHz RF power needed to accelerate the main beam. In the baseline design, the drive beam is foreseen to be produced by a thermionic electron gun and a sub-harmonic bunching system [2]. However, the bunching system generates parasitic satellite pulses, which get lost during the acceleration process. This can create radiation issues and will reduce the system power efficiency.

These limitations can be avoided if a photoinjector is used as a drive beam source and the required time structure for the CLIC beam combination scheme [1] is already produced on the laser side. Such a photoinjector option for the CLIC drive beam is currently under study at the high-charge photoinjector PHIN [3], which was originally developed and constructed to study its feasibility as drive beam source for the CLIC Test Facility 3 (CTF3). Practically satellite-free beam production with the required time structure has been demonstrated at PHIN [4].

However, the CLIC drive beam parameters are challenging for a photoinjector (Table 1) and efforts are on-going to improve the PHIN parameters towards CLIC requirements [5]. In particular the combination of 140 µs long trains, 8.4 nC bunch charge, 2 ns bunch spacing and 50 Hz macro-pulse repetition rate for CLIC is beyond the parameters of any existing photoinjector. This unique parameter set has a strong impact on the photocathode lifetime and also on the laser system: The required long and high-intensity laser pulses cause a degradation of the beam quality during the 4^{th} harmonics frequency conversion process, which generates the ultra-violet laser beam needed for standard Cs_2Te photocathodes. Since the 2^{nd} harmonics conversion process to produce green light is not affected by this problem, a potential solution is to use photocathodes sensitive to green light such as Cs_3Sb or K_2CsSb instead of Cs_2Te cathodes. For the CLIC photoinjector studies Cs_3Sb has been chosen because the existing production setup for Cs_2Te could be used, which made it possible to extensively profit from the experience gained with Cs_2Te. In this paper the latest results of the Cs_3Sb photocathode studies at PHIN will be presented. In parallel, R&D work on the surface characterization of photocathodes [6] and further development of the laser system are also on-going at CERN.

Table 1: PHIN and CLIC Design Parameters

Parameter	PHIN	CLIC
Charge / bunch (nC)	2.3	8.4
Train length (µs)	1.2	140
Bunch spacing (ns)	0.66	2.0
Bunch rep. rate (GHz)	1.5	0.5
Number of bunches	1800	70000
Macro pulse rep. rate (Hz)	5	50
Charge / train (µC)	4.1	590
Beam current / train (A)	3.4	4.2
Bunch length (ps)	10	10
Charge stability	<0.25%	<0.1%
Cathode lifetime (h) at QE > 3% (Cs_2Te) or QE > 0.5% (Cs_3Sb)	>50	>150
Norm. emittance (µm)	<25	<100

PHIN PHOTOINJECTOR

Layout

The PHIN photoinjector is installed at an off-line test stand at CTF3 (Fig. 1). It consists of a 2.5 cell RF cavity operated at 3 GHz and two solenoids, which provide the focusing of the electron beam. A test beam line is available with various diagnostic elements for beam measurements. The electron beam is produced by illuminating a Cs_2Te or Cs_3Sb photocathode with an ultra-

SURFACE CHARACTERIZATION AT CERN OF PHOTOCATHODES FOR PHOTOINJECTOR APPLICATIONS

I. Martini, E. Chevallay, V. Fedosseev, C. Hessler, H. Neupert, V. Nistor, M. Taborelli, CERN, Geneva, Switzerland

Abstract

R&D on photocathodes takes place at CERN within the CLIC (Compact Linear Collider) project. Photocathodes are produced as thin films on Oxygen Free copper substrate using a co-deposition technique, and characterized in a dedicated laboratory with a DC photo-electron gun. A new UHV carrier vessel compatible with CERN's XPS (X-ray Photoelectron Spectroscopy) analysis equipment has been commissioned and is used to transport photocathodes from the production laboratory to perform a systematic study of different compounds used as photoemissive materials. In this paper photocathodes used in a RF photoinjector will be characterized and the correlation of their surface properties with their performance will be investigated.

INTRODUCTION

Within the CLIC (Compact Linear Collider) project, feasibility studies of a photoinjector option for the drive beam as an alternative to its baseline design using a thermionic electron gun [1] are on-going. This R&D program covers both the laser and the photocathode side. The main challenge for a drive-beam photoinjector is to achieve high bunch charges, long trains and high bunch repetition rates together with sufficiently long cathode lifetimes. Cs_2Te cathodes, sensitive to ultra-violet (UV) laser beam, produced at CERN showed good quantum efficiency and reasonable lifetime in the high-charge PHIN RF photoinjector [2]. However the CLIC design parameters are more demanding (Table 1). The available laser pulse energy in UV for 140 µs long pulse trains is currently limited due to a degradation of the beam quality during the 4th harmonics conversion process. Using green laser beam in combination with Cs_3Sb cathodes would overcome this limitation.

Both Cs_3Sb and Cs_2Te photocathodes were produced at CERN by co-deposition process and tested in the PHIN RF photoinjector (more detail in ref. [3]). In this paper the cathode surface composition is analysed through XPS technique and correlated to the cathode performance.

CATHODES PRODUCTION AND CHARACTERIZATION

In the CERN photoemission laboratory the cathodes are produced by co-deposition technique resulting in high Quantum Efficiency (max QE~20% for Cs_2Te, max QE~7% for Cs_3Sb) [4,5]. The different chemical elements (Cs, Te or Sb) are evaporated at the same time to mix together in the vapour phase before the deposition onto the OFE copper substrate.

Table 1: CLIC and PHIN Beam Parameters

Parameter	CLIC	PHIN
Charge/bunch (nC)	8.4	2.3 (nominal) 9.2 (achieved)
Bunch length (ps)	10	10
Bunch rep. rate (GHz)	0.5	1.5
Number of bunches	70000	1800
Train length (µs)	140	1.2
Charge/train (µC)	590	4.1
Macro pulse rep. rate (Hz)	50	5
Charge stability (%)	<0.1	<0.25
Beam current/train (A)	4.2	3.4
Cathode lifetime (h) at QE>3% (Cs_2Te), QE>0.5% (Cs_3Sb)	>150	>50

The cathodes are illuminated with a UV (or green for Cs_3Sb) laser beam during the deposition in order to measure the QE evolution and optimize the process accordingly. The deposited layer thicknesses vary between tens to hundreds of nm [5].

PROGRESS ON A COMPACT ACCELERATOR DESIGN FOR A COMPTON LIGHT SOURCE*

K. Deitrick[1†], J.R. Delayen[1,2], B.R.P. Gamage[1], G.A. Krafft[1,2], T. Satogata[1,2]
[1] Center for Accelerator Science, Old Dominion University, Norfolk VA, 23529, USA
[2] Thomas Jefferson National Accelerator Facility, Newport News VA, 23606, USA

Abstract

A compact Compton light source using an electron linear accelerator is in design at the Center for Accelerator Science at Old Dominion University and Jefferson Lab. We report on the current design, including beam properties through the entire system based on a full end-to-end simulation, compare current specifications to design goals, and target areas for improvement.

INTRODUCTION

Compton Light Source

At present, there is a high level of interest in an inverse Compton light source with a compact floor plan due to the wide variety of applications such a system could facilitate. To this end, a preliminary design was developed and presented, with the necessary electron beam and resulting x-ray beam properties shown in Table 1 [1].

Table 1: Electron Beam Parameters at Collision, Compton Source Parameters

Parameter	Value	Units
Energy	25	MeV
Bunch charge	10	pC
Repetition Rate	100	MHz
Average current	1	mA
Normalized $\epsilon_{\rm rms}$	0.1	mm-mrad
$\beta_{x,y}$	5	mm
FWHM bunch length	3.0 (0.9)	psec (mm)
RMS energy spread	7.5	keV
X-ray energy	Up to 12	keV
Photons/crossing	1.6×10^6	
Flux	1.6×10^{14}	photon/sec
Average brilliance	1.5×10^{15}	photons/(sec-mm^2-mrad^2-0.1% BW)

Simulation Tools

A number of accelerator codes were used to develop an end-to-end simulation. CST Microwave Studio© (CST) is an electromagnetic (EM) field solver [2]. SUPERFISH is also an EM field solver, provided the geometry is cylindrically symmetic, developed by Los Alamos [3]. The tracking through the accelerating section was performed by ASTRA (A Space-charge TRacking Algorithm), which tracks particles through user-defined external fields [4]. Space charge was taken into account throughout, and the image charge due to the cathode was included within the gun.

After emerging from the linac, the beam dynamics were calculated by `elegant` [5]. Translating the final bunch produced by ASTRA into the SDDS format required by `elegant` was done by a specific function provided within the package for that purpose.

ACCELERATION

Electron Gun

The electron gun is a 500 MHz superconducting RF (SRF) quarter-wave design, originally based on the shape proposed by Harris et al. [6]. The design is highly reentrant in order to mitigate the growth of the transverse normalized emittance due to space charge. In order to remove a surface tangential discontinuity near the cathode, the design was slightly altered. The RF properties of the altered design are presented in Table 2 [7].

Table 2: RF Properties of the 500 MHz Quarter Wave Electron gun at $E_{\rm acc} = 1$ MV/m

Parameter	Value	Units
Frequency of accelerating mode	499.3	MHz
λ/4	150	mm
Design β	0.95	
Stored energy	44	mJ
QR_s	83.5	Ω
R/Q	154	Ω
Peak electric surface field (E_P)	3.67	MV/m
Peak magnetic surface field (B_P)	6.64	mT
E_P/B_P	1.81	mT/(MV/m)

In order to study the beam dynamics of a bunch, the EM fields of the gun calculate by SUPERFISH were exported and translated into the format required by ASTRA. A 10 pC bunch consisting of 2000 electrons with a plateau longitudinal distribution of length 24 ps, σ_r of 0.5 mm, and negligible initial emittance or transverse momentum was generated and tracked by ASTRA through the gun. Both the space charge of the bunch and the mirror-image contribution of the cathode were included in this simulation. The properties of the beam after the exit of the gun (15 cm from

TRANSVERSE TUNES DETERMINATION FROM MIXED BPM DATA *

P. Zisopoulos, Y. Papaphilippou, F. Antoniou, CERN, Geneva, Switzerland
A. S. Müller, E. Hertle, ANKA, Karlsruhe, Germany

Abstract

Decoherence due to non-zero chromaticity and/or amplitude dependent tune-shift, but also damping mechanisms can affect the accurate tune determination by leaving a limited number of turns for frequency analysis of the turn by turn (TbT) position data. In order to by-pass these problems, Fourier analysis of mixed TbT data from all BPMs can be employed. The approach is applied in two different accelerators, a hadron collider as the LHC and a synchrotron light source as the ANKA storage ring. The impact in the accuracy of the method in the case of missing BPM data is also discussed.

INTRODUCTION

The most common technique for measuring the tune involves application of refined Fourier analysis on recorded beam position data. In the presence of decoherence, the available interval of turns for analysis is limited [1]. An alternative method exists [2], [3], which allows a very fast and accurate tune determination and consists of combining the data from all the BPMs and analysing them.
In this paper, this method is tested on TbT data from the ANKA electron storage ring and the Large Hadron Collider (LHC). The Numerical Analysis of Fundamental Frequencies (NAFF) [4] is employed for the frequency analysis. The analysis is repeated after lowering the noise levels of the TbT data with the Singular Value Decomposition (SVD) method [5] and comparisons are carried out.

DESCRIPTION OF THE METHOD

The method requires the mixing of the original TbT BPM data. More specifically, if the number of BPMs is M, and their TbT signal is of the form $x_M = [x_M[1]x_M[2]...x_M[N]]$, where N the number of turns, the data from all BPMs can be mixed together in the form $\tilde{x} = [x_1[1]x_2[1]...x_M[1]...x_1[N]...x_M[N]]$. In this way, the sampling rate becomes $\frac{1}{M}$ and the new tunes are scaled with respect to the old ones as $\tilde{Q} = \frac{Q}{M}$, where $\tilde{Q}$ and Q are the new and old measured tunes respectively. A one turn periodic error exists, due to the lack of BPM symmetry neither in the longitudinal position nor to the machine optics which introduces an extra frequency modulation without affecting the results. Rescaling the new frequencies $\tilde{Q}$ with M, can determine the integer and fractional part of the betatron tune.

* The research leading to these results has received funding from the European Commission under the FP7 Research Infrastructures project EuCARD-2, grant agreement no.312453

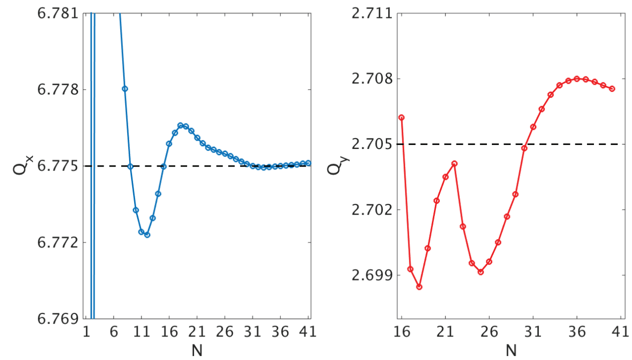

Figure 1: Tune measurements for ANKA. Horizontal tune is in the left column and the vertical tune in the right column. The black dashed line is the measurement produced from the ANKA tune-tracker.

MEASUREMENTS FOR ANKA

ANKA is a third generation light source which features a storage ring with a circumference of 110.4 m. Electron bunches are accelerated to a nominal energy of 2.5 GeV for the production of synchrotron radiation. Betatron oscillations are excited by using the injection kickers and the kick lasts for roughly 3 μs, i.e. 9 turns. Transverse beam position data are recorded from 35 BPMs for about 2000 turns. The ANKA tune-tracker [6] determines tunes of q_x=0.77 and q_y=0.70 for the horizontal and vertical plane respectively. The integer parts of the tunes are Q_x =6 for the horizontal plane and Q_y=2 for the vertical. The frequency analysis of the vertical TbT data shows strong transverse coupling in the frequency spectrum. This can be explained from the fact that the kick delivered to the bunches is horizontal.

In Fig. 1, results from tune measurements using the mixed TbT data method, are shown with respect to the number of turns. The method needs less than 10 turns to determine the horizontal tune and converge to a value within 40 turns. Regarding the vertical plane, this method needs 16 turns for the tune measurement due to the transverse coupling, while convergence is obtained in 37 to 45 turns. This is testified in the top plots of Fig. 2 where the absolute difference between consecutive tune values is presented as a function of the number of analysed turns. This difference becomes of the order of 10^{-4} within 25 turns for the horizontal plane and within 35 turns for the vertical plane. The trend of both curves is decreasing and oscillating with respect to the number of turns due to decoherence. The analysis is repeated after the original TbT data are decomposed in their singular modes and modes with not important information are eliminated. The amplitude modulation, due to the local beta functions, is removed with normalization of the data

LOCAL ORBIT RESPONSE MATRIX MEASUREMENT AT SLS

Masamitsu Aiba and Michael Böge, PSI, Villigen, Switzerland

Abstract

The experimental determination of linear optics is essential to achieve a high performance ring accelerator. One of the methods, linear optics from closed orbits, is widely employed to correct linear optics. Due to the ring nature, a quadrupole error at a location of the ring affects the entire orbit response measurement data. The orbit response, however, can be localised to a certain region of the ring when an orbit feedback (or orbit correction) is applied to the rest of the ring. The quadrupole errors located in the region, where the feedback is acting, then have no impact, and the ring optics can be examined locally. An application of this technique to the Swiss light source is discussed.

INTRODUCTION

The experimental determination of linear optics is essential to achieve a high performance ring accelerator. One of the methods, linear optics from closed orbits (LOCO) [1], is widely employed to correct linear optics. The orbit response matrix (ORM) is entered into the LOCO algorithm as an observable. It is the difference of beam positions at the beam position monitors (BPMs) that are measured by changing the corrector excitation currents. Since ORM is determined by the lattice focusing, the ring optics can be corrected by minimising the deviation of ORM from the ideal, model ORM (ORM deviation).

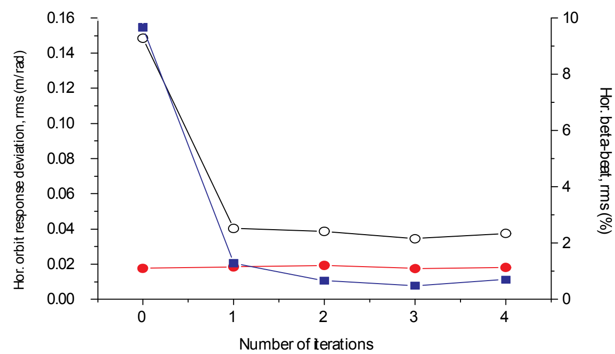
We applied LOCO to the Swiss Light Source (SLS) storage ring [2] and found significant discrepancy in the result as discussed in the next section. This motivated us to develop a method to examine the ring optics locally, i.e. "local orbit response matrix" (LORM) measurement. We present first measurements and our findings.

LOCO AT SLS

The relevant parameters of the SLS storage ring are listed in Table 1 and the result of LOCO correction iteration is shown in Fig. 1.

Table 1: SLS Storage Ring Parameters

Parameter	Value	Unit
Circumference	288	m
Beam energy	2.4	GeV
Number of TBA cells	12	-
Betatron tunes (H/V)	20.43/8.74	-
Number of BPMs/correctors	73/73	-
Number of quadrupoles	177	-



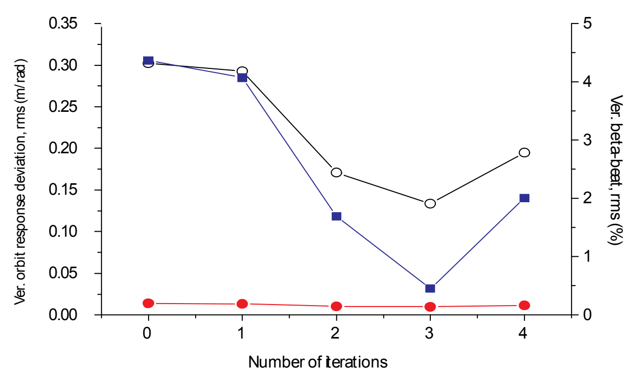


Figure 1: LOCO correction iteration result. The red curve is the ORM deviation after LOCO fit, and the black curve is the ORM deviation after another LOCO fit that excludes the quadrupole strengths from the fitting parameters. The ORM deviation is represented as single rms value over many ORM elements. The blue curve is the beta-beat found from LOCO fit. It is noted that the beta-beat is not found directly from LOCO measurement. Instead, it is inferred from the optics model by applying the quadrupole corrections found from the fit. The noise level (statistical error) of ORM measurement is 0.01 m/rad rms.

Figure 1 was obtained from LOCO optics correction iteration *with the machine*: we measure ORM, compute possible quadrupole corrections, vary the quadrupole excitation currents accordingly and measure again ORM. To compute the quadrupole corrections, the model ORM is fitted to the measured ORM by varying the quadrupole strengths, the corrector calibrations and the BPM calibrations. The coupling terms between the horizontal and vertical planes are not used in this study because the correction of beta functions is main concern. We apply singular value decomposition (SVD) for the fit with appropriate singular value cut (see Ref. [2] for detail).

The ORM deviation after the fit corresponds to the red curve in Fig. 1. We performed another fit at each iteration step with the corrector and BPM calibrations, excluding

ROUND BEAM OPERATION IN ELECTRON STORAGE RINGS AND GENERALISATION OF MOBIUS ACCELERATOR

Masamitsu Aiba, Michael Ehrlichman, and Andreas Streun, PSI, Villigen, Switzerland

Abstract

"Round beam" rather than a flat beam is preferable for a significant fraction of the beamline users in light sources. It is realised by equally distributing the natural emittance into the horizontal and vertical planes. There are a few approaches for the emittance distribution, and here we explore the so-called Mobius accelerator scheme, where a transverse (horizontal-vertical) emittance exchange results at each turn of beam revolution. The original proposal of Mobius accelerator was based on a set of five (or six) successive skew quadruples, requiring a dedicated long straight section. We generalise the Mobius accelerator to find other possible configurations. Applications to a light source storage ring lattice and a tracking result are also presented.

INTRODUCTION

A significant fraction of the beamline users at Swiss light source (SLS) prefer a "round beam" rather than a flat beam, and hence we study possible options in the context of a planned SLS upgrade, where the storage ring will be replaced with a very low emittance ring while utilising the existing building and injector complex [1]. For a small emittance beam, the emittance growth due to intra bunch scattering (IBS) can be significant, and thus a mitigation of the emittance growth is another motivation.

The coupling scheme is realised by equally distributing the natural emittance into the horizontal and vertical planes. There are a few approaches for the emittance equalisation. One method is to utilise a linear coupling resonance, where the horizontal and vertical emittances are exchanged over a period shorter than the radiation damping time. The other method that we explore in this study is the so-called Mobius accelerator [2].

GENERALISATION OF MOBIUS ACCELERATOR

The Mobius accelerator was originally proposed by Talman [2] and tested at CESR [3]. The transverse particle coordinates are interchanged at a location of the storage ring, and thus an immediate horizontal-vertical emittance exchange results at each turn of beam revolution. The synchrotron radiation induced emittance growth and damping is thus distributed equally among the two modes. The result is each mode has half the natural emittance. The coordinate interchange can be realised with five (or six) successive skew quadrupoles – Mobius insertion − as proposed in [2]. The requirements for the Mobius insertion are

- interchanging the transverse particle coordinates,
- and matching to the closed ring lattice parameters.

The Mobius insertion represented in a 4-by-4 transfer matrix is an off-diagonal block matrix,

$$\begin{bmatrix} 0 & D \\ D & 0 \end{bmatrix} \text{ with } D = \begin{bmatrix} 1 & L \\ 0 & 1 \end{bmatrix}. \tag{1}$$

The first requirement is obviously fulfilled with the above matrix. The second requirement is fulfilled when the lattice parameters (with skew quadrupoles turned off) are the same for the horizontal and vertical planes at both ends of the Mobius section and when the length L is adjusted to be the length of the Mobius insertion. It is straightforward to switch between the nominal operation mode (flat beam) to the round beam mode, simply turning on and off the skew quadrupoles.

It is of interest to explore possible configurations different from the above mentioned one not only for the Mobius accelerator but also for a coordinate interchange in a beam transport line. For example, a slice emittance measurement can be performed in both planes with a given transverse deflection cavity, which streaks the beam either in the horizontal or the vertical plane.

General Configuration

We assume arbitrary transfer matrices between skew quadrupoles to represent a general beam transport line:

$$(M_e)S_nR_nS_{n-1}R_{n-1}\cdots R_1S_1(M_s) \tag{2}$$

where S is the transfer matrix for skew quadrupole and R is an arbitrary uncoupled transfer matrix, which may include normal quadrupoles. The original configuration with five skew quadrupoles is also represented with the above notation with M being a drift matrix. The matrices M_e and M_s in parenthesis are discussed later.

Multiplying at the transfer matrix in a brute force manner generates many terms in the equations we need to solve. The equations are, however, significantly simplified using the normalised coordinates. The transfer matrix R in the normalised coordinate system is then simply a rotation matrix, and a thin skew quadrupole is represented as

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & -K & 0 \\ 0 & 0 & 1 & 0 \\ -K & 0 & 0 & 1 \end{bmatrix} \tag{3}$$

where K is the normalised skew quadrupole strength, k, multiplied by the length of the magnet, l, and the "effective" beta function,

$$K = \sqrt{\beta_x\beta_y}kl, \tag{4}$$

INVESTIGATION OF THE INJECTION SCHEME FOR SLS 2.0

A. Saa Hernandez* and M. Aiba, PSI, Villigen, Switzerland

Abstract

SLS 2.0, an upgrade of the Swiss Light Source (SLS), aiming at a natural horizontal emittance in the range of 100 pm, is planned and under study. This will be achieved by replacing the current magnet lattice of the electron storage ring by a new multibend achromat magnet lattice, while reusing the injector chain and most of the existing infrastructures. The new low emittance ring will impose more restrictive constraints on injection due to a smaller machine aperture and a very compact lattice, dominated by non-linearities. We performed a study to find the optimum injection scheme for SLS 2.0 among the conventional and more advanced schemes; namely multipole kicker injection (off-axis and also on-axis matched to the off-momentum closed orbit) and longitudinal injection.

INTRODUCTION

SLS 2.0, a low emittance upgrade of the Swiss Light Source (SLS) is planned and under study [1]. This will be achieved by replacing the current lattice of the storage ring by a new multibend achromat lattice [2], while reusing the injector chain and most of the existing infrastructures. Various lattices are currently being developed in an iterative process. The latest stable lattice version released, named *ah04n*, provides a natural horizontal emittance of 183 pm·rad in a 288 m ring circumference. But this lattice, as most low emittance lattices, imposes restrictive constraints on injection due to a small machine aperture (10 mm inner beam pipe) and dynamic aperture (~8 mm for on-momentum particles and <5 mm for particles with a momentum deviation of ± 3%). Additionally, the lattice is very strong-focusing and is dominated by non-linearities as natural chromaticities of -163/-70 in units of 2π (horizontal/vertical) have to be corrected. We investigated different injection options aiming to fulfill the following soft (S) and hard (H) constraints:

- (H) top-up compatible.
- (H) compatible with the booster output parameters: horizontal (vertical) emittance of 7 (1) nm·rad, bunch length of 19 mm and momentum spread of 0.08%.
- (S) avoid the use of a kicker bump, in order to improve the photon beam stability.
- (S) transverse on-axis injection in order to relax the requirements on dynamic aperture. The option of a round beam, under consideration at this stage of the design, could only be implemented if injection is (quasi) on-axis.
- (S) compact layout, ideally compatible with the installation of other devices in the same straight section.

INJECTION SCHEMES FOR SLS 2.0

Different injection options for SLS 2.0 are briefly described. After their drawbacks are considered they are either discarded or further developed.

Conventional Injection

The conventional injection scheme, also used at SLS [3], employs a static septum and a dynamic magnetic chicane (or kicker bump). The bump rises to bring the closed orbit to the vicinity of the septum at the time of injection and falls within a few electron beam revolutions to prevent the injected bunch being lost at the septum. In this scheme, the injected bunch is transversely separate from the circulating bunches and performs large betatron oscillations before it is merged into the circulating beam due to synchrotron radiation damping.

We built an injection insertion into the lattice *ah04n* on the long (10 m) straight section where the present transfer line from the booster ends. The injection point (IP) remains located in the middle of the straight and the four dipole kickers are symmetrically positioned at both sides of the IP. Kicker deflections of 2.2 mrad would be needed to generate a bump of 7 mm amplitude. Assuming a bump half-sine time of 4 μs, the kickers would be active for 4 turns. If a septum thickness of 2.5 mm and a conservative clearance value of 2.5 mm are also assumed the beam could not be injected with a distance smaller than 7.5 mm of the bumped orbit. The resulting oscillations around the stored beam during the first turns would have amplitudes >10 mm, bigger than the physical and dynamic apertures and therefore not feasible. A horizontal beta function bump could also be created with the use of the matching sections at both sides of the straight, but the consequent break of lattice symmetry is not desired at this point of the design. Therefore this injection scheme is not our favourite option for SLS 2.0.

An on-axis version of this scheme was implemented in LEP [4] and has also been investigated. In this scheme the kickers are situated on a dispersive straight section and the bunch is injected on-axis, but with a momentum offset, onto the corresponding closed orbit. We rapidly discarded this option for SLS 2.0 since the required dispersion (7.5 mm / 3 % = 2.5 m) is not compatible to the low emittance lattice design.

DESIGN STUDIES FOR AN UPGRADE OF THE SLS STORAGE RING

A. Streun, M. Aiba, M.Böge, M. Ehrlichman, Á. Saá Hernández, PSI, Villigen, Switzerland

Abstract

An upgrade of the Swiss Light Source (SLS) would replace the existing storage ring by a low aperture multibend achromat lattice providing an emittance of about 100–200 pm at 2.4 GeV, while maintaining the hall, the beam lines and the injector. Since emittance scales inversely cubically with the number of lattice cells, an SLS upgrade is challenged by the comparatively small ring circumference of only 288 m. A new concept for a compact low emittane lattice is based on longitudinal gradient bending magnets for emittance minimization and on anti-bends (i.e bends of opposite field polarity) to disentangle dispersion and horizontal beta function in order to provide the optimum matching to the longitudinal gradient bends while minimizing the contribution to chromaticity.

INTRODUCTION

The Swiss Light Source (SLS) is in user operation since 2001. The storage ring is a 12 triple bend achromat (TBA) lattice providing an equilibrium emittance of 5.0 nm at 2.4 GeV beam energy. SLS had to accommodate experiments covering a wide range of photon energies and polarizations, which resulted in a lattice layout with 3 different types of straights: 6 × 4 m, 3 × 7 m and 3 × 11.5 m. In 2005/06 the FEMTO insertion for laser-beam slicing and three 3 Tesla superbends were installed in order to provide sub-ps X-ray pulses and hard X-rays up to 45 keV. Today the SLS is fully equipped with 18 user beam lines and delivers about 5000 hours of user beam time per year at an availability of 97.3% (10 years average) [1].

In recent years, progress in technology and lattice design, mainly pioneered by the MAX IV project [2], introduced a generational change in the field of electron storage rings: multibend achromat (MBA) lattices based on the miniaturization of vacuum chambers and multipole magnets provide an increase of photon beam brightness by 1–2 orders of magnitude and a corresponding increase of spatial coherence. Thus, in a few years from now, the third generation lights sources may no longer be competitive with respect to most advanced experimental techniques like coherent imaging, ptychography, resonant inelastic X-ray scattering etc. So, like for many other facilities, an upgrade is considered for the SLS too. It is planned to replace the storage ring by a new one providing 100–200 pm emittance, while keeping the shielding walls, the beam line source points and the injector complex.

However, the circumference of the SLS is rather small compared to other machines, thus replacing the TBAs by MBAs alone will not provide the desired emittance: just scaling the lattice of MAX IV to the energy and size of SLS results in an emittance of about 1 nm, which would not justify a major upgrade. Also damping wigglers are precluded by lack of space.

A potential way out is based on a new type of lattice cell providing five times lower emittance, which will be presented in the next section. Design studies for an upgraded SLS based on this cell will be presented in the section after the next. The issues of dynamic aperture optimization, error sensitivity, injection schemes and possible round beam operation are treated elsewhere [3–6].

A NEW LOW EMITTANCE CELL

The Problem of the TME Cell

The minimum theoretical emittance (TME) ϵ^{TME} which can be provided by a gradient-free bending magnet of given deflection angle is well known [7], but a periodic and symmetric lattice cell which fulfills the matching conditions for the horizontal beta function $\beta_{xo}^{\mathrm{TME}}$ and the dispersion η_o^{TME} at the bend center, is of little practical use: the dispersion production of a bend is given by its curvature, $\eta'' = h = eB/p$, and acts like a defocusing force on the dispersion. Adjusting the horizontally focusing quadrupoles to match exactly the TME conditions for the dispersion *and* the beta function and finding a periodic solution, i.e. $\beta_x' = \eta' = 0$ a the cell ends, results in an over-focused beta-function and a very high horizontal betatron phase advance of 284.5°. The lattice cell thus needs a second focus in order to accommodate the excess betatron phase, so it becomes rather long and the optics is overstrained. As a consequence, only relaxed TME-cells are commonly used, where the cell phase advance is well below 180°, and the emittance is about a factor 3–6 larger than the TME. Defining dimensionless parameters

$$F = \epsilon/\epsilon^{\mathrm{TME}} \qquad b = \beta_{xo}/\beta_{xo}^{\mathrm{TME}} \qquad d = \eta_o/\eta_o^{\mathrm{TME}}$$

elliptic iso-emittance contours $F(b,d)$ are obtained as shown in Fig. 1 (left) [8].

Construction of a low emittance cell with unstrained optics proceeds by two steps:

1. disentangle beta function and dispersion using anti-bends,
2. minimize emittance using longitudinal gradient bends.

Anti-bends

Anti-bends (AB), i.e. bends of negative field forming a star-shaped rather than a polygonal lattice have been considered in the 1980s and 90s for isochronous rings or for enhanced radiation damping (“wiggler lattice”). The potential for emittance reduction had been noticed [9] but was never exploited.

ORBIT CORRECTION AND STABILITY STUDIES FOR ULTRA-LOW EMITTANCE STORAGE RINGS

M. Böge, M. Aiba, A. Streun, PSI, Villigen, Switzerland

Abstract

Ultra-low emittance storage rings exhibit extremely strong focusing and sextupolar chromaticity corrections. The therefore mandatory excellent centering of the closed orbit in the small aperture magnets is a challenging task and necessitates a proper beam diagnostics and correction layout. Correction and stability studies for a possible ultra-low emittance upgrade of the Swiss Light Source [1] are presented.

LAYOUT FOR BEAM POSITION MONITORS AND DIPOLE CORRECTORS

In order to perform a proper optics and orbit correction of ultra-low emittance rings it is necessary to provide a proper sampling of the optical functions. Especially the horizontal beta function and the horizontal dispersion, which are strongly suppressed in the center of the bending magnets in order to achieve small horizontal emittance [2], need to be corrected close to their design values in order to achieve ultimate performance. The necessary information in the center of the bends can be provided by means of photon beam position monitors (photon BPMs) [3]. It does not necessarily need correction capability at the same location since orbit response matrix (ORM) based optics correction methods [4] and the correction of dispersion orbits by means of the RF frequency only need the orbit information at these locations. In this context it is important to note that the detection of dispersion related orbit deviations is strongly improved by providing orbit measurements at large and small horizontal dispersion values.

The correction of the non-dispersive closed orbit can be provided by correctors adjacent to the bending magnets. Furthermore horizontal dipole correctors would be inefficient due to the very small horizontal beta function (see Fig. 1 on the next page). Otherwise it is highly desirable to have pairs of horizontal and vertical dipole correctors adjacent to electron BPMs (RF BPMs) in order to allow for transparent localized corrections especially in the vicinity of insertion devices in the case of an ultra-low emittance light source. For a comprehensive review of orbit control techniques refer to [5].

For one of the presently favored layouts (Version AD05F) of the upgrade of the Swiss Light Source (SLS-2) [1] 192 RF BPMs and the same number of adjacent horizontal/vertical correctors have been chosen in order to provide the necessary orbit correction capability. For the measurement of the beam positions in the centers of the bending magnets five photon BPMs have been added in each of the twelve arcs which adds another 60 photon BPMs to the system. Figure 1 on the next page depicts one arc section of SLS-2 (Version AD05F) together with the optical functions and the additional photon BPMs (#1-#5). Figure 2 summarizes the photon and RF BPM layout with 20+64=84 BPMs for one 3rd of the ring corresponding to a horizontal and vertical phase advance of 13.14 and 3.585 respectively. The BPMs are shown as "+" with the value of the corresponding horizontal (blue), vertical (red) beta function and the horizontal dispersion (green).

SCHEME FOR ORBIT CORRECTION

In the SLS-2 case the orbit correction is carried out utilizing a Singular Value Decomposition (SVD) [6] based orbit correction algorithm, which "inverts" the (192+60)x192 non-square ORMs treating the horizontal and vertical plane independently and using all 192 eigenvalues, which becomes feasible due to a "good-natured" SVD eigenvalue spectrum, a proper Beam-Based Alignment (BBA) [7] of quadrupoles and adjacent BPMs (half the element-to-element error corresponding to 4μm assumed in simulation) and a low noise BPM [8] ($\approx$50 nm resolution corresponding to 19-bit resolution assuming $\pm$25 mm maximum orbit excursions) and correction system ($\approx$1 nrad resolution corresponding to 20-bit for maximum corrector strength of $\pm$1 mrad) [9].

LAYOUT OF MAGNET SUPPORTS

Common magnet supports (girders) are very important in order to reduce the element to element alignment error in low emittance storage rings like SLS [10, 11]. They allow to reach a small relative misalignment of adjacent magnets on a girder (8 μm assumed in the simulation for SLS-2) which are the main source of orbit distortions and coupling. A single magnet structure containing different magnetic elements [12] serves the same purpose but removes the possibility of aligning magnets within the structure. For SLS-2 the choice of the magnet structure has not yet been made. But this does not matter for the simulation since in both cases the magnet structures are realized as "correlated" misalignments. For the simulation 12 girders of $\approx$18 m length have been chosen which cover the 12 arcs. 25 μm of absolute and 10 μm of relative misalignment from one girder to the next have been allowed. These small errors have been chosen since the simulation does not contain first turn steering ("beam threading") in order to get a closed orbit within the aperture limitations for large errors. Furthermore it is assumed that the ring has been re-aligned during commissioning time based on beam and mechanical survey data [13–15].

TPS LINAC RELOCATION AND BEAM TEST OF THE LTB TRANSFER LINE

H.P. Chang#, C.L. Chen, C.S. Fann, K.L. Tsai, Y.S. Cheng, S.Y. Hsu, K.T. Hsu, A.Y. Chen, Y.C. Lin, J. Liu, and K.K. Lin
National Synchrotron Radiation Research Center, Hsinchu, Taiwan

Abstract

The Taiwan Photon Source (TPS) 150 MeV linac has been relocated from its 2011 test site to the TPS linac tunnel in 2014. After functional test of the linac hardware modules, the beam parameters were carefully examined at a 31-degree bend diagnostic beam line LTD (linac to beam dump) and compared with previous results. Then, the 150 MeV electron beam was delivered to the linac to booster transfer line (LTB) for beam commissioning. The beam optics matching at both the LTB entrance (i.e. linac exit) and the LTB exit (i.e. injection point of booster) was performed for injection optimization purpose. The LTB lattice setting was verified in the beam steering through LTD and LTB with the help of diagnostics tools such as beam profile monitors (SM) and beam position monitors (BPM). The overall performance of the linac and LTB will be described in this report.

INTRODUCTION

The goal of TPS linac relocation and beam test of the LTB is to meet the requirement of the TPS beam commissioning planned in 2014. Relocation of the TPS linac was well prepared in 2013 and initiated when the TPS linac tunnel was available for the linac installation in 2014. Beam test of the linac and LTB has been performed on time in August 2014 according to the beam test scenario set by the Taiwan Atomic Energy Council [1-3].

We summaries the milestone of the TPS linac relocation processes as followings:

- May 2011 ~ Nov 2013: The linac was under the routine operation after its acceptance. The main tasks were performed during this period includes: familiar with system operation, training platform for colleagues, trouble shooting and failure analysis, and preparation for relocation.
- Nov 2013 ~ Feb 2014: The preparation for relocation includes the cable labelling of power and signal cables, disassembly of acceleration sections and waveguides.
- Feb 2014 ~ May 2014: On-site installation of functional modules and their testing.
- Jun 2014 ~ Aug 2014: Linac rf processing, beam test of linac, LTD, and LTB.

The overall performance of the linac and LTB transfer line will be described in the following sections.

TPS LINAC RELOCATION

The 150 MeV TPS linac has been operating at its test site since the acceptance test in 2011 [4,5]. It was shut down and packaged for the relocation in November 2013 and then it was moved to the TPS linac tunnel in February 2014. Linac installation was finished in three months. It included the installation and functional test of each linac module such as electron gun, the magnets (solenoid, corrector, and quadrupole), modulators etc. The rf processing was then performed for the preparation of beam test. Figures 1 and 2 show the relocated TPS linac and power supplies at the TPS site.

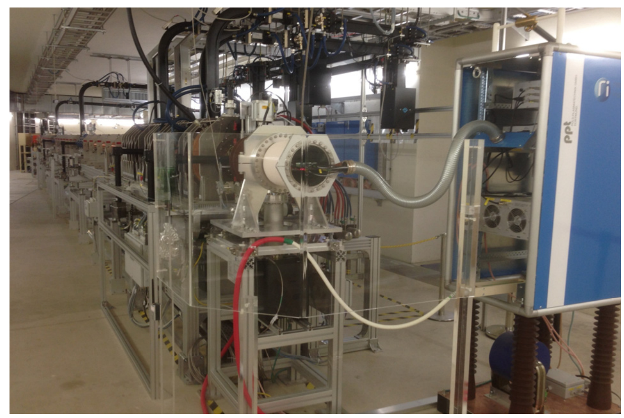

Figure 1: The linac installed in the TPS tunnel.

Figure 2: The power supply area of the TPS linac.

BEAM PARAMETERS MEASUREMENT

As illustrated in Figure 3, the 31-degree bend LTD is used as the linac diagnostic beam line [6]. Beam parameters at the exit were verified with profile monitoring, lattice manipulation and compare with the matching calculation.

The linac and LTB were ready for beam test in July 2014. On August 1, the Atomic Energy Council issued the permission of TPS radiation protection plan for beam commissioning. Beam test of linac and LTB was

DESIGN OF A RESONANT TRANSITION RADIATION SOURCE IN THE SOFT X-RAY RANGE

P. Wang, K. C. Leou, Department of Engineering and System Science, NTHU, Hsinchu, Taiwan
N.Y. Huang, W.K. Lau, A.P. Lee, NSRRC, Hsinchu, Taiwan

Abstract

Resonant transition radiation (RTR) can be generated from multi-layer structures when they are driven by relativistic electron beams. In consideration of using the NSRRC 90 MeV photoinjector as driver, we examined the feasibility of generating narrow-band soft x-rays from various multi-layer structures. Based on analytical theory, the expected angular-spectral distribution and photon yield of these radiators are calculated and compared.

INTRODUCTION

The feasibility of using multi-layer structures for generation of RTR in soft x-ray range is being investigated. We tentatively targeted the radiation energy of these structures centred at 2 keV and 620 eV. Radiation near this photon energy ranges found to be useful in research areas such as imaging of biomolecules, atom and molecular physics. The low-emittance NSRRC photoinjector system will be used to drive such RTR sources. In this system, the MeV electron beam from the laser driven photo-cathode rf gun are accelerated to its maximum energy of 90 MeV. The nominal parameters of the drive beam used in this study are listed in Table 1.

Table 1: Parameters of the Electron Beam Generated From the NSRRC Photoinjector

Beam energy	90 MeV
Emittance	0.8 mm-mrad
Bunch length	2.2 psec
Bunch Charge	100 pC

RESONANT TRANSITION RADIATION

The existence of transition radiation (TR) was predicted by Ginzburg and Frank in 1949[2]. For a charged particle traveling across the boundary between two media of different dielectric constants, the radiation fields can be calculated with classical electromagnetic theory. In the x-ray range, the dielectric constant can be described by Drude model adequately. The angular-spectral distribution of transition radiation from the boundary of two media being excited by a single electron at normal incidence is [3]:

$$\frac{d^2W_{TR}}{d\Omega d\omega} = \frac{e^2}{4\pi^2 c^3}\omega^2 \sin^2(Z_1 - Z_2)^2 \tag{1}$$

where

$$Z_{1(2)} = \frac{4c}{\omega[\gamma^{-2} + \theta^2 + (\omega_{p1(2)}^2/\omega^2)]} \tag{2}$$

$\omega_{p1(2)}$ is the plasma frequency of material 1 (or 2).

For an N-layer structure which is fabricated by interleaved stacking of material 1 with thickness l_1 and material 2 with thickness l_2, the angular-spectral distribution of RTR can be calculated from the following equation with the phase shift as well as absorption in materials are considered[3, 4]:

$$\left(\frac{d^2W_{TR}}{d\Omega d\omega}\right)_N = \left(\frac{d^2W_{TR}}{d\omega d\Omega}\right)F_1F_N \tag{3}$$

where the factor F_1 describes the inner-foil resonance such that

$$F_1 = 1 + \exp(-\sigma_1) - 2\exp(-\sigma_1/2)\cos(2\varphi_1) \tag{4}$$

and F_N describes the inter-foil resonance as

$$F_N = \frac{F_{Nn}}{F_{Nd}} \tag{5}$$

$$F_{Nn} = 1 + \exp(-N\sigma) - 2\exp(-N\sigma/2) \times \cos[N(2\varphi_1 + 2\varphi_2)]$$

$$F_{Nd} = 1 + \exp(-\sigma) - 2\exp(-\sigma/2) \times \cos(2\varphi_1 + 2\varphi_2)$$

where

$$\varphi_{1(2)} = l_{1(2)}/Z_{1(2)},$$

$$\sigma_{1(2)} = \mu_{1(2)}l_{1(2)},\ \ \sigma = \sigma_1 + \sigma_2.$$

$\mu_{1(2)}$ is the x-ray absorption coefficient of material 1(2).

From the equations of F_1 and F_N, the resonance conditions of RTR can be obtained.

$$\varphi_1 = (2n-1)\pi/2 \tag{6}$$

$$\varphi_1 + \varphi_2 = m\pi \tag{7}$$

BUNCH COMPRESSION IN THE DRIVER LINAC FOR THE PROPOSED NSRRC VUV FEL

N.Y. Huang#, W.K. Lau, A.P. Lee, NSRRC, Hsinchu, Taiwan
A. Chao, K. Fang, M.H. Wang, J. Wu, SLAC, Menlo Park, CA 94025, USA

Abstract

A bunch compressor is designed for the S-band driver linac system of the proposed NSRRC VUV free electron laser (FEL). Instead of using a more conventional rf harmonic linearizer, one main feature of this compressor is to use electron linearization optics to correct the nonlinearity in the energy-time correlation of the electron bunch longitudinal phase space. The strategy of compressor design will be discussed by an analytical calculation and particle tracking simulation. The beam dynamics which include the collective instabilities such as the space charge effects, the wake fields and the coherent synchrotron radiation (CSR) effects are discussed.

INTRODUCTION

A photocathode rf gun driver linac system for a proposed FEL facility by making maximum use of existing hardware at National Synchrotron Radiation Research Center (NSRRC) is under study [1]. The baseline design is a fourth harmonic high gain harmonic generation (HGHG) FEL seeded by a 266 nm laser to generate VUV radiation at 66.5 nm. The layout of the proposed facility is shown in Fig. 1. The length of the accelerator system from the gun cathode to the exit of the last linac section is about 28 m and the length of the diagnostics and FEL stations is about 8 m. The whole facility tightly fits into the existing $38\text{m}\times5\text{m}$ tunnel.

Generally, the electron beam after the bunch compressor has the profile of a banana shape instead of a single straight line in the longitudinal phase space. The high order dispersion term of the bunch compressor and the high order energy chirp of the accelerating rf wave are the origin of these nonlinearities. These nonlinearities set the limitation of compression in bunch length and lead to undesirable current spikes in the compressed bunch. In order to control this nonlinear effect, usually a higher harmonic rf section is added at the upstream of the compressor. However, such a linac section together with its klystron system requires additional expense. In this study, a magnetic compressor with linearization optics by the introduction of quadrupole and sextupole magnets is applied instead [2, 3]. The setup of this injector system is considered to be much more cost-effective.

BUNCH COMPRESSOR WITH LINEARIZATION OPTICS

Assume the energy of injected electron is relativistic, there is no relative phase slippage between the rf field and the electron, the energy of an electron after rf acceleration in a traveling wave constant gradient accelerating structure can be expressed as

$$E_f(z) = E_{i0}(1+\delta_i) + eV_0\cos(\phi_0 - kz), \qquad (1)$$

where V_0, k, ϕ_0 are the accelerating peak voltage, the wave vector and the initial rf phase respectively, δ_i is the initial uncorrelated energy spread which is induced by rf and space charge effect in the gun, z is the particle's longitudinal position relative to the bunch center. In this report, we define the bunch head as the electron with large relative longitudinal position, i.e. with relative earlier arrival time. The relative energy spread after passing through an rf section is [3]

$$\delta(z) = \frac{E_f(z) - E_{f0}}{E_{f0}} = a\delta_i + h_1 z + h_2 z^2 + h_3 z^3 + \ldots, \qquad (2)$$

where $a = E_{i0}/E_{f0}$ is the adiabatic damping factor and

$$\begin{cases} h_1 = \dfrac{keV_0}{E_{f0}}\sin\phi_0, \ 1^{\text{st}} \text{ order energy chirp} \\ h_2 = -\dfrac{k^2 eV_0}{2E_{f0}}\cos\phi_0, \ 2^{\text{nd}} \text{ order chirp} \\ h_3 = -\dfrac{k^3 eV_0}{6E_{f0}}\sin\phi_0, \ 3^{\text{rd}} \text{ order chirp} \end{cases}. \qquad (3)$$

The signs of the 1st order and the 3rd energy chirp depend on the operation of initial rf phase. The 2nd order energy chirp is always negative if the initial phase is for electron acceleration. A negative first order energy chirp $h_1<0$ means the bunch tail has higher energy than the bunch head. The chirped beam is then sent to a dispersive region for bunch compression. The longitudinal position of an electron traversing the dispersive region is described as

$$z_f = z_i + R_{56}\delta + T_{566}\delta^2 + U_{5666}\delta^3 + \ldots, \qquad (4)$$

where R_{56}, T_{566} and U_{5666} are the first, second and third order longitudinal dispersion. Neglect the initial high order correlations of energy spread, the longitudinal position of an electron can be expressed by combining Eq.2 and Eq.4 as,

HARDWARE IMPROVEMENTS AND BEAM COMMISSIONING OF THE BOOSTER RING IN TAIWAN PHOTON SOURCE

H. J. Tsai, J. Y. Chen, M. S. Chiu, P. C. Chiu, P. J. Chou, K. H. Hu, Y. C. Liu, F. H. Tseng, K. T. Hsu, C.C. Kuo, G. H. Luo and C. T. Chen
National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract
Taiwan Photon Source (TPS), a low emittance 3-GeV third-generation synchrotron light source, began its hardware integration testing, safety checkout and beam commissioning on August 12, 2014 [1]. The booster ring and the storage ring share the same tunnel in a concentric fashion; the booster ring has circumference 496.8 m, the largest among light source facilities in operation. A combined-function FODO lattice is adopted for the booster ring with natural emittance 10 nm-rad. After hardware improvements were completed, the commissioning of the beam in the booster ring began on December 12 and attained the 3-GeV design energy on December 16.

INTRODUCTION

Because of constraints at the site, the TPS booster ring shares the same tunnel with the storage ring [2]. The circumference of the booster ring is 498.6 m, the largest booster ring of light source facilities in operation. To reduce the number of magnets, dipole magnets combined quadrupole and sextupole components were adopted, as in SLS and ALBA [3, 4]. The sizes of magnets and vacuum chambers are optimized to save space, construction cost and power consumption. The major parameters of the TPS booster are listed in Table 1. The imperfection issues in hardware integration and commissioning results are reported in this article.

Table 1: Major Parameters of the TPS Booster Ring

Booster parameters	
Circumference	496.8 m
Length of straight section	6.02 m
Harmonic number	828
RF frequency	499.654 MHz
Bending radius, ρ	12.223 m
Betatron tune , ν_x/ν_y	14.380/9.302
Natural chromaticity, $\xi_x/\ \xi_y$	-16.82/-13.24
Momentum compaction	0.0024735
Damping partition, $J_x/J_y/J_e$	1.81/1.00/1.19
Energy spread at 3 GeV	0.095174 %
Natural emittance at 3 GeV	10.32 nm rad
Damping time, $\tau_x/\tau_y/\tau_e$, at 3 GeV	9.4/16.9/14.2 ms
Damping time, $\tau_x/\tau_y/\tau_e$, at 150 MeV	75/136/115 s
Energy loss per turn at 3 GeV	586 keV
Rate of ramping repetition	3 Hz

HARDWARE IMPROVEMENTS

Most installation work in the booster ring was completed by the end of July, 2014. The 150-MeV beam from the Linac to the entrance of the booster ring was available in mid-August; field acceptance tests and tuning of power supplies for the booster magnets were concurrently conducted with beam commissioning due to very tight installation schedule. Beam-based testing of the hardware and improvement of the booster subsystem were in progress. Several hardware glitches were discovered; the solutions were implemented swiftly, for example, the repair of a burned power supply of a booster dipole magnet due to overheating in a protection circuit board while conducting a test with full power rating at high power, the reduction of flat-top field variation of injection kicker from ±2% to ±0.4% and the residual field of post-pulse from +5% to ±0.4% for injection kicker with ferrite load, etc.

At the beginning of September, having the first turn in the booster ring was easily obtained by beam steering; after optimization of transfer efficiency and minimized of the charge loss in the Linac and transfer line, a multi-turn circulating beam was observed; the beam survived up to 35 ms in mid September, but it did not show up capturing and beam storage. We tried to correct the distortions of the beam orbit within 4 mm and to scan the RF frequency, phase and gap voltage but without beam capture phenomena. At the same time, we found that the corrector strengths were about three times the simulated values including the misalignment and tolerance of magnet-field. The vacuum pipe, made of stainless steel (SUS304), has a small elliptic cross section, 35 mm x 20 mm, and thickness 0.7 mm in booster. At the initial stage of beam commissioning, dimension distortions and misalignments of the pipes were critical. More care was taken to realign the chambers' and the magnets' positions. The key setback that stalled the progress of testing the booster hardware was found on November 12. The pipes had a high relatively permeability (ranging from 1.2 to 2.0), which induced from cold-drawn during manufacture [5] without proper annealing process. These unqualified chambers were taken apart and treated in vacuum oven up to 1050 °C, and then re-installed within three weeks. The relative permeability of the pipes, after that treatment, was reduced to be within 1.01 [6].

Several issues were encountered that jeopardized the stability and injection efficiency of the beam; three major problems were encountered, which the booster launching condition deviated 2 mm from optimum because of a leakage field of the DC extraction septum in the horizontal plane, which a random injection kicker strength decreased about -2 % due to misfiring induced on

DEVELOPMENTS IN CLARA ACCELERATOR DESIGN AND SIMULATIONS

P. H. Williams*, D. Angal-Kalinin, A. D. Brynes, D. Dunning, J. K. Jones, J. W. McKenzie, B. L. Militsyn, B. D. Muratori & N. R. Thompson, ASTeC, Daresbury Laboratory, Warrington, Cheshire, UK
S. Spampinati, University of Liverpool & The Cockcroft Institute, Warrington, Cheshire, UK

Abstract

We present recent developments in the accelerator design of CLARA (Compact Linear Accelerator for Research and Applications), the proposed UK FEL test facility at Daresbury Laboratory. The layout changes include a dedicated collimator in CLARA front end to provide some control over the dark current, changes to low energy diagnostics section and modifications to FEL modules. The progress in the design simulations mainly focuses on a comparison of using ELEGANT and CSRTrack for the Variable Bunch Compressor and first considerations of requirement of laser heater for CLARA.

THE CLARA ACCELERATOR

CLARA is a proposed 250 MeV FEL test facility at Daresbury Laboratory [1]. The front end of CLARA incorporates an S-bend to transport the beam to presently operational VELA facility [2] and the gun for CLARA will share the same RF and drive laser infrastructure [3]. The changes to CLARA layout presented here since IPAC14 [4] include: a dedicated collimator in CLARA Front End to reduce the dark current from the injector, removal of Transverse Deflecting Cavity (TDC) from the low energy diagnostics section, inclusion of the post-linac diagnostics section with TDC and changes to the FEL modules. Preliminary investigations of requirements on laser heater and updates on simulations in magnetic chicane mode using CSRTrack [5] are presented. The Front End of CLARA will be installed later this year with first beam commissioning starting early 2016.

CHANGES TO ACCELERATOR LAYOUT

There have been a number of changes to the layout of the CLARA accelerator since 2014 (see Fig. 1). The reasons for each change have either been the gaining of operational experience on VELA, unforeseen engineering constraints or the enabling of additional capabilities. The front end has been finalised and components are either delivered or on order. This includes linac-1, a 2 m S-band structure capable of accelerating beam to ~55 MeV and its attendant klystron and modulator; beam transport elements towards linac 2, S-bend to the existing VELA beamline and spectrometer; BPMs and diagnostic stations including screens, slits, collimators and Faraday cups. After linac-2, space for a possible laser heater has been retained, the variable bunch compressor (VBC) layout has been finalised and magnets and other components are currently under engineering specification. To save space the transverse deflecting cavity (TDC) and diagnostics immediately following the VBC have been removed, leaving one TDC section immediately following linac-4, and one immediately following the FEL. The baseline machine simulations have been altered to take account of these changes.

COLLIMATION IN FRONT END

Although CLARA is a relatively low power machine (maximum average beam power of around 10 W [1]), and severe beam loss problems are not anticipated, collimation is included in the front end lattice to mitigate effects of dark current and beam halo. We propose to include a gun collimator similar to that in VELA where a 1mm thick tungsten plate with different hole sizes is used to collimate gun dark current [6]. In CLARA, the collimator will be included in the drive on the first YAG station, immediately upstream of the first linac. The collimator will utilise cylindrical hole diameters of 4, 6 and 9 mm.

In addition, we propose an additional collimator in the matching section between the first two linac modules, where the beam energy is tens of MeV. We envisage a similar arrangement to that used at FERMI where thick copper collimators are used, with tapering to reduce wakefields and a choice of several different apertures [7]. The engineering specifications of this collimator are being finalised.

THE EVOLUTION OF THE TRANSVERSE ENERGY DISTRIBUTION OF ELECTRONS FROM A GaAs PHOTOCATHODE AS A FUNCTION OF ITS DEGRADATION STATE

L.B. Jones*, B.L. Militsyn, T.C.Q. Noakes
STFC Daresbury Laboratory, ASTeC & the Cockcroft Institute, Warrington WA4 4AD, UK

Institute of Semiconductor Physics (ISP), SB RAS, Novosibirsk 630090, Russia

Abstract

The brightness of a photoelectron injector is fundamentally limited by the mean longitudinal and transverse energy distributions of the photoelectrons emitted from its photocathode, and is increased significantly if the mean values of these quantities are reduced. To address this, ASTeC constructed a Transverse Energy Spread Spectrometer (TESS) [1] – an experimental facility designed to measure these transverse and longitudinal energy distributions which can be used for III-V semiconductor, alkali antimonide/telluride and metal photocathode research. We present measurements showing evolution of the transverse energy distribution of electrons from GaAs photocathodes as a function of their degradation state. Photocathodes were activated to negative electron affinity in our photocathode preparation facility (PPF) [2, 3] with quantum efficiency around 10.5 %. They were then transferred to TESS under XHV conditions, and progressively degraded through controlled exposure to oxygen. Data has been collected under photocathode illumination at 635 nm, and demonstrates a constant relationship between energy distribution and the level of electron affinity.

INTRODUCTION

The development of high–performance accelerator drivers for Free–Electron Laser facilities requires electron source technology which delivers a high–brightness electron beam for reasons that are well–documented [4]. Electron beam brightness in a linear accelerator is fundamentally limited by injector brightness, and this is itself limited by the source beam emittance or the *intrinsic emittance* of the cathode source. Electron beam brightness will be increased significantly by reducing the longitudinal and transverse energy spread in the emitted electrons, thereby creating a *cold beam*. To accomplish this goal, we must understand the mechanisms which define the intrinsic emittance whether these are related to the properties external to the photocathode such as surface roughness and preparation methods, or properties internal to the photocathode such as purity, doping level, crystal structure, band structure etc. Consequently, the study of photocathode physics and electron emission have become important areas for research by the worldwide accelerator community.

* lee.jones@stfc.ac.uk

TRANSVERSE ENERGY MEASUREMENT

To measure the transverse energy using TESS, a photocathode is illuminated with a tightly-focussed laser beam typically 100 μm FWHM in diameter at extremely low intensity, and its emission footprint recorded at some known distance from the photocathode surface. Assuming a vanishingly-small source size, and knowing the drift distance travelled by the photoelectrons, and the effective voltage through which they have been accelerated (defining their flight time), the transverse energy component required to generate the observed emission footprint can be determined.

On emission from a photocathode, the transverse energy of a photoelectron is a convolution of the component of the electron momentum parallel to the cathode surface immediately prior to emission and the effects of surface diffraction during the emission process. It is measurable as the beam emittance at some distance from the source, and data from the TESS place an upper limit on the mean transverse energy (MTE). Measurement of the angular distribution of photoelectrons from a surface is very difficult due to the necessity to work with extremely low–energy electrons which can be potentially mis–steered through exposure to stray electric and magnetic fields. Even the application of angle–resolved photoelectron spectroscopy to measure this angular distribution is challenging as the angular distribution is affected by the specific geometry of the vacuum chamber and experiment itself, so measurements will vary in each installation. In the case of GaAs, published work indicates that the emission cone is narrow with a half–angle of only 15 ° [5].

For GaAs photocathodes, the upper limit on transverse electron energy is determined primarily by three factors, these being the illumination wavelength, the level of electron affinity and the photocathode temperature. The profile of the measured transverse energy distribution curve (TEDC) itself depends on various elastic and inelastic electron scattering processes at the photocathode–vacuum interface, which are themselves dependent on a number of factors such as surface roughness, surface diffraction, material structure/crystallinity etc.

The TESS system provides the ability to measure this transverse energy, and to make direct comparisons between photocathodes which have been prepared in different ways or experienced different conditions during operation. This

Abstract

Recent developments on the VELA (Versatile Electron Linear Accelerator) RF photo-injector at Daresbury Laboratory are presented. These are three-fold; commissioning/installation, characterising and providing beam to users. Measurements for characterising the dark current (DC), 4-D transverse emittance, lattice functions and photoinjector stability are presented. User beam set ups to provide beam for electron diffraction and Cavity Beam Position Monitor development are summarised.

INTRODUCTION

VELA is a facility designed to provide a high quality electron beam for accelerator systems development, industrial and scientific applications. It comprises of a 2.5 cell S-band photocathode gun with copper photocathode providing beam to experiments in the accelerator hall and 2 dedicated user areas. More information on the layout, design and early commissioning can be found in [1,2].

INSTALLATION & COMMISSIONING

As well as first commissioning of a second user area, Beam Area 2, in preparation for users in May 2015 a number of new devices were installed, including, a copper cathode, gun klystron, and transverse deflecting cavity (TDC).

New Gun Klystron

The RF power to the photo-injector gun is provided by a Thales TH2157 klystron, which is incorporated in a ScandiNova K2 klystron modulator. The modulator consists of a number of parallel solid state IGBT switching modules providing the primary voltage to a pulse step-up transformer which is capable of providing a 250 kV, 150 A flat top pulse of 0.5 – 3 µS at a pulse repetition rate between 1 – 400 Hz, with rate of rise for the pulse of between 150 – 215 kV/µs. The klystron is a 10 MW klystron operating at 2998.5 MHz, the original was a 10 year old klystron provided by Strathclyde University. During the first period of VELA commissioning it was noted that the electron beam momentum was low and did not align well with the measured RF cavity power. An investigation established that; the peak RF power capability was less than 10 MW and not all of the power entering the cavity was accelerating the beam. The new klystron provided an increase in momentum from ~4.9 to ~5.1 MeV/c. The power in the cavity is currently under investigation with further modelling work planned.

Cathode Replacement

The new cathode was diamond polished to a roughness of 100 nm, but this process has resulted in some peripheral diamond inclusions visible under SEM. Although not ideal, this cathode is now being used as the original cathode was not well polished and the effect of machining (i.e. turning) marks could clearly be seen in the downstream beam distribution, e.g. Fig. 1. Also, it was hoped that a smoother polished surface would reduce the DC, as described below.

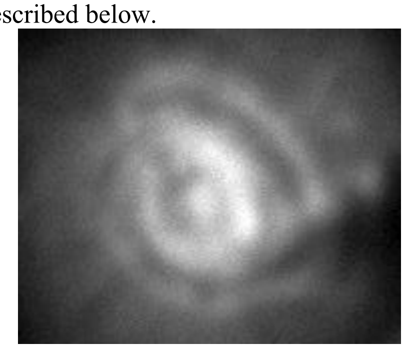

Figure 1: Beam image with rings attributed to machining marks on cathode.

Transverse Deflecting Cavity

The TDC, further explained in [3], is an S-band 9-cell copper cavity operating at 2998.5 MHz designed to provide a transverse kick of ~5 MV. Cold RF test characterisation has been performed and the cavity conditioned to 3.8 MW RF power at a repetition rate of 10 Hz and with a pulse width of 2.5 µs. Only a small number of vacuum events occurred during conditioning. An electron beam was then successfully transported through the TDC and first tests showed the expected behaviour: adjusting the TDC RF phase with constant RF amplitude moved the beam vertically on a downstream screen and increasing the RF gradient for a constant RF phase produced an increased vertical size of the beam image on the screen. Further characterisation of the TDC and electron bunch is planned for later in 2015.

REALISTIC UNDULATORS FOR INTENSE GAMMA-RAY BEAMS AT FUTURE COLLIDERS*

A. Alrashdi[1,2,3†], I. Bailey[1,2], and D. Newton[2,4]

Abstract

The baseline designs for the ILC and CLIC require the production of an intense flux of gamma rays in their positron sources. In the case of CLIC the gamma rays are produced by a Compton backscattering source, but in this paper we concentrate on undulator-based sources as proposed for the ILC. We present the development of a simulation to generate a magnetic field map based on a Fourier analysis of any measured field map. We have used a field map measured from the ILC helical undulator prototype to calculate the typical distribution of field errors, and used them in our calculations to produce simulated field maps. We show that a loss of gamma ray intensity of $\sim$ 8% could be expected, compared to the ideal case. This leads to a similar drop in positron production which can be compensated for by increasing the undulator length.

INTRODUCTION

In the ILC, to achieve the required gamma-ray flux, a 150 GeV electron beam needs to pass through a long helical undulator (approximately 147 m) with a K of 0.93 and a peak field on-axis of 0.88 T successfully. This undulator nominally contains 84 modules of active length 1.7825 m. Dipole magnets may be used to correct the beam in between the modules to redirect the beam to the central axis. Errors in the undulator field can alter the flux, energy distribution and polarisation of the gamma rays. Below we demonstrate a technique to quantify the effect of these errors.

MAGNETIC FIELD MAP

Ideal Magnetic Field Map

Equations 1 and 2 describe the magnetic field inside an ideal helical undulator,

$$B_x = B_0 \sin \frac{2\pi z}{\lambda_u} \tag{1}$$

$$B_y = B_0 \cos \frac{2\pi z}{\lambda_u} \tag{2}$$

where B_0 is the field strength, z is the distance along the primary axis of the undulator, and λ_u is the period size.

* This research was funded in part by the STFC Cockcroft Institute Core grant no. ST/G008248/1.
† aalrashdi@kacst.edu.sa

Measured Magnetic Field Map

There were two field maps measured from the ILC prototype undulator modules using a Hall probe on-axis [1]. Imperfections in the magnet winding or deformation of the magnet 'former' lead to errors in the field. The magnet prototype field map was manipulated to add tapering for the first 2 and last 2 periods to ensure that the electron will stay close to the centre of the undulator if injected along the centre.

Simulated Magnetic Field Map

In order to produce a simulated magnetic field map based on a measured field map. We introduced errors in the magnetic field strength as well as in the period size over the length of the undulator along the z direction. This is discussed in more detail here [2]. The model used ensures the simulated map will not have a discontinuity. We compared the Discrete Fourier Transforms of the x-projections of the magnetic fields within the undulator for the measured data and simulated data to tune the model.

Our studies suggest that similar trajectories are obtained for particles travelling through the simulated field whether or not the errors in the y projection of the field are calculated independently of those in the x projection of the field. For this work we assumed that the errors in x and y have the same characteristic size and distribution.

TRACKING THE ELECTRON INSIDE THE UNDULATOR

Below we refer to three types of undulator data: ideal, measured, and simulated which we used as input to the HUSR simulation code [3,4]. In the ideal case, an electron will feel an average magnetic field strength of zero and will be transported through the undulator with a total deflection of zero as long as it is injected at an appropriate angle or tapering is used. The electron is injected on axis and the measured and simulated fields are manipulated to add tapering for the first 2 and last 2 periods. Fig 1 shows the position of the electron on the x and y axes. The radius of the helical trajectory has a standard deviation of 8×10^{-12} m reflecting the small numerical uncertainty in the simulation.

Abstract

A comparison of quantum efficiency (QE) and work function (WF) measurements of polycrystalline and thin film metal photocathodes for use in normally conducting RF (NCRF) guns, similar to the S-band gun under development for the CLARA project at Daresbury, are reported. Cu and Nb thin films were grown on a Si substrate by magnetron sputtering and subsequently prepared by annealing and Ar ion sputtering. To determine the surface chemistry, X-ray photoelectron spectroscopy (XPS) was employed. QE measurements were enabled using a 265 nm UV LED. WF measurements were carried out using a Kelvin probe. Annealing the Cu thin film to 250°C yielded a QE of $1.2\cdot10^{-4}$; one order of magnitude higher than the QE for sputter cleaned and post annealed polycrystalline Cu. The optimum QE measurement for Nb thin film was $2.6\cdot10^{-4}$, which was found to be comparable to the results obtained for cleaned bulk Nb. Analysis of XPS data of these metals suggest surface composition and surface chemistry are main contributing factors to the QE and WF.

INTRODUCTION

Our interest in metal photocathodes stems from the installation of VELA (Versatile Electron Linear Accelerator) at Daresbury Laboratory (DL) [1]. As with many NCRF guns, VELA injector uses a metal photocathode for its fast response that allows for much shorter pulses, and it's relative insensitivity to the vacuum environment. VELA gun uses a Cu disk photocathode, integrated onto the back wall of the Cu cavity; this yields a QE of approximately 10^{-5}. Now the interest has turned to investigating alternative metals to Cu, with potentially better photocathode performance. The metal photocathodes will be installed in NCRF guns such as VELA and also high repetition rate guns for future 4th generation light sources test facility such as the Compact Linear Accelerator for Research and Applications (CLARA) [2], a proposed Free Electron Laser test facility, which will require a fast response time cathode with a reasonable QE.

A range of polycrystalline metals have already been investigated and several metals have been identified as yielding reasonable QE values (greater than 10^{-5}), namely Mg, Pb, Zr, Nb and Ti [3]. The next stage is to study the properties of these metals when deposited as thin films. The use of thin films could potentially evade problems of RF breakdown that commonly occur in adjoining metal disks to the Cu cavity [4].

This study will report a comparison of QE, work function and chemical composition of Cu and Nb thin films versus bulk metal cathodes.

EXPERIMENTAL PROCEDURE

Magnetron sputtering has been used to deposit metal thin films on Si(100) substrates; this is a preliminary experiment, and so for operational photocathodes an appropriate substrate material will be chosen. The Si substrates were cleaned and degreased in ultrasonic bath of acetone, IPA, methanol and then finally washed in deionised water. Nb and Cu were sputtered onto the Si substrate; Kr sputter gas was used at 3 mbar and the magnetron was operated at a DC power of 600 W.

As was the procedure for the polycrystalline cathodes, the thin films were then carefully inserted into a sample holder and then cleaned in an ultrasonic bath of acetone for 10 minutes before analysis.

An ESCALAB Mk II XPS instrument has been adapted for the purpose of preparing and analysing the cathode samples. For this experiment, surface analysis techniques were used to obtain measurements of QE, WF and surface chemical composition. The following measurements were carried out in the analysis chamber of the ESCALAB Mk II at a pressure of approximately 10^{-10} mbar.

A 265 nm LED with 12 nm bandwidth was used for excitation of the cathodes. The intensity of the LED was calibrated using a UV sensor. The resulting drain current from the cathode was measured using a pico-ammeter.

The KP Technology UHVKPm100 equipment installed in ESCALAB Mk II is used to create a potential difference between the cathode and the tip of the Kelvin probe, and thus infer a work function with a resolution of less than 3 meV.X-Ray Photoemission Spectra were measured Al Kα illumination and the emitted electrons energy analysed with a hemispherical analyser. The XPS system has an energy resolution of approximately 1.1 eV and a spatial resolution of 100 µm. This technique is used to qualitatively and quantitatively assess the cathode chemical composition.

Abstract

Particle-in-cell simulations were performed by using PARMELA to characterise an electron injector with a booster linac for the AWAKE project in order to provide the baseline specifications required by the plasma wakefield experiments. Tolerances and errors were investigated. A 3 GHz travelling wave structure designed by using CST code. Particles were tracked by using the field maps acquired from these electromagnetic simulations. These results are presented in comparison with the generic accelerating structure model within PARMELA.

INTRODUCTION

The AWAKE project is a proton driven plasma wakefield acceleration experiment by utilising the driver proton beam from CERN's SPS injector and a custom photo injector for the witness (trailing) electron beam [1, 2].

Figure 1 shows the layout of the injector consisting of an S-band standing wave RF gun (SW), previously used in CERN's PHIN photo injector [3], followed by laser optics to direct the laser onto the cathode. Beamline continues with beam current and position monitors and a pepper pot emittance measurement system suitable for a beam subject to space charge effects. A new S-band booster section (accelerating travelling wave structure, ATS) was designed by using CST suite [4] and introduced in the model to boost the beam energy to a region adjustable between 16 – 20 MeV. ATS is followed by a quadrupole triplet and a downstream screen to perform quadrupole scans for emittance measurement.

The tracking studies have been performed by using PARMELA [5]. For ATS the model provided by PARMELA and field maps extracted from CST were used and compared. Implementation of CST maps into PARMELA are discussed in the following sections.

BOOSTER LINAC

An S-band booster linac, ATS, was designed as a travelling wave structure with constant gradient of 15 MV/m through the entire structure (Fig.2) . It consists of 30 cells with 120° phase advance and varying radii matched to 1 μm precision. ATS was optimised for low reflection coefficient of about 2.5%. The multipole terms [7] due to transverse RF-kicks are 9.4241×10^{-7} mT, 7.8418×10^{-5} mT/m and 4.9×10^{-3} mT/m^2, respectively, from dipole to sextuple terms.

USING CST FIELD MAPS IN PARMELA

In order to use CST field maps in PARMELA tracking simulations, a MATLAB [6] script was prepared to format the standard CST field maps into the form required by PARMELA . The information that PARMELA requires on each line of a field map can be found in Table IV-2 from the program manual [5].

In PARMELA, two field maps must be provided for a travelling wave structure; one produced with Neumann boundary condition (cosine map) and the other with Dirichlet boundary condition (sine map). These fields which are shifted in phase by 90° are fed into PARMELA by using the TRWCFIELD command. A single TRWAVE line is used to represent the entire ATS including the bore tubes with lengths equal to a cell length at each end of ATS to account for the fringe fields.

BASELINE DESIGN

In order to maintain the balance between the emittance growth and the energy spread within ATS, a 10° off-crest phase was chosen for the baseline design by using the CST maps of the current design while the SW is optimised for the highest energy. In addition, the same beam dynamics conditions can be met with on-crest RF phase in the case of the PARMELA model for a travelling wave structure.

The space charge component of the emittance is compensated using the field produced by two solenoids located around the SW. Slightly different working points to satisfy the constant envelope condition were determined for the field distributions from PARMELA and CST models.

The beam dynamics specifications are presented in Table 1 in comparison with these two.

Table 1: Required specification and values produced with different models.

Parameter	Required	PARMELA Map	CST Map
E (MeV)	16	16	16
ΔE/E (%)	0.5	1.3	1.1
$\epsilon_{x,y}$ (mm mrad)	2	1.7,1.8	2.3, 2.5

[3]CERN, Geneva, Switzerland

Abstract

The John Adams Institute for Accelerator Science (JAI) has proposed the realisation of the Accelerator Science Laboratory (ASL) at the University of Oxford as a facility for the development of advanced compact light sources enabling accelerator science research and applications. The installation of a compact light source in the ASL is planned with two options for the accelerating technologies. Firstly, a conventional RF based accelerator is considered to be a driver for a short pulse THz coherent synchrotron radiation (CSR). The other option focusses on the radiation produced by a Laser Plasma Accelerator (LPA) advanced accelerator technique that will provide the possibility to shorten the length of the beamline. This paper presents results of the studies on beam dynamics for both options of compact light sources in the ASL.

INTRODUCTION

Compact advanced fourth generation light sources enable advanced research and experiments in a wide range of applications in small-scale facilities, especially at universities. The John Adams Institute for Accelerator Science (JAI) at the University of Oxford has been studying the possibility of establishing the Accelerator Science Laboratory (ASL) as an accelerator laboratory dedicated to advanced research with compact light sources. Many facilities worldwide aim to generate terahertz (THz) radiation, which is required in numerous scientific experiments and applications, such as imaging and spectroscopy of molecules, disease diagnostics and organism detection, electron beam diagnostics, safety non-destructive monitoring and weapons inspection. The THz radiation can be produced by various schemes, such as solid state oscillators, gas and quantum cascade lasers, coherent synchrotron radiation (CSR) and free electron lasers (FELs). Currently, the ASL aims at producing short pulse THz CSR from a dipole magnet with two options of acceleration technologies. The first option is based on the acceleration of electron beams with a conventional RF linac and shortening of the electron bunch length by a magnetic chicane bunch compression. The other is to utilize the electron beam with extremely short bunch length produced from laser plasma accelerator (LPA) in a bubble regime to produce the coherent radiation. This paper presents beam dynamics studies of the THz radiation source for the ASL in both options after [1] and the assessment of the achievable performance.

RF-DRIVEN RADIATION SOURCE

Beam Dynamics

A beamline of the THz radiation source based on the RF linac consists of a 1.6-cell S-band photocathode gun, an S-band cavity, an X-band harmonic cavity and a four-dipole magnetic chicane as shown in Fig.1. An electron beam emerges from a cathode in the RF gun. The S-band cavity accelerates the beam to reach the desired energy and employs the emittance compensation process to increase beam brightness. The X-band harmonic cavity is used for linearization of the beam longitudinal phase space, which offers better control of bunch length compression in the magnetic chicane. The synchrotron radiation is generated at the last dipole magnet of the chicane.

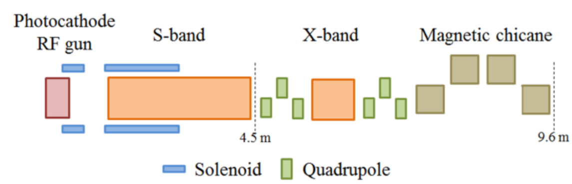

Figure 1: Layout of the RF-driven radiation source.

Beam dynamics of this RF-based radiation source has been studied with start-to-end (S2E) simulations starting from the beam at the photocathode gun to the generation of CSR. The simulation is separated into two parts: the injector, comprising the RF-gun and the S-band cavity and the second part comprising the X-band cavity, the bunch compressor and its matching section. Low bunch charge is considered in order to get short bunch length leading to our target to generate the short pulse THz radiation. Hence, the simulations were done based on two choices of bunch charge: 100 pC and 500 pC.

Injector

The first part of the S2E, from the photocathode gun to the end of the S-band cavity, was simulated with ASTRA [2] because of the dominance of the space charge effect on a low energy beam. RF frequency of both components is 2.856 GHz. A flat-top laser profile is considered in both 100 pC bunch and 500 pC bunch. After the gun, the electron beam is focussed by a solenoid to get the minimum beam waist at a position where the S-band cavity is located at in order to compensate emittance growth by using an appropriate accelerating gradient. The S-band cavity accelerates the beam to about 55 MeV and also operates off-crest in order to introduce a

INJECTION STUDIES FOR THE DIAMOND STORAGE RING

I.P.S. Martin, M. Apollonio, Diamond Light Source, Oxfordshire, U.K.
R. Bartolini, Diamond Light Source, Oxfordshire, U.K., and
John Adams Institute, University of Oxford, U.K.

Abstract

The Diamond storage ring will be upgraded during 2016 by replacing one of the existing double bend achromat (DBA) cells with a double-DBA (DDBA) cell [1]. It is anticipated that both the on and off momentum dynamic aperture will reduce as a result of this change. In order to prepare for this eventuality, injection into the Diamond storage ring has been recently studied in detail. In particular, the oscillation amplitude, angle and energy of the injected beam have been determined, along with the position of the stored beam with respect to the septum plate. Following these studies, the injected beam energy has been matched to the storage ring, and plans have been put in place to move the injection septum 4 mm closer to the stored beam centre line.

INTRODUCTION

The Diamond storage ring will be upgraded in August 2016 by replacing one of the existing DBA cells with a single DDBA cell [1]. The primary goal of this exercise is to increase the capacity for insertion device beamlines; however, the extensive design and engineering work involved also serves as a good basis from which to proceed towards a full low emittance upgrade of the entire storage ring [2].

When developing the upgrade lattice, the main focus has been on retaining the existing Twiss parameters at the ID source points, whilst at the same time minimising the impact of the upgrade on the lifetime and injection efficiency. At present it is anticipated the lifetime will drop by ~10% to 15%, with a similar drop in the injection efficiency [3]. A low-alpha lattice solution is also being developed in parallel to this work [4]. In this case the impact on the on- and off-momentum dynamic aperture is more dramatic, reducing the injection efficiency to close to zero (assuming the existing injection parameters).

In order to combat this reduction in injection efficiency, it has been proposed to reduce the separation between stored and injected beams from the existing 8.3 mm. This reduction could in principle be achieved by moving the stored beam closer to the septum plate by increasing the amplitude of the injection kicker magnets, or alternatively by applying a static orbit bump across the straight using the dipole corrector magnets embedded in the sextupoles. However, the preferred solution is to move the septum magnet from the existing position of -16 mm offset from the stored beam centre line to -12 mm offset. This has the advantage that the kicker magnets can then be run at a lower field (thereby reducing the disturbance to the stored beam during top-up injection cycles), and also allows for single-shot on-axis injection (forming part of the DDBA commissioning plan).

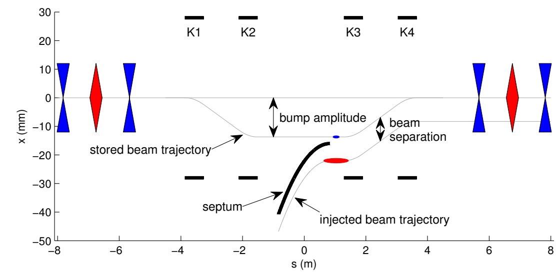

Figure 1: Injection schematic for the Diamond storage ring.

INJECTION SCHEME

Injection into the Diamond storage ring is carried out within a single long straight section. The scheme uses four pulsed kicker magnets to bump the stored beam towards the septum magnet, with the injected beam arriving at a nominal displacement of -8.3 mm from the stored beam. A schematic of the injection process is shown in Fig. 1, and the main parameters are given in Table 1.

The nominal beam separation was decided upon during the design phase after assuming highly pessimistic values for the stored and injected beam emittances, alignment tolerances on the septum plate and shot-to-shot variability in the injected beam trajectory. In principle, the separation could be reduced to the absolute minimum value of $3\sigma_{stored}$ + $3\sigma_{inj}$ + septum thickness = 5.8 mm. However, this would leave no contingency for trajectory or transient closed orbit errors due to non-closure of the kicker bump.

Table 1: Injection Parameters

Parameter	Value
Nom. injected beam size (1σ)	0.69 mm
Nom. stored beam size (1σ)	0.18 mm
Nom. septum displacement (inside edge)	-16 mm
Septum thickness	3.2 mm
Nom. bump amplitude	-13.7 mm
Max. bump amplitude	-18.8 mm
Nom. stored/injected beam sep.	8.3 mm
Storage ring revolution period	1.87 μs
Kicker pulse duration (half sine)	6 μs

MEASUREMENTS

In order to set a realistic limit on the minimum achievable stored and injected beam separation, studies have been made on the impact of various parameter changes. At the same time, investigations were carried out to identify potential detrimental effects resulting from the septum move.

FIRST TRANSPARENT REALIGNMENT TESTS AT THE DIAMOND STORAGE RING

M. Apollonio, P. Dudin, M. Hoesch, W. J. Hoffman, E. C. Longhi,
A. J. Rose, A. Thomson, Diamond Light Source, Oxfordshire, U.K.
R. Bartolini, Diamond Light Source, Oxfordshire, U.K. and John Adams Insitute, Oxford, U.K.

Abstract

The Transparent Realignment (TR) of the Diamond Storage Ring is a program of work to improve the mechanical alignment of the machine by carefully moving the magnet girders with a virtually zero impact on the associated beamlines. The girders can be moved by means of a 5-axis motion system under remote control via the EPICS toolkit from the Diamond Control Room. Currently three cells (three girders in each) have been equipped with a permanent protection system to prevent excessive deflection across each of the inter-girder vacuum bellows. The protection and motion systems are installed in the associated Control and Instrumentation Area (CIA). Full commissioning of the motion and protection systems have been completed. Results from the alignment test sessions are hereby reported.

INTRODUCTION

The realignment of a storage ring (SR) is key to reach low vertical emittances, down to few pm or even sub pm [1, 2]. Today the realignment or control of the alignment status of a machine is part of routine programmes in many facilities. At Diamond this request became more important after low coupling (C=0.3 %, ϵ_y = 8 pm rad) became the standard user mode in March 2013.

Care must be taken when correcting for mechanical misalignments, since moves can potentially impact on nearby insertion devices (IDs). The strategy to mitigate this effect has been devised and initially tested at the end of 2013. It consists in the careful use of orbit bumps (Golden Offsets, GO) at the primary BPMs facing an ID straight, that restore the orbit where it was prior to the alignment, as thoroughly described in [3]. In this paper we introduce the new remote control system, capable of moving three girders at a time, and show the results obtained in the realignment of straight-05. We focus on the effects of introducing GOs and subsequently remove them, with the beamline realigning to the new machine configuration. A view to future tests is presented at the end of the document.

SURVEY ASSISTED GIRDER ALIGNMENT (SAGA)

Choice of Cells to be Realigned

The horizontal and vertical planes are periodically surveyed at Diamond, as shown in [3, 4]. In the vertical plane figures are reported as levels of the girder edges respect to a best fit plane, interpolating all the monument levels as measured in a full survey campaign of SR. Figure 1 shows a snapshot of the vertical plane alignment as of June 2014, where variations as large as 600 μm are seen. In order to reduce the magnitude of the realignment moves a smooth curve was fitted to the monument positions whose period is about half of the SR length (561.6 m). The curve is a sine wave with a mildly variable amplitude, and the long wavelength ensures that a realignment to this baseline should be effective while keeping girder moves within few hundred microns. Figure 1 guides the choice of cells 4, 5 and 6 as parts of the lattice to be realigned, in an ideal continuation of the work previously done to align cell 3. The initial highly mis-aligned pattern in cells 4 and 5 (gray segments), has been brought to a more tamed configuration by April 2015, resulting in an overall aligned sequence from cell-3 to cell-5. As described later, this reduced the vertical corrector magnet (VCM) strength used to correct the orbit.

Survey is the primary source of information for the moves imparted to girders. Sometimes, however, the predicted change in corrector strength can be used as a guide to realignment, as indeed happened when realigning straight-05. realignment moves are monitored by the survey team, showing that imparted moves and survey data are in good agreement, with typical monument discrepancies of less than 15 μm.

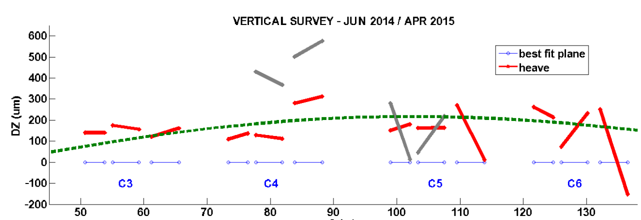

Figure 1: Vertical survey of the Diamond Storage Ring. The red segments join the monuments at girder edges, showing the present situation after the realignment of straight-05, while the gray ones show the state of the machine before it. The dashed green line is a fit to the 148 monument levels, which is used as realignment baseline (see text).

Girder Control

Until mid 2014 girders were individually moved by means of a stand-alone crate connecting a laptop hosting the software to control the 5-axis cam motors that perform a girder move in the corresponding degrees of freedom (sway, yaw, heave, pitch and roll about the s-axis of the girder).

A protection system of Linear Variable Differential Transformers (LVDT) was temporarily mounted to ensure that

HYBRID SEVEN-BEND-ACHROMAT LATTICE FOR THE ADVANCED PHOTON SOURCE UPGRADE*

M. Borland, V. Sajaev, Y. Sun, A. Xiao, ANL, Argonne, IL 60439, USA

Abstract

A hybrid seven-bend-achromat lattice has been designed for the APS upgrade. We describe the design goals, constraints, and methodology, including the choice of beam energy. Magnet strength and spacing is compatible with engineering designs for the magnets, diagnostics, and vacuum system. Dynamic acceptance and local momentum acceptance were simulated using realistic errors, then used to assess workable injection methods and predict beam lifetime. Predicted brightness is two to three orders of magnitude higher than the existing APS storage ring. Pointers are provided to other papers in this conference that cover subjects in more detail.

INTRODUCTION

The Advanced Photon Source [1] is a 7-GeV, 100-mA, 40-sector, 3^{rd} generation storage ring light source with a 1104-m circumference, providing beams to dozens of insertion device (ID) and bending magnet (BM) beamlines simultaneously. After more than 20 years of operation, a major upgrade of the lattice is under consideration. Since APS is an existing facility, a number of constraints must be imposed on any new lattice; these are described in [2].

The basic goal of the lattice design effort is to provide a much lower beam emittance and ultimately an enhancement of x-ray brightness by more than two orders of magnitude for x-rays above 20 keV. The approach is to use a multi-bend achromat (MBA) lattice [3–6], taking advantage of the E^2/M^3 scaling [7, 8] of the natural emittance ϵ_0 with the beam energy E and the number of dipoles per sector M.

After considering various concepts [9–11], it was determined that the ESRF-II "hybrid" concept [11] gave the lowest emittance by a factor of more than two. It also gave sextupoles that are three-to-four times weaker, leading to the adoption of this concept.

APS presently delivers 100 mA in 24 bunches about 75% of the time. For the upgrade, a total current of 200 mA with as few as 48 bunches is required, giving the same single-bunch current of 4.2 mA. The APS MBA lattice has a well-developed impedance model [12] that was used to predict single bunch current limits [13]. It shows that a chromaticity of +5 is needed in both planes to ensure the required single-bunch current.

Bunch-lengthening is important in order to preserve the emittance and improve the Touschek lifetime of low-emittance beams. The APS upgrade will incorporate a higher-harmonic cavity (HHC) for this purpose. Detailed studies of beam dynamics with the HHC have been performed [14, 15], leading to the conclusion that a bunch duration in excess of 50-ps rms is possible.

* Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

DESIGN METHODS

We started our design by scaling the ESRF-II lattice to the APS number of cells and the cell length. Through an iterative process, we developed a matching command file for `elegant` [16] that incorporated limitations from magnetic modeling as well as requirements for space between elements to accommodate vacuum and diagnostic components [17]. Owing to the large gradients and sextupole strengths coupled with the short magnet lengths, the equivalent hard-edge magnet strength limits are length-dependent; these limits are incorporated into the matching using fits to data from magnetic modeling [18]. In the early stages, the matching runs also included the overall ring geometry. The matching benefited from use of `Pelegant`'s parallel simplex optimizer [19, 20],

Wide-ranging tune scans were performed next. For each working point, we evaluated the dynamic acceptance (DA) and local momentum acceptance (LMA) using `Pelegant` for a nominal set of magnet errors assuming symmetrically-powered sextupoles. Multi-objective comparison of the results led to selection of a few promising regions, for which a multi-objective genetic algorithm (MOGA, similar to [21, 22]) was applied based on DA and Touschek lifetime [2, 23]. The algorithm was variously allowed to change the lattice linear optics and the sextupoles, with the sextupoles being given a two-sector translational symmetry (making for 12 sextupole families). Linear optics was varied both by high-level linear optics goals (e.g., tunes, maximum beta functions) and separately by direct variation of gradients; the latter seems more effective. Of the several regions explored, $\nu_x \approx 95.1$ and $\nu_y \approx 36.1$ yielded the best results. The lattice functions are shown in Fig. 1, while lattice properties are listed in Table 1.

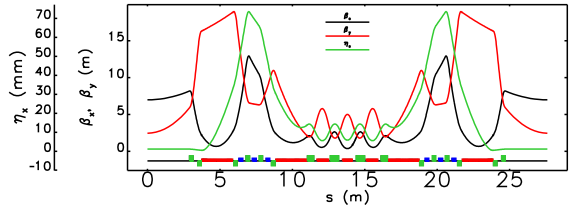

Figure 1: Lattice functions for the APS MBA lattice.

The DA, shown below, is small but suitable for on-axis swap-out injection [24–26]. An alternate lattice supporting accumulation is described in [27]. Figure 2 shows the

CALIBRATION OF FAST FIBER-OPTIC BEAM LOSS MONITORS FOR THE ADVANCED PHOTON SOURCE STORAGE RING SUPERCONDUCTING UNDULATORS*

J. Dooling†, K. Harkay, Y. Ivanyushenkov, V. Sajaev, A. Xiao, ANL, Argonne, IL 60439, USA
A. Vella, University of Illinois, Urbana-Champaign, IL 61801 USA

Abstract

We report on the calibration and use of fast fiber-optic (FO) beam loss monitors (BLMs) in the Advanced Photon Source storage ring (SR). A superconducting undulator prototype (SCU0) has been operating in SR Sector 6 (“ID6”) since the beginning of CY2013, and another undulator SCU1 (a 1.1-m length undulator that is three times the length of SCU0) is scheduled for installation in Sector 1 (“ID1”) in 2015. The SCU0 main coil often quenches during beam dumps. MARS simulations have shown that relatively small beam loss (<1 nC) can lead to temperature excursions sufficient to cause quenching when the SCU0 windings are near critical current. To characterize local beam losses, high-purity fused-silica FO cables were installed in ID6 on the SCU0 chamber transitions and in ID1 where SCU1 will be installed. These BLMs aid in the search for operating modes that protect the SCU structures from beam-loss-induced quenching. In this paper, we describe the BLM calibration process that included deliberate beam dumps at locations of BLMs. We also compare beam dump events where SCU0 did and did not quench.

INTRODUCTION AND MOTIVATION

The Superconducting Undulator Prototype (SCU0) is the first operating SCU in the APS storage ring (SR) [1]. SCU0 is installed in ID6 and has been producing photons for users since early 2013. The success of SCU0 has promoted the construction of SCU1. The length of the undulator in SCU0 is 0.33 m; in SCU1, the undulator length is 1.075 m. Often during beam dumps caused by the Machine Protection System (MPS), SCU0 quenches. Quenching inconveniences the x-ray users and potentially leads to magnet damage.

Simulations with MARS [2] have shown that relatively small beam losses (< 1 nC) can lead to temperature excursions sufficient to cause quenching when the SCU windings are near critical current. An initial model simulated a 1-nC, point beam of 7-GeV electrons striking the top of the vacuum chamber at the upstream end of the SCU0 magnet. With the beam starting upstream at the center of the chamber, this required a vertical angle of 4.3 mrad. Though unrealistically large, this beam trajectory allows a preliminary estimate of temperature rise within the SCU0 magnet windings for a given charge loss. Temperature excursions in the first 5 mm of undulator above the chamber are presented in

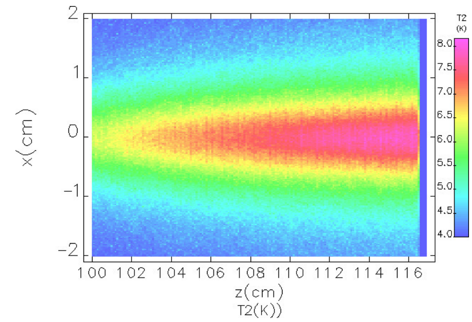

Figure 1: Temperature rise simulated in SCU0 after 1-nC of 7-GeV electrons strike the top of the vacuum chamber at the upstream end of the undulator (z=83 cm).

Figure 1 for an initial temperature of 4.2 K. Modeling with `elegant` [3] in other ID sectors shows that beam dumps deposit most of the beam on the upstream ID chamber transition section, making loss in the SCU0 undulator much more diffuse than indicated in Fig. 1. A temperature rise in excess of 1.9 K can lead to quenching at the SCU0 operating current of 500 A.

We present study and simulation results used to empirically calibrate the fast, fiber optic (FO) BLMs [4] installed in ID6. The calibration is then employed to evaluate losses recorded in ID6 caused by two separate beam dump events. In one case, the event did not lead to a quench of the SCU0 main coil, while in the other case, a quench did occur.

FIBER OPTIC BEAM LOSS MONITOR

Loss of primary, 7-GeV electrons leads to an electromagnetic (EM) shower composed of photons, electrons, and positrons. The high-purity, fused-silica fiber optic (FO) cable bundles are sensitive to all three of these EM shower components (in the case of photons, via pair production). Light is generated within the fibers via Čerenkov radiation as well as Optical Transition Radiation (OTR).

Experimental Description

Once light is generated within a fiber, the fiber provides a guide to an optical detector; in this case, Hamamatsu “subminiature” R7400 photomultiplier tubes (PMTs). Four fiber bundles are positioned in two pairs, one pair upstream of the SCU0 cryostat and the other downstream on the vacuum chamber transitions. The radiator ends of each bundle are placed parallel to the beam trajectory at the nominal beam centerline position; one bundle above and the other below

MULTI-BUNCH STABILITY ANALYSIS OF THE ADVANCED PHOTON SOURCE UPGRADE INCLUDING THE HIGHER-HARMONIC CAVITY*

L. Emery†, M. Borland, T. Berenc and R. Lindberg, ANL, Argonne, IL 60439, USA

Abstract

Multi-bunch stability simulations were done for the very-low-emittance hybrid seven-bend-achromat (H7BA) lattice proposed for the Advanced Photon Source (APS) upgrade. The simulations, performed using `elegant`, were meant to determine whether the long-term wakefields of the higher-order modes (HOMs) of the main 352-MHz cavities will produce an instability. The multi-particle simulations include the important effects of the Higher-Harmonic Cavity (HHC) and the longitudinal impedance of the new vacuum chamber. These realistic simulations show that the HHC provides additional damping in the form of the Landau damping. Still, the HOMs may likely produce a multi-bunch instability which can be cured with more effective HOM damping or a longitudinal feedback system.

INTRODUCTION

The present Advanced Photon Source (APS) ring has sufficient damping to suppress multi-bunch instabilities in the longitudinal and transverse planes. The APS Upgrade ring, with the Hybrid MBA optics [1], will have a larger current of 200 mA, somewhat smaller synchrotron radiation damping, and reduced longitudinal focusing. This will result in a higher tendency for (particularly) longitudinal multi-bunch oscillations generated from the wakefields of the higher-order mode resonances (HOMs) of the 352-MHz single-cell cavities of the APS ring. Even though only 12 of the original 16 cavities will be kept, the HOMs tend to act individually and any one or two of them may cause an instability.

Another difference from the present APS is the presence of a higher-harmonic cavity (HHC) [2], which stretches the bunch to reduce the IBS emittance growth and to make the lifetime longer [3]. The longitudinal dynamics are significantly changed with the HHC, which will provide some Landau damping to any longitudinal centroid oscillations.

To accurately include the HHC, which changes the potential well and makes the motion anharmonic, a tracking simulation must be done. Though we realize that reference [4] gives some analytical predictions, tracking is the most straightforward way to approach this problem (see for example [5]).

The HOM spectrum of each cavity was modeled by [6] from frequency-domain finite element code CST [7]. The ten lowest modes below the cut-off (1640 MHz) of the cavity beam pipe were selected. The spectrum is dominated by one strong HOM around 540 MHz, which has been damped by a factor of 8 in four of the cavities at APS. We assume that for the APS Upgrade all cavities will have this mode damped by the same amount. The other HOMs in the aggregate contribute about the same effect as this damped mode. The cavities were constructed differently from each other to systematically stagger the HOM frequency by at least 210 kHz (a little less than one revolution frequency). However, the frequencies of the individual HOMs are not known exactly and can change during operation. Thus we have a huge parameter space of possible HOM frequencies to explore, which requires a Monte Carlo approach.

We have done preliminary calculations of expected multi-bunch mode growth rates using a normal mode analysis [8], which assumes single-particle bunches and harmonic motion. This calculation method cannot include the effect of the HHC and impedance, which is a severe limitation. However, because the calculation is very fast, one can apply a large number of realizations of the possible 120 HOM frequencies (10 HOMs for each of the 12 cavities), and thereby obtain a cumulative distribution of expected growth rate.

In the section that follows we report on multi-particle tracking that fully includes the HHC and impedance. Here we perform calculations for far fewer HOM-spectrum scenarios.

Multi-bunch beam modes in the transverse plane are considered stable because of the coherent damping from the short-range transverse wake and the deliberately-chosen positive chromaticity. This stability is unaffected by the presence of the HHC. Results from a Monte Carlo calculation with dipole HOMs of randomized frequencies are given in Table 2.

PRELIMINARY MONTE CARLO CALCULATIONS

The stability of the modes were first examined by assuming that each bunch behaves as a point charge. Though we know this is an approximation, we can quickly perform Monte Carlo calculations of possible maximum growth rates and assess the need to make further calculations.

The main lattice parameters that control longitudinal growth rate are given in Table 1 and appear in the following equation for the maximum growth rate of a multi-bunch beam mode due to a single HOM resonance:

$$G = \frac{\alpha_c I_{\text{total}}}{2(E/e)\nu_s}(R_s f_{\text{HOM}}) \exp(-\omega^2\sigma_t^2), \quad (1)$$

where α_c is the momentum compaction, I_{total} is the stored current, E/e is the beam energy in eV units, ν_s is the synchrotron tune, R_s is the (circuit definition) shunt impedance of the monopole HOM, f_{HOM} is the frequency of the HOM

DEVELOPMENT OF AN ABORT KICKER AT APS TO MITIGATE BEAM LOSS-INDUCED QUENCHES OF THE SUPERCONDUCTING UNDULATOR*

Katherine C. Harkay#, Jeffrey C. Dooling, Yury Ivanyushenkov, Robert Laird, Frank R. Lenkszus, Cedric C. Putnam, Vadim Sajaev, Ju Wang, ANL, Argonne, IL 60439, USA

Abstract

The first superconducting undulator (SCU0) at the Advanced Photon Source (APS) has been delivering 80-100 keV photons for user science since January 2013. SCU0 often quenches during beam dumps triggered by the machine protection system (MPS). SCU0 typically recovers quickly after a quench, but SCU1, a second, longer device to be installed in 2015, may take longer to recover. We tested using injection kickers as an abort system to dump the beam away from SCU0 and the planned location of SCU1. An alternate trigger was tested that fires the kickers with MPS. We demonstrated that controlling the beam dump location with kickers can significantly reduce the beam losses at SCU0, as measured by fiber optic (FO) beam loss monitors (BLMs), and can also prevent a quench. A dedicated abort kicker system has been developed based on `elegant` simulations. A spare injection kicker was modified to produce the required waveform. Injection kicker tests, simulations, and the abort kicker design are described. Demonstration of this strategy in APS has implications for the APS Upgrade, where more SCUs are planned.

EXPERIMENTAL TESTS

A superconducting undulator, SCU0, installed in APS was found to quench 80% of the time during beam dumps triggered by MPS. Simulations and beam studies suggest that beam losses > 50 pC in a small coil volume deposit energy sufficient to raise the coil temperature above the NbTi critical temperature [1,2]. Quench recovery is typically fast enough to allow SCU0 to be operated once the beam is restored. The consequences of beam-induced quenches is potentially greater for the longer device, SCU1, since it may require longer recovery time.

FO BLMs [3] were installed in Sector 6 ("ID6") on the SCU0 vacuum chamber (warm) transitions to characterize the beam losses [2]. Horizontal injection kickers (IK) were used to test a beam abort system. The injector kicker pulse waveform is ~2 μs FWHM. In order to kick out a full turn, which is 3.68-μs long, two horizontal injection kickers were used as a pair, with the second kicker timing shifted by half a turn. We used IK1 (in Sector 38) and IK4 (in Sector 40) as a pair, and IK2 and IK3 (both in Sector 39) as another pair. The kickers were set to their maximum peak kicks of ~1.5 mrad and it was verified that the entire beam was lost. The studies were repeated for the nominal 102 mA stored in 24 and 324 uniformly-spaced bunches, two APS operating modes. In Table 1, the BLM integrated loss charge for an MPS trip is compared to that using the kickers. The results demonstrate that controlling the beam loss location with kickers can significantly reduce the beam losses at SCU0.

To test whether lower ID6 beam losses can prevent a quench, 102 mA were stored in 24 bunches and SCU0 was powered to a typical main coil current of 650 A. IK1 and IK4 were fired, dumping the entire beam, and SCU0 did not quench. In this case, the losses at SCU0 were below the BLM measurement threshold.

Table 1: Total Uncalibrated ID6 BLM Charge, Comparing MPS Beam Dumps with Injection Kickers

Dump type	24 bunches (nC)	324 bunches (nC)
MPS	444	480
IK1+IK4	1	6
IK2+IK3	30	44

BEAM ABORT SYSTEM

The present method of dumping the beam during an MPS trip is to interrupt the rf amplifier drive for 100 ms, which causes the beam to move towards the chamber wall as the rf field decays and the beam loses energy to synchrotron radiation. The beam is lost mostly on the smallest aperture, which is the ID4 vacuum chamber [4], but beam losses are also clearly observed at ID6 where SCU0 is installed. To control the loss location at the level required, a kicker will be employed to dump the beam away from ID chambers.

While the injection kicker tests were a successful proof of principle, the loss distribution is not ideal, in that beam is lost in ID1, the planned location of SCU1 (see Model validation). The beam abort system should limit losses at both SCU0 and SCU1. Also, injection kicker abort configurations are incompatible with top-up operation.

The new beam abort system will use a dedicated horizontal kicker in the Sector 36 rf straight section, that stays charged during user operation, and whose discharge is triggered by MPS. Should the abort kicker fail to fire, MPS would dump the beam as usual. Using a peak kick ≥ 1 mrad, the entire beam is lost on the chamber walls within a few turns. Beam losses are mainly on the thick septum chamber in the injection straight section [5].

STATUS OF THE APS UPGRADE PROJECT*

S. Henderson#
APS Upgrade Project, Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

A concept for an upgrade to the Advanced Photon Source based on a multi-bend achromat lattice is being developed at Argonne National Laboratory. An MBA upgrade to the APS will reduce the horizontal emittance by a factor of ~50. Coupled with superconducting undulators, the APS-U brightness will be two to three orders of magnitude beyond that which is available today at the APS.

INTRODUCTION

There is world-wide interest [1] in constructing 4th generation synchrotron radiation facilities with greatly reduced emittance based on multi-bend achromat (MBA) lattices [2]. MBA lattices promise to reduce the achievable horizontal emittance in electron storage rings by large factors, due to the favourable scaling of emittance [3] with the number of dipole magnets.

$$\varepsilon_x \propto \frac{E^2}{N_d^3} \quad (1)$$

Argonne National laboratory is developing a concept for a MBA upgrade to the Advanced Photon Source based on a multi-bend achromat lattice. This concept is the centerpiece of the Advanced Photon Source Upgrade Project (APS-U), which includes in addition to an upgrade to the storage ring, new insertion devices, front-ends and a suite of new and upgraded beamlines and associated optics and detector improvements.

APS-U CONCEPT AND PERFORMANCE

A conceptual design of the APS-U Project has been developed. The concept includes the following elements:

- A new 6 GeV MBA high-brightness storage ring in the existing APS tunnel
- Doubling of the ring stored beam current to 200 mA
- New insertion devices optimized for brightness and flux at the reduced storage ring energy
- New and upgraded beamline front-end systems of a common design for maximum flexibility
- A suite of new and upgraded beamlines designed for best-in-class performance with the high-brightness source
- Optics and detector improvements for remaning beamlines to take full advantage of MBA source properties
- Improved electron and photon stability

Table 1 compares the APS Upgrade storage ring design and performance parameters to those of the APS in present operation. The APS-U MBA lattice (described in more detail in [4]) is a seven-bend design based on the ESRF hybrid lattice concept [5]. The beam energy is reduced from the present 7 GeV to 6 GeV in order to further reduce the horizontal emittance. The beam current will be twice that which is routinely operated today.

Two operating modes are envisioned. The first mode is optimized for the highest possible brightness, and includes 324 regularly spaced bunches of 0.6 mA per bunch in a “flat-beam” configuration with 10% emittance coupling. A second mode – the timing mode – is optimized for a smaller number of equally spaced bunches with higher bunch current of 4.2 mA in a round-beam configuration with full emittance coupling to achieve an acceptable Touschek beam lifetime. The high-brightness mode achieves a horizontal emittance of 68 pm-rad, which is a factor of approximately 50 times smaller than present operation.

The brightness at 8 keV is a factor of 80 larger than today; the brightness at 20 keV is a factor of 340 larger than today, and that at 80 keV is a factor of 380 larger than today. The available coherent flux is higher by the same factors. The single bunch brightness is a factor of 25 greater than that achieved today.

Since the beam energy is reduced, undulator periods should be reduced accordingly to maintain similar first harmonic energies. In addition, APS-U will incorporate a suite of superconducting undulators, building upon recent developments of the last several years [6]. Front-ends will be upgraded to incorporate the recent High Heat Load Front-end concept that has been developed and successfully deployed at APS [7].

An MBA lattice at the APS opens new capabilities that don’t exist today in coherence techniques with high energy x-rays. Beamline investments, through an open proposal process, will ensure international competiveness of the beamline suite at the time of project completion and beyond. Targeted improvements to beamline optics are also incorporated into the concept to ensure that beamlines are positioned to take advantage of the MBA source properties.

Beam stability requirements are quite stringent [8]. Electron and photon stability requirements impact the engineering design at every level.

APS-U CONCEPTUAL DESIGN

Lattice

The APS-U lattice [4] is designed to optimize hard x-ray brightness by minimizing horizontal emittance in a MBA lattice. The lattice is composed of 40 identical sectors, each of which contains seven bending magnets.

DEVELOPMENT AND PERFORMANCE OF 1.1-M LONG SUPERCONDUCTING UNDULATOR AT THE ADVANCED PHOTON SOURCE*

Y. Ivanyushenkov#, C. Doose, J. Fuerst, K. Harkay, Q. Hasse, M. Kasa, D. Skiadopoulos, E.M. Trakhtenberg, Y. Shiroyanagi, E. Gluskin, ANL, Argonne, IL 60439, USA

Abstract

Development of superconducting undulators continues at the Advanced Photon Source (APS). The second superconducting undulator, SCU1, has been built and prepared for installation in the storage ring at the APS. This undulator has a 1.1-m long superconducting magnet and utilizes an improved version of the cryostat of the first superconducting undulator, SCU0. The results of the cold test of the SCU1 are presented in this paper.

INTRODUCTION

Superconducting undulators outperform other undulator technologies in terms of undulator peak field for a given period length and magnetic gap. The higher undulator field lead to higher photon fluxes, especially at higher photon energies. The advantage of superconducting undulator technology has been confirmed at the APS by operational performance of the SCU0. This undulator with a 0.3-m long magnet generates higher photon flux above 80 keV than a 2.4-m long hybrid undulator [1]. The next logical step was to increase the length of the SCU magnet. Such a milestone has been achieved with SCU1 – the second superconducting undulator developed at the APS. This paper gives a short description of the SCU1 and presents the cold test results of the undulator in detail.

SCU1 PARAMETERS

Parameters of SCU1 are listed in Table 1. The period length of 18 mm was chosen to have continuous photon energy coverage above 40 keV. The length of the magnet is 1.1 m – more than 3 times the length of the SCU0 magnet.

Table 1: Main Design Parameters of SCU1

Parameter	Value
Cryostat length, m	2.06
Magnetic length, m	1.1
Undulator period, mm	18
Magnetic gap, mm	9.5
Beam vacuum chamber vertical aperture, mm	7.2
Undulator peak field, T	0.97
Undulator parameter, K	1.63
Photon energy at fundamental, keV	11.7-25

#yury@aps.anl.gov

SCU1 DESIGN

Cryostat

The SCU1 uses a cryostat, which is an improved copy of the SCU0 cryostat [2]. Modifications include the addition of optical windows to the cryostat vacuum vessel that allow direct observation and measurement of the cold mass vertical position inside the cryostat. Also, several thermal links were added to improve cooling of the cold mass support frame. Kevlar strings that support the cold mass in the cryostat have been improved as well.

Magnet

The SCU1 magnet is continuously wound with a superconducting wire onto a low-carbon steel former, or a core (see Fig. 1). The winding scheme is different from the one used in the SCU0 magnet. Instead of first winding all odd grooves and then making a 180-degree turn and winding back all even grooves, the turn is now made after winding each groove. In the new core design, magnetic poles are left only on the face side of the core and the poles on the other sides are non-magnetic. Also, three liquid helium (LHe) channels in the SCU0 design are replaced with a larger diameter single channel in the SCU1 core. As a result of the design simplification, the cost of a 1.1-m SCU1 core is about the same as that of a 0.3-m long SCU0 core. It is worth highlighting that the SCU1 cores were fabricated to a very high level of precision. The measured groove dimensions were within 30 μm rms.

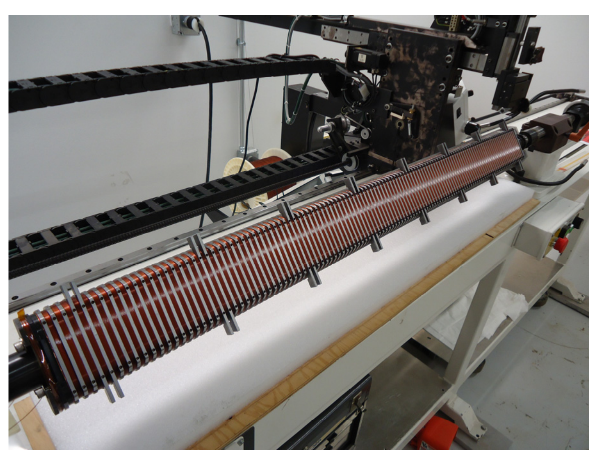

Figure 1: SCU1 magnet core on winding machine.

Similar to SCU0, a commercially available NbTi superconducting round wire is used in the SCU1 magnet, except a wire diameter of 0.6 mm is chosen instead of the 0.7 mm diameter used in the SCU0. The smaller wire size

FAST INJECTION SYSTEM R&D FOR THE APS UPGRADE*

F. Lenkszus, A. Xiao, J. Carwardine, A. Cours, G. Decker, L. Morrison, X. Sun, J. Wang, F. Westferro, C.Y. Yao, ANL, Argonne, IL 60439, USA
A. Krasnykh, SLAC, Menlo Park, CA 94025 USA

Abstract

The MBA upgrade for the APS will operate with bunch swap out and vertical on-axis injection. The planned 324 bunch fill pattern places difficult demands on the injection and extraction kickers. The present concept uses dual stripline kickers driven by high voltage (HV) pulsers. Minimizing perturbation on adjacent bunches requires very fast rise and fall times with relatively narrow (< 20 ns), 15 kV pulses. To achieve these requirements, a multifaceted R&D program has been initiated. The R&D includes the HV pulser, stripline kicker and HV feedthrough. The requirements for injection and extraction, progress on prototype development, and results of our HV pulser investigations are discussed.

INTRODUCTION

The Advanced Photon Source (APS) storage ring will be upgraded to use a multiband achromat (MBA) lattice to provide enhanced hard x-ray brightness and coherent flux to beam-lines [1]. The MBA lattice will operate with bunch swap out and vertical on-axis injection. In this scheme, a target bunch will be extracted to a beam dump and the resulting empty RF bucket filled with a replacement bunch from the APS injectors. The planned 324 bunch fill pattern with its 11.4 nanosecond bunch spacing places very demanding requirements on the extraction and injection systems to minimize perturbations to the stored bunches immediately upstream and downstream of the target bunch. The extraction and injection sections will each consist of four dual blade small-aperture stripline kickers with each kicker driven by a fast dual output high voltage pulser. In addition, the injection section will include a Lambertson septum. Parameters for the injection/extraction sections are listed in Table 1.

To address these requirements, an R&D program is underway which includes the kickers, fast high voltage pulsers and high voltage feedthroughs.

KICKER

Swap-out injection will require pulsed deflecting kickers fast enough to select individual bunches spaced as closely as 11.4 ns without significantly disturbing neighboring bunches.

*Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

Table 1: Injection/Extraction Parameters

Key Parameters		
Total Kick Angle	2.88	mrad
Number of Kickers	4	
Kicker Strength	1	mrad/m
Length of Each Kicker	72	cm
Blade to Blade Voltage	30	kV
Vertical Aperture	9	mm
Minimum Bunch Spacing	11.4	ns
Maximum Residual kick to Stored Beam	< 2.5	% amplitude
Pulse Rise Time (10%-90%)	4.5	ns
Pulse Width (90%-90%)	5.9	ns
Pulse Fall Time (90%-10%)	4.5	ns

Physics

Impedance-matching plays an essential role in achieving maximum kicker strength, reducing local high voltage concentration, which can lead to breakdown, and minimizing beam impedances. The optimization strategy is to match the differential impedance as close as possible to a 50 ohm line impedance, while allowing some mismatch in the common mode impedance [2]. A "vaned" body geometry has been adopted to provide better common mode impedance matching, while "D" shaped blades are used to improve field uniformity within the good field region. Figure 1 shows the cross section of the kicker.

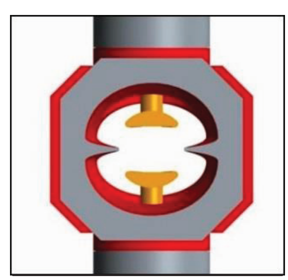

Figure 1: Kicker cross section.

The kicker has tapered end sections to better match the impedance to the feedthroughs. The design has been optimized by running a multi-objective optimization process with a 2D simulation program. A 3D simulation

PRELIMINARY EXPERIMENTAL INVESTIGATION OF QUASI ACHROMAT SCHEME AT ADVANCED PHOTON SOURCE*

Yipeng Sun†, Hairong Shang, ANL, Argonne, IL 60439, USA

Abstract

Next generation storage rings require weaker dipole magnets and stronger quadrupole focusing to achieve very low emittance. To suppress the geometric and chromatic optics aberrations introduced by the strong sextupoles, achromat and quasi achromat schemes are applied in the lattice design to improve the beam dynamics performance. In this paper, some preliminary experimental investigation of the quasi achromat scheme at the Advanced Photon Source (APS) are presented. Three different operation lattices are compared on their beam dynamics performance. Although none of these operation lattices achieve ideal quasi achromat condition, they have certain relevant features. It is observed that fewer resonances are present in the nominal operation lattice which is most close to quasi achromat required conditions.

OVERVIEW

First-order and second-order achromats [1] have been applied in particle accelerators for a long time. The geometric and chromatic aberrations are eliminated by adopting integer betatron phase advance in certain beamlines. Similar third-order achromat design approaches were developed analytically and numerically [2] [3], where the concepts of repetitive identical cells and integer phase advance are used. For the next generation storage ring lattice designs, a third order geometric achromat is proposed with the assistance of harmonic sextupoles [4]. Quasi-achromat [5] is also proposed, which aims to minimize terms that are most relevant to the beam dynamics performance such as dynamic acceptance (DA) and lifetime. ESRF is proposing a hybrid multi-bend achromat (MBA) upgrade where the local cancellation scheme of $-I$ phase separation is employed [6]. Both quasi-achromat schemes and local cancellation schemes [6] are considered in the Advanced Photon Source (APS) MBA upgrade lattice design studies [5] [7].

In the lattice design studies, it is observed that fewer resonances are present in the achromat and quasi-achromat schemes. To investigate the beam dynamics performance of the achromat and quasi-achromat schemes, some preliminary experimental studies are performed at the APS storage ring. The APS storage ring is a third generation synchrotron-radiation light source, with a circumference of 1104 meters and an effective beam emittance of 3.13 nm. Three different operation lattices with different features have been compared. These lattices are the nominal lattice, hybrid lattice, and reduced horizontal beam size (RHB) operation lattice. For the APS storage ring nominal lattice, the linear optics in one of 40 identical sectors is shown in Fig. 1 where the starting and ending point are the insertion device (ID) center. The betatron phase advance is 0.905 in horizontal plane and 0.481 in vertical plane, which are close to the quasi-achromat condition [5]. In the horizontal plane, the total betatron phase advance is equal to integer every 10 repetitive cells. In the following sections, some experimental results are discussed. The bunch fill pattern is 24 bunches that are evenly distributed in the storage ring.

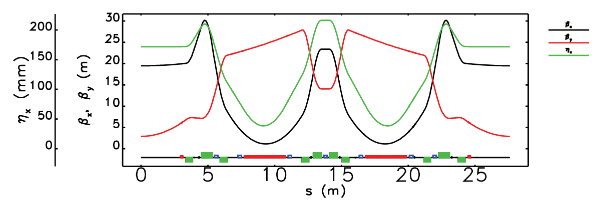

Figure 1: Twiss parameters in one arc section of APS storage ring. Green blocks represent quadrupoles, red blocks represent dipoles, and blue blocks represent sextupoles.

NOMINAL OPERATION LATTICE

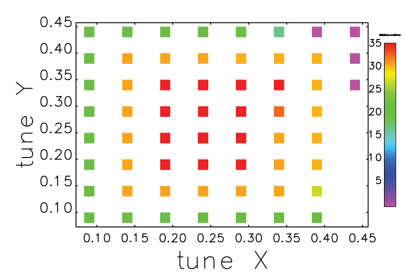

Figure 2: Stored beam current on ν_x-ν_y space during fractional tunes scan on nominal APS lattice.

The nominal APS operation lattice has 40 identical cells, with the optics in one such cell shown in Fig. 1. The standard operation mode of the APS storage ring has a total beam current of 102 mA, evenly distributed in 24 single bunches with top-up injection. Before the latest APS run, both the linear and nonlinear optics has a periodicity of 40. In the latest run, a smaller aperture ID vacuum chamber is installed at ID4, which has impact on injection efficiency and lifetime. It is noted that the minimum physical aperture of APS ring is located at ID4. The sextupoles in two sectors besides this ID chamber are optimized to manipulate the stored beam transverse phase space [8]. The nonlinear optics periodicity is slightly affected in these two sectors. The chromaticity is corrected to +2 in both horizontal and vertical planes. In Fig. 2 a stored beam current contour map

ALTERNATE LATTICE DESIGN FOR ADVANCED PHOTON SOURCE MULTI-BEND ACHROMAT UPGRADE*

Yipeng Sun†, Michael Borland, ANL, Argonne, IL 60439, USA

Abstract

A 67-pm hybrid-seven-bend achromat (H7BA) lattice is proposed for a future Advanced Photon Source (APS) multi-bend-achromat (MBA) upgrade. This lattice requires use of a swap-out (on-axis) injection scheme. Alternate lattice design work has also been performed to achieve better beam dynamics performance than the nominal APS MBA lattice, in order to allow beam accumulation. One of such alternate H7BA lattice designs, which still targets a very low emittance of 76 pm, is discussed in this paper. With these lattices, existing APS injector complex can be employed without the requirement of a very high charge operation. Studies show that an emittance below 76 pm can be achieved with the employment of reverse bends in an alternate lattice. We discuss the predicted performance and requirements for these lattices and compare them to the nominal lattice.

OVERVIEW ON ALTERNATIVE LATTICE DEVELOPMENT

In the nominal lattice design [1] for the APS Multi-Bend Achromat (MBA) upgrade, the equilibrium emittance is pushed to the lowest achievable value employing reasonable magnet technology. To this end, seven dipole magnets with transverse or longitudinal gradients, plus strong quadrupole focusing are adopted in each arc cell. The associated strong nonlinearities make the dynamic acceptance not large enough for beam accumulation given the large injected beam size and allowing for a reasonable septum thickness. On-axis swap-out injection seems to be the only workable method for this lattice.

Lattice alternatives have been explored with relaxed goals for the emittance, which may achieve better beam dynamics performance than the nominal lattice, plus possibility for off-axis accumulation. Off-axis accumulation has several advantages. It requires minimal changes from existing systems (injectors, control, timing, etc.). It does not require new techniques as for the on-axis injection scheme (very fast kickers, high-charge-booster, beam dump, etc.). However, it may require better magnet quality, alignment precision, power supply stability, and beam trajectory/orbit control. It may also require additional octupoles and power supplies for these magnets, in order to achieve larger acceptance. Finally, using accumulation restricts the use of small horizontal gaps in IDs (insertion device).

Three different types of lattice structure, from five-bend achromat (5BA) to eight-bend achromat (8BA), were investigated and compared in terms of their requirements on the techinical systems and their beam dynamics performance:

- MAX-IV style: uniform TME cells [2]
- ESRF-II hybrid-lattice style: dispersion bump with -I separation [3]
- SIRIUS-inspired [4]: combination of MAX-IV and ESRF-II

Reverse dipole fields in focusing quadrupole magnets [5] are also considered and adopted in the lattice design. Of all these lattices investigated, a Hybrid-7BA lattice design appears to be the most promising in terms of allowing for the possibility of off-axis accumulation. This design is presented in some detail below. The general lattice design considerations and constraints are discussed in [1].

ALTERNATE H7BA LATTICE DESIGN

Magnets

To generate the dispersion bump more efficiently than uniform dipole magnets and achieve a smaller equilibrium emittance, two 6-section longitudinal gradient dipoles (LGD) are employed at both sides of the dispersion bump. A uniform dipole section length of 0.27 m is adopted. The maximum dipole field is 0.45 T in the LGDs, whereas it is 0.73 T in the central dipoles with transverse gradient. The maximum quadrupole gradient is 82 T/m. All the quadrupole magnets are within engineering design limits with more than a 10% margin, while all the sextupole magnets are within engineering design limits with more than a 20% margin. The maximum pole-tip fields are: 1 T for quadrupoles; 0.6 T for sextupoles; 0.3 T for octupoles. Similar to the nominal lattice design, a 3-pole-wiggler is placed in the center of each cell, to be used for bending magnet beamlines. In each cell, six focusing quadrupole magnets are integrated with reverse dipole fields—a feature not yet included in the nominal lattice—to further optimize the emittance and dispersion. The total number of magnets (dipoles, quadrupoles and sextupoles) is the same as used in the nominal lattice design.

Comparison with Nominal Lattice

Compared to the nominal lattice, the alternate H7BA lattice design has three potential advantages:

- Uniform-section-length dipole magnets are easier to produce and operate.
- Each cell has 2.5 meters of free space available for other accelerator components (e.g., injection kickers, skew quadrupoles, steering magnets, etc.).
- Four additional 0.32 m spaces are available to install ocutpoles near the dispersion peak in each cell.
- The ID straight length increased from 5.8 m to 6.1 m.

ADVANCED PHOTON SOURCE INJECTION RELATED SIMULATION AND MEASUREMENT*

Yipeng Sun†, ANL, Argonne, IL 60439, USA

Abstract

Injection efficiency is one of the key factors in ensuring successful operation of storage ring light sources. In this paper, injection simulation and measurement studies at the Advanced Photon Source will be presented. The tracking simulations and measurements are compared in terms of the dynamic aperture and injection efficiency. Injection efficiency is also measured on the betatron tunes space and on different stored beam orbits.

OVERVIEW

This section introduces the basic concepts for the simulation and measurement studies discussed in the following sections, including: injection scheme, septum position, stored/injected beam separation, smaller measured ID4 physical aperture, definition of measured injection efficiency, etc..

The main ring at the Advanced Photon Source (APS) is a third-generation synchrotron radiation light source research facility. The circumference is 1104 meters and the beam effective emittance is 3.13 nm. The APS accelerator complex is composed of electron guns, linac, transport lines, a particle accumulator ring (PAR), a booster, and a storage ring. The electron beam is accelerated from 450 MeV to 7 GeV in the booster synchrotron over a half second. The electron beam is then injected into the 7 GeV storage ring through a booster-to-storage ring transport line (BTS). The linear optics in one of 40 sectors at APS storage ring is shown in Figure 1. A thick septum, a thin septum and four injection kickers (IK1, IK2, IK3, IK4) are employed in two sectors of the ring as the injection system. Injection efficiency into the storage ring is a key parameter to ensure successful operations of the light source.

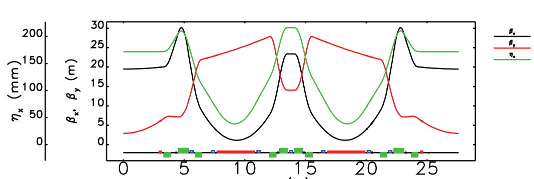

Figure 1: Twiss parameters in one arc section of APS storage ring. Green blocks represent quadrupoles, red blocks represent dipoles, and blue blocks represent sextupoles.

The closed injection bump is shown by the black curve in Fig. 2. The injection kickers are optimized for better injection efficiency and acceptable impact on the stored beam, as a result of which the injection ocsillation is shared between the stored and injected beams. Figure 2 shows trajectories of the stored (red curve) and injected (green curve) bunches using the non-closed bump. Beam separation between injected beam and stored beam closed orbit (without injection bump) at the septum location was set to 22 mm. For closed-bump injection, the stored bunch is not disturbed (black curve), but the oscillation of injected bunch is larger, shown by the blue curve in Fig. 2.

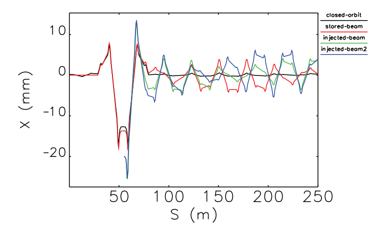

Figure 2: Beam trajectories for injection. Black: stored beam, closed bump. Blue: injected beam, closed bump. Red: stored beam, non-closed bump. Green: injected beam, non-closed bump. The septum magnet is at 56 m.

The position of the septum magnet with respect to the closed orbit of the stored beam was measured and is shown in Fig. 3. In Fig. 3 the electron beam lifetime (in minutes) is plotted in x-y space at the septum. It is observed that the septum is at x=-17 mm. Good agreement is achieved between two measurement methods, which are based on steering correctors, and BPM set points (plus orbit feedback) respectively. The measurement also agrees with the design.

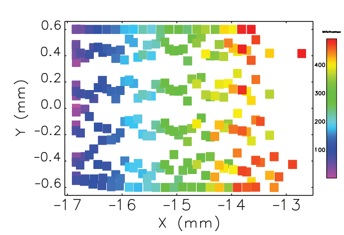

Figure 3: Beam-based measurement of the septum magnet position relative to stored beam. Color map showing the beam lifetime measured in minutes (5 to 500 minutes).

The minimum physical aperture of Advanced Photon Source is at ID4, which was ± 15 mm in x, and ± 2.5 mm in y. In the latest run, a smaller aperture vacuum chamber is installed at ID4. Beam-based physical aperture measurements show that ID4 now has a real aperture of roughly ± 13 mm in x, and ± 1.5 mm in y. Injection efficiency was

RESULTS OF MAGNETIC MEASUREMENTS OF 2.8 m LONG VERTICALLY POLARIZING UNDULATOR WITH THE DYNAMIC COMPENSATION OF MAGNETIC FORCES*

Isaac Vasserman, Nikita Strelnikov, Emil Trakhtenberg, Joseph Xu, Efim Gluskin
ANL, Argonne, IL 60439, USA

Abstract

A novel undulator prototype with a horizontal magnetic field and dynamic compensation of magnetic forces has recently been developed at the Advanced Photon Source (APS) as a part of the LCLS-II R&D program. This undulator should meet stringent requirements for any LCLS-II insertion device. These requirements include limits on the field integrals and phase errors for all operational gaps, and the reproducibility and accuracy of the gap settings. Extensive mechanical testing has resulted in a performance that meets the requirements on the undulator gap setting. The magnetic tuning has been accomplished by applying a set of magnetic shims. As a result, the satisfactory performance of the undulator prototype has been demonstrated.

INTRODUCTION

The absolute majority of synchrotron radiation (SR) sources, including free electron lasers (FEL), utilize insertion devices (IDs) with a vertically oriented magnetic field. This preferential direction is the result of the strong asymmetry – the horizontal size is much larger than the vertical one – of the electron beam cross-section in the storage rings, which is the main source of synchrotron radiation. Although e-beam in FELs is quite symmetric in the transverse plane, ID designers have not taken real advantage of it thus far. This status quo could soon be changed because of recent advancements in the design of ultra-small emittance storage rings. Such machines promise to operate with round e-beams and execute on-axis injection. Therefore, the development of novel planar IDs with horizontal magnetic fields becomes a practical matter.

There are at least two major advantages of rotating ID geometry by 90 degrees. One is related to the rotation of the polarization plane of emitted radiation, which results in the transformation of monochromators and experimental set-ups to the "gravity neutral" systems. In many cases it would significantly simplify the construction and operation of these set-ups. The second advantage is also related to the "gravity neutral" design, but now applies to the undulator mechanical system. When such a design is combined with the magnetic force compensation system, the ID gap drive mechanism could become quite compact without sacrificing stringent requirements on the accuracy and reproducibility of the ID gap control.

Currently all FELs around the world utilize the traditional approach in the design of ID gap drive mechanisms, regardless of the type of IDs: out of vacuum, in-vacuum, APPLE-type, etc. These designs are loaded with very strong, often bulky beams that are able to withstand tremendous magnetic forces without noticeable distortions, and with very precise mechanical components that permit control of the ID magnetic gap value at a micron level. Typically the fabrication of such devices requires unique machine tools that can process several meter beams within a few microns of precision. Recently, after more than a decade of developments, European XFEL successfully constructed several dozen 5-m long IDs with a very sophisticated ID drive system that meets XFEL specifications [1]. SACLA XFEL in Japan has followed the design of in-vacuum IDs developed for the Spring-8 storage ring [2], and FERMI FEL in Trieste, Italy [3] is using APPLE-type IDs for its soft x-ray FEL. Newly built XFEL in Pohang, South Korea is adopting European XFEL ID design [4], and Swiss FEL follows SACLA's footsteps by choosing in-vacuum IDs [5].
The alternative ID design based on the "gravity neutral" concept with the dynamic compensation of magnetic forces has recently been developed at the APS.

First, a short prototype (847-mm-long) of an ID with the dynamic compensation of magnetic forces was designed, built and tested at the APS of the Argonne National Laboratory. The ID magnetic forces were compensated by the set of conical springs with exponential force change placed along the ID strong back [6]. Based on the magnetic measurements of the ID effective magnetic field (Beff), it has been demonstrated that the magnetic gaps within an operating range were controlled accurately and reproducibly within ± 1 micron. Successful tests of this ID prototype led to the design of a 2.8-m long device based on the same concept. Schematics of the 2.8-meter long prototype are shown in Fig. 1. There were load cells attached to the actuators to control the uncompensated force remaining due to preload and errors in matching the magnetic force and spring force.

LCLS INJECTOR LASER MODULATION TO IMPROVE FEL OPERATION EFFICIENCY AND PERFORMANCE

S. Li*, D. Bohler, J. Corbett, A.S. Fisher, S. Gilevich, Z. Huang, A, Li, D. Ratner, J. Robinson, F. Zhou, SLAC, Menlo Park, CA 94025, USA

Abstract

In the Linear Coherent Light Source (LCLS) at SLAC, the injector laser plays an important role as the source of the electron beam for the Free Electron Laser (FEL). The injector laser strikes a copper photocathode which emits photo-electrons due to photo-electric effect [1]. The emittance of the electron beam is highly related to the transverse shape of the injector laser. Currently the LCLS injector laser has hot spots that degrade the FEL performance. The goal of this project is to use adaptive optics to modulate the transverse shape of the injector laser, in order to produce a desired shape of electron beam. With a more controllable electron transverse profile, we can achieve lower emittance for the FEL, improve the FEL performance and operation reliability. We first present various options for adaptive optics and damage test results. Then we will discuss the shaping process with an iterative algorithm to achieve the desired shape, characterized by Zernike polynomial deconstruction.

INTRODUCTION

The injector laser of a Free Electron Laser (FEL) is a source to produce electron beams which are then accelerated to relativistic speed and generate coherent radiation in the undulator. At Linear Coherent Light Source (LCLS) at SLAC, the injector laser consists of a Ti:Sapphire laser system, producing 2 ps laser pulses at 760 nm wavelength. The infrared laser is then converted to ultraviolet wavelength (253 nm) via nonlinear process in a frequency tripler. The laser strikes a copper photocathode which emits photo-electrons due to the photo-electric effect [1].

Currently the LCLS injector laser has hot spots in its transverse profile. Figure 1 is a typical example of the transverse profile of the LCLS injector laser (left) and electron beam (right) near cathode. Non-uniformities in laser profile and cathode quantum efficiency lead to the non-uniformities in electron beam, which increase the electron beam emittance in the downstream linac and FEL. Lower emittance electron beam can enhance FEL performance. Other studies have shown certain types of laser transverse profile lead to lower electron emittance [2, 3]. Therefore, with adaptive optics, we can distinguish two major advantages. One is to remove non-uniformities in the electron beam, and the other is to shape the beam into an arbitrary profile [4].

In this paper, we present various options for the adaptive optics to modulate the injector laser, and show damage test results for these materials. We also discuss the shaping process with an iterative algorithm, in which Zernike polynomial reconstruction is used to characterize the transverse shape of the laser.

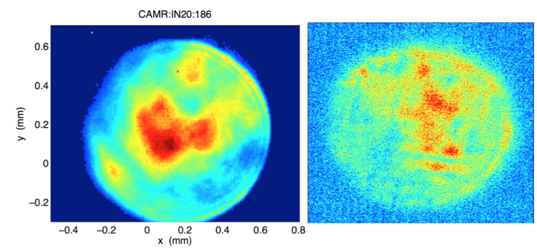

Figure 1: Example of LCLS injector laser transverse profile (left). Example of electron beam transverse profile (right).

ADAPTIVE OPTICS

There are various options for adaptive optics. We have considered Digital Micro-mirror Device (DMD), liquid crystal Spatial Light Modulator (SLM), and Deformable Mirror (DM). These materials have different properties and work in different wavelength ranges. In this section we will briefly describe how each device works and present damage test results.

Infrared (IR) Beam: DMD and SLM

The diagram of the damage test is shown in Fig. 2. The test was done at the HOLE laser lab at SLAC, with a laser identical to the LCLS injector laser. The laser is a 2 ps pulsed laser at 760 nm wavelength 120 Hz. The waveplate and polarizer allow us to tune the laser beam energy. The iris cuts the beam and is imaged through a lens onto the sample plane. The beam energy varies from 20 μJ to 1 mJ. At the image plane we replaced the camera with the sample and let the laser hit the chip at different spots for an exposure time up to 40 minutes. We gradually increased the beam energy and moved the sample across the surface until we saw visible damage on the pixels. Then we took the sample to the microscope lab and looked at the damage under microscope.

The Texas Instrument DLP7000 is a DMD made of an array of micro-mirrors. When powered on, each individual micro-mirror can deflect at ±12° angle. The shaping process is done by grouping individual micro-mirrors to macro-mirrors which consist of, for example, 5×5 micro-mirrors. For a certain macro-mirror, we can randomly turn off a number of micro-mirrors according to the ratio of cur-

SIMULATION STUDY OF INJECTION PERFORMANCE FOR THE ADVANCED PHOTON SOURCE UPGRADE*

A. Xiao†, V. Sajaev, ANL, Argonne, IL 60439, USA

Abstract

A vertical on-axis injection scheme has been proposed for the hybrid seven-bend-achromat (H7BA) [1] Advanced Photon Source upgrade (APSU) lattice. In order to evaluate the injection performance, various errors, such as injection beam jitter, optical mismatch and errors, and injection element errors have been investigated and their significance has been discovered. Injection efficiency is then simulated under different error levels. Based on these simulation results, specifications and an error-budget for individual systems have been defined.

INTRODUCTION

A hybrid seven-bend-achromat (H7BA) lattice has been designed for the APSU. It features a 67 pm natural emittance and its brightness exceeds today's APS by two to three orders of magnitude. Strong nonlinear effects associated with the design present a great challenge to the injection design. Based on investigations made for several different injection configurations, an on-axis single sector "swap-out" vertical injection scheme was adopted, and the injection performance was calculated including various machine errors.

The change of Courant-Snyder invariant $\Delta A_u = A_u - A_{u,0}$ is used to determine quantitatively which injection errors dominate, ($A_u = \gamma_u u^2 + 2\alpha_u uu' + \beta_u u'^2$, where u stands for x or y, γ_u, α_u and β_u are corresponding optical function at the injection point, $A_{u,0}$ is the value in ideal conditions). For an error that causes equivalent emittance increase, A_u stands for the equivalent emittance with errors; for an error that causes beam centroid motion, A_u is equivalent to the amplitude of the motion, as $\Delta u = \sqrt{\Delta A_u \beta_u}$.

This paper first describes the types of errors that were included in the injection study. It then gives calculated ΔA_u under various error levels, which are chosen based on our past operational experience and on assumptions about the new hardware systems. The range of ΔA_u is obtained by summarizing contributions from all types of errors, and the significance of each sub-system error is identified. The injection performance is studied by simulating injection efficiency at different ΔA_u levels. The specifications and an error-budget for individual systems are given based on the overall injection performance requirement. To validate the obtained specifications, a simulation that includes shot-to-shot variations of various parameters is done, and results are given at the end. The injection efficiency is simulated by 1000-turn tracking a bunch consisting of 2000 particles with a distribution corresponding to that of the booster. Synchrotron radiation, apertures, rf systems, etc. are included in tracking.

TYPE OF INJECTION ERRORS

Many imperfections could occur during injection:

Transverse Optical Function Mismatch

This is a systematic error. Because of the filamentation process after injection, a transversely mismatched injected bunch is equivalent to a matched bunch with emittance ellipse enclosing the entire mismatched bunch ellipse, as seen in Fig. 1. The emittance increase $\Delta A = A - A_0$ depends on the magnet strength errors in the booster to storage ring (BTS) transport line, and on how well the optical functions can be corrected.

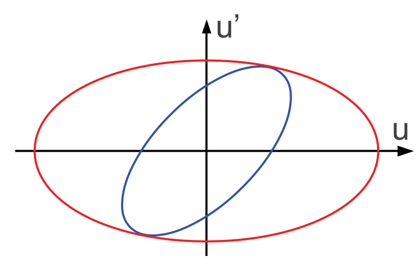

Figure 1: Optical function mismatch at the injection point. Blue - mismatched injected beam emittance A_0; red - equivalent injected beam emittance A.

To evaluate how ΔA varies versus the magnet strength error level, the current APS BTS line design, with an arbitrary matrix added at the end to match optical functions at the injection point, is used as the simulation model. Mismatched optical functions and associated ΔA are calculated at three magnet strength error levels: 1%, 2%, and 3%. 5000 uniformly distributed random cases are simulated for each error level, and the maximum of ΔA for all cases with beta function error of less than 5%, 10%, and 15% are calculated, see Fig. 2. Beta function error is used because this parameter is convenient to measure and correct in practice. From Fig. 2, it is seen that emittance increase depends strongly on the magnet strength error level, in a way that is not strongly reflected in the beta function error at the injection point. Based on our operational experience, three cases are chosen for the injection performance simulation studies: no optical errors; beta error level at 10% and magnet strength error level at 1%, which gives $\Delta Ax = 20$ nm and $\Delta Ay = 4$ nm; beta error level at 10% and strength error level at 2%, which gives $\Delta Ax = 40$ nm and $\Delta Ay = 8$ nm.

DESIGN STUDY OF THE HIGHER HARMONIC CAVITY FOR ADVANCED PHOTON SOURCE UPGRADE*

S.H. Kim#, M.P. Kelly, P.N. Ostroumov, T. Berenc, G. Decker, J. Carwardine,
ANL, Argonne, IL 60439, USA

Abstract

A higher-harmonic cavity is planned for the proposed Advanced Photon Source (APS) multi-bend achromat (MBA) lattice to increase the bunch length, improve the Touschek lifetime and increase the single-bunch current limit. We have investigated a range of options including 3rd, 4th, and 5th harmonics of the main radio frequency (RF) system, as well as configurations with and without external RF power couplers. The current baseline is a single 4th harmonic superconducting cavity with adjustable RF couplers and a slow tuner which provide the flexibility to operate over a wide range of beam currents. The cavity is designed to provide 0.84 MV at 1408 MHz for the nominal 6 GeV, 200 mA electron beam, and 4.1 MV main RF voltage. In this paper, we discuss the harmonic cavity parameters based on analytical calculations of the equilibrium bunch distribution and make comparisons to other options.

INTRODUCTION

The APS at Argonne National Laboratory is planning an upgrade based on a MBA lattice for which the transverse emittance will be much smaller [1,2]. Beam dynamics studies show very small transverse beam sizes, ~10 µm rms in both the horizontal and vertical directions, which will result in more frequent Touschek scattering. To reduce the Touschek scattering probability a higher harmonic bunch lengthening RF system will be required and in this paper we will present how this improves the Touschek lifetime [1,2].

Physics parameters for the higher-harmonic cavity (HHC) have been derived from this study. Possible options for the HHC were as follows:

- Harmonic number, for example, 3rd, 4th, or 5th.
- Superconducting or normal conducting.
- Passive (driven only by beam) or active mode (including an external RF generator).
- In passive mode, with or without external RF power couplers.

As a baseline design we have chosen a 4th harmonic superconducting cavity operated in the passive mode with external RF power couplers terminated in matched loads. This was done based on analytical calculations of the equilibrium longitudinal bunch distribution for the combined RF voltage of the main and higher harmonic system. A unique feature of this design compared to that of other machines, such as ALS and ELETTRA [3,4], will be the use of adjustable RF power couplers. In combination with a frequency tuner, this permits adjustment of both the amplitude and phase of the harmonic voltage such that the cavity can be optimized for different beam currents even in the passive mode of operation.

In the following section, we will discuss the ‘optimum’ bunch lengthening condition, the harmonic number, the choice for superconducting technology, and operation at different beam currents. Non-optimum conditions will also be discussed. The detailed design of the HHC is presented in [5] and particle tracking simulations with the HHC are discussed in the [6].

HHC PARAMETERS

Optimum Bunch-Lengthening Condition

The longitudinal charge distribution in a bunch was analytically calculated from the potential well generated by the main and harmonic RF voltage. The combined RF voltage V seen by an electron at phase ϕ is represented by [3,7]

$$V(\phi) = V_m\{\sin(\phi + \phi_m) + k\sin(n\phi + \phi_h)\}, \quad (1)$$

where V_m is the main RF voltage, k is the ratio of the harmonic voltage to the main RF voltage, n is the harmonic RF number, ϕ_m is the phase of the main RF, ϕ_h is the phase of the harmonic voltage. The charge distribution, ρ, in equilibrium with radiation damping and quantum excitation can be represented by [3,8]

$$\rho(\phi) = \rho_0 \exp\left(\frac{-\Phi(\phi)}{\alpha_c^2\sigma_e^2}\right), \quad (2)$$

where ρ_0 is a normalization factor, α_c is the momentum compaction factor, σ_e: the relative RMS energy spread, and Φ is the potential defined by [3,7]

$$\Phi(\phi) = \frac{\alpha_p}{2\pi h E_s}\int_0^{\phi}\{eV(\phi') - U_0\}d\phi', \quad (3)$$

where E_s is the synchronous energy, h is the harmonic number of the main RF relative to the ring revolution frequency, and U_0 is the energy loss per turn. In this study, we use the following values: V_m = 4.1 MV, U_0= 2.24 MeV, h = 1296, α_c= 5.86×10^{-5}, σ_e=9.5×10^{-4}.

The ‘optimum’ condition for bunch lengthening is to cancel the slope of the main RF at the bunch center such that the potential well is flat around the bunch center. Under this condition, the first and second derivatives of $V(\phi)$ must vanish at the synchronous phase [3,7]. The

INSTABILITY THRESHOLDS FOR THE ADVANCED PHOTON SOURCE MULTI-BEND ACHROMAT UPGRADE*

R. R. Lindberg, ANL, Argonne, IL 60439, USA, and A. Blednykh, BNL, Upton, NY 11973, USA

Abstract

An important operating mode for the multi-bend achromat (MBA) upgrade at the Advanced Photon Source (APS) calls for 200 mA average current divided evenly over 48 bunches. Ensuring that the desired 4.2 mA single bunch current can be stably stored requires a detailed understanding of the impedance in the MBA ring. We briefly discuss modeling sources of impedance using the electromagnetic codes `GdfidL` and `ECHO`, and how we then include both geometric and resistive wall wakefields using the tracking code `elegant` to predict collective instabilities. We first validate our procedures by comparing APS experimental measurements to tracking predictions using the APS storage ring impedance model. We then discuss the MBA impedance model, for which we find that a chromaticity of 5 units is sufficient to obtain the required 4.2 mA single bunch current. Finally, we mention certain design changes that may reduce the impedance and allow for a reduction in chromaticity.

INTRODUCTION

There are many potential sources of instabilities, but observations at high-energy storage rings such as the APS have shown that the dominant collective effects are typically due to impedances/wakefields. To be more specific, transverse wakefields give rise to transverse beam instabilities that ultimately limit the single-bunch current at the APS, while longitudinal wakefields predominantly lead to bunch lengthening (which usually eases operational requirements), an increase in energy spread (which is typically not too detrimental), and rf-heating of vacuum components (which can be problematic). Transverse impedances will continue to be the dominant driver of collective effects for the MBA. Hence, understanding and calculating the impedance is critical for accurate predictions of the single-bunch current limit. Here we describe our efforts to model wakefields and predict collective effects for the APS MBA Upgrade including the bunch-lengthening higher harmonic cavity (HHC).

IMPEDANCE MODEL AND SIMULATION

We have adapted to the MBA lattice the impedance model and tracking simulation methods that Y.-C. Chae developed for the APS over the past decade. This model has successfully reproduced various impedance-driven collective effects observed in the APS ring [1, 2]; extending it to the MBA was straightforward once the primary impedance sources were identified and analyzed. In this model, the effects of impedances/wakefields are represented by a single "impedance element" in the code `elegant` [3]. To reduce the distributed impedance from the entire ring to a localized perturbation, we first divide the impedance into its resistive wall and geometric components. We compute the resistive wall contribution using analytic formulas, and calculate the geometric impedance with numerical simulation codes. We list the various resistive wall and geometric impedance sources identified for the MBA storage ring in Table 1.

We use two codes to compute the geometric impedance. We compute the wakefields for components possessing axial symmetry using the 2D `ECHO` code [4], while structures that vary in 3D are analyzed with the commercial code `GdfidL` [5]. To balance numerical efficiency and accuracy, within these codes we model the (point particle) wakefields by the wake potential generated by a 1-mm long bunch, as this approximation has had good success in predicting the onset of various instabilities in the present APS. In addition, we have performed several numerical tests that use wake potentials derived from shorter electron bunches, and these have proven to give the same results in terms of the single-bunch current limit for the APS-U lattice.

The total transverse wake potential of the ring is found by weighting each contribution by its local beta-function and summing. For example, if we label each element by j and the vertical geometric beta-function at that element by $\beta_{y,j}$, the weighted geometric wakefield along y is

$$\langle \beta_y W_y^{\text{geo}} \rangle = \sum_{\text{elements } j} \beta_{y,j} W_{y,j}^{\text{geo}}. \tag{1}$$

An analogous expression holds for W_x, while the total longitudinal wakefield is the simple sum $\langle W_z^{\text{geo}} \rangle = \sum_j W_{z,j}^{\text{geo}}$.

The corresponding impedances are then computed via the discrete Fourier transform, and the "total impedance" is obtained by adding the geometric and resistive wall contributions. Finally, we use these impedances with the particle tracking code `elegant` as a single element by dividing by the lattice function $\beta_{x,y}$ at its chosen location.

We show how well our impedance model and tracking simulations can perform by comparing the predictions of the present APS impedance model to recent experiments in Fig. 1. The first two plots show that the APS impedance model does a very good job predicting the longitudinal behavior; the first plot compares the current-dependent bunch lengthening predicted by simulation (blue points) with a fit to experimental data in red, while the second panel shows reasonably good agreement for both the microwave instability threshhold at approximately 6-7 mA and the subsequent growth in energy spread as I_{bunch} increases. Finally, the last panel compares the predicted single bunch current stability threshhold with I_{limit} measured at the APS storage ring for various levels of the chromaticity ξ defined by

MODELING OF IMPEDANCE EFFECTS FOR THE APS-MBA UPGRADE*

R.R. Lindberg, ANL, Argonne, IL 60439, USA and A. Blednykh, BNL, Upton, NY 11973, USA

Abstract

Understanding the sources of impedance is critical to accelerator design, and only becomes more important as vacuum chambers become smaller and closer to the electron beam. The multibend achromat upgrade at the Advanced Photon Source (APS) requires small, 22-mm diameter vacuum chambers and even smaller (6 mm) gaps for the insertion devices, so that both rf heating and wakefield-driven transverse instabilities become important concerns. We discuss modeling the primary sources of geometric impedance using the electromagnetic finite difference codes GdfidL and ECHO, and how these codes are influencing vacuum and accelerator component design.

INTRODUCTION

The vacuum design of the planned multi-bend achromat (MBA) upgrade at the APS must consider many often competing factors. First, the pumping must be able to achieve an ultra-high ($\lesssim$ 1 nTorr) vacuum, which is accomplished using local ion pumps in tandem with distributed pumping provided by high surface sorption materials such as non-evaporative getter (NEG) coatings. Second, engineers must find a way to handle the high heat loads associated with synchrotron radiation, both to maintain component integrity and to limit photon-stimulated desorption of gas molecules from the chamber walls. Third, the chambers must be compatible with the magnet design, and permit efficient extraction of bending magnet and undulator radiation for science.

While there are other vacuum design considerations, this list is sufficient to show that the desires of vacuum engineers are typically in conflict with those of an accelerator physicist interested in minimizing beam related wakefields/impedances. These wakefields result from changes in vacuum chamber geometry, and can lead to damaging levels of rf-heating and/or intensity-dependent instabilities. Here, we discuss our efforts to model the geometric sources of impedance associated with the MBA, and how our results are informing vacuum design.

MBA IMPEDANCE MODEL

We analyze the geometric impedance of the MBA using three basic steps. First, we try to identify the primary sources of impedance associated with a particular vacuum design. Second, we use electromagnetic codes to numerically calculate the wakefields associated with each impedance element. Third, we assess the effects of the wakefields on rf heating and beam stability. The next few paragraphs will discuss each of these steps in more detail.

* Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

Table 1: Elements that contribute to the geometric impedance (BPM = beam position monitor).

Sector (×40)		Ring	
Element	**Num.**	**Element**	**Num.**
BPM	12	Inject. kicker	4
ID BPM	2	Extract. kicker	4
ID transition	1	Feedback	2
Bellow	14	Stripline	1
Flange gap	52	Aperture	2
Crotch abs.	2	Fund. cavity	12
In-line abs.	12	Rf transition	4
Gate valve	4	Harm. cavity	1

We identify potential sources of impedance by drawing heavily on our experience with the present APS impedance model [1], since this model has shown rather good agreement with experimentally measured collective effects at the APS storage ring. We have found that important sources of impedance include both those from large changes in geometry, such as the insertion device (ID) transitions and injection/extraction kickers, and from relatively small perturbations that occur many times in the ring, like the bellows and flange gaps. We list the elements that presently compose the MBA impedance model in Table 1.

We then numerically simulate each impedance element to extract the longitudinal and transverse wakefields. We employ the 2D ECHO code [2] to solve for wakefields in axially symmetric elements, which presently include the flange gaps and in-line photon absorbers. Structures without axial symmetry are analyzed using the 3D commercial code GdfidL [3]. ECHO directly outputs wakefields of a given multipole order (we require the $m = 0$ longitudinal and transverse dipole wakes), while we derive the transverse dipole, quadrupole, and monopole wakefields from GdfidL output after a small amount of post-processing.

Finally, we assess the effects of wakefields using a combination of analytic tools and tracking-based simulations. We apply analytic expressions such as the loss factor to obtain important information regarding the energy loss and potential rf-heating issues, and the tracking code elegant [4] to predict detailed information regarding the influence of collective effects on beam stability. Note that the numerically calculated wakefields are actually those excited by a Gaussian bunch of duration σ_b, which in turn yields an impedance whose high-frequency components are suppressed by a Gaussian filter of width $1/\sigma_b$. Several test cases have shown that the predicted collective effects are independent of σ_b provided $\sigma_b \leq 1$ mm, and we use the bunch length $\sigma_b = 1$ mm for all wakefield simulations. More details on the tracking results can be found in [5].

HIGH CHARGE DEVELOPMENT OF THE APS INJECTOR FOR AN MBA UPGRADE*

C.-Y. Yao#, N. Sereno, Ju Wang, M. Borland, Doug Horan, H. Shang, X. Sun, K. Harkay, R. Lindberg, J. Calvey, Advanced Photon Source,
Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

The APS MBA (multi-bend achromat) upgrade storage ring will employ a "swap out" injection scheme and requires a single-bunch beam with up to 20 nC from the injector. The APS injector, which consists of a 375-MeV linac, a particle accumulator ring (PAR), and a 7-GeV synchrotron (Booster), was originally designed to provide up to 6 nC of beam charge. High charge injector study is part of the APS upgrade R&D that explores the capabilities and limitations of the injector through machine studies and simulations, and identifies necessary upgrades in order to meet the requirements of the MBA upgrade. In the past year we performed PAR and booster high charge studies, implemented new ramp correction of the booster ramp supplies, explored non-linear chromatic correction of the booster, etc. This report presents the results and findings.

INJECTOR TIMING

At 2 Hz operations we have achieved ~10 nC in the PAR. In order to achieve up to 20 nC beam charge the injector cycle must be extended to at least 1 s to accumulate enough Linac bunches, and to allow sufficient damping time. A prototype timing module that supports both 2Hz and 1Hz operations has been designed and is currently under hardware test.

NON-LINEAR RAMP FOR THE BOOSTER MAIN SUPPLIES

The Booster accelerates beam from 375-MeV injection energy to 7-GeV extraction energy in 224 ms. Damping time, bunch length and beam stability varies during this process. We mainly rely on chromatic correction and radiation damping to maintain beam stability.

Chromatic correction for the booster is complicated by the eddy current in the vacuum chamber due to ramping of the dipole field. The original sextupole strengths are designed to maintain a +1 chromaticity in both planes at extraction energy. This is inadequate for high charge beam. In order to provide higher chromatic correction at low beam energy we developed a new ramp correction programs that support non-linear ramps for the quadrupole and sextupole supplies. Figure 1 shows a non-linear ramp for the SD sextupole supply. This allows us to apply high chromatic correction during the first half of the ramp where the beam instability is stronger.

*Work supported by the U.S. Department of Energy, Office of Science, under Contract No. DE-AC02-06CH11357.
#cyao@aps.anl.gov

We are also considering upgrading the sextupole power supplies to higher current ratings to achieved a chromaticity of 6 to 7 in both planes in the full Booster cycle.

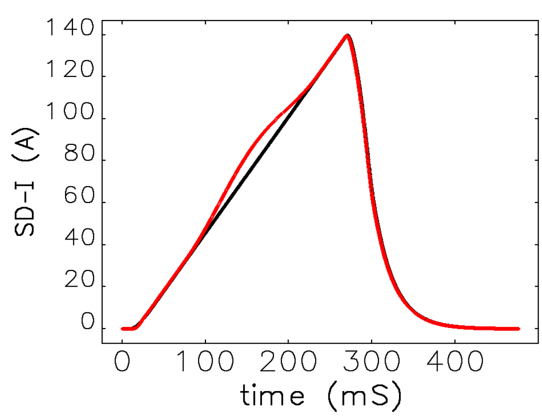

Figure 1: SD magnet new non-linear (Red) and original linear (Black) ramps.

NEW BPM AND CORRECTOR RAMP SYSTEM

A new Booster BPM system has been designed that utilizes a BSP-100 [1] module that was originally developed for APS storage ring. The new system will provide up to 10 average beam orbit readings along the 224 ms energy ramp.

A V344 arbitrary waveform generator (AWG) module and a V490 ADC module [2] are selected for the new corrector ramp control system.

The BPM system is under test and EPICS interface for a single V344 module has been tested. Full implementation is under way.

ANALYSIS OF BOOSTER CHAMBER IMPEDANCE

The Booster vacuum chamber is made of 316L stainless steel, and the associated longitudinal and transverse impedance was obtained using standard analytic formulas. In addition, Table 1 lists the vacuum components that represent the main contributions to the geometric impedance. The wakefields due to these elements were calculated using the 3D electromagnetic code GdfidL [3], with the exception of the rf cavities.

FIRST BEAM AND HIGH-GRADIENT CRYOMODULE COMMISSIONING RESULTS OF THE ADVANCED SUPERCONDUCTING TEST ACCELERATOR AT FERMILAB*

D.J. Crawford#, C. Baffes, D. Broemmelsiek, K. Carlson, B. Chase, E. Cullerton, J. Diamond, N. Eddy, D. Edstrom, E. Harms, A. Hocker, C. Joe, A. Klebaner, M. Kucera, J. Leibfritz, A. Lumpkin, J. Makara, S. Nagaitsev, O. Nezhevenko, D. Nicklaus, L. Nobrega, P. Piot, P. Prieto, J. Reid, J. Ruan, J. Santucci, W. Soyars, G. Stancari, D. Sun, R. Thurman-Keup, A. Valishev, A. Warner, S. Wesseln, Fermilab, Batavia, IL 60510, USA

Abstract

The advanced superconducting test accelerator at Fermilab has accelerated electrons to 20 MeV and, separately, the International Linear Collider (ILC) style 8-cavity cryomodule has achieved the ILC performance milestone of 31.5 MV/m per cavity. When fully completed, the accelerator will consist of a photoinjector, one ILC-type cryomodule, multiple accelerator R&D beamlines, and a downstream beamline to inject 300 MeV electrons into the Integrable Optics Test Accelerator (IOTA). We report on the results of first beam, the achievement of our cryomodule to ILC gradient specifications, and near-term future plans for the facility.

INTRODUCTION

A superconducting radio frequency (SRF) accelerator test facility is currently under construction at Fermilab. Once complete, the accelerator will consist of a photoinjector front-end, two superconducting booster cavities, a 50 MeV beamline, a beam acceleration section consisting of one ILC-type cryomodule, multiple downstream beamlines, the IOTA storage ring with various diagnostics to conduct beam tests, and a high-power beam dump. This paper describes the commissioning effort of the facility to date. [1]

Front-end

The front-end consists of a 1.5 cell normal conducting RF Gun resonating at 1.3 GHz with a peak accelerating gradient of up to 45 MV/m, a cesium telluride (Cs_2Te) cathode for photoelectron production, a 3 ps pulsed 263 nm ultra-violet (UV) laser delivery system, and a diagnostic area for measuring the charge and spot size of the photoelectron beam. [2] The UV laser system is tuneable from 1 to 3000 micro-bunches within a 1 ms bunch train at a maximum 5 Hz repetition rate. Two solenoid magnets, each capable of a peak field of 0.28 T at 500 A, surround the RF Gun cavity. The main solenoid provides the appropriate field for focusing the electron beam to the booster cavities. The bucking solenoid cancels the magnetic field from the main solenoid at the photocathode surface in order to minimize beam emittance.

Booster Cavities

There are 2 small cryomodules after the front-end known as Capture Cavity 1 (CC1) and Capture Cavity 2 (CC2). Each of these cryomodules contains one 9-cell L-band cavity operating at 1.3 GHz, driven by a 300 kW klystron, and capable of average accelerating gradients >22 MV/m. These cavities will also be used to “chirp” the beam, i.e. generate a time-momentum correlation, in preparation for bunch compression in the chicane. Downstream of these cavities is space allotted for a future SRF 3.9 GHz cavity intended to be used for bunch linearization during bunch compression. [3]

Currently, CC2 is installed and CC1 will be installed upstream of CC2 during summer 2015 and will allow for a maximum beam energy of 50 MeV.

50 MeV Beamline

After CC2, the electron beam enters the 50 MeV beamline. There is a quadrupole doublet to control the beam size for emittance measurements, a matching section into a chicane, a 4-dipole chicane for bunch compression (R56 = -0.18 m), and a matching section into a 22.5° vertically downward bending dipole. This dipole, upstream of the absorber, will serve as the low energy spectrometer. The 50 MeV beam absorber is capable of accepting up to 550 W of beam power. [3, 4]

The beamline also consists of 13 horizontal and vertical trim dipole magnets, 6 transverse profile monitors (TPM), 19 beam position monitors (BPM), 2 toroids, 2 wall current monitors (WCM), and 8 beam loss monitors connected to the Machine Protection System (MPS). Each TPM contains either a 100 µm thick cerium-doped yttrium aluminum garnet (YAG) screen or a 100 µm thick lutetium yttrium oxyorthosilicate (LYSO) screen. Each TPM also contains an optical transition radiation (OTR) foil of 25 µm or 1 µm thick, and a 1951 USAF optical resolution target for pixel and resolution calibration. The TPM in the chicane has a slit mask experiment installed in the OTR position.

Installation of the 50 MeV beamline was completed earlier this year. A schematic beamline is shown in Fig. 1.

MODEL OF DARK CURRENT IN SRF LINAC

A. Sukhanov*, N. Solyak, A. Saini, I. Tropin, Fermilab†, Batavia, IL 60510, USA

Abstract

Currently, few linacs based on 9-cell TESLA-type SRF cavities are being designed or bult, including XEFL, LCLS-II and ILC. Dark current electron generated by field emission in SRF cavities can be captured and accelerated in the linac up to hundreds MeV before they removed by focusing magnets. Lost dark current electrons interact with the materials surrounding SRF cavities and magnets, produce electromagnetic showers and contribute to the radiation in the linac tunnel. In this paper we present a model of dark current in a linac based on TESLA cavities. We show preliminary results of the simulation applied to ILC main linac.

INTRODUCTION

In superconducting radio-frequency (SRF) cavities electrons can be emitted from the surface of the cavity in the region of the high electric field via field emission (FE). Emitted electrons are then may be captured in accelerating regime and contribute to the dark current (DC). Because of their broad angular, space and phase distribution, large fraction of dark current particles is lost downstream of the originating cavity, in subsequent cavities of the linac, focusing magnets and other beam line components. Lost particles may cause additional heat and RF loading on superconducting cavities. If lost electrons from DC have large enough energy, they produce electromagnetic showers of secondary particles which irradiate cables and electronic components inside the cryostat (cryo-module, CM) containing cavities. Radiation penetrating beyond CM walls may affect electronics in the linac tunnel and personnel and electronics in the service part of the tunnel. Thus, design of SRF linacs requires extensive investigation of DC radiation in order to protect accelerator components from radiation damage and optimize thickness and cost of the radiation shields. Some of the recent studies of DC in SRF linacs are listed in [1–4].

In this paper we describe a model of dark current in SRF linac. Our model combine tracking of electrons in RF field of cavities and magnetic field of focusing magnets with simulation of interactions of lost particles with the materials of the accelerator components.

MODEL

We use MARS package to simulate interaction of DC particles with the materials of linac components and surrounding infrastructure. In order to understand average and maximum radiation conditions and minimize time consuming MARS simulation, we separate our study into following steps:

- Losses inside individual cavity. Radiation from particles lost inside the same cavity where they were emitted. The normalized level of radiation is the same for each cavity in the linac.
- Losses from DC produced by a single cavity. We assume that only one cavity in a string of cavities between focusing magnets[1] contributes to DC. In a worst case emitting cavity is located next to the magnet. Survived DC electrons are accelerated through the string and lost in the next magnet.
- Losses from DC generated by all cavities.

In this paper we focus on steps 1 and 2 and leave step 3 for the future studies.

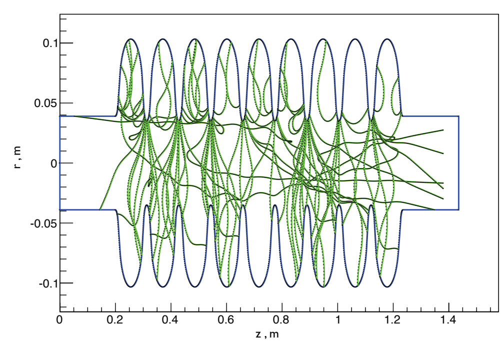

Figure 1: Trajectories of the FE electrons.

Field Emission Model

We use SuperLANS code to calculate RF field in the 9-cell TESLA-type cavity. Time dependence of the electric field is assumed to be $E \sim \cos(\omega t + \phi)$, where RF phase ϕ varies from 0 to 2π. Emitter locations are chosen randomly according to uniform distribution along the cavity surface from the entrance of the 1st cell to the exit of the 9th cell. Each emitted electron is assigned the weight calculated from Fowler-Nordheim model: $W_{FN}(E) = N_{FN}(\beta_{FN}E)^2 \exp(-B_{FN}\varphi^{3.2}/\beta_{FN}E)$, where $B_{FN} = 6.83 \cdot 10^3$, niobium work function $\varphi = 4.2$ eV, and field enhancement factor β has a typical value of 100. Normalization constant N_{FN} is selected such that $W_{FN}(E_{max}) = 1$, where maximum surface electric field in TESLA cavity is $E_{max} = 2E_{acc}$, and E_{acc} is accelerating field on the cavity axis[2]. For subsequent tracking and MARS simulation we select track with $W_{FN} > 0.01$.

DEVELOPMENT OF NONLINEAR INJECTION KICKER MAGNET FOR ALS ACCELERATOR*

Chris Pappas, David Robin, Christoph Steier, Changchun Sun, Charles Allen Swenson, Jin-Young Jung, Dennis Baum, LBNL, Berkeley, CA 94720 USA

Abstract

The ALS in now engaged in the construction of a new hard x-ray beam line and insertion device for protein crystallography. The scope of work entails the reconfiguration of ALS Sectors 1-3 to make room for the new insertion device. The project will require the melioration of the ALS injection system as well as the development of a longitudinal RF kicker. A key aspect of the injector work is the development and integration of a nonlinear injection kicker (NLK) magnet system to facilitate top off injection without noticeable motion of the beam. The technology will, in principal, ultimately allow the removal of the conventional bump injection magnets presently located in ALS Sector 1. The nonlinear injection concept has been explored at several other light sources [1]. We examine the beam dynamics and magnet design requirements to adapt this technology to the ALS lattice with its 1.9 GeV beam. The work will review the injection beam matching, tracking simulations, the electromagnetic design and tolerance analysis, and power supply design. The paper will also review the project plan for the integration of this technology into the ALS.

INTRODUCTION & NLK TECHNOLOGY

NLK technology offers the promise of a compact space efficient injection technology without the inclusion of injection bump magnets common to 3rd generation storage rings like the ALS. The technology is attractive for this reason. Other laboratories have build and tested prototypes of NLK designs with varying success [2,3], however none are presently now in use for a user facility. Soleil and MAXIV are working together on a modified BESSY design they plan to use at both facilities [4]. The reason NLKs have thus far not used for operations has been lower injection efficiency compared to conventional kicker approaches. The successful accelerator integration of the NLK requires the co-development of several key-supporting technologies such as: the optimization of the magnetic field shape to match the requirements for the injected and stored beams, a magnetic design and measurement technology that allows shim correction of field errors resultant from construction tolerances, and a reliable method for spatial fiducialization of the magnetic fields. The NLK technology under development at ALS employs a novel winding configuration resultant from a genetic algorithm to optimize injection efficiency. The windings symmetry is neither quadrupolar or sextupolar.

*This work was supported by Lawrence Berkeley National Laboratory under U.S. Department of Energy Contract No. DE-AC02-05CH11231.

REQUIREMENTS FOR ALS, DESIGN METHODOLOGY & OPTIMIZATION

The ALS requirements have evolved from the concept developed at BESSY and is presently in development at Soleil. These concepts position eight magnet buses at 45° from the axis. The inner buses are driven with current in one direction and the outer buses with current of the opposite polarity. A BESSY type magnet geometry, flux lines, and the normalized y component of the **B** field are shown in Figure 1. The ideal magnet has the advantage of zero field, and dB/dx on axis, however is not an optimal field shape for injection into the ALS due to the 275 nm beam emittance of the ALS injection booster.

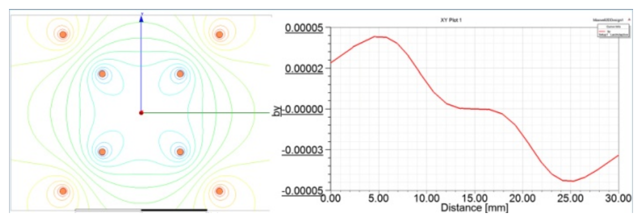

Figure 1: Modified BESSY magnet flux and **B**y.

From tracking simulations it became clear that the shape of the field in a BESSY type magnet is not optimal for injection into the ALS. In particular, a profile that has a wider zero field region near the axis, rises more steeply to the peak, and then decays more slowly would improve the injection efficiency. An exploration of the wire symmetries using analytic solutions for the magnetic fields indicated that the field could be flattened in the region of the injected beam while maintaining the field requirements for the stored beam. The resultant wire geometry could be called a double diamond configuration as illustrated in Figure 2. Another aspect of the design study entailed a tolerance analysis of both winding configurations. The resultant magnetic field errors in the stored beam region were comparable for either winding configuration indicating the validity of the approach.

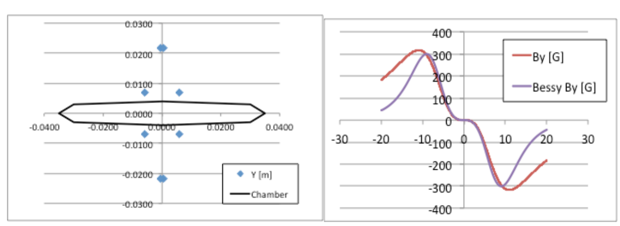

Figure 2: ALS NLK winding configuration and comparative plot of **B**y for the ALS and X wire configurations.

PROGRESS OF THE R&D TOWARDS A DIFFRACTION LIMITED UPGRADE OF THE ADVANCED LIGHT SOURCE*

C. Steier†, A. Anders, D. Arbelaez, J. Byrd, K. Chow, R. Duarte, J. Jung, T. Luo, A. Madur, H. Nishimura, J. Osborn, C. Pappas, L. Reginato, D. Robin, F. Sannibale, S. De Santis, R. Schlueter, C. Sun, C. Swenson, W. Waldron, E. Wallen, W. Wan, LBNL, Berkeley, CA 94720, USA

Abstract

Improvements in brightness and coherent flux of about two orders of magnitude over operational storage ring based light sources are possible using multi bend achromat lattice designs [1]. These improvements can be implemented as upgrades of existing facilities, like the proposed upgrade of the Advanced Light Source, making use of the existing infrastructure, thereby reducing cost and time needed to reach full scientific productivity on a large number of beamlines. An R&D program funded by internal laboratory funds was started at LBNL to further develop the technologies necessary for diffraction-limited storage rings (DLSR). It initially involves five areas, and focuses on the specific needs of soft x-ray facilities: vacuum system/NEG coating of small chambers, injection/pulsed magnets, RF systems/bunch lengthening, magnets/radiation production with advanced radiation devices, and beam physics design optimization. Some hardware prototypes have been built. The work will expand in the future to demonstrate necessary key technologies at the subsystem level or in beam tests and include new areas like photon beamline optics.

INTRODUCTION

To achieve diffraction-limited performance throughout the soft x-ray (SXR) range, the ALS-U proposal pushes the limit of accelerator design beyond the level of the first examples of multi bend achromat (MBA) light sources currently under construction. Because ALS-U is a smaller and lower energy machine than all other proposed MBA machines or upgrades, with a resulting larger effect of intrabeam scattering (IBS), it requires design solutions different from those being pursued for the higher energy projects [2]. Therefore an R&D program funded by laboratory directed research and development funds (LDRD) was started in early FY14 at LBNL with the goal of reducing the technical risks of a soft x-ray diffraction limited storage ring and to optimize the possible performance of an eventual upgrade proposal.

Similar to the approach elsewhere, we have chosen a multi-bend achromat lattice, in our case with nine bends (9BA), and retained twelve arcs as in the existing ALS [3] (see Figure 1). No damping wigglers are foreseen and round beams will be used. Lattice optimization is ongoing, including optimization of the nonlinear dynamics wih genetic algorithms, similar to past work for the ALS brightness upgrade [4].

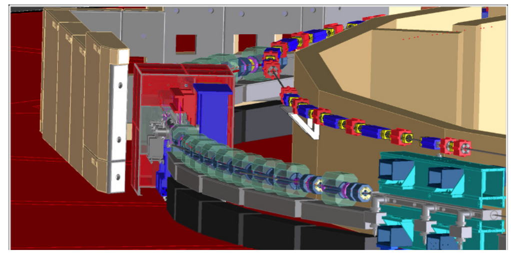

Figure 1: Model of ALS-U storage ring, accumulator and existing undulators in the ALS tunnel.

Including the effects of IBS, harmonic cavities, as well as insertion devices, the baseline lattice provides equal emittances of about 50 pm at 500 mA in both planes, yielding straight section beamsizes of around 10 μm. The electron beam ellipse is matched well to the diffraction ellipse leading to excellent brightness performance for soft x-rays (see Figure 2).

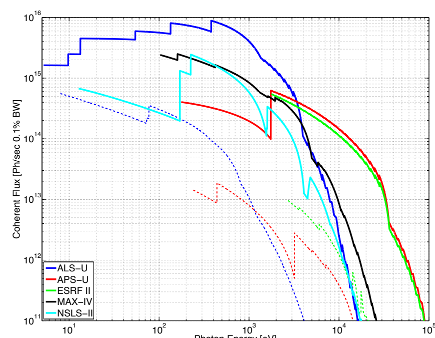

Figure 2: Coherent flux envelopes for ALS-U (blue) and several other facilities and upgrades. Dashed lines indicate pre-upgrade performance of facilities in operations now.

R&D PROGRAM

The R&D program at LBNL towards soft x-ray diffraction limited light sources initially involved five areas: Vacuum system/NEG coating of small chambers, Injection/pulsed magnets, RF systems/bunch lengthening, magnets/radiation production with advanced radiation devices, and Beam Physics optimization of the overall upgrade proposal. Several hardware protoypes have been built and the work includes demonstration of necessary key technologies at the subsystem level or in beam test. The program was recently expanded to include new areas, like photon beamline optics. It concentrates on the areas with the highest technical risk,

MICROBUNCHING PHENOMENA IN LCLS-II *

M. Venturini†, J. Qiang, C. Papadopoulos
LBNL, Berkeley, CA 94720 USA
Y. Ding, P. Emma, Z. Huang, G. Marcus, A. Marinelli, Y. Nosochkov, T. Raubenheimer, L. Wang, M. Woodley
SLAC, Menlo Park, CA 94025 USA

Abstract

The microbunching instability has long been recognized as a potential limiting factor to the performance of X-ray FELs. It is of particular relevance in LCLS-II [1] due, in part, to a layout that includes a long bypass beamline between the Linac and the undulators. Here we focus on two aspects of the instability that highlight the importance of 3D effects.

ANOMALOUS HEATING

'Trickle' Heating

The Laser Heater (LH) is the established method to control the microbunching instability, exploiting the microbunching sensitivity to energy-spread induced mixing. In LCLS-II the LH is located at the exit of the injector at about 100 MeV beam energy; it consists of a 0.54 m undulator placed in the middle of a weak 4-dipole chicane and a $\lambda_L = 1030$ nm laser system. Concerns about the 'trickle' heating effect, discovered during LCLS commissioning [2], motivated the high-resolution numerical studies with the code IMPACT [3] presented here. Trickle heating is an echo-like phenomenon, in which the E/z micro-correlations generated by the laser/electrons interaction in a finite-dispersion region induce z/x correlations on the same micro-scale downstream of the LH (while the E/z micro-correlations are eventually washed out by the finite transverse emittance). The z/x correlations appear at relatively well localized points along the lattice separated by π phase advance in the horizontal betatron motion. The associated longitudinal space-charge forces modify the electron energy resulting into anomalous heating, which is undesirable, as it may compromise accurate control of the heater operation. To speed up the numerical calculations without sacrificing accuracy, we simulate a flat-top bunchlet meant to model a short section of the bunch core (but long enough to span many laser wavelengths). For the $Q = 100$ pC bunches discussed here the peak current in the core is $I_{\rm pk} \simeq 14$ A. For high fidelity simulations, the particle charge is the same as that of a physical electron (this is the case for the results of all the simulations presented in this paper). We track the bunchlet with initial gaussian energy density and σ_{E0} slice rms energy spread, starting from the exit of the injector, a few meters upstream of the LH chicane; σ_{E0} from high brightness injectors is not known very well but is expect to be on the order of 1-2 keV, including IBS effects: in our simulations we exercised a range of values. The action of the laser on the beam is modeled as a point-like interaction inducing a sinusoidal energy modulation and occurring in the middle of the physical undulator. The electron dynamics through the undulator itself is modeled as that of a drift (IMPACT has the capability to track the electrons through the undulator and laser-pulse fields, but it is time consuming and unnecessary for our purposes here). The bunch is followed through the LH chicane and a 50-m long collimation section to the entrance of the first Linac section (L1). An example of bunchlet longitudinal phase space is shown in Fig. 1, left picture. The prominent energy chirp, due to longitudinal space charge in the short bunchlet, is removed in the analysis before determining the energy spread distribution shown in the right picture. For comparison, the density observed at the exit of the LH chi-

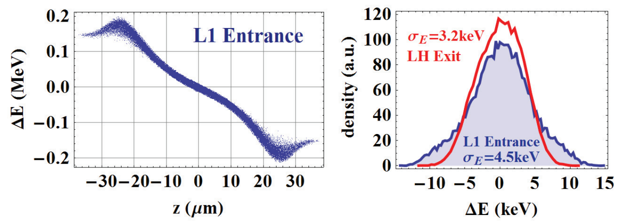

Figure 1: Longitudinal phase-space (left) of bunchlet at entrance of L1 and energy density in the core (right, blue curve). For comparison, the red curve on the right figure is the energy density at exit of the LH chicane;$\sigma_{E0} = 2$ keV.

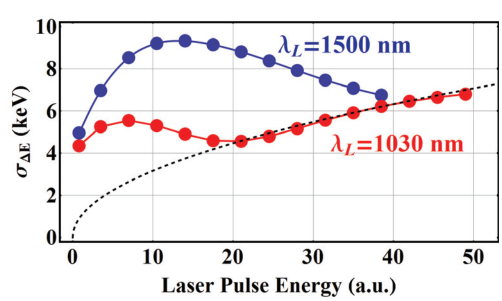

Figure 2: Energy spread at the entrance of L1 (two choices of laser wavelengths) showing evidence of the 'trickle' heating effect; $\sigma_E = 0.1$ keV. The dashed line is the nominal heating in the absence of collective effects.

Abstract

Photocathode emission properties are critical for electron beam applications such as photoinjectors for free electron lasers (FEL) and energy recovery Linacs (ERL). We investigate whether emission properties of photocathodes can be manipulated through the engineering of the surface electronic structure. The multilayers described here have been predicted to have emission properties in correlation with the film thickness. This paper describes how ultra-thin multilayered MgO/Ag/MgO films in the crystallographic orientations (001) and (111) multilayers were synthesized and characterized. Preliminary results of work function measurements are provided.

Films were grown by pulsed laser deposition at 130 °C for the (001) orientation and 210 °C for the (111) orientation at a background pressure of ~ 5×10-9 Torr. Epitaxial growth was monitored in-situ using reflection high-energy electron diffraction, which showed single crystal island growth for each stage of the multilayer formation. Photoelectron spectroscopy was used to track the chemical state transition from Ag to MgO during the deposition of successive layers. The Kelvin probe technique was used to measure the change in contact potential difference, and thus work function, for various MgO layer thicknesses in comparison with bare single crystal Ag(001)and Ag(111) thin films. The work function was observed to reduce with increasing thickness of MgO from 0 to 4 monolayers as much as 0.89 eV and 0.72 eV for the (001) and (111) orientations, respectively. Photoelectron spectra near the Fermi level revealed electron density shifts toward zero binding energy for the multilayered surfaces with respect to the clean Ag surfaces.

INTRODUCTION

Much of the development of photocathode materials has been aimed to the growth of photoemissive thin films with low work function (WF), and high quantum efficiency (QE) [1]. It has been shown, in some cases, that metal-insulator junctions can lead can lead to the modification of the WF for coverages of a few monolayers of metal oxides on metallic substrates, both theoretically and experimentally [2-5]. Reduction of WF and increase of QE can be achieved simultaneously by coating metal surfaces with Cs or CsBr [6,7]. Cs ion implantation on Cu, Ag and Au has also been shown to also reduce the WF and increase QE while still retaining the robustness of a metal, nonetheless, sacrificing the crystalline quality of the substrate [8]. However, the production of electron beams suitable for new photoinjector technologies in many instances requires low emittance beams from the cathode itself [2]. Therefore, the cathode intrinsic emittance plays an increasingly important role in new electron beam source designs [1].

A theoretical model by Nemeth et al. [2] describes the density functional theory (DFT) simulation of a multilayered structure MgO/Ag(001)/MgO in the configuration of 4 monolayers of Ag(001) flanked by n monolayers (ML) of MgO, where n is a small integer. This model indicates that it is possible to reduce the emittance of a photoemitted electron beam as the surface band structure exhibits a narrowing the density of states near the Γ-point neighboring the Fermi level when the thickness n of the MgO layers is 2 or 3 monolayers. In addition, this and other similar model [3] predict a work function drop of 1 eV to 1.5 eV from that of a bare Ag(001) surface. Measurements using atomic and Kelvin probe force microscopies (AFM and KPFM) show that even the deposition of MgO on a Ag(001) single crystal substrate produces a work function drop of 1.1 eV (1 ML) and 1.4 eV (2 ML) from the work function of the silver substrate, for 1 and 2 monolayers respectively [4,5].

More recently, an effort to quantify the effect on the emittance of 4 monolayers of MgO deposited on a Ag(001) substrate was carried out by Droubay et al. [9] who used Angle Resolved Photoelectron Spectroscopy (ARPES) to show that there was an enhancement of the photoemission intensity at the Γ-point near the Fermi level for the MgO coated Ag(001) in comparison with the uncoated Ag(001) substrate. Nonetheless, the ARPES spectrum for the MgO coated surface also exhibited the presence of sharp side bands near the Brillouin Zone boundaries which had the effect of increasing the total intrinsic emittance to 0.97 μm/mm from 0.47 μm/mm for the bare Ag(001) surface.

In this paper we present test results of multilayered MgO/Ag/MgO films as photoemitters. These multilayers were synthesized by Pulsed Laser Deposition (PLD) and characterized by Reflection High-Energy Electron Diffraction (RHEED) and Photoelectron Spectroscopy (PES) to show the formation of the crystalline and chemical structure of the multilayered films. It was found that there was a gradual decrease of the relative work function for MgO coated Ag surfaces in the (001) and (111) crystallographic orientations with respect to that of uncoated surfaces as the thickness of the flanking layers increased.

NUMERICAL INVESTIGATION OF A CASCADED LONGITUDINAL SPACE-CHARGE AMPLIFIER AT THE FERMILAB'S ADVANCED SUPERCONDUCTING TEST ACCELERATOR *

A. Halavanau[1], P. Piot[1,2]

[2] Accelerator Physics Center, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

In a cascaded longitudinal space-charge amplifier (LSCA), initial density noise in a relativistic e-beam is amplified via the interplay of longitudinal space charge forces and properly located dispersive sections. This type of amplification process was shown to potentially result in large final density modulations [1] compatible with the production of broadband electromagnetic radiation. The technique was recently demonstrated in the optical domain [2]. In this paper we investigate, via numerical simulations, the performances of a cascaded LSCA beamline at the Fermilab's Advanced Superconducting Test Accelerator (ASTA). We especially explore the properties of the produced broadband radiation. Our studies have been conducted with a grid-less three-dimensional space-charge algorithm.

INTRODUCTION

Longitudinal space-charge driven microbunching instabilities arising in bunch compressors (BC) were predicted and observed over the last decade [3–5] . It was recently proposed to employ this microbunching instability mechanism to form attosecond structures in a bunch for the subsequent generation of intense broadband radiation pulses [2, 6]. The experimental setup that enables the generation of space-charge-induced modulation is relatively simple: it consists of focusing sections (e.g. FODO cells) where energy modulations due to the space-charge impedance arise, interspaced with bunch compression chicaness. The BCs convert the incoming energy modulation into a density modulation. Several of these (FODO+BC) modules are cascaded so to result in a large final density modulation. Such a modulated beam can be then used to generate coherent radiation at the wavelengths comparable to the modulation period. The purpose of this paper is to explore the possible use of this scheme at the Advance Superconducting Test Accelerator (ASTA) currently under commissioning at Fermilab.

SPACE-CHARGE EFFECTS IN LSCA

When transverse and longitudinal space-charge forces are approximately equal, or longitudinal space-charge force begins to dominate, the particle dynamics within the bunch becomes complicated [7] and microbunching process can be affected by transverse instabilities to a large extent. As transverse space-charge forces are suppressed by a factor of $1/\gamma^2$, one has to operate at sufficiently large γ to decrease the contribution from transverse space-charge effects. That fact justifies the use of the high energy beamlines (> 300 MeV) (such as ones planned at ASTA facility). Our studies show that the LSCA process is still possible at lower energies, but it requires wider beam sizes to reduce the contribution from the transverse space-charge fields.

The estimated gain per one chicane in LSCA is proportional to space-charge impedance $Z(k,r)$ [8]:

$$G = Ck|R_{56}|\frac{I}{\gamma I_A}\frac{4\pi L_d|Z(k,r)|}{Z_0}e^{-\frac{1}{2}C^2k^2R_{56}^2\sigma_\delta^2}, \quad (1)$$

where R_{56} is the BC longitudinal dispersion, $I_A = 17$ kA is the Alfvèn current, L_d is the drift length, σ_δ is the rms fractional energy spread, $C \equiv \langle z\delta\rangle/\sigma_z$ is the chirp, and $Z_0 \equiv 120\pi$ is the free-space impedance.

The exponential term in Eq. 1 induces a high-frequency cut-off of the modulation. Note, that after traveling through a BC, the modulation wavelength will be shortened by a compression factor $(1 + R_{56}C)$. The impedance $Z(k,r)$ is partially determined by the properties of the wakefields inside the BC [8]. Later on, the LSC impedance was shown to mainly cause the effect [1, 6]. The on-axis LSC impedance is given by [9]

$$Z(k) = -i\frac{Z_0}{\pi\gamma\sigma}\frac{\xi_\sigma}{4}e^{\xi_\sigma^2/2}\mathrm{Ei}(-\frac{\xi_\sigma^2}{2}), \quad (2)$$

and has a maximum at modulations with wave numbers around $k = \gamma/\sigma_\perp$, where $\sigma_\perp$ is the rms transverse beam size. Thus, by tuning of the betatron function, transverse emittance, beam energy, and compressor parameters, one has some flexibility in selecting the final modulation wavelength.

To characterize the current (density) modulations one can introduce the bunching factor

$$b(\omega) = \frac{1}{N}\Big|\sum_n \exp(-i\omega t_n)\Big|, \quad (3)$$

where t_n is the temporal coordinate of the n-th macroparticle and N is the total number of particles. The electromagnetic radiation emitted by a bunch of electrons is of the form $\frac{dW}{d\omega d\Omega} = [N + N(N-1)b(\omega)^2]\frac{dW}{d\omega d\Omega}|_1$, where $\frac{dW}{d\omega d\Omega}|_1$ represents the single-electron radiation spectral fluence associated to the considered electromagnetic process.

NUMERICAL STUDY OF THREE DIMENSIONAL EFFECTS IN LONGITUDINAL SPACE-CHARGE IMPEDANCE*

A. Halavanau[1], P. Piot[1,2]
[1] Department of Physics and Northern Illinois Center for Accelerator & Detector Development, Northern Illinois University, DeKalb, IL 60115, USA
[2] Accelerator Physics Center, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

Longitudinal space-charge (LSC) effects are generally considered as detrimental in free-electron lasers as they can seed instabilities. Such "microbunching instabilities" were recently shown to be potentially useful to support the generation of broadband coherent radiation pulses [1,2]. Therefore there has been an increasing interest in devising accelerator beamlines capable of sustaining this LSC instability as a mechanism to produce a coherent light source. To date most of these studies have been carried out with a one-dimensional impedance model for the LSC. In this paper we use a N-body "Barnes-Hut" algorithm [3] to simulate the 3D space charge force in the beam combined with ELEGANT [4] and explore the limitation of the 1D model often used.

INTRODUCTION

Space-charge forces are essential to account for in realistic beam dynamics simulations. The nature of these forces lies in particle-to-particle Coulomb interaction. However, the numerical complexity of the problem grows as $O(N^2)$, where N is the number of particles. Therefore, it is not possible to exactly compute all space-charge contributions. Several approximation techniques can be used: mean-field on a grid approximation [5], space-charge impedance [6], analytical sub-beams or ensembles model [7]. All of those methods reduce the problem's complexity via some approximations which ultimately limits the maximum attainable spatial resolution.

Space-charge problem is very similar to the well-known N-body problem in celestial mechanics. One of the most effective algorithms for the gravitational N-body problem is the so called "tree" or Barnes-Hut (BH) algorithm [3], which scales as $O(N \log N)$. In this paper we present the results obtained using a modified version of the program available at [8]. Such a code was successfully employed to simulate early beam dynamics in photocathode [9]. Other more efficient algorithm have been recently developed [10, 11] and will be eventually used in further refinement of our work.

METHOD & VALIDATION

For the studies presented in this paper and our cascaded space charge amplifier study [17], we used the BH algorithm as an external script within the ELEGANT simulations. At a user-specified axial locations along the accelerator beam line, space charge kicks were applied. The distribution at the defined locations was saved and Lorentz transformation to the bunch rest frame was applied. The BH algorithm was used to obtain the 3D electrostatic field $\mathbf{E}'$. This field was then transformed in the laboratory frame and the obtained electromagnetic fields $(\mathbf{E}, \mathbf{B})$ were used to compute the Lorentz force on each of the macroparticles composing the beam. We used an impulse approximation so that only the momentum was altered by the space charge force. The distribution then was finally passed back to ELEGANT and tracked up to the next space-charge kick where the above process repeated. The main assumption in our calculations was that there was no magnetic field in the rest frame. This assumption although not strictly valid, was shown to hold for the beam with low energy spread typically produced in photoinjectors [12]. We henceforth refer to the combination of the BH algorithm with ELEGANT as "ELEGANT-BH".

To validate our simulations we both rely on analytical results and simulations carried out with the ASTRA program [5]. We first consider a 3D homogeneous ellipsoidal bunch with electric field linearly dependent on the position within the charge distribution as [13]

$$E_u(u) = \frac{C}{\gamma^2}\frac{(1-f)u}{r_u(r_x+r_y)r_z}, \text{ and } E_z(z) = \frac{Cf}{r_x r_y r_z}z, \quad (1)$$

where $C \equiv 3Q/(4\pi\epsilon_0)$, $u \in [x, y]$, $r_{x,y,z}$ are the ellipsoid semiaxes, $f \approx \sqrt{r_x r_y}/3\gamma r_z$ and Q is the bunch charge. The simulated fields are in excellent agreement with the field given by Eq. 1 as shown on Fig. 1. To assess longer-term

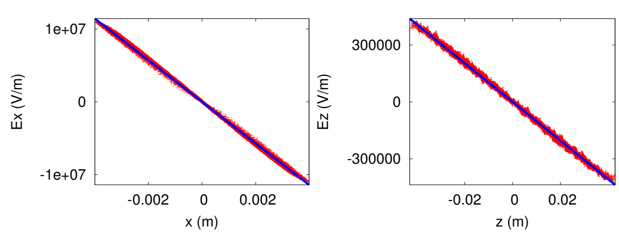

Figure 1: Transverse (left) and longitudinal (right) electric field experienced by the macropaticle simulated with ELEGANT-BH (symbols) and obtained from Eq. 1 (lines).

tracking, we compared the evolution of the beam envelope over a drift space. For a stationary uniform beam the transverse envelope evolution is governed by [14]

$$a''_{x,y} - \frac{\varepsilon^2_{rx,ry}}{a^3_{x,y}} - \frac{K}{2(a_{x,y}+a_{y,x})} = 0, \quad (2)$$

DEVELOPMENT OF A FIELD-EMISISON TYPE S-BAND RF-GUN SYSTEM FOR HIGH BRIGHTNESS ELECTRON SOURCE APPLICATIONS

Y. M. Shin[1,2], A. Green[1], N. Barov[3]
[1]Department of Physics, Northern Illinois University, Dekalb, IL 60115, USA
[2]Accelerator Physics Center (APC), FNAL, Batavia, IL 60510, USA
[3]Far-Tech Inc., San Diego, CA 92121, USA

Abstract

Electron beams emitted from a cold cathode are thermally stable and mono-energetic with a small phase-space volume. We have been developing a field-emission type RF-gun system for high brightness electron source applications, including electron scattering/diffraction and tunable coherent X-ray/THz generation. The system consists of a single-gap gun-cavity and an S-band klystron/modulator capable of powering the gun with up to 5.5 MW peak (PRR = 1 Hz, duration = 2.5 μs). The designed gun built with the symmetrised side-couplers has surface field on the cathode ranging 50 – 100 MV/m with 1.3 – 1.7 MW klystron-power and 1.2 field ratio (HFSS). ASTRA simulations also indicate that the gun produces the beam with transverse emittances of less than 1 mm-mrad with 10 – 20 pC bunch charge at 500 keV beam energy. Under the gun operating condition, particle tracking/PIC simulations (CST) show that a single-tip CNT field-emitter produces short pulsed bunches (~ 1/10 RF-cycle) with small emittance (≤ 0.01 mm-mrad) and high peak current density (≥ 10,000 kA/cm^2). After the gun is fully installed and commissioned, a CNT-tip cathode will be tested with RF-field emission.

INTRODUCTION

Beam brightness cannot be improved, but only spoiled along the downstream accelerator. Therefore, high quantum efficiency (QE) and low intrinsic emittance, plus long lifetime, are very necessary for injector-type electron sources. The beam emitters of the electron sources are required to have a high QE and uniform emission at the longest possible wavelength with fast response time (< 100 ps). Emittance can be diluted by space charge expansion seeded by non-uniform electron emission. In order to minimize intrinsic emittance, cathode surfaces should preferably be atomically flat within a few nanometers of peak-to-peak variation. Furthermore, operating lifetime of more than 1 year with a reasonable vacuum level of 10^{-10} Torr range and easy, reliable cathode cleaning or rejuvenation/re-activation is strongly preferred.

Linac-based coherent radiation sources need bright electron beams, but injectors comprised of conventional DC-guns and RF-bunchers for longitudinal pulse compression have inherent limitations in reducing transverse and longitudinal emittance. While thermionic and photo-cathodes have been most widely employed with injectors for accelerator machines, certainly there are some practical limits in applying them to a compact, high brightness electron source [1–4].

Usually, field emitters have been studied for the applications of long pulse operation. The main advantages of field emission are that it simply generates pulsed beam and that the beams emitted under the emitters have low transverse emittance. Normally, the thermionic cathodes and field emitters are tolerant of poor vacuum and they have a long operating lifetime. However, the beam from the electron sources usually has long a bunch length (> 100 ps) and large longitudinal emittance with a lack of beam-profile control. Although high beam currents could be created and accelerated by an electron gun with field-emitters, it is difficult to find stable and reproducible operating conditions. Recently, various cathode materials have been extensively developed for vacuum microelectronic applications [5]. While actual RF devices like field-emitter tube amplifiers are still based on tip arrays of refractory metals, cathodes with nano-crystalline diamond materials would be preferred, if the field emitters have sufficient uniformity and high current stability.

CNT-TIP FIELD-EMITTER CATHODE

Flat panel display technology with commercial interest has stimulated research on the fabrication and characterization of nanostructured materials for field emission applications. However, it turned out that low cost fabrication over large areas is very challenging, particularly for applications demanding large emission currents requiring robust emitter materials. It was found that CNTs are quite suitable for the application as they are low-cost, robust, nano-structured material [6]. Previously, field emission of CNT cathodes was demonstrated with multi-walled carbon nanotubes (MWNTs) as well as single-walled carbon nanotubes (SWNTs) [7]. Carbon nanotubes have several advantages over other field-emitting materials. In contrast to commonly used emitters such as tungsten, a nanotube is not a metal, but a structure built by covalent bonds. The activation energy for surface migration of the emitter atoms is thus much larger than for a tungsten electron source. Therefore, the tip can withstand extremely strong fields (several V/nm). Depending on the exact arrangement of the carbon atoms, the cylinders are semiconducting or metallic conductors and the tubes can be closed or open at one or both ends. Furthermore, when compared with other film field emitters such as diamond or amorphous carbon structures, CNTs show a high aspect ratio, a small radius of

DEVELOPING AN IMPROVED PULSED MODE OPERATION FOR DUKE STORAGE RING BASED FEL*

S.F. Mikhailov#, H. Hao, V.G. Popov, Y.K. Wu
FEL Laboratory/TUNL, and Dept. of Physics, Duke University, Durham, NC 27708, USA

Abstract

The Duke FEL and High Intensity Gamma-ray Source (HIGS) facility is operated with an e-beam from 0.24 to 1.2 GeV and a photon beam from 190 to 1060 nm. Currently, the energy range of the gamma-ray beam is from 1 MeV to about 100 MeV, with the maximum total gamma-ray flux about 3E10 gammas per second around 10 MeV. The FEL is typically operated in quasi-CW mode. Some HIGS user experiments can benefit tremendously from a pulsed mode of FEL operation. For that purpose, a fast steering magnet was developed years ago [1] to modulate the FEL gain. This allows a build-up of a high peak power FEL pulse from a well-damped electron beam. However, the use of this gain modulator at low e-beam energies can dramatically limit e-beam current due to beam instability and poor injection. It also suffers from the problem of a significantly reduced e-beam lifetime. To overcome these shortcomings, we developed and successfully tested an RF frequency modulation technique to pulse the FEL beam. In this paper, we will describe this development, and report our preliminary results of this improved pulsed FEL operation.

DUKE FEL/HIγS FACILITY

The Duke storage ring is designed as a dedicated FEL driver and a host of several FEL wigglers in a thirty-four meter long FEL straight section. The main parameters of the Duke accelerators and FEL's are listed in Table 1.

A planar optical-klystron FEL, the OK-4 FEL, consists of two planar wigglers sandwiching a buncher magnet.

Table 1: Parameters of Duke Accelerators and FELs

Accelerators	Storage ring	Booster injector
Operation energy [GeV]	0.24-1.2	0.16-1.2
Maximum current [mA]	125	15
Circumference [m]	107.46	31.902
Revolution frequency [MHz]	2.79	9.397
RF frequency [MHz]	178.55	
FELs	OK-4	OK-5
Polarization	Horizont.	Circular
No. of wigglers	2	4
No. of regular periods	33	30
Wiggler periods [cm]	10	12
Maximum peak field [kG]	5.36	3.17
Maximum K_w	5.00	3.53
Maximum current [kA]	3.0	3.5
FEL wavelength [nm]	190 - 1064

# smikhail@fel.duke.edu

A circular optical-klystron FEL employs up four OK-5 helical wigglers, two of them in the middle of the straight section are switchable with two planer OK-4 wigglers. In 2005, operating with two OK-4 and two OK-5 wigglers simultaneously, we demonstrated lasing of the world's first distributed optical klystron FEL, the DOK-1 FEL, with a record FEL gain for storage ring based FELs [2].

DEVELOPMENT OF RF FREQUENCY SWITCH (Q-SWITCH)

Typically, in all the wiggler configurations and polarizations, the Duke FEL is operated in a quasi CW mode. For some user experiments, a pulsed FEL may become exceptionally beneficial. This allows users to additionally reduce the noise background by two to three orders of magnitude using time discrimination synchronized with FEL macro-pulses. To enable a pulsed mode of FEL operation, a fast steering magnet (so called FEL gain modulator) was developed [1]. It decouples the e-beam from the FEL beam in the interaction region for most of time, but periodically allows a brief overlap of the electron and FEL beams. This enables a pulsed mode of FEL operation with a high peak power in the FEL macro-pulses. The low-energy regime is the most commonly demanded for the nuclear physics experiments using a pulsed beam. The production of gamma ray beams of high intensity requires also high beam currents.

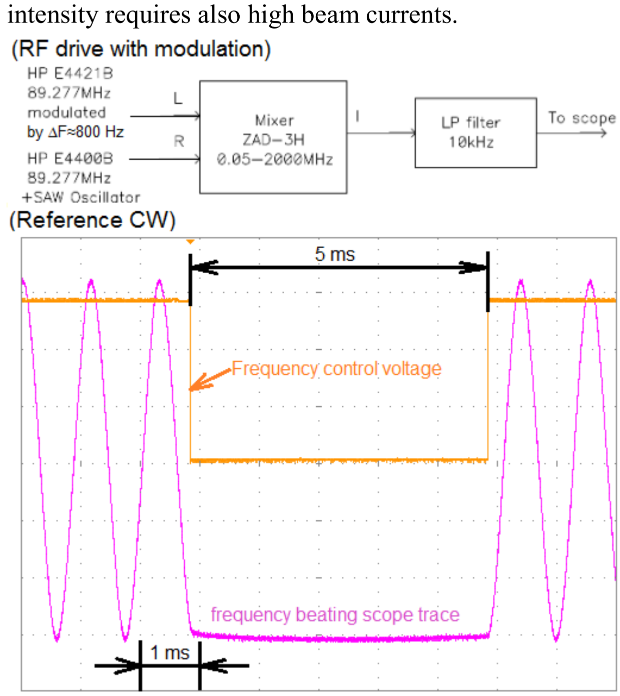

Figure 1: Fast switch of the RF frequency as demonstrated by the transition in time of the beating between the RF drive signal and a CW reference signal.

EXTENDING OK5 WIGGLER OPERATIONAL LIMIT AT DUKE FEL/HIGS FACILITY*

Patrick Walter Wallace#, Mark Emamian, Hao Hao, Stepan F. Mikhailov, Victor Popov, Ying K. Wu
FEL/Duke University, Durham, North Carolina
Jingyi Li
FEL/Duke University, Durham, North Carolina; USTC/NSRL, Hefei, Anhui

Abstract

Since 2007 the HIGS facility has been operated to produce both linearly and circularly polarized gamma-ray beams using two FELs, the planar OK-4 FEL and helical OK-5 FEL. Presently, with the OK-5 FEL operating at 192 nm, we can produce circularly-polarized gamma-ray beams between 1 and 100 MeV for user applications. Gamma-ray production between 80 and 100 MeV required an extension of the OK-5 wiggler operation beyond the designed current limit of 3.0 kA. In 2009, we upgraded cooling and machine protection systems to successfully extend OK-5 operation to 3.5 kA. To realize HIGS gamma-ray operation beyond 100 MeV and ultimately toward 150 MeV (the pion-threshold energy), with various limitations of the VUV mirror technology, the OK-5 wigglers will need to be operated at an even higher current, between 3.6 and 4.0 kA. In this paper we present our technical solution to further extend the operation range of the OK-5 wigglers, and report our preliminary results with high-current wiggler operation.

BACKGROUND

Need for Higher Wiggler Current

The energy of gamma-rays produced in the Duke Free Electron Laser (FEL) depends on the FEL lasing wavelength, the energy of the stored electron beam, and the magnetic field strength of the wiggler magnets [1]. The maximum gamma energy at the High Intensity Gamma Source (HIGS) currently available for users is 100 MeV, using 190 nm FEL mirrors and operating with 1.05 GeV electrons and a current of 3.5 kA in the OK-5 wigglers. There are important experiments which need higher energy gammas (eg. proton spin polarizability), up to 110–120 MeV. Having no expectation in the short-term of obtaining robust and highly reflective mirrors for shorter wavelengths, nor of a significant increase of the electron beam energy in the storage ring, we need to identify ways to operate the wigglers at higher currents.

The main design and operational parameters of the OK-5 wigglers are given in Table 1.

Table 1: Parameters for OK-5 Wigglers

Polarization	Circular
No. of wigglers	4
No. of regular periods	30
Wiggler period [cm]	12
Maximum current [kA]	3.5
Maximum magnetic field [kG]	3.17
Maximum K_w	3.53
FEL wavelength [nm]	190 - 1064

Figure 1: T-Rex power supplies at Duke FEL.

2009 Upgrade

Prior to 2009, operating the wigglers at the design maximum of 3.0 kA, and using the shortest wavelength of conventional mirrors (240 nm), the maximum gamma energy was limited to 60 MeV. Raising the wiggler current up to 3.6 kA, gamma energies of 70 MeV would be achievable. Testing showed that operation above 3.0 kA tripped the magnet over-temperature switches (65 °C Klixons), and a new set was installed (90 °C). Next, we found that long-term operation above 3.5 kA increased the resistance of the magnet coils and connecting bus bars enough that the TRANSREX (T-Rex) power supply (see Figure 1) reached the maximum output voltage limit (about 100 V) when driving two wigglers in series, which limited wiggler current to 3.5 kA. The final steps of the upgrade were to add water flow switches to the cooling water return flows as protection against sudden loss of water flow, and to install new, faster response-time

LIGHT SOURCE AND ACCELERATOR PHYSICS RESEARCH PROGRAM AT DUKE UNIVERSITY*

Y.K. Wu†
FEL Laboratory, Triangle Universities Nuclear Laboratory and Department of Physics, Duke University, Durham, NC 27708-0319, USA

Abstract

The light source and accelerator physics research program at Duke Free-Electron Laser Laboratory (DFELL), Triangle Universities Nuclear Laboratory, is focused on the development of the storage ring based free-electron lasers (FELs), and an FEL driven state-of-the-art Compton gamma-ray source, the High Intensity Gamma-ray Source (HIGS). With a maximum total flux about 3×10^{10} γ/s and a spectral flux of more than 10^3 γ/s/eV around 10 MeV, the HIGS is the world's most intense Compton gamma-ray source. Operated in the energy range from 1 to 100 MeV, the HIGS is a premier Compton gamma-ray facility in the world for a variety of nuclear physics research programs, both fundamental and applied. In this paper, we will describe our ongoing accelerator physics and light source development program in the areas of the storage ring magnetic optics characterization and compensation, FEL physics, and development of gamma-ray beams in the higher energy range (100 to 158 MeV).

INTRODUCTION

The primary light sources at the Duke Free-Electron Laser Laboratory (DFELL), Triangle Universities Nuclear Laboratory (TUNL), are storage ring based free-electron lasers (FELs) [1] and the FEL driven High Intensity Gamma-ray Source (HIGS) [2]. At the DFELL, we operate three accelerators: (1) a 0.16 – 0.27 GeV linac pre-injector; (2) a 0.16 – 1.2 GeV full-energy, top-off booster injector; and (3) a 0.24 – 1.2 GeV electron storage ring. The Duke storage ring is a dedicated host for an oscillator FEL with several wiggler configurations. This FEL is the photon beam driver for the world's most intense Compton gamma-ray source, the HIGS which produces intense gamma-ray beams from 1 to 100 MeV with a maximum total flux about 3×10^{10} γ/s and a maximum spectral flux of more than 10^3 γ/s/eV around 10 MeV. The Compton gamma-ray beam at the HIGS is highly polarized (linear or circular), and has an excellent energy resolution. Since 2008, the accelerator facility has been operated mainly as the Compton gamma-ray source facility for routine user research in the area of nuclear physics and nuclear astrophysics. The layout of the accelerator facility is shown in Figure 1 and a list of key parameters of the Duke booster injector and storage ring are summarized in Table 1.

Table 1: Parameters for the Duke booster injector and storage ring. The storage ring FELs can be operated using two different sets of wigglers with the wiggler switchyard.

Parameter	Value
Booster Synchrotron	(Main Injector)
Circumference [m]	31.902
RF frequency [MHz]	178.55
Number of RF buckets	19
Injection energy [GeV]	0.16 – 0.27
Extraction energy [GeV]	0.16 – 1.2
Storage Ring	
Operation energy	0.24 – 1.2 GeV
Circumference	107.46 m
RF frequency	178.55 MHz
Number of RF buckets	64
Max beam currents	
One-bunch (FEL)	95 mA ($\geq$ 0.6 GeV)
Two-bunch (HIGS)	~ 125 mA ($\geq$ 0.5 GeV)
Multi-bunch (60)	> 300 mA ($\geq$ 0.5 GeV)
Duke FELs	(Wiggler Switchyard)
Linear and circular pol.	Two planar OK-4 wigglers
	plus two helical OK-5 wigglers
Circular polarization	Four helical OK-5 wigglers

STORAGE RING LATTICE CHARACTERIZATION

Since 2013, we have devoted substantial time and effort to characterizing and compensating the magnetic optics of the Duke storage ring in order to optimize its operation. One of major challenges in this area stems from the use of all combined function quadru-sextupoles in the arcs in order to minimize the cross-talk between adjacent magnets of different types in the very compact arc lattice [3]. These magnets are standard quadrupoles but are powered by two different currents in the inner and outer coils. Consequently, the magnetic centers are separated from the geometric centers typically by more than 2 mm. The actual beam orbit in each magnet is not unknown in advance, and is subject to the change of the settings of quadrupole and sextupole components. In addition, the BPMs in the arc are instrumented relative to the geometric center of the quadru-sextupoles, making them much less reliable/accurate monitors for beam orbit measurements and lattice calibration.

Collectively, these issues present some significant difficulty to use the LOCO method [4] to calibrate the Duke storage ring lattice. Therefore, we worked to develop a direct beta-function measurement technique using the global tune changes caused by varying the strength of a quadrupole

PULSED-WIRE MEASUREMENTS FOR INSERTION DEVICES

D'Audney, S. Stellingwerff, S.G. Biedron, S.V. Milton
Colorado State University, Fort Collins, CO, 80521 USA

Abstract

The performance of a Free-Electron Laser (FEL) depends in part on the integrity of the magnetic field in the undulator. Correcting magnetic field imperfections within the undulator is important for optimal FEL gain. Thus, the magnetic field must be properly mapped. A pulsed wire method is a quality method to achieve this when a traditional Hall device cannot be used. The pulsed-wire method works by sending a square current pulse through the wire, which will induce an interaction with the magnetic field due to the Lorentz force. This force causes the wire to be displaced, and this displacement travels along the wire in both directions as an acoustic wave. Measurement of the displacement in the wire over time using a motion detector yields the first or second integrals of the magnetic field. Dispersive effects in the wire are corrected using algorithms resulting in higher accuracy results. Once the fields are known, magnetic shims can be placed where any corrections are needed.

INTRODUCTION

The performance of a Free-Electron Laser (FEL) depends in part on the quality of the magnetic field in the undulator. The magnetic field on the axis of the undulator is transverse and sinusoidally varying due to the periodic sequence of dipoles. The length of these periods, and the electron beam energy, determine the wavelength of the radiation that will be generated. When a relativistic electron bunch from the particle accelerator is injected into the undulator, the static magnetic fields create transverse oscillations in the particles' trajectory. These oscillations cause the electrons to emit energy. The ideal trajectory of a relativistic electron bunch inserted along the axis is sinusoidal in the plane of oscillation. Phase errors are produced when the path of the electron is not the ideal sinusoidal trajectory, due to imperfections in the magnetic field. The dipole magnets should compensate each other to limit phase errors and diminish the divergence of the electron bunch to the optical beam. In the case of an FEL, phase errors in the electron trajectory lead to a reduction in electron beam bunching. This effect causes a reduction in the energy transfer from the e-beam to the optical field and hence, reduces FEL gain [1,2]. Thus, the magnetic field must be mapped and tuned to a level acceptable to efficient FEL operation. A pulsed-wire method can be used to determine the profile of the magnetic field.

Traditionally, the fields within these devices have been measured with high accuracy using a Gauss meter or Hall probe; however, with the advent of more complex and superconducting undulators these types of probe systems may not always be a viable option. Topographies such as narrow undulator gaps or cryogenic environments in superconducting undulators restrict measurement access. A pulsed wire method is an attractive option to map the magnetic field in a noninvasive manner [3-5]. In our particular case, the undulator has large metal spacers to keep the undulator gap steady. These spacers make it a solid candidate for a pulsed wire experiment.

The pulsed-wire method described here overcomes several effects that have previously limited the method's accuracy in characterizing the magnetic field in an undulator. The principal component of this technique is a thin current-carrying wire, specifically a 75-um Copper Beryllium wire which is used to simulate both the velocity and trajectory of a charged particle within the undulator. The Lorentz force acting upon the current within the wire causes movement in the wire, and this force is proportional to the local magnetic field acting on it. The resultant motion then propagates as a wave along the length of the wire. The displacement of the wire is measured by an optical detector and then processed using MATLAB algorithms. A schematic of a basic pulsed-wire method is shown in Fig. 1. To establish an absolute value for the pulsed-wire measurements being done, a characterized reference magnetic field is required. This field is applied along the wire external to the undulator fields and used to calibrate the measured undulator fields.

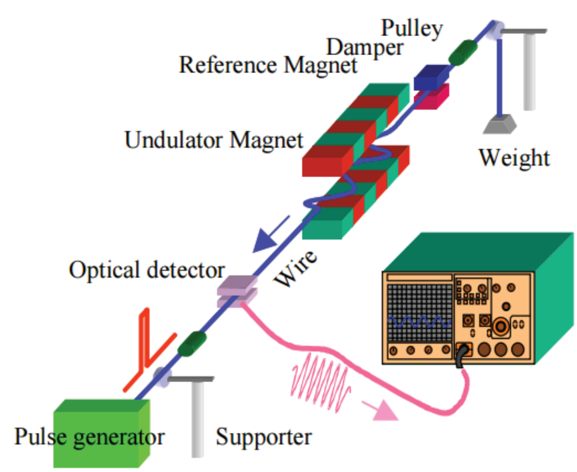

Figure 1: Simplified pulsed wire setup [6].

In the past, dispersive and finite pulse width effects within the wire have had undesirable consequences on the measured field profile. Recently developed algorithms compensate for these effects and increase the accuracy of the measurements [6]. Magnet imperfections can be easily corrected by using small magnetic shims once the field is characterized [2, 7].

AN IMPROVED ANALYTIC MODEL OF ELECTRON BACK-BOMBARDMENT IN THERMIONIC-CATHODE RF GUNS

J. P. Edelen#, S. G. Biedron, J. R. Harris, S.V. Milton, Colorado State University, Fort Collins, CO
J. W. Lewellen, LANL, Los Alamos, NM

Abstract

This paper describes work done at Colorado State University to improve upon the recent theory developed to predict the back-bombardment power in single-cell thermionic-cathode electron guns. The previous theory used a square-wave approximation of the time varying field to solve for the total kinetic energy deposited on the cathode due to the back-bombarded electrons. In addition the transit time factor was added as a correction to compensate for the non-sinusoidal field. By solving for the back-bombardment power using a sinusoidal field, the transit time factor can be removed and therefore a better overall model is produced. These alterations continue to accurately predict how back-bombardment varies as a function of the gun parameters and provides improvement when compared to the existing theory.

INTRODUCTION

Recent work has successfully developed a first principles model that accurately predicts the back-bombardment power for single-cell thermionic-cathode electron guns as a function of the design parameters, Equation 1 [1]:

$$P_{ave} = \frac{3E_0 I c^2}{4\alpha^2 f v_{eff}} TK \qquad (1)$$

Here E_0 is the peak RF field in the gap, α is the RF wavelength normalized to the gap length ($\alpha = \lambda_{rf}/L_{gap}$), f is the RF frequency, I is the average beam current, v_{eff} is the effective velocity of electrons in the gap defined by Equation 2, T is the transit time factor defined by Equation 3, and K is the field normalization factor defined by Equation 4.

$$v_{eff} = c\sqrt{1 - \left(1 + \frac{qE_0\lambda}{2m_0c^2\alpha}\right)^{-2}} \qquad (2)$$

$$T = \frac{\sin(\pi c/\alpha v_{eff})}{\pi c/(\alpha v_{eff})} \qquad (3)$$

$$K = \frac{\int_0^{L_{gap}} E(z)dz}{E_0\lambda/\alpha} \qquad (4)$$

In the previous work we used a square wave in order to reveal exact solutions to the equations of motion and solve for the back-bombardment power. Follow-on studies indicated that a sinusoidal field could also be used to solve for the back-bombardment power, contingent on the constant velocity principle used in the previous work.

This paper presents a modification to the theory that utilizes a sinusoidal time varying field, which makes for a better a-priori model and allows for the omission of the transit time factor from the back-bombardment power equation. We begin with an overview of the modification to the theory and compare these results with both the previous model and the numerical solutions to the relativistic equations of motion. The new model is then compared with simulations performed using SPIFFE [2]. Finally we provide a quantitative comparison between the new model and the existing model over a wide range of parameters.

ADDITION OF A SINUSOIDAL FIELD TO THE BACK-BOMBARDMENT MODEL

To solve for the back-bombardment power, the effective kinetic energy as a function of the electron emission time is calculated using Equation 5.

$$K_{eff}(t_0) = v_{eff}\int_{t_0}^{t_0+t_{transit}} E_0\sin(\omega t)dt \qquad (5)$$

Here $t_{transit}$ is the particle transit time. The particle transit time is different for particles that exit the gun and those that are back-bombarded. For particles that exit the gun the transit time is $t_{transit}^{fw} = \lambda/(\alpha v_{eff})$. For particles that are back-bombarded the transit time is a function of the emission time given by $t_{transit}^{bb}(t_0) = 4(\tau/2 - t_0)$ [1]. Solving Equation 5 for both the output case and the back-bombardment case, gives the effective kinetic energy of all the particles as a function of their emission time (Green line in Figure 1). This was compared with the result of numerically integrating the relativistic equations of motion of the same representative geometry, which gives the blue line in Figure 1. Additionally the model derived in previous work by using a square wave field is given in black.

This shows that there is still a fairly poor agreement for the output beam, however the new model is much better than the previous model. However, when computing the back-bombardment power only the area under the curve to the right of the discontinuity is of interest. Inspection of both the blue and green curve shows that this is indeed a reasonable approximation.

SIMULATION AND ANALYSIS OF LASER/ELECTRON BEAM INTERACTION FOR USE AS A FREE ELECTRON LASER

J.A. Einstein#, S.G. Biedron, S.V. Milton, H.P.Freund,
Colorado State University, Fort Collins, CO 80525, USA
G. Dattoli, ENEA – Divisione Fisica Applicata Centra Rierche Frascati, Roma, Italy

Abstract

Through the use of simulation tools and theoretical analysis techniques, the Free Electron Laser process is investigated for a wiggler that is generated by an ultrafast laser system. The development and availability of such systems allows for novel FEL designs due to the high peak power of such lasers. Even though such high powers are possible, difficulties arise due to inhomogeneity in the laser pulse. This project looks at simulation results for a system with a realistic laser pulse profile and looks in to the pulse-shape effects on various system parameters. Models are presented for the expected behavior with important parameters noted, as well as highlighting possible difficulties that might occur experimentally. While head-on interaction has been proven experimentally for the short wavelength regime [1], we believe that using a co-propagating laser can provide benefits that have currently been untested. This experimental setup is outlined in Lawler, J et al [2], and we are currently simulating how the use of an ultrashort laser pulse as an electromagnetic wiggler will affect characteristics of the output radiation.

INTRODUCTION

Free electron lasers (FELs) are a highly tunable, flexible light source, with significant opportunities to act as high power, low wavelength sources for industry and research. An FEL relies upon a highly periodic, alternating field to take advantage of electron motion to generate light. Current undulator designs require the use of strong magnets or electro magnets to generate a strong enough field, and often need to be quite long to obtain the desired level of coherence in the output light.

Several new undulator designs have been proposed and tested, including a microwave undulator [3], and several designs have been proposed for optical undulators of various design [4], [5], and a co-propagating optical design [2].

Recent advances in the peak energies possible with ultrafast laser sources and in beam shaping and control allow for the use of optical pulses as an undulator. This allows for a significant decrease in the required length of an undulator and allows for the use of lower electron beam energies while still generating low-wavelength light. The miniaturization of the system leads to several advantages, not the least of which is a significant decrease in cost. In addition, the use of a laser pulse as the undulator allows for the use of COTS components for the transport and shaping optics.

Joshua.Einstein@colostate.edu

This paper presents results of a simulation of the proposal from Lawler, et al, in reference [2], modified by the use of an ultrafast laser. This design uses a co-propagating, sheared laser pulse to generate an undulator-like field.

Proposed Experimental Setup

The experimental design is based on transporting an ultrashort pulse through a series of optical components to shear the wave fronts in to a uniform, undulator-like design. Several methods have been considered for how to shear a laser pulse, with various benefits for each depending on the qualities of the incoming laser pulse.

We propose a system using an ultrashort pulse that is sheared using a blazed grating with necessary correction optics and diagnostics. A schematic of the interaction can be seen in figure (1). Several proposals have been made for perpendicular illumination of the beamline, and integrating some of those ideas with ours will be beneficial [6].

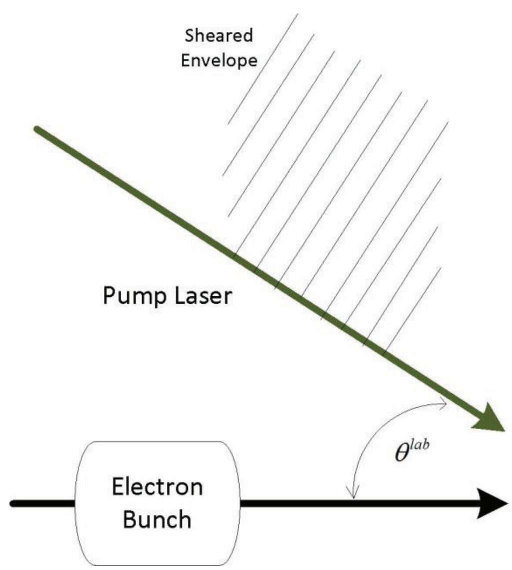

Figure 1: Beam interaction schematic.

Simulation Setup

Two simulation codes were used for simulating the undulator section of the proposed design. ONEDFEL is a 1D, non-time-averaging code, and MEDUSA is a full 3D simulation code [6]. In order to approximate the envelope of an ultrafast pulse, the already built-in feature of undulator tapering was used. This function used a sin2 envelope instead of a Gaussian, but is valid for simulating the effect of such a variable field undulator.

PEPPo: USING A POLARIZED ELECTRON BEAM TO PRODUCE POLARIZED POSITRONS

A. Adeyemi*, Hampton University, Hampton, VA, USA
on behalf of the PEPPo Collaboration

Abstract

An experiment demonstrating a new method for producing polarized positrons has been performed at the CEBAF accelerator at Jefferson Laboratory. The PEPPo (Polarized Electrons for Polarized Positrons) concept relies on the production of polarized e^+/e^- pairs originating from the bremsstrahlung radiation of a longitudinally polarized electron beam interacting within a 1.0 mm tungsten pair-production target. This paper describes preliminary results of measurements using an 8.2 MeV/*c* electron beam with polarization 84% to generate positrons in the range of 3.1 to 6.2 MeV/*c* with polarization as high as ~80%.

INTRODUCTION

Polarized positrons are a powerful probe for the investigation of numerous physics phenomena. At thermal energies, polarized positrons may be used to study spintronic properties of materials [1]. Accelerated to GeV energies, the comparison between polarized electron and positron scattering cross-sections tests the precision of the electromagnetic interaction for the investigation of nucleon and nuclear structure [2]. At TeV energies, polarized positrons are essential for testing the Standard Model in the context of the International Linear Collider (ILC) [3].

Polarized positrons are produced in radioactive beta-decay [4], or by man-made methods such as the Sokolov-Ternov self-polarization of unpolarized positrons in a storage ring [5] or resulting from pair-production following the irradiation of nuclei with circularly polarized gamma rays. For the latter method, circularly polarized gamma rays can be produced via Compton back-scattering [6] or using a helical undulator [7]. Both techniques produced positrons with a high degree of positron spin-polarization and demonstrated the potential for high yield. However, both methods require very high electron beam energies 10-100 GeV and elaborate technologies.

In this work, we demonstrate a new technique for the production of polarized positrons, and with very low beam energy ~10 MeV. The idea, suggested in the late 1990's in the context of the ILC [8, 9], relies on the production of circularly-polarized gamma rays by the bremsstrahlung produced using polarized electrons; these photons then create polarized positrons via pair-production on nuclei. By demonstrating the technique at low energy, we avoid issues associated with high power targets and activation, illustrating the applicability of this technique to the design of future polarized positron sources, whether at similar or much higher energy where yield may be significantly increased.

* adeyemi@jlab.org

EXPERIMENT

The PEPPo experiment [10] was installed at the Jefferson Lab CEBAF injector where a highly spin-polarized 84% electron beam with energies up to 10 MeV could be provided. The electron beam could be delivered for characterization to either a Mott scattering electron polarimeter or a precision electron spectrometer; alternatively it could be sent to the PEPPo apparatus (see Fig. 1) which included: the e^+/e^- production target, a quarter-wave solenoid to collect positions within a large divergence angle, a combined-function spectrometer to select and focus discrete positron momenta slices, a pair of coincidence positron annihilation detectors, and a second solenoid to transport and focus positrons through an 8 mil Al window to the PEPPo polarimeter.

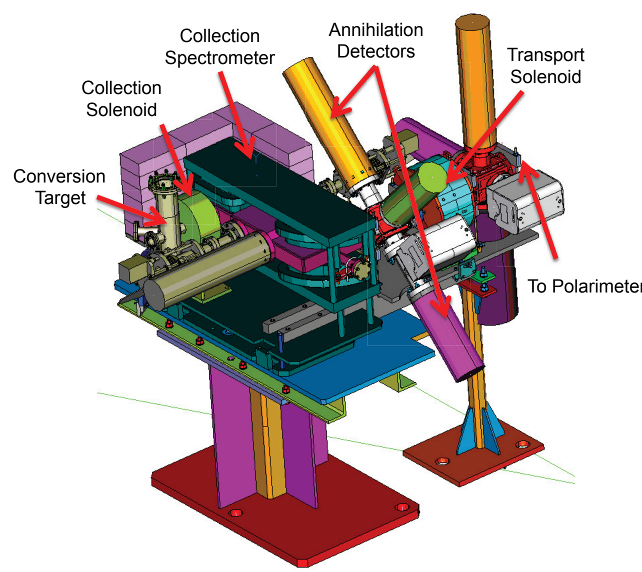

Figure 1: Vacuum beam line includes the insertable production target, a solenoid to collect e^+, a double-bend spectrometer to define the momentum acceptance, a positron annihilation detector, and a second solenoid to transport e^+ to an exit vacuum window in front of the polarimeter.

PEPPO POLARIMETER

The PEPPo polarimeter (see Fig. 2) is a Compton transmission type polarimeter that relies on the bremsstrahlung spectrum produced by longitudinally polarized positrons (or electrons) having small energy and angular distributions interacting with a reconversion target at the entrance of the polarimeter. The polarimeter takes advantage of the differential cross section for the Compton scattering of circularly polarized bremsstrahlung photons with a longitudinally polarized electron target (P_T) [11]. The measurement of the

OPTIMIZATION OF AN IMPROVED SASE (iSASE) FEL*

L. Gupta†, Cornell University, CLASSE, Ithaca NY 14853, USA
K. Fang, J. Wu, SLAC National Accelerator Lab, Menlo Park CA, 94025, USA

Abstract

In order to improve free electron laser technology for the future LCLS II at SLAC, a new strategy for creating radiation with increased temporal coherence is under development. The improved Self-Amplified Spontaneous Emission (iSASE) FEL utilizes phase shifters which allow for the spontaneously emitted radiation to interact with and stimulate more electrons to radiate coherently. Five phase shifters were simulated, with 34 normal-conducting undulators and focusing-defocusing quadrupoles as an LCLS II FEL lattice using the FEL software Genesis 1.3. Two general schemes, one providing a total phase shift of arbitrary distribution, the other providing a sequential or distributed phase shift, were simulated and optimized using a simulated annealing algorithm. The results suggest that the phase shifters must provide a total shift comparable to the bunch length, and the shifts must be distributed with one large shift, followed by smaller shifts.

INTRODUCTION

A new frontier in fundamental science research, with applications in biological, material, and various other physical sciences, is the use of free electron lasers, or FELs. Only a few FELs exist at various particle accelerator facilities around the world, including the Linear Coherent Light Source (LCLS) at SLAC, and new designs are being developed for use in conjunction with improved accelerators. Specifically, the LCLS II at SLAC will use superconducting technology that could produce brighter hard x-ray FELs than is currently possible at existing FEL facilities. Currently, the LCLS FEL has been able to produce hard x-rays that allow for angstrom resolution imaging [1]. However, the bandwidth of the current LCLS FEL is large relative to that of a transform limited laser. As there is need for highly coherent FEL radiation, FELs must be improved to provide such radiation to users.

Improved SASE (iSASE)

A new strategy for constructing FELs is the improved Self-Amplified Spontaneous-Emission (iSASE) undulator, which can overcome the limitations of a SASE FEL [2, 3]. The key disadvantage that must be overcome in the SASE FEL is the limited slippage that occurs; therefore increasing the slippage would increase the temporal coherence of the emitted radiation. The slippage is artificially increased in the iSASE FEL by adding phase shifters, that increase the path travelled by the electron bunch [2]. By increasing the path length of the electron bunch, the radiation, which is not affected by the phase shifter, continues on a straight trajectory and is able to “catch-up" to the head of the electron bunch. Due to this improvement, the randomly emitted radiation is able to stimulate further coherent radiation from the entire bunch, which increases the overall temporal coherence of the FEL radiation [2, 3]

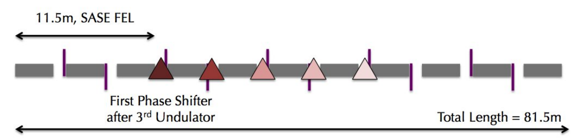

Figure 1: The base-lattice layout for the simulated FEL; the first phase shifter was placed after the third undulator, with focusing and defocusing quadrupoles maintaining the beam optics through the FEL.

The iSASE FEL has only been in development at SLAC for a short period of time, yet has already been shown to work as the theory predicts in both simulations and experimentally [2]. Because the initial simulations show that the iSASE FEL could produce coherent radiation, the next step in the design process is to optimize the chicanes within the undulator system. The program Genesis 1.3, with improvements made for the current simulation requirements, can be used to simulate an iSASE FEL and return information about the radiation that would be generated in such an FEL undulator system [2–4]. In order to design an efficient and effective iSASE FEL, the chicane lengths and positions within the FEL must be optimized such that the temporal coherence and the brightness of the radiation are maximized, and the radiation bandwidth is minimized. The integration of an optimized iSASE FEL with the LCLS II at SLAC could therefore be a significant development in FEL technology.

SIMULATION SET-UP

In order to optimize the phase shifter strengths for an LCLS II type, normal conducting FEL, a lattice the following lattice was set-up. First, the base-lattice was created with 34 undulators and 33 quadrupoles set up in a focusing-defocusing layout, over the 81.5 m long FEL.The lattice also included five phase shifters, the first of which was placed after the third undulator (three gain lengths), creating essentially a short SASE FEL with known slippage length, l_{slip}. Each phase shifter consists of four bending magnets, and is 40 cm long. A general schematic is shown in Fig. 1. Once the lattice was constructed, the focusing and defocusing strengths for the lattice were calculated and the beta functions for the beam were simulated in Tao, the tool for accelerator optics, which runs using Bmad (charged particle simulation subroutine library). Once the beta function

CESR UPGRADE AS A HIGH-ENERGY, HIGH-BRIGHTNESS X-RAY LIGHT SOURCE*

J. Shanks†, D.L.Rubin, CLASSE, Ithaca, NY 14853, USA

Abstract

The Cornell Electron Storage Ring (CESR) operates most of the year as the Cornell High Energy Synchrotron Source (CHESS). CESR was originally designed and operated as an electron/positron collider, circulating high-emittance beams in order to maximize luminosity. Beam lines were developed to extract x-rays from both electron and positron beams. The two beams share a common vacuum chamber, and are electrostatically separated to avoid collisions. The requirement to store counter-rotating beams significantly constrains the storage ring optics, limiting emittance and, beam current, and bunch distributions. The proposed upgrade eliminates two-beam operation in favor of a single optimized on-axis beam. Several new undulator-based beam lines are planned. The horizontal emittance is reduced in steps, first from 90 nm to 20 nm at 5.3 GeV, and then in a ring-wide upgrade to as low as 300 pm at 6 GeV. The low-emittance optics are based on multi-bend achromats with combined function bends. The details of the optics, apertures, and magnet parameters are presented.

INTRODUCTION

The Cornell Electron Storage Ring (CESR) is a 768-meter e^+/e^- storage ring, with operating energies 1.8–5.3 GeV. Originally developed to operate parasitically while CESR collided electrons and positrons for high energy physics [1,2], CHESS takes advantage of the counter-rotating beams, with seven lines illuminated by light from the positron beam and four from the electron beam. With the conclusion of the particle physics program in 2008, CESR continued to circulate both species of particles, in order to feed the existing CHESS beam lines.

Maintenance of two-beam operation places a long list of constraints on the optics [3,4], including minimum achievable emittance, and injection efficiency. Top-off injection is limited to a single species as the single synchrotron injector is shared by both electrons and positrons.

Here, a proposal is outlined that optimizes performance with a single beam, and that can accommodate additional insertion devices. All CHESS beam lines would be reconfigured to accept an undulator source, and all beam lines would be oriented in the same direction. The same sextant where the beam lines are located is also the source of a disproportionate fraction of the total emittance. Reconfiguration of the lattice in this sextant with double-bend achromat (DBA) cells thus allows re-orientation of the beam lines as well as a substantial reduction of the horizontal emittance.

† js583@cornell.edu

PROPOSED UPGRADE

CESR presently uses a FODO-style lattice, with a long straight section for the former CLEO detector. The strong dipoles required for bending into the CLEO straight presently contribute $\approx 60\%$ of the radiation integral I_5, and thus dominate the horizontal emittance.

The proposed upgrade replaces one sextant of the lattice centered at the CLEO straight with six double-bend achromat (DBA) cells. Between each DBA there will be a four-meter zero-dispersion straight for insertion devices. Figure 1 demonstrates how the new layout will remove the CLEO detector straight, following the arc of the ring more continuously. The change in CESR will mandate removing part or all of the CLEO detector that remains in the experimental hall.

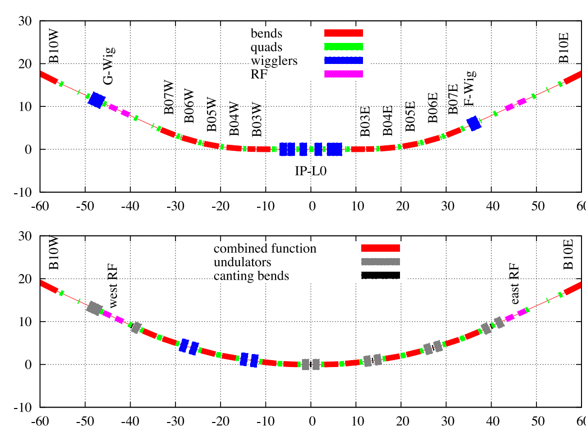

Figure 1: Top: existing user area layout. Bottom: proposed change to user area, removing the CLEO detector straight. All counter-clockwise beam lines will be replaced with clockwise-facing lines, and all beam lines will utilize undulator sources.

Twiss parameters are shown for one DBA cell in Fig. 2, and for the entire ring in Fig. 3. Magnet parameters for one DBA cell are shown in Table 1. Dipoles in the DBA cells will be combined-function dipole-quadrupoles, contrasting with the fixed-purpose dipoles presently installed throughout CESR. Two of the three quadrupoles in each DBA will reuse existing magnet stock. As with the rest of CESR, all quadrupoles in the upgraded region will be independently powered in order to retain flexibility in the optics.

An unusual feature of the proposed lattice is a lack of sextupoles in the DBA sextant. CESR does not presently have sextupoles through this sextant, relying on sextupoles in the remaining 5/6 of the ring to compensate chromaticity and nonlinear dynamics. Dynamic aperture is $> 20\sigma$ of the stored beam.

TWO-DIMENSIONAL CALCULATION OF CHANNELING RADIATION SPECTRUM FOR HIGH-BRIGHTNESS HARD X-RAY PRODUCTION

Wade D. Rush, Jack J. Shi
Department of Physics & Astronomy, The University of Kansas, Lawrence, KS 66045, USA

Abstract

The channeling radiation spectrum is calculated without using the one-dimensional approximation in the planar channeling radiation model or the single-string approximation in the axial channeling radiation model. The obtained spectrum of the two-dimensional channeling radiation is significantly different from those previously calculated with the approximations. The calculation presented here is of the channeling radiation experiments conducted at Fermilab Advanced Superconducting Test Accelerator (ASTA) photoinjector with electron beam energies of 20 to 50 MeV and a diamond target. The computational method developed in this work can be applied to general cases of different crystals and beams with different energy and emittances.

INTRODUCTION

High-energy channeling radiation is produced by a relativistic electron beam interacting with a crystal lattice when the beam channels through the crystal. When an ultra-relativistic electron enters a crystal, the electron will channel through the crystal lattice if its incident angle relative to a specific lattice direction is sufficiently small [1]. A high-intensity ultra-relativistic electron beam could produce high-brightness hard X-rays due to the perturbation of the transverse motion of beam electrons in the crystal. To study this channeling radiation theoretically and numerically, the interaction between the lattice ions and beam electrons has previously been modelled with two different approximations. In the planar channeling approximation [2–4], the radiation from beam electrons is calculated approximately using the Bloch wave function of the electrons solved in a one-dimensional transverse space. In the axial channeling model [2, 5], on the other hand, a single-string approximation of the lattice potential results in a rotational symmetry in the two-dimensional transverse space that greatly simplifies the computational complexity of the original problem of two-dimensional energy bands calculation. Even though these approximations have been justified by the fact that the most relevant energy states for the channeling radiation are those deeply bound states, it is not clear what the conditions are for the validity of the approximations, especially for the case of high-brightness electron beams. In this paper, the channeling radiation spectrum is calculated numerically by solving the Bloch wave function in the two-dimensional transverse space without using the planar or axial channeling approximations. This study is for the upcoming channeling radiation experiments on Fermilab ASTA facility with a 20 to 50 MeV electron beam incident on a diamond lattice along the [-110] lattice direction [6, 7]. In this study, we used a 14.6 MeV electron beam with rms emittance of 0.1 μm in the both transverse directions and the beta functions at the crystal are 4.0 m in the both directions.

LATTICE INTERACTIONAL POTENTIAL IN TRANSVERSE PLANE

When a relativistic beam electron channels through a crystal, the ions of the crystal lattice interact with the electron and affect the motion of the electron. The change of the electron motion results in the emission of photons. Since the longitudinal motion of the electron is ultra-relativistic, the interaction from the ions is too weak to have any effect on the longitudinal motion. The transverse motion of the electron is non-relativistic and the interaction from the ions could have a significant effect on the motion. For the transverse motion, in this study, the interaction potential $V(x, y)$ in the transverse plane is obtained by averaging the lattice potential $V_{cell}(\vec{r})$ in three-dimensional space along the longitudinal direction, where $V_{cell}(\vec{r})$ is the interaction potential of the ions in one unit cell and calculated by using Doyle-Turners formula based on a fitting to the electron scattering factor of the crystal [8]. Due to the periodicity of the lattice in the transverse plane, $V(x, y)$ can be written as a Fourier expansion with the reciprocal lattice vectors projected to the transverse plane. For a beam channeling along the [-110] direction of diamond lattice, the x and y axis of the transverse plane can be chosen to be along the [110] and [001] direction, respectively, and the reciprocal lattice constants of the transverse plane are $b_1 = 2\sqrt{2}\pi/a$ and $b_2 = 2\pi/a$ for the two directions, where a is diamond lattice constant. The interaction potential for the transverse motion of beam electrons can then be written as

$$V(x, y) = \sum_{k_1, k_2=-\infty}^{\infty} V_{k_1,k_2}\, e^{i(k_1 b_1 x + k_2 b_2 y)} \tag{1}$$

where the expansion coefficients V_{k_1,k_2} are calculated using the formulas given in [5] and the summations of k_1 and k_2 need to be truncated at $\pm k_{max}$ for a numerical solution of the Schrödinger equation of the beam electron in the lattice. In this study, it was found that the convergence of the truncation occurs at $k_{max} = 20$ as the change of $V(x, y)$ due to the additional terms of $k_{max} > 20$ is negligible. Figure 1 plots $V(x, y)$ in a unit cell and shows that the interaction potential in the transverse plane does not have a rotational symmetry of the potential used in the axial channeling approximation. The asymmetry of $V(x, y)$ between the x and y direction is because the two-dimensional lattice in the transverse plane becomes rectanglar as $b_1 \neq b_2$, which results from the projection of the cubic diamond lattice to the transverse plane.

X-BAND RF PHOTOINJECTOR FOR LASER COMPTON X-RAY AND GAMMA-RAY SOURCES*

R.A. Marsh†, G.G. Anderson, S.G. Anderson, D.J. Gibson, C.P.J. Barty
Lawrence Livermore National Laboratory, Livermore, CA 94550, USA

Abstract

Extremely bright narrow bandwidth gamma-ray sources are expanding the application of accelerator technology and light sources in new directions. An X-band test station has been commissioned at LLNL to develop multi-bunch electron beams. This multi-bunch mode will have stringent requirements for the electron bunch properties including low emittance and energy spread, but across multiple bunches. The test station is a unique facility featuring a 200 MV/m 5.59 cell X-band photogun powered by a SLAC XL4 klystron driven by a Scandinova solid-state modulator. This paper focuses on its current status including the generation and initial characterization of first electron beam. Design and installation of the inverse-Compton scattering interaction region and upgrade paths will be discussed along with future applications.

INTRODUCTION

Accelerator-based x-ray and gamma-ray sources are expanding rapidly, with several large facilities in construction both in Japan and in Europe [1, 2]. LLNL has a successful history utilizing gamma-rays generated by a linac-driven, laser-based Compton scattering gamma-ray source [3, 4, 5, 6]. Next generation advancements in linac-based x-ray and gamma-ray production require increasing the average flux of gamma-rays at a specific energy (that is, $N/eV/sec$ at the energy of interest). One way to accomplish this is to increase the effective repetition rate by operating the RF photoinjector in a multi-bunch mode, accelerating multiple electron bunches per RF macro-pulse. This multi-bunch mode will have stringent requirements for the electron bunch properties including low emittance and energy spread, but across multiple bunches. An X-band test station has been built and commissioned at LLNL to develop multi-bunch electron beams and generate x-rays. This paper summarizes progress and describes the current status and future direction of the project.

Building on the design work for a 250 MeV gamma-ray source, and leveraging hardware and engineering done for the VELOCIRAPTOR X-band accelerator [7], LLNL established an X-band test station for laser-Compton research and development. The current test station parameters are summarized in Table 1. Beam dynamics are summarized in Fig. 1 for a 100 pC bunch generated in the Mark 1 X-band RF gun and accelerated by a single T53 traveling wave accelerating section. The goals of establishing the test station have been a demonstration of X-band technology for laser-Compton applications and pushing the state-of-the-art with novel interaction concepts. The current goals of the test station efforts are first x-ray demonstration, initial x-ray application experiments, electron beam optimization, demonstration of multiple electron bunches spaced as close as every RF bucket, and upgraded controls systems. Success has been achieved on all of these fronts, with preliminary results reported in this paper and [8].

STATUS OF THE MARIE X-FEL ACCELERATOR DESIGN*

J.W. Lewellen#, K.A. Bishofberger, B.E. Carlsten, L.D. Duffy, F.L. Krawczyk, Q.R. Marksteiner, D.C. Nguyen, S.J. Russell, R.L. Sheffield, N. Yampolsky, LANL, NM 87545, USA

Abstract

The Matter-Radiation Interactions in Extremes (MaRIE) facility is intended to probe and control the time-dependent properties of materials under extreme conditions [1]. At its core, the "MaRIE 1.0" X-FEL is being designed to deliver pulse trains of ~10^{10} 42 keV photons, with a minimum bunch spacing of 2.4 ns, enabling time-dependent studies particularly of mesoscale phenomena. The X-FEL accelerator is also intended to deliver a series of 2 nC electron bunches to enable electron radiography concurrently with the X-ray pulse train, so as to provide multi-probe capability to MaRIE.

In 2014, the reference design for the MaRIE X-FEL 12 GeV driver linac was changed from an S-band normal-conducting to an L-band superconducting linac to accommodate pulse trains up to 100 µs in duration. This paper does not present a complete solution for the MaRIE linac design; rather it describes our current reference design, achieved parameters, areas of concern and paths towards mitigation of identified issues.

REQUIRED PERFORMANCE

The MaRIE X-FEL is intended to generate coherent 42 kV X-ray photons using a 12 GeV electron beam. This places tight constraints on the electron beam slice emittance and energy spread. Table 1 lists the some of the major performance requirements for the MaRIE linac.

REFERENCE DESIGN

Design Overview

The MaRIE linac is a 12 GeV, superconducting electron linear accelerator based on the use of ILC-type cryomodules. The general layout is shown in Figure 1. The majority of the linac consists of ILC-type cryomodules [2] containing 1.3 GHz TESLA-type 9-cell cavities. The 3.9 GHz (3^{rd}-harmonic) modules [3] are located before the bunch compressors to provide for linearization of the longitudinal bunch profile prior to compression. Dual-chicane bunch compressors are located at 250 MeV and 1 GeV. Following the end of the linac the beam passes through an energy droop corrector [4], the beam switchyard (incorporating smooth-pipe dechirpers) and finally the undulators, with space reserved for in-situ diagnostics in each section.

Table 1: Major Performance Goals for the MaRIE Linac

Parameter	Units	Value
Beam energy	GeV	12
Linac frequency	GHz	1.3
Cavity gradient	MV/m	31.5
Max. macropulse duration	µs	100
Bunches / macropulse		10 – 100
Bunch charge, XFEL	nC	0.1 nominal 0.2 max
Bunch charge, eRad	nC	2
Intrabunch energy spread		$\leq 1\cdot10^{-4}$
Slice energy spread		$\leq 1.5\cdot10^{-4}$
RMS slice emittance	µm	≤ 0.2

Beam Source

The design assumes an 0.2 µm rms normalized transverse emittance at the undulator entrance, placing stringent performance requirements on the photoinjector. The MaRIE photoinjector is based on a modified PITZ design: a 1.6-cell normal-conducting structure resonant at 1.3 GHz, with a coaxial RF feed to promote field symmetry. The PITZ gun has obtained a normalized emittance of 0.2 µm at 100 pC [5] so its demonstrated performance represents a good starting point for the MaRIE injector.

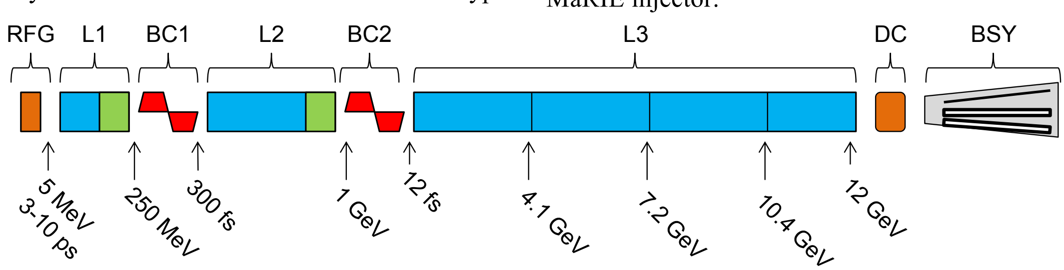

Figure 1: Schematic layout of the MaRIE linac. Room-temperature structures are copper-colored; 1.3 GHz superconducting in blue; 3.9 GHz superconducting in green. RFG is the photoinjector; L1-L3 are the three major sections of the MaRIE superconducting linac; BC1 and BC2 are the first and second dual-chicane bunch compressors; DC is the energy droop corrector; and BSY is the beam switchyard region.

The MaRIE gun design uses a redesigned solenoid with the axial magnetic field peak much closer to the cathode [6]. A very small laser spot is required to avoid

FEASIBILITY STUDY FOR AN X-RAY FEL OSCILLATOR AT THE LCLS-II*

T. J. Maxwell#, J. Arthur, Y. Ding, W. M. Fawley, J. Frisch, J. Hastings, Z. Huang, J. Krzywinski, G. Marcus, SLAC, Menlo Park, CA 94025, USA
K.-J. Kim, R. R. Lindberg, D. Shu, Y. Shvyd'ko, S. Stoupin, ANL, Argonne, IL 60439, USA

Abstract

We show that a free-electron laser oscillator generating X-ray pulses with hard X-ray wavelengths of order 0.1 nm is feasible using the presently proposed FEL-quality electron beam within the space of existing LCLS-II infrastructure when combined with a low-loss X-ray crystal cavity. In an oscillator configuration driven by the 4 GeV energy electron beam lasing at the fifth harmonic, output x-ray bandwidths as small as a few meV are possible. The delivered average spectral flux is at least two orders of magnitude greater than present synchrotron-based sources with highly stable, coherent pulses of duration 1 ps or less for applications in Mössbauer spectroscopy and inelastic x-ray scattering.

INTRODUCTION

Contemporary light sources based on the X-ray free electron laser such as the LCLS [1] and SACLA [2] utilizing self-amplified spontaneous emission (SASE) are now in operation delivering previously unrealizable per-pulse X-ray brightness enhanced over synchrotrons due to the partial longitudinal coherence and full transverse coherence from the high-gain X-ray amplification of ultra-short pulses. However, due to the stochastic nature of the SASE process, the production of stable, fully coherent X-ray pulses remains a challenge for accelerator-based light source facilities world-wide. Hard X-ray self-seeding (HXRSS) demonstrated improved longitudinal coherence and spectral brightness [3] by reducing the X-ray bandwidth mid-amplification to concentrate downstream gain into a narrower spectrum. While this has led to a 2- to 5-fold increase in brightness, HXRSS still relies on the SASE seed, not reaching full, stable longitudinal coherence.

Since the advent of proposed high-rep rate, superconducting FEL linac drivers such as that of the LCLS-II [4], new potential solutions emerge. In this Manuscript, we revisit one scheme based on the continuous recirculation of X-rays to be used for seeding subsequent shots: the low-gain X-ray FEL oscillator (XFELO) [5]. In an XFELO, a low-loss X-ray cavity is wrapped around the FEL undulator, as in an optical FEL oscillator. Where the beam rep rate is equal to the round-trip time of the cavity and the single-pass, low-gain power increase exceeds the round-trip power loss (to initiate start up), the intra-cavity power builds exponentially over many passes, saturating as the single-pass gain comes to equilibrium with the loss. We consider whether a device satisfying these starting requirements is feasible for an LCLS II-type beam, and with what basic considerations.

LAYOUT

Constructing a low-loss X-ray cavity on a scale sufficient to contain an FEL undulator presents difficult challenges. As a best candidate, we suppose an XFELO geometry using high-reflectivity diamond crystal mirrors in a near-backscattering Bragg geometry [6]. To allow for central energy tunability, we adopt the proposal of [7], as illustrated in Figure 1. The electron beam is injected magnetically into the undulator. Four symmetrically arranged Bragg crystals are used to recirculate the hard X-ray output, with two (or two sets of) compound refractive lenses (CRLs) providing cavity focusing. The first crystal following the undulator would be made thin to allow a 4% out coupling of useful radiation.

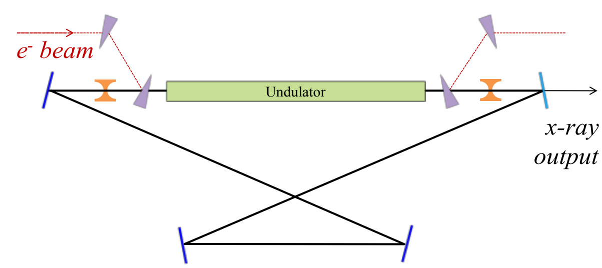

Figure 1: XFELO four crystal, two CRL cavity geometry

The baseline LCLS-II calls for a 4 GeV electron beam energy with variable gap undulators to allow X-ray generation from 0.25 – 5 keV. As the XFELO operates in low-gain, we consider a fifth harmonic XFELO [8] to allow operation well within the hard X-ray regime above 8 keV. At the LCLS-II repetition rate of 0.929 MHz, a round-trip cavity length of 323 m would be required. With the primary restriction of beam rate presumed to be the average beam power on the MW-class primary beam dumps of the ~1 MHz beam at 4 GeV and 100 pC per bunch, we consider doubling the beam rate to 1.86 MHz at a reduced 50 pC per bunch so that the cavity length may be shortened to 161 m.

Under these assumptions, several photon energies are achievable using diamond crystals. In particular, 14.4 keV of the C* (337) reflection, 9.13 keV with C* (333), and

NARROWBAND CONTINUOUSLY TUNABLE RADIATION IN THE 5 TO 10 TERAHERTZ RANGE BY INVERSE COMPTON SCATTERING*

Z.R. Wu, K. Fang, M.-H. Wang, J.H. Wu,
SLAC National Accelerator Lab, Menlo Park, CA 94555, USA

Abstract

5 to 10 THz has recently become the frontier of THz radiation sources development, pushed by the growing interests of spectroscopy and pump-probe material study in this frequency range. This spectrum “Gap” lies in between the several THz range covered by Electro-Optical crystal based THz generation, and the tens of THz range covered by the difference frequency generation method. The state-of-the-art EO crystal THz source using tilted pulse front technique has been able to reach ~ 100 MV/m peak field strength, large enough to be used in an inverse Compton scattering process to push these low energy photons to shorter wavelengths of the desired 5-10 THz range. The required electron beam energy is within 1~2 MeV, therefore a compact footprint of the whole system. The process would occur coherently granted the electron beam is bunched to a fraction of the radiation wavelengths (several microns). A system operating at KHz or even MHz repetition rate is possible given the low electron energy and thus low RF acceleration gradient required. This work will explore the scheme with design parameters and simulation results.

INTRODUCTION

Terahertz has been a frequency range of a plethora of molecular spectral features and dynamic characteristics, yet lack of strong sources to probe or drive the samples under study. Both transient pulses of extraordinary peak electric field strength and multi-cycle narrowband radiation of high brightness and frequency tunability are very much desired, preferably at high repetition rate for the purpose of ultrafast dynamics study. Despite of recent rapid growth on THz light sources, high-brightness tunable narrowband radiations are still rare to none on the chart, both in the low-frequency (1-5 THz) range and in the high-frequency (5-10 THz) range [1]. This type of sources are particularly interesting because of their peak power thus exceptional peak field strength to drive nonlinear effects or absorptive samples, meanwhile narrowband oscillation to exclusively excite specific vibrational or rotational modes of molecules. From the state-of-the-art terahertz source map shown in Fig. 1, the most promising source that currently covers the 5-10 THz range is the quantum cascade laser (QCL). However, it could barely reach 100 mWatt average output power level at 10 THz and needs to be operated at LHe cryogenic temperatures. Continuous-wave operation of QCL also implies low peak power.

This paper intends to propose a narrowband, continuously tunable, high peak power source in the 5-10 THz range, based on inverse Compton scattering process (ICS). Low-frequency seed light can be obtained via tabletop laser based THz generation, which is then scattered by electrons to high frequencies into the targeted 5-10 THz range. In order to enhance the electron/photon interaction, the pulse front of THz seed light can be tilted and its transverse mode modulated to a uniform profile rather than Gaussian distribution. The final radiation achieved is ultra-bright due to its small bandwidth and high peak power, and its central frequency can be continuously tuned by altering electron energy or scattering angle.

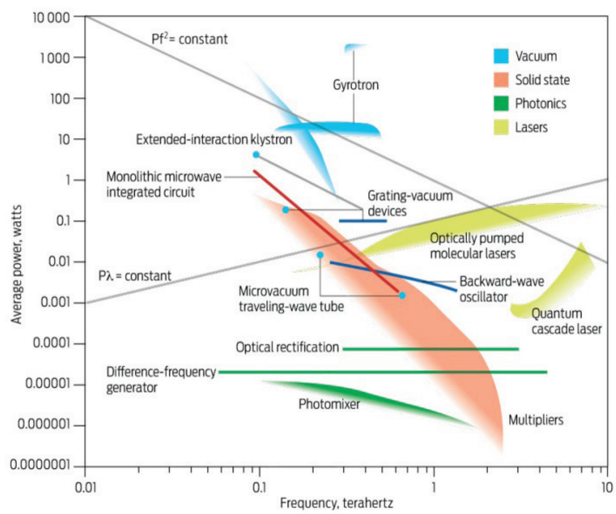

Figure 1: A radiation sources map in the 0.01 to 10 THz range. The power-frequency slope of Pf^2= constant is expected for RF based devices to develop into higher THz frequencies, whereas the power-wavelength line of $P\lambda$= constant is expected for commercial laser based sources. PHOTON YIELD ESTIMATION

Recent developments in high power near-Infrared laser have enabled delivery of high pulse energy THz transients from a tabletop system, based on optical rectification process in nonlinear EO crystals [2]. Groups at SLAC laser department have demonstrated generation of THz pulses of about 2 ps long and ~50 uJ energy, using a room-temperature $LiNbO_3$ EO crystal pumped by 800 nm laser of 3 mJ pulse energy at 1 kHz repetition rate. Liquid

DISPERSIVE PROPERTY OF THE PULSE FRONT TILT OF A SHORT PULSE OPTICAL UNDULATOR*

M-H. Wang†, J. Wu, and Z. Wu, SLAC, Menlo Park, CA 94040, USA
J. Liang, Department of Biomedical Engineering, Washington University in St. Louis, St. Louis, MO 63130, USA

Abstract

A short pulse laser can be used as an optical undulator to achieve a high-gain and high-brightness X-ray free electron laser (FEL) [1]. To extend the interaction duration of electron and laser field, the electron and laser will propagate toward each other with an small angle. In addition, to maintain the FEL lasing resonant condition, the laser pulse shape need be flattened and the pulse front will be titled. Due to the short pulse duration, the laser pulse has a broad bandwidth. In this paper, we will first describe the method of generalized Gaussian beam propagation using ray matrix. By applying the Gaussian beam ray matrix, we can study the dispersive property after the pulse front of the short laser is tilted. The results of the optics design for the proposal of SLAC Compton scattering FEL are shown as an example in this paper.

INTRODUCTION

With rapid progress in generating table-top terawatt laser pulse and fiber optics, the optical undulator can provide effective magnetic field B_u on the order of kilo-Tesla, which can provide strong enough effective undulator strength K for lasing. To fulfil an optical undulator for FEL, the interaction range of electron and laser pulse should be with 10-20 FEL gain length, and the equivalent undulator strength K should be kept constant for a given radiation γ. In order to increase the electron and laser pulse interaction range, the laser and electron need to co-propagate synchronously.

It is known that the angular dispersion (AD) will generate pulse front tilt (PFT). Gratings are ideal for this purpose as they can introduce large linear angular chirps. Nevertheless, besides the PFT, AD will also increase spatial dispersion (SD). As the pulse propagates, different frequency in the pulse becomes increasingly separated from each other. AD will also introduce negative group-delay dispersion (GDD). Both SD and GDD will lead temporal broadening of the laser and degrade the performance of the optical undulator in FEL. Therefore it is important to investigate the dispersive property before the PFT laser is sent to interact with an electron bunch.

The geometrical optics uses ray transfer matrix (also called ABCD matrix) to trace the light ray path through space and optical devices. Take one dimension ray trace for example:

$$\begin{pmatrix} x \\ \theta \end{pmatrix}_{out} = \begin{pmatrix} A & B \\ C & D \end{pmatrix}_n \cdots \begin{pmatrix} A & B \\ C & D \end{pmatrix}_1 \begin{pmatrix} x \\ \theta \end{pmatrix}_{in} \quad (1)$$

where x is position, θ is the slope and matrices 1 to n represent different optical components or spaces. The radius of curvature of the ray is $q = \frac{x}{\theta}$. The ABCD law for the radius of curvature is:

$$q_{out} = \frac{Aq_{in}+B}{Cq_{in}+D} \quad (2)$$

It is easy to extend the ray transfer matrix to two dimensions. Where A, B, C, and D become 2 by 2 matrices.

The ABCD matrix could be extended to "ray-pulse" matrices which takes account of dispersive effects in both spatial coordinates (as in the usual paraxial ABCD matrix approach) and in the temporal domain [2]. These matrices could be applied to write a space-time integral analogous to a generalized Huygens integral. By using both ray-pulse matrices and the propagation laws for Gaussian ray pulses which are space and time varying, the conventional results for Gaussian beams through various optical components could be derived. In this paper, we will first describe the method of generalized Gaussian beam propagation using ray matrix. By applying this method, we will investigate the dispersive properties of the optics design for the proposal of SLAC Compton scattering FEL.

GENERALIZED GAUSSIAN BEAM PROPAGATION USING RAY MATRIX

A short pulse laser is a finite size Gaussian beam. The electric field of the laser propagating along the z-axis in (x, ω) space can be expressed as:

$$E(x,\omega) = E_0 \exp\left(-\frac{\omega^2\tau_0^2}{4}\right)\exp\left(-i\frac{k_0x^2}{2q}\right) \quad (3)$$

where k_0 is the nominal wave-number, ω is the offset from the centre angular frequency, τ_0 is the pulse length and q is the complex q parameter of a Gaussian beam:

$$\frac{1}{q(z)} = \frac{1}{z+iZ_R} = \frac{1}{R(z)} - i\frac{\lambda_0}{\pi W^2(z)} \quad (4)$$

where Z_R is the Rayleigh range, $R(z)$ is the radius of curvature of the wave front, λ_0 the nominal wave length and $w(z)$ is the spot size $w(z) = w_0\sqrt{1+(\frac{z}{z_R})^2}$ with w_0 being the waist size.

A comprehensive matrix method for propagating Gaussian ultrashort pulses with Gaussian spatial profiles having spatio-temporal couplings was given by Kostenbauder [2]. The ray-pulse matrix for an optical system that introduces couplings can be written as [3]:

A BUNCH COMPRESSION METHOD FOR FREE ELECTRON LASERS THAT AVOIDS PARASITIC COMPRESSIONS *

S.V. Benson#, D.R. Douglas, C.D. Tennant, F.G. Wilson,
Jefferson National Accelerator Facility, Newport News, VA 23606, USA
D. C. Nguyen, Los Alamos National Laboratory Los Alamos NM 87545 USA

Abstract

Virtually all existing high energy (>few MeV) linac-driven FELs compress the electron bunch length through the use of off-crest acceleration on the rising side of the RF waveform followed by transport through a magnetic chicane. This approach has at least three flaws: 1) it is difficult to correct aberrations- particularly RF curvature, 2) rising side acceleration exacerbates space charge-induced distortion of the longitudinal phase space, and 3) all achromatic "negative compaction" compressors create parasitic compression during the final compression process, increasing the CSR-induced emittance growth.

One can avoid these deficiencies by using acceleration on the falling side of the RF waveform and a compressor with M_{56}>0. This approach offers multiple advantages: 1) It is readily achieved in beam lines supporting simple schemes for aberration compensation, 2) Longitudinal space charge (LSC)-induced phase space distortion tends, on the falling side of the RF waveform, to enhance the chirp, and 3) Compressors with M_{56}>0 can be configured to avoid spurious over-compression.

We will discuss this bunch compression scheme in detail and give results of a successful beam test in April 2012 using the JLab UV Demo FEL.

INTRODUCTION

To preserve electron beam brightness in a linac based accelerator used as an FEL driver it is necessary to produce a long, low peak current bunch in the injector, accelerate off crest in the accelerator, and then bunch in a bunch compressor. Brightness preservation is difficult due to the effects of LSC, coherent synchrotron radiation (CSR), and RF curvature. The canonical method for compression is to accelerate on the rising side of crest and compress in a chicane, which requires use of negative momentum compaction. It is possible however to reverse this and accelerate on the falling side of crest and compress in a bend with positive momentum compaction. When used in an energy recovering linac (ERL), this option has many advantages.

COMPRESSION OPTIONS

We describe here a low-energy compression method, which is a parallel-to-point longitudinal map. At higher beam energies, one usually wants to have a two-stage compression. Though this example describes the low energy procedure, the same ideas described below may still apply to the final compression of a high-energy system.

Negative Momentum Compaction Compressor

In most linear accelerators the simplest method of achieving a non-zero momentum compaction is to use a magnetic chicane. This is illustrated in Fig. 1. The beam is accelerated on the rising portion of the RF waveform, leading to the higher energy electrons being in the rear of the bunch. A transport system with negative momentum compaction then compresses the bunch. Note that the second order momentum compaction (T_{566}) is non-zero positive in a chicane, and is thus the wrong sign to correct for the RF curvature in the electron bunch. RF curvature is generally handled using harmonic RF, which is used to create a nearly linear voltage versus time and to additionally compensate for the T_{566} of the chicane.

Longitudinal space charge tends to accelerate the head of the bunch and decelerate the tail. This reduces the energy spread of the bunch, which is helpful in matching the energy spread to the acceptance of the FEL. In some cases however, it can produce second or third order curvature in the distribution, which decreases the peak current after the compressor unless it can be compensated using the harmonic RF and transport settings.

Similarly, CSR can produce curvature that can cancel part of the RF curvature on the bunch. If too large, however, it can produce a monoenergetic segment in the longitudinal phase space. This part of the bunch cannot be compressed due to the lack of any time-energy correlation. This is shown schematically in Fig. 2.

The emittance growth due to CSR can be large in a negative momentum compaction bending system because the compaction in a single dipole is always positive. This means that the momentum compaction of the transport upstream of the last dipole must be more negative than is required to simply bunch the beam. The beam is, for example, over-bunched in the earlier magnets of a chicane, and then slightly debunched to the optimum length in the last dipole. There is thus a parasitic compression that is inherent in a chicane compressor.

CONTROL OF SYNCHROTRON RADIATION EFFECTS DURING RECIRCULATION WITH BUNCH COMPRESSION*

Abstract

Studies of beam quality during recirculation [1] have been extended to an arc providing bunch compression with positive momentum compaction [2]. It controls both incoherent and coherent synchrotron radiation (ISR and CSR) using methods including optics balance [3] and generates little microbunching gain. We detail the dynamical basis for the design, discuss the design process, give an example, and provide simulations of ISR and CSR effects. Reference will be made to a complete analysis of microbunching effects [4].

METHODS FOR CSR/ISR CONTROL

Recirculation and energy recovery are established means of cost-performance optimization. Their use for FEL drivers can be challenging because of the impact of CSR on beam quality, and the desirability of limiting machine size and complexity. Here, we describe a method providing bunch length compression and recirculation in a modest footprint (~10 m diameter at ~1 GeV) while limiting beam quality degradation due to CSR. The method is scalable to higher energy (by increasing bend radius and machine diameter).

"Conventional" Compressor Design

A FODO-based recirculation arc can be used as a compressor; as $M_{56}>0$, an incident bunch with an appropriate energy chirp will be compressed with advantages discussed elsewhere [5]. When employed as a means of final bunch compression, the impact of CSR is however dramatic and detrimental. Using a simple 1-D CSR model in DIMAD [6], we studied compression of a 150 pC, 0.5 μm-rad normalized emittance beam to ~70 fsec x 0.1% δp/p while bending through 180° at 0.71 GeV in an arc comprising eight quarter-integer FODO cells with bend radius of 2 m. The beam emittance increases as a consequence of phase space redistribution driven by the CSR interaction, but effects can be mitigated as follows:

1. Chromatically correct the lattice and compensate lattice and CSR-induced curvature in the longitudinal phase space, *i.e.*, set T_{566}. Here, this is assumed to have been done in upstream transport so as to allow compression of small relative momentum spreads while avoiding use of strong nonlinearities. We model it with a quadratic phase-energy correlation in the incoming beam (a T_{655} term).
2. Introduce lattice perturbations to suppress linear x-δp/p and x'-δp/p correlations in the beam by introducing perturbative dispersion trims.
3. Trim chromatic corrections to suppress CSR-induced nonlinear phase space distortions [7].
4. Optimize the betatron match by varying beam input parameters to minimize output emittance.

After optimization, the output emittance was ~2 mm-mrad, representing a factor of four growth in the input.

The cause of the phase space redistribution is clear: as the bunch compresses, energy modulation across the bunch due to CSR increase dramatically. As a result, the compensation described by Di Mitri et al. [8] breaks down despite the presence of desirable betatron phase and amplitude relationships inherent to the achromat. Small shifts introduced when the bunch is long are inadequate to offset the larger shifts induced when the bunch is short.

Excitation-Modulated Compressor Design

Breakdown in emittance compensation can be mitigated by redistribution of bending along the beamline and optimization as described above. The method is simple: increase the angle of bending in initial FODO cells – thereby enhancing the impact of CSR early in the beam line while the bunch is long – and decrease the bending angle in the final FODO cells, reducing the effect of CSR while the bunch is short. Initial simulation of such an excitation-modulated system shows immediate benefit. An optimized linearly declining bend (using dipoles of 40°, 35°, 30°,… 10°, 5°) presented less emittance degradation than a conventional arc. Guided by the concepts of optics balance [9] and magnifying achromats [10] (in both, upstream and downstream perturbations are balanced by the choice of the intervening lattice optics), we added a dispersion generator to provide additional control of the beam and lattice, and manually adjusted the bending pattern to minimize output emittance. Care in selection of bend angles further reduced emittance dilution; choice of bend radius managed ISR effects.

As in the conventional arc, the degraded output phase space presented correlated distortions that could be compensated by perturbing the beam line optics as described above, limiting growth of normalized emittance from 0.5 to 1 μm-rad, a factor of two lower than in the

CONTROL OF SYNCHROTRON RADIATION EFFECTS DURING RECIRCULATION*

D.R. Douglas#, S.V. Benson, A. Hofler, R. Kazimi, R. Li, Y. Roblin, C.D. Tennant, Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA,
G.A. Krafft, B. Terzic, Old Dominion University, Norfolk, VA, 23529, USA,

Abstract

We use results by Di Mitri et al. [1] as the basis of a method for suppression of synchrotron-radiation-driven beam quality degradation during recirculation.

Use of second-order achromatic superperiodic recirculation transport based on individually isochronous and achromatic superperiods of low-quantum-excitation lattices is found to provide control of both emittance degradation from coherent synchrotron radiation (CSR) and microbunching instability (μBI) gain. Use of such low excitation lattices and choice of sufficiently large bend radius also insures incoherent synchrotron radiation (ISR) driven effects are well-managed.

METHODS FOR CSR/ISR CONTROL

Di Mitri *et* al. have derived conditions under which CSR-induced emittance growth can be suppressed during transport through bending systems [1]. We apply these conditions using a simple methodology to generate a design for a recirculation transport line giving little emittance growth even at high bunch charges, and exhibiting low microbunching instability gain.

The method (described in more detail elsewhere [2]) is as follows: utilize superperiodic recirculation transport phased as in a second-order achromat, with individually isochronous and achromatic superperiods. Each superperiod is to be based on low-quantum-excitation structures of familiar types, such as three-bend achromats (TBA), Chasman-Green (two-bend) achromats, or theoretical-minimum-emittance cells (TME). Modulation of focusing, choice of betatron phase advance, dispersion modulation, or other means is then used to make individual superperiods achromatic and isochronous. Use of low excitation lattices and sufficiently large bend radius then insures ISR effects are well-managed.

Choice of rational period tune with overall second-order achromatic structure – coupled with individual period isochronicity – then insures that the conditions for the suppression of CSR-driven emittance growth as described in [1] are met. This was observed in earlier studies [3], but in addition to the control of CSR-induced emittance degradation we have found that this also suppresses microbunching instability gain over a broad range of parameter space [4].

* This material is based upon work supported by the U.S. Department of Energy, Office of Science, Office of Nuclear Physics under contract DE-AC05-06OR23177.
#douglas@jlab.org

The suppression of microbunching gain appears to relate to limits placed on modulation of momentum compaction by the use of periodically isochronous transport. As will be seen from the examples below, the gain is very low for a periodically isochronous arc with small compaction modulations and modest R_{51}, R_{52}, and R_{56}, while similar, but aperiodic, structures with large compaction oscillations have high gain.

Control of ISR

As noted above, ISR control can be provided by use of an appropriate combination of a low-quantum-excitation transport lattice architecture and adequately large dipole bending radii [5].

APPLICATION OF DESIGN METHODOLOGY

Nearly all requirements for CSR suppression in a recirculator are met by the original design concept for the CEBAF arcs [6]. Control can be enhanced by adding provisions for small bend-plane beam envelope in the dipoles and provision for control of terms such as T_{566} (though this is in principle possible with only minor modification of the "stock" CEBAF transport system [7]).

We have thus generated a slightly modified version of the CEBAF arc transport line, based on TME focusing cells [8]. When four cells – each with 90^o betatron tune – are concatenated, an achromatic (to second order) but nonisochronous superperiod results (Figure 1).

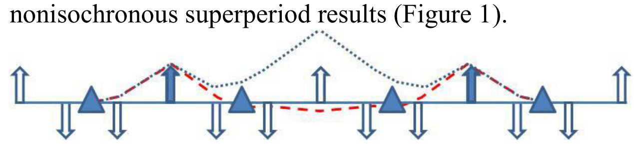

Figure 1: TME-cell-based superperiod structure for recirculation arc concept design. Natural dispersion of second order achromat – dotted blue line; modulated dispersion of isochronous linear achromat – dashed red.

By increasing the strength of the highlighted quadrupoles (which have 180^o betatron phase separation), the dispersion can be driven down in the inner dipoles, the tunes split, and a linearly achromatic, isochronous superperiod obtained. As with CEBAF, optimization using all quad families then allows choice of tune, matched envelopes, enforced achromaticity, and selection of momentum compaction. Choice of rational superperiod tune and corresponding multiplicity then gives – with appropriate sextupole correction – a second-order

FIRST e$^-$/ γ COMMISSIONING RESULTS FOR THE GLUEX EXPERIMENT/HALL D AT CEBAF*

M. McCaughan†, T. Satogata, Y. Roblin, J. Benesch
Thomas Jefferson National Acceleration Facility (TJNAF), Newport News, VA 23606, USA

Abstract

Experimental Hall D, with flagship experiment GlueX, was constructed as part of the 12 GeV CEBAF upgrade. A new magnetically extracted electron beam line was installed to support this hall. Bremsstrahlung photons from retractable radiators, are delivered to the experiment through a series of collimators following a long drift to allow for beam convergence. Coherent Bremsstrahlung generated by interaction with a diamond radiator will achieve a nominal 40% linear polarization and photon energies between 8.5 and 9 GeV from 12.1 GeV electrons, which are then tagged or diverted to a medium power 60kW electron dump. The expected photon flux is 10^7-10^8 Hz. This paper discusses the experimental line design, commissioning experience gained since first beam in spring 2014, and the present results of beam commissioning by the experiment.

HALL DESIGN AND CONSTRAINTS

Design constraints in the layout of Hall D included a project requirement that the Hall be 100m from the road, thus resulting in an 8 degree pitch in the ramp relative to the North Linac elevation. [1] Space constraints for optical elements resulted in a sensitivity to the input envelope and an inability to null leakage vertical dispersion at the bottom of the ramp. This provides for interesting tuning idiosyncrasies including nulling horizontal and minimizing vertical dispersion to the 5C00 retractable dump, envelope matching with the dispersion leakage, and correcting any leakage at the top of the ramp using the dipole string and pairs of quadrupoles on the ramp. The electron dump has a safety limit of the lower of 60 kW or 5 uA with an administrative limit of 3 uA imposed by the Hall at any energy. Design Twiss parameters are shown in Fig. 1.

GlueX is the flagship experiment of the new experimental Hall D, its goal being to provide critical data needed to quantitatively understand quark and gluon confinement in quantum chromodynamics (QCD). GlueX uses the photo-production of exotic hybrid and light mesons via the coherent bremsstrahlung technique to produce a linearly polarized photon beam of up to 9 GeV, as these mesons explicitly manifest gluonic degrees of freedom in the confinement regime, and thus of great interest to study. [2]

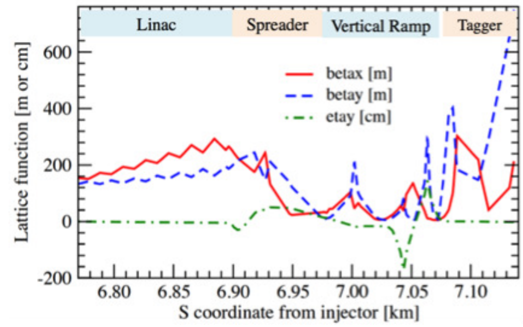

Figure 1: Twiss Parameters in Hall D.

ENGINEERING RUN I (SPRING 2014)

A number of 12 GeV project goals were accomplished during this run, most notably delivering beam of at least 2nA at above 10 GeV to both the 5C00 retractable dump as well as the tagger dump through the 12 GeV capable beam line at 5.5 passes. Emittance measurements & differential orbit data was taken throughout the machine for summer analysis. The analysed data was later fed into the model via body gradient error correction, synchrotron light losses, etc. Spring saw first beam through vast portions of the upgraded accelerator (passes 4+) with first beam in arc 10 on 2 May 14. Sixth pass beam was then sent through the North Linac, threaded through the B-spreader, arriving for the first time at the 5C00 dump at 3:53 on 3 May14, after which orbits & path length were optimized. [3] Numerous differential orbit measurements were conducted for later analysis & testing on the two new synchrotron light monitors was performed.

Following the setup of CEBAF at a familiar energy (6.1 GeV) so as to not stress RF/magnets while treading first beam through the reassembled machine, the total energy was scaled to 10.5 GeV. Scaling went less than ideally & the machine had to be setup again from first principles at the higher energy resulting in a delay of several days. Beam returned to the 5C00 dump at 2:53 on 7 May 2015 with ~80% transmission. Path length, dispersion corrections, & envelope matching in the machine later improved transmission. Differential orbit data was collected to characterize the problems, localizing them to parts of the spreaders & recombiners, where they were then minimized with orbit & optics changes. In preparation to send beam to the Tagger dump a set point based on the Tosca model was found (8.21 MG*cm), & a compromise set point of 8 MG*cm selected to start with to account for synchrotron light losses. After continued improvements to orbit, optics, & path length beam returned to the 5C00 dump at 20:24 7 May 14.

COMMISSIONING OF THE 123 MeV INJECTOR FOR 12 GeV CEBAF*

Y. Wang, A. Hofler and R. Kazimi, Jefferson Lab, Newport News, VA 23606, USA

Abstract

The upgrade of CEBAF to 12GeV included modifications to the injector portion of the accelerator. These changes included the doubling of the injection energy and relocation of the final transport elements to accommodate changes in the CEBAF recirculation arcs. This paper will describe the design changes and the modelling of the new 12GeV CEBAF injector. Stray magnetic fields have been a known issue for 6 GeV CEBAF injector, the results of modelling the new 12GeV injector and the resulting changes implemented to mitigate this issue are describe in this paper. The results of beam commissioning of the injector are also presented.

BRIEF HISTORY

The Continuous Electron Beam Accelerator Facility (CEBAF) at Jefferson Lab was originally designed in the mid-1980s to provide 4 GeV of continuous electron beam. In 2009 the beam energy was successfully raised to 6 GeV after refurbishment of ten 25 MeV capable (C25) cryomodules, and the injector energy was raised from 45 MeV to 67.5 MeV. The injector and other sections of the beamline had the capacity to support 6 GeV operations; therefore, no hardware upgrades were needed for the injector.

As the CEBAF scientific program progressed, in the late-1990s the laboratory and the user community developed a scientific case that demanded a higher energy – the 12 GeV upgrade of CEBAF [1]. Upgrading CEBAF to 12 GeV will enable the generation and study of exotic meson states, contributing to a better understanding of the confinement and the forces within the nuclei. An extended period of 12 GeV installation started in May 2012, and the beam-based commissioning started in October 2013.

HARDWARE CHANGES [2]

There are two major changes in the injector (shown in Fig.1and Fig. 2). The first change is to replace the second full C25 cryomodule just upstream of the injection chicane with a 100 MeV capable one (C100). To meet the energy requirement of the 12 GeV CEBAF and maintain the 0.11284 energy ratio between the injector and the linacs, the injector energy was increased from 67.5 MeV to 123 MeV. In the 6 GeV injector, the beam energy started at 130 keV at the gun increasing to ~500 keV after the capture RF element and ~6 MeV at the exit of the 2-cavity SRF booster. The final injector beam energy (up to 67.5 MeV) was reached after transport through two full C25 type cryomodules. The energy required for the 12 GeV injector is 123 MeV, well beyond the capability of two C25 crymodules. Changing the second cryomodule to C100 provided the extra needed energy gain [3]. C100's maximum achieved energy gain during cryomodule commissioning was 115 MeV satisfying 12 GeV operations with sufficient headroom.

The second change stems from the interference with the new high energy beam recirculation transport arc for the 12 GeV upgrade (at the same elevation). Several injector elements were moved to provide enough physical clearance. The injector full energy spectrometer dipole and diagnostic dump line were shifted upstream by 4.57 m. The bending angle of the spectrometer line was changed for a better physical fit between beamline elements. The start of the injector chicane was moved upstream by 20.51 m. The spacing between the 5-quad matching section in the dispersion free line is shortened due to this change.

With the increased energy, several beam transport and corrector magnets were improved or added. The number of trim magnet girders in the chicane region was increased from 7 to 9 to provide good flexibility for alternative optics that can vary the M_{56} compression in the chicane. Each girder has a beam position monitor (BPM), a horizontal corrector, a vertical corrector, and a quad. Both the spectrometer dipole magnet and the power supply remained unchanged but operate at a higher current, but the power supplies for the four chicane dipoles were upgraded from 10 A to 12 A to match the increased beam momentum. Four of the five matching quads were upgraded from QD type to QB type to provide stronger focusing power. Ten correctors were upgraded from AT type to DB and DJ type to have more steering strength (shown in Table 1).

Table 1: Magnet types and their strength

Type	Quad Strength (Gauss)	Dipole Strength (G-cm)
QD	3250	
QB	14143	
AT		328
DB		926
DJ		981
BT		2826

Beam diagnostics were added. Two viewers and two beam wire scanners were added to the matching section to speed up the optics matching process. A BPM was, also, added to have two BPMs to establish the proper trajectory

OBSERVATION OF SIGNIFICANT QUANTUM EFFICIENCY ENHANCEMENT FROM A POLARIZED PHOTOCATHODE WITH DISTRIBUTED BRAG REFLECTOR*

S. Zhang#, M. L. Stutzman, and M. Poelker, Jefferson Lab, Newport News, Virginia, USA
Y. Chen, and Aaron Moy, SVT Associates, Inc., Eden Prairie, Minnesota, USA

Abstract

Polarized photocathodes with higher Quantum efficiency (QE) would help to reduce the technological challenge associated with producing polarized beams at milliampere levels, because less laser light would be required, which simplifies photocathode cooling requirements. And for a given amount of available laser power, higher QE would extend the photogun operating lifetime. The distributed Bragg reflector (DBR) concept was proposed to enhance the QE of strained-superlattice photocathodes by increasing the absorption of the incident photons using a Fabry-Perot cavity formed between the front surface of the photocathode and the substrate that includes a DBR, without compromising electron polarization. Here we present recent results showing QE enhancement of a GaAs/GaAsP strained-superlattice photocathode made with a DBR structure. Typically, a GaAs/GaAsP strained-superlattice photocathode without DBR provides a QE of 1%, at a laser wavelength corresponding to peak polarization. In comparison, the GaAs/GaAsP strained-superlattice photocathodes with DBR exhibited an enhancement of over 2 when the incident laser wavelength was tuned to meet the resonant condition for the Fabry-Perot resonator.

INTRODUCTION

The nuclear physics research at Jefferson Lab requires high energy and high current polarized electron beams that originated from a low energy polarized electron source. Superior quality photocathodes producing both high QE and electron polarization are key to critical elements to guarantee the successful implementation of the existing physics programs and are also of vital importance in satisfying the demand of future machines such as the medium-energy electron-ion colliders (MEIC) [1] currently under intensive study. Although polarization over 85% has been achieved, the QE is still relatively low, usually ~ 1%. In this report, we present the characterization and study of a new type of strained-superlatice photocathode designed to significantly improve the QE while still maintaining high electron polarization.

As shown in Fig. 1(a), usually the incident laser beam makes only a single pass through the active layer of a standard GaAsP/GaAs photocathode structure, with most of the laser energy deposited in the substrate, leading to unwanted cathode heating. For high current applications where the laser power can reach Watt-levels, this may serve to evaporate the cesium from the surface and reduce the QE [2].

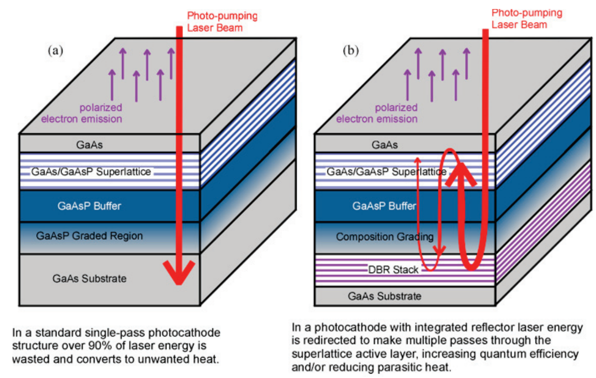

Figure 1: Illustration of (a) a standard strained-superlattice photocathode with a single-pass laser beam, and (b) the photocathode combined with a DBR mirror for confining the unabsorbed laser beam within the active layer.

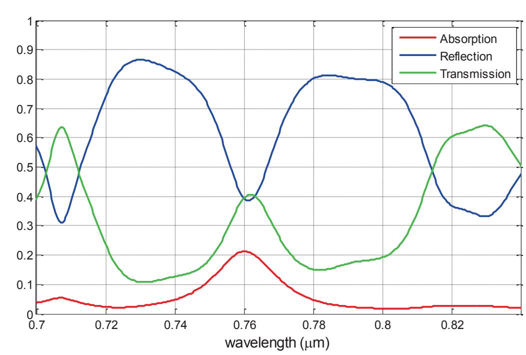

Figure 2: Calculation of absorption, reflectivity and transmission of a photocathode with DBR structure.

To overcome this issue, a new structure was proposed [3] by combining the device active layer with a semiconductor-based mirror structure as illustrated in Fig. 1(b), where a Fabry-Perot (FP) cavity around the active layer is formed using a distributed Bragg reflector (DBR) as a bottom mirror and surface-to-vacuum reflection as the top mirror (Fig. 1b). Such an optical configuration allows effectively confinement of the laser beam inside the active layer region and therefore increases the amount of light absorbed by the photocathode without increasing the pump laser power. A calculation of absorption, reflectivity and transmission of a DBR photocathode at

ON THE CHARACTERIZATION OF A CCR SOURCE*

A. V. Smirnov#, RadiaBeam Technologies Inc., Santa Monica, CA 90404, USA

Abstract

Peak and spectral brightness of a resonant long-range wakefield extractor are evaluated. It is shown that the brightness is dominated by beam density within the slow wave structure and antenna gain of the outcoupling. Far field radiation patterns and brightness of circular and high-aspect-ratio planar radiators are compared. A possibility to approach the diffraction limited brightness is demonstrated. Role of group velocity in designing of the Cherenkov source is emphasized. The approach can be applied for design and characterization of various structure-dominated sources (e.g., wakefield extractors with gratings or dielectrics, or FEL-Cherenkov combined sources) radiating into a free space using an antenna (from microwave to far infra-red regions). The high group velocity structures can be also effective as energy dechirpers and for diagnostics of microbunched relativistic electron beams.

INTRODUCTION

For generation of a relatively narrow bandwidth mm-sub-mm wave radiation resonant Cherenkov radiation can be an attractive alternative to undulator radiation due to the exceptional compactness of the radiator and capability to operate at lower energies. Such a coherent Cherenkov radiation (CCR) source is usually supplied by an antenna and employs a circular [1] or planar configuration [2,3]. Most of FIR FEL sources do not employ radiating structure and operate in a diffraction limited mode due to attainability of low emittance electron beams (namely, with geometric emittance lower than the emittance of diffraction limited photon beam $\lambda/2\pi$).

An attempt is made to pave an engineering path for characterization of structure-dominated sources employing radiators (or extractors). The sources comprising an antenna are not limited by CCR mechanism but may also include undulator with fast or slow-wave structure (e.g., mm-wave Bragg resonator and waveguide), or Cherenkov-FEM combined sources [4]. .

ANTENNA GAIN AND BRIGHTNESS

Unlike unbounded FEL and undulator the radiation pattern from a structure-dominated source is formed by an antenna, whereas the beam serves only as a launcher for the structure. It is convenient to express the power density S and brightness B via the modal antenna directivity D_n or gain G_n [5] assuming nearly normal orientation of the detector with respect to the incident rays:

$$S=\frac{dP_{ff}}{dA}=\frac{1}{4\pi R_d^2}\sum_n G_nP_n,\quad B=\frac{d^2P_{ff}}{dAd\Omega}\approx\frac{1}{4\pi A_A}\sum_n G_nP_n,\qquad(1)$$

where R_d is the distance between the source and the detector (object), $R_d>>W_A$, W_A is the maximum antenna dimension, $R_d>>W_A^2/\lambda$, A_A is the antenna aperture area, $G_n=(1-|\Gamma_n|^2)\eta_nD_n$, $D_n=4\pi P_{ff}^{-1}dP_{ff}/d\Omega$, P_{ff} is the modal power of far-field radiation, $d\Omega$ and dA are the infinitesimal small solid angle and area, and P_n is the modal power on the transition from the slow-wave structure to the antenna having return loss Γ_n and modal efficiency η_n.

The modal energy and power radiated at the structure exit can be calculated analytically [6,7]. For a single microbunch and single mode operation the peak brightness can be calculated as follows:

$$B_{1b}=\frac{G_n}{4\pi A_A}\frac{\omega}{4}\frac{r}{Q}|v_{gr}|\cdot\left(\frac{q\Phi}{1-\beta_{gr}/\beta}\frac{1-\exp(-\alpha L)}{\alpha L}\right)^2,\qquad(2)$$

where $\omega=2\pi f$ is the circular frequency of the resonant Cherenkov radiation $\omega=h(\omega)v$, $h(\omega)$ is the wavenumber defined by the structure dispersion, q is the bunch charge, L is the structure length, $r=E_z^2/(dP/dz)$ is the shunt impedance, $\beta=v/c$, $v_{gr}=\beta_{gr}c$, is the group velocity, Q is the Q-factor, $Q|\beta-\beta_{gr}|>>1$, $\alpha=\pi f/Qv_{gr}$ is the attenuation, and $\Phi=\exp(-(\omega\sigma_t)^2/2)$ is the formfactor for a Gaussian bunch having r.m.s. duration σ_t.

For a long ($t>t_f=L/v_{gr}$) train of coherent microbunches with interval T_b less than the drain time $T_d=L(v_{gr}^{-1}-v^{-1})$ the brightness can be calculated as follows:

$$B_{train}=\frac{G_n}{4\pi A_A}\frac{\omega}{4}\frac{r}{Q}\frac{1}{|v_{gr}|}\left|I\Phi L\frac{1-e^{-\alpha L(1+ia_s)}}{\alpha L(1+ia_s)}\right|^2,\qquad(3)$$

where I the beam current within the train, $a_s=2Q(f/f_b-1)/(1-v_{gr}/v)$ is the generalized detuning, and $f_b=1/T_b$ is the frequency of the microbunched train (or its resonant sub-harmonic).

The spectrum FWHM of the radiation induced by a single microbunch is determined by the inversed radiation pulse length which is equal to the drain time. Therefore the peak spectral brightness for that case is evaluated as:

$$\frac{\Delta B_{1b\_Peak}}{\Delta f}\approx\frac{G_n}{4\pi A_A}\frac{\omega}{4}\frac{r}{Q}\frac{L}{1-\beta_{gr}/\beta}\cdot\left(q\Phi\frac{1-\exp(-\alpha L)}{\alpha L}\right)^2.\qquad(4)$$

For a long (~steady state) coherent train of microbunches the spectral brightness is proportional to the train duration $>t_f$ at $T_b^2<<T_d^2$ and neglecting jitter within the train. In transient mode (i.e. for pulse lengths comparable to the t_f) the spectral brightness under these conditions can be estimated as product of (3) and the filling time t_f.

For some applications an averaged brightness can be more important rather than the peak brightness. For the "single bunch" mode of radiation the averaged brightness

Abstract

A number of methods for producing sub-picosecond beam microbunching have been developed in recent years. A train of these bunches is capable of generating THz radiation via multiple mechanisms like transition, Cherenkov and undulator radiation. We utilize a bunch train with tunable spacing to selectively excite high order $TM_{0,n}$ modes in a multimode structure. In this paper we present experimental results obtained at the Accelerator Test Facility of Brookhaven National Laboratory.

INTRODUCTION

THz radiation production is of great interest in science and industry. There are many approaches to the development of THz sources [1], for example laser driven THz emitters, solid state oscillators (high frequency diodes), quantum cascade laser-based and electron beam driven. In this paper we present a THz source based on wakefield excitation by an electron beam. When electron beam passes through a slow-wave structure (power extractor) it decelerates due to emitting Cherenkov radiation (wakefield). The power extractor can be designed to be tunable and operate at THz frequencies. In this case the beam will generate THz radiation. It is important, however, that the beam spectrum has THz frequency content; a DC current will not be able to excite THz radiation.

In the past decade, many approaches have been investigated to generate THz micro bunches that include: bunch generation from a photoinjector with micro laser pulses produced by birefringent crystals [2]; bunch train with a picosecond separation using an emittance exchanger combined with transverse beam masking and other similar techniques [3, 4]; some bunch compression techniques [5, 6] and a two-step approach based on beam self-wake energy modulation followed by a compression in chicane [7, 8].

Once the bunch train with sub-picosecond spacing (and hence a THz frequency content) had been generated it can be used to generate THz radiation by various mechanisms: transition, Cherenkov, undulator and Smith Purcell radiation. In this paper we report on experimental results of high order mode generation in a multimode dielectric loaded wakefield structure by a sub-picosecond bunch train. In Figure 1 a spectrum of TM_{0n} modes is presented on the left. On the right a spectrum of the bunch train is shown in blue. In a multimode structure bunch train will excite modes that belong to its spectrum hence selecting only one or two modes. This paper is a continuation and improvement of our work reported earlier [9].

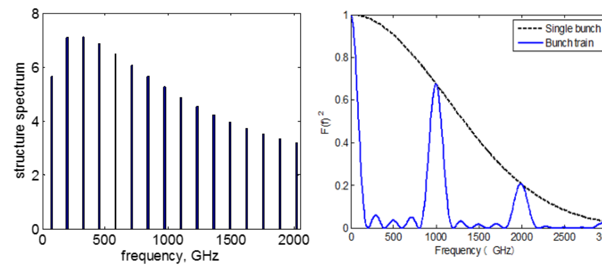

Figure 1: Left: Cherenkov spectrum of the multi-mode wakefield structure. Right: Formfactor of single bunch and bunch train.

EXPERIMENT

The experiment using a tunable bunchtrain was performed at the Accelerator Test Facility at Brookhaven National Laboratory. Figure 2 shows the general experimental layout.

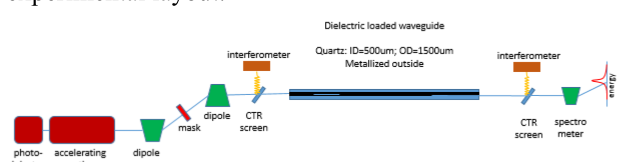

Figure 2: Experiment setup at ATF beamline.

For this experiment, the electron bunch was accelerated off-crest in the linac (to introduce an energy chirp, linear correlation between energy and longitudinal position of the particle) to 60 MeV and sent through a "dogleg" type magnetic achromat with two identical dipole magnets. A beam collimator mask was placed at the high dispersion point between the dipoles where the beam transverse size was dominated by the chirp induced in the linac. Therefore the transverse pattern introduced by the mask appeared in the longitudinal charge density distribution after the achromat. The image of the beam taken directly after the mask and shown in Figure 3 (top) represents the longitudinal beam distribution after the dog leg. The actual distance between these beamlets appearing in the longitudinal direction after the dogleg was measured by the interferometer equipped with a helium-cooled bolometer that received the coherent transition radiation (CTR) signal emitted by the beamlets passing through a thin foil. From these measurements the distance between beamlets was determined and the phosphor screen image after the mask was calibrated. This measurement is

Abstract

We report the observation of de-chirping of a linearly chirped (in energy) electron bunch by its passage through a 4 inch long rectangular waveguide loaded with two silicon bars 0.25 inch thick and 0.5 inch wide. Silicon being a semiconductor has a conductivity that allows it to drain the charge fast in case if some electrons get intercepted by the dechirper. At the same time the conductivity is low enough for the skin depth to be large (on the order of 1 cm) making the silicon loaded waveguide a slow wave structure supporting wakefields that dechirp the beam.

INTRODUCTION

The free electron laser (FEL) is considered to be the main candidate for a short wavelength (UV to X-ray), short pulse (femto- to attosecond) light source. Demands on the electron beam needed to drive this class of FELs have become more and more challenging, including high repetition rate (~ MHz), high peak current (a few kA), and low emittance (sub-micron normalized emittance) [1].

Short pulses (subpicosecond) are central to many of the next generation light source initiatives that are typical of modern linear accelerators. At the same time, at the output of the last compressor the electron beam will be left with a small chirp to compensate for wakefield effects through the rest of the accelerating stages [2, 3]. Although relatively small, this energy spread needs to be compensated using a specially designed device. The use of a Cherenkov dielectric wakefield compensation scheme ("silencer") to correct the correlated energy distribution (chirp) of a short, low emittance electron bunch was originally suggested in references [4, 5]. This technology using an adjustable dielectric compensating structure can be applied to a soft X-ray FEL SRF linac. We study dielectric loaded accelerating structures as chirp compensating devices. The first dielectric loaded dechirper was demonstrated at Accelerator Test Facility (ATF) of Brookhaven [6]. At the same time a standard iris-loaded structure was proposed as a dechirper for NGLS [8]. We demonstrated a tunable (via aperture size) planar chirp compensating structure that can accommodate various scenarios for beam chirp at the accelerator facility recently [8]. In this paper we present experimental results from Accelerator Test Facility (ATF) of Brookhaven National Laboratory (BNL) where a tunable semiconductor-based dechirper was tested.

TUNABLE CHIRP CORRECTOR

Short bunches with high peak currents in the kA range are desirable for applications like FEL. They are obtained by compression of the energy-chirped beam in a chicane. Compressed beam after chicane carries residual chirp – energy variation along the beam. For successful lasing of the FEL this chirp has to be removed. A passive device, dechirper, was suggested to remove this residual chirp [4, 5]. Nearly every new FEL project entertains the idea of using dechirper for chirp correction.

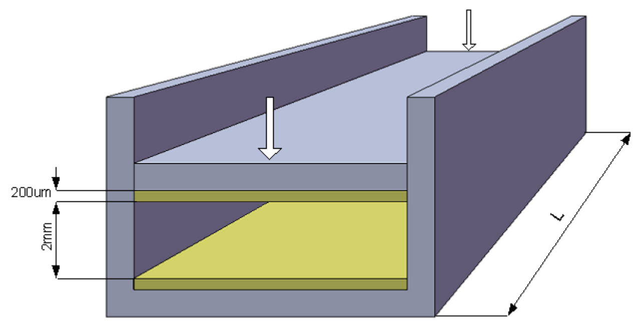

Figure 1: Conceptual design of a tunable dielectric loaded rectangular chirp corrector.

Figure 1 shows a photo and a schematic of a *tunable* dechirper. It is a dielectric loaded waveguide. Alternatively it can be corrugate wall waveguide. High current electron beam passing through such structure generates wakefield (cherenkov radiation). Spectrum of such wakefield is shown on Figure 2. Most importantly there is a wake inside the beam itself: the head decelerates the tail (Figure 3).

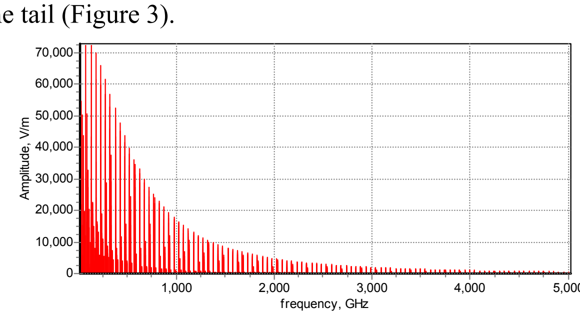

Figure 2: Spectrum of modes excited by the σz = 10 micron gaussian beam (equivalent to the rising edge of the quasi-rectangular beam) inside the 1 mm thick alumina plates, 600 micron gap structure.

MULTIPACTING-FREE QUARTER-WAVELENGTH CHOKE JOINT DESIGN FOR BNL SRF *

Abstract

The BNL SRF gun cavity operated well in CW mode up to 2 MV. However, its performance suffered due to multipacting in the quarter-wavelength choke joint. A new multipacting-free cathode stalk was designed and conditioned. This paper describes RF and thermal design of the new cathode stalk and its conditioning results.

INTRODUCTION

The 704 MHz half-cell SRF gun was designed to provide up to 350 mA, 2 MV electron beams for ERL [1] at BNL, which is a R&D project for future RHIC projects: eRHIC [2], Coherent-Electron-Cooling [3], and Low Energy RHIC Electron Cooler [4]. Without a cathode stalk insertion, the SRF gun cavity reached the design voltage of 2 MV in CW mode in horizontal tests. However, strong multipacting in the quarter-wavelength choke-joint occurred during commissioning with a copper cathode stalk. Multipacting in the choke-joint was later understood with simulations [5]. While the beam commissioning was carried out with this cathode stalk and successfully generated first beam in November 2014 [6], a multipacting-free choke joint has been designed, tested and showed that it is truly multipacting-free. This paper discusses multipacting issues observed in the old cathode stalk, and then presents the multipacting-free choke-joint design and test results.

MULTIPACTING IN THE SRF GUN

Figure 1 shows the SRF gun cryomodule. The 704 MHz half-cell SRF cavity is the core part of the module. A quarter-wavelength choke-joint cathode is used to support photo-cathode. A pair of opposing fundamental power couplers (FPCs) is used to deliver up to 1 MW of RF power in CW mode. A high temperature superconducting solenoid (HTSS) is employed to compensate space charge. A room-temperature ferrite HOM damper with ceramic break is used to damp HOM power. Without a cathode stalk insert, the gun cavity was successfully commissioned and reached the design goal of 2 MV in CW mode. However, strong multipacting occurred during commissioning with a copper cathode stalk insert. Figure 2 shows signals during the cathode stalk conditioning, when strong multipacting was observed. The reflected power could be as low as 50% of the forward power when multipacting is active. The main reason for multipacting was distortion of grooves due to BCP and high SEY in the stainless steel area. After spending some time conditioning mutipacting (to suppress it), we were able to operate the gun at 1.9 MV with 18% duty factor. We used this cathode stalk for beam commissioning in pulse mode, while a new multipacting-free cathode stalk was designed.

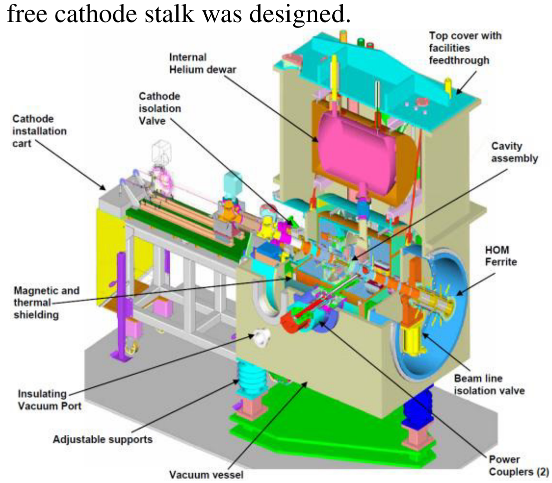

Figure 1: ERL SRF gun cryo-module.

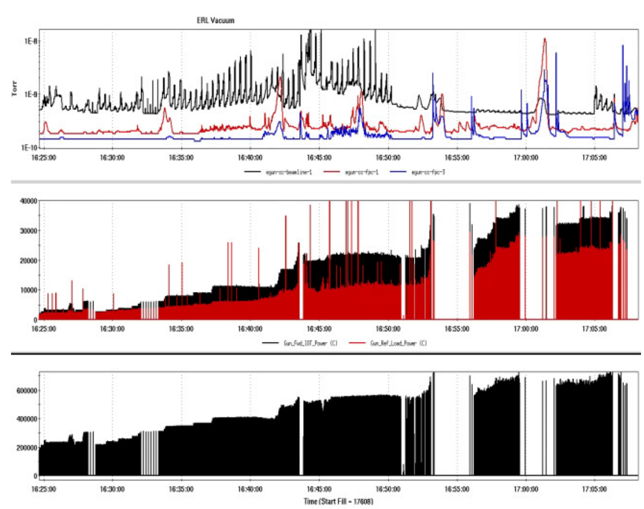

Figure 2: Signature of strong multipacting in the cathode stalk: vacuum behavior (above); reflected and forward power difference due to multipacting (middle); cavity voltage (bottom).

EXPERIMENTAL AND SIMULATIONAL RESULT OF MULTIPACTORS IN 112 MHz QWR INJECTOR

T. Xin[#,1,2], I. Ben-Zvi[1,2], S. Belomestnykh[1,2], J. C. Brutus[1], J. Skaritka[1], Q. Wu[1], B. Xiao[1]
[1]Brookhaven National Laboratory, Upton, NY 11973
[2]Stony Brook University, Stony Brook, NY 11794

Abstract

The first RF commissioning of 112 MHz QWR superconducting electron gun was done in late 2014. The coaxial Fundamental Power Coupler (FPC) and Cathode Stalk (stalk) were installed and tested for the first time. During this experiment, we observed several multipacting barriers at different gun voltage levels. The simulation work was done within the same range. The comparison between the experimental observation and the simulational results are presented in this paper. The observations during the test are consisted with the simulation predictions. We were able to overcome most of the multipacting barriers and reach 1.8 MV gun voltage under pulsed mode after several round of conditioning processes.

INTRODUCTION

The CeC PoP system is being installed in the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory [1]. The commissioning of 112 MHz QWR superconducting electron injector with the beam pipe coaxial fundamental power coupler (FPC) and choke joint cathode stalk was done in late 2014 and continued into early 2015. During the test we observed mainly three bands of multipacting barriers which correspond to the resonators located in cavity, FPC and cathode stalk, respectively. The observed multipactors consistent with the previously simulated results given by Track3P package.

EXPERIMENT SETUP

The general layout of experiment is showed in Figure 1. The cryomodule of 112 MHz QWR gun was connected with RHIC main Helium loop via a Quiet Helium Source and working at 4.3 K.

Beam pipe coaxial FPC can transmit up to 2 kW RF power and establish 2 MV gun voltage in the cavity. The inner conductor of the FPC is water cooled and the surface of the FPC is gold plated in order to reduce emissivity. The location of the FPC tip was designed to be adjustable within a ±2 cm range for the sake of coupling tuning [2].

The half wavelength cathode stalk was also install for the commissioning. The stalk was designed to create a choke joint between the cathode plane and the cavity nose cone. Special impedance mismatching is utilized so that the RF loss on the surface of the stalk is minimized. The surface of stalk is also gold plated to reduce the static thermal load to the cryosystem.

The design parameters of the injector are shown in Table 1. The cavity is designed to run at 112 MHz in CW mode. The energy gain of electron is 2 MeV and repetition rate is 78 kHz. During this experiment we didn't use the multi-alkali cathode but a dummy molybdenum puck as the placeholder to provide correct RF boundary condition.

Table 1: Design Parameters of the 112 MHz Electron Injector

Parameters	Value
Frequency	112 MHz
Charge per Bunch	1~3 nC
Repetition Rate	78 kHz
Acceleration Voltage	1~2 MV
Cavity Q_0	1.8e8
R/Q	122 Ω

Experimental Results

Several multipacting barriers were observed during the commissioning of the injector. We've already seen the 50 kV barrier in the previous experiment with this cavity [3]. The new structures in this experiment are the FPC and cathode stalk. Both of them are coaxial structures hence are vulnerable to multipacting. As the matter of fact, we observed three most persistent barriers while ramping up the cavity voltage. The first one was found near 50 kV, which we knew is located in the cavity. The second and third relatively strong barriers were encountered when gap voltage was in the range of 100 kV to 200 kV and 600 kV to 800 kV respectively. Since the field strength in the FPC gap is much stronger than that of the cathode stalk, we believe the former multipactor is located in the FPC and the latter one in the cathode stalk. This expectation is further confirmed by simulation results given by the SLAC Track3P package and will be discussed in more detail in the next section.

After several rounds of conditioning, most of the multipacting barriers were overcame and the cavity can now reach 1.8 MV gun voltage in pulsed mode and 1.3 MV in CW mode. The CW mode voltage is limited by field emission. Further condition process is undergoing.

Abstract

The 704 MHz SRF gun successfully generated the first photoemission beam in November of 2014. The configurations of the test and the sub-systems are described. The latest results of SRF commissioning, including the cavity performance, cathode QE measurements, beam current/energy measurements, are presented in the paper.

INTRODUCTION

The R&D ERL [1] at BNL is an electron accelerator designed for high average current, up to 350 mA. It serves as a test bed for future RHIC projects, such as eRHIC [2], Coherent-Electron-Cooling [3], and Low Energy RHIC Electron Cooler [4]. The 704 MHz half-cell SRF gun is designed to provide 0.5 A, 2 MeV electron beam. Commissioning of the SRF gun is being carried out in stages: without a cathode stalk (finished in early 2013), with a copper cathode stalk (finished in fall of 2013), and beam commissioning (started in mid-2014) [5, 6, 7]. The 704 MHz half-cell SRF gun has successfully generated electron beams in November of 2014. This paper discusses the first beam test results.

BEAM COMMISSIONING LAYOUT

Following the step-by-step commissioning plan, the first beam commissioning of the SRF gun was done with a straight beam line ending up at a faraday cup, instead of going through a Zig-Zag, a merging scheme for the high- and low-energy beams consisting of dipole magnets bending in the vertical plane designed to minimize emittance growth [8]. The beam line configuration is shown in Figure 1. The Cs_3Sb photocathode [6, 7] was deposited on the cathode stalk with copper substrate (a new cathode stalk will use Ta substrate) in the cathode deposition system located outside the ERL blockhouse. Then, the cathode stalk was moved to the ERL blockhouse inside a cathode transport cart and inserted into the SRF gun. A load-locked system is used for the connection between the SRF gun and the cathode transport cart. Following the 704 MHz half-cell SRF cavity, there is a high temperature superconducting solenoid (HTSS), a room-temperature HOM absorber (Now, instead of the absorber, a room temperature solenoid was installed there for better beam quality), a laser cross, an Integrated Current transformer (ICT), a Beam Position Monitor (BPM), a vertical and horizontal beam corrector, a beam halo monitor, a pepper pot beam emittance measurement, a beam profile monitor and a Faraday cup. The dipole magnet for bending electron beams to the Zig-Zag is locked out for the first beam tests.

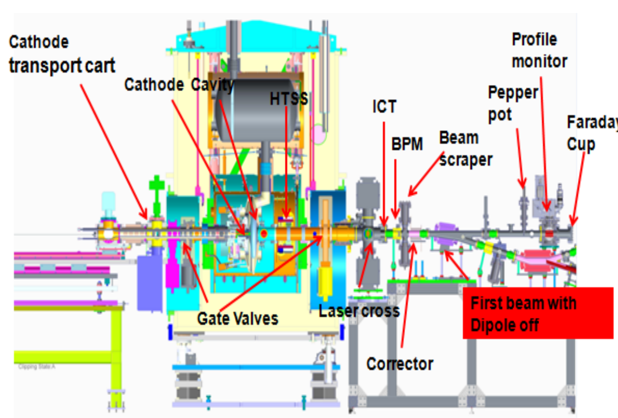

Figure 1: First beam commissioning configuration.

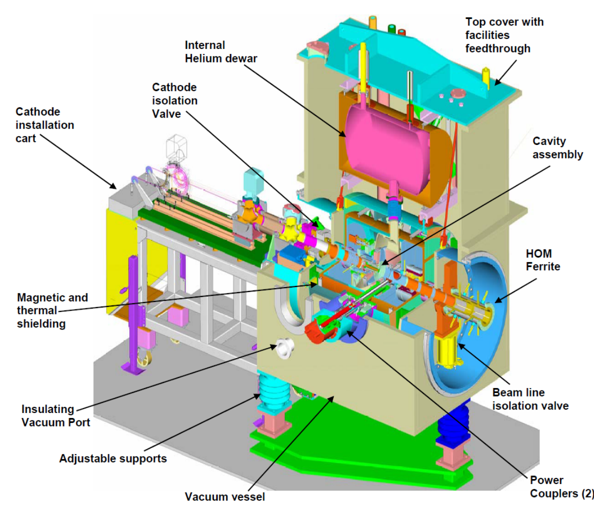

Figure 2: SRF gun cryomodule.

Abstract

The injector for the National Synchrotron Light Source II (NSLS-II) storage ring consists of a 3 GeV booster synchrotron and a 200 MeV S-band linac. The linac was designed to produce either a single bunch with a charge of 0.5 nC of electrons or a train of bunches up to 300 ns long containing a total charge of 15 nC. The booster was designed to accelerate up to 15 nC each cycle in a train of bunches up to 300 ns long. Linac commissioning was completed in April 2012. Booster commissioning was started in November 2013 and completed in March 2014. All of the significant design goals were satisfied including beam emittance, energy spread, and transport efficiency. While the maximum booster charge accelerated was only 10 nC this has proven to be more than sufficient for storage ring commissioning and operation. The injector has operated reliably during storage ring operation since then. Results will be presented showing measurements of linac and booster operating parameters achieved during commissioning and initial operation. Operating experience and reliability during the first year of NSLS-II operation will be discussed.

INTRODUCTION

The NSLS-II is a third generation electron storage ring at Brookhaven National Laboratory [1]. It was commissioned in 2014 and began user operations in February, 2015. The NSLS-II injector consists of a 3 GeV booster synchrotron, a 200 MeV S-band linac, the associated transport lines, and the storage ring injection straight (Fig. 1). The linac is capable of producing either a single bunch of up to 0.5 nC of charge or a train of bunches up to 300 nS long containing a total charge of 15 nC. The linac was commissioned in 2012 and met all of its design specifications with one exception: only 11 nC was accelerated in multibunch mode instead of the 15 nC specified [2]. Since then up to 13 nC has been accelerated within the specified 0.5% energy spread.

The 3 GeV booster is a 158.4 m circumference synchrotron developed jointly by Brookhaven National Laboratory (BNL) and the Budker Institute of Nuclear Physics (BINP) [3, 4]. Danfysik developed the dipole power supplies as a subcontractor on the booster project. The booster has a four-fold symmetric design lattice using combined function magnets to create a FODO-like lattice in each quadrant with matching quadrupole triplets at both ends of each quadrant [5]. The RF system uses a 7 cell PETRA type 500 MHz cavity. The booster operates at a 1 Hz repetition rate but was designed to be upgraded to 2 Hz. Booster commissioning was completed in March 2014 and has delivered electrons to the NSLS-II storage ring since then.

The storage ring injection straight contains 4 half-sine 8.5 mrad kicker magnets. Each kicker is excited by an IGBT pulser with 10 series stages of 20 parallel IGBTs per stage. The kicker magnets and pulsers were built at BNL. The kickers produce a 5.4 μsec pulse which is slightly longer than twice the 2.6 μsec revolution time of the storage ring. This has not been a problem so far but the pulse width can easily be reduced by using smaller pulse capacitors. The system was designed to pulse at 10 kV but only 7.9 kV is required for operation. Amplitude stability σ<0.015% was demonstrated over 24 hours of operation in the pulsed magnet laboratory in a non temperature controlled environment.

An out-of-vacuum, 150 μsec, 100 mrad septum from Danfysik is used for storage ring injection. The system has demonstrated an amplitude stability <0.1%, time jitter <10 ns, and leakage field <8 μT-m.

BOOSTER COMMISSIONING RESULTS

Booster commissioning was started in late November 2013 and completed by March 2014. All major design goals for the booster were met except that the maximum charge accelerated in multibunch mode (MBM) was only 10 nC compared to a design goal of 15 nC. Since <3 nC per cycle from the booster has been required for the first year of storage ring commissioning and operation it was decided not to spend additional time increasing the

NSLS-II RADIO FREQUENCY SYSTEMS *

J. Rose†, F. Gao, A. Goel, B. Holub, J. Kulpin, C. Marques, M. Yeddulla
NSLS-II, BNL, Upton, NY 11973, USA

Abstract

The National Synchrotron Light Source II is a 3 GeV X-ray user facility commissioned in 2014. The NSLS-II RF system consists of the master oscillator, digital low level RF controllers, linac, booster and storage ring RF sub-systems, as well as a supporting cryogenic system. Here we will report on RF commissioning and early operation experience of the system.

INTRODUCTION

The NSLS-II radio frequency system was designed as a whole from the master oscillator, its distribution to subsystems, from digital field controllers to high power amplifiers driving normal and superconducting cavities. The RF drives the grid of the planar triode in the DC electron gun creating the electrons that are bunched and accelerate to 200 MeV in the 2.998 GHz linac, are captured and accelerated in the 499.68 MHz bucket of the booster RF and accelerated to 3 GeV. The 3 GeV electrons extracted from the booster are injected into the RF buckets of the superconducting cavities in the storage ring where they are accumulated up to 500 mA. This paper describes these systems.

MASTER OSCILLATOR

The master oscillator is the reference frequency for the RF systems as well as the master clock for the timing system. Because it is the ultimate source of amplitude and phase noise imposed on the beam through the RF cavity field, specifications from x-ray beam line requirements were derived [1]. These are given in Table 1.

Table 1: Longitudinal Beam Stability Requirements

	Phase Jitter Δθ [°]	**Momentum Jitter Δp/p [%]**
Timing-dependent experiments	0.14	0.005
Vertical divergence (from momentum jitter)	2.4	0.09
10% increase in σ_s due to filamentation	1.8	0.065
Vertical centroid jitter	0.82	0.03

In order to meet the demands of timing experiments we took the timing dependent experiments requirements of 0.14 degrees phase jitter and 0.005 % momentum jitter as the requirement for the RF system. The master oscillator must contribute no more than a fraction of this. We chose an Agilent E8257D synthesized signal generator with low phase noise options. Frequency agility is required for a number of applications, including measurement of chromaticity, measurement of dispersion and compensation of orbit length due to wavelength shifters. Of these, chromaticity measurements are the most demanding. With the parameters of the NSLS II baseline design ($\alpha = 3.68\ 10^{-4}$, $\gamma = 5871$, $f_{rf} = 500$ MHz) and the assumption that the tune change $\Delta\nu_{x,y}$ should be at least 3 times the tune spread $\sigma\ \nu_{x,y}$ to get good resolution for the tune measurement when measuring small chromaticity's down to $\xi_{x,y} = 0.1$, and an educated guess for the tune spread of $5.\ 10^{-3}$ in both transverse planes, we obtain $\Delta f_{rf} = -\ \alpha\ 3\sigma\ \nu_{x,y}\ f_{rf} / 0.1 \approx \pm 29$ kHz

The generator allows for software commanded phase continuous frequency modulation which will be used for the above measurements as well as in a slow frequency or "radial" loop to make corrections for small changes in electron beam orbit caused by seasonal or diurnal temperature variations in ring circumference. The MO output is amplified and split to be distributed to the storage ring RF cavity field controllers, injector RF systems, the timing system, a streak camera and the bunch by bunch feedback system.

DIGITAL CAVITY FIELD CONTROLLER

The starting point for the NSLS-II cavity field controller was the architecture of the SNS controller designed by Doolittle et al [2]. This architecture utilizes up/down conversion from RF to the 50 MHz IF frequency using LO and AD/DA clocks derived from the Master Oscillator frequency, which is also the synchrotron ring RF frequency. New hardware was designed [3] for the NSLS-II RF frequency of 499.68 MHz. The most significant improvement was in the development of new firmware to provide new capability necessary for the operation of a synchrotron. Given the number, types and variety of cavities that they are to control, modular FPGA code and conditional compilation was used. For example, instantiation of feedback, interlock components and ramp generators are conditional depending on the needs of the RF system towards which the build is targeted.

Storage Ring Compilation

The Storage Ring compilation contains the feedback logic with set-point generation and feedback gain control. It also contains a ramp down block which when triggered by an external interlock ramps the fixed field set point to zero in a 1ms timescale. This prevents tripping the transmitter on reverse power as would happen should the RF drop out in microseconds.

EXPERIENCE WITH FIRST TURNS COMMISSIONING IN NSLS-II STORAGE RING

S. Seletskiy#, G. Bassi, J. Bengtsson, A. Blednykh, E. Blum, W. Cheng, J. Choi, R. Fliller, W. Guo, R. Heese, Y. Hidaka, S. Kramer, Y. Li, B. Podobedov, T. Shaftan, G. Wang, F. Willeke, L. Yang, X. Yang, BNL, Upton, NY 11973, USA

Abstract

In this paper we describe our experience with commissioning of the first turns in the NSLS-II storage ring. We discuss the problems that we encountered and show how applying a dedicated first turns commissioning software allowed us to diagnose and resolve these problems.

INTRODUCTION

The first phase of the NSLS-II Storage Ring (SR) commissioning [1-3] took place in the spring of 2014. As a result of the first phase the routine injection efficiency of better than 90% was achieved. The beam was successfully accumulated up to 25 mA. One of the main challenges in establishing the beam in the SR was obtaining first few turns.

Below we describe our experience with obtaining first few turns and eventually a spiralling beam in the NSLS-II Storage Ring.

SR DESCRIPTION

The 3 GeV Storage Ring [4] consists of 15 short straight (low-β) and 15 long straight (high-β) sections. It contains 30 double bend achromats (DBA). The SR lattice is shown in Fig. 1.

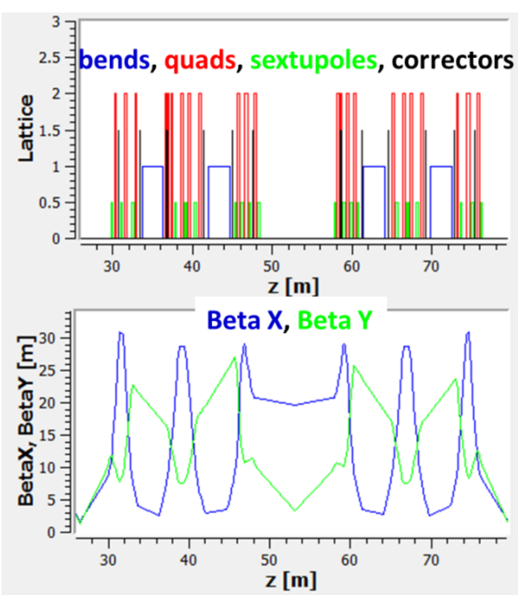

Figure 1: NSLS-II Storage Ring lattice.

Injection into the SR is performed with the aid of the DC and pulsed injection septa and four fast kickers forming a closed bump [5]. The injected beam exits the pulsed septum parallel to and with -24.5 mm displacement from the central axis of the injection straight section. In design injection scheme the stored beam is moved in the injection region towards the injected beam and returned back on axis at the exit of the fourth kicker. The injected beam has residual betatron oscillations of about 10 mm at the exit of injection section. Schematic of injection section (IS) is shown in Fig 2.

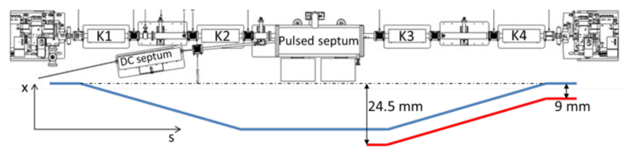

Figure 2: SR injection section and designed injection scheme (red colour represents injected beam, blue colour represents stored beam).

FIRST TURNS AND ON-AXIS INJECTION

The initial SR lattice was set to the design values. All SR sextupoles were set to zero current for the first turn commissioning. For the safety reasons the beam charge during initial commissioning was kept below 1 nC and injection rate was 0.3 Hz.

We decided to perform initial injection in the SR on axis, i.e. to minimize the betatron oscillations of injected beam. To achieve on-axis injection we applied horizontal -11 mm DC bump, which was created with the aid of regular beam trajectory correctors, on top of the AC bump in the injection straight. An example of such symmetric DC bump is shown in Fig. 3.

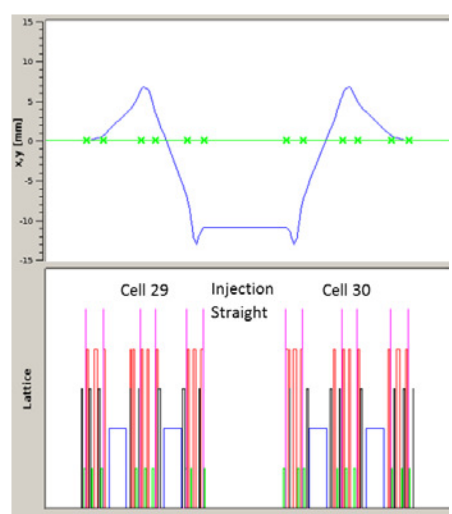

Figure 3: Horizontal DC bump in injection straight section.

HIGH LEVEL APPLICATION FOR FIRST TURNS COMMISSIONING IN NSLS-II STORAGE RING

S. Seletskiy#, A. Blednykh, J. Choi, Y. Hidaka, B. Podobedov, G. Shen, L. Yang
BNL, Upton, NY 11973, USA

Abstract

The typical problems occurring during commissioning of the first turns in the storage rings include shorted coils or reversed polarity of the magnets, cross-cabling of magnet power supplies and reversed polarity of BPMs. In this paper we describe a dedicated high level control application, which was created and utilized for commissioning of the first turns in the NSLS-II storage ring.

INTRODUCTION

Years of experience in commissioning of storage rings (SR) show that obtaining first few turns commonly is one of the main challenges in establishing the beam in the SR. A typical storage ring is a complicated system consisting of hundreds (if not thousands) of devices. While it has been a routine practice to perform thorough integration tests prior to attempting the first injection into the ring, various hardware problems during SR commissioning with the beam are nonetheless rather common. Such problems usually hinder obtaining the first turns in the SR and result in significant loss of time.

Examples of the problems faced by various synchrotron facilities during commissioning the first turns in the storage rings include magnets with reverse polarities [1,2], cross-cabling of magnet power supplies [1], shorted magnet coil [3], obstruction of physical aperture in the SR [2,3], wrong polarity of beam position monitors (BPMs) [2] and mismatch between pulsed magnets waveforms [4,5].

Below we describe dedicated First Turn Analysis (FTA) software that was created with the goal of quickly finding possible problems described above. The FTA was successfully used for commissioning of the first turns in NSLS-II storage ring and proved to be a valuable tool [6].

GENERAL IDEA

The general idea of the First Turns Analysis tool was inspired by OPTIM [7]. Our goal is to combine interactive simulations of beam trajectory with live online measurements of beam position monitors. By interactive simulations we mean that when any parameter of the accelerator model is changed in the interactive GUI the user immediately sees the updated results on respective plots.

By updating the model simultaneously with the settings of the actual magnets and by plotting together the resulting beam trajectories predicted by the model and the live BPM readings one can obtain a rather powerful tool for analysis of the beam dynamics. Indeed, from comparing the simulated and the real trajectories one can easily deduce the source of their digression. The wrong polarity of the magnets can be quickly detected from trajectory response to the change in magnet settings. The same is true for cross-cabled magnets. As for the shorted magnet coils, the comparison of simulated and real differential trajectories shall be enough for their detection.

The beauty of this approach is that it does not require any additional off-line analysis. Any accelerator physicist equipped with such software shall be able to quickly pin-point the origin of the problem.

CODE DEVELOPMENT

As many other NSLS-II software applications [8] our code is written in Python [9]. For communications with the BPMs and magnet power supplies we rely on APHLA [10] – Python middle layer developed specifically for NSLS-II.

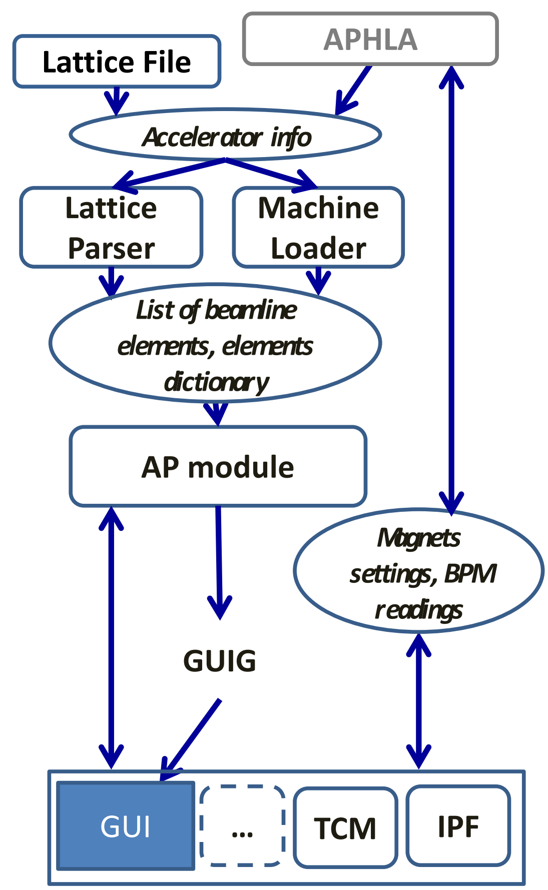

Figure 1: General overview of the FTA software architecture.

We took a modular approach to the design of the FTA code. Its most important modules include: the Accelerator

ANALYSIS OF POSSIBLE BEAM LOSSES IN THE NSLS II STORAGE RING

Y. Li, S. Seletskiy#, W. Guo, R. Fliller, S. Kramer, B. Podobedov, T. Shaftan, B. Wahl, F. Willeke, BNL, Upton, NY 11973, USA

Abstract

The NSLS-II accelerators are installed within radiation shielding walls that are designed to attenuate the radiation generated from an assumed beam loss power to a level of <0.5mrem/h at the outer surface of the bulk shield walls. Any operational losses greater than specified level are expected to be addressed by installing supplemental shielding near the loss point in order to attenuate the radiation outside the shield wall to the design level. In this paper we report the analysis of the electron beam missteering in the NSLS-II Storage Ring for the determination of supplementary shielding.

INTRODUCTION

The missteering (caused by operator's mistake or by a magnet failure) of the electron beam freshly injected into NSLS-II Storage Ring (SR) [1] can result in unacceptable radiation levels on experimental floor. Design of respective radiation protection shielding [2] relies on detailed analysis of physically possible steering errors. In this paper the potential angles and offsets of the missteered beam are calculated by implementing the cascaded parameter scan (CPS) [3]. This method was originally developed for the top-off safety analysis, was realized in a parallel python code and benchmarked with other top-off safety simulators developed in SLAC and LBNL. The results of the studies were double-checked with independent simulations using simplified magnets fields profiles and a smaller number of tracked beam particles (explained below). The detailed description of the analysis results is given in [4].

SR DESCRIPTION

Figure 1 schematically shows the lattice of NSLS-II Storage Ring. The SR lattice contains 30 double bend achromats (DBA). There are 15 short straight (low-β) and 15 long straight (high-β) sections.

The storage ring is designed to accept 3GeV electron bunches from the Booster. An interlock in the Booster to Storage Ring transport line [7] constrains the injected beam energy within a window of 2 - 3.15GeV.

Our analysis is based on particle tracking, which is performed by solving a set of ordinary differential equations describing electron motion in magnetic field. The magnets field profiles are obtained from their 3D models. To simplify the calculation while keeping the adequate accuracy [5, 6] we use 1D transverse profiles for quadrupoles and sextupoles and 2D profile for dipoles in the horizontal middle plane. Figure 2 shows magnetic fields used in the simulations.

The dipole power supply current and voltage are interlocked within 2% window. Each dipole has a back-leg winding, which can contribute ≤ 3% field variation. The total possible dipole field range scanned was chosen as ±5% around its nominal setting.

The range for the other SR magnets was set by the maximum current of their power supplies and their possible magnetic fields, as listed in [4].

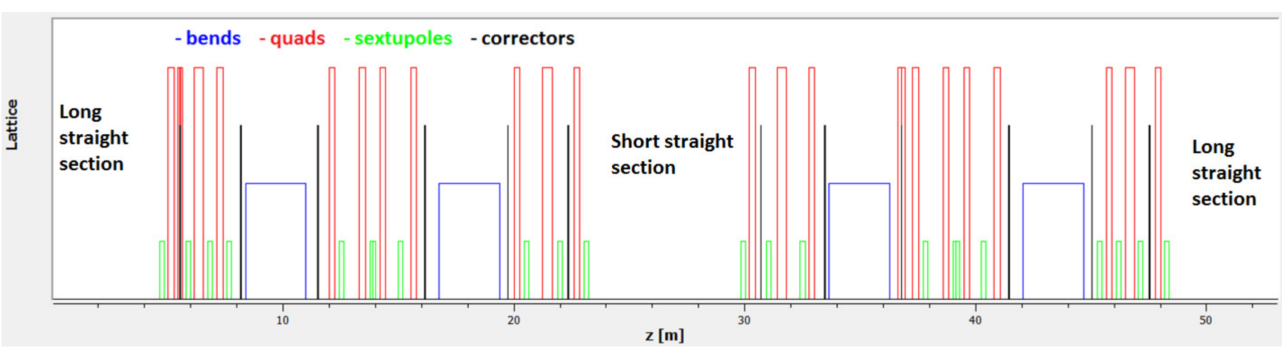

Figure 1: NSLS-II SR lattice.

BEAM STEERING ANALYSIS

The CPS utilizes the following beam tracking algorithm. We start with the phase space of beam trajectories defined by the geometric acceptance of the long straight section. Such phase space area covers all possible incident beam trajectories.

Next, we track trajectories within the phase space through the first beamline element varying its field and the beam energy over their full range. We record each beam trajectory's coordinates in phase space after it passes the magnet and find the maximum angle and position of trajectories not intercepted by the magnet yoke. Then we discard the trajectories that were lost on the vacuum chamber and the surviving trajectories define a phase space volume. This phase space was used to

ANALYSIS OF POSSIBLE BEAM LOSSES IN THE NSLS II BSR TRANSFER LINE

S. Seletskiy#, R. Fliller, W. Guo, S. Kramer, Y. Li, B. Podobedov, T. Shaftan, B. Wahl, F. Willeke,
BNL, Upton, NY 11973, USA

Abstract

The NSLS-II accelerators are installed within 0.8 – 1 m thick radiation shielding walls. The safety considerations require attenuating the radiation generated from possible electron beam losses to a level of <0.5mrem/h at the outer surface of the bulk shield walls. Any operational losses greater than specified level shall be addressed by installing supplemental shielding near the loss point. In this paper we discuss simulation studies that identified potential beam loss locations. Results of these studies were used for identification of imposed radiation risks and for specification of the supplemental shielding design necessary to mitigate those risks.

INTRODUCTION

The NSLS-II accelerator complex [1] consists of 200 MeV linac, the Booster accelerating beam to 3 GeV, the 3 GeV Storage Ring (SR) and the two transfer beamlines – Linac to Booster transfer line and Booster to Storage Ring (BSR) transfer line. Missteering of the e-beam that can be caused by operator's mistake or by magnet failure can result in unacceptable radiation levels on experimental floor. Design of personnel radiation protection shielding [2] at NSLS-II relies on detailed analysis of physically possible steering errors in various parts of accelerator. In this paper we describe such analysis for the Booster to Storage Ring transfer line. An inventorial description of the beam steering considerations in the BSR and of their effect on radiation safety can be found in [3].

BEAMLINE DESCRIPTION

Below we consider three beamlines (Fig. 1): the Booster extraction section (ES), the Booster to Storage Ring transfer line phase 1 (BSR-P1) and the BSR transfer line phase 2 (BSR-P2).

The Booster ES consists of four slow bumps forming local closed 4-bump BU1, BU2, BU3 and BU4, four fast kickers K1, K2, K3 and K4, pulsed septum magnet SP1 and a DC septum magnet SP2. These magnets are utilized for the extraction of the beam from the Booster into the BSR line. All four bumps (B1-4) are powered in series. Pairs of kickers K1-2 and K3-4 are powered in series as well.

The BSR-P1 line consists of five quadrupoles (Q1, Q2, Q3, Q1BD and Q2BD) and one bending magnet (B1). These magnets transport beam to the beam dump when bending magnet B2 is turned off.

The BSR-P2 includes Q1-Q3 and B1 as well as quadrupoles Q4-Q14 and bends B2-B4. These magnets transport beam to the Storage Ring. Injection into the Storage Ring is performed with SP3 and IS, which are the DC and pulsed SR injection septa respectively. The SR injection region is analysed for in [4, 5].

Detailed description of each of the BTS beamlines elements is given in [3].

BEAM STEERING ANALYSIS IN ES

Although the ES magnets are supposed to be used only at extraction energy of 3 GeV technically they can fire at any point of Booster ramp. Since these magnets are powered in series there are three scenarios to consider: either kickers K1 and K2 fire, or K3 and K4 fire, or four bumps BU1-4 fire. With the approach to the analysis described farther in this paper and under provision that bumps BU2-4 are treated independently from bump BU1 (see below) the three described scenarios cover all possible local beam losses that can happen under any feasible ES settings.

COMMISSIONING OF ACTIVE INTERLOCK SYSTEM FOR NSLS II STORAGE RING

S. Seletskiy#, C. Amundsen, J. Choi, J. De Long, K. Ha, C. Hetzel, H. Hseuh, Y. Hu, P. Ilinski, S. Kramer, Y. Li, M. Maggipinto, J. Mead, D. Padrazo, T. Shaftan, G. Shen, O. Singh, R. Smith, W. Wahl, G. Wang, F. Willeke, L. Yang, BNL, Upton, NY 11973, USA

Abstract

The NSLS-II storage ring is protected from possible damage from insertion devices (IDs) synchrotron radiation by a dedicated active interlock system (AIS). It monitors electron beam position and angle and triggers beam dump if beam orbit exceeds the boundaries of pre-calculated active interlock envelope. In this paper we describe functional details of the AIS and discuss our experience with commissioning of the AIS for the first eight IDs installed in the storage ring.

INTRODUCTION

The final phase of the NSLS-II Storage Ring (SR) commissioning [1-3] took place in the fall of 2014. This phase included commissioning of first eight insertion devices (three damping wigglers (DW), one elliptically polarized and four planar in-vacuum undulators) and raising stored beam current to 50 mA. The final SR commissioning phase also included commissioning of the six beamlines (two of three DWs do not have beamlines) and of respective beamline frontends (FE).

One of the most important tasks for this phase was commissioning of the ID active interlock (AI), which protects the SR and the FEs components from possible damage from ID synchrotron radiation (IDSR).

There is another part of the AIS, which protects the SR from bending magnets synchrotron radiation. This part of the system is not discussed in this paper.

Below we describe our experience with the AI commissioning.

AIS DESCRIPTION

The active interlock is designed [4] to continuously monitor beam orbit in IDs and to drop the beam in case it exits predefined AI envelope (AIE) [5]. Typical AIE is an xx' or yy' phase space rectangle of +/-0.5 mm and +/-0.25 mrad. Fig. 1 schematically shows signals that the AI is monitoring for each ID.

The AIS calculates beam angle and deflection at the center of the drift between two neighbouring beam position monitors (BPMs) [6] from respective BPMs readings (10 kHz data). The beam current readings are obtained from the storage ring DCCT. In case of canted IDs the current of the canting magnets, which create a local bump on the beam orbit, are monitored by the AI as well.

The statuses of the bending magnet photon shutter (BMPS) and the frontend photon shutter, a.k.a. ID photon shutter (IDPS), are also monitored by the AI.

When the e-beam is not interlocked the BMPS and the IDPS protect the FE and the beamline from bending magnet synchrotron radiation and from IDSR respectively.

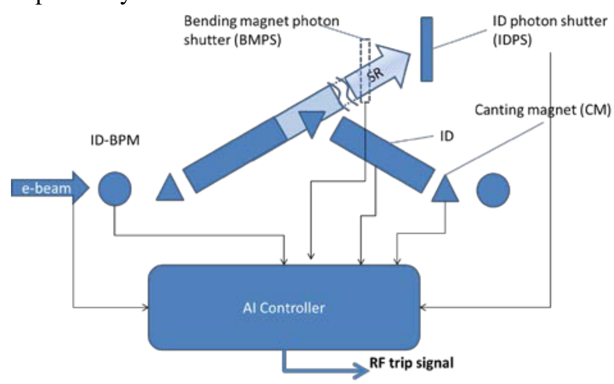

Figure 1: Schematic of signals from various hardware to the AIS. Here we show the canted IDs for the purpose of generality.

The overall structure of active interlock system is schematically shown in Fig. 2.

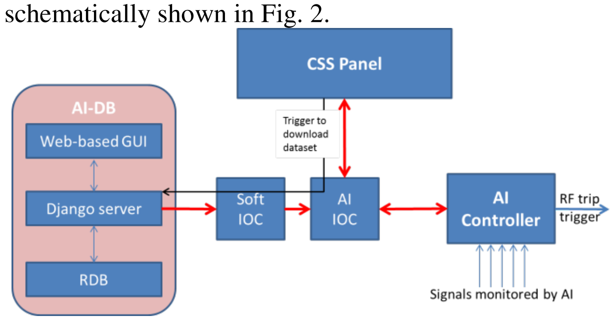

Figure 2: Schematics of the Active Interlock System.

The main functional block of the AIS is the AI controller (AIC). It performs the monitoring of various hardware signals and "makes a decision" on whether the beam shall be dumped. The beam dump is realized by tripping low level RF. The FPGA was chosen for AIC to minimize the response time of the AIS.

The information about AIE for each ID and about respective BPMs is downloaded to the AIC from the AI database (AI-DB). The AI-DB runs on Django server [7] with underlying MySQL relational database and a web-based GUI.

The GUI for the AIS is realized in Control System Studio (CSS) [8] as a standard CSS panel.

The logic of the AIC is shown in Fig. 3.

The logic gates encircled by the green line are responsible for engaging the active interlock. It is getting engaged either when the beam current is above 0.2 mA

Abstract

Alkali antimonide photocathodes are a strong contender for the cathode of choice for next-generation photon sources such as LCLS II or the XFEL. These materials have already found extensive use in photodetectors and image intensifiers. However, only recently have modern synchrotron techniques enabled a systematic study of the formation chemistry of these materials. Such analysis has led to the understanding that these materials are inherently rough when grown through traditional sequential deposition; this roughness has a detrimental impact on the intrinsic emittance of the emitted beam.

Sputter deposition may provide a path to achieving a far smoother photocathode, while maintaining reasonable quantum efficiency. We report on the creation and vacuum transport of a K_2CsSb sputter target, and its use to create an ultra-smooth (sub nm roughness) cathode with a 2% quantum efficiency at 532 nm.

ROUGHNESS AND EMITTANCE

The Alkali Antimonides are a class of materials (I_3V semiconductors) often used as photocathodes, both in detectors [1] and accelerators [2]. Many of these compounds are capable of achieving a quantum efficiency (QE) of several percent for green light, making them attractive for high average current accelerator applications. The typical sequential deposition process used to form these materials results in a cathode which is very rough (25 nm RMS for a 50 nm thick cathode, with a 100 nm spatial period) [3]. This results in an undesirable field dependence of the intrinsic emittance [4,5]; an emission field of 6 MV/m is sufficient to double the intrinsic emittance of a K_2CsSb cathode illuminated with green light (the expected value should be 0.5 µm/mm [6]). Assuming a simple sinusoidal modulation of the surface height, the field-induced emittance growth can be shown to be given by Eq. (1)

$$\varepsilon_{rough} = \sigma_{x,y}\sqrt{\frac{\pi^2 a^2}{2m_0 c^2 \lambda} Ee} \tag{1}$$

where a is the amplitude, λ is the wavelength of the surface height modulation, σ is the rms beam size and E is the field gradient. Figure 1 shows the effect of roughness using this model for an amplitude of 25 nm and a surface wavelength of 100 nm. These values are typical for a sequential thermal deposition process. We can see that at fields that are relevant to high gradient photo-guns, there would be a drastic increase in emittance. We can also use this same model to detemine the amplitude necessary so that we can achieve room temperature kT defined emittance (0.225 microns / mm rms). We assume that the wavelength of the sinusoidal modulation is always 4 times the amplitude, as often observed in thin film growth. For a field of 20 MV/m, we find that a roughness amplitude of less than 1 nm is required. This is close to the roughness of super-polished etched Silicon,

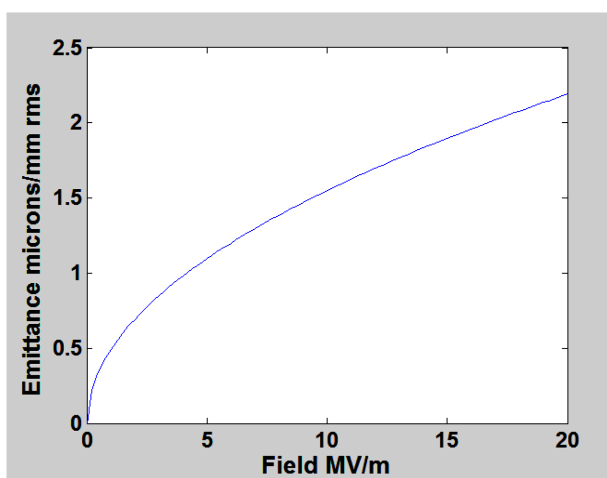

Figure 1: Dependence of emittance on field, for a sinusoidal modulation of the surface with an amplitude of 25 nm and a period of 100 nm.

NSLS-II STORAGE RING INJECTION OPTIMIZATION*

G.M. Wang#, T. Shaftan, E. Blum, W.X. Cheng, J. Choi, Y. Li, S. Seletskiy, Y. Tian, L. Yang, L.H. Yu, BNL, Upton, NY, 11973, U.S.A

Abstract

The National Synchrotron Light Source II (NSLS-II) is a state of the art 3 GeV third generation light source at Brookhaven National Laboratory. The SR is designed to work in top-off injection mode. The injection straight includes a septum and four fast kicker magnets with independent amplitude and timing control. The beam injection is designed as 9.5 mm off-axis in x plane and on-axis injection in y plane. To capture the injected beam within the SR acceptance for high injection efficiency, it requires 6-D phase space match. Besides that, the fast kickers formed local bump is also required to be locally to minimize the injected beam extra betatron oscillation and keep the stored beam disturbance within the specification, 10 % beam size to minimize the injection transient. This paper will present our injection commissioning experience.

INTRODUCTION

The National Synchrotron Light Source II (NSLS-II) is a 3 GeV, ultra-small emittance (H: 1 nm-rad and V: 8 pm-rad), high brightness third generation light source [1].

The Storage Ring phase I commissioning started in Mar. 2014 and finished in one and a half months later to achieve 25 mA stored beam current with >90% injection efficiency.

The designed beam injection is 9.5 mm horizontal off-axis injection and vertical on axis injection. The commissioning strategy is to circulate beam first by doing on-axis injection [2] with sextupoles and RF off, then get the stored beam with sextupoles and RF on and finally move to nominal off-axis injection [3] to accumulate high beam current with good injection efficiency. In this paper, we describe our experience.

SR INJECTION OVERVIEW

The NSLS II storage ring injection system is located in one 9.3 m long straight section. As shown in Fig. 1, it consists of four kickers, a DC septum and a pulsed septum for beam injection. The four kicker magnets, producing a closed bump in x plane for stored beam, are placed symmetrically in the straight section. Their bending angles are the same but in different bend direction. The stored beam gets the maximum bump amplitude at the middle of injection straight line. There are one injection straight flag, 4 BPMs and two neutron beam loss monitor are dedicated for injection related beam monitor and study. BPMs P1 and P4 are centered on the SR stored beam orbit, P2 is shifted by X = -5.8 mm off center and P3 is shifted by X = -15 mm from SR stored beam center. These four BPMs are inside the local fast bump and can be used for the bump amplitude study. 180 BPMs along the ring were used for the bump leakage study.

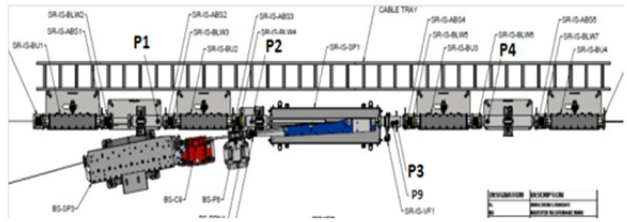

Figure 1: Top view of the SR injection straight section.

When the injected beam arrives, kickers K1 and K2 kick the stored beam towards the septum knife by 15 mm. The stored beam and the injected beam merge at the exit of the AC septum. Kickers K3 and K4 will kick both beam, so that the stored beam returns to its designed orbit, and the injected beam is off-axis oscillation. These kickers angle are 7.5 mrad with 5.2 μs kicker pulse length, two times long of storage ring revolution. The stored beam bump amplitude is 15 mm. The injected beam and stored beam relative position at the exit of septum is shown in Fig. 2. The designed stored beam equilibrium orbit is 17.5 mm away from septum knife with 2.5 mm safe region away from septum knife. At the end of bump, injection beam is 9.5 mm away from stored beam close orbit, which requires ~11 mm SR acceptance, comparing with the SR designed acceptance 15 mm [4].

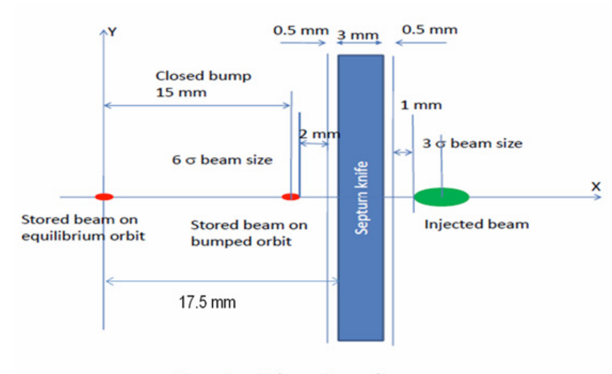

Figure 2: Injected beam and stored beam relative position at the exit of septum.

FAST KICKERS STUDY

Each kicker has independent voltage and timing control. The kicker voltage to the kick strength conversion is not very precise from the lab measurement. The timing delay is separated into two control parts. One is for four kickers' common delay relative to the injection time, and the other is for each kicker precise delay to compensate the cable length or beam arrival time difference. The initial timing trigger for all kickers is

BNL, Upton, NY, 11973, U.S.A

Abstract

The National Synchrotron Light Source II (NSLS-II) is a state of the art 3 GeV third generation light source at Brookhaven National Laboratory. As many facilities worldwide, NSLS II uses the EPICS control system to monitor and control all accelerator hardware. Control system studio (CSS) is used for simple tasks such as monitoring, display, setting of PVs. browsing the historical data, et. al. For more complex accelerator physics applications, a collection of scripts are mainly written in Python and part from Matlab during commissioning. With the close collaboration and fully support from control group, more and more CSS features were developed for operation convenience and several high level applications are interfaced with users in CSS panels for daily use based on softiocs. This paper will present the tools that we have been used.

INTRODUCTION

The National Synchrotron Light Source II (NSLS-II) is a 3 GeV, ultra-small emittance (1 nm-rad), high brightness third generation light source [1]. The storage ring commissioning started in Mar. 2014 and took ~ two months and reached the key performance parameters (goal: 25 mA), 50 mA with superconducting RF cavity in July 2014 [2,3]. Since Feb. 2015, it started to provide the user operation for phase I project beam lines.

As many other facilities [4,5], NSLS II chose the Experimental Physics and Industrial Control System (EPICS) as its control system to monitor and control the accelerator hardware. It interfaces to the accelerator instruments and devices (such as Power supply, digitizer, and motor) with IOC (Input Output Controllers). Channel Access is used as the interface to the machine process variables (PVs).

The typical control applications include two types, simple monitor/control device and complex accelerator physics application for studies and machine optimization (measurements, data analyses and applying correction). Mainly, we use cothread to access the process variables (PVs) in Python script for complex accelerator physics applications and the CSS (BOY) [6] panel for simple tasks such as monitoring, displaying and setting of the machine Process Variables (PVs). The PVs history can be saved from data archive system. Besides, MATLAB is also available for programming and EDM panels are also used. All source codes including panel configurations are controlled and managed by mercurial version in the control system.

To keep the beam commissioning time efficient, various tools were developed for data displaying, collecting and processing. Besides machine status and physics applications, we also developed the daily used operation tools [7], such as save/compare/restore tool, data archive and browsing, alarm and warning monitor, elog, eticket, channel finder service and applications.

In this paper, we'll present our commissioning tools experience.

MACHINE STATUS APPLICATION

All of the monitor and control panels are created with software tools in Control System Studio (CSS), which is an Eclipse-based collection of tools to monitor and operate large scale control systems. The interface allows the operators to edit the desired ramp/soak profiles and provides the option to use predefined recipes.

The NSLS-II operation panels [8] include the user panels and the expert panels. They display the device status and parameters (setpoint and readback) and show the device performance. A user panel shows only information that user is required, such as the magnet current setpoint, readback or fault status. The expert panel shows all the information that expert can fully control the device or diagnose the device, such as power supply operation mode, fault details.

HIGH LEVEL APPLICATION

Besides the devices status and control, we also develop high level applications to realize the accelerator physics application tools. It is to translate the raw/processed data from PV to the "physics" parameters, such as from beam size reading to beam emittance or orbit measurement and correction.

An extensive set of libraries and scripts [9] have also been written in Python for more dynamic and physics related study. A high level physics applications (HLAs) library, which maps flat EPICS process variables (PVs) to object oriented accelerator components, was developed. This mapping is dynamical and configurable from channel finder service (CFS). CFS associates PVs with properties and tags. HLAs library constructs an accelerator structure based on PVs properties and tags and make them with the search feature and group manipulatable. This makes high level application user more convenient, such as operation type of elements (BPMs, correctors) or individual element based on their name pattern, position… HLAs library also wraps the unit conversion functions between physics unit and hardware unit.

Yang, X. Yang, L. Yu, BNL, Upton, NY 11973, USA

Abstract

The National Synchrotron Light Source II (NSLS-II) is a state of the art 3 GeV third generation light source at Brookhaven National Laboratory. During spring/ summer of 2014, the storage ring was commissioned up to 50 mA without insertion devices. In the fall of 2014, we began commissioning of the project beamlines, which included seven insertion devices on six ID ports. Beamlines IXS, HXN, CSX-1, CSX-2, CHX, SRX, and XPD-1 consist of elliptically polarized undulator (EPU), damping wigglers (DW) and in-vacuum undulators (IVU) covering from VUV to hard x-ray range. In this paper, experience with commissioning and operation is discussed. We focus on reaching ring storage ring performance with IDs, including injection, design emittance, compensation of orbit distortions caused by ID residual field, source point stability, beam alignment and tools for control, monitoring and protection of the ring chambers from ID radiation.

INTRODUCTION

The National Synchrotron Light Source II (NSLS-II) is a 3 GeV, ultra-small emittance (1 nm-rad), high brightness (>10^{21} photons s^{-1} mm^{-2} $mrad^{-2}(0.1\%BW)^{-1}$) third generation light source [1]. It can support 60~80 beamlines stemming from insertion devices, three pole wiggles and bending magnets. The storage ring (SR) commissioning took about two months and reached and exceeded key performance parameters (KPP were 25 mA at 3 GeV of the beam energy) with superconducting RF cavity during July 2014 [2-4]. Once the start-up goals were accomplished we moved to phase-I insertion devices commissioning. The insertion device (ID) and their front end (FE) commissioning commenced in Oct., 2014 and took about 2 months for all the project IDs so that the beamline commissioning with the beam began in Dec. 2014. Since then all installed IDs operate routinely supplying light for the NSLS-II users at the level of 50 mA of circulating current.

NSLS-II design is based on 30 cells of double-bend-achromat lattice, including 15 long straight sections (9.3 m) and 15 short straight sections (6.6 m). The IDs [5] location and their main parameters are listed in Table 1.

In this paper we describe the results of the ID commissioning including compensation of their effects on closed orbit, perturbation of linear optics, optimization of emittance and injection efficiency, as well as the ID source point alignment along the front-ends, testing of equipment protection system and reaching high beam stability.

Table 1: NSLS II Phase I IDs Main Parameters

Beam Line	Type	L [m]	λ [mm]	K_{max}	Gap [mm]
CSX1/ CSX2	EPU49	4	49	2.6 (heli) 4.3 (Lin) 3.2 (vlin) 1.8 (45d)	11.5
IXS	IVU22	3	22	1.52	7.4
HXN	IVU20	3	20	1.83	5.2
CHX	IVU20	3	20	1.83	5.2
SRX	IVU21	1.5	21	1.79	6.4
XPD/ PDF	DW100	6.8	100	~16.5	15.0

ID COMMISSIONING

Changing ID gaps affects stored beam closed orbit, perturbs linear optics (inducing tune shift and beta beat), reduces injection efficiency. All project IDs were commissioned in several steps: 1) aligning beam orbit in an ID with the stored beam in low current, (along with the ID elevation adjustment if available); 2) measuring ID field integrals and minimizing related orbit distortions by setting fields in the ID trim coils (usually the latter took several iterations so to reach residual distortions on the ~μm level; 3) collect correction ID coil currents into a single lookup table and interpolate the measured values for a range of gaps; 4) measure the optics distortion at different gaps and correct them distortion by comparing with the ideal model; 5) assess and optimize ID impact on the injection efficiency.

Close Orbit Perturbation and Compensation

The ID impact on the beam dynamics in the first order comes from the non-zero 1st and 2nd residual magnetic field integrals. These integrals introduce local orbit position and angle shifts and lead to closed orbit distortion. This effect is local and is compensated by the ID trim coils, installed on both ID ends.

The closed orbit change as a function of the ID gap is on the order of 20 μm rms for the IVUs, 40 μm rms for the EPU and 150 μm rms for DWs. After the first iteration, the rms value of residual orbit is corrected to <5 μm. After a few iterations, the final residual orbit rms value is under 2 μm.

Abstract

The National Synchrotron Light Source II (NSLS-II) is a state of the art 3 GeV third generation light source at Brookhaven National Laboratory. While the installation activities in the booster-synchrotron are nearly completed and waiting for the authorization to start the booster commissioning, the injector and accelerator physics group have engaged into the Integrated Testing phase. We did the booster commissioning with simulated beam signals, called extended integrated testing (EIT) to prepare for the booster ring commissioning. It is to make sure the device function along with utilities, timing system and control system, to calibrate diagnostics system, debug High Level Applications, test and optimize all the operation screens to reduce the potential problems during booster commissioning with beam.

INTRODUCTION

The NSLS-II [1] is a state of the art 3 GeV third generation synchrotron light source at Brookhaven National Laboratory. The injection system consists of a 200 MeV linac, a booster ring 3 GeV, transport lines and the storage ring injection straight. The linac commissioning was in April 2012. The booster commissioning [2] includes Linac to Booster transport line, Booster and Booster to dump transport line. But the start of the booster commissioning was moved towards later in the project schedule due to increase in the scope of the booster ARR review and uncertainty.

To make the beam commissioning smooth and efficient, a new phase of booster commissioning was introduced, Extended Integration Test (EIT) [3]. In this phase we will model the beam-induced signals through the EPICS controls and test and optimize all engineering screens and High-Level applications and safety systems with the actual hardware controls and operating subsystems but only with simulated beam signals without the real beam present in the machines. This phase is likely to reduce the time of the booster and transport line (TL) commissioning with the beam, train the commissioning team and reduce safety concerns related to the commissioning and operations.

In this paper, we report our experience with booster extended integrated testing.

#gwang@bnl.gov

EXTENDED INTEGRATION TEST

Extended Integrated Testing is carried out to exercise the beam commissioning without beam.

The EIT objectives are following through the commissioning sequence:

1) Passing the beam through transport lines.
2) Matching the beam emittance with the accelerator acceptance.
3) Observation and correction of the beam trajectory at the first turn closing.
4) Beam optimization during injection and RF capture.
5) Accelerating beam along the energy ramp.
6) Extracting beam.
7) Measuring the extracted beam parameters in the diagnostics transport line.

It provided the environment to test applications for routine beam parameters measurement and correction. Meanwhile, real time alarms and interlock signals was also engaged in the operation system and this trained operators on commissioning and operations of the live machine safely.

The hardware operates as in the actual commissioning, including power supplies, vacuum, diagnostics and RF systems. Equipment Protect System and Personal Protection System will be tested during the unit and integrated testing stages.

The beam signals for the non-existing beam are simulated and generated by a computer program, ELEGANT [4]. Then they are transported by the same data channel as the real beam signal would travel. In this process, we test and optimize all the operation screens, high level applications by subsystem with the actual hardware controls. This function is realized by setting the diagnostics related PVs to the simulation mode. These diagnostic devices require reconfiguration of the EPICS records: Booster beam diagnostics (36 BPMs, 1 DCCT, 1 FCT, 6 Beam flags, 2 SR monitors, 1 Tune measurement system), LTB part II diagnostics (3 BPMs, 4 Beam flags, 1 FCT), BSR TL part I diagnostics (4 Beam flags, 4 BPMs, 1 ICT, 1 FCT and 1 Faraday cup). 'Beam' signals include closed orbit readings, turn by turn data from BPMs system, beam intensity signals, beam image signals and so on. The unknown imperfections of the booster alignment are included in the model as well. The hardware real readback including power supplies, RF and timing systems, are feed into Elegant Model and controlled by high level applications.

NSLS-II INJECTOR HIGH LEVEL APPLICATION TOOLS*

G.M. Wang#, T. Shaftan, E. Blum, R. Fliller, Y. Hu, X. Yang
BNL, Upton, NY, 11973, U.S.A

Abstract

The National Synchrotron Light Source II (NSLS-II) is a state of the art 3 GeV third generation light source at Brookhaven National Laboratory. The injection system consists of a 200 MeV linac, a 3 GeV booster synchrotron and transfer lines in connection of linac, booster and storage ring. The transfer lines, designed and built from BNL, are equipped with sufficient diagnostics to commission to characterize the beam parameters from linac and booster. In the paper, we summarized the high level applications tools, beam emittance, energy and energy spread measurement, developed during the injector commissioning.

INTRODUCTION

The NSLS-II [1] is a state of the art 3 GeV third generation synchrotron light source at Brookhaven National Laboratory. It consists of a 200 MeV linac, a booster ring accelerating beam from 200 MeV to 3 GeV, a 3 GeV Storage ring and transport lines in between them. Both transfer lines are equipped with sufficient diagnostics to commission along with linac/booster and characterize their beam parameters.

As many other facilities [2,3], NSLS II chose the Experimental Physics and Industrial Control System (EPICS) as its control system to monitor and control the accelerator hardware. It interfaces to the accelerator instruments and devices (such as Power supply, digitizer, and motor) with IOC (Input Output Controllers). Channel Access is used as the interface to the machine process variables (PVs).

The typical operation applications include two types, simple monitor/control device and complex accelerator physics application for studies and machine optimization (measurements, data analyses and applying correction). Mainly, we use cothread to access the process variables (PVs) in Python script for complex accelerator physics applications and the CSS (BOY) [4] panel for simple tasks such as monitoring, displaying and setting of the machine Process Variables (PVs). Besides, MATLAB is also available as an alternative tool and EDM panels are used for Linac control system from the linac vendor Research Instruments, GmbH. All source codes including panel configurations are controlled and managed by mercurial version in the control system.

Both Python and CSS are new environment for accelerator control. Python has a lot of libraries and strong support from scientific computing community. It has very powerful functions for scientific calculation and logic control. CSS has simple feature to display/control PVs with simultaneous data sharing environment, but with a lot of new features for operations convenience, such as create olog entry, data browser to view history, et.al, which benefits the strong support from control group. So NSLS II all the related commissioning and operation tools are developed from scratch. In fact, a lot of highly operation demanding high level applications were developed based on soft IOCs and combined python and CSS advantages together with powerful calculation and convenient display interface.

To keep the beam commissioning time efficient, we did the the subsystem integration test and extended integration test [5]. In this paper, we'll present main applications for injector commissioning and operation.

MACHINE STATUS APPLICATION

All of the monitor and control panels are created with software tools in Control System Studio [6] (CSS), which is an Eclipse-based collection of tools to monitor and operate large scale control systems. The interface allows the operators to edit the desired ramp/soak profiles and provides the option to use predefined recipes.

The NSLS-II operation panels [7] include the user panels and the expert panels. They display the device status and parameters (setpoint and readback) and show the device performance. A user panel shows only information that user is required, such as the magnet current setpoint and readback. The expert panel shows all the information that expert can fully control the device or diagnose the device, such as power supply operation mode and magnet temperature.

Figure 1 shows one example for BR current monitor, include the FCT output for each turn current and number of bunches, the DCCT beam current along ramping, which average many turns data signal.

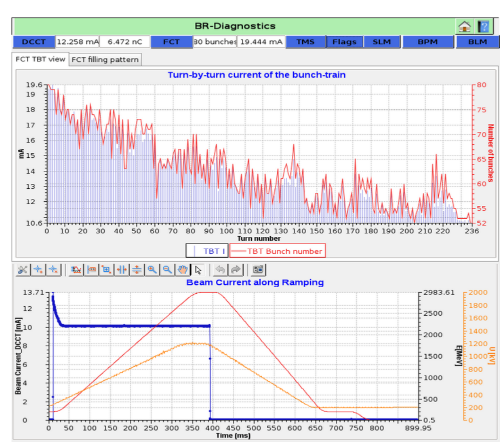

Figure 1: Booster ring current monitor along ramping.

NSLS-II STORAGE RING COUPLING MEASUREMENT AND CORRECTION*

G. Wang#, L. Yu, Y. Li, T. Shaftan, L. Yang, BNL, Upton, NY 11973, USA

Abstract

The National Synchrotron Light Source II (NSLS-II) is a state of the art 3 GeV third generation light source at Brookhaven National Laboratory. To achieve the goal, 8 pm level vertical beam emittance, the coupling due to the misalignment in quads and vertical beam offset in sextuples must be corrected. Traditional method, based on response matrix, such as LOCO, is wildly used measure and corrects the coupling. In this paper, we present a new method to measure and correct the coupling with BPMs TBT data from fast kickers or pingers excited betatron oscillation. Besides the TBT data, other method, is also used to characterize the coupling.

INTRODUCTION

The National Synchrotron Light Source II (NSLS-II) is a 3 GeV third generation light source [1,2] with ultra-low horizontal emittance (1 nm-rad). In the vertical plane, the designed emittance is < 8 pm-rad, reaching the x-ray diffraction limit. They are very critical to increase NSLS II brightness $>10^{21}$ photons s^{-1} mm^{-2} $mrad^{-2}(0.1\%BW)^{-1}$ and affect beam lifetime.

The vertical plane emittance main contributions are the betatron coupling and vertical dispersion [3]. The linear coupling comes from the misalignment (rolling) of quadrupoles and the vertical orbit displacement through sextupoles induced skew quadrupole effect. The vertical dispersion comes from the coupling contribution (such as all coupling errors from quads roll, sextuples offsets, main dipole magnets pitch, skew quadrupoles at locations with non-zero horizontal dispersion) and non-coupling contribution (such as vertical offset in quadrupoles induced dipole kick).

The common method to assess the linear coupling is to measure the minimum tune separation [4] between two coupling modes. Experimentally, the minimum tune separation is measured by tuning quadrupoles to bring horizontal and vertical tunes as close as possible. Another common way used in storage ring to assess the coupling to fit orbit respond matrix non-zero off-diagonal elements with LOCO [5] algorithm to identify coupling source and the needed corrector strength. There are other ways to observe the coupling effect, such as the vertical beam size, beam lifetime and horizontal excitation betatron oscillation effect on vertical residual betatron oscillation.

In this paper, a new method is discussed to measure and correct the betatron coupling with BPMs TBT data from fast kickers or pingers excited betatron oscillation. As the turn by turn data cannot reflect the vertical dispersion effect, the coupling correction is separated into two steps. First, the vertical dispersion is corrected with dispersive skew quadrupoles. Then the coupling is corrected with the non-dispersive skew quadrupoles from turn by turn data. This order cannot change, as dispersive skew quadrupoles affect both dispersion and coupling, but non-dispersive skew quadrupoles only affect betatron coupling.

One big advantage of this method is that this method only takes seconds to excite the beam, collect the data and apply the correction.

VERTICAL RESIDUAL BETATRON OSCILLATION MINIMIZING

If beam is excited by one injection kicker (horizontal plane only, with negligible vertical component), with initial offset $\vec{x}_0 = [0, \Delta x', 0, 0]^T$ at the location of the kicker, and it will do the betatron oscillation in the following turns. Ignoring the radiation damping, the subsequent BPM readings for next several turns are written as

$$\vec{x}_n = R^n \vec{x}_0$$

where n is the turn index and R is the storage ring's one-turn transport matrix. $\vec{x}_n = [x, x', y, y']^T$ includes BPMs reading in horizontal and vertical plane. We measure the dependence of the vertical residual oscillation on the skew quadrupoles currents, and write it as a matrix

$$M_{n,ij} = \frac{\Delta y_{i,n}}{\Delta I_j}$$

where ΔI_j is the current change of the j^{th} skew quadrupole, $\Delta y_{i,n}$ is the i^{th} BPM's n^{th} $(n \geq 1)$ turn y readings.

Thus the needed skew quadrupoles strengths for coupling correction can be obtained by solving the following linear equations

$$y_{i,n} = M_{n,ij} I_j.$$

The minimum number of turn-by-turn data should cover a full betatron oscillation. Usually several iterations are needed to let the solution to converge.

EXPERIMENTAL RESULT

NSLS II is designed as 30 cell double-bend-achromatic lattice, 15 super periods. In order to control the vertical beam size, each cell is designed to have a skew quadrupole. In the odd numbered cells, they are located in

DESIGN OF THE NSLS-II TOP-OFF SAFETY SYSTEM*

R. P. Fliller III#, L. Doom, G. Ganetis, C. Hetzel, P.K. Job, Y. Li, T. Shaftan, S. Sharma, O. Singh, G-M. Wang, Z. Xia. Brookhaven National Laboratory, Upton, NY, 11973, USA

Abstract

The NSLS-II accelerators finished commissioning in the fall of 2014, with beamline commissioning underway. Part of the design for the NSLS-II is to operate in top off mode. The Top Off Safety System (TOSS) is presently being installed. In this report we discuss the Top Off Safety System design and implementation, along with the necessary tracking results and radiological calculations.

INTRODUCTION

All modern synchrotron light sources are built to operate in a mode of quasi-continuous injection known as top off injection [1-3]. This mode of operation allows for more stable operation by keeping the beam current constant, and hence the thermal load on beamline optics constant. However, this mode of operation presents a unique safety hazard, that is, injection into the storage ring with the photon shutters open. This may allow the possibility of freshly injected electron beam to pass through a beamline front end into the first optics enclosure and cause unacceptably large radiological dose on the experimental floor. A properly designed safety system is required to prevent this from occurring.

The design of the Top Off Safety System (TOSS) for the NSLS-II is the culmination of many years of work.[4-6]. In this paper, we report on the requirements and design of the various interlocks of the TOSS. We discuss the various interlocks and apertures required for safe top off and the maximum credible incident in the event of an errant injected bunch.

HAZARD ANALYSIS

The tracking which was performed to specify the interlocks for top off safety is discussed in various places. [4,5,7]. In brief, a safe point is specified in the beamline front ends and the goal of the tracking is to ensure that no injected electrons can go beyond the safe point. For reasons of computational expediency, the decision was made to track positrons backward from the safe point into the nearest straight section of the storage ring. Particles which can be tracked to the nearest storage ring straight section denote unsafe trajectories. Certain apertures in the storage ring and front end, along with a set of interlocks are specified eliminate all unsafe trajectories. The interlocks will be the same for all front ends, and the apertures will be specified on a per front end case. Common designs of the front ends simplify the specification of apertures, with similar apertures called out for multiple beamlines.

Figure 1 shows a typical analysis. Tracking starts at the right of the figure and attempts to find all trajectories which can propagate through all of the apertures to the left. The red lines show the envelope of trajectories. The various magnets are shown by the colored boxes. The dipole magnet deflects the trajectories into the vacuum chamber for all possibilities allowed by the interlocks and aperture misalignments. Because no trajectories propagate to the left and therefore this beamline is safe.

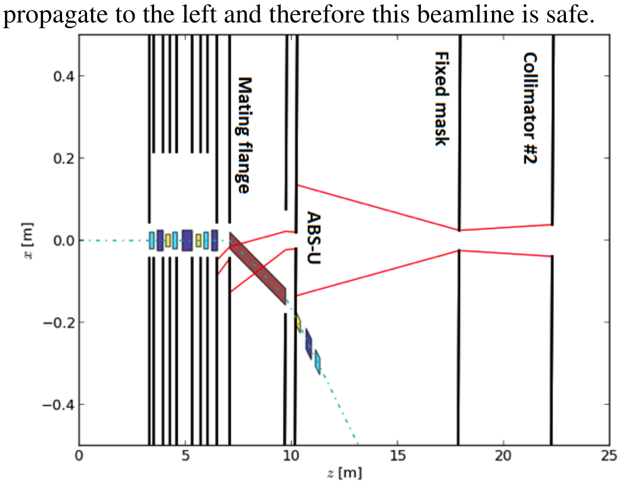

Figure 1: Example of particle tracking for SRX beamline. Tracking starts at Collimator #2 on the right and attempts to get to the storage ring straight on the left. The red lines denote the envelope of trajectories. No trajectories pass to the straight, therefore these are safe.

The tracking calculations do not assume the presence of stored beam in the ring. Neglecting this allows the calculations to find unlikely scenarios where injected beam may escape the ring, but may be incompatible with stored beam. The interlocks and apertures render all trajectories safe. Including a stored beam interlock removes the possibility of many of these scenarios, making the possibility of injected beam escaping down a front end to the safe point even more unlikely.

When x-rays are being delivered to a beamline during top-off, the safety shutters are in theopen position and the first optical enclosure (FOE) will be secured with no access to the personnel. The primary radiological safety concern for the top-off injection is where injected electrons are conveyed through the front-end and strike the safe point, which is closest to the ratchet wall collimator.

The radiological calculations use the front end with the largest apertures to date, which is the SRX beamline. The dose rate during top off operation was calculated for

LOCO APPLICATION TO NSLS2 STORAGE RING DISPERSION AND BETA BEATING CORRECTION

Xi Yang†, BNL, Upton, NY 11973, USA

Xiaobiao Huang, and James A. Safranek, SLAC, Menlo Park, CA 94303, USA

Abstract

During the short run in early July, 2014, we made changes to the setup of Matlab Linear Optics from Closed Orbits (LOCO) for NSLS-II and applied it successfully to the linear optics correction. The Matlab middle layer (MML) setup was also verified with Input-Output tests for all quadrupole families. The LOCO setup was further tested with an intentional quadrupole error. After the successful LOCO correction, the RMS beta beating was reduced from the initial value of 5.5% to 1.9% in x, and 5.6% to 1.0% in y. The RMS horizontal dispersion error was reduced from 21 mm to 6 mm. It is critical to keep the same closed orbit for LOCO correction. Because some correctors were nearly saturated at the time, closed orbit couldn't be controlled for additional iterations. We expect LOCO to achieve better optics correction after the orbit control is improved.

INTRODUCTION

LOCO has been a powerful beam-based diagnostics and optics control method for storage rings and synchrotrons worldwide ever since it was established at NSLS by J. Safranek [1]. This method measures the orbit response matrix and optionally the dispersion function of the machine. The data are then fitted to a lattice model by adjusting parameters such as quadrupole and skew quadrupole strengths in the model, BPM gains and rolls, corrector gains and rolls of the measurement system. Any abnormality of the machine that affects the machine optics can then be identified. The resulting lattice model is equivalent to the real machine lattice as seen by the BPMs. Since there are more than five BPMs per betatron period in NSLS2 storage ring, the model is a very accurate representation of the real machine. According to the fitting result, one can correct the machine lattice to the design lattice by changing the quadrupole and skew quadrupole strengths. LOCO is so important that it is routinely performed at many electron storage rings to guarantee machine performance, especially after the Matlab-based LOCO code [2] became available. The Matlab version includes a user-friendly interface, with many useful fitting and analysis options.

MATLAB LOCO CODE IMPROVEMENT

Full Jacobian (J) calculation takes four hours for NSLS2 storage ring compared to five minutes linear J in a standard laptop. Besides, J doesn't change significantly when the solution is close to the global minimum. Therefore, a selection between calculating a new or reusing an existing J at every LOCO iteration has been implemented in "loco.m". The standard size of J for NSLS2 storage ring (SR) is ~130k·2k. Singular Value Decomposing (SVD) JTJ (~2k·2k) instead of J for all fitting methods is implemented to speed up the SVD calculation. Using the Optimized weights for all fit parameters minimizes the changes of quadrupole gradients while at the same keeping the good fitting result. Reducing quadrupole families and grouping neighbouring quadrupoles in the fitting are introduced to cure the degeneracy problem caused by the coupling between fit parameters. Five families, QL1, QL2, QH1, QH2, and QM2, instead of all eight families, QL1, QL2, QL3, QH1, QH2, QH3, QM1, and QM2, are used in the LOCO fitting. Also, two QM2 quadrupoles at the same cell are grouped together. All these new features have been tested before updating the relevant codes.

CRITICAL ISSUES BEING EXAMINED

The following lists the most important steps that one has to check before LOCO application:

1. LOCO connection to machine

   Matlab middle layer (MML) mapping between hardware and channel access in the control system has been examined for all the quadrupoles, sextupoles, correctors, and BPMs. They are in good agreement.

   MatLab codes that generate LOCO files and implement optics correction have been checked and no error is found.
2. Quadrupole saturation

   $\Delta K/K = \Delta I/I$ is not accurate. As an example of QM2 quadrupoles, at the operational current ~140A, K/I=1.2·$\Delta K/\Delta I$, as shown in Figure 1.

   Our solutions are: iterate several times; use unit conversion, amp2k.m and k2amp.m, based on measured magnet excitation curves in MML for ΔI [3].
3. Quadrupole hysteresis

   Cycle magnets after optics corrections are applied.
4. BPMs not reproducible

   Use constant current and filling pattern
5. Orbit control

   The tolerance on orbit reproducibility has to be well understood and setup properly.

SKEW-QUAD PARAMETRIC-RESONANCE IONIZATION COOLING: THEORY AND MODELING*

A. Afanasev#, George Washington University, Washington, DC 20052, USA
Y. Derbenev, V.S. Morozov, A. Sy, Jefferson Lab, Newport News, VA 23606, USA
R.P. Johnson, Muons, Inc., Batavia, IL, USA

Abstract

Muon beam ionization cooling is a key component for the next generation of high-luminosity muon colliders. To reach adequately high luminosity without excessively large muon intensities, it was proposed previously to combine ionization cooling with techniques using a parametric resonance (PIC). Practical implementation of PIC proposal is a subject of this report. We show that an addition of skew quadrupoles to a planar PIC channel gives enough flexibility in the design to avoid unwanted resonances, while meeting the requirements of radially-periodic beam focusing at ionization-cooling plates, large dynamic aperture and an oscillating dispersion needed for aberration corrections. Theoretical arguments are corroborated with models and a detailed numerical analysis, providing step-by-step guidance for the design of Skew-quad PIC (SPIC) beamline.

INTRODUCTION

Experiments at energy-frontier colliders require high luminosities, of order 10^{34} cm^{-2} sec^{-1} or more, in order to obtain reasonable rates for events having point-like cross sections. High luminosities require intense beams, small transverse emittances, and a small beta function at the collision point. For muon colliders, high beam intensities and small emittances are difficult and expensive to achieve because muons are produced diffusely and must be cooled drastically within their short lifetimes. Ionization cooling is a major first step toward providing adequate luminosity without large muon intensities, and its 6D-implementation with a helical cooling channel was described in Ref. [1]. Further reduction of emittances requires anomalously large magnetic fields in ionization-cooling channels, but the use of parametric resonance allows relaxing this requirement, while providing significant beam cooling effects [2].

PIC CONCEPT

In the PIC technique the resonant approach to particle focusing can achieve equilibrium transverse emittances that are at least an order of magnitude smaller than in conventional ionization cooling. The main principle is similar to half-integer parametric resonant extraction from a synchrotron, except for targeting different variables of the phase space [2]. Briefly speaking, parametric resonance provides focusing of the muon beam at periodic locations down the beamline; the beam angular spread is naturally maximized at these locations, therefore unw anted angular smearing (or "heating") due to multiple Coulomb scattering in ionization-cooling plates has the least effect.

While the concept of PIC has been around for a few years, its practical implementation faced several difficulties that were addressed by an Epicyclic PIC proposal [3] and proposed epicyclic twin-helix magnetic structure [4]. The latter uses a superposition of two opposite-helicity equal-period equal-strength helical dipole harmonics and a straight normal quadrupole. Here we propose and develop a technique that will help to avoid (integer) resonances in such a system that requires periodic focusing, making the important step toward its engineering design.

COUPLING RESONANCE IN PIC

Our proposal is based on inducing a linear betatron coupling resonance in PIC transport line between the horizontal (x) and vertical (y) planes. Previously developed (and described in Ref. [4]) twin-helix magnetic system is supplemented with skew quads that generate coupling between horizontal and vertical betatron motion.

Let us consider the effect of such coupling, first in a simplified model. The equations for coupled betatron oscillations are

$$x_b'' + k_x^2 x_b + g y_b = 0$$
$$y_b'' + k_y^2 y_b + g x_b = 0$$

where $k_x^2 = K^2 - n$, $k_y^2 = n$, with K^2 and n denoting the curvature function and quad strength, respectively. Coupling g is provided by 45^o-skewed quadrupoles.

In the case of constant coefficients, the above system has an analytic solution described by superposition of two normal-mode oscillations with wave vectors $k_{1,2}^2 = \frac{1}{2}(k_x^2 + k_y^2 \pm \sqrt{(k_x^2 - k_y^2)^2 + 4g^2})$.

$$x_b(s) = C_1 \cos(k_1 s) + C_1' \sin(k_1 s) + G \cdot (C_2\, cos(k_2 s) + C_2'\, sin(k_2 s))$$
$$y_b(s) = -G \cdot (C_1 \cos(k_1 s) + C_1' \sin(k_1 s)) + C_2\, cos(k_2 s) + C_2'\, sin(k_2 s),$$

where $G = (k_2^2 - k_y^2)/g = -(k_1^2 - k_x^2)/g$, and s is the path length along the reference trajectory. The constants are obtained from initial conditions at s=0:

INTERACTION REGION FOR A 100 TeV PROTON-PROTON COLLIDER

R. Martin*, CERN, Geneva, Switzerland and Humboldt University Berlin, Germany
R. Tomás, CERN, Geneva, Switzerland
B. Dalena, CEA/IRFU, Gif-sur-Yvette, France

Abstract

As part of its post-LHC high energy physics program, CERN is conducting a study for a new proton-proton collider, FCC-hh, running at center-of-mass energies of up to 100 TeV, pushing the energy frontier of fundamental physics to a new limit. At a circumference of 80-100 km, this machine is planned to use the same tunnel as FCC-ee, a proposed 90-350 GeV high luminosity electron-positron collider. This paper presents the design progress and technical challenges for the interaction region of FCC-hh.

INTRODUCTION

FCC-hh aims to provide proton collisions almost one order of magnitude higher than the Large Hadron Collider (LHC), posing a great challenge for the interaction region optics.

The current lattice for the interaction region is shown in Fig. 1. Each side of the Interaction Point (IP) consists of a final triplet, a beam separation section and a matching section, followed by the dispersion suppressor (not pictured here). For the dispersion suppressor (DS), two options are currently considered: a half bend DS and an LHC-like DS. The decision for one DS design will be based on optics considerations as well as a cost optimum in terms of dipole filling factor and number of independently powered quadrupoles.

Table 1: Parameters for the FCC-hh Interaction Region (IR) [1]

	Baseline	Ultimate
Beam energy [TeV]	50	
IR length [m]	1400	
Number of IPs	2 + 2	
Luminosity [10^{34}cm^{-2}s^{-1}]	5	20
IP β function β^* [m]	1.1	0.3
Normalized emittance [μm]	2.2	

Final Triplet

In a first approach, the LHC interaction region design was scaled up by a factor of $(50/7)^{1/3} \approx 2$, resulting in an L^* of 46 m. This early design showed a large radiation load from the debris at the IP. As a solution, the longer triplet design of HL-LHC [2] was adapted. To mitigate the radiation dose further, the quadrupoles were lengthened by an additional ≈ 30 %, giving a length of 20 m for Q1 and Q3 and 17.5 m for Q2a/b . At the same time, L^* was reduced to 36 m in order to keep the maximum β function at the same level [3]. With a coil aperture of 100 mm and a shielding thickness

* roman.martin@cern.ch

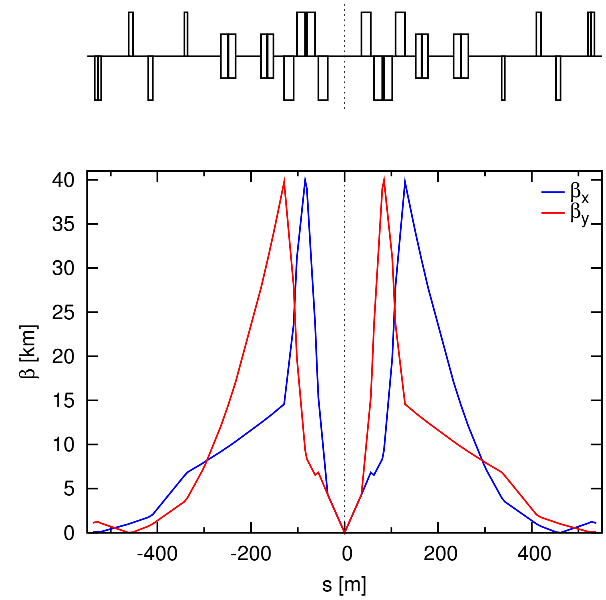

Figure 1: FCC-hh interaction region design with $\beta^* = 0.3$ m and $L^* = 36$ m.

of 15 mm, the radiation dose for this triplet is acceptable (Fig. 2).

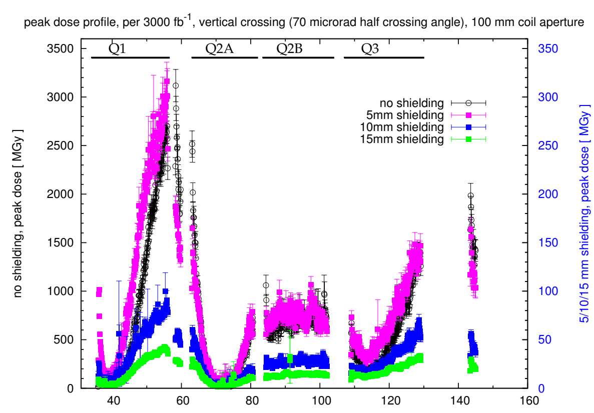

Figure 2: Radiation dose in the triplet magnets from physics debris with (right scale) and without (left scale) shielding. For 15 mm shielding and the shown integrated luminosity of 3000 fb^{-1}, the dose looks acceptable [4].

Beam Separation

As in the LHC layout, the two beams are colliding under a small crossing angle introduced by orbit correctors. Both beams pass the same final triplet and are separated and re-

STUDY OF THE DYNAMIC RESPONSE OF CLIC ACCELERATING STRUCTURES

E. Daskalaki, NTUA, Athens, Greece
V. Rude, ESGT-CNAM, Le Mans, France
A. Vamvakas, M. Duquenne, H. Mainaud-Durand, S. Doebert, CERN, Geneva, Switzerland

Abstract

CLIC is a linear electron-positron collider, 48 km long, consisting of more than 20000 repetitive modules. The target beam size of 1 nm dictates very tight alignment tolerances for the accelerating structures (AS). In order to assess the effect of short-term RF power interruptions (breakdowns or failure modes) on the alignment, the dynamic behaviour of the AS was investigated on the prototype two-beam module. On a dedicated experimental setup, the thermal and mechanical time constant (TC) was monitored as a function of ambient temperature, water flow and power. The experimental results showed that the thermal TC ranged between 4 and 11 minutes and presented strong correlation with the cooling water flow. These results were in very good agreement with the theoretical expectations. The displacement dynamics were found to be comparable with the thermal ones. The study indicates that temperature measurement, which is a fast and easy process, can be used as an indicator of the AS displacement. Moreover, it is shown than the transient response can be efficiently controlled through appropriate regulation of the cooling water flow.

INTRODUCTION

CLIC [1] is a multi-TeV normal conducting electron-positron collider foreseen to be constructed in two 21-km long linacs comprising more than 20000 repetitive modules. The principle of CLIC lies on the concept of two beams, a high-energy Main Beam (MB) and a low-energy, high-intensity Drive Beam (DB). The MB is accelerated in the Accelerating Structures (AS) by the RF power produced from the Power Extraction and Transfer Structures (PETS) of the DB. The alignment tolerances of CLIC are very tight due to the low target beam size of 1 nm. All components must be pre-aligned without beam with an accuracy of 10 µm. Alignment can be affected by the power dissipation on the components estimated to be 7 kW per module during normal operation.

A prototype two-beam module has been assembled in order to study the thermo-mechanical behavior of CLIC components [2]. In the module, the power is applied by electrical heaters, while ambient conditions and cooling can be regulated. Until now, temperature and alignment have been extensively studied during steady-state under different operating conditions [3]-[5]. However, in order to assess the effect of short-term power interruptions, e.g. during a failure mode, the study of transient response is important.

In this paper, the dynamic thermo-mechanical response of the CLIC AS is investigated as a function of the main operation conditions of CLIC, i.e. the water flow, ambient temperature and dissipated power. The correlation of the thermal and mechanical response is evaluated as well as the agreement of the experimental results to theoretical expectations.

THEORETICAL ANALYSIS

When the AS is powered-up, the power of the heater (P_h) is assumed to be distributed among the AS material (P_{cu}), the water (P_{water}) and the air (P_{air}):

$$P_h = P_{cu} + P_{water} + P_{air} \tag{1}$$

The time response of each power component is described as follows [6]:

$$P_{cu}(t) = m_{cu} c_{p,cu} \frac{dT_{cu}(t)}{dt} \tag{2}$$

$$P_{water}(t) = \dot{m}_w c_{p,w} \left[T_w(t) - T_w(0) \right] \tag{3}$$

$$P_{air}(t) = hA_{cu} \left[T_{cu}(t) - T_\infty \right] \tag{4}$$

where $c_{p,x}$ the heat capacity, m_{cu} the AS mass, A_{cu} the AS surface, $\dot{m}_w$ the water mass flow, h the heat transfer coefficient, and T_∞, T_{cu} and T_w the ambient, AS and outlet water temperatures respectively. Combining Eq. 1-4, the temperature response of the AS is described by a first order differential equation with the following analytic solution:

$$T_{cu}(t) = T_{ss} - ce^{-t/\tau} \tag{5}$$

where T_{ss} is the steady-state AS temperature, c is a constant and τ is the time constant (TC) given by:

$$\tau = \frac{m_{cu} c_{p,cu}}{\dot{m}_w c_{p,w} + hA_{cu}} \tag{6}$$

The TC describes the speed of a first-order system's response to a step input and equals the time to reach the 62.3% of its steady-state. A similar approach can be followed for the AS power-down.

Based on the theoretical analysis, the TC depends on the material and geometry (mass and surface) of AS and is inversely proportional to the water flow.

TRACKING SIMULATION FOR BEAM LOSS STUDIES WITH APPLICATION TO FCC

M. Boscolo, INFN-LNF, Frascati, Italy; H. Burkhardt, CERN, Geneva, Switzerland

Abstract

We present first results on FCC-ee beam losses using a tracking simulation tool originally developed and successfully applied to Flavor Factories designs.

After a brief description of the tool, we discuss first results obtained for FCC-ee at top energy, both for the Touschek effect and radiative Bhabha scattering.

INTRODUCTION

CERN recently launched in a worldwide collaboration the new study for a design of a “Future Circular Collider” FCC with a circumference of about 100 km to be built in the CERN area; the target is a hadron collider (FCC-hh) at centre-of-mass energies close to 100 TeV with possible intermediate step of a e^+e^- collider (FCC-ee) in the centre-of-mass energy range of 90 – 400 GeV [1].

One of the challenges for FCC is to reach very high luminosities in combination with low or at least acceptable backgrounds and radiation levels in the interaction regions. To reach this goal, the interaction region design needs to cope with both the machine and detector constraints in a balanced machine detector interface (MDI) design. This is obtained by studies that include the simulation of the accelerator-related detector backgrounds, which can be divided in two main sources: losses of beam particles (the main focus of this paper) and synchrotron radiation [2]. Particle effects that cause beam losses can be generated either by single beam effects, mainly Touschek and beam-gas scattering all around the ring, or by beamstrahlung, radiative Bhabha, e^+e^- pairs production, referred to as *IP backgrounds*. At FCC all these effects need dedicated studies.

The timeline of the FCC design study aims for CDRs to be ready by the end of 2018. In the present stage the lattice design and beam parameters are evolving; the beam loss rates are expected to vary accordingly. We present here the tools that will be used to perform these studies for all the optics and at the different energies, together with the first results.

TOOL FOR MDI SIMULATIONS

To perform the tracking simulations of beam losses for the Machine Detector Interface studies we have started from the tool developed for the Flavor Factories [3], with the plan to adapt and upgrade it to the requirements of FCC. This is an on-going work and first results are presented here. We started to evaluate the Touschek and radiative Bhabha processes for the current optics.

The work can be subdivided in two different steps:

- read the machine lattice description and generate the twiss and aperture files;
- track the beam particles with the proper Monte Carlo depending on the effect under investigation.

MACHINE LATTICE

The starting point of the studies is the machine lattice layout in the form of the MAD-X input files [4]. As a first step, we run the MAD-X program to produce the twiss tfs file which contains the magnetic lattice description.

The beam loss estimates presented in the following sections have been obtained for the currently proposed lattices [5-6]. Parameters relevant for these studies are listed in Table 1.

Table 1: FCC-ee Parameters Relevant for Beam Losses Estimate

parameter	unit	
Beam Energy	GeV	175
Total length	km	100
Particles/bunch	10^{11}	4
Energy Spread	10^{-3}	2.6
Emittance x/ y	nm / pm	2.1 / 4.3
β_x^* / β_y^*	m	0.5 / 0.001
Emittance x/ y	nm / pm	2.1 / 4.3

The horizontal and vertical physical apertures are defined by means of an external file. As a start, we have assumed here a constant physical aperture of 2 cm and 4 mm in the horizontal and vertical planes, respectively. More reliable predictions will be possible when the apertures in the machine and in particular in the IP region have been defined. Our main focus here is on the discussion of the methods and trends, rather than on lifetime and loss rate numbers that may still change a lot.

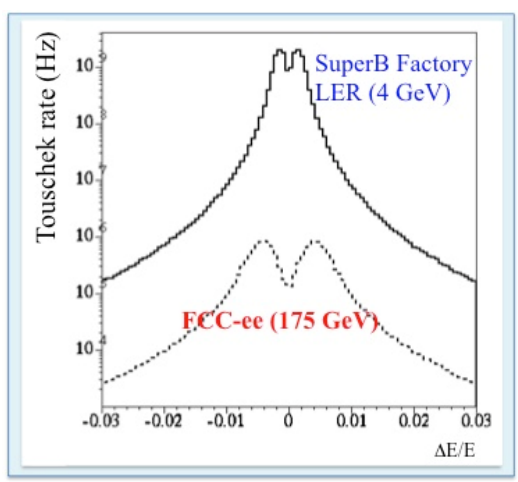

Figure 1: Rate of Touschek particles for FCC-ee (dotted line) compared to SuperB LER (black line).

STUDY OF ELECTRON CLOUD INSTABILITIES IN FCC-hh

K. Ohmi, KEK, Tsukuba, Japan
L. Mether, D. Schulte, F. Zimmermann, CERN, Geneva, Switzerland

Abstract

Electron cloud effects are serious issue for LHC and future hadron colliders, FCC-hh. Electron cloud causes coherent instabilities due to collective motion between beam and electrons. Electron cloud also causes incoherent emittance growth due to nonlinear force of beam-cloud electron force. We discuss the fast head-tail instability and the emittance growth in FCC-hh.

INTRODUCTION

The future circular hadron collider FCC-hh has been designed as 50 TeV×50TeV proton collider with 100 km circumference. The relativistic gamma factor (γ=53,000) is higher than those of many electron storage- ring light sources. The wave lengths of the emitted photons are in the X-ray region, which is comparable with those as light sources. Electrons are produced by the photons which hit the surface of the beam screen inside the cryostat.

Electrons are attracted and accelerated by the beam force. Electrons accumulated in the beam chamber may contribute an additional heat load to the cryostat, and cause beam instabilities and emittance growth. In this paper we focus on the beam instabilities and emittance growth caused by the electron cloud.

THRESHOLD ELECTRON DENSITY OF FAST HEAD-TAIL INSTABILITY

Electrons oscillate in the field of the proton beam. The oscillation frequency near the beam centre is given by

$$\omega_e = \sqrt{\frac{\lambda_p r_e c^2}{\sigma_y(\sigma_x+\sigma_y)}} \tag{1}$$

where λ_p and $\sigma_{x(y)}$ are the line density of the proton bunch and its transverse beam size, respectively. r_e is the classical electron radius.

Electron cloud induces a short range wake force with the frequency of Eq. (1). Threshold of electron density is determined by a balance of the strength of the wake field and Landau damping due to the slippage (synchrotron motion). The threshold density is given by [1,2]

$$\rho_{e,th} = \frac{2\gamma\nu_s\omega_e\sigma_z/c}{\sqrt{3}KQr_0\beta L} \tag{2}$$

K characterizes how many electrons contribute to the instability and Q is the quality factor of the wake field. We use $K=\omega_e\sigma_z/c$ and the empirical formula $Q=\min(\omega_e\sigma_z/c,7)$. Table 1 shows parameters for FCC-hh and the corresponding electron threshold density. The tune shift induced by an electron cloud at the threshold density is also included in the table.

Table 1: Parameter List for FCC-hh.

		inj	top
Energy	E(TeV)	3.3	50
Bunch population	N_p (10^{10})	10	10
Emittance	ε (nm)	0.625	0.0413
Averaged beta	β (m)	200	200
Bunch length	σ_z (m)	0.08	0.08
Synchrotron tune	ν_s	0.0019	0.0019
Electron freq.	$\omega_e/2\pi$	3.56GHz	14 GHz

Tune shift at thr.	$\Delta\nu_{th}$	0.00039	0.00033

SYNCHROTRON RADIATION AND PHOTO-ELECTRON EMISSION

Charge particles passing through a bending magnet emit photons in the form of synchrotron radiation. The number of photons emitted by a particle per metre is expressed as

$$N_\gamma = \frac{5\alpha}{2\sqrt{3}}\frac{\gamma}{\rho_{Bend}} \tag{3}$$

For FCC-hh, with ρ_{bend}=11.3 km, the number is 0.035/p.m (per proton metre) at 50 TeV and 0.0023/p.m at injection energy of 3.3 TeV. The critical energy

$$E_c = \frac{3\hbar c}{2}\frac{\gamma^3}{\rho_{Bend}} \tag{4}$$

is 3.96 keV at 50 TeV (1.1 eV at 3.3 TeV). The quantum efficiency of photoelectron emission is 0.2-0.3 for shallow angle of photon incidence. Most of the photons hit the outside wall of the screen. Some part of the reflected photons hit a wide area of wall. The number of electrons produced by a bunch passage per metre is 10^9 (50 TeV) - 10^8 (3.3 TeV). Considering the chamber cross section 10 cm^2, the density resulting from the photoelectrons of a single bunch, $\rho_e=10^{12}$ - 10^{11} m^{-3}, already is higher than the instability threshold. Electron production can be suppressed by several kinds of surface

STUDY OF BEAM-BEAM EFFECTS IN FCC-he

K. Ohmi, KEK, Tsukuba, Japan
F. Zimmermann, CERN, Geneva, Switzerland

Abstract

Beam-beam effects of the ring-ring scheme of FCC-he and LHeC are being studied using weak-strong simulations. The beam-beam tune shift of the electron beam is one order larger than that of proton beam. The study of the electron motion under the beam-beam interaction is the main subject. Luminosity and equilibrium beam size and beam lifetime are analysed.

INTRODUCTION

Proton (hadron)-electron collision is one of the operation modes of FCC. Either an ERL or a storage ring is considered for the electron beam accelerator. In this paper we focus on the storage ring, i.e. the so-called ring-ring scheme. The electron beam collides with proton beam with energy E=50 TeV. The shape of the FCC proton beam is close to round, with equal emittances in both transverse planes. The electron beam should have the same beam size at the collision point. The emittance of the proton beam is very small, ε=0.04 nm. β^*_{xy}=0.4/0.1 m for the proton beam gives the IP beam size σ_{xy}=4/2 μm. On the other hand, the rms bunch length of the proton beam is very long, i.e. 8 cm, to be compared with only 1-2 mm for the electron beam. To optimally match the beam sizes at IP, the choice of the electron-beam emittance and β^*_{xy} is multi-faceted. Strong hourglass effect appears for β^*_{xy} squeezed to values smaller than the proton bunch length. The allowed synchrotron-radiation power of 50 MW limits the total bunch intensity of electron beam. The beam-beam tune shift of proton beam is rather small, while that of electron beam tends to be large. We can choose either $\beta^*_{xy}\sim\sigma_z$ or $\beta^*_{xy} \ll \sigma_z$. The study of the beam-beam interaction for large beam-beam tune shifts in a weak-strong model is the main subject of this paper.

Table 1: Parameter List of FCC-he [1]

	Electron		Proton

beam-beam ξ	0.13	0.13	0.022
L [10^{34}cm^{-2}s^{-1}]	6.2	0.7	

BEAM-BEAM SIMULATION METHOD

We are using weak-strong simulations in which the proton beam is represented by a fixed Gaussian distribution of macro-particles, that is, the proton and electron beams are regarded as the strong and weak beams, respectively.

The proton beam (bunch) is sliced into 100-200 pieces longitudinally. The number of pieces required depends on the ratio of σ_z/β_y. The electro-magnetic field of a proton beam traveling at the speed of light is formed in the plane perpendicular to the traveling direction. The electro-magnetic field of each slice depends on the charge in a slice of thickness dz and on the distribution (Gaussian in x-y plane). The motion of the weak beam particles is modelled by applying kicks corresponding to the integrated effect of the electro-magnetic field per slice followed by drifts between slices. The kick, which a charged particle with a deviation of (x,y) from the center of the distribution experiences, is expressed using Bassetti-Erskine formula [2]. The beam size $\sigma_{xy}(s)$ where electron particle (z) collides with a proton slice (z_i) depends on the collision point s: $s=(z-z_i)/2$. $\sigma_{xy}(s)$ is determined by the beta function variation near the IP. A longitudinal kick is applied to guarantee the symplecticity [3]. The beamstrahlung is also taken into account [4, 5].

LUMINOSITY SIMULATION FOR FCC-he AND LHeC

Simulations are performed using 10,000 macro-particles for the luminosity calculation [5]. The collision range of two beams with bunch length σ_{zp} (protons) and σ_{ze} (electrons) is $s \approx \pm(\sigma_{z,p}+\sigma_{z,e}) \approx \pm\sigma_{z,p}$. The ratio between proton bunch length and electron IP beta function β_{ye} is σ_{zp}/β_{ye}~10 at 120 GeV or 20 at 60 GeV. The area s~β_{ye} is divided into 10 steps to ensure a good convergence of the simulation. The total number of bunch slices (z_i) is chosen 100 (120 GeV) and 200 (60 GeV). The simulations are performed over 2,000 and 20,000 turns for 120 and 60 GeV, respectively. These simulation periods correspond to 2000/144=14 times, or 20,000/1,152=17 times, the radiation damping time, respectively. The transverse tune is chosen as (ν_x, ν_y)=(0.54,0.61), which has been found to be the best working point for FCC-ee [6]. The synchrotron tune is chosen as 0.025.

Luminosity and beam sizes of the electron beam are evaluated turn by turn. Figure 1 shows the evolution of luminosity. The luminosity drops very quickly in collisions for both 120 GeV and 60 GeV e^-, much below the design values of 7×10^{33} and 6.2×10^{34} cm^{-2}s^{-1}, respectively.

D. Satoh, TITECH, Tokyo, Japan

Abstract

The SuperKEKB main ring is currently being constructed for aiming at the peak luminosity of 8 x 10^{35} $cm^{-2}s^{-1}$. The electron/positron injector linac upgrade is also going on for increasing the intensity of bunch charge with keeping the small emittance. The key upgrade issues are the construction of positron damping ring, a new positron capture system, and a low emittance photo-cathode rf electron source. The injector linac beam commissioning started in the October of 2013. In this paper, we report the present status and future plan of SuperKEKB injector commissioning.

INTRODUCTION

The KEKB project has successfully completed its decade operation in the June of 2010. During the KEKB operation, the injector linac provided the different flavors of electron and positron beams to four independent storage rings; KEKB e-, e+, PF, and PF-AR rings. The linac beam is injected into each storage ring in every time interval of 20 ms since the linac parameters of timing and low level rf phase can be arbitrary controlled up to 50 Hz for the simultaneous top-up injection of three rings except PF-AR. For the simultaneous top-up injection, an event based timing control system has been implemented to the injector linac control system in the October of 2008 [1]. The achievement of simultaneous top-up injection made a strong impact on the triumph of KEKB project. It improve the KEKB and PF stored current stabilities up to 0.05% and 0.01%, respectively.

Figure 1 and Table 1 show the layout and the main parameters of SuperKEKB injector linac, respectively. Toward SuperKEKB project [2], the main issue is the high bunch charge transportation with keeping small emittance. For increasing the positron intensity, the flux concentrator and 10 large aperture S-band accelerating structures have been successfully manufactured and installed into the beam line [3, 4]. As a low emittance and high intensity electron source, we have designed and installed a photo-cathode rf gun cavity based on a noble new scheme in the summer of 2013 [5]. For the new rf gun system, a new laser system has been also built for aiming at the temporal modulation to obtain the longitudinal square shape beam which can help to reduce the energy spread [6, 7].

BEAM COMMISSIONING

Overview

The beam commissioning started in the October of 2013. At the beginning phase of beam commissioning, we mainly devoted the tuning of rf gun laser system for aiming at the high intensity bunch charge generation.

THE LUMINOSITY REDUCTION WITH HOURGLASS EFFECT AND CROSSING ANGLE IN AN E-P COLLIDER

Yuemei Peng*, Key Laboratory of Particle Acceleration Physics and Technology, Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China
Yuhong Zhang, Thomas Jefferson National Accelerator Facility, Newport News, Virginia, USA

Abstract

This paper derived the luminosity reduction caused by crossing angle and hourglass effect in an asymmetric collision. Here, we gave the general expressions of the geometrical reduction factor of luminosity for the asymmetric case caused by crossing angle and hourglass effect, for tri-Gaussian bunches colliding. We also gave it simple expression in some special cases to recover the earlier results, such as the formulas for only hour-glass effect exist and only crossing angle exist. The expressions used in e-p collider are also analysed in detail.

INTRODUCTION

An electron-ion colliders CehC based on CepC-SppC have been envisioned in China for reaching new frontiers of high energy and nuclear physics. In order to have larger collision frequency, bunch spacing is very small in the *CehC* design. This will cause the problem of parasitic collisions: bunches may interact with each other not only at the interaction point (IP) but also at points around the IP, which can be avoided by collision with a crossing angle. The proton beam have much longer bunch length than the electron beam, though both of them have the bunch length comparable to the betatron function at the interaction point, the hourglass effect is still can't neglected.

There had been several expressions of collision luminosity, which treat collision with the head-on collision of asymmetric beams with hourglass effect [1, 2], angled collision of round beams with hourglass effect [3], the angled collision of symmetric beams with hourglass effect [4] and asymmetric angled collision with hourglass effect [5]. Here, the word symmetric or asymmetric is concerned with the beam sizes of colliding beams but not the beam energies.

This paper uses the integral method to give a more general expression of the geometrical reduction factor of luminosity for asymmetric tri-Gaussian bunches angled collision with hourglass effect.

LUMINOSITY FOR ANGLED COLLISION WITH HOURGLASS EFFECT

Consider two bunches of particles with densities $\rho_1(x,y,s,t)$ and $\rho_2(x,y,s,t)$, the number of particles is N_1 and N_2, all particles are assumed to move with the common velocity $\vec{v}_1$ and $\vec{v}_2$. Then, the colliding luminosity is given by the overlap integral both in time and in space [6]

$$L = N_1 N_2 N_b f_{rev} K \int \iiint_{-\infty}^{+\infty} \rho_1 \rho_2 \, \mathrm{dxdydsdt} \,. \qquad (1)$$

Where, f_{rev} is the revolution frequency, K is the kinematic factor, which is expressed as

$$\mathrm{K} = \sqrt{(\vec{v}_1 - \vec{v}_2)^2 - (\vec{v}_1 \times \vec{v}_2)^2 / c^2} \,. \qquad (2)$$

x, y, s are the coordinates in the lab frame. However, the distribution functions are assumed Gaussian distributions only in the commoving frame, namely,

$$\rho_1(x_1, y_1, s_1, t) = \rho_{1x}(x_1)\rho_{1y}(y_1)\rho_{1s}(s_1 - ct)$$

$$\rho_2(x_2, y_2, s_2, t) = \rho_{2x}(x_2)\rho_{2y}(y_2)\rho_{2s}(s_2 - ct)$$

Here,

$$\rho_{iz}(u) = \frac{1}{\sigma_{iz}\sqrt{2\pi}} exp\left(-\frac{u^2}{2\sigma_{iz}{}^2}\right) \quad i = 1,2, \quad z = x, y, \qquad (3)$$

$$\rho_{is}(s - s_0) = \frac{1}{\sigma_{is}\sqrt{2\pi}} \exp\left(-\frac{(s-s_0)^2}{2\sigma_{is}{}^2}\right), \quad i = 1,2, \qquad (4)$$

$$\sigma_{iz} = \sigma_{iz}^* \sqrt{1 + \frac{s_i{}^2}{\beta_{iz}^{*\,2}}} \,. \quad i = 1,2, \qquad z = x, y, \qquad (5)$$

If there is a crossing angle $\emptyset$ in horizontal (x, s)-plane in the collider, we need to transform the co-moving frame coordinates to the lab frame coordinates, shown in figure 1.

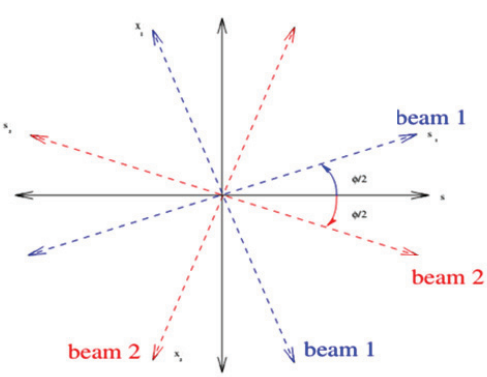

Figure1: Coordinates transformation.

$$\begin{cases} x_1 = x \cdot cos\frac{\emptyset}{2} - s \cdot sin\frac{\emptyset}{2}, s_1 = s \cdot cos\frac{\emptyset}{2} + x \cdot sin\frac{\emptyset}{2} \\ x_2 = -x \cdot cos\frac{\emptyset}{2} - s \cdot sin\frac{\emptyset}{2}, s_2 = -s \cdot cos\frac{\emptyset}{2} + x \cdot sin\frac{\emptyset}{2} \end{cases} \qquad (6)$$

A PRELIMINARY DESIGN OF THE CEPC INTERACTION REGION*

Y.W. Wang#, S. Bai, H.P. Geng, T.J. Bian, X.H. Cui, D. Wang, J. Gao, Y.S. Zhu
IHEP, CAS, Beijing, 100049, PRC

Abstract

CEPC (Circular Electron and Positron Collider) is a circular Higgs Factory with optimized energy 240 GeV. In order to achieve luminosity as high as $2 \times 10^{34} \mathrm{cm}^{-2}\mathrm{s}^{-1}$, CEPC calls for a small vertical beta function at IP ($\beta_y^* = 1.2$ mm) which was provided by the final focus of the interaction region. In this paper, a preliminary design of the CEPC interaction region was presented. The optimization of dynamic aperture with interaction region insertion and the machine detector interface was discussed as well.

INTRODUCTION

CEPC (Circular Electron and Positron Collider) is a circular Higgs Factory with optimized energy 240 GeV [1]. In order to achieve luminosity as high as $2 \times 10^{34} \mathrm{cm}^{-2}\mathrm{s}^{-1}$, CEPC calls for a small vertical beta function at the interaction point (IP) ($\beta_y^* = 1.2$ mm) which was provided by the final focus of the interaction region. In this paper, a preliminary design of the CEPC interaction region (IR) was presented. The optimization of dynamic aperture with IR insertion and the machine detector interface was discussed as well. Table 1 shows the key parameters of the interaction region.

Table 1: Key Parameters of the Interaction Region [1]

Parameters	Unit	Value
Distance from QD0 to IP [$L*$]	m	1.5
Number of IP [N_{IP}]	-	2
Beam energy [E]	GeV	120
Emittance [$\varepsilon_x/\varepsilon_y$]	m • rad	6.12E-09 / 1.84E-11
Beta function at IP [β_x^*/β_y^*]	mm	800 / 1.2
Bunch length total [$\sigma_{z,tot}$]	mm	2.88
Energy spread total [$\sigma_{\delta,tot}$]	%	0.177
Luminosity / IP [L]	$\mathrm{cm}^2\mathrm{s}^{-1}$	2.04E+34

The IR of CEPC has been designed with the following requirements:

- Provide small beam sizes at the IP.
- The large chromaticity generated by final doublet (FD) must be compensated locally in order to achieve a large momentum acceptance of 2% for the whole ring.
- The solenoid field from the detector compensated to minimize its perturbation on the beam motion .
- The sizes of the accelerator equipment inserted into the detector should be constrained to provide the largest possible angular acceptance for the detector.
- The beam-induced background should be acceptable for the detector.

INTERACTION REGION

Optics Design

In order to achieve very high luminosity, CEPC calls for a small vertical beta function at IP ($\beta_y^* = 1.2$ mm). The small β_y^* require the final quadrupole as close to the IP as possible in order to minimize the chromaticity and keep the beta function lowest possible at the final quadrupole, as shown in Eq. 1. ξ_y is the vertical chromaticity generated in the final quadrupole QD0, β_y is the vertical beta function at QD0 and L^* is the distance from the IP to QD0. To facilitate the design of final focus, we choose $L^* = 1.5$ m.

$$\xi_y \simeq \frac{L^*}{\beta_y^*}, \beta_y \simeq \frac{L^{*2}}{\beta_y^*} \tag{1}$$

The chromaticity correction scheme of final focus (FF) had been well developed for the linear collider programs from 1980s, such as SLC, NLC, FFTB [2-4], and adopted by the circular collider programs such as SuperB [5] and SuperKEKB [6]. CEPC also adopt a FF optics similar to the linear colliders'. Unlike the single pass feature in a linear collider, the final focus design of a circular collider has to fix many specific issues.

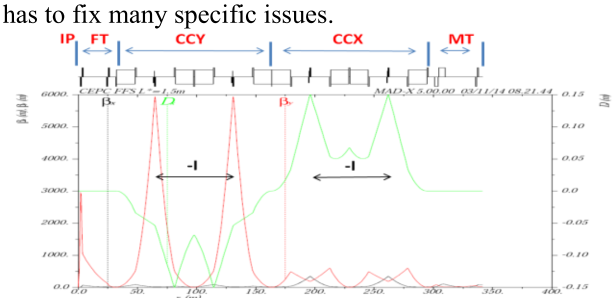

Figure 1: Lattice functions of the final focus.

The final focus system is a telescopic transfer line, starting from IP, which includes: a final telescopic transformer (FT), chromaticity correction section on the vertical plane (CCY), chromaticity correction section on the horizontal plane (CCX) and matching telescopic transformer (MT), see Fig. 1.

ORBIT CORRECTION IN CEPC*

S. Bai#, H.P. Geng, J. Gao, IHEP, Beijing, China

Abstract

With the discovery of the higgs boson at around 125GeV, a circular higgs factory design with high luminosity (L ~ 10^{34} $cm^{-2}s^{-1}$) is becoming more popular in the accelerator world. The CEPC project in China is one of them. To reduce the cost, pretzel scheme was considered in CEPC orbit design. The presence of every kind of errors and misalignments will destroy the pretzel orbit. In this paper, we correct the distorted pretzel orbit in the CEPC main ring using the dipole correctors and beam position monitors. The pretzel orbit was recovered and the maximum corrector strengths are got.

INTRODUCTION

With the discovery of a Higgs boson at about 125 GeV, the world high-energy physics community is investigating the feasibility of a Higgs Factory, a complement to the LHC for studying the Higgs [1]. There are two ideas now in the world to design a future higgs factory, a linear 125 × 125 GeV e^+e^- collider and a circular 125 GeV e^+e^- collider. From the accelerator point of view, the circular 125 GeV e^+e^- collider, due to its low budget and mature technology, is becoming the preferred choice to the accelerator group in China. To reduce the cost, only one tunnel may be digged. In this case, e+ and e- bunches will be travelled in the same tunnel and separated by several electrostatic sperators. This is so called the “pretzel” scheme [2] which has already been demonstrated in LEP. The position of the pretzel closed orbit in CEPC main ring is affected by the field errors and the alignment errors in the magnets. The orbit errors are mainly due to displaced quadrupoles. Deviations of the beam orbit from the ideal positions can be detected by the beam position monitors (BPM) located near each quadrupole. The closed orbit errors as measured by these monitors can be corrected by a series of dipole correctors near each quadrupole.

In this paper, the field errors and alignment errors of the magnets are first specified. The distorted closed orbit is then calculated and corrected by the approximately distributed dipole correctors. The maximum strengths of correctors are got for manufacture.

THEORY

The orbit correction vector $\overrightarrow{\Delta_c}$ at all the monitors is related to the beam bump $\vec{\theta}$ at all the correctors by [3]:

$$\overrightarrow{\Delta_c} = T\vec{\theta} \tag{1}$$

Where T is a m x n matrix with m the number of monitors and n the number of correctors; the elements of T are

$$T_{ij} = \frac{\sqrt{\beta_i \beta_j}}{2\sin \pi\nu} \cos \nu(\pm\pi + \phi_i - \phi_j) \tag{2}$$

Where ν is the betatron wave number, β is the betatron function; ν φ is the betatron phase. The plus sign in front of π is used for the case of $\varphi_i < \varphi_j$ and the minus sign for $\varphi_i > \varphi_j$. The orbit deviation is given by:

$$\overrightarrow{\Delta} = \overrightarrow{\Delta_0} + \overrightarrow{\Delta_c} \tag{3}$$

Where $\overrightarrow{\Delta_0}$ is the orbit deviation measured before correction. The sum of the squares of the orbit deviation

$$S = \sum_{i=1}^{n} (\Delta_{0i} + \Delta_{ci})^2 \tag{4}$$

We wish to find the vector $\overrightarrow{\theta_n}$ which minimizes the value of S, i.e., $\partial S / \partial \theta_n = 0$ for n=l, 2, ... N.

IMPERFECTIONS IN THE MAGNETS

The CEPC machine imperfections mainly consist of the field errors and misalignment errors of every kinds of magnets, bending magnets, quadrupoles and sextupoles. The largest contributions to the orbit distortions come from the misalignment of the quadrupoles. We choose the imperfections setting similar to LEP [4]:

Table 1: LEP Magnet Error Parameters

	Dipole	Quadrupole
<y> mm	0.2	0.1
<x> mm	0.3	0.1
<tilt> mrad	0.1	0.1
<△B/B> rms values	5e-4	
<△K/K> rms values		5e-4

THE DISTORTED PRETZEL ORBIT WITH ALL ERRORS

With all the field and misalignment errors of the magnets given in the above table 1, which are distributed in Gaussian and cut at three sigma, the horizontal and vertical orbit deviation at all the BPMs before orbit correction, are shown in figure 1 and figure 2:

STUDY ON THE TRANSVERSE PAINTING DURING THE INJECTION PROCESS FOR CSNS/RCS*

M.Y. Huang#, S. Wang, N. Huang, J. Qiu, S.Y. Xu, L.S. Huang
1：China Spallation Neutron Source, Institute of High Energy Physics, Chinese Academy of Sciences, Dongguan, China
2：Dongguan Institute of Neutron Science, Dongguan, China

Abstract

For the China Spallation Neutron Source (CSNS), a combination of the H^- stripping and phase space painting method is used to accumulate a high intensity beam in the Rapid Cycling Synchrotron (RCS). In this paper, firstly, the injection processes with different painting ranges and different painting methods were studied. With the codes ORBIT and MATLAB, the particle distribution and painting image were obtained. Then, the reasonable painting range which is suitable for the aperture size and magnet gap can be selected. Since the real field uniformity of BH3 and BV3 is not completely in conformity with the design requirement, the painting method and painting range also need to be selected to reduce the effects of bad field uniformity.

INTRODUCTION

CSNS is a high power proton accelerator-based facility [1]. The accelerator consists of an 80MeV H^- linac which is upgradable to 250MeV and a 1.6GeV RCS with a repetition rate of 25Hz which accumulates an 80MeV injection beam, accelerates the beam to the designed energy of 1.6GeV and extracts the high energy beam to the target. The design goal of beam power for CSNS is 100kW and capable of upgrading to 500kW [2].

For the high intensity proton accelerators, the injection with H^- stripping is actually a practical method. In order to reduce the beam losses in CSNS/RCS, the phase space painting method is used for injecting the beam of small emittance from the linac into the large ring acceptance [3].

Due to the aperture size at the BH3/BV3 position becomes smaller and the real field uniformity of BH3/BV3 in some place is greater than the design requirement, the reasonable painting range and painting method for CSNS/RCS need to be studied and chosen again [4].

PAINTING RANGE AND PARTICLE DISTRIBUTION

For CSNS/RCS, the previous aperture size at the BH3/BV3 position during the injection region was 163mm. However, due to the space at the BH3/BV3 position was so narrow, the aperture size was changed to smaller (150mm). Because of this, the transverse painting range, the painting method and the particle motion distribution during the injection process need to be studied again in detail.

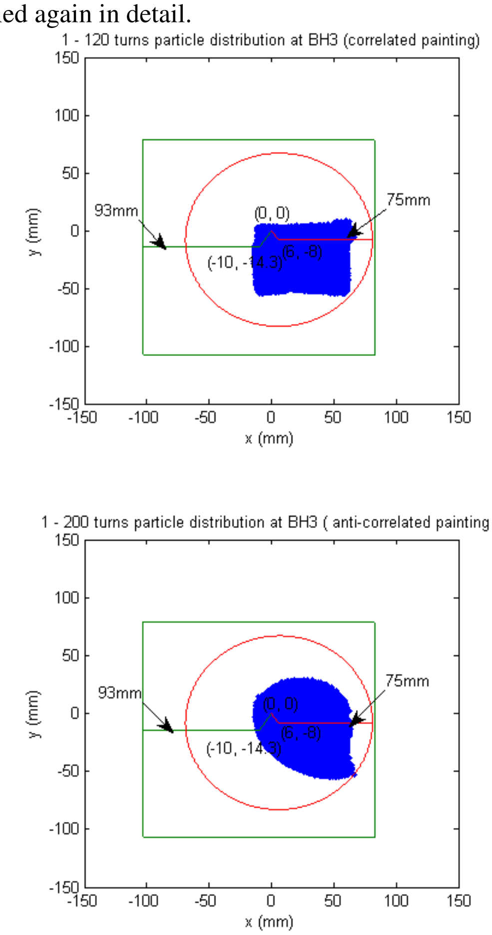

Figure 1: The particle distribution of all the 200 turns at the BH3 position for correlated painting and anti-correlated painting, respectively.

With the code ORBIT [5], the injection processes with different painting methods and painting ranges can be simulated. The painting image and particle distribution of each turn can be obtained. Then, using the code MATLAB, the particle distribution data of each turn can be analyzed and the data of all the 200 turns can be combined together. Then, it can be estimated that whether the aperture size and the magnet gap of BH3/BV3 will be suitable for the particle motion of all the 200 turns. Therefore, the reasonable painting range and painting method can be obtained.

STUDY OF BACKGROUND AND MDI DESIGN FOR CEPC*

T.Yue, Q.Qin, Key Laboratory of Partical Acceleration Physics and Technology, IHEP, Beijing, China

Abstract

CEPC (circular electron positron collider) is a high energy electron positron collider proposed by IHEP, which is designed to provide e^+e^- collisions at the centre-of-mass energy of 240 GeV and deliver a peak luminosity greater than $1\times10^{34}cm^{-2}s^{-1}$ at each interaction point. The super high energy brings many challenges in machine design, especially in the control of background and protection of detectors. We describe the preliminary research result about background and MDI design.

INTRODUCTION

CEPC is short for circular electron positron collider with 120 GeV beam energy. Now we have just finished the Pre-CDR of it. Based on the lattice and IR design released now, we have made some preliminary research on background and MDI design. The research will be updated with the future lattice design.

MAIN PARAMETERS AND IR DESIGN

The main machine parameters are list in Table1.

Table 1: The Main Parameters of CEPC

Parameter		Unit
Beam energy [E]	120	GeV
Circumference [C]	54.752	Km
Luminosity [L]	2.04E+34	cm-2s-1
Number of IP [NIP]	2	
Bunch number [nB]	50	
betax at IP	0.0012	m
betay at IP	0.8	m

In general, the sensitive region for the detectors is within several meters from IP. For CEPC, we just concern about the region within ±4meters from IP. The layout of IR and MDI design are illustrated in Figure 1. There are four quadrupole magnets in this region, two of them designed for focusing and others for defocusing.

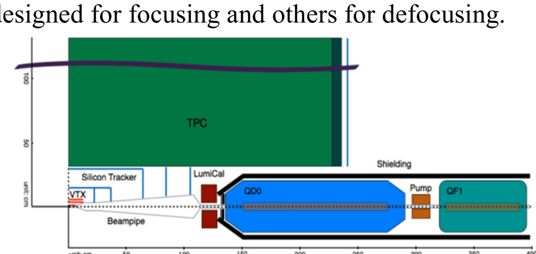

Figure 1: Layout of the MDI of CEPC.

The beam background of CEPC consists of synchrotron radiation background and lost particles background. The synchrotron radiation background has two sources, from the last bending magnets and from the quadrupole magnets in the final focus region. As for the lost particles background, there are many background source for CEPC, but the main source are beamstrahlung and radiative bhabha scattering.

SR BACKGROUND

When the beam passes through the last bending magnets upstream the IP, its orbit will be bended by the magnetic field with a SR fan emitted along the orbit direction. This SR fan will scan the IR region and may make damages on the detectors. In addition, for the beam size effect in horizontal and vertical plane, the particles in the edge of the beam will see the magnetic field of quadrupole magnets because of the displacement. Then it will also emit a SR fan and this SR also need to be analyzed.

The energy spectrum of the SR photons can be characterised by the critical energy [1], which can be calculated by the following formula.

$$E_c = \frac{3}{2}\hbar c\gamma^3 / \rho \tag{1}$$

For the last bending magnets upstream the IP, the bending radius of it is about 3780m,. Substitute it into the formula 1 with a 120GeV energy, we can get the critical energy of the photons from the last bending magnets is about 938KeV. As a comparison, the SR spectrum in LEP at 45.6GeV is less than 100GeV [2]. As for the SR photons from quadrupole magnets, we can still calculate the critical energy as the formula 1 with a new definited bending radius.

$$(1/\rho)_{quad} = kr^*\sqrt{\varepsilon_x\beta_x + \varepsilon_y\beta_y} \tag{2}$$

where the term with a square root symbol is the radial RMS beam size. The critical energy of the SR photons from quadrupole magnet is proportion to the beam size. If we assume a 12 times RMS beam size, the corresponding critical energy is about 23MeV which is pretty high.

In order to estimate the photons distribution and power distribution of SR in the IR, We use a code provided by Mike Sullivan to simulate the synchrotron radiation background, the simulation result is showed in Figure 2.

ION POLARIZATION CONTROL IN THE MPD AND SPD DETECTORS OF THE NICA COLLIDER

A.D. Kovalenko, A.V. Butenko, V.D. Kekelidze, V.A. Mikhaylov, JINR, Dubna, Russia
A.M. Kondratenko, M.A. Kondratenko, STL "Zaryad", Novosibirsk, Russia
Yu.N. Filatov, MIPT, Moscow, Russia

Abstract

Two solenoid Siberian snakes are placed in the opposite collider's straight sections are used to control deuteron's and proton's polarization in the NICA collider. Solenoid snakes substantially reconstruct beam's orbital motion. The change of the polarization direction in the vertical plane of MPD and SPD detectors occurs due to insertion of polarization control (PC) solenoids in the magnetic lattice of the collider. The solenoids rotating particle's spin by small angels practically do not influence on the beam's orbital motion parameters. The dynamic of the polarization vector as function of the orbit length for cases of longitudinal and vertical polarization in the MPD and SPD detectors are presented.

SPIN TRANSPARANCY MODE IN NICA

NICA project at JINR is aimed at the experiments with polarized protons and deuterons at both SPD and MPD detectors over beam momentum range from 2 to 13.5 GeV/c [1, 2]. To control efficiently polarization of protons and deuterons as well it was proposed to use the collider in, so called, "spin transparency" mode, which is realized if two identical solenoid Siberian Snakes are placed in the opposite straight sections of the collider (Fig. 1) [3].

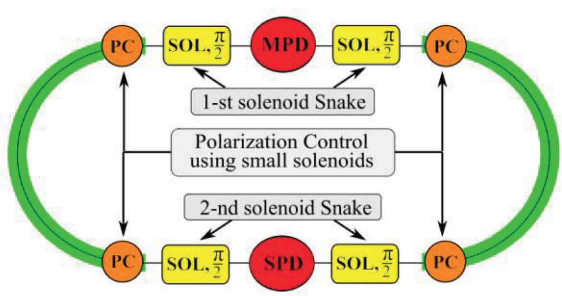

Figure 1: The polarization control scheme of protons and deuterons in the NICA collider.

The Snakes are divided symmetrically onto two parts by MPD and SPD setups. The transparency mode means that the influence of the fields generated by the two Snakes and the collider's arcs doesn't change the spin direction from turn to turn, i.e. the magnetic system is transparent for the spin. The NICA collider with two Snakes becomes similar to the figure-8 collider project at JLAB [4]. The field integrals of half solenoid Snake for protons and deuterons at maximum momentum are equal to 12.5 T·m and 40 T·m respectively.

BEAM POLARIZATION MANIPULATION IN SPD AND MPD DETECTORS

The unique feature of a spin transparency accelerator is the possibility to obtain any particle polarization using small magnetic field integrals [3]. The proton and deuteron polarization in the NICA collider ring can be efficiently controlled by weak solenoids. Any angle between the polarization and the beam direction lying in the vertical plane of SPD (MPD) detector can be obtained by introducing polarization control (PC) insertions. Each PC insertion is based on two weak solenoids separated by arc's dipoles. A symmetric scheme of polarization control with two PC insertions located at the both sides of the SPD (MPD) detector is presented in Fig. 2.

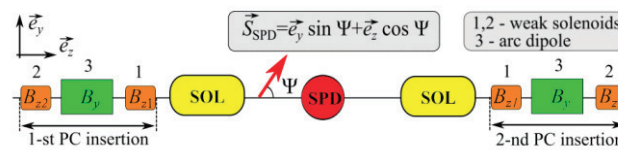

Figure 2: Polarization control by means of weak (PC) solenoids in SPD (MPD) detector.

The spin tune ν induced by PC insertions should exceed substantially the strength of $\nu = 0$ spin resonance. The strength is determined by the beam's emittances and by misalignments and manufacturing imperfections of the collider's magnetic system elements. Spin tune values are estimated to $\nu_p = 0.01$ and $\nu_d = 0.003$ for proton and deuteron case respectively.

A scheme of the snake's solenoids and weak PC solenoids positions is presented in Fig. 3. The eight snake's solenoids of 5.5 m long each are marked with yellow. The ten PC solenoids of 0.4 m long each are marked with orange. The snake solenoid fields are equal to 2.3 T for protons and 7.3 T for deuteron at the maximum momentum.

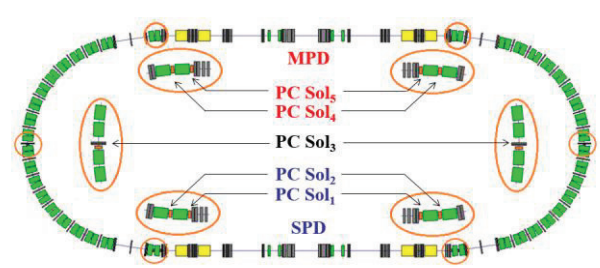

Figure 3: Placement of PC solenoids in NICA collider.

INTERACTION REGION FOR CRAB WAIST SCHEME OF THE FUTURE ELECTRON-POSITRON COLLIDER (CERN)*

A. Bogomyagkov†, E. Levichev
BINP, Novosibirsk 630090, Russia

Abstract

Design study in CERN of the accelerator that would fit 80-100 km tunnel called Future Circular Colliders (FCC) includes high-luminosity e^+e^- collider (FCC-ee) with center-of-mass energy from 90 to 350 GeV to study Higgs boson properties and perform precise measurements at the electroweak scale [1–3]. Crab waist interaction region provides collisions with luminosity higher than 2×10^{36} $cm^{-2}sec^{-1}$ at beam energy of 45 GeV. The small values of the beta functions at the interaction point and distant final focus lenses are the reasons for high nonlinear chromaticity limiting energy acceptance of the whole ring. The paper describes interaction region for crab waist collision scheme in the FCC-ee, principles of tuning the chromaticity correction section in order to provide large energy acceptance.

INTRODUCTION

One of the limiting factors of high energy e^+e^- collider (FCC-ee) is beamstrahlung [4–6], which limits the beam life time. Consideration of this effect by different authors gave several sets of parameters to achieve high luminosity and feasible beam lifetime. The first one is based on head-on collisions [7], the second is relying on crab waist collision scheme [6, 8] with crossing angle $2\theta = 30$ mrad. Both sets implement the same values of beta functions at the interaction point (IP): $\beta_x^* = 0.5$ m, $\beta_y^* = 0.001$ m and require energy acceptance of the ring more than ±2% to provide feasible beam life time. Advantages of the crab waist set are higher luminosity (7.5 times at 45 GeV) and crossing angle that provides natural separation of the bunches. The list of parameters relevant to present work is in Table1.

Lattice of the interaction region (IR) should satisfy several requirements:

1. since successor to FCC-ee is proton accelerator, the IR tunnel should be straight;
2. small values of IP beta functions produce large chromaticity, which should be compensated as locally as possible in order to minimize excitation of nonlinear chromaticity;
3. synchrotron radiation power loss should be significantly smaller than in the arcs;
4. synchrotron radiation at high energy will produce flux of high energy gamma quanta, therefore the lattice should minimize detector background;
5. small beta functions at IP enhance effects of nonlinear dynamics, decreasing dynamic aperture and energy acceptance of the ring, therefore the lattice should be optimized to provide large dynamic aperture and energy acceptance.

Table 1: Relevant Parameters for Crab Waist IR [6]

	Z	W	H	tt
Energy [GeV]	45	80	120	175
Perimeter [km]	100			
Crossing angle [mrad]	30			
Particles per bunch [10^{11}]	1	4	4.7	4
Number of bunches	29791	739	127	33
Energy spread [10^{-3}]	1.1	2.1	2.4	2.6
Emittance hor. [nm]	0.14	0.44	1	2.1
Emittance ver. [pm]	1	2	2	4.3
β_x^*/β_y^* [m]	0.5 / 0.001			
Luminosity / IP [10^{34} $cm^{-2}s^{-1}$]	212	36	9	1.3
Energy loss / turn [GeV]	0.03	0.3	1.7	7.7

FINAL FOCUS QUADRUPOLES

The minimum distance from IP to the face of the first quadrupole is chosen to be $L^* = 2$ m which at the present moment looks like a good compromise between beam dynamics [9] and detector constraints. Having the minimum distance the maximum reliably achievable gradient defines the quadrupole length. In the present study we demanded the quadrupole strength to be lower than 100 T/m, which is a very relaxed condition. Particles trajectories from IP through the FF doublet are on Figure 1 together with lines at several angles representing detector blind spot and rectangles for bare apertures of the quadrupoles. Quadrupole parameters length, gradient and radius of aperture at $E = 175$ Gev are presented in Table 2. The distance between bare apertures for the first quadrupoles is 3.5 cm, for the second pair the distance is 14.2 cm.

LATTICE

The IR lattice should provide desired values of optical functions at IP and compensate geometrical and chromatic aberrations which define dynamic aperture (DA) and energy acceptance of the ring. The optics of IR consists of sev-

Abstract

The understanding and control of the transverse beam halo distributions is an important issue to reduce sources of background noise in Future Linear Colliders (FLC) and specifically at ATF2. A realistic model of the beam halo in the old extraction line of the ATF damping ring was obtained in 2005, based on wire scanner measurements. Recently, new measurements were done in the new extraction line of ATF2, using both wire scanners, in 2013, and Optical Transition Radiation monitors (OTR), in 2014. The beam halo propagation through the ATF2 beamline by means of tracking simulations has been investigated using as input a purely Gaussian and uniform beam halo model.

INTRODUCTION

ATF2 [1] is a scaled down version of the Final Focus System (FFS) of the FLC with the two main goals of obtaining a vertical beam spot size at the virtual Interaction Point (IP) of 37 nm and to stabilize the beam at the nanometer level. For the beam size measurement at the IP a novel technique is used based on a laser interferometer beam size monitor (Shintake monitor). The beam halo consists of tails extending far beyond the Gaussian core of the beam that could be intercepted by the beam pipe creating undesired photonic background. In FLC, such particle losses would be unacceptable and could have devastating effects on the experiments. In ATF2, halo hitting on the beam pipe after the IP can generate a large amount of background limiting the Shintake monitor performance. Therefore, it is of great importance to understand the beam halo distribution and to control the background that could be generated by it. In order to investigate the beam halo distribution in ATF2 measurements were done in 2013 in the EXT line and post-IP with the wire scanners following the procedure done in 2005 in the old ATF2 beamline [2]. Complementary, in 2014, measurements were taken with the multi-OTRs system which is located close to the EXT line wire scanners. All the data has been analyzed and a summary of the measurements done in the EXT line is presented on this paper. In addition to these measurements, by the end of 2014 a Diamond Sensor (DS) has been installed in the Post-IP line of ATF2 in order to perform dedicated beam halo measurements [3, 4].

BEAM HALO MEASUREMENTS IN THE EXT LINE OF ATF2

The ATF2 beamline is divided in three sections: the Extraction Line (EXT) with the diagnostics and matching sections, the Final Focus System (FFS) and the Post-IP line with some diagnostics and the dump. In Fig. 1 the location of the different devices being used to investigate the beam halo and background in the ATF2 beam line are depicted. In the EXT line we find the wire scanners and the OTR system and in the post-IP line we have one wire scanner and the recently installed DS.

Wire Scanners Beam Halo Measurements

At ATF2 five wire scanners are used to measure the beam size at different locations. In our experiment the wire scanner named MW2X located in the EXT line was used. A Cherenkov detector and a Photomultiplier (PMT) at around 26 m downstream of MW2X is installed to detect the bremsstrahlung photons generated by the wire scanners when scanning the beam. A different set of beam halo measurements were performed in April, June and December 2013 using MW2X in the EXT line. During these runs the beam energy was 1.3 GeV and the beam intensity was between 5-7 10^9 electrons. The optics configuration used was ten times the nominal β_x^* and the nominal β_y^* at the IP $(10\beta_x^* \times 1\beta_y^*)$. The beam halo scans have been performed with different PMT voltages in order to increase the sensitivity of the wire scanner. Then, the data was normalized to the lowest voltage and left and right scans have been combined because the beam halo observed in the EXT line is symmetric. The data combined is fitted to a power function of the number of sigmas following the analysis done in [2]:

$$\rho_{V,H}/N = (A/N)X^{-b} \tag{1}$$

where $\rho_{V,H}$ is the vertical and horizontal beam halo density respectively, N is the total number of particles, A, b are constants, and X is the number of sigmas.

In Fig. 2 it is shown all the data taken in 2013 with MW2X wire scanner corresponding to the vertical (top) and horizontal (bottom) beam halo distribution. The resulting fit for all the combined data is the following:

$$\begin{aligned} \rho_V/N &= (9 \pm 4)X^{-(7.3\pm0.3)} \quad 3 < X < 5 \\ \rho_V/N &= (0.001 \pm 0.001)X^{-(1.5\pm0.3)} \quad X > 5 \end{aligned} \tag{2}$$

BUILDING A LUMINOSITY MODEL FOR THE LHC AND HL-LHC *

F. Antoniou, G. Arduini, Y. Papaphilippou, G. Papotti, CERN, Geneva, Switzerland

Abstract

One key objective of the High Luminosity LHC Upgrade is to determine a set of beam parameters and the hardware configuration that will enable the LHC to reach a peak luminosity of 5×10^{34} cm^{-2} s^{-1} and ultimately 7.5×10^{34} cm^{-2} s^{-1} with leveling, allowing an integrated luminosity of 250-300 fb^{-1} per year. In order to determine the integrated performance, it is important to develop a realistic model of the luminosity evolution during a physics fill. In this paper, different mechanisms affecting luminosity lifetime in the LHC are discussed and a luminosity model is presented. The model is bench-marked with data from LHC Run I.

INTRODUCTION

The performance of a collider is best described by the luminosity (integrated over time), which, in general, is given by [1]:

$$\mathcal{L}(t) = \frac{n_b f_{\text{rev}} N_1(t) N_2(t)}{2\pi\sigma_x(t)\sigma_y(t)} H\left(\sigma_s(t), \beta^*\right) F_{\text{geom}}(\sigma_s(t), \beta^*),$$

where n_b the number of colliding bunches, f_{rev} the revolution period, $N_{1,2}$ the number of particles per bunch for each beam, $\sigma_{x,y}$ the rms horizontal and vertical beam sizes at the collision point, β^* the beta function at collision (assuming round optics) and σ_s the rms bunch length. Due to the crossing angle at collision ϕ and the fact that the beta function varies rapidly around the interaction point (IP), a geometric $F_{\text{geom}}(\sigma_s, \beta^*)$, and the hourglass effect reduction factor $H(\sigma_s, \beta^*)$ should be considered.

In 2012, LHC ran at a top energy of 4 TeV and was filled with 50 ns spaced bunches. During collisions different mechanisms arise, causing emittance blow up and/or current losses, leading to luminosity decay in time. In the case of LHC, a simple exponential fit with a constant lifetime over time, cannot describe the luminosity decay. It is thus of paramount importance of identifying and understanding the different complex and interleaved mechanisms leading to luminosity degradation, building finally a model which is essential for optimizing the machine performance and for making accurate predictions for the future of the collider. Such a model can be implemented in an on-line tool for following the luminosity behavior of each LHC fill.

There were several studies concerning the LHC luminosity lifetime [2–8], mainly based on semi-empirical laws through statistical analysis of the LHC run I data. Although luminosity is a macroscopic indicator of global collider performance, the observed bunch-by-bunch (bbb) variations in the transverse and longitudinal emittances and in current, impacts its evolution and finally the integrated luminosity

per fill. This is clearly shown in Fig. 1, where the bbb integrated luminosity is color-coded with the ratio of the bunch current over transverse emittance (assuming round beams), or initial brightness, at the beginning of collisions for fill 3232. An accurate model should be able thus to represent the contribution of each bunch to luminosity. In this paper, different mechanisms affecting luminosity lifetime in the LHC are discussed and the status of a LHC luminosity model, taking into account the bbb variations, is presented.

EMITTANCE EVOLUTION

The emittance evolution of the beams in the LHC during the flat bottom (FB), the ramp and the first part of the flat top (FT) (before the squeeze) is dominated by the intra-beam scattering (IBS) effect [9]. During the squeeze and while the beams are brought to collision, the situation becomes more complicated, as during the LHC run I certain bunches were becoming unstable causing emittance blow up and losses [10]. During collisions a combination of effects including burn-off, IBS, beam-beam, noise, etc., cause emittance blow up and current losses [3].

Based on the assumption that IBS is the dominant effect during FB, scaling laws can be derived by using sim-

ALTERNATIVE OPTICS DESIGN OF THE CLIC DAMPING RINGS WITH VARIABLE DIPOLE BENDS AND HIGH-FIELD WIGGLERS

S. Papadopoulou, F. Antoniou, Y. Papaphilippou, CERN, Geneva, Switzerland

Abstract

The CLIC Damping Rings baseline design aims to reach an ultra-low horizontal normalised emittance of 500 nm-rad at 2.86 GeV, based on the combined effect of TME arc cells and high-field super-conducting damping wigglers, while keeping the ring as compact as possible. In this paper, an alternative design is described, based on TME cells with longitudinally variable bends and an optimized Nb_3Sn high-field wiggler. The impact of these changes on ring optics parameters and the associated optimisation steps are detailed taking into account the dominant effect of intrabeam scattering.

LAYOUT AND DESIGN REQUIREMENTS

The CLIC Damping rings (DRs) have to accommodate a 2.86 GeV beam and should damp it down to normalized horizontal and vertical emittances of 500 nm-rad and 5 nm-rad respectively. The longitudinal normalised emittance should be kept below 6 keV·m. The requirements for ultra-low emittances in all three planes give rise to a series of collective effects [1], with intrabeam scattering (IBS) being the dominant one.

The DRs' layout consists of a racetrack with two arcs and two long straight sections (LSS). The arcs are composed by theoretical minimum emittance (TME) cells and the LSS by FODO cells filled with damping wigglers. Space is also reserved for RF cavities, injection and extraction equipment [2]. The lattice functions between the arcs and the straight sections are matched from the dispersion suppressors and beta matching sections.

In this paper, an alternative design using longitudinally variable bends in the arc TME cells and an optimized high-field wiggler in the FODO cells is proposed. Through this approach, it is possible to achieve the desired output parameters and at the same time decrease the ring's circumference.

LONGITUDINALLY VARIABLE BENDS

Longitudinally variable dipoles, whose magnetic field varies along their length, can provide lower horizontal emittances than a uniform dipole of the same bending angle [3,4]. Actually in order to achieve that, the bending radius ρ_x of a variable bend should have an evolution similar to the one of the uniform dipole's dispersion invariant $\mathcal{H}(s)$ [5–9]: maximum magnetic field should be applied at their center, and it should be decreasing towards the edge of the dipole.

Two examples of variable bends are presented in this paper, they are described by the bending radii forming a step (green line) and a trapezium shape (blue line), as shown in Fig. 1. They are characterised by two lengths L_1 and L_2 with different bending radii ρ_1 and ρ_2. The evolution of the

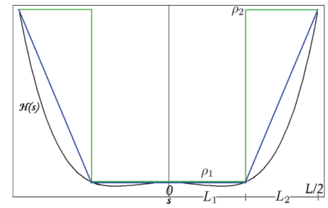

Figure 1: The evolution of the dispersion invariant $\mathcal{H}(s)$ along the uniform dipole (black line) and the bending radius evolution along the variable bends- coloured with green for the step and with blue for the trapezium profile.

bending radius ρ_{st} and ρ_{tr}, for the step and the trapezium profile, respectively, are:

$$\rho_{st}(s)= \begin{cases} \rho_1, & 0<s<L_1 \\ \rho_2, & L_1<s<L_1+L_2 \end{cases}$$

$$\rho_{tr}(s)= \begin{cases} \rho_1, & 0<s<L_1 \\ \rho_1+\dfrac{(L_1-s)(\rho_1-\rho_2)}{L_2}, & L_1<s<L_1+L_2 \end{cases}$$

The emittance reduction factor $F_{TME} = \epsilon_{TME_{uni}}/\epsilon_{TME_{var}}$ is the ratio of the absolute minimum emittances of a uniform with respect to a variable field dipole, and its parametric behaviour can be obtained using analytical expressions for the TME cells [9]. For this study, it is useful to define the lengths and bending radii ratios as $\lambda = L_1/L_2$ and $\rho = \rho_1/\rho_2$, respectively. In Fig. 2, the F_{TME} is parametrized with ρ and λ with the restriction of $\lambda > 0.1$, for the step (left) and the trapezium (right) profile. The areas where F_{TME} is high are blue-colored, while red-colored are the

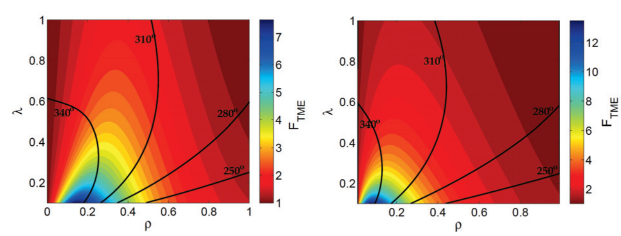

Figure 2: The parametrization of the emittance reduction factor F_{TME} with ρ and λ for the step (left) and the trapezium (right) profile. The black contour lines correspond to different values of the horizontal phase advance.

areas where the reduction is insignificant. For both profiles the highest possible reductions are localized in the limits where $\lambda \to 0.1$. The reductions achieved for the trapezium profile are higher than the ones for the step profile [7]. In the case of non uniform dipoles, even for the TME optics conditions, the horizontal phase advance μ_x always depends on ρ and λ. It is clear that remarkable reductions are reached for phase advances lower than the unique phase advance of the uniform dipole's TME ($\mu_x = 284.5°$). This

LESSONS LEARNED FROM THE FIRST LONG SHUTDOWN OF THE LHC AND ITS INJECTOR CHAIN

K. Foraz, M. Barberan, M. Bernardini, J. Coupard, N. Gilbert, D. Hay, S. Mataguez, D. McFarlane, E. Vergara, CERN, Geneva, Switzerland

Abstract

The First Long Shutdown (LS1) of the LHC and its Injector chain, which started in February 2013, was completed by the first quarter 2015. A huge number of activities have been performed; this paper reviews the process of the coordination of LS1 from the preparatory phase to the testing phase. The preparatory phase is a very important process: an accurate view of what is to be done, and what can be done is essential. But reality is always different, the differences between what was planned and what was done will be described. The paper will recall the coordination, reporting and decisional processes, highlighting points of success and points to be improved in terms of general coordination, in-situ coordination, safety coordination, logistics and resource management.

INTRODUCTION

After a long shutdown lasting two years (LS1), the Large Hadron Collider (LHC) and the whole accelerator chain are now running, and the physics in LHC at an energy of 13TeV will start as early as June 2015. The restart of the LHC marked the completion of a very challenging, intense and enriching period, the LS1.

As defined by the directorate of CERN the LS1 aims to perform all activities needed for a safe and reliable operation of the accelerator complex at nominal energy, taking into account essential rules: safety first, quality second and schedule third.

ORGANISATION

The LS1 started in February 2013, and the preparatory phase last two years. Since the beginning, the project leader, F. Bordry, has been nominated, and the project structure has been built. The LS1 Committee has been created, as the steering committee, concerned with all technical and organisational aspects of the LS1 for the CERN accelerator complex. [1]

Several sub-projects structures have been created, with specific activities and scopes. In the LHC machine the major projects were the Superconducting Magnets and Circuits Consolidation (SMACC) and the Radiation to Electronics (R2E); these projects reported directly to the LS1 committee, and ad hoc project structures have been established. In the Injectors (PSBooster, PS, SPS) several projects have also been performed, and the project leaders reported directly to their Group leaders, who reported the overall progress to the LS1 committee; in these cases, no specific structures have been implemented. Concerning the maintenance activities, for the whole accelerator complex, they were under the responsibility of the Group leaders.

Follow Up

In the LHC machine, specific indicators have been implemented to follow up the major projects as SMACC (Figure 1) and R2E; the maintenance and other activities were followed by the LS1-LHC dashboard, which gave the overall overview of the progress of all the activities in the LHC machine [2]. In the Injectors, one progress curve per injector has been created, to follow up the progress of projects and maintenance activities.

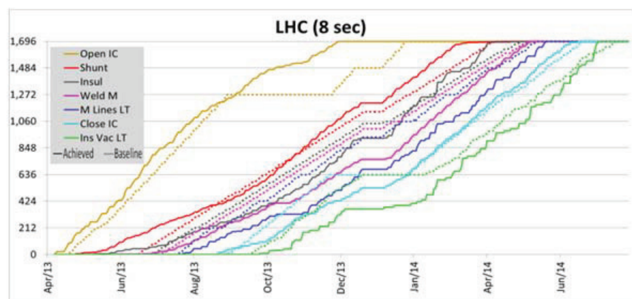

Figure 1: – LS1-SMACC Dashboard.

For each machine, LHC, SPS, PS and PSBooster a technical coordinator has been appointed. The technical coordination is part of the EN-MEF Group, and the main role is to manage activities in the short and medium term. The technical coordinators chair weekly coordination meetings following up the progress of activities and the main milestones, reviewing safety aspects and issues, and gathering all the stakeholders. The technical coordinators were following the Quality Assurance Process ensuring that 3D integration studies were kept up to date, Engineering Change Requests (ECR) are edited, and their follow-up is correctly implemented. Moreover from time to time, they provided ad hoc support to equipment groups in order to ensure a smooth progress.

Baseline Versus Reality

In the accelerator complex, the Long Shutdown 1 roadmap included (Figure 2):

- A preliminary test phase in order to detect existing faults,
- A preparatory phase including lock-out,
- The work phase,
- The recovery of operational conditions,
- The hardware tests.

UPDATED SIMULATION STUDIES OF DAMAGE LIMIT OF LHC TERTIARY COLLIMATORS*

E. Quaranta†, A. Bertarelli, R. Bruce, F. Carra, F. Cerutti, P. Gradassi, A. Lechner, S. Redaelli, E. Skordis, CERN, Geneva, Switzerland

Abstract

The tertiary collimators (TCTs) in the LHC, installed in front of the experiments, in standard operation intercept fractions of 10^{-3} halo particles. However, they risk to be hit by high-intensity primary beams in case of asynchronous beam dump. TCT damage thresholds were initially inferred from results of destructive tests on a TCT jaw, supported by numerical simulations, assuming simplified impact scenarios with one single bunch hitting the jaw with a given impact parameter. In this paper, more realistic failure conditions, including a train of bunches and taking into account the full collimation hierarchy, are used to derive updated damage limits. The results are used to update the margins in the collimation hierarchy and could thus potentially have an influence on the LHC performance.

INTRODUCTION

During the first run in 2010-2013, the Large Hadron Collider (LHC) [1] was successfully operated at energies up to 4 TeV and at stored energies of 146 MJ with proton beams [2]. In 2015, the operation will resume after a long shutdown at an energy of 6.5 TeV, with the aim of achieving 7 TeV in the future. Further upgrades of luminosity are foreseen within the High-Luminosity LHC (HL-LHC) project, by increasing the beam intensity, reducing the beam emittance and decreasing β^* at the Interaction Points (IPs).

Given the destructive potential of such energetic beams, a multi-stage collimation system [3] must ensure efficient beam halo cleaning, prevent the superconducting magnets quench and protect the machine in case of beam failures. The investigation of the consequences of the LHC beam impacts in case of single turn beam losses on the tertiary collimators, which are made of a tungsten heavy alloy (Inermet180) and not robust enough to intercept large beam intensities, close to the IPs is fundamental to ensure machine protection and has also consequences on the luminosity performance [3, 4].

The LHC filling scheme has a gap of about 3 μs without beam, to allow the 15 extraction kicker magnets (MKDs) to rise up to full field during a standard beam dump. Nevertheless, faults could lead to an asynchronous beam dump, where the MKDs trigger is not synchronised with the abort gap. The worst scenario is represented by the spontaneous misfiring of one kicker module, followed by the re-triggerig of all the others, the so-called *single module pre-firing* [5]: due to the slowest rising time up to the total kicker field that is required for the extraction of the beam in Point 6 (IP6), several bunches may receive an intermediate kick and be sent directly to sensitive equipment, as machine aperture and non-robust collimators. During the operation at low β*, the next aperture bottleneck downstream of the dump protections in IR6 might be the TCTs at the interaction points [6]. It is therefore important to understand safe limits for the present TCTs, which have their active parts made of Inermet180.

In the past, first damage estimates for tungsten collimators were calculated through advanced simulations [7]. One single bunch with variable intensity impacting the TCT jaw at a fixed impact parameter was considered. The distribution of the energy density deposited by the protons provided inputs for complex wave propagation calculations to reproduce the dynamic responses in the impacted structure of the collimator. These thresholds have been updated in light of recent beam tests at the CERN HiRadMat facility [8, 9].

A new simulation setup is now available that introduces an initial step of particle tracking simulations to study a more realistic scenario of failure and impacts on the TCTs. After introducing the improved simulation chain used for this study, on overview of the most relevant scenarios for the LHC will be given, followed by simulation setup for the case of tertiary collimators hit by protons scattered out from IR6 collimators (for this reason labelled as "secondary protons" from now on, to be distinguished from particles hitting directly the TCT, called instead "primary protons") in the nominal 7 TeV optics for Beam 2. To conclude, results and new damage limits will be presented for this case.

THE SIMULATION CHAIN

Particle Tracking with SixTrack

Particle tracking simulations were performed using a modified version of the SixTrack collimator routine [10–12]. A single MKD module pre-fire was simulated for a train of LHC protons at 7 TeV with the full collimation system in place. The real 25 ns beam time structure was considered accounting for bunch spacing between consecutive impacts: each of them receives a different kick angle according to the rising of the kicker field. Thus, fractions of several bunches will impact on the TCT jaw.

SixTrack simulations were done for a perfect machine, without errors on optics, apertures and collimators. Possible errors are accounted for by scanning TCT positions around their nominal settings, down to apertures of IR6 protection devices. Only the TCT settings in the low-β* insertions IR1 and IR5 were modified, since these would be the most exposed locations in case of a dump failure of Beam 1 and Beam 2, respectively. The coordinates of the particles in SixTrack that experience inelastic interaction inside the TCTs provide inputs for full shower simulations.

BETATRON CLEANING FOR HEAVY ION BEAMS WITH IR7 DISPERSION SUPPRESSOR COLLIMATORS *

P. D. Hermes†, CERN, Geneva, Switzerland and University of Münster, Germany
R. Bruce, J. M. Jowett and S. Redaelli, CERN, Geneva, Switzerland

Abstract

The betatron collimators in IR7 constitute the backbone of the collimation system of the LHC. A fraction of the secondary halo protons or heavy-ion fragments, scattered out of the primary collimator, is not captured by the secondary collimators but hits cold magnets in the IR7 dispersion suppressor (DS) where the dispersion starts to increase.

A possible approach to reduce these losses is based on the installation of additional collimators in the DS region. In this paper, simulations of the cleaning efficiency for Pb^{82+} ions are used to evaluate the effect of the additional collimators. The results indicate a significant improvement of the heavy-ion cleaning efficiency.

INTRODUCTION

The CERN Large Hadron Collider (LHC) [1] is a proton and heavy-ion collider designed for an unprecedented energy of 7 Z TeV (with Z indicating the charge multiplicity). The envisaged High Luminosity (HL) LHC upgrade is aiming to increase the total stored proton beam energy from the present design value of 362 MJ to 700 MJ [2]. Also the LHC heavy-ion programme aims to deliver more luminosity to the experiments by an increase of the number of stored $^{208}Pb^{82+}$ ions [3].

A multi-stage collimation system [1, 4] is installed to provide adequate protection of the superconducting magnets and avoid quenches. The primary (TCP) and secondary (TCS) collimators, as well as the shower absorbers (TCLA) are installed in the two collimation insertions IR3 (momentum cleaning) and IR7 (betatron cleaning), while tertiary collimators (TCT) protect the superconducting triplet magnets of the experimental insertions. For both, proton and heavy-ion operation, the most critical locations of beam cleaning losses are the dispersion suppressor (DS) magnets of IR7. Protons which were subject to single diffractive scattering in the TCPs and heavy-ions having undergone fragmentation processes to isotopes with different magnetic rigidities are likely to be absorbed in this region where the dispersion increases. The heavy-ion collimation inefficiency in this region was measured and simulated to be two orders of magnitudes worse than with protons. This could become a limiting factor for the reachable luminosity, in spite of the much smaller heavy-ion beam intensities [5, 6].

The cleaning performance of the collimation system is quantified by the number of lost nucleons $N_{\mathrm{loc}}(s) = \sum_i n_i(s) A_i$ (with n_i being the number of lost nuclei of the isotope i and A_i the mass number) at the position s over the distance Δs normalized by the total number of losses at the collimators N_{tot}, the so called local cleaning inefficiency $\eta(s)$, given by [7]

$$\eta(s) = \frac{N_{\mathrm{loc}}(s)}{N_{\mathrm{tot}}\,\Delta s}. \tag{1}$$

With regard to the envisaged increase of the stored proton beam energy, the installation of additional collimators (called TCLD) is discussed at the DS regions of IR7. Simulations for protons predict a significant improvement of the cleaning efficiency with these collimators [8–10].

In this article, we study the simulated cleaning efficiency of the collimation system for a beam of $^{208}Pb^{82+}$ ions for the three cases: no TCLD, one TCLD in cell 8 (TCLD8) and two TCLDs installed in the cells 8 and 10.

SIMULATION METHOD

The proposed layout of the collimation system with the TCLD collimators as well as the collimator settings and beam properties are presented in detail in [9]. The concept is based on the replacement of two 8.33 T dipole magnets [1] in the cells 8 and 10 (at distances of 292.4 m and 371.9 m from IP7) of the IR7 DS by two shorter and stronger dipole magnets respectively [11]. The freed space is used for the installation of the TCLDs.

In proton operation, a large fraction of the particles interacting with the TCP are scattered into the secondary collimators and absorbers or hits the TCP again on a subsequent turn, making the collimation system very efficient. With heavy-ion beams, numerous ions are fragmented into isotopes with different magnetic rigidities while their angular deviations are mostly not sufficient to be intercepted by the TCS. In consequence, the local cleaning inefficiency in the DS is much more critical in the heavy-ion case than in the proton case. For many of the incoming ions, the collimation system acts effectively like a single-stage system with the primary collimators only.

SixTrack [12, 13] is a program designed for multi-turn proton tracking in storage rings. It provides an integrated environment for symplectic tracking based on a thin-lens model of the accelerator lattice together with a Monte-Carlo module to simulate proton-matter interactions in the collimators [14]. The particle loss positions in the aperture are computed by comparing the simulated particle tracks with a detailed model of the machine aperture. Losses in the collimators are identified if protons undergo inelastic interactions (except single-diffractive scattering) with the material.

SIXTRACK SIMULATIONS OF BEAM CLEANING DURING HIGH-BETA OPERATION IN THE LHC

R. Bruce*, CERN, Geneva, Switzerland

Abstract

The 1000 m high-beta run in the LHC provided very clean conditions for observing experimental backgrounds. In ATLAS, a much higher background was observed for Beam 2 than for Beam 1, suspected to be caused by upstream showers from beam losses on collimators or aperture. However, no local beam losses were observed in the vicinity. This paper presents SixTrack simulations of the beam cleaning during the high-beta run. The results demonstrate that, for the special optics and collimator settings used, the highest loss location in IR1 is at the TAS absorber just in front of the ATLAS detector, where no beam loss monitor is installed. Furthermore, the highest losses are seen in Beam 2. The results could thus provide a possible explanation of the ATLAS observations, although detailed shower calculations would be needed for a quantitative comparison.

INTRODUCTION

The schematic layout of the the CERN Large Hadron Collider (LHC) [1] is shown in Fig. 1. It has two counter-rotating beams (B1 and B2) and consists of 8 arcs and 8 straight insertion regions (IRs). At the end of its first proton physics run, in 2012, the LHC collided 4 TeV beams using an optical β-function β^* =60 cm at the high-luminosity experiments ATLAS [2] and CMS [3]. This value was optimized to be as low as possible [4], for highest luminosity, in order to increase the rate of rare events.

Downstream of ATLAS and CMS, the forward physics experiments ALFA [2] and TOTEM [5] are installed, which are specialized at measuring the proton-proton cross section from elastic scattering. In order to accurately measure the scattering angles of outgoing protons, TOTEM and ALFA require a minimum angular divergence at the interaction point (IP). So instead of the small β^* used in the high-luminosity runs, which imply a large angular divergence at the IP, these experiments benefit from a very large β^*.

Therefore, short special physics runs were performed with a particular high-β optics, where the largest value used was β^* =1 km during LHC fill 3216 on October 24 in 2012 [6]. This run was carried out at low intensity for machine protection reasons and used special collimator settings. The primary collimators (TCP) in the betatron cleaning insertion IR7 [7] were used to scrape down the beam to about 2 σ [8] (σ is defined as the local beam size calculated using the standardized normalized emittance of 3.5 μm and the ideal β-function) and then retracted by about 0.5 σ. This removed the beam halo in the scraping range and allowed to minimize the background at the forward-physics experiments. Other scrapings were performed using the TCP in the momentum cleaning insertion IR3, to remove the off-momentum tails. Cycles of TCP scraping and subsequent retraction had to be repeated several time, after a re-population of beam tails that reached the TCP cut.

* roderik.bruce@cern.ch

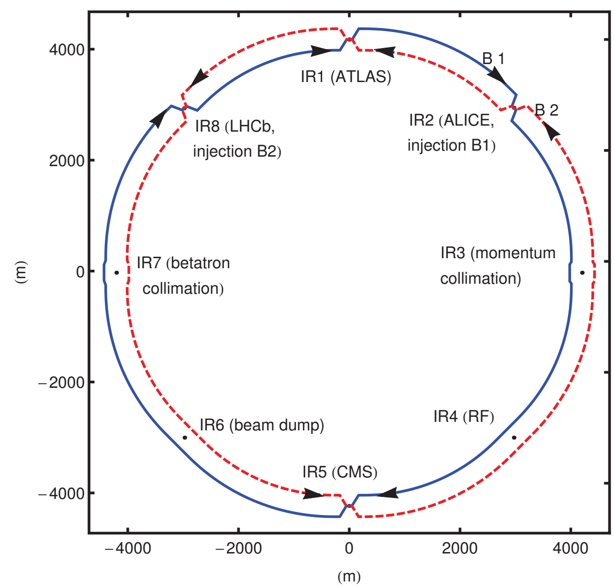

Figure 1: The schematic layout of the LHC (the separation of the two rings is exaggerated). The two beams are brought into collision at the four experiments ATLAS, ALICE, CMS and LHCb. Figure taken from Ref. [9].

BACKGROUND IN HIGH-β RUN

Beam-halo induced background occurs in the LHC experiments when halo protons initially hit a TCPs and then scatter back into the beam to an oscillating orbit, which leads to a final loss position on collimators or the machine aperture close to the experiments [10]. The unwanted background signals are caused by secondary shower particles that enter the detectors.

ATLAS and CMS were acquiring data during the high-β run. The low intensity and low luminosity provided very clean conditions to observe beam-halo induced background, since, during the scraping by the collimators, this was by far the dominating beam loss process. However, some intriguing observations were made by ATLAS [11]. A clear increase of background was observed in the counter-clockwise rotating B2 in strong correlation to beam scraping in IR3. This background was much stronger than what was observed in B1 and when the beam was scraped in IR7. Furthermore, during the IR3 scraping, no beam loss monitors (BLMs) close to ATLAS indicated local losses, that could be the origin of the observed background.

COLLIMATOR LAYOUTS FOR HL-LHC IN THE EXPERIMENTAL INSERTIONS*

R. Bruce†, F. Cerutti, L.S. Esposito, J.M. Jowett, A. Lechner, E. Quaranta, S. Redaelli, M. Schaumann, E. Skordis, G. Eleanor Steele, CERN, Geneva, Switzerland
H. Garcia Morales, R. Kwee-Hinzmann, Royal Holloway, University of London, Surrey, UK

Abstract

This paper presents the layout of collimators for HL-LHC in the experimental insertions. On the incoming beam, we propose to install additional tertiary collimators to protect potential new aperture bottlenecks in cells 4 and 5, which in addition reduce the experimental background. For the outgoing beam, the layout of the present LHC with three physics debris absorbers gives sufficient protection for high-luminosity proton operation. However, collisional processes for heavy ions cause localized beam losses with the potential to quench magnets. To alleviate these losses, an installation of dispersion suppressor collimators is proposed.

INTRODUCTION

It is planned to upgrade the CERN Large Hadron Collider (LHC) [1] to the High-Luminosity LHC (HL-LHC) [2, 3] after about 10 years of operation. The main goal of the upgrade is to achieve an integrated proton luminosity of about 3000 fb^{-1} over a decade at each of the high-luminosity experiments ATLAS and CMS. For this goal, it is needed to operate with a yearly luminosity production that is more than an order of magnitude higher than in the first LHC run [4]. This can be made possible by using beams with higher intensity and lower emittance, as well as smaller β-functions (15 cm, to be compared with the nominal 55 cm) at the interaction points (IPs).

In its nominal proton configuration, the LHC operates with beams at an unprecedented energy of 7 TeV with a total stored beam energy of about 362 MJ per beam. The two beams are guided by superconducting magnets, which risk to quench if just a tiny fraction of the full beam is lost locally. In order to protect the cold magnets, a multi-stage collimation system has been installed [1, 5, 6]. The collimators are mainly installed in the insertion regions (IRs) called IR3 (momentum cleaning) and IR7 (betatron cleaning). However, there are also collimators installed around the IPs: Tertiary collimators (TCTs) provide local protection on the incoming beam, and physics debris absorbers (TCLs) are installed on the outgoing beam to intercept collision products.

The HL-LHC poses new challenges for the collimation system. The total stored energy will increase to about 700 MJ per beam (2.2×10^{11} protons per bunch), and the higher luminosity causes a higher rate of collision debris. Furthermore, major upgrades and layout changes are foreseen in the experimental IRs. As an example, the layout around ATLAS, in IR1, is shown in Fig. 1 for both the first LHC run in 2010–2013 (Run 1) and for HL-LHC. Most notably, in order to allow a very small $\beta^* = 15$ cm, new large-aperture inner triplet quadrupoles will be installed, and the novel ATS optics scheme [7] will be deployed. The layout at CMS, in IR5, is identical.

Apart from protons, the LHC operates also a shorter period every year with heavy ions (mainly Pb^{82+}). Physical processes in the collisions, specific to heavy ions, create secondary beams with altered magnetic rigidity that are lost in very localized spots, where they risk to quench magnets [8, 9]. This could become critical in HL-LHC with an upgraded heavy-ion luminosity.

It is crucial to ensure that the HL-LHC is well protected by its collimation system during both proton and heavy-ion operation. This article investigates the local protection around the experiments and the need for upgrades. The global performance of the IR3 and IR7 beam cleaning system is discussed elsewhere [10, 11].

INCOMING BEAM

In the present LHC, a pair of TCTs (called TCT4), consisting of one horizontal and one vertical collimator, is installed in cell 4 on the incoming beam in front of each experiment. They should protect the local aperture bottlenecks that arise in the triplets in cells 1–3, when β^* is squeezed to small values, from both unavoidable losses during regular operation and accidental losses during beam failures, in particular asynchronous beam dumps. They should also decrease the experimental background [12]. All these aspects have to be verified for HL-LHC.

In HL-LHC, with $\beta^* = 15$ cm using ATS optics [7, 13], the critical aperture bottlenecks to be protected are no longer necessarily only in the triplet [14], which will be replaced to have a significantly larger aperture. The β-functions upstream of the TCT4 will also be significantly larger than in the nominal configuration, which could potentially introduce new bottlenecks, in particular in cells 4–5. If significant losses would be expected there, additional protection should be considered. This can be achieved by the installation of an additional pair of TCTs in cell 5, called TCT5, which should protect cells 4–5.

To assess the need of local protection in the experimental IRs in case of asynchronous beam dumps, we use SixTrack [15, 16] to simulate the losses around the LHC with the same method as in Refs. [17, 18]. We use the HL-LHC lattice version 1.0 [19] with baseline collimator settings [20]. Initial studies without any TCTs in the experimental IRs

COLLIMATION CLEANING AT THE LHC WITH ADVANCED SECONDARY COLLIMATOR MATERIALS*

E. Quaranta†, R. Bruce, A. Mereghetti, S. Redaelli, A. Rossi
CERN, Geneva, Switzerland

Abstract

The LHC collimation system must ensure efficient beam halo cleaning in all machine conditions. The first run in 2010-2013 showed that the LHC performance may be limited by collimator material-related concerns, such as the contribution from the present carbon-based secondary collimators to the machine impedance and, consequently, to the beam instability. Novel materials based on composites are currently under development for the next generation of LHC collimators to address these limitations. Particle tracking simulations of collimation efficiency were performed using the Sixtrack code and a material database updated to model these composites. In this paper, the simulation results will be presented with the aim of studying the effect of the advanced collimators on the LHC beam cleaning.

INTRODUCTION

The collimation system of the CERN Large Hadron Collider (LHC) is designed to efficiently absorb high energy beam losses and assure machine protection [1, 2]. Its multi-stage architecture is based on primary and secondary collimators (TCPs and TCSGs, respectively), made of a carbon-fiber-carbon composite (CFC). This choice has been made to guarantee good thermal stability and high robustness against beam induced losses for the collimators with the jaws the closest to the beam. Tungsten-based tertiary collimators (TCTs) and absorbers with higher particle stopping potential are instead devoted to protect the LHC experimental regions and reduce the background to experiments, at the expense of robustness against beam losses.

Since the first design of the present system [2], non-metallic collimators largely contribute to the impedance of the whole machine [3], mainly because of the low electrical conductivity of the CFC. The impedance is an electromagnetic concern of paramount importance in particular for the High Luminosity (HL) upgrade of the LHC [4], which aims at doubling the bunch intensity and at reducing the beam emittance.

Consequently, an intense R&D program has started at CERN to explore novel materials for new collimator jaws which could possibly replace some of the present CFC ones. The idea is to combine the excellent thermal properties of graphite or diamond with those of metals and metal-based ceramics of high mechanical strength and, above all, good electrical conductivity. The most promising materials identified so far are Molybdenum Carbide - Graphite (MoGr) composite and Copper-Diamond (CuCD) composite [5].

The effect of novel composite materials on the cleaning performance of the LHC collimation system must be investigated and the results used to complete the picture of the collimator material specifications. Therefore, a palette of materials is implemented in the tools used for LHC halo cleaning simulations. The first outcomes of the study are presented in this paper.

IMPLEMENTATION OF NEW MATERIALS IN SIXTRACK

The particle tracking code Sixtrack with collimation features [6–8] was upgraded to implement new composite materials. This setup is used as state-of-the-art simulation tool for collimation studies at the LHC. When energetic particles interact with matter, as for the LHC proton beams with the collimator material, scattering mechanisms occur. These mechanisms are reproduced in SixTrack by a Monte-Carlo code deriving from the K2 scattering routine [9], which has been also recently reviewed and improved [10].

Four composite materials, some of them already used in present collimators and others of interest for future collimation upgrades, have been added to the existing material database in SixTrack: MoGr and CuCD as alternatives to CFC for primary and secondary collimators; Inermet180, a tungsten heavy alloy used in the jaws of tertiary collimators and absorbers; Glidcop, a copper-based composite.

The routine treats mono-element materials. Thus, composite materials are dealt with by calculating off-line "effective" input parameters starting from material composition, as discussed below. The most important ones are listed in Table 1, along with the composition. For comparison, the same table lists CFC, already coded in SixTrack as pure carbon.

The atomic number Z and atomic weight A of each compound material was derived as average weighted on the atomic fraction of their components

$$p = \sum_i at_i \cdot p_i, \tag{1}$$

where p is the property of the compound to be computed, p_i are the values of the property, extracted from the Particle Data Group database [11], for the i-th element present in the material and at_i the atomic content of each element in the composite.

While traversing a medium and interacting with the electromagnetic field of the target atoms, a charged particle may lose energy by ionization according to the Bethe-Bloch

TOOLS FOR FLEXIBLE OPTIMISATION OF IR DESIGNS WITH APPLICATION TO FCC

H. Burkhardt, CERN, Geneva, Switzerland
Manuela Boscolo, INFN-Frascati, Italy

Abstract

The interaction regions of future high-luminosity colliders require well balanced designs, which provide both for a very high luminosity and at the same time keep backgrounds and radiation at tolerable levels. We describe a set of flexible tools, targeted at providing a first evaluation of losses in the interaction region as part of the design studies, and their application to FCC.

INTRODUCTION

Studies on "Future Circular Colliders" FCC with emphasis on a hadron collider at centre-of-mass energies of the order of 100 TeV and as possible intermediate step an e^+e^- collider for the 90 to 400 GeV energy centre-of-mass energy range, to be installed in a new 80 to 100 km long tunnel, were recently launched by CERN in worldwide global collaboration [1].

Combining the requirements for very high luminosity at high beam energies with the need for low or at least tolerable background and radiation levels to the experiments at the interaction regions will be particularly challenging and require a well balanced machine detector interface design and optimization.

The FCC studies are currently in an early design stage. In this phase, the machine description can be expected to change frequently, and detailed aperture and material information will not always be available.

TOOL SET FOR MACHINE DETECTOR INTERFACE SIMULATIONS

We have started to develop a tool set "MDISim" for **M**achine **D**etector Interface **SIM**ulations. MDISim can be subdivided in three different steps.

1. Read machine lattice description, generate twiss, survey and geometry files
2. Visualization of the geometry and analytic estimates including calculation of synchrotron radiation
3. Detailed simulation of the passage of particles through materials

We use and combine the existing standard tools, MAD-X [2], ROOT [3] and GEANT4 [4]. We will now describe the steps in more details.

1 – MACHINE LATTICE

The basis and starting point for the studies is the magnetic lattice machine description in the form of MAD-X input files. In the first step, we run the MAD-X program using "MDISim" default twiss and survey selections and attributes, to produce detailed twiss and survey tfs-files for the magnetic lattice and accelerator geometry description. R-matrix or sector map information can optionally be selected for output in the twiss file to enable tracking by mapping in the second step. Running MAD-X to generate the twiss and survey files is very fast. It takes less than 10 seconds to generate the files for a 100 km machine with 50 000 elements. The two files contain tables with all relevant information element by element, as required as input for the second step.

The global parameters relevant for the whole machine like the beam energy, particle type and number of particles are provided in the header of the twiss table. The twiss file uses local *Courant Snyder* coordinates s, x, y where s is the position along the circumference and x, y the horizontal and vertical distance from the design orbit. The transverse coordinates (x, y) can be increased using a scalefactor. The survey file specifies the element positions x, y, z in a global Euclidian coordinate system.

2 – VISUALIZATION OF THE GEOMETRY AND ANALYTIC ESTIMATES

The second step starts by reading and merging the twiss and survey files generated by MAD-X. Both local "Courant Snyder" as well as global Euclidian coordinates (with transverse Euclidian coordinates renamed to $x2$, $y2$) are now available at the end of each element. In addition translation from local to global coordinates and vice versa is made available by linear transformation (shift plus rotation) for any arbitrary position. This makes it straightforward to add tracks from beam loss simulations [5] or magnetic lattice tracking, given in local coordinates, to the geometry display which uses Euclidian coordinates.

For the second step we use ROOT, linked to our MDISim library package which deals with tfs-file reading and merging, ROOT geometry generation and analytic estimates.

The graphics capabilities (zoom, rotation, selection or deselection of components) of ROOT with EVE and OpenGL are used to display the geometry [6] as shown in Fig. 1.

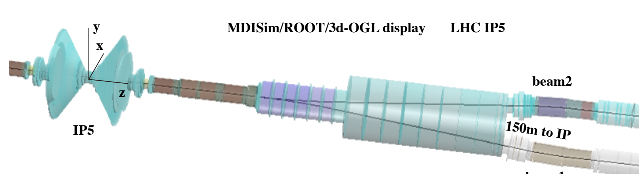

Figure 1: Display of the LHC IP5 geometry. Transverse (x,y) dimensions were increased by a factor of 100.

The program is designed to already start to work with only a minimum amount of information required. Any section

STUDY OF MUON BACKGROUNDS IN THE CLIC BEAM DELIVERY SYSTEM

H. Burkhardt, L.Gatignon, A. Latina, D. Schulte, R. Tomas, CERN, Geneva, Switzerland
B. Pilicer *, E.Pilicer, I. Tapan, Uludag University, Bursa, Turkey

Abstract

We describe the detailed modelling of muon background generation and absorption in the CLIC beam delivery system. The majority of the background muons originates in the first stages of halo collimation. We also discuss options to use magnetised cylindrical iron shields to reduce the muon background flux reaching the detector region.

INTRODUCTION

For the Compact Linear Collider (CLIC) project, high energy beam will be transported to the interaction region (IR) by the Beam Delivery System (BDS) [1]. The BDS is 2796 m long and consists of four sections which are diagnostics, energy and betatron collimation and final focus, respectively. The betatron collimation section has horizontal and vertical spoilers ($\sim 1\,X_0$) and absorbers ($\sim 20\,X_0$) to remove halo particles. The interaction of the halo particles with the spoilers and absorbers produces secondary particles including muons. Most of the secondary particles will be absorbed rather locally. High energy muons are not stopped by the absorbers and may reach the experimental detectors at the interaction point. Here we study how the background muon flux to the detector can be reduced using cylindrical magnetized shielding blocks of 5 m or $\sim 300\,X_0$ length. The main processes for muon production are gamma conversion into muon pairs (Bethe-Heitler process, $\gamma e^- \rightarrow \mu^+\mu^-e^-$) and annihilation of positrons with atomic electrons into muon pairs ($e^+e^- \rightarrow \mu^+\mu^-$). For the study described here we use the BDS of the CDR, and include the process of e^+e^- annihilation into hadrons ($e^+e^- \rightarrow$ hadrons) as an additional source for background muons [2]. The description of an earlier study can be found in [3].

MUON PRODUCTION PROCESSES

We use Geant4 (version Geant4.10.01) for the simulation of the interaction of the beam particles and secondary particles with the material in the beam line [4, 5]. The cross sections for the electromagnetic processes which are at the origin of muon production are shown in Fig. 1 as a function of the incoming beam energy, up to 1.5 TeV (maximum beam energy for CLIC).

The kinetic energy of atomic electrons in matter is very small compared to the beam energies considered here. In a very good approximation, we are dealing with the annihilation of high energy positrons with electrons at rest. The

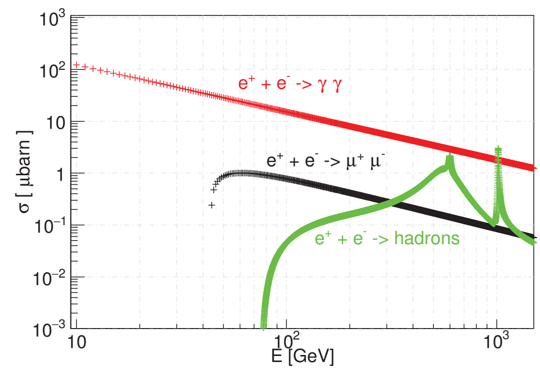

Figure 1: Cross sections for annihilation into two gammas (red markers), $\mu^+\mu^-$ (black markers) and hadrons (green markers) in laboratory frame energy.

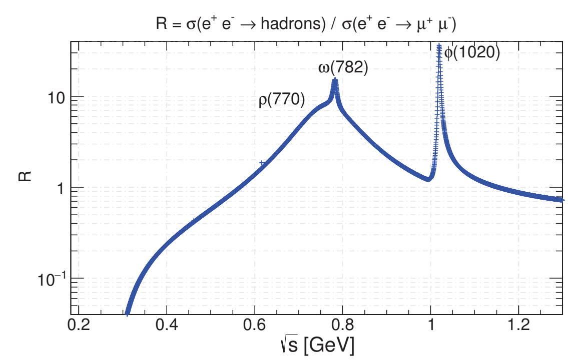

Figure 2: Ratio R = $\sigma_{e^+e^-\rightarrow hadrons}/\sigma_{e^+e^-\rightarrow\mu^+\mu^-}$ as function of the center of mass energy frame.

relevant centre of mass energy for the annihilation of high energy positrons of energy $E_{\rm beam}$ with electron of mass m_e at rest is $\sqrt{2 \cdot m_e \cdot E_{beam}}$, or 1.24 GeV at 1.5 TeV beam energy [2]. The ratio R of hadron to muon cross sections for the relevant centre-of-mass energy range is shown in Fig. 2. The peaks in the cross section for annihilation to hadrons correspond to the masses of vector resonances. The first two peaks visible at around 600 GeV beam energy correspond to $\rho(770)$ and $\omega(782)$. The peak around 1 TeV beam energy corresponds to the $\phi(1020)$. At these beam energies, the muon production by collimation of high energy positrons will be increased compared to muon background by electron collimation.

The hadrons produced in e^+e^- annihilation at these energies are : K^+K^-, K_SK_L, $\pi^+\pi^-$, $\pi^+\pi^-\pi^0$, $\pi^0\gamma$, $\eta\gamma$. The charged pions, kaons and the K_L are relatively long lived and will only rarely produce background muons by hadron decay. High energy photons produced in the decay of the

CIVIL ENGINEERING OPTIMISATION TOOL FOR THE STUDY OF CERN'S FUTURE CIRCULAR COLLIDERS

C. Cook, B. Goddard, P. Lebrun, J. Osborne, Y. Robert, CERN, Switzerland
C. Sturzaker, M. Sykes, Y. Loo, ARUP, UK
J. Brasser, R. Trunk, AMBERG, Switzerland

Abstract

The feasibility of Future Circular Colliders (FCC), possible successors to the Large Hadron Collider (LHC), is currently under investigation at CERN. This paper describes how CERN's civil engineering team are utilising an interactive tool containing a 3D geological model of the Geneva basin. This tool will be used to investigate the optimal position of the proposed 80 km-100 km perimeter tunnel. The benefits of using digital modelling during the feasibility stage are discussed and some early results of the process are presented.

INTRODUCTION

A five year international design study at CERN to investigate the feasibility of 'Future Circular Colliders' (FCC), potential successors to the Large Hadron Collider (LHC), began with a kick-off meeting held in Geneva in February 2014. The emphasis of the study is on a hadron collider with a centre-of-mass energy of the order of 100 TeV in a new 80 km – 100 km tunnel as a long-term goal. The design study includes a 90-350 GeV lepton collider, seen as a potential intermediate step. A lepton-hadron collider option is also being examined.

By the end of its construction in 2008, civil engineering accounted for around one third of the consolidated project cost of the LHC. Therefore, significant importance is placed on the civil engineering design when investigating the feasibility of the FCC. The earliest stages of any construction project offer the most opportunity for maximising quality and reducing total project costs. With this in mind, CERN is working in partnership with world leading engineering consultancies to utilise the latest methods and technology in order to ensure the best possible outcome from the first stages of design.

This paper describes the use of an interactive tool containing a 3D geological model of the Geneva basin. The Tunnel Optimisation Tool (TOT) is being used to assess the feasibility of the designs of the FCC study currently under study and their orientation with respect to the geology, terrain, surface constraints, their connection to the LHC and other siting considerations.

STUDY SCOPE

The Leman Basin, which contains the LHC, is surrounded by natural formations creating sensible boundaries for the FCC study area. Previous experience from the construction of CERN's previous particle colliders, LEP and LHC, has shown that the properties of the Leman Basin sedimentary rock, known as 'molasse', provide good conditions for tunnelling. During the excavation of the tunnel for CERN's Large Electron-Positron (LEP) collider, significant problems were caused by water ingress from the limestone formations in the Jura mountain range which lies to the west of Geneva.

For this reason, one of the primary aims when positioning the FCC tunnel is to maximise the fraction of the tunnel length in the molasse rock and minimise that in the limestone. Another primary concern is to orientate the tunnel in a way that limits the depth around its perimeter, therefore minimising the total depth of the shafts. These two primary concerns lead to natural boundaries in the form of the Jura range to the northwest, the Vuache mountain to the southwest and the Pre-Alps to the southeast and east. A boundary is placed in the north due to the increasing depth of Lake Geneva in the northerly direction.

THE DIGITAL APPROACH

The very first stages of a construction project offer the highest opportunity for overall reduction of cost, schedule and environmental impact (Fig. 1). A digital approach to the FCC feasibility study has enabled the CERN civil engineering team to extract the maximum value from the large amount of available data relating to the terrain, geology, hydrology, environment and built-environment of the Geneva basin, including man-made hazards such as geothermal boreholes. Locating the optimal position for any given design of the FCC tunnel requires all elements of this data to be analysed simultaneously.

BEAM DYNAMICS REQUIREMENTS FOR THE POWERING SCHEME OF THE HL-LHC TRIPLET*

M. Fitterer, R. De Maria, S. Fartoukh, M. Giovannozzi, CERN, Geneva, Switzerland

Abstract

For the HL-LHC, β^* values as small as 15 cm are envisaged as baseline scenario for the high luminosity insertions IR1 and IR5, thus leading to an increase of the maximum β-functions in the inner triplet (IT). The larger beta-functions in the IT result in a higher sensitivity of the beam to any linear or non-linear, static or dynamic, field imperfections in the IT region. In this paper, we summarize accordingly the tolerances of the triplet power supplies in terms of current ripple, stability and reproducibility. Both the baseline IT powering scheme and other alternative schemes will be presented, the later reducing the tune shift caused by a current modulation and thus weakening its possible impact on the long term stability.

INTRODUCTION

A modulation in the current of a power supply in general results in a change of the magnetic field which in turn causes a modulation of the normalized quadrupole strength. Possible effects of this modulation on the linear optics are β-beat, orbit deviations and a tune modulation, where the expected tune shift is given by the well known formula:

$$\Delta Q = \frac{1}{4\pi} \oint \beta(s) \Delta k(s) ds \tag{1}$$

with $\Delta k(s)$ being the modulation of the normalized quadrupole strength due to the modulation of the current by the power converter (PC) itself. As shown in [1] the β-beat and orbit deviation are small in case of the IT PCs in IR1 and IR5, while the effect on the tune is non-negligible. In addition, the modulation of the tune can also have an effect on the non-linear beam dynamics [2, 3] and has been experimentally demonstrated at several machines (e.g. at the SPS and HERA [4–7]), where the modulation resulted in a reduction of the beam life time and increased losses. In order to avoid a performance degradation due to the effect of a modulation of the PC current, an extensive beam dynamics study has been launched with the aim to specify the required tolerances. A short summary of this study is given in this paper.

MODEL OF THE IT POWER CONVERTERS

The first step in the specification of the tolerances of the IT PCs from a beam dynamics point of view, is to translate the voltage and current specification of the PC into a modulation of the normalized quadrupole strength. For the IT PCs two regimes are in general distinguished:

- **current-control:** for low frequencies (< 0.1 Hz) the current of the PC is directly controlled and the modulation of the quadrupole strength can be seen as random noise in the < 0.1 Hz range.
- **voltage-control:** due to the different components of a PC and the power grid itself, certain frequencies are present in the current spectrum, in general referred to as "ripple frequencies". The tolerances for the different frequencies are usually given in terms of voltage.

As the magnetic field scales linearly with the current, the normalized quadrupole strength is given by:

$$k(f) = T_{\mathrm{Itok}}(f) \times I_{\mathrm{PC}}(f) \tag{2}$$

in case of a direct control of the current.

To translate the voltage modulation in a modulation of the normalized quadrupole strength, the following model has been applied:

$$k(f) = T_{\mathrm{Itok}}(f) \times T_{\mathrm{VtoI,load}}(f) \times V_{\mathrm{PC}}(f) \tag{3}$$

where T_{Itok} is the transfer function from the PC current to the normalized quadrupole strength, which is assumed to be constant, $T_{\mathrm{VtoI,load}}(f)$ is the transfer function of the circuit seen by the PC and $V_{\mathrm{PC}}(f)$ is the voltage modulation. The circuit of the super-conducting IT magnets seen by the PC ($T_{\mathrm{VtoI,load}}(f)$) can in general be represented by an RL circuit. This implies that the higher the magnet inductance of the circuit, the stronger the attenuation of the modulation of the current and thus normalized quadrupole strength. In this model the effect of the cold bore, absorbers and beam screen is not included due to which an additional frequency dependent attenuation is expected.

IT POWERING SCHEMES

For the HL-LHC IT three different powering schemes are considered at the moment, which are illustrated in Fig. 1. The scheme "Baseline" is the current baseline powering scheme [8, 9], and the schemes "Q1Q2Q3" and "Q1Q2a-Q2bQ3" are alternative powering schemes under consideration. As will be shown later, the scheme Q1Q2a-Q2bQ3 features the smallest tune shift in the current-control regime and the scheme Q1Q2Q3 in the voltage-control regime due to its large inductance ($L_{\mathrm{tot}} = L_{\mathrm{Q1}} + L_{\mathrm{Q2}} + L_{\mathrm{Q3}}$). The magnet inductance and resistance used for the calculation of the normalized quadrupole strength with Eqn. 3 are summarized in Table 1.

CROSSING SCHEME AND ORBIT CORRECTION IN IR1/5 FOR HL-LHC*

M. Fitterer, R. De Maria, S. Fartoukh, M. Giovannozzi, CERN, Geneva, Switzerland

Abstract

In this paper we review the orbit correction strategy and crossing scheme adjustment for the HL-LHC orbit correctors in IR1/5 in view of the new optics and layout version HLLHCV1.1. The main objectives are to optimize the crossing scheme, in particular to reduce the strength of the orbit correctors at D2, and to validate the strength specifications of the several orbit corrector magnets involved, including a budget reserved for the correction of the orbit distortions from various sources.

INTRODUCTION

One of the objectives in view of the preparation of the new HL-LHC layout version HLLHCV1.1 [1,2] compared to HLLHCV1.0 [2], was the review of the necessary orbit corrector strength based on [3,4] and investigation of a possible reduction of the strength of the correctors at D2 (MCBRD) and at Q3 (MCBX3). Such a reduction is based on the reuse of the Q4 quadrupole of the nominal LHC as a new Q5 for the HL-LHC. Thanks to the two additional orbit correctors at Q5 (Fig. 1), it is then possible to extend the crossing scheme until Q5 inclusive and reduce the corrector strength.

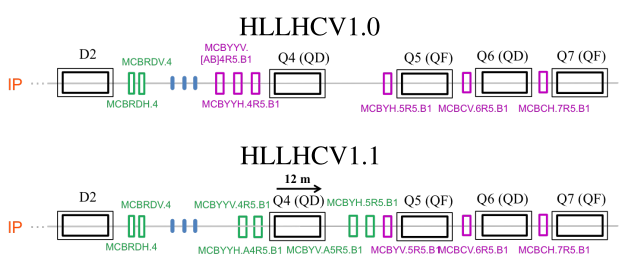

Figure 1: Schematic layout of the orbit correctors in IR1/5 in the D2 to Q7 region (longitudinal positions are not to scale). Representatively, IR5 Beam 1 right of the IP is shown. Orbit correctors used (additionally) for the crossing scheme are indicated in green and orbit correctors only used for orbit correction in pink. For Beam 2 the plane of correction is inverted for the orbit correctors at Q4, Q5 and Q6 due to the change of polarity of the quadrupoles for the other beam.

The orbit correctors in IR1 and IR5 in general have to provide sufficient strength for coping with the following aspects:

1. crossing and separation schemes,
2. beam based alignment of crab cavities,
3. luminosity and Van der Meer scans,
4. correction of inner triplet (IT) misalignment and feed-down from transfer function errors,
5. correction of closed orbit distortions generated by the arc imperfections.

The corrector strength for crossing and separation, luminosity and Van der Meer scans, and correction of IT errors depends only on the IT strength and the chosen crossing angle and separation. During the pre-squeeze the IT strength increases from injection to pre-squeezed optics and stays constant during the telescopic squeeze [5] and for all squeezed optics (round and flat). In most cases the studies are therefore only conducted for the injection optics at 7 TeV with $\beta^* = 6$ m, and for round collision optics marking the two "corner" cases during the pre-squeeze, where the round collision optics configuration has been chosen as reference for all squeezed optics. The results for the other squeezed optics can be then obtained by linear scaling with the crossing angle and separation, if changed. All optics parameters are summarized in Table 1.

Table 1: Optics parameters for layout HLLHCV1.1 and HLLHCV1.0."xing" is the half crossing angle and "sep" is the half separation. "round" and "flat" optics are squeezed collision optics. The optics parameters for injection (inj) are given after the ramp at 7 TeV.

	$\beta^*_{x/y}$ [m]	xing [μrad]	sep [mm]
pre-squeeze	0.44/0.44	±295	±0.75
round	0.15/0.15	±295	±0.75
flat	0.30/0.075	±275	
inj (7 TeV)	6.0/6.0	±295	±0.75

In this paper we only give a short summary of the main results, explicitly points 1, 2 and 4. Further details can be found in [6].

CORRECTION OF TRIPLET MISALIGNMENT AND FEED-DOWN FROM TRANSFER FUNCTION ERRORS

In order to asses the required corrector strength for misalignment and transfer function errors of the IT, Monte Carlo simulations using MAD-X have been conducted. For all simulations 10 000 seeds have been used. As a worst case scenario uniformly distributed errors have been assumed using the following reference values:

- ±0.5 mm transverse alignment errors,
- ±10 mm longitudinal alignment errors,
- $\pm 2 \times 10^{-3}$ relative gradient errors.

All results can be scaled linearly as the transverse alignment and relative quadrupole gradient errors both scale linearly

HLLHCV1.1: OPTICS VERSION FOR THE HL-LHC UPGRADE*

R. De Maria, S. Fartoukh, M. Fitterer, CERN, Geneva, Switzerland

Abstract

The optics and layout of the HL-LHC are evolving as the new hardware is being studied and integrated, any additional requirements from the experiments detailed, and other constraints of different nature clarified. Here we present the changes of version 1.1 of the optics and layout with respect to the previous version 1.0, which include the current hardware choices and an outlook on the main resulting optics limitations and the possible future evolutions of the layout.

INTRODUCTION

The High-Luminosity LHC project (HL-LHC) [1] relies on a reduction of β^* at the interaction points (IP) of the ATLAS and CMS experiments, IP1 and IP5 respectively. Larger aperture magnets [2] are foreseen to be compatible with the increased beam size in the interaction region (IR) and crab cavities [3] to compensate for the geometric reduction factor introduced by the crossing angle. The achromatic telescopic squeeze scheme (ATS) [4] is foreseen to preserve optics flexibility and guarantee the correction of the chromatic aberrations when reducing β^*, at the cost of extending the optics transitions to the arcs and neighbouring insertions and of increasing the beam size in the arcs. The new scheme also requires a stronger quadrupole in IR6 and will benefit from an additional sextupole in the arcs around the IR1,5.

This paper presents the latest baseline layout and optics models of the HL-LHC, labelled HLLHCV1.1, which is an evolution of HLLHCV1.0 and previous layouts [5]. We will also give an outlook of the future evolution of the layout based on recent developments from hardware studies.

LAYOUT

The HL-LHC layout is based on the nominal LHC with changes in particular in the straight sections of IR1 and IR5. A summary of the layout changes with respect to the LHC is given in Table 1. Figure 1 shows a sketch of the layout for the right part to IR5 (the left part is symmetric with respect to the IP and the layout of IR1 is identical to the IR5 layout). The main changes from HLLHCV1.0 to the HLLHCV1.1 are:

- updated triplets and interconnection lengths,
- change of position of the Q4 magnets,
- one additional cavity module (4 instead of 3) per side, beam and per IR,
- a different hardware for Q5 (MQY at 1.9 K) in IR1 and IR5 instead of a new MQYL (longer MQY) type,
- a different hardware for Q5 in IR6 (an additional MQY, thus two MQYs, instead of a new MQYL type magnet),
- revised orbit corrector layout in the D2-Q4 area [6].

* The HiLumi LHC Design Study is included in the HL-LHC project and is partly funded by the European Commission within the Framework Programme 7 Capacities Specific Programme, Grant Agreement 284404.

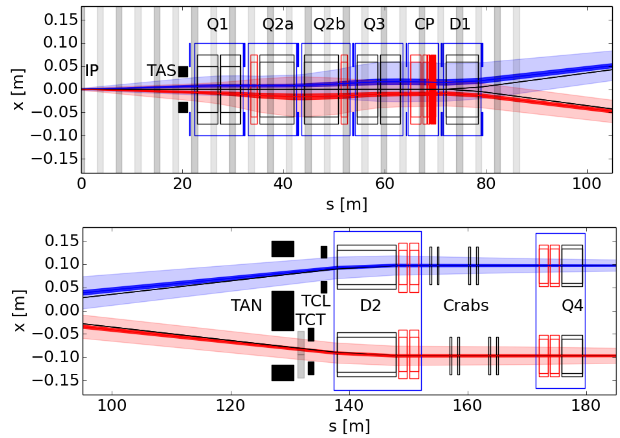

Figure 1: Sketch of the Layout on the Right Side of IP1 and IP5 from the IP to D1 (top) and from D1 to Q4 (bottom). Dark blue and red area show the 2σ beam envelops of Beam 1 and Beam 2. Light blue and red areas show the 12 σ beam envelops with imperfections (20% beta beating and 2 mm orbit error). On the top plot, gray bands highlight the location of the parasitic encounters for 25 ns bunch spacing and small blue boxes the BPMs.

The Q4 has been moved towards the arc in order to reduce the required voltage of the crab cavities and with the additional benefit of more available space for the additional crab cavity module and other equipment to be installed in the crab cavity region. Furthermore, the crab cavity modules are arranged in a different layout: two staggered pairs to optimize the required deflecting voltage regardless of the crossing plane. In HLLHCV1.0 the crossing and separation scheme bumps were closed just before the crab cavities with the orbit corrector at D2 (MCBRD), in order to minimize the orbit at the location of the crab cavities, however leading to a large strength of the MCBRD orbit correctors. In HLLHCV1.1 a considerable reduction has be achieved by sharing the strength needed for the crossing scheme bump between the orbit corrector at Q4 and the MCBRD at D2 at the cost of a non-zero residual orbit at the location of the crab cavities [6]. HL-LHC optics needs stronger Q5s in IR1/IR5/IR6 than those of LHC and for IR1/IR5 also with larger aperture. For Q5 HLLHCV1.1 adopts less expensive solutions as compared to the new magnet type (MQYL) proposed in HLLHCV1.0. In IR1/IR5 the existing MQM is replaced with the current Q4 (MQY) fitted to be cooled at 1.9 K to reach 200 T/m. Another alternative would have been to use a double MQYY as Q5 in IR1/IR5 to give more strength in Q5 (used mainly for large β optics) and more aperture that could be used in alternative optics schemes [7]. In IR6 doubling the existing MQY brings enough strength for the ATS squeeze optics.

BPM TOLERANCES FOR HL-LHC ORBIT CORRECTION IN THE INNER TRIPLET AREA*

M. Fitterer, R. De Maria, CERN, Geneva, Switzerland

Abstract

For the HL-LHC beam spot sizes as small as 7 mum are considered for the high luminosity insertions IR1 and IR5. In addition, the luminosity has to be levelled over several hours by changing beta* resulting in constant changes of the optics and thus orbit changes. The small beam size and the continuous optics changes in general make the alignment of the beams at the IP challenging. In order to avoid continuous luminosity scans for the alignment of the beams at the IP, the orbit correction has to rely on the readings of the BPMs in the IT region. In this paper we review the requirements on resolution and accuracy of the BPMs and compare different options for the placement of the BPMs in the IT region.

INTRODUCTION

The aim of the simulations presented in this paper is the definition of the precision and ranking of the BPMs in IR1/5 in terms of their efficiency. Explicitly the following points have to be specified:

- **the precision needed for a sufficient fill to fill reproducibility**: The minimum precision is defined by the precision required to find collisions at the beginning of a fill, while optimally the BPM precision should allow to find 1% of the luminosity at the beginning of the fill using only the BPMs and without the aid of luminosity scans.
- **the precision needed during one fill:** Assuming that the BPMs are recalibrated at the beginning of the fill, the BPM precision needs to be sufficiently good to keep the beams in collision without loss of luminosity, explicitly keeping the luminosity loss smaller than 1%.

ORBIT CORRECTION IN THE NOMINAL AND HL-LHC

Orbit Correction in the Nominal LHC

In the current LHC the orbit is corrected for each beam individually using a SVD and limiting the number of eigenvalue [1] . Explicitly a global orbit correction is performed and no individual correction of interaction regions (IRs). In all IRs, three BPMs per side and per beam are installed in the inner triplet area, which are however not used in standard operation at the moment. From experience in the LHC, BPMs closest to the IP are in gernal best for the correction of the orbit at the IP and a correction is usually still possible with 2 out of 3 BPMs.

* The HiLumi LHC Design Study is included in the High Luminosity LHC project and is partly funded by the European Commission within the Framework Programme 7 Capacities Specific Programme, Grant Agreement 284404.

Furthermore, around 10 μm of orbit drift at the IP are observed from fill to fill and around 100 μm during a period of several months [2]. The behaviour of the drifts also suggests a ground motion like behavior with the orbit deviation mainly originating from the misalignment of quadrupoles.

The general strategy for the LHC orbit correction is:

1. correct to the golden orbit of the previous fill at the end of the squeeze
2. conduct a lumiscan to optimize luminosity. The obtained orbit then redefines the "golden orbit"
3. orbit correction to the golden orbit defined by the initial lumiscan. The BPMs at the IT are explicitly not included in the correction.
4. in case of a relevant drop in luminosity, additional lumiscans are conducted

Orbit Correction in the HL-LHC

Between the nominal LHC and the HL-LHC differences and similarities exist in respect of the orbit correction. As the experiments can not accept the peak luminosity delivered by the HL-LHC, β^*-leveling over several hours is foreseen in order to reach the maximum integrated luminosity. A change in β^* entails a change of the optics which in turn results in a change of the orbit. In view of the orbit correction, two cases should be distinguished for the β^*-leveling:

- leveling using the pre-squeezed optics, for which the magnet strength in IR1/5 is changed for the squeeze of the same. This is the case for $\beta^* > 0.44$ m.
- leveling using the squeezed optics, for which the magnet strength in IR1/5 stays constant but instead the strength in the adjacent IRs is changed (IR2/8 and IR4/6). This is the case for $\beta^* < 0.44$ m.

Using the squeezed optics for the β^*-leveling might be preferred in view of the orbit correction as IR1/5 stay unchanged. This case would be similar to the nominal LHC, assuming that the orbit at the entrance and exit of IR1/5 can be controlled sufficiently well.

The orbit deviations in mm due to ground motion are expected to be similar for the HL-LHC as for the LHC. The reason is that the machine stays unchanged except for the IT and the integrated quadrupole strength of the nominal and the HL-LHC triplet is approximately the same, and thus the same orbit deviation in terms of mm are expected. However, the HL-LHC envisages smaller beam spot sizes than the LHC making the luminosity more sensitive to small orbit deviations.

The general orbit correction strategy for the HL-LHC could be:

LHC TRANSFER LINES AND INJECTION TESTS FOR RUN 2

C. Bracco, J.L. Abelleira, R. Alemany-Fernandez, M.J. Barnes, W. Bartmann, E. Carlier, L. Drøsdal, M.A. Fraser, K. Fuchsberger, B. Goddard, J. Jentzsch, V. Kain, N. Magnin, M. Meddahi, J.S. Schmidt, L.S. Stoel, J. Uythoven, F. M. Velotti, J. Wenninger, CERN, Geneva, Switzerland

Abstract

The Transfer Lines for both rings of the LHC were successfully recommissioned with beam in preparation for the start-up of Run 2. This paper presents an overview of the Transfer Line and Sector Tests performed to bring the LHC back into operation after a two-year period of shut-down for consolidation and upgrade. The tests enabled debugging of critical software and hardware systems and validated changes made to the transfer and injection systems. The beam-based measurements carried out to validate the optics and machine configuration are summarised along with the hardware systems.

INTRODUCTION

A combination of bumpers, fast kickers (MKE) and DC electromagnetic septa (MST and MSE) is installed in two SPS Long Straight Sections (LSS6 for Beam 1 and LSS4 for Beam 2) to extract the 450 GeV proton and ion beams towards the LHC [1]. The beams are then transported along two ~3 km long Transfer Lines (TL: TI 2 and TI 8) to the LHC. A system of collimators (TCDIs) is installed at the end of each TL to protect the LHC aperture from large amplitude oscillations due to failures occurring upstream in the line or during SPS extraction.

The injection into the LHC [2] is performed in two Insertion Regions (IR2 and IR8) towards a series of five Lambertson type septum magnets (MSI). Four kicker magnets (MKI) deflect the beam onto the LHC orbit.

The LHC injection system is particularly critical due to the use of high voltage fast (900 ns rise time) kickers and the relative likelihood of failure scenarios (i.e. erratic firing, flashovers, etc). A passive absorber (TDI) is installed at 90° phase advance from the injection kicker to protect the LHC aperture in case of kicker misfiring. The TDI is also used to stop the beam during injection setup.

Accurate hardware checks are performed during the machine check-out period following long shutdowns and/or relevant modifications. Tests with beam are also required to fully validate the systems and insure the correct functionality of each equipment. For this purpose TL and Sector Tests were carried out before the startup of the second LHC Run (in November 2014 and March 2015 respectively). A summary of the performed checks and of the most relevant outcomes are presented.

LS1 ACTIVITIES

The CERN accelerator complex underwent a long period of consolidation works in view of the second LHC run and operation at 6.5 TeV. Among others, upgrades were performed on the SPS extraction, TL and LHC injection systems. In the following only the activities directly related to the TL and Sector Test measurements are mentioned.

The quadrupole magnets of the SPS ring, TI 2 and TI 8 were re-aligned.

A clean and steady injection into the LHC strongly depends on the stability of the beam trajectory in the TLs. A reference trajectory, which allows to minimise the injection oscillations into the LHC, has to be defined. A periodic re-steering of the lines is then necessary to compensate for the long term drifts which are induced by variations of the SPS orbit. Current ripples at the MSE Power Converter (PC) were identified as the major source of shot-to-shot variations in the horizontal trajectory of both TLs [3]. Already during Run 1 several mitigation measures were put in place (recabling and new configuration of the PC output filters) and the ripple was reduced from 20 A (2011) down to 4 A (2012). Further upgrades were applied during LS1.

On top of the shot-to-shot variations, a bunch-by-bunch pattern could be observed which sampled the MKE waveform. During LS1 the last unserigraphed MKE in LSS4 was replaced with a serigraphed magnet to lower the impedance. Moreover, adjustments were applied to two of the Pulse Forming Networks (PFNs) to try to flatten the MKE waveform.

A number of consolidations were applied to the MKIs in order to reduced the ferrite yoke heating and the flashover rate [4]. The ceramic chambers were equipped with a full complement of screen conductors and a modified external metal cylinder at the capacitively coupled end. This required a full validation of the high voltage performance of the MKI magnets.

TL TEST

The TL test consisted in extracting both Beam 1 and Beam 2 from the SPS and transporting them until the absorber blocks (TED) located at the end of TI2 and TI8 respectively. This exercise was performed using pilot bunches of ~5×10^9 protons.

SPS Extraction

In preparation for the TL test, SPS extraction setup and aperture measurements were carried out on October 21st 2014. The defined settings for the bumpers, kickers and septa were compared with the theoretical values and those used in 2012; they were well consistent and the beam could be successfully extracted.

A scan of the aperture at the septa was accomplished by scaling the amplitude of the extraction bump with the MKE on (extraction channel) and off (circulating beam aperture).

COMPARISON OF BEAM SIZES AT THE COLLIMATOR LOCATIONS FROM MEASURED OPTICS AND BEAM-BASED COLLIMATOR ALIGNMENT AT THE LHC

G. Valentino*, R. Bruce, A. Langner, S. Redaelli, R. Tomás
CERN, Geneva, Switzerland

Abstract

At the Large Hadron Collider (LHC), the collimation hierarchy is defined in units of the betatron beam size using the sizes at each collimator location. The beam size at a given collimator can be inferred from the gap measurement during beam-based alignment campaigns, when the collimator touches a reference beam halo defined with the primary collimators. On the other hand, the beta functions at each collimator are also measured as a part of the standard LHC optics validation. This paper presents a comparison of the beam size measurements at the collimator locations applying these two techniques for different machine configurations. This work aims at determining which is the most reliable method for setting the collimator gaps at the LHC.

INTRODUCTION

The LHC accelerates two counter-rotating beams to a nominal energy of 7 TeV, corresponding to 362 MJ of stored energy per beam. An uncontrolled beam loss of only 7.6×10^6 p s^{-1}m^{-1} in a superconducting magnet can induce enough heating to cause a quench. In Run 1, a multi-stage system composed of 43 collimators per beam was operated to protect the LHC against losses of circulating beam [1]. Each collimator is composed of two jaws which need to be positioned equidistant from the beam, based on the beam centre and beam size at the collimator location. The upstream and downstream corners of each jaw can be moved independently by dedicated stepper motors. Most of the LHC collimators are located in Insertion Region (IR) 3 and IR 7 to clean particles with large momentum and betatron offsets, respectively. The IR7 horizontal aperture is shown in Fig. 1. The collimators are installed in the horizontal, vertical and skew planes to ensure the best coverage of the transverse phase space.

COLLIMATOR ALIGNMENT

The beam center and the beam size at each collimator are measured during a commissioning period at the start of the run. These values are measured for four machine modes: injection, flat top, squeezed separated, and colliding beams, and are used to calculate the operational jaw settings for the whole run. Thanks to the reproducibility of the beam orbit, one set up per machine mode per year has proven to be sufficient for now. Alignments are repeated if the machine configuration (e.g. β^*, crossing angle) is changed.

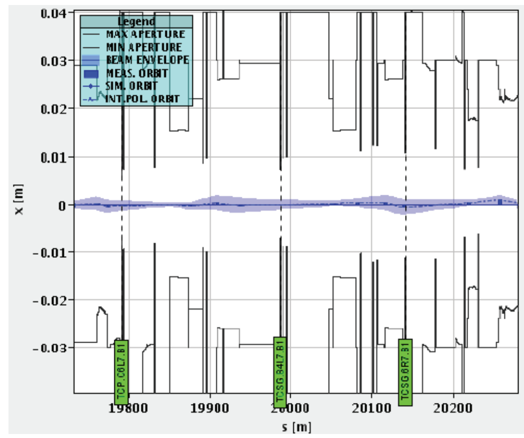

Figure 1: The IR7 horizontal aperture and beam orbit, with the envelope denoting the 1-σ beam size. The green text boxes show names of a few IR7 horizontal collimators.

Each collimator is set up using a four-step procedure [2]. The jaw of a reference collimator, taken to be the IR7 primary collimator (TCP) in the same plane as the collimator to be aligned, is first moved in steps of 5 μm (top energy) or 20 μm (injection energy). A feedback loop is used to stop the movement when the beam losses from a downstream Beam Loss Monitor (BLM) exceed a pre-defined threshold [3] (step 1). The opposite jaw is then aligned to the beam. After the reference cut in the halo is established, the i^{th} collimator i can be aligned (step 2). The reference collimator is re-aligned to the beam to account for halo depletion during the previous alignment (step 3). Finally, the collimator is retracted to the hierarchy positions (step 4).

At the start of the horizontal collimator alignment, the momentum halo is cut using the primary collimator in the high-dispersion region in IR3. This ensures that the halo intercepted by the other collimators is dominated by the betatron contribution, and has proved to give more stable and reliable results [6] for the beam centres. The inferred beam size at the collimator i is expressed in terms of the jaw half gap and the reference cut in units of σ, n_1:

$$\sigma_i^{\text{inf}} = \frac{x_i^{\text{L}} - x_i^{\text{R}}}{n_1^{k-1} + n_1^k} \quad (1)$$

where x_i^{L} and x_i^{R} are the left and right aligned jaw positions, and k is an index for the number of reference collimator alignments. The half-gap opening n_1 in units of σ for the two reference collimator alignments is calculated

NON-LINEAR COUPLING STUDIES IN THE LHC

T. Persson, E. H. Maclean, R. Tomás, CERN, Geneva, Switzerland
Y. I. Levinsen, ESS, Lund, Sweden

Abstract

The amplitude detuning has been observed to decrease significantly as the horizontal and vertical tunes approach each other. This effect is potentially harmful since it could cause a loss of Landau damping, hence giving rise to instabilities. The measured tune split $(Q_x - Q_y)$ versus amplitude is several times bigger than what can be explained with linear coupling. In this paper we present studies performed to identify the dominant sources of the non-linear coupling observed in the Large Hadron Collider (LHC).

INTRODUCTION

Linear transverse coupling has been studied thoroughly in a large number of accelerators. In light sources it plays an important role for the equilibrium emittance and it has been demonstrated to enhance other resonances [1, 2]. In the Large Hadron Collider (LHC) the control of the coupling is also of importance for a reliable tune feedback. The approach to correct the coupling in the LHC has been to first correct the strong local sources during commissioning [3] and then use two orthogonal knobs to correct the observed drifts of the global coupling [4]. The two knobs are designed to correct the real and the imaginary part of the C^- respectively. The absolute value of the $|C^-|$ is, in the linear theory, equal to the $\Delta Q_{\min}$ which is the closest approach of the transverse tunes [5]. A lot of progress in the control of the linear coupling was made during Run I of the LHC. The improvements included a better understanding of the resonance driving terms relation to the $|C^-|$, as well as improved data filtering and a tool to measure and correct the coupling based on the injection oscillations [6, 7].

The off-momentum dependence of the coupling, also known as the chromatic coupling was studied and a successful correction was demonstrated in [8]. These efforts have resulted in a good understanding and control of the linear and the off-momentum coupling in the LHC. In this article we discuss studies to identify sources of an observed amplitude dependence of the transverse coupling.

EXPERIMENTAL OBSERVATIONS

Particles with different amplitude will be focused differently in sextupoles but since the focusing is also dependent on the phase the effect almost cancels out. Octupoles magnets on the other hand introduce a bigger amplitude dependence of the tunes. This is of importance to reduce collective effect instabilities in the LHC. The behavior of this detuning is dependent on the powering of the octupoles but is also influenced by other resonances in the tune diagram.

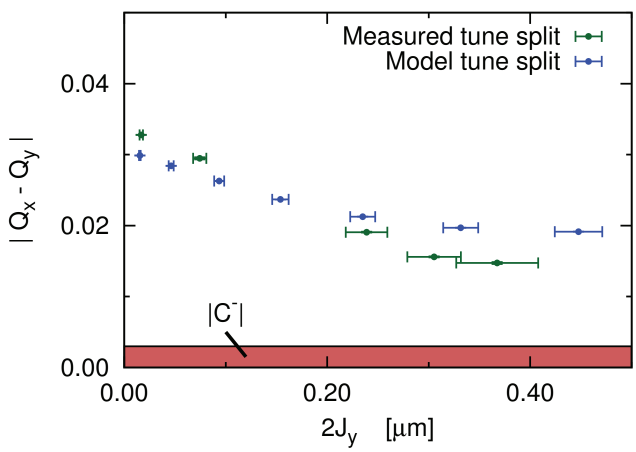

Figure 1: The tune split as a function of the action from the measured data as well as from the simulation based on the nonlinear model of the LHC. The linear $|C^-|$ was measured during the study and is indicated by the red area.

The naive expectation is that in a situation with coupling the detuning would be similar to the situation without coupling far away from the $|C^-|$ and only close to the stopband change the behaviour. During Non-linear dynamics studies in 2012 it was observed that this was not the case [9]. When large vertical kicks were applied to the beam the tunes did not approach each other as much as one would expect from the amplitude detuning. Instead the tune split seemed to saturate at a distance 4 times larger than the linear $|C^-|$. During the measurement the action was also measured and the large increase of the horizontal action for vertical kicks could not be explained by means of linear coupling. These observations gave rise to the interpretation of an amplitude dependent $|C^-|$. This feature was also well reproduced in the non-linear model of the LHC as seen in Fig. 1. The non-linear model of the LHC contains the best available knowledge about the errors in magnets as well as misalignment. The simulation was performed using tracking and the linear coupling was matched to the measured values. The magnitude of the kicks were also reproduced in the simulation.

IDENTIFICATION OF SOURCES

The non-linear model of the LHC contains many sources of non-linear errors and misalignment. In order to determine which type of sources were needed to cause an am-

ANALYSIS OF INTENSITY-DEPENDENT EFFECTS ON LHC TRANSVERSE TUNES AT INJECTION ENERGY

T. Persson, R. De Maria, M. Giovannozzi, R. Tomás, CERN, Geneva, Switzerland
Y. Wei, IHEP, Beijing, China

Abstract

The LHC Run I has provided a huge amount of data that can be used to deepen the understanding of the beam behaviour. In this paper the focus is on the analysis of transverse tunes at injection energy to detect signs of intensity-dependent effects. BPM data, recording the injection oscillations of the operational beams during the ring-filling phase, have been analysed in detail to enable extracting useful information about the tune shift vs. injected beam intensity. The data processing and the results are discussed in detail, including also possible implications for future operation.

INTRODUCTION

During the first years of LHC operation [1] a gold mine of observations and beam measurements has been collected. Among the several aspects of beam dynamics that can be probed thanks to these data, the evolution of the transverse tunes along the cycle are of particular interest [2]. The tune variation is mainly governed by the magnetic fields and any time-variation of the quadrupolar fields is impacting on the tune stability, which, in turns, might affect the accelerator's performance. Moreover, comparison of the measured tune evolution against the known features of the magnetic model can lead to improvements to the predictivity of the model in view of, e.g., defining a feedforward correction to ease the feedback system.

The data taken during normal operation have already highlighted a good agreement with the prediction of the magnetic model. However, a clear sign of intensity-dependent effects has been observed [2]. Such an effect is visible in the tune evolution during the filling process at injection in the LHC. The standard data analysis applied in Ref. [2] could not provide any quantitative estimate of the tune shift as a function of beam intensity. This effect had been quantified in Ref. [3] based on a number of assumptions for the estimate of the so-called Laslett coefficients [4, 5] (see also Refs. [6–8] for additional detail on this topic). Also in the case of the tune variation with intensity, a feedforward approach could be taken to devise a compensation strategy. Clearly, one should also asses whether this effect could impact the beam dynamics and the beam quality, and a quantitative evaluation of the phenomenon is the first step in this process.

In this paper an improved analysis of the data collected during the operational LHC fills, mainly during the 2012 physics run, is presented. It allows deriving the measured tune shift as a function of intensity. The delicate and interesting topic of comparing the theoretical estimate with observations is left aside for the time being.

MEASUREMENT METHODS

The LHC Base-Band-Tune, BBQ [9], is the most sensitive instrument for tune measurement and provides reliable measurements for single bunches or when the LHC transverse damper (ADT) is not active. For the case of circulating bunch trains, the signal level drops below the noise lines corresponding to 50 Hz harmonics and the noise introduced by the ADT, thus preventing any reliable measurement (see Fig. 1). BBQ data are logged continuously in the form of turn-by-turn data, post-processed spectra, and estimated tune values. Continuous turn-by-turn data are only available for limited periods of time.

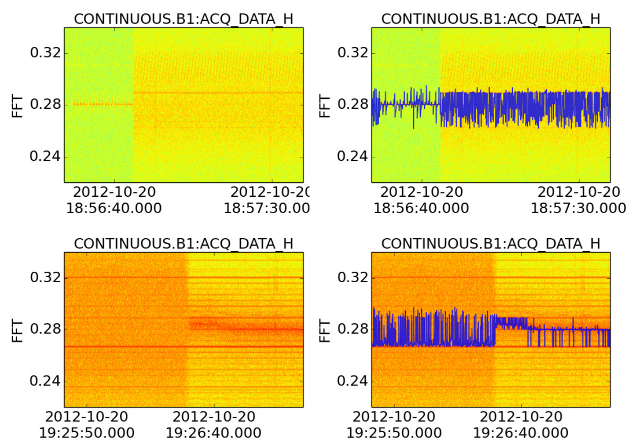

Figure 1: Horizontal BBQ spectra as a function of time (right) with superimposed estimated tune values (blue lines) during the injection process. In the top-left plot the horizontal (0.28) and vertical tunes (0.31) can be recognized when only a pilot bunch is present. However, as soon as other bunches are injected and the ADT activated the noise exceeds the signal level and the estimated tunes are extremely noisy. The bottom figures show the transition when the ADT is switched off, revealing again the tune signature. In fact, the estimated tune values become more reliable, although still occasionally lock on noise lines.

The LHC ADT [10] uses special BPMs and electronics to provide sensitive bunch-by-bunch, turn-by-turn beam position measurements. The 4 BPMs are installed in the insertion region (IR) 4 in the quadrupoles Q7 and Q9 for both beams and transverse planes. Raw data are not logged systematically, as only the 2000 turns of the first injected bunch are available in the logging database. An example of the information available from these BPMs is shown in Fig. 2, where typical injection oscillation signals are shown. A fit with an exponentially decaying sinusoid shows an excellent

INTERACTIONS BETWEEN MACROPARTICLES AND HIGH-ENERGY PROTON BEAMS

S. Rowan*, A. Apollonio, B. Auchmann, A. Lechner, O. Picha, W. Riegler, H. Schindler, R. Schmidt, F. Zimmermann, CERN, Geneva, Switzerland

Abstract

A known threat to the availability of the LHC is the interaction of macroparticles (dust particles) with the LHC proton beam. At the foreseen beam energy of 6.5 TeV during Run 2, quench margins in the superconducting magnets will be 2-3 times less, and beam losses due such interactions may result in magnet quenches. The study introduces an improved numerical model for such interactions, as well as Monte-Carlo simulations that give the probability of such events resulting in a beam-dump during Run 2.

INTRODUCTION

The phenomenon of UFOs (Unidentified Falling Objects), i.e., interactions of falling macroparticles (dust particles) with the proton beam, is well documented [1, 2]. Similar effects are known from other, mostly electron and anti-proton machines [3, 4, 5]. The LHC is the first proton machine where this phenomenon can be found. Figure 1 shows observations of UFO rates during the LHCs Run 1 with beam energies up to 4 TeV. With up to 13 UFOs per hour during a 25-ns bunch-spacing test run, falling macroparticles were estimated to become a significant threat to the availability of the LHC when operating at 6.5 TeV [6]. Such interactions produce particle showers that deposit energy in the adjacent superconducting magnets, possibly leading to magnet quenches. The current strategy to mitigate the effects this phenomenon is to detect the beam-losses with beam-loss monitors, and to trigger a preventative beam dump as soon as a threshold is exceeded.

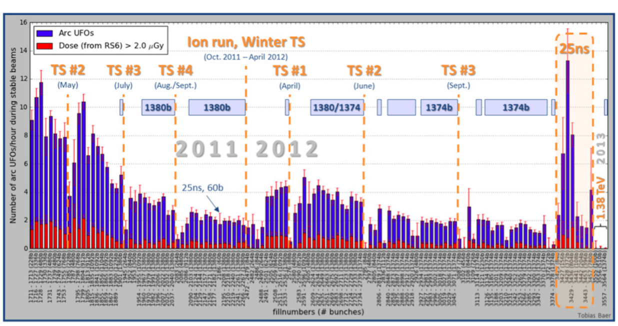

Figure 1: Number of arc UFOs per hour during stable beams in 2011 and 2012. Courtesy T. Baer.

There have been a number of detailed particle-shower simulations and beam-loss experiments to improve the understanding of such quench events [7, 8]. In order to estimate the true extent of the threat and to study relevant mitigation strategies, a numerical model of such macroparticle-to-beam interactions has been constructed, progressing on previous works [9, 10]. The simulated proton-loss rate was translated into signals in the beam-loss monitors (BLMs) based on the above particle-shower simulations. With this model, Monte-Carlo simulations have been carried out to reproduce measured data from 2012, and to extrapolate to Run 2 operating conditions.

NUMERICAL MODEL

A typical interaction between a macroparticle and the high-energy proton beam interaction - commonly referred to as a UFO event, is described as follows:

- A macroparticle (dust) falls from the beam screen or vacuum chamber.
- The macroparticle is ionized by elastic collisions with the proton beam releasing free electrons.
- Inelastic collisions result in particle showers recorded by BLMs, and potential quenches.
- The macroparticle is repelled by the beam's electric field.

Equation of Motion

The macroparticle's acceleration $\ddot{\vec{r}}$, with $\vec{r}$ the transverse position vector, is determined by gravity and by the force exerted by the electric field of the beam $\vec{E}$ on the macroparticle charge Qe,

$$\ddot{\vec{r}}(x, y, t) = \frac{Q(t)e}{m}\vec{E}(x, y) + \vec{g}, \tag{1}$$

with e the electron charge, m the macroparticle mass, g the gravitational constant, and $\vec{E}$ modeled by the Bassetti-Erskine formula [11] with recommendations for numerical stability from [12]. The total beam charge per unit length is given by $N_\mathrm{p}e/C$, with C the LHC circumference and N_p the total number of protons in the beam.

Macroparticle Charge Rate

Elastic interactions with the macroparticle lead to ionization. As a result, the charge rate, $\dot{Q}$, determines the beam's electric field influence. The charging formula, which is related to the Bethe-Bloch formula, is derived from the distribution N_e of knock-on electrons found in [13] with appropriate approximations,

$$\frac{\partial^2 N_\mathrm{e}}{\partial T \partial z} \approx 2\pi r_\mathrm{e}^2 m_\mathrm{e} c_0^2 n \frac{1}{T^2}. \tag{2}$$

IMPACT OF BEAM LOSSES IN THE LHC COLLIMATION REGIONS

E. Skordis*, R. Bruce, F. Cerutti, A. Ferrari, P. G. Ortega, P. D. Hermes,
A. Lechner, A. Mereghetti, S. Redaelli, V. Vlachoudis
CERN, Geneva, Switzerland

Abstract

The upgrade of the LHC energy and brightness, from the 2015 restart at close to design energy until the HL-LHC era with considerable hardware development and layout renewal, poses tight challenges in terms of machine protection. The collimation insertions and especially the one dedicated to betatron cleaning (IR7), where most of the beam halo is intercepted to spare from losses the cold sectors of the ring, will be subject to a significant increase of radiation load, whose leakage to the nearby dispersion suppressors must be kept sustainable. The past LHC run, while displaying a remarkable performance of the collimation system, offered the opportunity for a demanding benchmarking of the complex simulation chain describing the beam losses and the macroscopic effects of the induced particle showers, this way strengthening the confidence in the reliability of its predictions. This paper discusses the adopted calculation strategy and its evolution options, showing the accuracy achieved with respect to Beam Loss Monitor measurements in controlled loss scenarios. Expectations at design energy, including lifetime considerations concerning critical elements, will also be presented.

INTRODUCTION

The design stored energy of the Large Hadron Collider (LHC) [1] of about 362 MJ per beam is capable of causing catastrophic damage to the machine. However, even a very small fraction of that can induce both quenches of the superconducting (SC) magnets as well as material damage. Consequently, the inevitable proton losses have to be adequately intercepted before touching the machine aperture.

The collimation system installed in the LHC [2, 3] proved to be capable of sustaining up to 1MW of impacting protons for 1 s [4, 5] and protecting the machine from damage and quench. However the collimators themselves are not designed to absorb the entirety of the energy of the halo protons but rather divert it to an area with less sensitive equipment. The most exposed area is the insertion region (IR) 7 [6], where 3 different kinds of collimators, primaries (TCP), secondaries (TCSG) and active absorbers (TCLA), hierarchically extract the beam halo particles and absorb part of the primary, secondary and tertiary shower. The rest of the energy is deposited in the other LHC elements and eventually in the tunnel walls. A tiny but potentially harmful fraction leaves the IR7 straight section and reaches the dispersion suppressor (DS) where the SC magnets are installed.

To be able to make accurate predictions of the collimation performance in future running scenarios, and ensure that magnets are sufficiently protected, it is crucial to have a reliable and well-benchmarked simulation chain. Sixtrack [7, 8] and FLUKA [9-11] are the two simulation tools used for the tracking of the protons and the calculation of the secondary particle shower development and its effects, respectively. In order to validate the predictions, Beam Loss Monitor (BLM) signals are also simulated and compared against measurements for well-defined scenarios such as the collimation quench test in 2013 [2]. The goal of this paper is to present the updated results of the energy deposition calculations for the IR7 and the BLM benchmark with the most recent developments in the simulation procedure.

SIMULATION CHAIN

Tracking of Protons around the LHC Ring

The first necessary step of the simulation chain is to track the halo protons around the ring and create a map of proton hits in the collimators. The tracking is done using Sixtrack, a six-dimensional phase space multi-turn tracking code that uses thin-lens element-by-element tracking through the magnetic lattice.

Together with a detailed aperture model, Sixtrack has been using its own built-in Monte Carlo code to deal with interactions, other than nuclear inelastic events, between beam particles and collimator jaw material. In this way a distribution of inelastic interactions in the LHC collimators is produced as initial condition for FLUKA [12]. Nowadays, the development of the Sixtrack-FLUKA active coupling [13] takes advantage of the specialized and highly benchmarked interaction models of FLUKA as well as of the detailed geometrical models of the collimator devices to describe all kinds of interactions in a consistent way, improving the simulation accuracy.

Particle Shower Simulations

As a second step, the general purpose particle physics Monte Carlo code FLUKA is used in order to calculate the values of interest (e.g. thermal load in critical elements, power density in the SC coils, dose in the warm magnets, BLM signals etc.) from the particle showers initiated by protons interacting with the collimators. All the relevant elements in the IR7, including collimators, magnets, BLMs, device supports, cables, tunnel walls, etc. are modelled in detail and then accurately assembled by the LineBuilder [14] to create a geometry of several hundreds of meters (Fig. 1).

ERL WITH NON-SCALING FIXED FIELD ALTERNATING GRADIENT LATTICE FOR eRHIC*

Dejan Trbojevic, J. Scott Berg, Stephen Brooks, Yue Hao, Vladimir N. Litvinenko, Chuyu Liu, Francois Meot, Michiko Minty, Vadim Ptitsyn, Thomas Roser, Peter Thieberger, Nicholaos Tsoupas, Brookhaven National Laboratory, Upton, Long Island, New York, USA

Abstract

The proposed eRHIC electron-hadron collider uses a "non-scaling FFAG" (NS-FFAG) lattice to recirculate 16 turns of different energy through just two beam lines located in the RHIC tunnel. This paper presents lattices for these two FFAGs that are optimised for low magnet field and to minimise total synchrotron radiation across the energy range. The higher number of recirculations in the FFAG allows a shorter linac (1.322GeV) to be used, drastically reducing cost, while still achieving a 21.2 GeV maximum energy to collide with one of the existing RHIC hadron rings at up to 250GeV. eRHIC uses many cost-saving measures in addition to the FFAG: the linac operates in energy recovery mode, so the beams also decelerate via the same FFAG loops and energy is recovered from the interacted beam. All magnets will be constructed from NdFeB permanent magnet material, meaning chillers and large magnet power supplies are not needed. This paper also describes a small prototype ERL-FFAG accelerator that will test all of these technologies in combination to reduce technical risk for eRHIC.

INTRODUCTION

A possible future Electron Ion Collider (EIC) at Brookhaven National Laboratory will be placed in the existing tunnel of the superconducting Relativistic Heavy Ion Collider (RHIC→eRHIC) [1-5]. This is a design for the additional electron accelerator to provide polarized electrons with an energy range from 5 to 21 GeV. Electrons will collide with existing polarized protons or ^{3}He, or with other heavy ions from deuterons to Uranium.

The existing RHIC has been producing fascinating results so far with extraordinary performance above any expectations. RHIC represents a complicated chain of many accelerators, starting with the Electron Ion Beam Source (EBIS) with Radio Frequency Quadrupole (RFQ) and the polarized proton source (development of polarized ^{3}He has already started). It is the only collider in the world with the ability to collide unequal species and polarized protons. RHIC was the first to measure the formation of a "perfect liquid" consisting of quark gluon plasma (QGP). This system of accelerators and one of the two superconducting rings in RHIC will be reused in the future EIC while electrons will be provided by a new accelerator. Electron acceleration comes from a single superconducting linac with an energy gain of 1.322 GeV, accelerator design for producing electrons with energies up to 21.2 GeV is based on up to 16 passes through the linac with energy recovery (ERL). After polarized electrons are accelerated to the top energy (eRHIC has 15.9 or 21.2 GeV modes) and collided with the polarized protons or ions, their energy is recovered in the same linac. There are the same number of decelerating passes through the linac as accelerating passes, but at negative voltage (180° phase) so the energy is recovered. They reach the initial injection energy during the last pass. The "blue" hadron ring is shown schematically above the two electron beam lines (upper left corner in Fig. 1). Orbit offsets in the NS-FFAG electron rings are shown in Fig. 2. The hadron Interaction Region (IR) magnets are shown at the bottom of Fig. 1 with electrons and ions

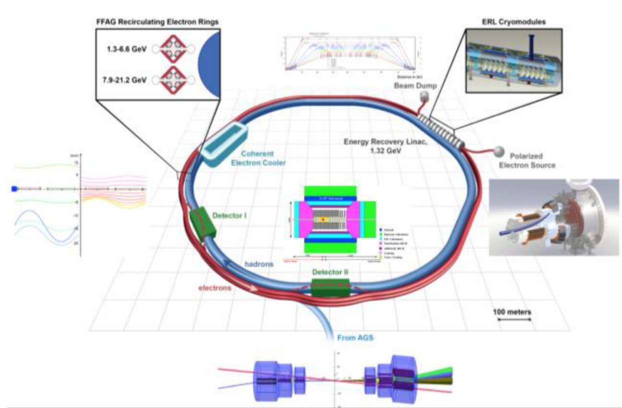

Figure 1: Layout of eRHIC: Existing "blue" superconducting hadron ring (centre); Two electron NS-FFAG beam lines (top left, with beam orbits on left); Polarized electron Gatling gun (right); Combiners and separators (top centre); Interaction region schematic (bottom) at the 6 o'clock point; and the superconducting linac (top right).

A MICROSCOPE FOR GLUONS

An EIC will be used to study the "spin puzzle" to determine quark and gluon contributions to the total proton spin, including the spatial distribution of quarks and gluons inside nuclei – a "microscope for gluons".

eRHIC Parameters

The new EIC collider eRHIC should achieve very high luminosities of the order of 10^{34} due to the expected small emittance of both electron and proton/ion beams. A new coherent electron cooling scheme is proposed for the

CHANGES TO THE TRANSFER LINE COLLIMATION SYSTEM FOR THE HIGH-LUMINOSITY LHC BEAMS

V. Kain, O. Aberle, C. Bracco, M. Fraser, F. Galleazzi, E. Gianfelice-Wendt, A. Kosmicki, F. Maciariello, M. Meddahi, F.-X. Nuiry, G. Steele, F. Velotti, CERN, Geneva, Switzerland

Abstract

The current LHC transfer line collimation system will not be able to provide enough protection for the high brightness beams in the high-luminosity LHC era. The new collimation system will have to attenuate more and be more robust than its predecessor. The active jaw length of the new transfer line collimators will therefore be 2.1 m instead of currently 1.2 m. The transfer line optics will have to be adjusted for the new collimator locations and larger beta functions at the collimators for absorber robustness reasons. In this paper the new design of the transfer line collimation system will be presented with its implications on transfer line optics and powering, maintainability, protection of transfer line magnets in case of beam loss on a collimator and protection of the LHC aperture.

INTRODUCTION

The transfer line collimators in the SPS-to-LHC transfer lines have been designed to attenuate and be robust enough for ultimate LHC intensity at 450 GeV. After the high luminosity upgrade the LHC will require beams from injectors with a brightness much increased with respect to the nominal or even ultimate LHC intensities.These parameters will only be achievable after substantial upgrades in the LHC injectors themselves [1]. The beam characteristics after the LHC Injector Upgrade (LIU) and the LHC ultimate beam which are relevant for the discussion in this paper are summarized in Table 1.

Table 1: LIU beam parameters in the SPS at 450 GeV [1]. BCMS stands for the beam production scheme "Batch Compression, Bunch Merging and Splitting"

	$p^+/bunch$	ε	$N_{bunches}$
Ultimate	1.7×10^{11}	$3.5\ \mu m$	288
Standard LIU	2.3×10^{11}	$2.1\ \mu m$	288
BCMS LIU	2.0×10^{11}	$1.3\ \mu m$	288

The impact of 450 GeV LIU beams on a collimator will create high energy deposition within a few microseconds and hence very high dynamic loads. The jaws will have to be made of materials of high shock resistance. Highest shock resistance can be found in carbon based materials with densities of 1.4 g/cm^3 to 1.8 g/cm^3. As the damage potential for equipment scales with brightness, the new collimators will have to provide roughly a factor 3 more attenuation to arrive at the same protection level as the current collimation system. The collimator jaws will therefore have to become 2.1 m long instead of the 1.2 m. The material choice will be detailed below.

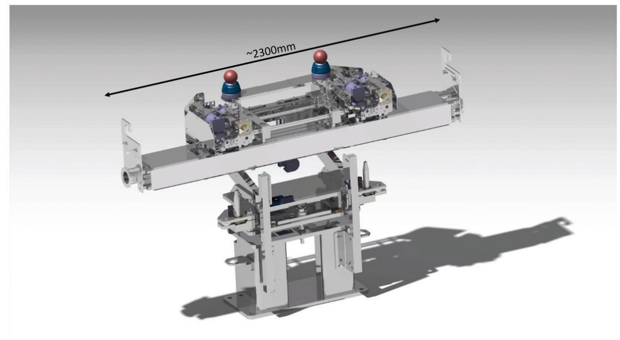

Figure 1: First version of 3D design of LIU transfer line collimator.

In the following the solution for the LIU transfer line collimators (TCDIs) and the remaining uncertainties on the design choice will be presented. The required modifications of the TI 8 optics will also be summarized and the implications on the protection of the LHC at injection discussed. A detailed functional specification of the LIU SPS-to-LHC transfer line collimation system can be found in [2].

CONCEPTUAL DESIGN OF THE LIU SPS-TO-LHC TRANSFER LINE COLLIMATORS

The design of the LIU TCDIs is based on the existing collimators installed in TI 2 and TI 8 [3]. The main difference is the requirement for longer jaws. A first version of the 3D design is shown in Fig. 1. The tolerances for jaw movement range, setting and alignment are also compatible with those originally specified. The allowed surface roughness will however be ± 100 μm instead of currently ± 50 μm.

Another difference might be the jaw material. Currently Steinemann R4550 Graphite is used. The peak energy deposition seen in the jaw varies as a function of the impact parameter, with larger values seen as the impact parameter increases. The increase in peak energy deposition and, correspondingly, temperature is not reflected in the thermomechanical stresses seen in the material, which are worst in the case of a 1 σ impact parameter. The results of the simulations with BCMS beam impacting a TCDI jaw at 1 σ, for both Steinemann R4550 Graphite (density1.83 g/cm^3) and 3D carbon-carbon (density 1.7 g/cm^3) jaw materials, are summarized in Table 2. For each material a different equivalent stress criterion was used [4]. The relevant robustness criterion for graphite is the Mohr-Coulomb criterion

PROTECTION OF SUPERCONDUCTING MAGNETS IN CASE OF ACCIDENTAL BEAM LOSSES DURING HL-LHC INJECTION*

A. Lechner†, M.J. Barnes, C. Bracco, B. Goddard, F. L. Maciariello, A. Perillo Marcone, N.V. Shetty, G. Steele, J. Uythoven, F.M. Velotti, CERN, Geneva, Switzerland

Abstract

The LHC injection regions accommodate a system of beam-intercepting devices which protect superconducting magnets and other accelerator components in case of missteered injected beam or accidentally kicked stored beam, e.g. due to injection kicker or timing malfunctions. The brightness and intensity increase required by the High Luminosity (HL) upgrade of the LHC necessitates a redesign of some devices to improve their robustness and to reduce the leakage of secondary particle showers to downstream magnets. In this paper, we review possible failure scenarios and we quantify the energy deposition in superconducting coils by means of FLUKA shower calculations. Conceptual design studies for the new protection system are presented, with the main focus on the primary injection protection absorber (TDI) and the adjacent mask (TCDD).

INTRODUCTION

The transfer lines from the SPS join the LHC in the ALICE and LHCb experimental insertions (IR2 and IR8) where four kicker magnets (MKIs) apply the final vertical deflection (0.85 mrad) on injected bunch trains [1]. To protect machine components in case of MKI malfunctions and timing errors, the injection regions accommodate a system of beam-intercepting devices and masks. The main element of the protection system is the TDI, a movable two-sided absorber installed at a phase advance of 75–95° from the MKIs. The TDI is located between a pair of superconducting dipoles (D1 and D2), which reduce the beam separation and bring the counter-rotating beams onto colliding orbits. In case of beam impact on the TDI, the single-bore D1 downstream of the TDI is the most exposed magnet and is protected by a mask (TCDD) which intercepts secondary particle showers leaking from the TDI. The TDI and TCDD are complemented by further collimators and masks downstream in the insertion regions, which provide some additional protection in case of phase errors.

The High Luminosity (HL) upgrade of the LHC requires an increase of the bunch intensity at LHC injection from 1.15×10^{11}/1.7×10^{11} (nominal/ultimate LHC) to 2.3×10^{11} protons. Together with a smaller beam emittance, this yields a significantly higher brightness than existing injection protection devices were designed for. These beam parameters not only pose a challenge for the robustness of absorber materials, but put new demands on the protection of superconducting magnets, particularly the D1 magnet.

* Research supported by the High Luminosity LHC project
† Anton.Lechner@cern.ch

Following a review of possible failure scenarios, this paper evaluates the protection provided by the existing TDI and TCDD and proposes potential solutions to reduce the energy density in the D1 coils. Other relevant aspects related to the upgrade of LHC injection protection devices, particularly the material robustness, are presented in another paper [2].

FAILURE SCENARIOS

In order to sufficiently protect the LHC during injection but also allow for some operational margin, the TDI jaws are maintained at a half gap of $6.8\sigma_n$ [3], where σ_n corresponds to the nominal LHC emittance (ε_n=3.5 μm·rad). With a β-function of ~43 m, this yields a jaw opening of approximately 7.6 mm. It is assumed that the same settings can be retained for HL-LHC operation since no significant optics changes are foreseen in the injection regions. A malfunction of the MKIs can affect either the injected or stored beam, but also both beams in the same event for specific kicker timing errors. As can be seen in the Table 1, different failure modes can affect a maximum of either 159 or 288 bunches (plus some bunches which are swept) and can give rise to different kick strengths, which in turn lead to different impact positions on the TDI jaws.

In case no kick is applied to the injected bunch train or in case circulating bunches are deflected with 100% of the MKI kick strength (timing error), beams typically impact on the TDI some 30–35 mm from the absorber block edge. The energy deposition in downstream magnets is however significantly higher if bunches impact close to the edge or if they graze along the jaws since secondary particle showers can escape through the TDI gap. Such events occur if the injected beam is deflected by approximately 90% or 110% (impact on the upper or lower jaw, respectively), or if the

Table 1: Overview of possible injection failure scenarios. Combination of different failures are not considered. The expected kick strength is expressed as a percent fraction of the nominal kick strength. Swept bunches are not included in the table.

Failure case	Bunches	Kick strength
Charging failure	288 (inj.)	99–101%
Main switch erratic	159 (inj. or circ.)	≤100%
Main switch missing	288 (inj.)	75%
Magnet breakdown	≤288 (inj.)	75–125%
Timing error	≤288 (inj.)	0%
	≤288 (circ.)	100%

CONSIDERATIONS FOR THE BEAM DUMP SYSTEM OF A 100 TeV CENTRE-OF-MASS FCC HH COLLIDER

T. Kramer, M.G. Atanasov, M.J. Barnes, W. Bartmann, J. Borburgh, E. Carlier, F. Cerutti, L. Ducimetière, B. Goddard, A. Lechner, R. Losito, G.E. Steele, L.S. Stoel, J. Uythoven, F. Velotti, CERN, Geneva, Switzerland

Abstract

A 100 TeV centre-of-mass energy frontier proton collider in a new tunnel of 80–100 km circumference is a central part of CERN's Future Circular Colliders (FCC) design study. One of the major challenges for such a machine will be the beam dump system, which for each ring will have to reliably abort proton beams with stored energies in the range of 8 Gigajoule, more than an order of magnitude higher than planned for HL-LHC. The transverse proton beam energy densities are even more extreme, a factor of 100 above that of the presently operating LHC. The requirements for the beam dump subsystems are outlined, and the present technological limitations described. First concepts for the beam dump system are described and the feasibility discussed, highlighting in particular the areas in which major technological progress will be needed. The potential implications on the overall machine and other key subsystems are described, including constraints on filling patterns, interlocking, beam intercepting devices and insertion design.

INTRODUCTION

CERN is leading an international collaboration for the conceptual design of colliders housed in a new tunnel of 80-100 km circumference in the Geneva region. In the frame work of the FCC-hh collider study [1] a major challenge will be the safe disposal of the up to 8 GJ beams. The extraction system must function with extreme reliability during beam presence, from 1st injection up to extraction with top level beam energy, to minimize the risk of severe damage to the machine. The dumping action must be synchronized with a particle free abort gap and the magnetic field of the extraction and dilution elements must closely track the beam energy. Asynchronous emergency dump action, allowed in the LHC, needs to be avoided as far as possible as it would be a major issue for the protection devices. The beam rigidity is more than seven times higher than in the LHC: this, together with machine protection considerations imposes ambitious hardware parameters. In addition the stored beam energy itself presents a serious challenge for the interception and dump devices. An overview of the relevant FCC-hh parameters is given in Table 1. Three different extraction concepts are being studied [2] and are further outlined in this paper together with the main extraction system elements.

Table 1: FCC-hh Parameters [2]

Beam parameter	Unit	Injection	Extraction
Kinetic Energy	TeV	3.3	50
Beta/Gamma		~1/3518	~1/53290
Revolution time	µs	~333	~333
Magnetic rigidity	T·km	11.0	166.8
Emittances (transv.)	µm	2.2	2.2
Stored beam energy	GJ	0.65	8.5

EXTRACTION CONCEPTS

All extraction concepts assume a fast extraction scheme, with one dedicated dump system per beam, which extracts the beam in a single turn towards an external dump block. Therefore fast kickers, strong septa and dilution kickers are needed. Other versions of these designs with special insertion magnet concepts, e.g. quadrupoles which allow for beam passage through the cryostat, are under consideration and would require lower strengths for the kickers and/or septa. The abort gap for all versions is assumed to be 3 µs.

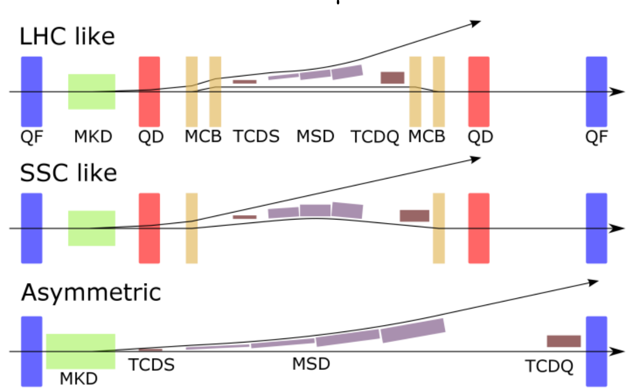

Figure 1: Preliminary insertion concepts.

LHC Scaled / LHC Like Concept

The LHC beam dump system (LBDS) [3] has been reviewed and scaled to the FCC energies as a first approach. This design uses a kicker (MKD, Fig. 1) and septum (MSD) placed around a quadrupole (QD), to enhance the kick. For the first purely scaled system hardware parameters were not advantageous hence in a "LHC like" version the optics were tuned and an

Abstract

The injector complex of the LHC is undergoing important changes in the light of the LIU project to provide brighter beams to the LHC. For this reason and as part of the High Luminosity LHC project the injection protection system of the LHC will be upgraded in the Long Shutdown 2 (2018 - 2019) to be able to protect downstream elements against injection failures with the high brightness, high intensity HL-LHC beams. The upgraded LHC injection protection system will consist of a segmented injection protection absorber TDIS and auxiliary collimators and masks. The layout modifications are described, and the machine element protection and absorber jaw robustness studies are presented for the new systems.

INTRODUCTION

The injection protection system of the LHC is being upgraded as part of the HL-LHC project [1]. The upgrade of the injector complex to prepare the higher intensity proton beam for the HL-LHC is taking place under the LIU project [2] and is foreseen to be finished in the LHC Long Shutdown 2 (2018 – 2019). This means that also the upgrade of the injection protection system as described in this paper should be finished by 2019.

The LHC injection protection system consists of a number of absorbers, part of them movable, to intercept the beam in case of failures of the LHC injection kicker magnets. The different elements are described in [3]. The different kicker failure modes and the TCDD absorber protecting the D1 separation dipole are described in [4].

INJECTION ABSORBER TDIS

Absorber Material Considerations

The injection absorber TDIS is the primary protection of the LHC against injection failures and must be able to withstand the impact of a full injection train consisting of 288 bunches in the case of injection kicker (MKI) failures [3]. Different candidate materials for the absorber blocks are presently being considered, including different grades of boron nitride, graphite and carbon-reinforced-carbon, all having a low density, a low coefficient of thermal expansion, a high strength and a low Young's modulus. Graphite R4550 (SGL) is so far the preferred candidate, as is it seems to be a good compromise in terms of availability of shapes, machinability, costs and performance.

To study the energy deposition and stress wave propagation in the absorber blocks during beam impact, simulation studies based on FLUKA [5, 6] and ANSYS [7] were carried out. Table 1 shows the obtained Mohr-Coulomb Safety factor for Graphite R4550 for different HL-LHC beam parameters. The results correspond to the worst case scenario, where 288 bunches impact close to the jaw edge. The Mohr-Coulomb Safety factor, which is explained in detail in [3], must be greater than 1 in order to guarantee the absorber survival. As can be seen in the table, this is just the case for Standard HL-LHC beam parameters, while in the case of the smaller BCMS type beams and a bunch intensity of 2.0e11 protons, the number of injected bunches will need to be reduced to 240 bunches per injection.

It should be noted that the material limits used for this analysis are rather conservative. Currently a test bench is under preparation to expose blocks of the above candidate materials to proton beams with equivalent brightness in order to observe their behaviour (HiRadMat experiment to be carried out at CERN in 2016).

Table 1: HL-LHC Beam Parameters at Injection with Resulting Mohr-Coulomb (MC) Safety Factor for TDIS Jaw Made of Graphite R4550

Beam	Emit, x,y [μm]	Nb [p/bunch]	# bunches	MC Safety Factor
Standard	2.0	2.3e11	288	1.01
BCMS	1.3	2.0e11	288	0.90
BCMS	1.3	2.0e11	240	1.43

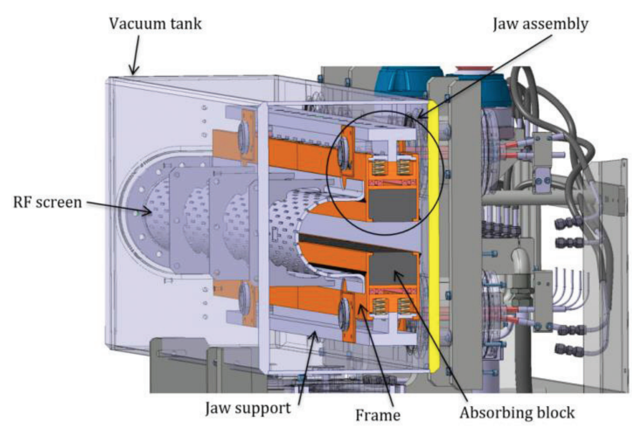

Figure 1: Preliminary design of one TDIS module.

Design Considerations

The preliminary TDIS design consists of three modules of equal length, containing different absorber materials. The first two modules consist of low-Z absorber blocks for which the above mentioned Graphite R4550 is assumed. The third module consists of higher Z materials.

NEW METHOD FOR VALIDATION OF APERTURE MARGINS IN THE LHC TRIPLET*

V. Chetvertkova, R. Schmidt, F. Velotti, D. Wollmann, CERN, Geneva, Switzerland

Abstract

Safety of LHC equipment including superconducting magnets depends not only on the proper functioning of the systems for machine protection, but also on the accurate adjustment of the protective devices such as collimators. In case of a failure of the extraction kicker magnets, which are part of the beam dumping system, it is important to ensure protection of the superconducting triplet magnets from missteered beam. The magnets are located to the right of Interaction Point 5 (IP5) and are protected by one set of collimators in the beam dumping insertion in IR6 and another set close to the triplet magnets. In this paper, a new method for verification of the correct collimator position with respect to the aperture is presented. It comprises the application of an extended orbit bump with identical trajectory as the beam trajectory after a deflection by the beam dump kickers. By further increasing the bump amplitude and successively moving in/out the collimators in the region of interest, the accurate positioning of the collimators can be validated. The effectiveness of the method for LHC IP5 and IP1 and both beams is discussed.

INTRODUCTION

Missteered beams could put in danger accelerator equipment by creating losses at unexpected locations, which could lead to quenches of the superconducting components or damage of the exposed parts in case of larger beam losses. One of the reasons for missteered beam in the LHC is the firing of all the 15 modules of the extraction kicker (MKD) non-synchronously with the abort gap [1]. In this case individual bunches will experience a kick of lower amplitude then needed to direct the beam into the beam dump channel. Missteered bunches should be intercepted by the TCDQ-TCSG assembly [2]. If this fails, the TCT collimators should intercept the beam. Figure 1 presents the collimators between the MKD and the triplet (MQX) as seen by Beam 2. However, if these collimators are not properly aligned other equipment will be in danger, depending on the optics, i.e. phase advance from the MKD. Asynchronous dumps are expected to occur at least once per year.

Such missteered clockwise (Beam 1) and counter-clockwise (Beam 2) beams might be harmful for the triplets in the interaction points IP1 and IP5, respectively. Checking the aperture margins is of particular relevance when operating with the collision optics and the ATS (Achromatic Telescopic Squeeze) beam optics [3], because in these cases the respective triplets will be the aperture bottlenecks if the collimators are not set properly.

* Work supported by COFUND grant PCOFUND-GA-2010-267194

For this reason it is crucial to assure the proper settings of collimators around the triplets that are also at risk in case of asynchronous beam dumps together with a wrong setting of other protection devices. This paper suggests an alternative method of checking the aperture margins of the collimators and the triplets.

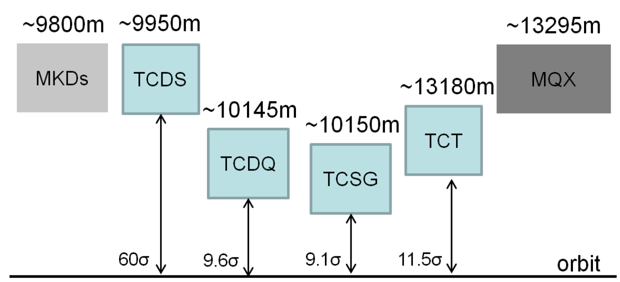

Figure 1: Scheme of collimators between the MKD and the MQX at IP5 [4] for Beam 2 (the zero of the coordinate system is at IP1). The longitudinal location of the component is shown (above) together with the retraction (below, expressed in beam σ-units) from the reference orbit.

METHOD

The proposed aperture-validation method is based on the fact that the beam trajectory of missteered beam can be reproduced by creating a 4-corrector orbit bump. The present study is devoted to the validation of the aperture margins around the MQX; therefore the global orbit bump is established around it. For beam 2, the bump starts before the MKD and closes after the IP5. Figure 2 shows a comparison of a trajectory of missteered beam and an orbit bump, corresponding to 1 µrad deflection angle at the MKD, calculated with ATS optics. The maximum of the orbit bump in both collision and ATS optics is observed in the triplet, for injection optics this is not the case.

The experimental measurements could be performed in two different ways: (1) by moving out the collimators, (2) by moving them in. For both approaches it is important to know the beam size, e.g. to cut the tails of the beam using primary collimators (TCP) in Sector 7.

The former approach starts with moving in the collimators to the initial positions. When increasing the amplitude of the bump one will start seeing losses by the Beam Loss Monitors (BLMs) at the TCDQ and the TCSG since their offsets from the centre of the vacuum chamber (in beam-σ units) are smaller than for the TCT. Knowing the beam size and the amplitude of the orbit bump (deflection angle at the MKD) it is possible to evaluate the offset of the collimators once the losses are registered. Before proceeding with the measurements of the aperture

ROADMAP TOWARDS HIGH ACCELERATOR AVAILABILITY FOR THE CERN HL-LHC ERA

A. Apollonio, M. Brugger, L. Rossi, R. Schmidt, B. Todd, D. Wollmann, M. Zerlauth, CERN, Geneva, Switzerland

Abstract

High Luminosity-LHC is the future upgrade of the LHC that aims at delivering an integrated luminosity of 3000 fb-1 over about 10 years of operation, starting from 2025. Significant modifications [1] will be implemented to accelerator systems, including new superconducting magnets, crab cavities, superconducting links, new collimators and absorbers based on advanced materials and design and additional cryo-plants. Due to the limit imposed by the number of simultaneous events at the experiments (pile-up) on peak luminosity, the latter will be levelled to $5*10^{34}$ $cm^{-2}s^{-1}$. The target integrated luminosity can only be achieved with a significant increase of the total available time for beam collisions compared to the 2012 LHC run, despite a beam current that is planned to double the nominal 0.58 A. Therefore one of the key figures of merit to take into account for system upgrades and new designs is their impact on the accelerator availability. In this paper the main factors affecting LHC availability will be discussed and predictions on the impact of future system upgrades on integrated luminosity presented. Requirements in terms of the maximum allowed number of dumps for the main contributing systems to LHC unavailability will be derived.

INTRODUCTION

High availability is becoming one of the key requirements for many accelerator facilities in the world. In the past only few categories of accelerators were considered as availability-critical. These are typically user-oriented facilities like synchrotron light sources and medical accelerators. Nowadays the challenging objectives on new projects around the world impose to consider availability as a fundamental requirement from early project and design stages. HL-LHC is the first particle collider with a defined integrated luminosity target [1]. HL-LHC aims at producing 250-300 fb^{-1} per year, for a total of 3000 fb^{-1} over about 10 years of operation. For ultimate parameters, the project is aiming at 400 fb^{-1} per year.

The considered baseline for the yearly LHC run time for physics production is 160 days. This implies an average integrated luminosity production of 1.9 fb^{-1} per day. For comparison, the total integrated luminosity produced by the LHC in 2011 was 5 fb^{-1}. Such increase of luminosity production has strong implications on availability requirements. Figure 1 shows that considering 2012 LHC availability and nominal HL-LHC parameters, a yearly production of 200 fb^{-1} could be achieved [2, 3]. Availability is expressed in the chart as a function of two quantities, the so-called *machine failure rate* and the *average fault time*. The *machine failure rate* indicates the fraction of premature beam aborts (i.e. beam dumps) which are initiated by machine protection systems upon the detection of any system failure. In 2012 the machine failure rate amounted to 70 %. Every time the beams were dumped, an average of 5.5 h – the so-called turnaround time - was required before colliding beams could be re-established. The *average fault time* measures the time spent to recover operating conditions after a fault occurs. In [3] it was shown that the fault time ranges from few minutes to many hours, depending on the fault and system root cause.

Improving these figures is mandatory to achieve the challenging goals of integrated luminosity of the HL-LHC project. The plot shows that an improvement of about 50 % of the average fault time, combined with a reduction of about 20 % of the machine failure rate will be required. This has strong implications on the system designs.

In this paper the main limitations to LHC availability will be discussed, based on the experience with the first LHC run (2010-2012). A strategy to identify individual system requirements in view of the HL-LHC era will be presented.

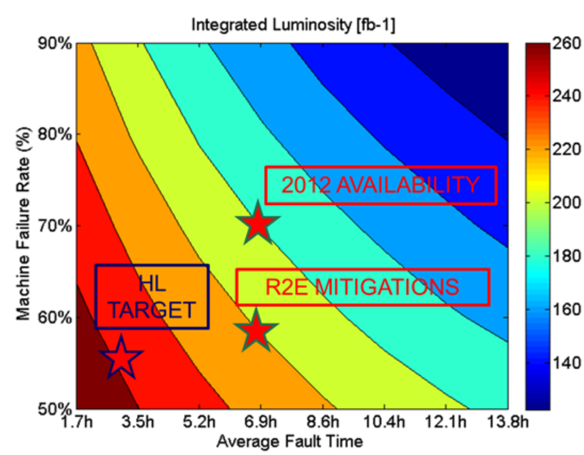

Figure 1: Fault time classification from 2012 observations.

LIMITING FACTORS FOR HL-LHC AVAILABILITY

The first LHC run allowed identifying possible availability bottlenecks for future LHC runs. Several system failure modes and effects were identified as critical for operation. Considering HL-LHC operation requires extrapolating the current knowledge to new operating conditions, i.e. increased energy and beam intensity and reduced operational margins for all systems. LHC run 2 (2015-2018) will represent an important

RF DESIGN OF THE CLIC STRUCTURE PROTOTYPE OPTIMIZED FOR MANUFACTURING FROM TWO HALVES

Hao Zha, Alexej Grudiev, CERN, Geneva, Switzerland
Valery Dolgashev, SLAC, Menlo Park, CA 94025, United States

Abstract

We present the RF design of a 12GHz Compact Linear Collider (CLIC) main linac accelerating structure prototype. The structure is made from two longitudinally symmetric halves. The main manufacturing process of each half is precision milling. The structure uses the same iris dimensions as the CLIC-G structure [1] but the cell shape is optimized for milling. The geometry is optimized to reduce the surface electric and magnetic fields and the modified Poynting vector. This design can potentially reduce fabrication cost.

INTRODUCTION

Accelerating structures are usually manufactured by precision turning of individual cells, andcombined with precision milling for complex parts such as rf power couplers. These multiple parts are brazed into a complete structure. An alternative approach is the use of precision milling to cut cells into metal blocks that comprise either halves or quarters of the complete structure [2, 3].

In this paper we describean accelerating structure milled out of two halves and brazedtogether. One of the main motivations for this work is to study the high gradient performance of accelerating structures made with novel manufacturing methods. We found experimentally [4,5] that metal surfaces that are in metal-to-metal contact but not bonded or brazed have poor high power performance. We also have experimental evidence that small gaps (under 1 mm) were damaged even in setups where there were no currents flowing through the gaps (see damage of the disk rim in Fig. 6 of [6]).

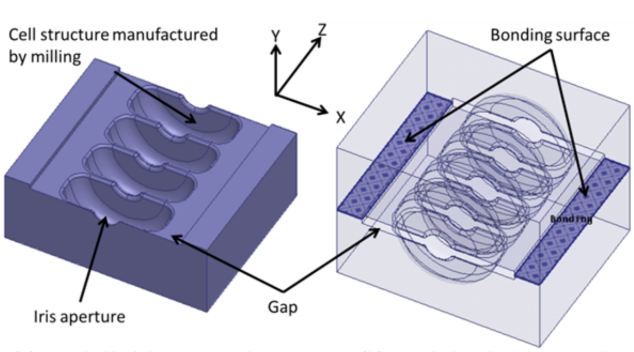

Figure 1: Manufacturing accelerating structure by milling on two halves of copper plate (HFSS model [7]).

Thus we introduced the 1 mm gap between the two halves of the structure to avoid un-brazed metal-to-metal contacts (shown in Fig.1). The gap is in cut-off at the working frequency to minimize fields leaking toward brazed surfaces and it is thus reducing the effect of imperfections of brazing fillets on rf performance. We note that a similar approach could be used to reduce trapping of long-range wakefields in the structure [4].

The full tapered structureincludes 24 regular travelling wave cells and 2 matching cells. It works at 11.994GHz with $2\pi/3$ mode. Each regular cell uses the same iris dimensions as the CLIC-G structure [8]. The structure uses a so called waveguide coupler, with matching transitions to standard WR-90 waveguides. The geometry is optimized to simplify the machining process, as well as to reduce the maximum surface electric and magnetic fields andthe local modified Poynting vector(*Sc*) [9].We used the commercial finite element code HFSS [7]for the simulations.

RF OPTIMIZATION OF SINGLE CELL GEOMETRY

One quarter of the cell prototype of the HFSS model is shown in Fig. 2. The flatbed besides the cell represents the gap between two halves. This single cell model will be used to optimize of the geometry.

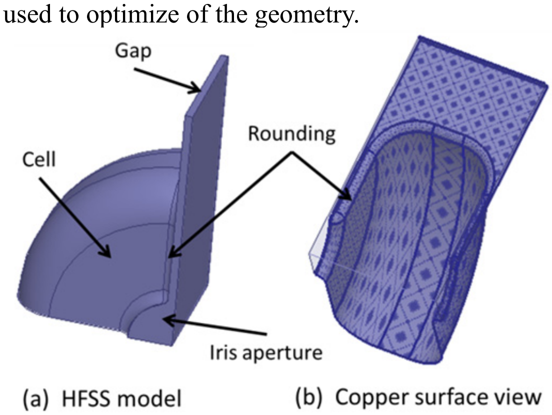

Figure 2: Initial geometry before the optimization.

The gap design changes the boundary condition in the cell and consequently affectsthe surface field. Figure 3 shows the comparison of our new structure with the regular un-damped middle cell of CLIC-G (T24). Wenote that the larger gap will significantly increase the maximum surface field and *Sc*.We use 1mm gap as compromise between increasing surface fields and degrading high power performance due to small gap (Fig. 6 in [6]).

OPTIMIZATION OF THE RF DESIGN OF THE CLIC MAIN LINAC ACCELERATING STRUCTURE

Hao Zha, Alexej Grudiev, CERN, Geneva, Switzerland

Abstract

We present a new optimized design of the accelerating structure for the main linac of CLIC (Compact Linear Collider). The new structure has lower surface magnetic fields and larger wall rounding compared to the baseline design described in the CLIC Concept Design Report (CDR). This new design should reach higher accelerating gradients and has a reduced manufacturing cost. The details of the RF design procedure and the obtained results are presented in this paper.

INTRODUCTION

The baseline design of the Compact Linear Collider main linac is called 'CLIC-G', which was described in the CLIC Conceptual Design Report (CDR) [1]. In recent few years, a lot of work related to this design was carried out. High power tests on the prototype structure with beam loading were made to understand the high-gradient limits [2]. A beam-based wakefield measurement verified the suppression of the long-range transverse wakefield of this design [3]. Mechanical design and manufacturing cost assessment of CLIC-G structures were studied [4]. It resulted that further improvement of the CLIC-G design is possible. RF and wakefield studies were carried out and a new optimized design to CLIC-G with lower pulse temperature rise and reduced manufacturing cost was presented.

RF DESIGN

A single cell of the CLIC-G structure is shown in Fig. 1. Four waveguides terminated with RF loads suppress the transverse wakefields. The waveguide geometry enhances the surface magnetic field and results in a higher surface pulse temperature rise, which is the likely explanation of higher break-down rate of the CLIC-G structure than the corresponding un-damped structure operating at the same gradient [5]. Gaps located between the cavities and waveguides are so-called waveguide openings. The widths of the openings are smaller than the waveguide width, in order to reduce the maximum magnetic field. Smaller opening however reduce the coupling of higher order modes (HOMs) from cavities to the RF loads. Thus the waveguide openings play an important role in balancing high power performance and wakefield suppression. The profile edge of the wall geometry in the cavity contains a straight line plus two quarter elliptical arcs and has been optimized to minimize the surface field. Rounding (0.5 mm) is used along the bottom edge to fit the machining.

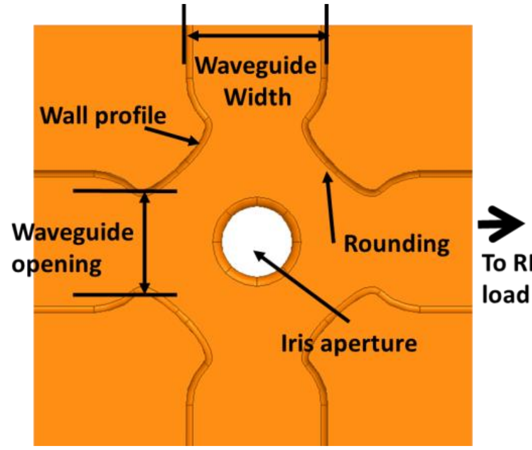

Figure 1: Geometry of a single CLIC-G cell.

The radii of the iris aperture in the CLIC-G design are from 3.15 mm to 2.35 mm. The average value and tapering of the iris aperture was determined by the global optimization considering the performance and the total cost [6]. The iris profiles have been optimized to minimize the surface electric field and the modified Poynting vector *Sc* [7]. This iris geometry is already well designed and will not be changed in this work. The cell geometry optimization is thus concentrated on the wall profile, waveguide geometry and the rounding.

Wall Profile

BEAM-BASED MEASUREMENTS OF LONG RANGE TRANSVERSE WAKEFIELDS IN CLIC MAIN LINAC ACCELERATING STRUCTURE

Hao Zha, Andrea Latina, Alexej Grudiev, Walter Wuensch, Daniel Schulte, Anastasiya Solodko, CERN, Geneva, Switzerland
Giovanni De Michele, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland and Paul Scherrer Institut, Villigen PSI, Switzerland
Erik Adli, University Of Oslo, Oslo, Norway
Nate Lipkowitz, Gerald S. Yocky, SLAC National Laboratory, Menlo Park, California, USA

Abstract

The baseline design of CLIC (Compact Linear Collider) uses X-band accelerating structures in the main linacs. Every accelerating structure cell has four waveguides, terminated with individual RF loads, to damp the unwanted long-range transverse wakefields in order to maintain beam stability in multi-bunch operation. In order to experimentally verify the calculated suppression of wakefields, a prototype structure has been built and installed in FACET test facility at SLAC. The results of the measurements of the wakefields in the prototype structure, by means of positron and electron bunches, are presented.

INTRODUCTION

The main linac of the Compact Linear Collider (CLIC) uses X-band normal conducting structures operating at an accelerating gradient of 100MV/m [1]. In order to increase luminosity and minimize power consumption, multiple bunch trains are accelerated in each RF pulse. The multi-bunch trains however introduce a demanding beam stability issue because transverse misalignments between the beam and the rf structures result in the excitation of long-range transverse wakefields, which kick transversely the following bunches. Beam dynamics calculations indicate that a transverse wakefield kick of a bunch on the following bunch must be suppressed to less than 6.6 V/pC/m/mm, in order to maintain the beam stability in the main linac [2].

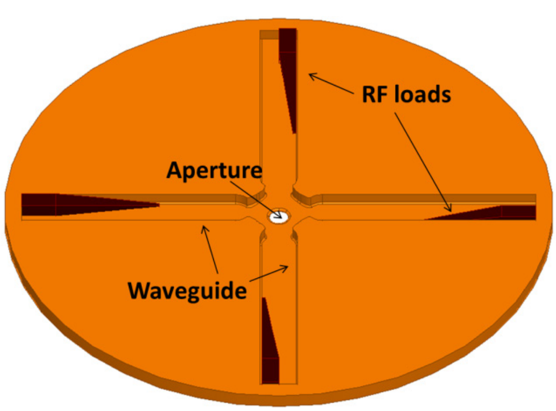

Figure 1: Geometry of single CLIC-G cell.

Figure 1 shows geometry of one CLIC accelerating structure disk. This geometry was well designed for both the high power performance and the wakefield suppression [3]. Given the availability of both electron and positron bunches simultaneously, the time-domain long-range wakefields of X-band structure could be measured at the FACET facility in SLAC National Accelerator Laboratory [4]. Figure 2 shows the measurement setup: NRTL (North -Ring-To-Linac) and SRTL (South-Ring-To-Linac) are independent beam lines and provide relativistic electron and positron bunches respectively. Both beam lines merge at LINAC02, where the test structure is located. The positron beam (drive bunch) was set to travel the test structure with a transverse offset to excite a transverse wakefield; the following electron bunch (witness bunch) is deflected by this wakefield.

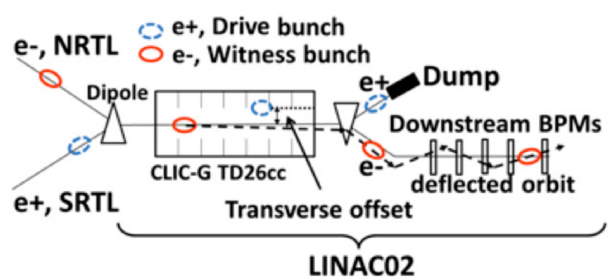

Figure 2: Layout of the experiment.

Downstream of the structure a dipole magnet splits the trajectories of the witness and drive bunches: the positron bunch is dumped, and the wakefield is inferred from the deflection of the electron orbit as measured by the downstream beam positron monitors (BPMs). Similar experiments have previously been performed at the FACET facility [5-7] and at the AWA facility in Argonne National Laboratory [8].

A dedicated prototype structure was built to carry out this experiment. The geometry of such prototype was the one of the CLIC 3 TeV baseline accelerating structure: the so-called CLIC-G TD26cc design, which contains 26 regular cells and compact input and output power couplers [3]. The structure cells were made of aluminium disks clamping together with long bolts. This simplified construction is acceptable for this experiment since the loaded Q of the dipole mode is very low, of the order of 10. The damping waveguides were terminated by silicon

SCENARIOS FOR CIRCULAR GAMMA-GAMMA HIGGS FACTORIES

R. Aleksan, CEA Saclay, Paris, France; A. Apyan, Northwestern U., Evanston, USA
Y. Papaphilippou, F. Zimmermann, CERN, Geneva, Switzerland

Abstract

The Higgs boson can be produced directly in gamma-gamma collisions generated by laser Compton back scattering off 80-90 GeV electron or positron beams. We discuss options for realizing a gamma-gamma Higgs factory using a high-energy circular e+e- collider, and/or its top-up injector ring, and compare the parameters and advantages of such a facility, including the expected performance, with those for a Higgs factory based on a recirculating linac, such as SAPPHiRE.

MOTIVATION

Even if no new unexpected finding is unveiled by the coming LHC Run 2, the evidence for non-baryonic dark matter, the cosmological baryon-antibaryon asymmetry and non-zero neutrino masses call for physics beyond the Standard Model. New particle accelerators are necessary to explore this physics. At present two design studies are underway for large accelerator complexes, i.e. the global Future Circular Collider (FCC) study [1] and the Chinese CepC/SppC [2]. In this paper we explore the possibility to realize a $\gamma\gamma$ collider Higgs factory based on the infrastructure of a future circular lepton collider, considering the example of the FCC-ee. A $\gamma\gamma$ Higgs factory can be realized by back-scattering two counter-propagating focused 80-90 GeV electron bunches off a laser pulse some ~1 mm before the e^-e^- collision point so that the backscattered γ's collide with a small spot size.

PRINCIPLE

In case the FCC-ee is used as the basis for such a $\gamma\gamma$ collider, the necessary electron bunches can be extracted from the two rings of the FCC-ee collider, one of which would need to have a magnet polarity opposite to the one required for its (e+) operation in the e+e^- collision mode. For the $\gamma\gamma$ option, we consider only e- beams since the luminosity will crucially depend on the rate at which the particle beams can be produced and accelerated. Generating a sufficient rate of positrons would be challenging. At a beam energy of 80-90 GeV about 4000 bunches per beam can be stored in the two collider rings, with a bunch intensity corresponding to ~100 MW of synchrotron radiation in total. After injection an initial synchrotron-radiation damping period of about 1000 turns (about two transverse amplitude damping times) is granted to establish the equilibrium emittances. Then one bunch per turn is extracted and collided in a dedicated bypass $\gamma\gamma$ interaction line with a bunch taken from the other beam; see Fig. 1.

Since the FCC-ee design features a single booster injector [3,4], which, in this application, would also need to switch polarity for injecting into one or the other ring, we can consider a cycle pattern, where one ring is half empty when the injection for the second ring takes place. The cycle is illustrated in Fig. 2, for a booster period of 1 s, and a booster-field ramp rate close to 500 G/s (corresponding to ~170 GeV/s, comparable to the SPS energy-ramp rate for the CNGS beam). For this cycle, the maximum total synchrotron radiation power in the two collider rings is only 3/4 of the amount one would expect when filling both rings completely.

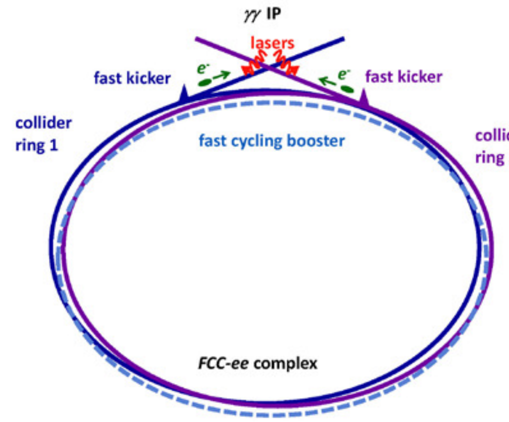

Figure 1: Schematic $\gamma\gamma$ collider based on filling the two FCC-ee collider rings with e^- bunches and extracting one bunch per beam and per turn into a dedicated $\gamma\gamma$ line.

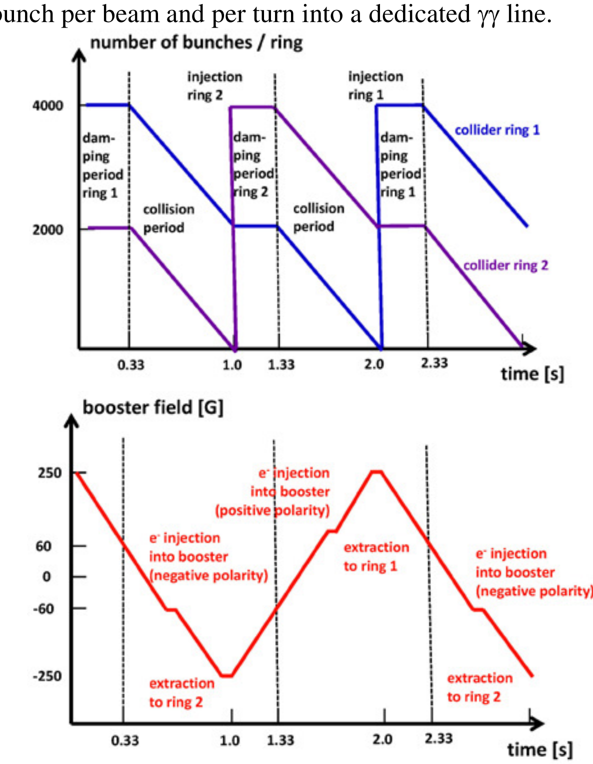

Figure 2: Cycle pattern for the two collider rings (top) and for the fast cycling booster (bottom). The injection energy is taken to be 20 GeV.

MITIGATING PERFORMANCE LIMITATIONS OF SINGLE BEAM-PIPE CIRCULAR e^+e^- COLLIDERS

M. Koratzinos, University of Geneva, Switzerland and F. Zimmermann, CERN, Geneva, Switzerland.

Abstract

Renewed interest in circular e^+e^- colliders has spurred designs of single beam-pipe machines, like the CEPC in China, and double beam pipe ones, such as the FCC-ee effort at CERN. Single beam-pipe designs profit from lower costs but are limited by the number of bunches that can be accommodated in the machine. We analyse these performance limitations and propose a solution that can accommodate O(1000) bunches while keeping more than 90% of the ring with a single beam pipe.

SINGLE BEAM-PIPE LIMITATION

The CEPC collider [1] is a single beam-pipe e^+e^- collider with the main emphasis on 120 GeV per beam running with possible running at 45 and 80 GeV. Bunch separation is ensured by a pretzel scheme and the maximum number of bunches is limited to 50. This very small number of bunches for a modern Higgs factory introduces luminosity limitations at 120 GeV, and severe limitations at any eventual 45 GeV running.

A machine of the size of CEPC at 120 GeV ought to be designed to be operating at the beam-beam limit and not reach the beamstrahlung limit first. The best way to reach this goal is by keeping the bunch charge low and emittances as small as possible. A large momentum acceptance also helps. Another way (and the route chosen for the CEPC) is to keep the bunches as long as possible, but this gives rise to lower instability thresholds as well as to geometric luminosity loss. According to our calculations and with reasonable assumptions for the length of the FODO cell and phase advance, we arrive at an optimal number of bunches of around 120 at 120 GeV [2]. The accommodation of this number of bunches with the pretzel scheme would be more demanding.

For an eventual running at 45 GeV the limit of 50 bunches would be inadequate, as hundreds of bunches would be needed to explore the full potential of the machine [2].

THE 'BOWTIE' DESIGN

Without changing the basic design philosophy of the project, where the single-beam pipe approach was chosen to minimise cost, we can envisage an approach that preserves the low cost of the single beam pipe and at the same time accommodates hundreds of bunches without the use of a pretzel scheme. This approach is illustrated in Figure **1**. All arcs contain a single beam pipe but the straight sections where the experiments are located are increased in length and after the RF section a series of electrostatic separators splits the two beams sufficiently far apart transversely so that separate beam pipes and magnetic elements can be used to manipulate the electron and positron beams individually, and without any parasitic collisions. The length of the electrostatic separator section would be around 100 m on both sides of the straight section. Since now the beams travel in separate beam pipes, great flexibility about the choice of collision angle is ensured. The FCC-ee is pursuing a crab waist approach which gives excellent performance at low energies and where the crossing angle is 30 mrad.

Assuming a total length of the double beam pipe to be 2×2000m, and assuming that bunches within a train can be separated longitudinally by as little as 2 m (7 ns) then 2×1000 bunches for each species can be accommodated in the machine.

The ratio of single to double beam pipe would be ~4/52 or about 8%. Note that the cost increase would be much smaller than the above figure and actually the cost per luminosity unit would be greatly improved.

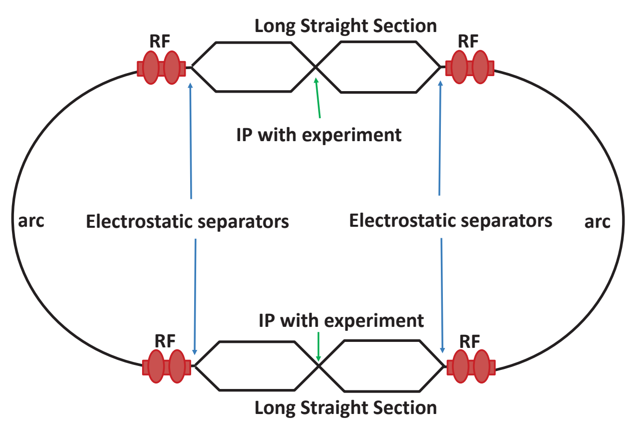

Figure 1: Schematic of the 'bowtie' idea (not to scale).

ELECTROSTATIC SEPARATORS

For illustration purposes we have chosen the LEP electrostatic separators [3]. These were 4 m long, 11 cm wide and the maximum operating voltage was 220 kV. Each separator produced a maximum deflection of 145 μrad at 55 GeV. These separators were not without problems: aspects that need to be looked at include possible impedance issues in view of the awkward shape of the separators and reliability issues due to sparking provoked by synchrotron radiation.

Using 12 of these LEP separators (48 m total length) operated at maximum voltage would provide a separation of 20 mm ×2 to the two beams after a distance of 50 m, and a further drift space of 50 m would increase the beam

FIRST CONSIDERATIONS ON BEAM OPTICS AND LATTICE DESIGN FOR THE FUTURE ELECTRON-POSITRON COLLIDER FCC-ee

B. Haerer, B. J. Holzer, F. Zimmermann CERN, Geneva, Switzerland
A. Bogomyagkov, BINP, Novosibirsk, Russia

Abstract

Following the recommendations of the European Strategy Group for High Energy Physics, CERN launched the Future Circular Collider Study (FCC) to investigate the feasibility of a new large circular collider for high energy physics research. This paper presents the constraints on the design of the lattice and optics of the lepton collider version of FCC, that has to be optimised for four different beam energies and parameter sets. Special emphasis is put on the need for a highly flexible magnet lattice in order to achieve the required beam emittances for the four energies and on the layout of the interaction region that will have to combine an advanced mini-beta concept, an effective beam separation scheme and a local chromaticity control to optimise the momentum acceptance and dynamic aperture of the ring.

INTRODUCTION

The lepton collider part of the FCC study is based on racetrack geometry with a circumference of about 100 km and foresees the design of an electron-positron collider, running at four different centre-of-mass energies to allow precision measurements at the Z resonance, at the energy with maximum Higgs production rate, as well as above the WW and t-tbar thresholds [1]. For each energy the beam parameters depend crucially on the synchrotron light emission and the lattice has to be optimised to provide the emittance target values that are summarised together with the general beam parameters in the parameter list of Table 1. The general layout of the machine is shown in Figure 1.

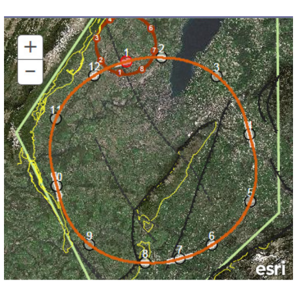

Figure 1: Geometry of the FCC storage ring.

MAIN PARAMETRES

The general parameters [2] have been optimised for each beam energy and are determined by the overall synchrotron radiation load that can be accepted in the design. In general, for all operation energies the same global synchrotron radiation limit of P_γ =50 MW has been assumed, leading e.g. to a considerable higher number of stored bunches at the lowest operation energy and to a large variation of beam emittances over the complete energy range of the machine.

Table 1: FCC-ee Parameters at Four Different Beam Energies

	Z	W	H	t
Beam Energy (GeV)	45.5	80	120	175
Current (mA)	1450	152	30	6.6
Bunch population 10^{11}	1.8	0.7	0.46	1.4
Bunch number	16700	4490	1360	98

General Layout of the Lattice Cells

The design of the basic cell follows the usual rules for particle beams that are determined by synchrotron radiation aspects. The basic cell that has been chosen for 175 GeV operation is shown in Figure 2. It combines four dipole magnets and two main quadrupoles in a 50 m long FODO cell.

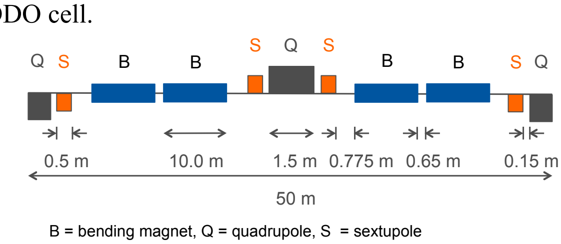

Figure 2: FODO cell chosen for the arc design. The cell parameters are optimised for maximum dipole fill factor and design emittance.

Applying the usual scaling laws for the beam emittance of lepton rings, the dispersion and the arc beta function,

$$\varepsilon = \left(\frac{\delta p}{p}\right)^2 \left(\gamma D^2 + 2\alpha D D' + \beta D'^2\right) \qquad (1)$$

$$\hat{D} = \frac{\ell^2}{\rho} * \frac{\left(1 + \frac{1}{2}\sin\frac{\psi_{cell}}{2}\right)}{\sin^2\frac{\psi_{cell}}{2}}$$

Abstract

The FCC (Future Circular Collider) study represents a vision for the next large project in high energy physics, comprising an 80–100 km tunnel that can house a future 100TeV hadron collider. The study also includes a high luminosity e^+e^- collider operating in the centre-of-mass energy range of 90–350 GeV as a possible intermediate step, the FCC-ee. The FCC-ee aims at definitive electro-weak precision measurements of the Z, W, H and top particles, and search for rare phenomena. Although FCC-ee is based on known technology, the goal performance in luminosity and energy calibration make it quite challenging. During 2014 the study went through an exploration phase. The study has now entered its second year and the aim is to produce a conceptual design report during the next three to four years. We here report on progress since the last IPAC conference.

INTRODUCTION

The discovery of the Higgs boson with a mass of around 125 GeV has recently revived interest in circular colliders [1]. The FCC-ee study reported here was kicked off in February 2014. It is an ambitious project that aims to perform physics studies in a variety of different beam energies, the main ones being 45 GeV for precision studies of the Z boson, 80 GeV for precision studies of the W, 120 GeV for the Higgs and 175 GeV for the top quark. Other beam energies might also be needed (notably a monochromatic run at 63 GeV is being investigated). Running at different energies requires different machine configurations and parameter sets have already been published [2] to serve as a baseline. For instance, the 45 GeV running is characterised by high beam current (1.5 A) putting stringent requirements to the power couplers of the RF system. On the other hand, the 175GeV running is characterised by the need for very low emittances to mitigate the beamstrahlung problem and relatively high total RF voltage (12 GV). High momentum acceptance is also needed for high energy running (175 GeV and to a lesser extend 120 GeV), also to mitigate the beamstrahlung effects. The parameter set already published is expected to evolve as more performant solutions are being engineered. The largest potential improvement is the development of the 'crab waist' interaction region scheme, where a large crossing angle (30 mrad) and crab sextuples allow for beam-beam parameters much larger than with the head-on baseline scheme, resulting in much higher luminosity at the Z running and modest gains all the way up to the Higgs running. The past year was explicitly intended to be an exploratory phase without the aim for convergence on a specific solution. Nevertheless, work in a number of areas has resulted in multitude of papers submitted for presentation at IPAC15, which this contribution aims to summarise.

CIVIL ENGINEERING

The civil engineering team at CERN are investigating the feasibility of an 80 km – 100 km tunnel in the Geneva basin to house the FCC machines [3]. Like any civil engineering feasibility study for a large-scale project, one of the major challenges is the management and manipulation of an enormous amount of spatial data. A feasibility study is an inherently iterative process as new data comes to light and parameters of the study evolve.

The traditional approach therefore requires significant resources in terms of time and man-power. However, to more effectively and efficiently conduct the study, CERN is employing the use of a specially designed interactive tool, containing a 3D geological model of the Geneva basin. The Tunnel Optimisation Tool (TOT) has been developed and is based on commercially available Geographical Information System (GIS) software.

A tunnel design is uploaded to TOT and positioned within the geology of the Geneva basin. The tool then outputs key information for a given setup including the geology intersected by the tunnel, the shaft depths, interaction with the built-environment, including buildings and geothermal boreholes and interaction with the environment including environmentally protected areas.

Another challenge for the study has been making a quantitative comparison between different solutions. Given the high number of variables and multiple objectives for optimisation (minimise shaft depths, minimise tunnel length in limestone, minimise length and slope of injection tunnels from the LHC, etc.), some form of detailed analysis is required. Comparison also needs to not only be made between two positions of the same tunnel but also between two tunnels of different circumference.

A list of factors related to the cost/risk of construction of each element of the FCC project (tunnel, shafts and caverns) have been compiled which are based on engineering experience of tunnelling projects. The data from TOT is extracted and multiplied by the relevant factor, giving a total cost/risk value to any given solution.

An alternative method of analysis is also under investigation. This is the use of an optimisation algorithm,

COMBINED OPERATION AND STAGING FOR THE FCC-ee COLLIDER*

M. Benedikt†, B. Holzer, E. Jensen, R. Tomas, J. Wenninger, F. Zimmermann, CERN, Geneva Switzerland; A. Bogomyagkov, E. Levichev, D. Shatilov, BINP, Novosibirsk, Russia

Abstract

FCC-ee is a proposed high-energy electron positron circular collider that might initially occupy the 100-km FCC tunnel which would eventually house the 100 TeV FCC-hh hadron collider. The parameter range for the e^+e^- collider is large, operating at c.m. energies from 90 GeV (Z-pole) to 350 GeV ($t\bar{t}$ production) with beam currents ranging between 1.5 A and 7 mA, at fixed synchrotron radiation power of 50 MW per beam, and the radiative energy loss varying from about 30 MeV/turn to 7500 MeV/turn. This presents challenges for the radiofrequency (rf) system due to the varying rf voltage requirements and beam loading conditions. In this paper we present a possible gradual evolution of the FCC-ee complex by step-wise expansion, and possibly reconfiguration, of the superconducting rf system and of the optics. The performance attainable at each step is discussed, along with possible advantages and drawbacks.

PHYSICS GOALS AND ENERGIES

The highest priority of a potential future e^+e^- collider in the 100-km FCC tunnel is Higgs production at a centre-of-mass energy of about 240 GeV corresponding to the peak rate of $e^+e^- \to ZH$ events. The second FCC-ee priority is running on the Z pole (91 GeV c.m.) with exceptionally high luminosity in order to generate 10^{12}–10^{13} Z's over a couple of years. Further FCC-ee collision energies will be at the $t\bar{t}$ threshold ($\sim$ 350 GeV c.m.), at the WW threshold, and possibly, with energy monochromatization, on the $e^+e^- \to H$ resonance ($\sim$125 GeV). The baseline physics program assumes no longitudinal polarization. However, scaling from LEP experience, some transverse polarization of non-colliding bunches is expected at the Z and up to the WW threshold, which can be used for precise calibration of the beam energy.

PARAMETERS AND OPERATION MODES

The number of FCC-ee interaction points (IPs) could be 2 or 4. A model used to describe the performance of LEP [1] suggests that with two collision points the maximum beam-beam tune shift and the luminosity per IP could be about 40% higher than with four collision points. However, the collision conditions for many of the FCC-ee scenarios are rather different from those at LEP. Preliminary weak-strong simulations for FCC-ee indicate a weaker dependence on the number of IPs, i.e. only a 10–20% gain in the maximum beam-beam tune shift at 240 GeV c.m. with 2 instead of 4 IPs [2] and even less (or no) gain at 91 GeV c.m. However, our further discussion assumes two IPs.

For constant synchrotron radiation power, e.g. 50 MW per beam, at lower beam energy the beam current increases as the inverse fourth power of energy. The much higher beam current at lower energy implies a correspondingly increased number of bunches.

Indeed, the requirements on the rf system differ substantially at low and high energies. On the Z pole the beam current is about 1.5 A, but the energy loss per turn only some 30 MeV and the rf voltage required is moderate. The cavity impedance is a concern for this mode of operation [3]. In consequence, the smallest number of cavities which can still provide 2×50 MW to the beams would be desired. Conversely, when running at the ZH peak or at the $t\bar{t}$ threshold the beam current is much lower, 30 or 7 mA, but the energy loss per turn amounts to 1.7 or 7.6 GeV, respectively, calling for a total rf voltage of up to 11 GV. Because of the lower beam current and higher beam energy, the cavity impedance is less of a concern here. Therefore, a staging where cavity modules are installed in steps appears natural.

The geometric emittance from the arcs scales as $\theta_b^3\gamma^2$ [4], where θ_b denotes the bending angle per arc cell and γ the Lorentz factor. The natural emittance decrease at lower energy can be counteracted by choosing longer optical cells in the arcs. The baseline parameter set of FCC-ee [5] assumes a 50-m arc FODO cell length, required for ZH and $t\bar{t}$ running, a 100 m cell length for the WW threshold and a 300-m cell length at the Z pole [6]. The increased cell length at lower energies allows for the geometric emittance to stay roughly constant or even to increase, at similar bunch charge, in order for the beam-beam tune shift to remain at, or below, the expected energy-dependent limit [1].

If the cell length is held constant, equal to 50 m, at the lower beam energies the emittance shrinks substantially. In this case the beam-beam tune shifts can still be kept under control, however, with the help of a large crossing angle, complemented by crab-waist sextupoles. In such a crab-waist scenario, the luminosity at the Z pole is about an order of magnitude higher than for the baseline [7]. The low-emittance crab-waist running implies extremely small vertical emittance values. Table 1 compares some example parameters (based on analytical calculations, and not fully optimized) for the proposed schemes at two beam energies.

It may be possible to further reduce the rf voltage, much

FCC-hh HADRON COLLIDER — PARAMETER SCENARIOS AND STAGING OPTIONS*

M. Benedikt†, B. Goddard, D. Schulte, F. Zimmermann, CERN, Geneva, Switzerland;
M.J. Syphers, MSU, East Lansing, U.S.A.

Abstract

FCC-hh is a proposed future energy-frontier hadron collider, based on dipole magnets with a field around 16 T installed in a new tunnel with a circumference of about 100 km, which would provide proton collisions at a centre-of-mass energy of 100 TeV, as well as heavy-ion collisions at the equivalent energy. The FCC-hh should deliver a high integrated proton-proton luminosity at the level of several 100 fb^{-1} per year, or more. The challenges for operating FCC-hh with high beam current and at high luminosity include the heat load from synchrotron radiation in a cold environment, the radiation from collision debris around the interaction region, and machine protection. In this paper, starting from the FCC-hh design baseline parameters we explore different approaches for increasing the integrated luminosity, and discuss the impact of key individual parameters, such as the turnaround time. We also present some injector considerations and options for early hadron-collider operation.

BASELINE PARAMETERS

The FCC hadron collider FCC-hh will provide pp collisions at a centre-of-mass energy of 100 TeV using 16-T Nb_3Sn magnets in a tunnel of about 100 km circumference (FCC-hh baseline) [1, 2, 3, 4].

The FCC design beam current of 0.5 A is about equal to the LHC design and obtained with 10^{11} protons per bunch at a bunch spacing of 25 ns. An alternative parameter set with a reduced bunch spacing of 5 ns and correspondingly scaled charge and emittance will also be explored.

Scaling the interaction region from the LHC design, the free distance from the interaction point (IP) is increased, from 23 m to more than 40 m, and the IP beta function is doubled, to $\beta^*_{x,y} = 1.1$ m. With these parameters the FCC baseline luminosity becomes 5×10^{34} cm^{-2}s^{-1}, equal to the luminosity of the High-Luminosity LHC (though with more energetic collision debris), and, as for the HL-LHC, the integrated luminosity per year is about 250 fb^{-1}, assuming 180 days per year scheduled for physics operation, and an availability of 70%.

PHYSICS GOALS

The key physics goals of the FCC are the complete exploration of the Higgs boson and a significant extension, via direct and indirect probes, of the search for physics phenomena beyond the Standard Model [5]. The baseline FCC-hh integrated-luminosity goal of 3 ab^{-1} translates into a discovery reach of about 32 TeV for Standard-Model like couplings. Raising the luminosity by a factor of 10 increases the discovery reach only by about 20% in energy. The higher luminosity leads to much increased event rates, and better statistics, at low masses, and would, for example, allow measuring the Higgs self coupling to better than 5%. Synthesizing the discussions from several theory workshops, an ultimate integrated luminosity goal of 10–20 ab^{-1} for the FCC-hh seems well justified [5].

INCREASING INTEGRATED LUMINOSITY

The FCC-hh luminosity can be increased in a number of ways. First, the IP beta function may be reduced. An advanced interaction-region (IR) optics is already being developed, which can reach $\beta^*_{x,y} = 30$ cm [6], yielding almost a factor 4 gain in peak luminosity. Second, the beam-beam limit of $\Delta Q_{\rm tot} = 0.01$ assumed in the baseline, appears conservative as the LHC and the Tevatron have routinely been running with two times larger values, and as more than three times higher tune shifts have been obtained in LHC beam experiments without any noticeable impact on beam lifetime or emittance growth [7]. Much stronger radiation damping at the FCC-hh (transverse emittance damping time of 1 h) might further boost the achievable beam-beam tune shift if the effect of the radiation damping is similar to the one found on lepton colliders [8]. In addition, head-on beam-beam compensation by electron lenses, recently demonstrated at RHIC [9], is likely to support even higher tune shifts. For all the above reasons we consider the possibility of a total beam-beam tune shift as high as $\Delta Q_{\rm tot} = 0.03$ (sum of two IPs). Third, we assume that the initial turnaround time t_{ta} (the period from the end of one physics fill to the start of the next physics collisions) can be reduced from 5 hours in the baseline to 4 h, after a couple of years of beam operation.

Based on the above considerations we envisage two operational phases of the FCC-hh. “Phase 1” corresponds to the baseline with a peak luminosity of 5×10^{34} cm^{-2}s^{-1} and an average luminosity production of 250 fb^{-1} per year. “Phase 2” achieves about a factor 6 higher peak luminosity of $\sim 3 \times 10^{35}$ cm^{-2}s^{-1} and produces more than 1000

FCC-ee: ENERGY CALIBRATION

M. Koratzinos, A. Blondel, University of Geneva, Geneva, Switzerland; E. Gianfelice-Wendt, Fermilab[1], Batavia IL, USA; F. Zimmermann, CERN, Geneva, Switzerland.

Abstract

The FCC-ee aims to improve on electroweak precision measurements, with goals of 100 keV on the Z mass and width, and a fraction of MeV on the W mass. Compared to LEP, this implies a much improved knowledge of the centre-of-mass energy when operating at the Z peak and WW threshold. This can be achieved by making systematic use of resonant depolarization. A number of issues have been identified, due in particular to the long polarization times. However the smaller emittance and energy spread of FCC-ee with respect to LEP should help achieve a much improved performance.

INTRODUCTION

Accurate energy determination is a fundamental ingredient of precise electroweak measurements. In the case of LEP1 the centre of mass energy at and around the Z peak was known with an accuracy of around 2×10^{-5}. The exact contribution of the energy error to the mass and the width of the Z are presented in [1].

The proposed circular collider FCC-ee [2] is capable of delivering statistics a factor ~10^5 larger than LEP at the Z and WW energies, therefore there is a need not only to achieve similar performance as far as energy determination is concerned, but to do significantly better.

The beam energy of large storage rings continuously changes due to internal and extraneous causes. This evolution can be modelled, but energy changes are many orders of magnitude larger than the instantaneous accuracy of a depolarization measurement. For example, small changes in the diameter of the ring due to elastic deformations of the earth's crust (due to, for instance, tidal forces) can have a big effect on the energy of the electrons and positrons. This is due to the small momentum compaction factor α_c which relates changes in energy to changes in the orbit length of a storage ring:

$$\frac{\Delta E}{E} = -\frac{1}{\alpha_c}\frac{\Delta L}{L} \tag{1}$$

where L is the orbit length. Table 1 shows changes in energy for a $4\cdot10^{-8}$ circumference change (typical for tide-induced changes) for LEP and FCC-ee.

The many other effects that contribute to energy changes are discussed in [3]. None of them has a very fast changing component, so monitoring the energy every ~10 minutes would ensure a negligible extrapolation error.

The RF configuration can give rise to different energies at the IPs and for electrons and positrons, as can the slightly different orbit for the separated rings, therefore both species should be measured, something that was not done at LEP.

Table 1: Change in energy of a 45GeV beam for a circumference change of $\mathbf{4\cdot10^{-8}}$

Storage ring	Circumference (km)	α_c	ΔE (MeV)
LEP	27	$2\cdot10^{-4}$	9
FCC-ee	100	$5\cdot10^{-6}$	360

The only method that can provide the accuracy needed is the so-called resonant depolarization technique [3], each measurement of which has an instantaneous accuracy of O(10^{-6}). It is based on the fact that the spin of an electron in a storage ring (in a perfectly planar machine and in the absence of solenoids) will precess $a\gamma$ times for one revolution in the storage ring, where a is the anomalous magnetic moment and γ the Lorenz factor of the electron and therefore the spin tune ν is

$$\nu = a\gamma = \frac{aE}{mc^2} = \frac{E[MeV]}{440.6486(1)[MeV]} \tag{2}$$

Deviations from the above formula are small and are discussed in [4] and [5]where they were found negligible for LEP, but should be revised in view of the much improved precision aimed at the FCC-ee.

The average of all spin vectors in a bunch is defined as the polarization vector $\vec{P}$. Therefore the average energy of a bunch can be computed by selectively depolarizing a bunch of electrons or positrons which have been polarized to an adequate level and measuring the frequency at which this depolarization occurs. Beam polarization is usually measured by laser polarimeters which exploit the spin dependence of the Compton scattering cross section. The accuracy with which the instantaneous average energy of the bunch is computed using this method is O(100KeV) – a value much smaller than the beam energy spread.

TRANSVERSE POLARIZATION

Electron and positron beams in a storage ring naturally polarize due to the Sokolov-Ternov effect [6]. For the purposes of energy calibration, important figures of merit are the asymptotic value of polarization that can be reached and the time constant of polarization build-up.

The maximum achievable polarization value is given by the theory as

$$P_{max} = \frac{8}{5\sqrt{3}} \cong 0.924 \tag{3}$$

BEAM CLEANING IN EXPERIMENTAL IRS IN HL-LHC FOR THE INCOMING BEAM*

H.Garcia-Morales†, Royal Holloway University of London, United Kingdom
R. Bruce, S. Redaelli, CERN, Geneva, Switzerland

Abstract

The HL-LHC will store 675 MJ of energy per beam, about 300 MJ more than the nominal LHC. Due to the increase in stored energy and a different interaction region (IR) optics layout, the collimation system for the incoming beam must be revisited in order to avoid dangerous losses that could cause quenches or machine damage. This paper studies the effectiveness of the current LHC collimation system in intercepting cleaning losses close to the experiments in the HL-LHC. The study reveals that additional tertiary collimators would be beneficial in order to protect not only the final focusing triplets but also the two quadrupoles further upstream.

INTRODUCTION AND MOTIVATION

The optics of the HL-LHC [1] is based on the Achromatic Telescope Squeezing (ATS) scheme [2]. This scheme allows to push the LHC nominal β^* to about 15 cm at IP1 and IP5. The reduction of β^* implies an increase of the β-function at the Final Triplet (FT) region, as well as in the matching section. In addition, the bunch charge and consequently the stored energy in the beam is aimed to increase by almost a factor 2. Therefore, it is foreseen to replace the FT and the quadrupoles Q4 and Q5 by new magnets with larger apertures. Nevertheless, the available normalized aperture is tight, which might expose these magnets to beam losses that could potentially cause quenches. Therefore, the collimation system must be revisited in order to ensure acceptable loss levels.

MACHINE CONDITIONS

The betatron cleaning insertion allows to limit the transverse extension of the beam halo by "cleaning" particles with large betatron amplitudes. The momentum cleaning system catches the longitudinal losses induced by off-momentum particles. The whole system provides a multistage cleaning [3,4] with primary collimators closest to the beam, followed by secondary collimators. Special attention must be put in the Interaction Regions (IRs) in order to avoid high levels of beam background deposited in the detector and possible quenches and damages in the FT due to the aperture bottleneck. For that reason, additional tertiary collimators (TCTs) are introduced just upstream of the FT.

The collimation performance is assessed in simulations using SixTrack [5, 6] and quantified in terms of the local cleaning inefficiency η, defined as the ratio of the local losses N_{loc} over a distance Δs to the total losses on collimators N_{tot} [7],

$$\eta = \frac{N_{\mathrm{loc}}}{N_{\mathrm{tot}}\Delta s} \tag{1}$$

Table 1: Nominal TCT Openings at Different IRs.

	IR1	IR2	IR5	IR8
$n_{\mathrm{TCT}}[\sigma]$	8.3	30	8.3	30

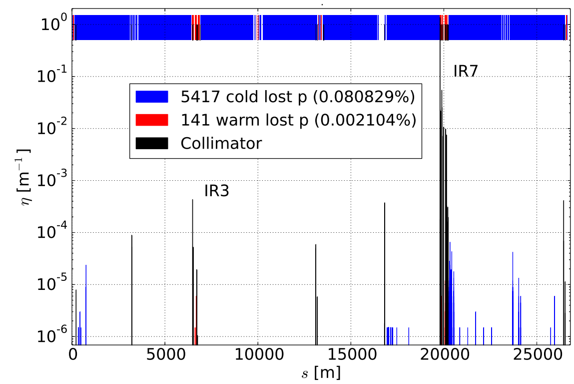

Figure 1: Example of a loss map representing the losses along the ring for Beam1 considering nominal apertures and Tertiary collimators in their nominal setting (8.3σ). Black lines represent losses in collimators, blue lines losses in cold regions and red lines are losses in warm regions.

In Fig. 1 the loss map for the HL-LHC version 1 optics and $\beta^* = 15$ cm for beam 1 and horizontal halo (initial losses on horizontal TCP), as simulated with SixTrack, is shown under nominal collimator configuration. The betatron (IR7) and momentum cleaning (IR3) insertions are clearly identified with large black spikes representing losses in collimators. Blue and red spikes represent losses in cold and warm regions respectively.

QUADRUPOLE APERTURE SCAN

The FT aperture represents a key parameter in the upgrade of the LHC optics towards the HL-LHC. In order to evaluate the beam losses, we have performed simulations using SixTrack where magnet aperture has been reduced as an effective approach to take into account several sources of errors. Pessimistic conditions of the machine such as alignment, orbit and optics errors can be seen as an effective aperture reduction.

The magnet aperture in IR1 and IR5 have been scanned individually for different magnets of the FT as well as Q4

BEAM INDUCED BACKGROUND SIMULATION STUDIES AT IR1 WITH NEW HIGH LUMINOSITY LHC LAYOUT*

R. Kwee-Hinzmann†, S. M. Gibson, John Adams Institute at Royal Holloway
University of London, Egham, UK
R. Bruce, F. Cerutti, L.S. Esposito, A. Lechner, CERN, Geneva, Switzerland

Abstract

In the High Luminosity LHC (HL-LHC), the collimation system will be upgraded in the high-luminosity experimental regions. Additional protection is planned for the Q4 and Q5 magnets that are located further upstream of the tertiary collimators that protect the inner triplet magnets. We evaluate the effect of this proposed collimation layout for the incoming beam 1 on machine-induced background in the experimental area of IR1 (ATLAS). The main scenario is the round optics with β^* of 15 cm, but a flat scenario is also briefly discussed.

INTRODUCTION

The High Luminosity (HL) LHC is a major upgrade project to produce in total 3000 fb^{-1} integrated luminosity for each, ATLAS and CMS, starting installation around 2023 [1]. In particular, the upgrade plans affect the experimental insertion regions (IR) IR1 and IR5, housing ATLAS and CMS respectively, to reach higher luminosities. The optics have been re-designed (ATS – achromatic telescopic squeeze – optics [2]) and require e.g. larger-aperture magnets for squeezing the optics to 15 cm in the horizontal and vertical plane at the high-luminosity interaction points (IPs) 1 and 5 in order to achieve the luminosity goal. New possible aperture bottlenecks arise due to HL-LHC layout changes, and the quadrupoles Q5 and Q4 may no longer be sufficiently protected, see also Fig. 1. To address this, the collimation system [3, 4] will be upgraded in the experimental IRs. While these upgrades are in detailed in [5], the focus of this paper is on upgrade plans for the incoming beam. The new layout forsees to place in cell 5 a vertical and horizontal tertiary collimator (TCT5s for TCTH.5 and TCTV.5). As they are further away from the exisiting horizontal and vertical collimators (TCT4s that are TCTH.4 and TCTV.4), as illustrated in Fig. 1, they could help reducing beam-induced halo background. This paper presents a first estimate of the reduction based on simulations.

BEAM HALO BACKGROUND

Beam particles in the accelerator oscillate around an ideal orbit but diffuse out the beam core due to various beam dynamics effects (e.g. particle-particle scattering within a bunch, interactions between colliding bunches, scattering with residual gas-molecules) forming the *beam halo* and unavoidable losses. The task of the collimation system is to

TCSG7	7	7.7
TCT IR1/5	8.3	10.5

safely remove these halo particles in two dedicated insertion regions, IR7 for betatron and IR3 for momentum cleaning [3, 4]. Tertiary collimators (TCTs) in IR1 and IR5 complement the IR7/3 collimators and are installed to protect the inner triplet magnets. Halo protons leaking from IR7/3, should mostly be stopped by the TCTs. While interacting with the collimator material, they produce particle showers that contribute to the machine-induced halo background. This background source is considered in the following.

BEAM HALO SIMULATION SETUP

The simulation is performed in two parts, analogue to [7]. First, a tracking code, SixTrack [8], is used to track halo proton distributions customised by the user through a magnetic field lattice, see also [9]. The beam halo is usually simulated in horizontal (h) and vertical (v) distributions. When a collimator is hit, a built-in, recently updated Monte-Carlo model [10] decides on the physics process. Protons continue in the lattice until they dissociate in an inelastic interaction with the collimator material or (in a post-processing step) are lost on the aperture. As a result, loss locations around the ring can be identified and protons lost on the TCTs serve in second step as an initial distribution in FLUKA [11, 12].

Two cases were simulated, TCT4s only and TCT4s + TCT5s, to quantify the effect of the TCT5s for incoming beam 1 (B1). Inelastic interactions are forced in FLUKA at locations given by SixTrack on the TCT4s and (when included) TCT5s which generate a particle flux towards the experiment. All shower particles are recorded at the machine-detector interface plane at 22.6 m from the IP.

HL-LHC SIMULATION SCENARIOS

We assume the nominal HL-LHC scenario with 2.2×10^{11} protons per bunch, 2736 bunches per beam, 25 ns bunch spacing and a beam energy of 7 TeV. For the study of colli-

SIMULATION OF HOLLOW ELECTRON LENSES AS LHC BEAM HALO REDUCERS USING MERLIN*

H. Rafique†, R. J. Barlow, University of Huddersfield, Huddersfield, UK
R. Appleby, S. Tygier, University of Manchester, Manchester, UK
R. Bruce, S. Redaelli, CERN, Geneva, Switzerland

Abstract

The Large Hadron Collider (LHC) and its High Luminosity (HL) upgrade foresee unprecedented stored beam energies of up to 700 MJ. The collimation system is responsible for cleaning the beam halo and is vital for successful machine operation. Hollow electron lenses (HELs) are being considered for the LHC, based on Tevatron designs and operational experience [1], for active halo control. HELs can be used as soft scraper devices, and may operate close to the beam core without undergoing damage [2]. We use the Merlin C++ accelerator libraries [3] to implement a HEL and examine the effect on the beam halo for various test scenarios.

INTRODUCTION

HELs are novel devices which generate and control a hollow beam of electrons through an accelerator beam pipe. By directing the accelerator beam through the HEL beam, one may achieve various effects via the electromagnetic interaction. At the Tevatron, electron lenses (ELs) have been used for beam beam compensation (solid electron beam) [4], removal of beam from the abort gap (solid electron beam) [5], and halo scraping (hollow electron beam) [2].

It was originally proposed [6] that ELs could be used for tune spreading, satellite bunch removal, and halo scraping in the LHC. When combined with a multi-stage collimation scheme such as that in the LHC, HELs become an enhancer, increasing the diffusion, and the impact parameter of halo particles hitting the primaries [7].

The benefits of a HEL in a collimation scheme are numerous; firstly the electron beam is well controlled, and has many operation modes that may enhance the collimation of halo particles. The HEL beam can intercept the machine beam at a greater insertion (lower σ) than a solid scraper, as there is no heat load to manage, and no effect on machine impedance. The HEL can be switched on and off whereas a solid scraper would need to be inserted, and though both require alignment setup, the HEL may be used on a turn by turn, or even bunch by bunch basis. This means that the HEL can be used to deplete the halo, so that beam losses are minimised in the case of a rapid orbit jitter or crab cavity failure in HL-LHC.

MERLIN HEL MODEL

Merlin makes a number of assumptions when modelling the HEL:

- Fringe fields are ignored.
- Multipole field components created by e^- beam asymmetries are ignored.
- The e^- beam is azimuthally symmetric.
- Edge effects from the HEL beam are ignored (transverse area of interest ≈ few mm, longitudinal ≈ few m).
- Only the active part of the HEL is considered (toroids and solenoids are ignored).
- The HEL is run such that the electrons travel in the same direction as the proton beam, so that the HEL kick given to a machine particle is focussing.

Implementation

For a HEL of length L, with electron beam current I, the kick for a particle at a transverse displacement r, neglecting the electron radial profile is given by Eq. 1 [8].

$$\theta_{max}(r) = \frac{1}{4\pi\epsilon_0 c^2} \frac{2LI(1+\beta_e\beta_p)}{(B\rho)_p\beta_e\beta_p} \frac{1}{r} \tag{1}$$

where β_e and β_p are the Lorentz β of the HEL electron beam, and machine proton beam respectively, and $(B\rho)_p$ is the proton beam rigidity.

Including the electron radial profile, the kick may be reduced, for example for a perfect HEL profile (uniform between R_{min} and R_{max} and axially symmetric) it is given by Eq. 2 [8].

$$\theta_{kick} = \begin{cases} 0, & r < R_{min} \\ \frac{r^2-R^2_{min}}{R^2_{max}-R^2_{min}}\theta_{max}, & R_{min} < r < R_{max} \\ \theta_{max}, & r > R_{max} \end{cases} \tag{2}$$

Merlin contains both this perfect profile and a more realistic radial profile, based on the parameterisation of the measured beam profile [9]. The kicks for both profiles are shown in Fig. 1. R_{min} and R_{max} were set to 4 and 6.8 σ respectively.

In practice integration of a HEL into the LHC is non-trivial . The HEL is a superconducting device and therefore needs access to the LHC's high pressure He supply. As the HEL operates on one LHC beam, space between the two beam lines is required. Two candidate locations have been identified as RB-44 and RB-46, both in IR4, either side of the RF insertion [10]. Using Merlin, a HEL was implemented into the LHC lattice at RB-46. The optics parameters are shown in Table 1.

Operation Modes

The Merlin HollowElectronLensProcess offers 4 operation modes, similar to the HEL model in SixTrack [11].

STRONG-STRONG SIMULATIONS OF β^*-LEVELLING FOR FLAT AND ROUND BEAMS

M. Crouch, University of Manchester and The Cockcroft Institute, U.K.
B. D. Muratori, ASTeC, STFC Daresbury Laboratory and The Cockcroft Institute, U.K.
R. B. Appleby, University of Manchester and The Cockcroft Institute, U.K.

Abstract

Simulations of β^* luminosity levelling using the strong-strong beam-beam code *COMBI* are undertaken. Simulations for both flat and round beam profiles are discussed and analysed with respect to the coherent spectra. It is shown that bunches with a round beam profile will have a beam-beam parameter that is independent of β^* over the levelling steps. Flat bunches however will have a beam-beam parameter that is dependent on β^* over the levelling steps since the beam aspect ratio will change. This will change the tune of the π-mode as the β^* is levelled, which could lead to a resonance crossing.

INTRODUCTION

The High Luminosity Large Hadron Collider (HL-LHC) upgrade will allow the LHC to reach ever higher luminosities. However an increase in luminosity will lead to higher "pile up" in the machine detectors. To prevent higher "pile up" in the machine detectors luminosity levelling has been suggested, which will hold the luminosity constant over the duration of a physics run. There are a number of suggested methods of levelling the luminosity, although β^*-levelling at IP1 and IP5 (Interaction Point) in combination with offset levelling at IP8 are the baseline methods of luminosity levelling [1]. Levelling by reducing the β^* as the luminosity decays exponentially will hold the longitudinal vertex density constant throughout the process for head on collisions. This is required by the detectors.

Flat beams have been proposed as an alternate method of operation if crab cavities are not installed in the HL-LHC. Flat beams will provide a low β-function at the IP, allowing higher luminosities to be reached.

In this paper, results from luminosity levelling using a 4D strong-strong beam-beam code are discussed and analysed for the case of β^*-levelling without offset using the Soft Gaussian approximation. Here a constant bunch intensity is assumed, resulting in a luminosity increase as the β-function at the IP changes.

LEVELLING MATRIX

Since the action of changing the β-function at the IP is an adiabatic process, the emittance in both planes should be conserved before and after the levelling step. To describe this within the code, a levelling matrix is applied such that as the spatial component of the particle phase space is reduced, the momentum of the particle phase space is increased. This can be derived by considering the phase space ellipse and the particle spatial and momentum components. The initial particle position and momentum can be expressed as a function of the β^* before and after the levelling step. The beams are focused in the transverse spatial components, which is given by

$$\frac{u_1}{u_2} = \sqrt{\frac{\beta^*_{1,u}}{\beta^*_{2,u}}} \tag{1}$$

where $u = x, y$ and the subscripts 1, 2 indicate before and after the levelling step. Likewise in the transverse momentum plane, the particles undergo a defocusing given by

$$\frac{p_{u,1}}{p_{u,2}} = \sqrt{\frac{\beta^*_{2,u}}{\beta^*_{1,u}}}. \tag{2}$$

The levelling map can be expressed as a matrix and is given by

$$\begin{pmatrix} u_2 \\ p_{u,2} \end{pmatrix} = \begin{pmatrix} \sqrt{\frac{\beta^*_{2,u}}{\beta^*_{1,u}}} & 0 \\ 0 & \sqrt{\frac{\beta^*_{1,u}}{\beta^*_{2,u}}} \end{pmatrix} \begin{pmatrix} u_1 \\ p_{u,1} \end{pmatrix}. \tag{3}$$

This matrix is applied between the levelling steps in both the horizontal and vertical plane to ensure that the emittance is conserved.

In this article, flat and round beam profiles were investigated to determine any possible emittance growth that may arise due to the levelling process. Only head on collisions at a single IP were simulated, although multiple IP collisions are undergoing investigation. Introducing an asymmetry between planes such that $\beta^*_x \neq \beta^*_y$ allows the flat beam option to be studied for the simple case of a single head on collision per turn at one IP. The β-function at the IP was reduced every $500K$ turns (approximately 44 seconds in the machine). The β-function at the IP for the round beam was reduced in steps of,

$$\beta^*_{x,y} = 0.60\ m \rightarrow 0.40\ m \rightarrow 0.20\ m \rightarrow 0.15\ m,$$

The β^* for the flat beam profile was reduced only in the vertical plane, in steps of,

$$\beta^*_y = 0.60\ m \rightarrow 0.40\ m \rightarrow 0.20\ m \rightarrow 0.10\ m \rightarrow 0.075\ m,$$

while the β-function at the IP in the horizontal plane is held constant at $\beta^*_x = 0.3$ m. Note that in these simulations, the bunch intensity is assumed to be held constant at $n_b = 2.2 \times 10^{11}$ protons per bunch. This provides a worse case scenario in terms of the beam-beam interaction. The starting parameters for the simulations are given by the HL-LHC parameters in Table 1,

A NEW ILC POSITRON SOURCE TARGET SYSTEM USING SLIDING CONTACT COOLING*

Wei Gai#, Darrell Scott Doran, Robert Erck, George Fenske, Victor Guarino, Wanming Liu
ANL, Argonne, IL 60439, USA

Abstract

The R&D of the baseline positron source target for ILC is still ongoing after TDR due to the uncertainty of rotating vacuum seal and water cooling system of the fast spinning target wheel. Different institutes around the globe have proposed different approaches to tackle this issue. A spinning target wheel system with sliding contact cooling has been proposed by ANL. The proposed system eliminated the needs of rotating vacuum seal by using magnet bearings and vacuum compatible motor driven solid spinning wheel target. The energy deposited from positron production process is taken away via sliding cooling pads sliding against the spinning wheel.

INTRODUCTION

The ILC baseline positron source [1] is a helical undulator based positron source which produces 2×10^{10} positrons per bunch at the IP with the nominal ILC bunch structure and pulse repetition rate. It is designed with a 50% overhead and can deliver up to 3×10^{10} at injection into the 0.075 mrad transverse dynamic apertures of the damping ring. The main electron linac beam has an energy that varies between 100 and 250 GeV and passes through ~150m of helical undulator, with a 1.15 cm period and a K value of 0.92. At 150 GeV, the first harmonic cut-off of the photon drive beam is 10.1 MeV and the beam power is ~63 kW. Approximately 4.4 kW of this power is deposited in the target in ~1mm rms spot. A windowless moving target is required to handle the high beam power and heat deposition.

The ILC baseline positron production target [1] is a rotating titanium alloy wheel. The target wheels sit in a vacuum enclosure at 10^{-8} Torr (needed for NC RF operation), which requires vacuum seals for access to the vacuum chamber. The rotating shaft penetrates the enclosure using one vacuum pass-through. The R&D of target remains on-going. Even though the vacuum specification of the rotating vacuum seal has been demonstrated, its lifetime and reliability still requires further R&D. Many alternative target schemes have been discussed by collaborating researchers around the globe. The simplest one have been discussed is to use differential pumping to replace the rotating vacuum seal and keep the current configuration of water cooling from inside the target wheel. This scheme could eliminate the possible failure of the vacuum but still have the potential mechanical problem associated the water cooling channels inside the target wheel. To further address the ILC positron source target issue, DESY group proposed a radiation cooling scheme [2] and ANL group proposed a discrete target system [3].

The discrete target system adopted the concept of EM rail gun to eliminated the mechanical motion coupler of any kind between inside and outside of vacuum and thus eliminated the potential life time and reliability problem of the current ILC target system. But it needs a larger scale of changing to the current ILC positron source layouts which is not preferred.

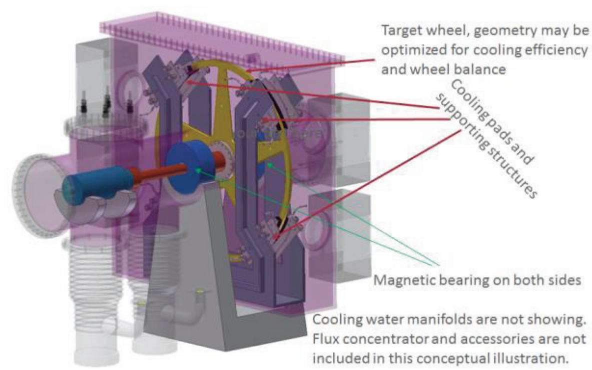

Figure 1: Conceptual illustration.

The original problem with the spinning wheel target is introduced as a result of water cooling from inside of the spinning target wheel. If we were not trying to cool the target from inside the spinning wheel, we won't need the rotational water union and thus eliminate the potential premature failure of the target system. The DESY group is working on the radiation cooling scheme. As a backup plan, we are looking into the sliding contact cooling scheme. The details of this sliding contact cooling scheme for ILC undulator based positron source are presented here in this paper.

GENERAL CONSIDERATIONS

As illustrated in Fig. 1, instead of cooling the target with water flow inside the target wheel, we use spring loaded cooling pads sliding against the target wheel and taking away the energy deposited in target resulting from positron production. Inside the cooling pads are cooling channels with cooling liquid flowing constantly. Since

AN ALTERNATIVE HIGH LUMINOSITY LHC WITH FLAT OPTICS AND LONG-RANGE BEAM-BEAM COMPENSATION *

Stéphane Fartoukh, CERN, Geneva, Switzerland, Alexander Valishev, FNAL, Batavia, IL, USA, Dmitry Shatilov, BINP, Novosibirsk, Russia

Abstract

In the baseline scenario of the High-Luminosity LHC (HL-LHC), the geometric loss of luminosity in the two high luminosity experiments due to collisions with a large crossing angle is recovered by tilting the bunches in the interaction region with the use of crab cavities. A possible backup scenario would rely on a reduced crossing angle together with flat optics (with different horizontal and vertical β^* values) for the preservation of luminosity performance. However, the reduction of crossing angle coupled with the flat optics significantly enhances the strength of long-range beam-beam interactions. This paper discusses the possibility to mitigate the long-range beam-beam effects by current bearing wire compensators (or e-lens). We develop a new HL-LHC parameter list and analyze it in terms of integrated luminosity performance as compared to the baseline. Further, we evaluate the operational scenarios using numerical simulations of single-particle dynamics with beam-beam effects.

INTRODUCTION

The HL-LHC is being designed to deliver an integrated luminosity of at least 250 fb^{-1}/year in each of the two high-luminosity LHC experiments, ATLAS and CMS [1, 2]. The ambitious performance target for ATLAS and CMS cannot be met without pushing to the extreme both the optics, namely β^* [3], and the beam parameters at the exit of the LHC injector chain [4]. It relies as well on a number of key innovative and challenging technologies, such as: (i) new larger aperture superconducting magnets in order to preserve the transverse acceptance of the two high-luminosity insertions at low β^*, and (ii) crab cavities, which are high-frequency RF transverse deflectors creating quasi head-on collisions at the interaction point (IP) despite of the crossing angle, hence preserving the luminosity gain with $1/\beta^*$. The instantaneous luminosity is however limited by several factors, in particular by the total number of interactions per bunch crossing (pile up) and its line density, which can rapidly degrade the quality of the data collected for the physics analysis. In this respect, the HL-LHC relies on a levelled luminosity not exceeding 5×10^{34} cm^{-2}s^{-1} for a 25 ns bunch spacing (about 2750 bunches per beam), and corresponding to about 140 pile up (PU) events on average per bunch crossing with a peak line density of 1.25 event/mm. This is achieved through the use of challenging

luminosity levelling techniques, presently via a gradual reduction of β^* in order to compensate for the proton burn off during the physics store. In order to sustain such a high luminosity over a typical period of 8-10 hours, the beam parameters, in particular the total beam current, shall correspond to a so-called virtual luminosity, which would be of the order of 2×10^{35} cm^{-2}s^{-1} should all the other parameters, for instance β^*, be pushed to the limit at the beginning of the levelling process. The aim of this paper is to propose an alternative set of parameters and scenarios in terms of optics and hardware needed, which stays competitive with the present HL-LHC baseline both in terms of physics data quantity (integrated performance) and data quality (pile up density).

PERFORMANCE REACH OF ALTERNATIVE SCENARIOS IN COMPARISON WITH THE BASELINE

The baseline parameters of the HL-LHC (25 ns version [5]) and two alternative scenarios are listed in Tab. 1. The list includes key values, such as the virtual luminosity (taking into account the hour-glass effect and the RF curvature

M. Chung, UNIST, Ulsan 689-798, Korea

Abstract

Characteristic of a helical lattice for six dimensional muon ionization cooling will be presented to utilize for a bright muon source. The beta function and the dispersion in the lattice are tunable by adjusting the helical magnetic component. As a result, the cooling decrements and the equilibrium beam emittance in transverse and longitudinal phase spaces are flexible. A helical magnetic component can be adjusted by changing the geometry of helical solenoid magnets. Manipulating a cooling path is an important capability in a bright muon source to serve a high quality muon beam for various muon beam applications.

INTRODUCTION

A bright muon source is an ultimate tool to realize precise measurements in high-energy particle experiments. Muons are a true elementary particle, hence background events in $\mu^+\mu^-$ collisions are significantly less complicated than hadron colliders. Since muons are 200 times heavier than electrons they can be accelerated to a multi-TeV energy without any synchrotron-radiation losses. Beamstrahrung is negligible in high energy $\mu^+\mu^-$ collisions, hence the energy spread in a multi-TeV muon collider is significantly narrower than that in electron-positron collisions. The s-channel Higgs boson production rate in $\mu^+\mu^-$ collisions is 40,000 times larger than in electron-positron colliders ($\sigma_{Higgs} \propto m^2_{l^+l^-}$). Thus, a muon collider Higgs factory is the only machine that can directly measure the mass width of Higgs bosons. Besides, a high energy muon storage ring provides an intense monochromatic neutrino beam.

Since muons are a tertiary particle the initial muon beam temperature after pion decays is too hot to admit the beam into the conventional accelerator complex. The beam should be cooled down to adequate temperature for a muon accelerator complex within a muon life time. To achieve fast cooling, a helical muon six-dimensional (6D) phase space ionization Cooling Channel (HCC) is proposed. Theoretically, the 6D beam volume can be reduced 10^6 in a 300 m-long HCC. It consists of a high-pressure H_2 gas-filled helical RF system which is incorporated into a helical magnet. Gas in the RF cavities acts as not only an ionization cooling matter but also buffering dark currents to achieve high RF gradients in multi-Tesla fields. The helical magnetic component is generated by using a helical solenoid coil. Since the HCC lattice is a continuous structure there is no betatron resonance. It realizes a huge momentum acceptance.

The helical solenoid coil is flexible to tune the beta function and the dispersion by adjusting the geometry of coil and adding the correction magnet [1]. The lattice parameters are the key to manipulate the cooling decrements and the equilibrium emittance in transverse and longitudinal phase spaces. We demonstrate the theoretical predictions for the phase space mapping to design the cooling path and a numerical evaluation at the specific cooling condition for conceptual design of the HCC.

FLEXIBILITY OF HCC

The HCC linear theory in a homogeneous cooling matter was derived by Derbenev and Johnson [2]. The theory was confirmed by comparing with various numerical results [3–5]. Figures 1 and 2 show the validation of HCC theory. We used G4Beamline in the simulation effort [6]. H_2 gas pressure is 160 atm at room temperature and 20 60μm-thick-Be RF windows per meter are equally distributed on the beam path. According to the theory, the transverse betatron

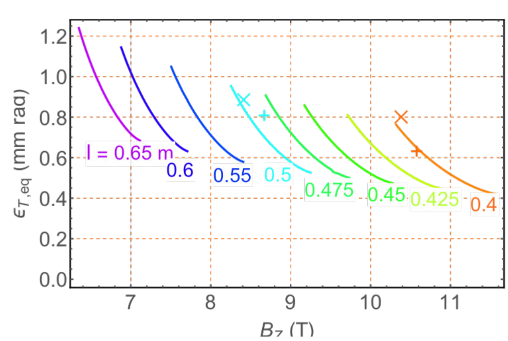

Figure 1: Prediction (a solid line) and the numerical result (a cross mark) of the transverse equilibrium emittance. Values in the plot represents the helical period, λ.

function, $\hat{\beta}_T$ is characterized by the helical period, λ and the solenoidal field strength, B_z, i.e. $\hat{\beta}_T$ is lower in shorter λ and/or stronger B_z. Therefore, lower equilibrium ε_T is made at shorter λ and/or stronger B_z and vice versa. On the other hand, the longitudinal betatron function, $\hat{\beta}_L$ is characterized by a momentum slip factor, η which is given by the dispersion, D. According to the theory, D becomes closer to the energy transition, i.e. $\eta \sim 0$ (isochronous) in stronger

BEAM-BEAM SIMULATION OF CRAB CAVITY WHITE NOISE FOR LHC UPGRADE*

J. Qiang#, LBNL, Berkeley, CA94720, U.S.A.
J. Barranco, T. Pieloni, CERN, Geneva, Switzerland
K. Ohmi, KEK, Tsukuba, 305-0801, Japan

Abstract

High luminosity LHC upgrade will improve the luminosity of the current LHC operation by an order of magnitude. Crab cavity as a critical component for compensating luminosity loss from large crossing angle collision and also providing luminosity leveling for the LHC upgrade is being actively pursued. In this paper, we will report on the study of potential effects of the crab cavity white noise errors on the beam luminosity lifetime based on strong-strong beam-beam simulations.

INTRODUCTION

The High Luminosity (HL) LHC upgrade [1], aims at a tenfold increase (3000 fb^{-1}) of the integrated luminosity by 2035 as compared to its initial goal (300 fb^{-1}). This will be achieved by an increase of the instantaneous luminosity by almost an order of magnitude and therefore we expect the beam to beam electromagnetic interactions (i.e. beam-beam effects) to become stronger. It is important to evaluate the potential impact of these effects on the beam quality (e.g. emittance) in the high luminosity upgrade. In the HL-LHC upgrade, crab cavities (CCs) are proposed to compensate for geometric luminosity loss due to the crossing angle operation in collision which will lead to a 70% loss of luminosity. On the other hand, crab cavities may also have a detrimental impact on the beam quality due to imperfections. Phase noise errors in the CCs lead to a fluctuation of the bunch centroid position at the interaction point, which causes emittance growth. Amplitude errors in the CCs cause bunch size fluctuations and emittance growth. Simulations were carried out to assess the implication of the phase errors for the LHC parameters [2, 3, 4]. New development in the HL LHC design parameters and the improvement of the simulation tool to include a transverse damper model [5] demands new simulations. In this paper we present the simulation results to study the effects of crab cavity phase and voltage white noise errors on the peak luminosity of colliding beams.

COMPUTATIONAL SETUP

All simulations presented in this study were done using a strong-strong collision model implemented in the code BeamBeam3D [6]. In order to reduce numerically induced emittance growth, and to gain computation speed, the fields were computed assuming a Gaussian particle distribution, instead of a self-consistent approach. This assumption is justified by the fact that the initial Gaussian particle distribution does not change significantly in a short period of time under stable conditions. In order to keep the residual noise level low, one million macroparticles were used. The particle distribution in the longitudinal direction was divided into 8 slices. Two collisions per turn, corresponding to the interaction points (IPs) 1 and 5 in the LHC, were simulated. The crossing plane was horizontal in one IP5 (CMS experiment) and vertical in the other IP (ATLAS experiment). Linear transfer maps, calculated using the working point tunes, were employed to transfer the beam between collisions. The crab cavities are located 90 degrees phase advance from each IP. To model the beam transport through the crab cavity, we have assumed a thin lens approximation where the transfer map in the *x*-*z* plane is given by

$$\begin{aligned} x^{n+1} &= x^n \\ P_x^{n+1} &= P_x^n + \frac{qV}{E_s}\sin(\omega z^n / c + \phi) \\ z^{n+1} &= z^n \\ \delta E^{n+1} &= \delta E^n + \frac{qV}{E_s}\cos(\omega z^n / c + \phi) x^n \end{aligned} \quad (1)$$

where V is the voltage of the crab cavity, E_s is the particle energy, ϕ is the phase of the cavity, and ω is the angular frequency of the cavity. A similar transfer map with x replaced by y is used in the y-z plane.

The damper model uses a Hilbert-notch filter and two pick-ups per beam and plane, as the actual system in LHC does [7]. The correction kick at turn n due to one pick-up is given by

$$\Delta X' \propto g \sum_m H_m(\varphi_H) \times (X_{n-d+1-m} - X_{n-d-m}), \quad (2)$$

where H_m are the coefficients of the Hilbert filter and φ_H is the phase that needs to be determined as a function of the tune and damper gain g, and d is the delay of the damper in the units of turns. The actual kick is the superposition of two terms associated with different pick-ups. In the simulation, the damper's gain was set to 0.05 at each pickup. Noise is inserted to match the measurement [5]. The detailed physical parameters used in the simulations are given in Table 1 [8].

EFFECTS OF CRAB CAVITY PHASE WHITE NOISE ERROR

Under ideal conditions, the crab cavity will compensate the crossing angle collision completely and there is no

STRONG-STRONG BEAM-BEAM SIMULATION OF BUNCH LENGTH SPLITTING AT THE LHC*

J. Qiang#, S. Paret, LBNL, Berkeley, CA 94720 USA
T. Pieloni, CERN, Geneva, Switzerland
K. Ohmi, KEK, Tsukuba, 305-0801, Japan

Abstract

Longitudinal bunch length splitting was observed for some LHC beams. In this paper, we will report on the study of the observation using strong-strong beam-beam simulations. We explore a variety of factors including initial momentum deviation, collision crossing angle, synchrotron tune, chromaticity, working points and bunch intensity that contribute to the beam particle loss and the bunch length splitting, and try to understand the underlying mechanism of the observed phenomena.

INTRODUCTION

LHC has made important scientific discovery since its beginning of operation. In some runs of 2012, it was observed that two colliding beams starting with similar longitudinal bunch length split up after some time due to selective transverse emittance blow-up that occurs at the end of the squeeze beam mode [1]. A study based on weak-strong simulation was reported last year [2]. In this paper, we have carried out strong-strong beam-beam simulations to understand the underlying mechanism that drives the bunch length splitting given the initial unequal transverse emittances of the two colliding beams [3].

COMPUTATIONAL SETUP

All simulations presented in this study were done using a strong-strong collision model implemented in the code BeamBeam3D [4]. In order to reduce numerically induced emittance growth, and to gain computation speed, the beam-beam fields were computed assuming a Gaussian particle distribution, instead of a self-consistent approach. This assumption is justified by the fact that the initial Gaussian particle distribution does not change significantly in a short period of time under stable conditions. One million macroparticles were used for each beam. The particle distribution along the longitudinal direction was divided into 8 slices. Two collisions per turn, corresponding to the Interaction Points (IPs) 1 and 5 in the LHC, were simulated. The crossing plane was horizontal at one IP and vertical at the other IP. Linear transfer maps, calculated using the working point tunes, were employed to transfer the beams between collisions. The damper model uses a Hilbert-notch filter and two pick-ups per beam and plane, as the actual system in LHC does [5]. The actual kick is the superposition of two terms associated with different pick-ups. An artificial 4 sigma aperture is assumed in the simulation to enhance the transverse particle losses from nonlinear beam-beam effects coming from the head-on and long range encounters in the LHC real configuration. This limit in aperture seems also a good choice since it is compatible with the expected dynamical aperture in the LHC during these observations [3]. The detailed physical parameters used in the simulations are given in Table 1.

Table 1: Physical Parameters used in the Simulations

Parameter	Value
N_p	1.5×10^{11}
$\varepsilon_{nb1}, \varepsilon_{nb2}$ / μm	2.5/3.5
β^* / m	0.6
σ / μm	18.8/22.2
σ_z / cm	9.74
Q_x	64.31
Q_y	59.32
Q_z	0.0019
θ / mrad	0.29
g_1, g_2	0.05/0.05
Damper noise	on
Collisions / turn	1 hor., 1 ver.

SIMULATION RESULTS

Using the above computational set-up, we carried out strong-strong simulations. Figure 1 shows the longitudinal rms bunch length evolution of two colliding beams with a machine chromaticity 15 and relative momentum deviation 0.0165%. The two beams starting with the same longitudinal bunch length split up after some time. Beam 1 is the beam with smaller emittance 2.5 mm, while beam 2 is the one with larger transverse emittance 3.5 mm. Due to the difference in emittance, beam 2 will experience different beam-beam effects from beam 1. The core of the beam 2 will see strong nonlinear beam-beam effects from the beam 1, while the core of the beam 1 will see mostly linear beam-beam effects from the core of the beam 2.

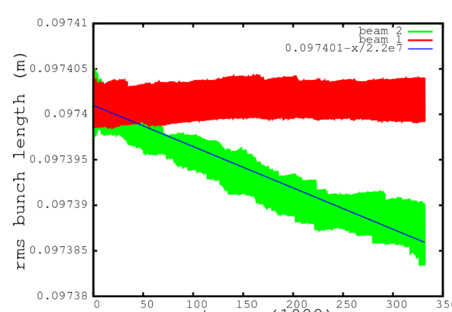

Figure 1: Longitudinal rms bunch length evolution of two colliding beams.

FIXED-ENERGY COOLING AND STACKING FOR AN ELECTRON ION COLLIDER*

S. Assadi, J. Gerity#, P. McIntyre, and A. Sattarov
Texas A&M University, College Station, TX 77845 USA

Abstract

The proposed designs for polarized-beam electron-ion colliders require cooling of the ion beam to achieve and sustain high luminosity. One attractive approach is to make a fixed-energy storage ring in which ions are continuously cooled and stacked during a collider store, then transferred to the collider and accelerated for a new store when the luminosity decreases. An example design is reported for a 6 GeV/u superferric storage ring for this purpose, and for a d.c. electron cooling system in which electron space charge is fully neutralized so that high-current magnetized e-cooling can be used to best advantage.

EIC DESIGNS

High-energy collisions of polarized beams of electrons and ions provide the possibility of extending the study of the spin structure and dynamics in nuclear matter to clarify the spin dynamics of quarks and gluons in nuclei [1]. Those studies require highly polarized beams of electrons and ions, colliding in an asymmetric pair of storage rings.

Several designs have been proposed for the purpose: eRHIC [2], in which polarized electrons from a recirculating electron linac (ERL) are collided with polarized ions in one ring of RHIC; MEIC [3], in which highly polarized beams of electrons and ions are collided in a pair of rings configured as a figure 8 lattice to naturally preserve high polarization; ENC [4], in which polarized beams are colliding in a pair of circular rings.

All such colliders share a common challenge: to accumulate a filling of intense ion bunches with high polarization so that they are ready for injection to the ion ring of the collider whenever the present store loses either luminosity or polarization.

Accumulation of intense beams of polarized ions requires a matching of particle flow between the low-energy stage and the high-energy stage of acceleration. The line current density in a bunch is limited at low energy by the space charge tune shift [5]

$$\Delta\nu_{SC} = \frac{NBIr_i\beta_y}{\pi\nu\beta^2\gamma^3\sigma_y(\sigma_x+\sigma_y)}$$

and by intrabeam scattering (IBS) [6]

$$\Gamma_{IBS} = \frac{N_b r_i^2 c}{64\pi^2\beta^3\gamma^2\epsilon_x\epsilon_y\sigma_p\sigma_s} L_C I$$

where N = total number of particles in a bunch, R = ring radius, B = ratio of peak to average current in bunches, $L_C \sim 20$ = Coulomb logarithm, I = amplification factor from image currents on the beam tube, $r_i = Z^2e^2/Am_pc^2$, a = r.m.s. beam radius, $\mathcal{E}_x, \mathcal{E}_y$ = invariant emittances, σ_p = fractional energy spread, and σ_s = bunch length.

Particle flow through the acceleration sequence must accommodate the strong energy dependence of Γ_{IBS} and $\Delta\nu_{\mathrm{SC}}$. It would not be possible to accelerate at low energy the line charge density that could be sustained in collision at high energy. Maximum bunch charge and minimum emittance are attained if ion bunches are accelerated to an intermediate (relativistic) energy and cooled using d.c. electron cooling. The same e-cooling can be used to accumulate repeated cycles of ion production to build bunch intensity to the limits imposed by Γ_{IBS} and $\Delta\nu_{\mathrm{SC}}$ at that energy. The cold stack is then available whenever the luminosity or polarization declines in a store.

This approach was used with great success in the Fermilab Recycler [7]. The choice of optimum energy for cooling and stacking is a balance: as energy increases the sustainable bunch line intensity increases, but also the maximal longitudinal drag force $F_\parallel$ and transverse damping rate $\Gamma_\perp$ from electron cooling decreases. These quantities in the co-moving frame come directly from the plasma physics of non-equilibrium relaxation between plasmas of electrons and ions [8]:

$$\Gamma_\perp^* = \frac{8\sqrt{2\pi}Z^2r_er_ic\mathcal{L}}{3}n_e^*\left(\frac{kT_e}{m_ec^2}+\frac{kT_i}{m_ic^2}\right)^{-3/2}$$

$$F_\parallel^* = 2\pi Z^2r_e^2m_ec^2n_e^*\mathcal{L}\left(\frac{c}{\Delta_\parallel^*}\right)^2,$$

where $\mathcal{L}$ is the Coulomb logarithm over the accessible range of impact parameters, and n_e^* is the electron density and T_e and T_i are the electron and ion temperatures in the co-moving frame.

The lab-frame quantities are γ-boosted appropriately:

$$\Gamma_\perp = \eta\Gamma_\perp^*/\gamma^2 \qquad F_\parallel = \eta F_\parallel^*/\gamma$$

where η is the fraction of the cooling ring circumference in which electron cooling is happening.

For the example of the MEIC design for ion acceleration, the approximate optimum choice of ion kinetic energy for cooling is ~6 GeV/u. The cooling ring design and the electron cooling discussion below pertain to that MEIC Ion Ring.

INITIAL MODELING OF ELECTRON CLOUD BUILDUP IN THE FINAL-FOCUS QUADRUPOLE MAGNETS OF THE SUPERKEKB POSITRON RING

J. A. Crittenden, CLASSE*, Cornell University, Ithaca, NY 14850, USA

Abstract

We present modeling results for electron cloud buildup in the final-focus quadrupole magnet nearest the interaction point in the SuperKEKB positron storage ring. The calculations employ as input recently obtained estimates of synchrotron radiation absorption rates on the vacuum chamber wall including the effect of photon scattering. While the effect both adds to and subtracts from photoelectron production at the points in the ring where unscattered photons strike the wall, it also produces cloud in the other regions. Results for beam-pipe-averaged and beam-averaged cloud densities are presented, as are estimates for the contribution to the fractional vertical coherent tune shift. The effect of the strong magnetic fields is studied and the dependence on the vacuum chamber surface secondary yield characteristics is considered. Cloud buildup is modeled with a 2D particle-in-cell macroparticle tracking code validated using recent measurements of electron trapping in a quadrupole magnet at the Cornell Electron Storage Ring Test Accelerator.

INTRODUCTION

The SuperKEKB e+e- collider is scheduled to begin operation in 2016. It will provide measurements of the decays of bound states of B quarks with unprecedented statistical precision. High luminosity operation depends on the strong field gradient region provided by the superconducting final-focus quadrupole magnets within 2 m of the interaction point (IP), with beta function values reaching as high 3000 m. Tune shifts near the interaction region have been calculated to be the dominant contribution to the total tune shift around the ring [1, 2]. These calculations did not include contributions from the final-focus quadrupole magnets. Recently, calculations of the synchrotron radiation distribution around the 4 GeV SuperKEKB positron ring including the effects of photon scattering on the walls of the vacuum chamber have become available [3]. The results show substantial rates of absorption in the final-focus quadrupoles, comparable to the highest rates in the arcs of the ring. In addition, the first measurements of electron trapping in a high-energy positron storage ring have been obtained recently in the context of the Cornell Electron Storage Ring Test Accelerator (CesrTA) program [4], allowing validation of an electron cloud buildup model for an ambient quadrupole magnetic field. The model successfully reproduced the trapping fraction when parameters were tuned to the signals observed in a time-resolving electron detector. Here we report on the initial application of this model for the case of cloud buildup in the upstream final-focus quadrupole nearest the IP in the SuperKEKB positron storage ring.

SUPERKEKB FINAL-FOCUS QUADRUPOLE MAGNETS

The final-focus quadrupole magnet nearest the IP in the positron ring, designated QC1RP, is 334 mm long and its center is located 935 mm from the IP. It operates at a field gradient of 68.74 T/m [5]. Superposed on this high-gradient quadrupole field is a non-uniform longitudinal field from the BELLE-II solenoid compensation magnets, as shown in Fig. 1 [6]. The longitudinal component of this field varies from about 1 T to approximately 2.5 T over the 334-mm length of the QC1RP magnet. For the purpose of the model described here, the solenoid compensation field has been assumed to be 2 T, rotated around the vertical axis by half the crossing angle, i.e. $\frac{83}{2}$ mrad, relative to the axis of the quadrupole field. Copper and TiN-coated surfaces are under consideration for the cylindrical, 21-mm-inner-diameter vacuum chamber.

PHOTON TRACKING AND CLOUD BUILDUP MODELING

The results from the X-ray photon scattering and tracking code which are used as input to the electron cloud buildup modeling in the QC1RP magnet [3] are shown in Fig. 2. Together with the overall photon absorption rate, the azimuthal distribution of absorbed photons (Fig. 2a)) is an important consideration for cloud development in a magnetic field, since cloud electrons are guided by the field lines, emphasizing the contribution of those produced on field lines near the beam which intersect the vacuum chamber wall. Figure 2b) shows the photon absorption rate to

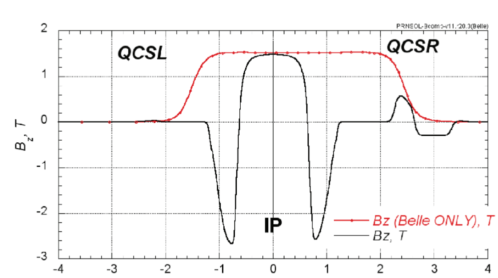

Figure 1: Longitudinal magnetic field component from the BELLE-II solenoid alone (red) and including the compensation field (black).

SYNCHROTRON RADIATION ANALYSIS OF THE SUPERKEKB POSITRON STORAGE RING

J.A. Crittenden and D.C. Sagan
CLASSE*, Cornell University, Ithaca, NY 14850, USA
T. Ishibashi and Y. Suetsugu
High Energy Accelerator Research Organization (KEK), 1-1 Oho, Tsukuba, Ibaraki 305-0801, Japan

Abstract

We report on modeling results for synchrotron radiation absorption in the SuperKEKB positron storage ring vacuum chamber including the effects of photon scattering on the interior walls. A detailed model of the geometry of the inner vacuum chamber profile has been developed and used as input to a photon tracking code. Particular emphasis is placed on the photon absorption rates in the electron-positron interaction region.

INTRODUCTION

The SuperKEKB e+e- collider will provide high-precision measurements of the production and decay of bound states of B quarks in the interactions of 4-GeV positrons with 7 GeV electrons. Commissioning is scheduled to begin in 2016. The design of the vacuum system [1] incorporates a variety of countermeasures to limit electron cloud buildup in the positron ring. The Cornell Electron Storage Ring Test Accelerator (CesrTA) program [2], in operation since 2008, has provided a wealth of information on the efficacy of such mitigation techniques via extensive measurements and model development which has also been used in the design of the International Linear Collider positron damping ring. [3, 4]. Here we report on results from a detailed modeling study of synchrotron radiation photon scattering and absorption on the interior surfaces of the vacuum chamber in the positron ring. In general, the effect of photon scattering on the walls of the vacuum chamber both adds and subtracts to the photon absorption rate (and therefore photoelectron production) at any point in the ring. However, such calculations can result in significant incident photon rates in regions where no synchrotron radiation strikes the wall directly.

VACUUM CHAMBER MODEL

Standard beam pipes in the positron storage ring have a circular beam channel and two rectangular antechambers on either side, as shown in Fig. 1. Synchrotron radiation photons irradiate the outer wall of the antechamber on the outside of the ring. The diameter of the beam channel and the half width at the horizontal axis are 90 mm and 110 mm, respectively. Strip-type non-evaporable getters (NEG) pumps are installed in the antechamber on the inside

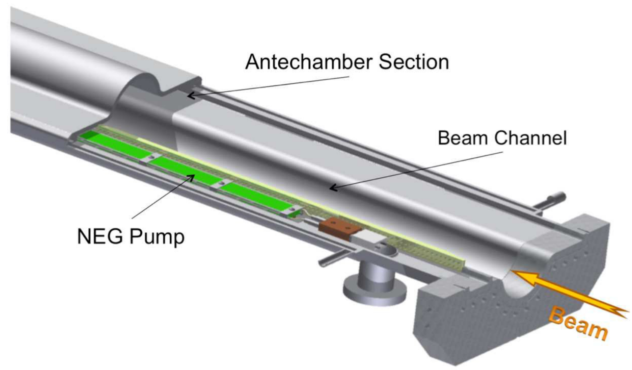

Figure 1: Schematic drawing of a beam pipe in arc sections of the positron storage ring.

of the ring. The pump channel is connected to the beam channel through a screen. A cross section of the standard beam pipe in the vacuum chamber model for the present calculations is shown in Fig. 2. The screens for the NEG pumps are defined as photon-absorbing walls in the model. In the wiggler sections, the photons strike both sides of the beam pipe, so both antechambers are used as channels for photon absorption. The rear walls of the antechambers are roughened to reduce scattering [1]; here we assume them to be totally absorptive. Circular beam pipes have been adopted in the interaction region (IR). The diameters vary in a staircase pattern from 80 mm at the entrance of the final focusing magnets (QCs) to 21 mm at the interaction point (IP). The beam pipes in the QCs on one side of the IP are

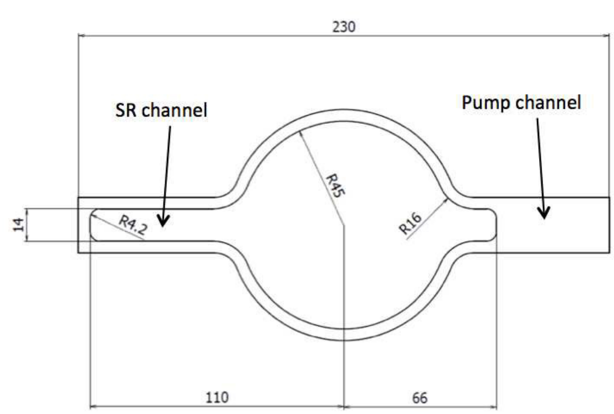

Figure 2: Cross section of the vacuum chamber model in the arc sections.

DESIGN OF A 6 TeV MUON COLLIDER*

M-H. Wang†, Y. Nosochkov, Y. Cai, SLAC, Menlo Park, CA 94025, USA
M. Palmer, FNAL, Batavia, IL 60510, USA

Abstract

A design of a muon collider ring with the center of mass energy of 6 TeV is presented. The ring circumference is about 6.3 km, and the β functions at collision point are 1 cm in both planes. The ring linear optics, the non-linear chromaticity correction scheme in the Interaction Region (IR), and the additional non-linear field orthogonal knobs are described. The IR magnet specifications are based on the maximum pole tip field of 20 T in dipoles and 15 T in quadrupoles. The results of the beam dynamics optimization for maximum dynamic aperture are presented.

INTRODUCTION

A muon collider is one of the potential candidates for a future energy frontier colliding machine. Considering requirements on energy, luminosity and wall power in operation, the preferred choice of the center of mass muon beam energy appears to be near 6 TeV [1]. In order to obtain peak luminosity of $\geq 10^{34}$ $cm^{-2}s^{-1}$ in the TeV range, a number of demanding requirements to the collider optics should be satisfied [2]. These include a low beta function (β^*) at the Interaction Point (IP), small circumference for high revolution frequency, large dynamic aperture, and low momentum compaction factor for a short bunch length ($\sigma_z<\beta^*$). The requirements are arising from a short muon lifetime and relatively large values of transverse emittance and momentum spread that can be realistically achieved with ionization cooling. They also come from the limitations on the maximum magnetic fields as well as the necessity to protect superconducting (SC) magnets and collider detectors from muon decay products. Another complication is the "hot spots" of radiation which can be induced by neutrinos from muon decay in straight sections [3]. As a result, straight sections without bending field must be very short. More detailed discussion of these requirements can be found in Ref. [2].

LINEAR OPTICS

For a 6 TeV muon collider ring, achieving a short circumference and strong focusing in the IR requires rather high magnetic field. In this design, we chose the circumference of ≈6.3 km (approximately the size of the Tevatron) and the maximum pole-tip field of 20 T in dipoles and 15 T in quadrupoles. We expect that future advances in SC magnet design will make achieving such a strong field possible. The designed ring lattice has a two-fold symmetry (periodicity) and consists of two identical IRs and two arcs.

† mhwang@slac.stanford.edu

Interaction Region

The Interaction Region is the most challenging part of a high luminosity collider due to the extremely high beta functions in the final focusing (FF) quadrupoles generating large non-linear chromaticity as well as creating high sensitivity to magnet errors. The designed optics of one half of the IR of the 6 TeV machine is shown in Fig. 1, where the IP is on the left-hand side with β^* = 1 cm in x and y planes. The IP is followed by a 6 m free space and a FF quadrupole doublet where vertical beta function reaches an extremely high value of 134 km. The remaining part of the IR is made of FODO-like lattice where most of the space between the quadrupoles is filled with dipole magnets to avoid hot spots of neutrino radiation. Due to the high beta functions, the FF quadrupoles generate very large non-linear chromaticity resulting in a non-linear chromatic tune shift and large energy dependent perturbation of beta functions. These effects must be locally compensated to avoid a severe degradation of the ring momentum acceptance.

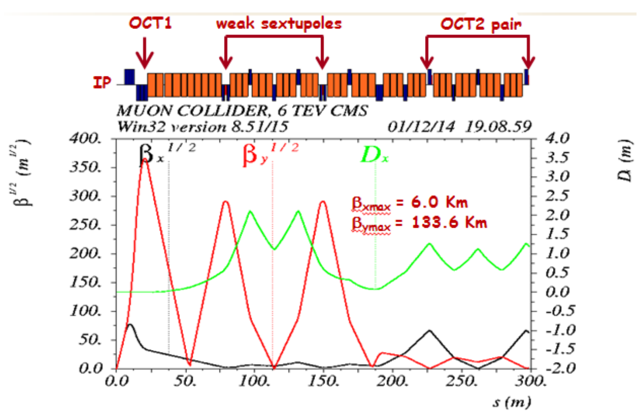

Figure 1: Linear optics of one half of the IR starting from IP. Two –I sextupole pairs (y and x) are placed at large β_y and β_x peaks for local correction of the FF quadrupole non-linear chromaticity. Positions of weak sextupoles and octupoles for additional non-linear correction are also shown.

The designed IR chromaticity correction scheme is based on two (x and y) non-interleaved pairs of sextupoles on each side of the IP, where the sextupoles in each pair are separated by –I transformation for cancellation of the 2nd order sextupole geometric (amplitude dependent) aberrations. The sextupoles are placed near the high beta peaks (x and y) to maximize their effective strengths. This correction scheme will be discussed in more detail later. At each end of the IR there is a dispersion suppressor FODO section followed by a ~40 m of non-dispersive

SCANNING SYNCHRONIZATION OF COLLIDING BUNCHES FOR MEIC PROJECT*

#Y. Derbenev, V. Popov, Jefferson Lab, Newport News, VA, USA
G. Kazakevich, Euclid TechLabs LLC, Cleveland, OH, USA
Yu. Chernousov, Institute of Chemical Kinetics and Combustion, Novosibirsk, Russia

Abstract

Synchronization of colliding beams is one of the major issues of an electron-ion collider (EIC) design because of sensitivity of ion revolution frequency to beam energy. A conventional solution for this trouble is insertion of movable bent chicanes in the arcs space. In our report we consider a method to provide space coincidence of encountering bunches of the crab-crossing orbits in the Interaction Region (IR) while repetition rates of two beams do not coincide. The method utilizes pair of fast kickers realizing a bypass for the electron bunches as the way to equalize positions of the colliding bunches at the Interaction Point (IP). A dipole-mode warm or SRF cavities fed by the magnetron transmitters are used as fast kickers, allowing a broad-band phase and amplitude control. The proposed *scanning synchronization* method implies stabilization of luminosity at a maximum via a feedback loop. This synchronization method is evaluated as perspective for the Medium Energy Electron-Ion collider (MEIC) project of JLab with its very high bunch repetition rate.

INTRODUCTION

In the MEIC's [1] medium ion energy range, maintaining a constant ion revolution frequency (given by the revolution frequency of electrons) with energy is troubled by a non-negligible change of the reference orbit in magnets. The earlier proposed baseline way of solving this problem is twofold. Firstly, at certain discrete energies corresponding to different harmonic numbers of the ion collider ring, synchronization of collisions is restored. The energy values are fairly closely spaced below at $\gamma \ll \sqrt{2q}$, where γ is ion Lorentz-factor, and q is number of bunches on the ion orbit. The correspondent maximum energy is about 36 GeV/u due to the very short bunch spacing of about 40 cm in MEIC, which may provide enough options for heavy ions with energies of only up to 40 GeV/u. However, there is a big energy gap from 36 to 100 GeV for protons. Covering the gaps between the harmonic energies is the second part of the synchronization problem. A number of different approaches to this issue have been proposed. Conceptually the simplest one is to adjust the ion ring circumference within the range of plus or minus a half of the 748.5 MHz RF wave length, i.e. by ±20 cm, using path-length movable chicanes as it is shown in Fig. 1, [2].

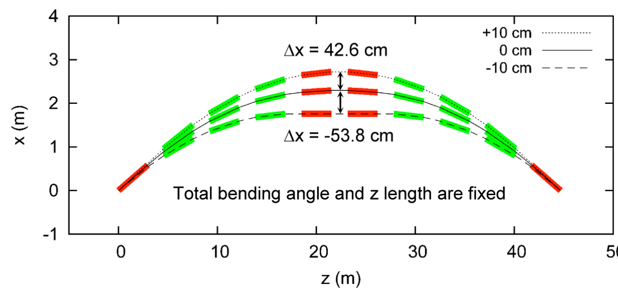

Figure 1: Schematic of an arc path-length chicane with movable magnets.

SCANNINNG SYNCHRONIZATION DYNAMIC CONCEPT

We consider a possibility of synchronization of the electron-ion colliding beams avoiding change of the orbit circumference. Instead, we consider a scheme of the cross-colliding beams with collision point moved periodically by a small scanning the beam directions in real time. For very most of the e-i bunch pairs, this scanning compensates for time delay of ion arrival at the nominal (central) Interaction Point (IP). The direction tilt of bunches is produced by RF deflecting resonators with varying amplitude and/or phase of the RF voltage, Fig. 2.

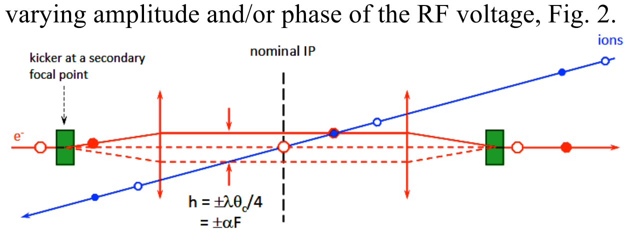

Figure 2: Schematics of the RF controlled bypass of e-beam for e-i synchronization by moving the collision point in real time.

The RF kicker is supposed to provide transverse variation of bunch trajectories in the Interaction Region (IR) in range of: $h = \pm \lambda\theta/4 = \pm\alpha F$.

Here: λ=40 cm is bunch spacing, θ =50 mr is crossing angle, α is kick angle produced by the maximum RF voltage amplitude, and F is focal distance of the IR focusing magnet block. At F =4 m we obtain h =5 mm, and required maximum kick α =1.25 mr. Maximum longitudinal deviation of the collision point will be 10 cm. Note that, in case that shift of the *collision point* (CP) is shared equally with the ion beam, the bypass parameters for each of two beams are reduced by a factor of 2, together with the similar reduction of the CP deviation.

CONCEPTUAL MEIC ELECTRON RING INJECTION SCHEME USING CEBAF AS A FULL ENERGY INJECTOR*

Jiquan Guo#, Fanglei Lin, Robert Rimmer, Haipeng Wang, Shaoheng Wang, Yuhong Zhang, JLAB, Newport News, VA 23606, USA

Abstract

The Medium-energy Electron-Ion Collider (MEIC) proposed by Jefferson Lab is planning to use the newly upgraded 12 GeV CEBAF 1497 MHz SRF CW recirculating linac as a full-energy injector for the electron collider ring. The electron collider ring is proposed to reuse the 476MHz PEP-II RF system to achieve high installed voltage and high beam power. The MEIC electron injection requires 3-10 (or 12) GeV beam in 3-4μs long bunch trains with low duty factor and high peak current, resulting in strong transient beam loading for the CEBAF. In this paper, we propose an injection scheme that can match the two systems' frequencies with acceptable injection time, and also address the transient beam loading issue in CEBAF. The scheme is compatible with future upgrade to 952.6 MHz SRF system in the electron ring.

INTRODUCTION

The MEIC proposed by JLab is a high luminosity electron-ion collider with 3 to 10 GeV electrons and 20 to 100 GeV protons (or up to 40 GeV per nucleon for heavy ions), with the possibility to upgrade to higher energy [1, 2]. The nominal beam current in the electron ring is 3 A, but the current is also limited by synchrotron radiation power at high energy, and by RF cavity impedance induced coupled bunch instability at low energy [3]. The newly upgraded 12 GeV CEBAF linac is chosen as the full energy injector for the electron ring. It's also natural to consider reusing the high power RF system of the recently retired PEP-II in MEIC's electron ring, since PEP-II was designed for similar beam current and system RF power [4]. Although PEP-II and CEBAF have different RF frequencies, we note that 7/22 (very close to 1/π by incident) of the CEBAF linac's 1497 MHz frequency is 476.3 MHz, which is within the operational range of PEP-II's 476 MHz RF system.

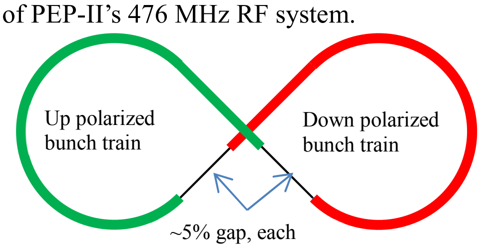

Figure 1: Bunch trains in the MEIC figure-8 ring

In the baseline design, each of the MEIC collider rings will provide two bunch trains with opposite spin polarization in the same ring, with two gaps of ~5% circumference in between, as shown in Fig. 1. The gaps result from the injection kickers' rise/fall time, and will also serve for the purposes of ion clearing etc. Under the full current operation, every bucket in the bunch train will be filled. In case the current is far below the beam-beam limit due to other limiting factors such as synchrotron radiation power, the bunch rep-rate may be reduced to a fraction of the RF frequency for higher luminosity.

Currently the harmonic number of the electron ring is set at 3416, with a circumference of around 2150 m and the revolution time of 7.17 μs.

THE ELECTRON INJECTION SCHEME

The electron ring will use transverse phase space injection. For each kicker cycle, a polarized bunch train with the length of ~45% collider ring circumference (3.23 μs) will be injected into the 1st half ring, followed by another oppositely polarized bunch train filling the 2nd half of the ring. The electron ring's transverse damping time τ_d ranges from 6 to 376 ms, depending on the beam energy and the use of damping wigglers. About $2\tau_d$ is needed to damp the injected beam before the next injection into the same half ring.

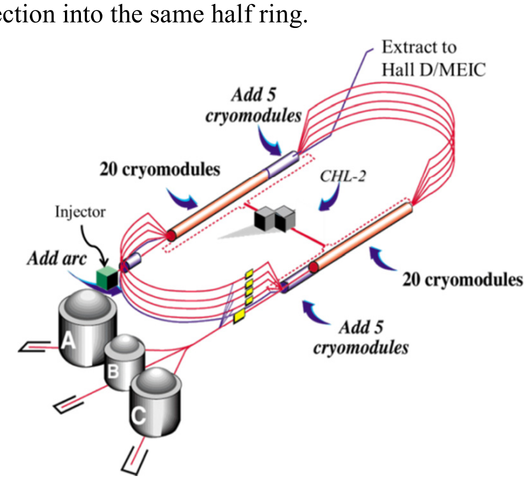

Figure 2: CEBAF after 12 GeV upgrade

Maximizing the Pulsed Bunch Train Current in CEBAF

To achieve a reasonable injection time, we need to maximize the pulsed beam current generated from CEBAF. As shown in Fig. 2, the beam in CEBAF can be accelerated during the 6 passes in the north linac and 5 passes in the south linac, before it's extracted to Hall D or MEIC. The CEBAF is capable of delivering CW extracted beam with ~1 MW beam power, nominally limited by the beam dump's CW power rating, but also limited by the system's total RF power. The beam current circulating in the linacs is usually 5-6 times of the

Abstract

The electron collider ring of the Medium-energy Electron-Ion Collider (MEIC) at Jefferson Lab is designed to accumulate and store a high-current polarized electron beam for collisions with an ion beam. We consider a design of the electron collider ring based on reusing PEP-II components, such as magnets, power supplies, vacuum system, etc. This has the potential to significantly reduce the cost and engineering effort needed to bring the project to fruition. This paper reports on an electron ring optics design considering the balance of PEP-II hardware parameters (such as dipole sagitta, magnet field strengths and acceptable synchrotron radiation power) and electron beam quality in terms of equilibrium emittances.

INTRODUCTION

The electron complex of the MEIC is designed to meet the physics requirements for the project [1]. These include a beam energy range of 3 to 10 GeV, a beam current of 3 A up to an energy above 6 GeV, a short bunch length (approximately 1 cm) and small transverse emittance over a wide energy range to support the luminosity requirement, and a longitudinal polarization of 70% or above at collision points with a reasonably long lifetime. In addition, the linear density of synchrotron radiation power is less than 10 kW/m and the total power less than 10 MW.

The CEBAF 5.5 pass SRF recirculating linac serves as a full energy injector to the MEIC electron collider ring. No further upgrade is needed beyond the current CEBAF 12 GeV upgrade in terms of beam current and polarization (> 85%). In the MEIC baseline design, the PEP-II 476 MHz RF system will be reused in the electron collider ring [2]. To synchronize the RF bucket between CEBAF whose RF frequency is 1497 MHz and the electron collider, we note that 7/22 of the CEBAF linac frequency is 476.3 MHz. This frequency is well within the operational range of the PEP-II 476 MHz cavities and klystrons. Details of the injection concept is discussed in these proceedings [3].

After the last recirculation in the CEBAF, the beam is sent to a transfer line after the north linac [4]. The transfer line between the linac and the MEIC electron collider ring is made of FODO cells with 120° of phase advance using the PEP-II Low Energy Ring (LER) dipoles and quadrupoles. The strengths of dipoles and quadrupoles are well within their specifications. There are a number of reasons to choose a phase advance of 120°. First, it keeps the quadrupole gradients low enough so that the PEP-II LER quadrupoles can be reused. Second, it is compatible with a missing dipole scheme for dispersion suppression. Third, such phase advance insures that there is no significant emittance growth due to synchrotron radiation during the transport of electron beam from the CEBAF to the MEIC electron collider ring. The length of the entire transfer ling is approximately 333 m.

The electron and ion collider rings of the MEIC are designed to follow the same footprint and share the same underground tunnel. The electron ring determines the overall geometry that the ion ring follows with the exception of the region around the IP due to the 50 mrad crossing angle. The dimension of the electron ring should be able to accommodate all machine components. This paper presents the electron collider ring optics design using the PEP-II High Energy Ring (HER) magnets.

ELECTRON COLLIDER RING DESIGN

The MEIC electron collider ring is designed as a FODO lattice in both arcs and straights, using the majority of PEP-II dipoles and quadrupoles within the limit of their strengths [5]. Particular machine blocks, such as spin rotators, interaction regions and RF sections etc., are designed as modules using new dipoles and quadrupoles, inserted and matched into the base line lattice.

Each arc has 34 normal FODO cells and 8 matching cells (4 in each end of the arc). The normal FODO cell is 15.2 m long and filled with two 5.4 m long PEP-II dipoles and two 0.56 m long PEP-II arc quadrupoles. Each quadrupole is followed by a PEP-II sextupole for chromatic compensation in the arcs. Though the dipole field strength of 0.3 T at 10 GeV in the MEIC is higher than the 0.27 T shown in [5], PEP-II dipoles can reach 0.363 T because they were originally designed for the PEP 18 GeV electron beam. For the MEIC application, each dipole has a 3.3 cm sagitta based on a bending angle of 2.8°. This sagitta is 1.1 cm larger than the PEP-II dipole sagitta of 2.2 cm, but it is still within the dipole good field region of 5 cm. The matching cell has the same length and magnets of the normal FODO cell, except that the quadrupoles are adjusted to match the optics between the normal FODO cell and the Universal Spin Rotator (USR). The spin rotator is designed with interleaved solenoids and dipoles, and quadrupoles in between for the optics, to rotate the electron polarization between the vertical (in arcs) and longitudinal (at IP) direction from 3 to 12 GeV [6]. Note that the spin rotator does not change the design orbit over the entire range of electron beam energies. The transverse orbital coupling induced by the longitudinal

TURNKEY SYSTEMS COST OPTIMIZATION BY ITERATIVE DESIGN OF MAGNETS AND POWER SUPPLIES

M. Cavellier, W. Beeckman, J.D. Holzmann, F. Forest, SIGMAPHI, Vannes, France

Abstract

For more than 30 years, Sigmaphi has been manufacturing magnets and power supplies. Its teams are now able to supply a complete particle beamline, from beam optics calculation to on-site installation and alignment. These combined skills allow design optimization for turnkey systems in order to reduce their purchasing and running costs. A common though widespread in scientific community is that savings are possible by making the complete (and optimized) design of a magnet before asking an industrial company to manufacture it. At first glance, only looking at the design cost, it may be true. But in most cases, considering the complete system and running costs, this hypothesis is false. Based on the average cost breakdown between material and workmanship in a magnet and the related power supply, it is highlighted how an iterative design can reduce the total cost of the system. Two examples of successful iterative designs are presented: a tunable kicker magnet with its pulser, and a 70 meters beamline designed, manufactured and installed by Sigmaphi.

INTRODUCTION

A common though widespread in scientific and accelerator's engineering community is that savings are possible by making the complete (and optimized) design of a magnet before asking an industrial company to manufacture it. At first glance, only looking at magnet costs, this may be true. But in most cases, considering the complete system and running costs, this hypothesis is false. Power supplies are the first "victims" of magnets size optimization, and the consequences on running costs can be dramatic.

The best practice is to adapt magnet design to standard power supplies, and mutualize magnets design as much as possible through what we call here "iterative design".

An example of successful iterative design is presented here.

GUIDELINE FOR ITERATIVE DESIGN

The entry point for designing a cost-adapted solution is functional needs. The one who designed his magnet without considering the task of his colleague from power supply can be sure that his system will not be optimized.

The main steps for iterative and cost-optimized design are:

- Beam optics.
- Magnets design, which give main parameters: bore or gap, effective length, field or gradient.
- Electrical parameters of magnets, through coils design.
- Determining if a standard "on-shelf" power supply is close to what is required. If not, all the possibilities must be explored to change coils and magnet design to fit standard power supply, keeping in mind the objective of using the device with the lowest power.
- Verifying that power consumption is lower than the initial target. If not, a new iteration starting from one of the stages above is necessary.
- In case of a beam line where several pairs of magnet/power supply are to be designed, check if there are possibilities to group magnet design: same bore diameter/length to use same coils, even if magnet is used at 70 or 80% of its full capacity.

  Of course, this last step is strongly limited by the space constrains you may have.

EXAMPLE

An example of successful iterative design led by Sigmaphi is given here. Sigmaphi was in charge of designing, manufacturing, installing and aligning a 70m beam line for JINR in Dubna, Russia: Acculina-2. Beam optics responsibility was held by JINR, but teams from both sides worked together to adapt it in order to reduce significantly running costs.

For this beam line, the necessary quantities of magnets are presented in Table 1, and part of the layout in Fig. 1.

Starting from the initial specification, seven iterations were necessary to come up with an optimized design of both magnets and power supplies.

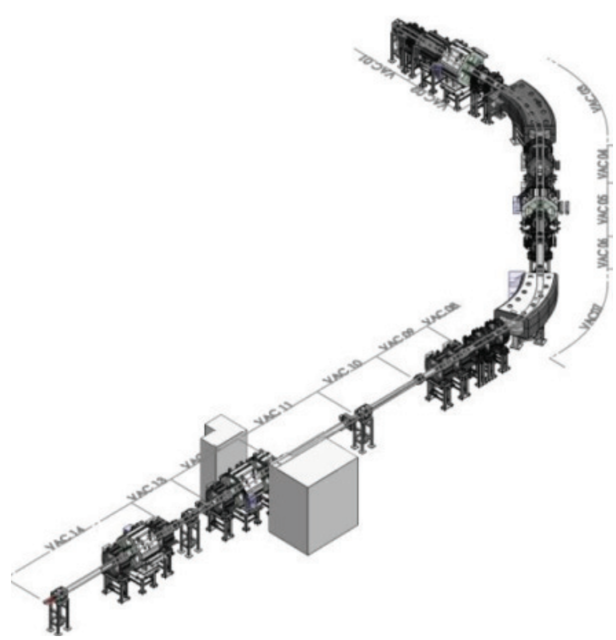

Figure 1: Partial layout of Acculina-2 beam line.

Abstract

We have investigated the effects of deep hydrogen implantation into *n*- and *p*-type silicon wafers ((100) oriented, with resistivity in the 1-20 Ω·cm range). Deep implantation has been achieved using the Hitachi-AccSys PL-7 RF LINAC set for 3.0 MeV beam energy, degraded to 1.8 MeV. Hydrogen has been implanted 30 µm below the wafer surface with an implant dose (fluence) >5x10^{15} cm^{-2}. Samples were partly covered by a metal mask during implant. Porous silicon has been formed on the exposed samples to study the effect of hydrogen irradiation. We have found that porous silicon formation is inhibited in the irradiated areas on *p*-type silicon and promoted on the *n*-type one.

INTRODUCTION*

Ion implantation into semiconductors is one of the key industrial applications of particle accelerators. Figure 1 shows the most common implantation energies, doses, and chemical species, employed in the semiconductor industry.

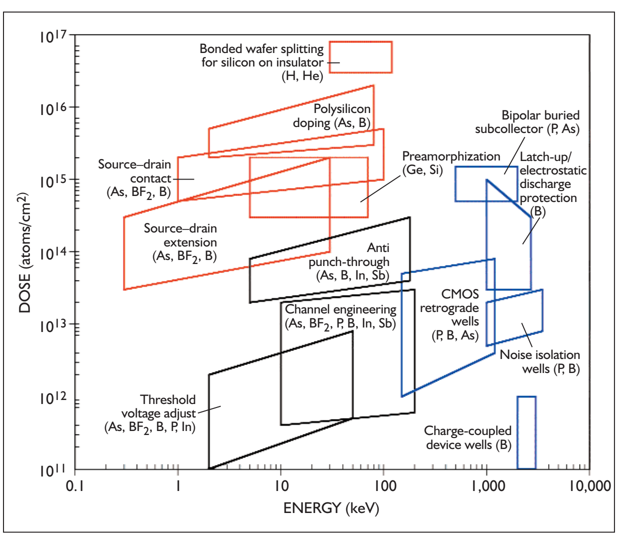

Figure 1: Process and dose application space for semiconductor industry. Hydrogen implantation has been used mainly for the manufacturing of SOI wafers where doses in excess of 5x10^{16} are required.

* Work supported by the TOP-IMPLART project funded by Regione Lazio.

Hydrogen implantation has been historically relegated to the manufacturing of SOI (Silicon-On-Insulator) wafers [1, 2] and, more recently, in the bulk micromachining of silicon in conjunction with the formation of porous silicon [3, 4].

CEA LETI has commercially exploited hydrogen implantation since 1994 [2] for the production of SOI wafers. The technique, known with the name "smart cut", uses protons (H$^+$ ions) to create lattice defects in correspondence of the stopping range. In this technology, 150 keV protons are used, corresponding to an implantation peak at 1.25 µm below the surface. A layer with dopant concentration of 10^{16} cm^{-3} has been achieved with implant dose (fluence) higher than 5x10^{16} cm^{-2}.

When the above concentration is reached it is possible to thermally trigger the coalescence of the defects to create "bubbles" in the silicon crystal and cleave the wafer along a plane parallel to its surface in a position corresponding to the stopping range.

Silicon micromachining technologies, based on hydrogen irradiation, follows the discovery that, irradiated areas cannot be converted into porous silicon [3]. The starting material was *n*- and *p*-type silicon 0.015-0.020 Ω·cm and 0.010-0.020 Ω·cm, respectively, and the proton energy was 2 MeV. The authors attributed that behavior to the defects induced by the proton beam in the silicon crystal. A more recent explanation of this phenomenon has been given in [5], in which the authors attribute the suppression of porous silicon formation to defect induced by the beam to *holes* transport through the lattice (porous silicon formation requires continuous *holes* supply). They simulated hole current of an irradiated structure into silicon using a commercial finite elements code (COMSOL) solving the Poisson's and continuity equation (in two dimensions) at different biases and verified their results experimentally.

In such technologies, porous silicon is used as sacrificial material, due to its etching selectivity with respect to silicon (up to 1x10^5:1, for potassium hydroxide (KOH) etch). In such technologies [4], silicon is patterned with a focused proton beam, e.g. Nuclear Microprobe [6], (essentially an high energy Focused Ion Beam) with a spot size of 200 nm to locally induce defects into the silicon lattice. Protons (or He ions) with energies in the range 0.25 MeV to 2 MeV at fluencies between 5x10^{14} cm^{-2} to 5x10^{15} cm^{-2} are employed. Complex three-dimensional structures can be realized with such technologies [7].

Abstract

In this work we present the latest update on the construction of the TOP-IMPLART proton LINAC at the ENEA C.R. Frascati Accelerators Laboratory. TOP-IMPLART is a 150 MeV proton accelerator for protontherapy applications funded by Regione Lazio (Italy). We have successfully commissioned the first 3GHz LINAC structure reaching the energy of 11.6 MeV (from 7 MeV), demonstrating the first proton acceleration in a SCDTL structures at this energy. The second SCDTL LINAC has been tuned and brazed and in delivery to the installation site, the third one is under construction.

INTRODUCTION

The TOP-IMPLART (Intensity Modulated Proton Linear Accelerator for RadioTherapy) accelerator [1-3] is a proton LINAC designed for medical applications (i.e. cancer treatment). This project, funded by the local government (Regione Lazio), is a joint venture of three Italian research institutions: ENEA, ISS, and IRE-IFO (the end-user). The accelerator, when completed, will deliver a proton beam with energy variable in the 85 MeV to 150MeV range (with a planned upgrade to 230 MeV, not yet funded). The funded TOP-IMPLART accelerator consists of three sections, an injector (up to 7 MeV), a medium energy section (7 MeV to 35 MeV), and a high-energy section (35 MeV to 150 MeV). The injector is a commercial LINAC, the PL-7 designed by Hitachi-AccSys, operating at 425 MHz with 100 µs wide pulses and a pulse repetition frequency (PRF) of 100 Hz (maximum). The rest of the accelerator operates at 2997.92 MHz with a pulse width of 4 µs. The medium energy section consists of four SCDTL (Side Coupled Drift Tube LINAC), an ENEA patented design, driven by a single 10MW klystron tube. The high-energy section of consists of 12 CCL structures driven by four 10MW klystron tubes.

The injector section is connected to the first SCTDL structure by a LEBT (Low Energy Beam Transfer Line) consisting of a first quadrupole doublet followed by a deflecting magnet and a second quadrupole doublet. The LEBT is meant to focus the beam to fit the SCDTL pipe that has 4 mm diameter, whereas the injector pipe is 35mm diameter. The deflecting magnet is used to deliver the proton beam to a vertical beam-line used in radiobiology experiments [4-6].

The operating frequencies of the injector and of the other LINACs are not in harmonic relation and phase synchronization between the two is not achievable. Phase synchronization strategy of the medium- and high-energy sections is presented in [7].

The task under completion is the construction of the medium energy section (from 7MeV to 35 MeV). The first structure has been successfully installed and commissioned and the second one is undergoing the final brazing before delivery to the installation site. The actual layout of the TOP-IMPLART accelerator is shown in Fig. 1.

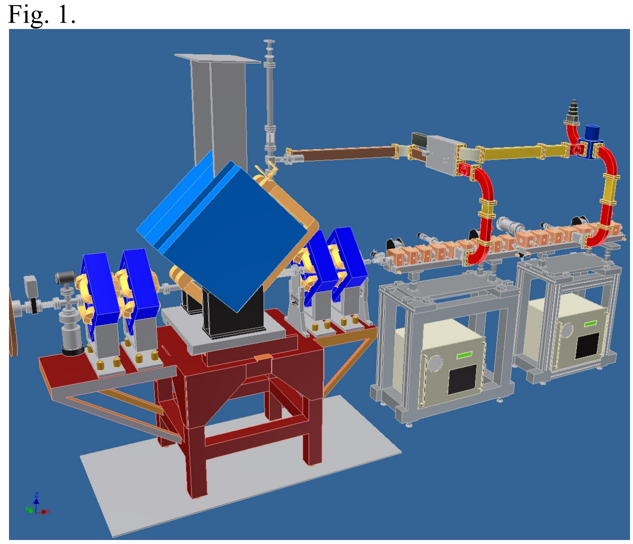

Figure 1: Layout of the TOP-IMPLART accelerator with the LEBT (left) and the first two SCDTL structures each one on his own table. The RF driving line is shown.

Each SCDTL structure is installed onto an independent table onto thermally isolated posts and is heated to the working temperature by a chiller unit placed under the structure itself. The RF driving line consists of a power splitter with adjustable split-ratio. Moreover, a waveguide switch is installed in the second structure branch, to dump RF power to a load when the second structure is used in transport mode only (for the 11.6 MeV beam).

SCDTL-1 OPERATION

The first SCDTL (referred as SCDTL-1) structure is in operation (Fig. 2). SCDTL-1 (1.1 m long) is composed of 9 DTL tanks with 4 side coupled cells per tank; in the intertank space PMQs (Permanent Magnet Quadrupoles) with gradient values around 197 T/m are placed. The structure is equipped with its own chiller that keeps temperature stable within 0.2 °C around 42 °C in such a way that the resonant frequency is exactly 2997.92 MHz. A motorized mechanical tuner can regulate the frequency

Abstract

The purpose of the BIOxTREME project, launched by ENEA (Italian National Agency for New Technologies, Energy and Sustainable Economic Development) and funded by ASI (Italian Space Agency), is to formulate new biological drugs having a stimulant activity on the immune system, finalizing the production for a "ready to use" resource in Bioregenerative Life Support Systems (BLSSs) for space missions intended for long-term duration, in deep space, and with multiple crews.

One of the project tasks is to study the effects of physical insults on plants, trying to simulate cosmic environment on the production platforms exposing biological material to ionizing radiation, static magnetic fields and microgravity.

In order to examine the biological effects, to test plant radio-resistance and to build dose-response curves we carried out proton irradiations of anthocyanin rich (red) "hairy roots" derived from the tomato cultivar Micro-Tom with different proton energies for several doses with the TOP-IMPLART accelerator at the ENEA Frascati Research center.

The biological samples were placed in a holder specially made in a movable real-time monitoring chamber calibrated in dose. The fluence-homogeneity measurements over the sample and the calibration of the monitoring system were performed using GafChromic EBT3 films, placed in air in the same position as the biological samples to be irradiated. The present paper describes the experimental set-up and reports the preliminary results.

THE BIOXTREME PROGRAM

Plants can be considered as natural 'bioreactors' for the production of bioactive molecules (e.g. amino acids, vitamins, pigments, antioxidants, complex carbohydrates, proteins, etc.) and biotechnological drugs also including adjuvants or immuno-stimulating molecules.

An important field of interest is the farming of plants in extreme conditions such as those found in the aerospace environment: the prospect of breeding plants in the Space is an essential requirement for long-duration exploratory-class manned missions because they would provide an important physical support as a resource ready for use in Bioregenerative Life Support Systems (BLSS).

The International Space Station and its crew in Space are subjected to galactic cosmic rays (GCR) and solar particle events (SPE). The GCR spectrum is composed primarily of high-energy protons and atomic nuclei, namely about 87% high energy protons, 12% alpha-particles and 1% heavier ions up to iron (HZE) instead SPE consist of low to medium energy protons and alpha-particles. Numerous Space flight and ground-based experiments have been performed to study the biological effects of cosmic radiation on humans in the perspective of manned space missions.

In 2014 ASI has funded the ENEA-project BIOxTREME (BIO-plant factories for the formulation of bioactive molecules endowed with microbicidal, immunostimulating and antioxidant activity, for life in extreme conditions) which aims to formulate new drugs for the astronauts involved in long-term space missions. One of the key features of these drugs is that they have to induce stimulating activity on the immune system through the optimization of the production of natural antioxidants present in plants [1].

The BIOxTREME project is devoted to simulate cosmic conditions exposing plant samples in proton beams, gamma rays, static magnetic fields and microgravity. One of the experimental objectives of the Biotechnology Laboratory at ENEA is the study of alterations in the normal physiology of the living plants in such extreme conditions by profiling biological effects according to "SYSTEM BIOLOGY" technologies, such as proteomics.

In the framework of this program, irradiation of red Micro-Tomato (Micro-Tom) "hairy roots" was carried out with low energy proton beams extracted from the TOP (Oncological Therapy with Protons)-IMPLART (Intensity Modulated Proton Linear Accelerator for RadioTherapy) linear accelerator in operation at ENEA Radiation Sources Laboratory [2].

MICRO-TOM 'RED' "HAIRY ROOTS"

Micro-Tom has been considered the best choice for use in BLSS during human spaceflights. It is a Tomato cultivar (*Solanum lycopersicum*) originally created for ornamental purposes [3] and further widely used as a model species in several studies that defined in detail of the genetic and physiological makeup of this plant. The dwarf phenotype (plant height= 15 cm approx.) is undoubtedly an advantage for growing in small spaces. The miniaturization was obtained by introducing three recessive mutations in the genetic background of tomato

HOW KNOWLEDGE AND TECHNOLOGICAL TRANSFER CAN DEVELOP INTO AN INDUSTRIAL REALITY: KYMA SRL CASE HISTORY

Raffaella Geometrante, Kyma S.r.l., Trieste, Italy
Mauro Zambelli, Kyma S.r.l., Trieste, Italy

Abstract

Kyma was established in 2007 as a spin-off company of Elettra-Sincrotrone Trieste, to design, realize and install all the 18 undulators of FERMI, the seeded FEL, at the time being built at the Elettra lab in Trieste, Italy. For Kyma establishment, Elettra-Sincrotrone Trieste formally transferred to the new company know-how and references relevant to Insertion Devices and, by a Knowledge Transfer monetarily evaluated, could participate to Kyma capital owning the 51% of the shares. In few years, Kyma became a well-known organization in the light source community. After more than forty Insertion Devices and sixty phase shifters designed and manufactured, Kyma is now recognized as a qualified partner for design and development of this kind of equipment. Some examples of Kyma industrial achievements in developing skills, knowledge, technologies methods of manufacturing transferred by Universities and Institution, will be presented. An example out of many: the joint effort between Kyma and Cornell University right now leading to the development of a new perspective into the ID world, i.e. the CHESS Compact Undulators (CCU).

ORIGIN AND STRUCTURE OF THE COMPANY

Kyma was established in August 2007 by Elettra - Sincrotrone Trieste S.C.p.A. (ST), with the primary purpose to design, realize and install the undulators for the FERMI@Elettra project, namely the new Free-Electron Laser, at the time being built at the ST site in Basovizza, Trieste, Italy.

The origin of Kyma relies on the 20-years experience of ST on the development, testing, installation and operation of insertion devices.

At the moment of the launch of the FERMI project a question about the possibility to start a spin-off company, fully devoted to the insertion devices design and manufacturing, was posed.

After a feasibility study during the year 2006 a European tender was launched to find possible suppliers of mechanical, magnetic and control subsystems for the realization of eighteen undulators for the FERMI@Elettra project.

In the tender a clause was included that the proponent(s) had to supply the undulators not directly, but through a new company to be set up together with Elettra - Sincrotrone Trieste.

The tender procedure was completed in spring 2007 and the new company was formally established in August of the same year.

Kyma is located in the Sincrotrone Trieste site in Basovizza, Trieste, an aerial view of which is shown in figure 1, where the FERMI@Elettra facility can be seen in the forefront.

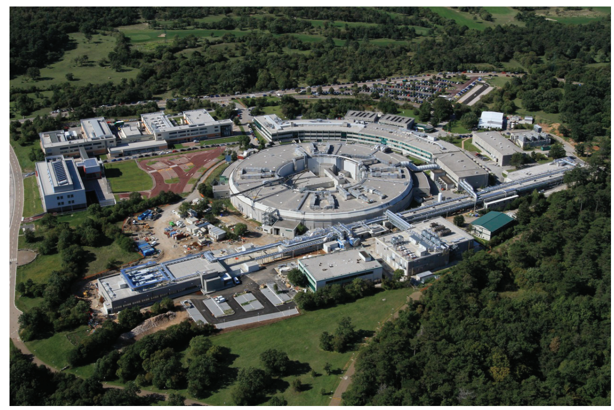

Figure 1: The Elettra site with the FERMI@Elettra Free-Electron Laser facility in the forefront.

Know-how and References

At the moment of the establishment of Kyma Srl, Elettra - Sincrotrone Trieste formally transferred to the new company all the know-how and the references relevant to insertion devices.

In fact the capital of the company was formed by 51% of shares as intangible assets supplied by Elettra - Sincrotrone Trieste and 49% of liquid capital supplied by the partners.

As a consequence of this approach, all the references of Elettra - Sincrotrone Trieste on insertion devices are now formally owned by Kyma Srl.

In this way, more than twenty years experience in design, assembling, characterization and operation of insertion devices at Elettra - Sincrotrone Trieste, meets now the manufacturing capabilities of the industrial partners, to build up a world-class company for insertion devices realization (see Fig. 2).

ALGORITHM OF RECONSTRUCTING PARTICLE DISTRIBUTION IN N-DIMENSIONAL PHASE SPACE FROM PROFILE IN BEAM TRANSPORT

T. Aoki#, Research & Development Group, Hitachi, Ltd., Hitachi, Japan

Abstract

A new method of reconstructing particle distribution from measured profile in beam transport is proposed. In this method, particle distribution in arbitrary dimensional phase space can be reconstructed from profiles in transport system. The particle distribution is obtained by solving a following equation: $I=D\rho$, where I is a counted number of particles at a single channel of the profile monitor, D is a matrix representing relation between I and ρ, and ρ is number of particles included in a single n-dimensional voxel of phase space at start point of the beam transport. We succeeded formulation of matrix D from transportation matrix of the beam transport R, and discovered that D is formulated as piecewise-polynomials of elements of R. We show details of the formulation of D and results of simulations of reconstruction of particle distribution in phase space by this method.

INTRODUCTION

Purpose of this study is to propose a new method of reconstructing particle distribution in phase space. In particle beam therapy, it is demanded to deliver a narrow beam to isocenter in order to realize conformal irradiation. To realize the narrow beam size at isocenter, a tuning of high energy beam transport (HEBT) system and measurement of beam is important. Conventionally, Quadrupole scan method [1] is applied for measurement in HEBT system. Quadrupole scan method is effective when particle distribution in phase space is Gaussian, and we can measure emittance ε, twiss parameters α and β. However, the particle distribution is not Gaussian, it is required that not only measurement of these parameters but also particle distribution in phase space is required. Because the beam energy is larger than 70MeV/u in HEBT, the slit scan method is not applicable for the measurement. Therefore we adopt the new method that improved phase space tomography method [2]. By this phase space tomography method, transverse phase space (x, x') and (y, y') distribution. However in beam tuning in particle therapy, the information about dispersion is need. In this study, we propose the new method which realizes a measurement of particle distribution in arbitrary dimensional phase space.

THEORY

Let $\rho(\boldsymbol{x}; z)$ be the distribution of the particle in phase space at the beam line position z. The phase space coordinates $\boldsymbol{x}$ are (x, x', y, y', s, δ). x and y are spatial transvers displacements from design orbit. δ is momentum displacement $\Delta p/p$. s is longitudinal displacement from beam centroid. x' and y' are dx/dz and dy/dz respectively. To obtain the distribution at specified point z_0 in HEBT, we measure the number of particles in small voxel of phase space from measured profile in HEBT. We define ρ_i as number of particles in ith voxel in phase space, I_{x_j} as number of particles counted in the jth channel of profile monitor at $x=x_j$. Assuming the distribution in the single voxel is flat, a relation of ρ_i and I_{x_j} become

$$I_{x_j} = \sum_{k=1}^{n} \int_{x_j-\frac{w}{2}}^{x_j+\frac{w}{2}} \phi_k(x) \cdot \rho_k \mathrm{d}x \tag{1}$$

where w is width of profile monitor channel, and $\phi_k(x)$ is projected volume of kth phase space voxel on x-axis. Assembling this relation, we get a equation

$$\boldsymbol{I} \stackrel{\text{def}}{=} \begin{pmatrix} I_1 \\ \vdots \\ I_m \end{pmatrix} = \boldsymbol{D} \begin{pmatrix} \rho_1 \\ \vdots \\ \rho_k \end{pmatrix} \stackrel{\text{def}}{=} \boldsymbol{D\rho} \tag{2}$$

where $\boldsymbol{D}$ is defined as

$$\boldsymbol{D} = \left(d_{ij}\right)_{\substack{1\le i\le k \\ 1\le j\le m}} \tag{3}$$

and

$$d_{ij} = \int_{x_j-\frac{w}{2}}^{x_j+\frac{w}{2}} \phi_i(x) \mathrm{d}x. \tag{4}$$

Therefore, we can obtain the particle distribution ρ by solving the eq.(2). To solve the eq.(2), it is required that the formula for projected volume $\phi_i(x)$ and enough number of measurement of profiles.

Derivation formula for Projected Volume

We derive the formula for projected volume of a N-dimensional parallelepiped constructed by N vectors $\boldsymbol{a}_1$, $\boldsymbol{a}_2$... $\boldsymbol{a}_N$. in this section. At first, In the case of N=1, it is clear that

$$\phi^{(1)}(x) = \frac{1}{c_1} \mathrm{rect}\left(\frac{x - x_\mathrm{c}}{c_1 a_1}\right) \tag{5}$$

where c_1 is a cosine of the angle between $\boldsymbol{a}_1$ and x-coordinate, a_1 a length of $\boldsymbol{a}_1$, x_c is a x-coordinate of centroid of the voxel, and rect(x) is the rectangular function defined as

$$\mathrm{rect}(x) \stackrel{\text{def}}{=} \begin{cases} 0, \text{if } |x| < \frac{1}{2} \\ 1, \text{if } |x| \ge \frac{1}{2} \end{cases} \tag{6}$$

Figure1 shows this situation. The 1 dimensional voxel is a segment of line in phase space. So, the projected volume is a rectangular function.

RF GUN BASED ULTRAFAST ELECTRON MICROSCOPY*

J. Yang#, K. Kan, T. Kondoh, Y. Yoshida, ISIR, Osaka Universiry, Osaka, Japan
J. Urakawa, KEK, Tsukuba, Japan

Abstract

Ultrafast electron microscopy (UEM) would be a powerful tool for the direct visualization of structural dynamic processes in matter. The resolutions of the observation on femtosecond time scales over sub-nanometer (even atomic) spatial dimensions have long been a goal in science. To achieve such resolutions, we have designed and constructed a femtosecond time-resolved relativistic-energy electron microscopy using a photocathode radio-frequency (RF) electron gun (RF based UEM). The RF gun has successfully generated a high-brightness electron beam with bunch length of 100 fs and emittance of near 0.2 mm-mrad, which are essential beam parameters for the achievement of nm-fs space-time resolution in the microscopy. Both the static measurements of both relativistic-energy electron diffraction and image have been succeeded. In this presentation, the activities on RF based UEM are introduced. The requirements and limitations of the beam parameters are reviewed. The concept and design of RF based UEM are reported. Finally, some demonstrations of the relativistic-energy UEM images are reported.

INTRODUCTION

Transmission electron microscopy (TEM) is a powerful tool to observe directly the image from specimen with high spatial resolution. When coupled with time resolution, it, which also called ultrafast electron microscopy (UEM), would be the strongest tool for the study of ultrafast dynamics in materials. Currently, the UEM with the time-spatial resolution of nanosecond and nanometer has been achieved in conventional TEM through the use of photo-activated electron source driven by a nanosecond laser in the non-space-charge-limited regime with ns-long pulse length. A large number of important phenomena, i.e. phase transformations, melting, re-solidification, nucleation and growth of damage in nanosecond time region, have been investigated. To achieve a high time resolution overcoming the space-charge limitation, we have proposed and designed a femtosecond time-resolved relativistic-energy electron microscopy using a photocathode radio-frequency (RF) electron gun. In 2009 [1,2], we have developed a RF gun to generate a low-emittance femtosecond-bunch electron beam: 100 fs and 0.1 mm-mrad, which are essential for the achievement of nm-fs space-time resolution in future. In 2010, we constructed successfully an instrument of ultrafast relativistic-energy electron diffraction (UED) using the RF gun [3-5]. The time resolution of 100 fs has been achieved. In 2012, a first prototype of RF gun based relativistic-energy TEM (which is called *rf-UEM*) has been constructed at Osaka University [6,7]. The resolutions of 1 nm and 100 fs in spatial and temporal respectively will be challenged. In 2014, a new RF gun with the highest repetition rate of 1 kHz was designed and produced to generate a further low-emittance and low-energy-spread electron beam in *rf-UEM*. Both the static measurements of relativistic-energy electron diffraction and image have been succeeded in the prototype. In this poster, the activities on UED and UEM are introduced. The concept and design of the new RF gun and the prototype of RF gun based relativistic-energy electron microscopy are reported. The beam dynamics and challenges in femtosecond RF gun will be discussed. Finally, some demonstrations of the relativistic-energy TEM images, the single-shot and time-resolved UED measurements are reported.

1 kHz NORMAL CONDUCTING RF GUN

To achieve the aim resolutions of 1 nm and 100 fs in spatial and temporal, an electron source in *rf-UEM* has to be able to generate a low emittance and low energy spread beam, such as 0.1 mm-mrad for the normalized emittance and 10^{-4} or 10^{-5} for the energy spread. In addition, low dark current and ultrahigh stabilities on charge and energy are also required. For these reasons, we have designed and fabricated a new structure RF gun with following optimum considerations and improvements:

- New shapes of the structures in both the RF cavity wall and the iris between the half cell and the full cell are designed near to the ideal contour to reduce the nonlinear electric fields. A large aperture of the iris was used to reduce the electric field on the cavity surface and to reduce both the transverse emittance and energy spread.
- The conventional laser injection ports in the half cell were removed for good field symmetry. A new insertion function of the photocathode in the cathode plate was designed. It will be used to develop a transmission photocathode to generate a further low thermal emittance beam from the RF gun.
- New wall-structural turners were designed in the half and full cells to adjust precisely the field balance.
- The field emission due to the strong electric field between the cathode plate and the half-cell cavity is the biggest problem in old type RF gun. In the new RF gun, the cathode plate was blazed on the half-cell cavity without the use of the helicon flex vacuum shield. The dark current from the new gun was greatly suppressed to <0.01 pC/pulse. Abstract

Aged large concrete structure, such as highways, bridges and boating docks, need to be inspected by un-destructive method in order to determine whether maintenance or rebuild. If maintenance work is appropriate, diagnosis will be needed. We have been developing un-destructive inspection system by using fast neutron which can penetrate thick concrete. Fast neutron detector is developed with plastic scintillator and semiconductor photon sensors. It can identify 16mmϕ steel rod through 300mm thick concrete. After prototyping detector experiments, new large area detector are designed and build.

INTRODUCTION

In Japan, many bridges were built in 1960 to 1970's, when Japanese economy had been expanded rapidly. So they will become end of life in next a few decades. However society will not able to rebuild all of them by budget limitation. It is urgent needs to develop and establish a method to investigate with un-destructive way.

Thirty nine percent of the bridges of Japan, which are longer than 15m, are built by pre-stressed concrete (PC) construction method [1]. It is combination of high tensile strength of steel and concrete's great compressive strength. Solid duct is inserted in the concrete structure. Steel rods or wires are put in the duct with pre-tension. Then the duct is filled by the concrete. However it has been known that techniques in 60's and 70's could not guarantee the duct was filled without void. Rain water can penetrate into voids in the duct through cracks in the concrete structure and make corrosions on the steel. Hence the steel rods or wires degrade their strength. As result, the structure may fall down. Thus it is important to investigate gap in the concrete and size of the steel rods or wires. The typical size of the duct is about 3cm diameter. Therefore our target is 3cm imaging resolution.

Fast Neutron

The absorption cross section of fast neutron, which energy is around 1MeV, is order of 1 barn (10^{-24}cm^2) against to major elements of concrete, oxygen, aluminium and silicon [2]. For X-ray case, it is order of 1000 barn [3]. Neutron has much higher penetration power for concrete structure. It is suitable to obtain transmission image.

Needs to Develop

The requirements, which are needed to establish fast neutron imaging system, are (1) transportable neutron source, (2) 2D fast neutron detector, and (3) image processing which can reconstruct as 3D view of the inside of concrete structure. Fig.1 shows final goal of the project. A neutron source is mounted on an automobile with a target station. Fast neutron is emitted to downward. Thus bridge floor is exposed to the fast neutron. Transmitted neutrons are detected underneath of the bridge by 2D fast neutron detector, which is attached to a swing arm.

By the Japanese law of concerning the prevention from the hazards due to radiation and others [4], it is allowed to operate transportable accelerator with less than 4MeV out of doors for un-destructive inspection of bridges.

Figure 1: Transportable neutron source and 2D fast neutron detector.

In this paper, we report about a prototype of 2D fast neutron detector, which was tested with accelerator-based compact neutron source.

Because the detector will be used out of doors, stable operation with mechanical movement, temperature and humidity excursion, and low power consumption are required. By the above technical reasons, combination of plastic scintillator and semiconductor photon sensor is chosen.

DEVELOPMENT OF A PULSE RADIOLYSIS SYSTEM BY ULTRA-FAST SUPER CONTINUUM PROBE LIGHT AT WASEDA UNIVERSITY*

Y. Ito†, Y. Soeta, Y. Hosaka, K. Sakaue, M. Washio, Waseda University, Tokyo, Japan

Abstract

We have been studying the pulse radiolysis using photo-cathode rf gun at Waseda Univ. Pulse radiolysis is one of the powerful methods to trace early chemical reactions by ionizing radiation. In pulse radiolysis, the probe light absorption, which produced by active species formed by electron beam of rf gun, is measured at each wavelength and made possible to trace reactions. Therefore, we have used the super continuum (SC) light for the probe light. The SC light has a broad spectrum and is generated by nonlinear optical effect caused by injecting picosecond laser to photonic crystal fiber (PCF). However, the resulting SC light was unstable because its peak intensity was not enough. We need to use a femtosecond pulsed laser which is expected to be stronger peak intensity than a picosecond laser. We have developed a mode-locked Yb-doped fiber laser based on Non-Linear Polarization Rotation as a femtosecond pulsed laser and the chirped pulse amplification system which will be able to amplify the femtosecond pulse. In this conference, we will report the performance of the SC light using this fiber laser system, recent results of pulse radiolysis experiments and the future plans.

INTRODUCTION

The photo-cathode rf gun has been developed at Waseda University, and pulse radiolysis has been studied as application of electron beam obtained by photo -cathode rf gun. In pulse radiolysis, the probe light absorption, which produced by active species formed by electron beam of rf gun, is measured at each wavelength and made possible to trace reactions. When we measure the lifetime of the target transient active species, temporal resolution of pulse radiolysis is determined mainly by the pulse width of electron beam and probe light. Probe light is required to be pulsed light with high intensity, good stability and broad spectrum. On these backgrounds, we have started to study SC light based on PCF for the probe light.

SUPER CONTINUUM (SC) LIGHT WITH PHOTONIC CRYSTAL FIBRT (PCF)

The SC light with PCF is a new technique of pulsed white light generation. Figure 1 (left) shows the cross-sectional micrograph of PCF. PCF is the optical fiber which is made of silica glass and clad has many micro air holes. The refractive index difference between core and clad become higher by these holes. It can realize the small core area of PCF and contributes to enhance the nonlinear optical effect. The SC light has a broad spectrum and is generated by nonlinear optical effect caused by the high peak intensity of pulsed laser in PCF. The spectrum of SC light previously generated by picosecond pulsed laser (4ps) is shown in Fig. 1 (right). It is clear that the SC light has enough spectral bandwidth, however, the resulting SC light was unstable because the peak intensity was not enough. Thus we started to use a femtosecond pulsed laser which is expected to be stronger peak intensity than a picosecond laser. We have developed a mode-locked Yb-doped fiber laser based on Non-Linear Polarization Rotation as a femtosecond pulsed laser. [1]

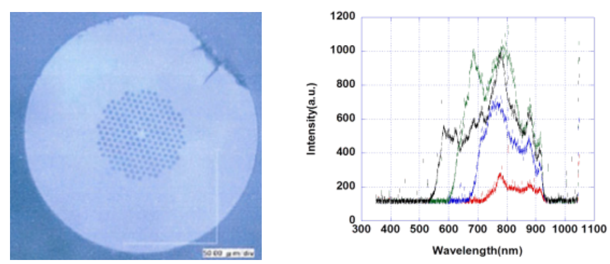

Figure 1: Cross-sectional micrograph of PCF (left) and the spectrum of SC (right).

Yb-DOPED FIBER

We have developed a fiber laser oscillator for injecting to PCF based on Yb-doped fiber as gain medium. Yb is one of the rare-earth elements and Yb-doped fiber is a fiber which is doped $Yb^{3+}$to the core. The energy level of Yb^{3+} has a simple structure compared with Er^{3+}, Nd^{3+}, and it is possible to ignore the excited state absorption, therefore excitation efficiency of Yb^{3+} is higher than the others. Yb-doped fibers make exceptional sources in the 1.0 – 1.1 μm wavelength range because of an excellent power conversion efficiency of over 80% and a broad tunability over several tens of nanometers. [2]

NONLINEAR POLARIZATION ROTATION (NPR)

Using Nonlinear Polarization Rotation as mode-locking method, we generate a pulsed laser. The NPR is one of the passive mode-locking methods. Figure 2 shows a mechanism of NPR mode-locking. In the fiber, a nonlinear optical effect tends to occur because a laser peak power becomes higher to the long interaction length and small core diameter of the fiber. In the passive mode-locked fiber laser, NPR with polarizer is commonly employed as a saturable absorber. When injecting linear polarized light to the fiber, phase difference is generated by difference of polarization intensity and a linear

DESIGN OF A SUPERCONDUCTING GANTRY FOR PROTONS

Cristian Bontoiu*, Jose Sanchez-Segovia, FABIS, Spain
Rafael Berjillos, Javier Perez Bermejo, TTI, Spain
Ismael Martel, Univ. of Huelva, Spain

Abstract

The last decade brought much interest in proton therapy within the medical and accelerator communities. Using normal conducting technology, the high-energy beams required can be handled only with large and heavy magnets which causes prohibitive costs. While lattice design work on a superconducting gantry has been carried out for a decade [1] there is yet no practical implementation. The University of Huelva in collaboration with the Andalusian Foundation for Health Research (FABIS) is currently involved in developing and assembling a prototype for a compact superconducting proton gantry [2]. Magnet design and performance is described along with beam dynamics results for the main gantry arcs and for the final spot scanning system using realistic magnetic field maps thoroughly.

INTRODUCTION

The gantry should operate within as much as possible of the medically relevant energy range 100 MeV to 250 MeV delivering proton bunches of about 1 mm rms transverse size with a beam divergence within 2 mrad. Due to space limitations its optical lattice can be made of combined-function magnets which both bend and focus the beam. Tumour scanning in depth involves change of the beam energy which is quicker than the jumps of current intensity allowed by the superconducting magnets and therefore the lattice must hold beams of variable energies at fixed field. The current lattice is composed of 36 magnets installed on two arcs of 2.5 m radius as shown in Fig. 1.

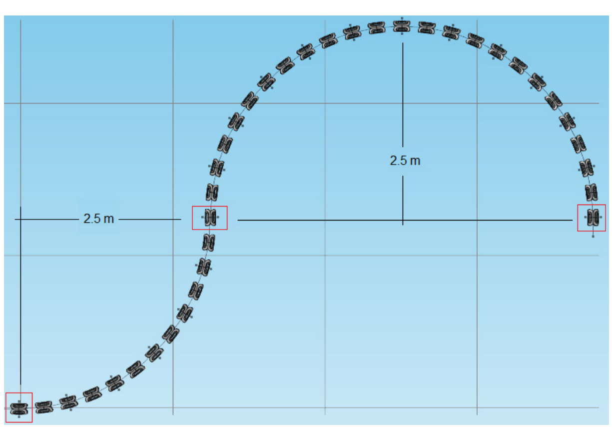

Figure 1: A lattice made of 36 combined-function magnets with the bending radius of 2.5 m.

MAGNET DESIGN

Successful operation of SC magnets in large scale projects like the LHC, has motivated and inspired the development of a simplified version of combined-function magnets using bent cos-θ dipole and quadrupole coils. They consists of one layer of quadrupole coils installed on the top of one layer of dipole coils, both layers spanning about 3.5° axially. Numerical modelling has been achieved in Comsol [3] resulting in three-dimensional magnetic field maps overlapped, scaled and used for particle tracking studies.

Dipole Coils

The dipole coils have been designed using three 1 cm thick coil blocks whose azimuthal distribution minimizes the b_3, b_5, b_7, b_9, b_{11} multipoles as described in [4]. A view is shown in Fig. 2 with the inner radius set at 5 cm.

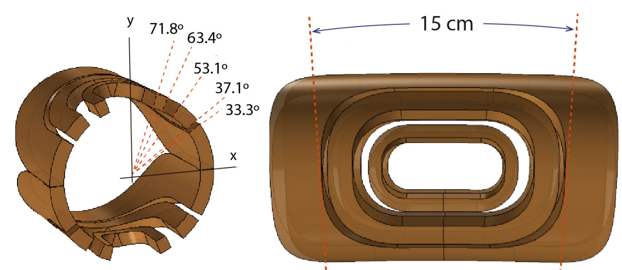

Figure 2: Three-dimensional layout of the SC dipole coils.

The dipole magnetic field is highly homogeneous, as it can be seen across the transverse cross-section in Fig. 3. A current density of about 350 A/mm^2 is required to handle proton beams of 250 MeV.

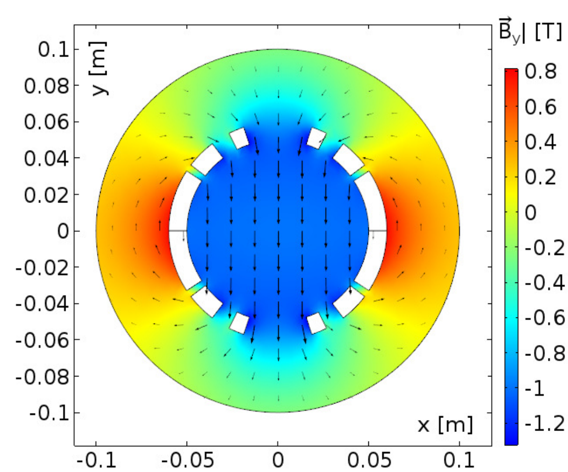

Figure 3: Dipole magnetic field distribution within the transverse cross-section plane.

EXPERIENCE ON SERIAL PRODUCTION OF THE QUADRUPOLE MOVERS WITH SUBMICROMETRIC REPEATABILITY FOR THE EUROPEAN XFEL*

J.Munilla#, J.Calero, L.García-Tabarés, A.Guirao, J.L.Gutiérrez, T.Martínez, E.Molina Marinas, F.Toral, C.Vázquez, CIEMAT, 28040, Spain
C. Martins, E. Ramiro, F. Ramiro, RAMEM, 28027, Spain
J.A. Gorrotxategi, B.Junkera, M.Tarragual, A.Urzainki, HTS/ZEHATZ, 20850, Spain

Abstract

CIEMAT is in charge of the design and manufacturing of the quadrupole movers with submicrometric repeatability for the XFEL.EU intersections. Prototyping of these precision devices was successful but manufacturing them in a serial production scheme (101 units) implies some changes at design, fabrication procedures and quality controls. This paper will present some of the main problems and solutions adopted to transform a prototype made at a research facility into a serial production at a conventional industrial company. Also, it describes the inspection and tests, the quality controls and reporting procedures. All the devices have been validated and recepted. This paper describes the adopted procedure and the performance of the serial units.

INTRODUCTION

Quadrupole Movers (QM) for the European XFEL [1] will be installed in the intersections between each pair of undulators. CIEMAT is fully responsible for the conceptual and engineering designs. 95 units are part of the Spanish in-kind contribution and 6 additional units were ordered by DESY.

During the research and development stage, three prototypes have been built from 2009 to 2012 [2]. In the last one, some design changes have been included to optimize serialized production and reduce costs at industry. XFEL-EU has given final acceptance on the prototype and technical specification for serial production in 2012. The production of the QMs has been split in two bunches to reduce risks, in special with the tight schedule. CIEMAT allocated two contracts for half of the serial production each one in 2013. Spanish companies RAMEM and HTS/ZEHATZ were awarded with the contracts.

FUNCTIONAL REQUIREMENTS

The complete list of parameters of the XFEL quadrupole movers has been published elsewhere [2]. Submicrometric repeatability for movements in 2 axes (horizontal and vertical) is the most challenging one. The vertical load to withstand is 75 kg, while small lateral forces are admissible (about 10 N).

In order to achieve a compact design, a wedged configuration was chosen for the vertical movement. Both axes include a high precision linear actuator and a closed-loop control system fed by two LVDT sensors. Precision adjustable limit switches and hard stops are needed to maximize quadrupole travel length without interference with the beam pipe.

All the QMs adjustments must be measured and reported. This information will allow parametric control and calibration for the intersection control system. Moreover, all the QMs should be interchangeable apart of these parameters.

QUALITY AND DOCUMENTATION REQUIREMENTS

The main objective of the quality assurance system is to guarantee the achievement of the technical specifications. Both manufacturers have created and maintained a quality management system (QMS) according to UNE-EN ISO 9001 and UNE-EN-9100 standards.

Also, to ensure quality and integrity of units from first manufacture steps to final reception at XFEL facilities, CIEMAT has designed a procedure based on three reports for each unit:

1. Manufacture Report includes materials and components certificates and metrology reports in order to ensure traceability. It is intended for internal use to prevent malfunctions or potential problems before assembling and testing.
2. Validation Report includes final repeatability test results, adjusting parameters and the verification of accomplishment for all specifications before delivery. This is uploaded to XFEL.EU document management system (EDMS) for future references. This report is made by manufacturer.
3. Reception Reports include additional verifications and tests after delivery. This report is done by CIEMAT as cross-check and it is also uploaded to EDMS. Any possible deviation or problem during transportation can be detected.

In addition to documentation explained above, special procedures have been stablished:

- An accessible code is permanently engraved onto each part in an area that does not affect its operation or the engineering tolerances. At the same time, it

GANTRY 3: FURTHER DEVELOPMENT OF THE PSI PROSCAN PROTON THERAPY FACILITY

A. Koschik*, C. Bula, J. Duppich, A. Gerbershagen, M. Grossmann, J.M. Schippers, J. Welte
PSI, Paul Scherrer Institut, 5232 Villigen, Switzerland

Abstract

PSI and its Center for Proton Therapy (CPT) is extending its research capabilities in the field of proton therapy and pencil beam scanning technology. Gantry 3 will be an additional treatment room at the PROSCAN facility at PSI, Villigen, Switzerland. It will feature a 360° scanning Gantry delivered by Varian Medical Systems. The Gantry design is based on Varian technology, which will be combined with advanced PSI active scanning technology.

The further development of fast energy switching as well as precise spot and continuous line scanning irradiation modes are main research topics at the PROSCAN facility. A major challenge with Gantry 3 is the link of the existing PSI PROSCAN system with the Varian ProBeam system, while retaining the system integrity and high performance level. Additionally, Gantry 3 will be installed and commissioned while keeping the other treatment rooms (Gantry 1, Gantry 2, Optis 2) in full operation.

The current development and project status is presented.

INTRODUCTION

PSI has a long-standing successful history in the development and application of irradiation technologies for treatment of cancer. With the inauguration of Gantry 1 in 1996 [1], PSI has pioneered the irradiation technique using actively scanned pencil proton beams. In 2007 the world's first 250 MeV superconducting cyclotron for proton therapy COMET was installed at PSI's PROSCAN facility [2].

Spot scanning, the proton-dose delivery technique developed at PSI is being further developed for fast re-painting and precise spot scanning on Gantry 2 [3] which is treating patients since 2013. The Optis 2 irradiation room allowing for accurate treatments of eye melanoma using passive scattering technology complements the PROSCAN facility.

PSI takes a further step by extending the research and treatment capabilities with an additional Gantry treatment room sponsored by the Swiss Canton of Zurich. Gantry 3 is realized in collaboration with Varian Medical Systems (VMS), which continues the fruitful research collaboration with Varian that has led to the development of the superconducting cyclotron COMET.

The main goal of the Gantry 3 project is to realize an additional scanning Gantry by 2016 with performance and capabilities comparable to PSI Gantry 2.

Figure 1 shows the layout of the PROSCAN facility with the cyclotron and the beam lines delivering the proton beam to the treatment areas Gantry 1, Gantry 2, Optis 2 and the new area Gantry 3. The new Gantry 3 will be installed behind a newly built extension of the existing fixed beam line for experiments.

PROSCAN BEAMLINE

Extracted beams from COMET are focused on a degrader, which can decrease the energy of the proton beams to the patient to any value in the range of 70 − 230 MeV. The degrader is followed by collimators and an energy selection system to obtain a well-defined beam emittance (max.30π mm mrad), and a maximum beam momentum spread of ±1.0%.

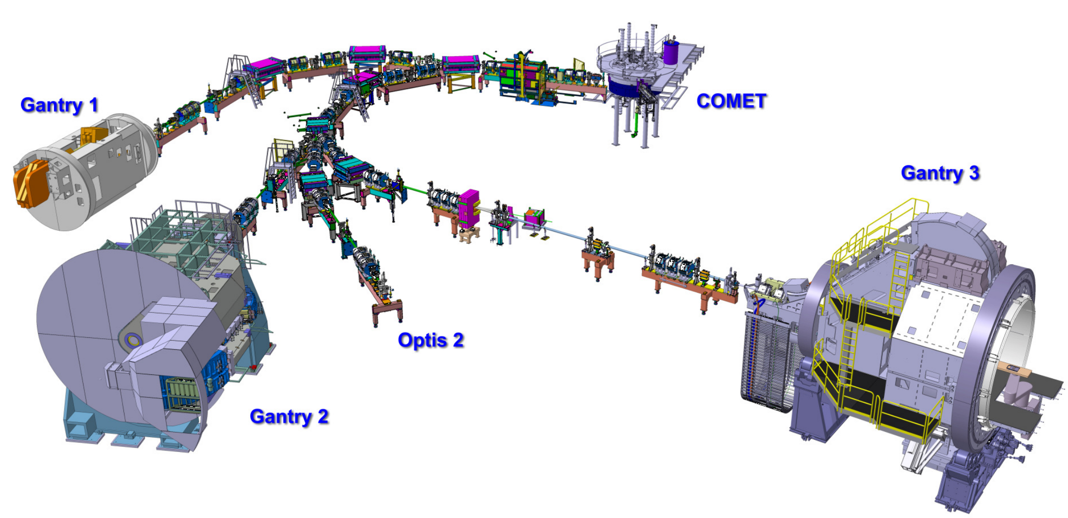

Figure 1: Layout of the PROSCAN facility beam lines including the new Gantry 3 area.

SINGLE-SHOT MULTI-MeV ULTRAFAST ELECTRON DIFFRACTION ON VELA AT DARESBURY LABORATORY

L.K. Rudge, S. Mathisen, P. Aden, R.J. Cash, J.A. Clarke, D.M.P. Holland, J.W. McKenzie, M.D. Roper, T.C.Q. Noakes, J. Jones, A. Kalinin, B.L. Militsyn, B.D. Muratori, D. Scott, F. Jackson, P. Williams, Y. Saveliev, D. Angal-Kalinin, M. Surman#, STFC ASTeC, Daresbury Laboratory, Daresbury, UK.
D.A. Wann, P.D. Lane, Dept. of Chemistry, University of York, York, UK.
J.G. Underwood, Dept. of Physics and Astronomy, UCL, London, UK.

Abstract

Accelerator-based Ultrafast Electron Diffraction (UED) is a technique for studying both static structure and sub-100 fs dynamic structural changes on the atomic scale. In this paper we present the first electron diffraction results, obtained in 2014, on the Versatile Electron Linear Accelerator (VELA) at Daresbury Laboratory. Diffraction patterns were observed with much less than 1 pC transported to the detection screen. Single-shot and multi-shot accumulated diffraction data are presented from single crystal and polycrystalline samples. Apertures of different sizes placed directly in front of the sample offer some control over the contamination due to dark current, but also reduce the charge contributing to the diffraction pattern. We discuss future developments for electron diffraction on VELA, including further beam optimisation, the measurement of bunch length with a newly installed Transverse Deflecting Cavity (TDC), and the plans for pump-probe studies.

INTRODUCTION

Structural science, particularly structural biology, is a major driver in the development of new light sources. However, many important materials such as membrane proteins and protein complexes cannot be crystalised into sufficiently large crystals for use in conventional X-ray diffraction arrangements and moreover, are often damaged by the beam before the data collection can be completed. A new approach is to use X-ray Free-Electron Lasers (FELs) to produce ultra-high intensity sub-100 fs X-ray pulses to allow single shot diffraction data to be recorded before the sample deteriorates, that is, the data collection is faster than the radiation damage. This approach is being pursued at SACLA [1] and LCLS [2]; for example LCLS have recently successfully carried out X-ray diffraction imaging of a giant Mimivirus [3].

Structural evolution on a time-scale comparable to that of the making and breaking of chemical bonds can also be studied with these high intensity X-ray FELs. Recently, ultrafast resonant soft X-ray diffraction experiments at LCLS allowed the optically stimulated changes of charge-density wave correlations in $YBa_2Cu_3O_{6.6}$ to be followed [4].

An attractive alternative approach to using X-ray FELs to study structural changes is ultrafast electron diffraction. Achieving the femtosecond time resolution needed to observe dynamic changes in molecules requires the use of multi-MeV electrons to reduce space charge effects that lengthen the bunch.

Electrons offer several advantages over X-rays for diffraction studies:

(1) Electrons have a Coulombic interaction with both the electrons and the nuclei of the target atom whilst X-rays only scatter from the electrons. Electrons thus have a scattering cross-section which is 4-6 orders of magnitude larger than that of X-rays.

(2) Electrons have a lower ratio of inelastic to elastic scattering cross-sections than do X-rays.

(3) Electrons deposit a lower energy into the target during inelastic collisions than do X-rays [5-7].

The net result is that electrons deposit three orders of magnitude less energy per useful scattering event than do X-rays, thereby reducing the damage done to the sample. While it is frequently argued that a 10 fs X-ray pulse will “beat” Coulomb explosion of the molecule, this may not be the case as the electron density from which X-rays are scattered is being disrupted on much faster (attosecond) timescales. In contrast, electrons scatter from the nuclei and so are much less susceptible to damage mechanisms which remove electron density. Ultrafast electron diffraction also has notable cost advantages over FELs for diffraction experiments since much smaller scale accelerators, such as VELA [8], can be used.

UED ON VELA

A description of the electron diffraction system on VELA has been presented elsewhere [9] where it was shown that, although sub-100 fs 1 pC bunches can be generated at the gun, the bunch length increases as the beam propagates along the accelerator. A schematic of the accelerator is shown in Fig. 1. For the electron diffraction experiments described in this article, VELA was operated at 4 MeV/c. Seven quadrupole magnets, located between the gun and the sample chamber, are used to shape the electron beam. The beam can be imaged on YAG screens at several places along the accelerator, including the sample position.

Abstract

The IsoDAR sterile-neutrino search calls for a high neutron flux from a 60 MeV proton beam striking a beryllium target, that flood a sleeve of highly-enriched ^{7}Li, the beta-decay of the resulting ^{8}Li giving the desired neutrinos for the very-short-baseline experiment. The target is placed very close to an existing large neutrino detector; all such existing or planned detectors are deep underground, in low-background environments. It is necessary to design a shielding enclosure to prevent neutrons from causing unacceptable activation of the environment. GEANT4 is being used to study neutron attenuation, and optimising the layers of shielding material to minimize thickness. Materials being studied include iron and two new types of concrete developed by Jefferson Laboratory, one very light with shredded plastic aggregate, the other with high quantities of boron. Initial studies indicate that a total shielding thickness of 1.5 meters produces the required attenuation factor, further studies may allow decrease in thickness. Minimising it will reduce the amount of cavity excavation needed to house the target system in confined underground spaces.

ISODAR EXPERIMENT

IsoDAR (Isotopes-Decay-At-Rest) is a novel, high intensity source of electron antineutrinos which aims for searches for physics beyond standard model [1]. The goal is to produce 1.29×10^{23} electron antineutrinos per year with a mean energy of 6.4 MeV. IsoDAR consists of an ion source, a cyclotron accelerating the protons to 60 MeV which impinge on a Be target placed next to a kiloton-scale scintillator detector [2]. The requirement of the accelerator is to deliver 10 mA proton beam at 60 MeV on the target. The solution to provide such a high current is to accelerate 5 mA beam of H_2^+ ions using the DAEDALUS injector cyclotron as a driver. As a results of the inelastic interactions of low energy protons or deuterons with the Be target ^{8}Li isotopes are produced which then decay producing electron antineutrinos. Apart from the ^{8}Li isotopes produced in the target, additional ^{8}Li is produced in the surrounding materials by secondary neutrons. Electron antineutrinos are detected by the inverse-beta decay (IBD) process in a detector and a possible choice for detector is KAMLAND in the Kamioka mine in Japan.

The IsoDAR target (Fig. 1) consists of a hollow cylinder of beryllium with the target proper being a 1.7 cm thick end face of the cylinder. The target thickness is calculated to optimise the production of neutrons and minimise heat deposited in the beryllium. The beam is spread over the 20 cm diameter face of the target by a wobbler magnet that decreases the peak power density deposited on the target. The secondary neutrons produced in the target are moderated in the cooling water before entering the sleeve where they are captured on ^{7}Li to produce ^{8}Li. The purity of the ^{7}Li in the FLiBe sleeve is 99.995%. The sleeve is surrounded by a graphite reflector to reflect the neutrons back into the sleeve.

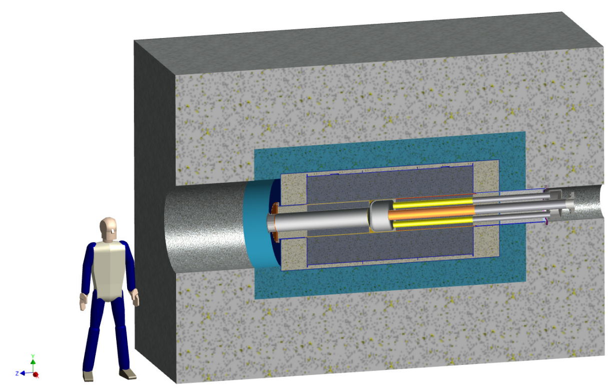

Figure 1: The IsoDAR target system and shielding. The target is a hollow centered cylinder surrounded by the FLiBe sleeve and a graphite reflector and cooled with water. The shielding in the current design consists of steel (shown in blue) and boron rich concrete (grey). A space for wobbler magnets is left in front of the target.

SHIELDING

The proposed site for the IsoDAR target is the KAMLAND control room which has the dimensions $3.5 \times 28 \times 2.25$ m. This space must contain the target assembly and the graphite reflector surrounding the sleeve while the remaining space (≈50 cm) will be used for neutron shielding. Preliminary calculations indicate that the space for neutron shielding will need to be enlarged particularly in the vertical direction. Techniques for rock removal must be discussed as blasting is not allowed.

Our collaborators from KAMLAND and RIKEN gave us valuable guidelines in establishing the requirements of the shielding and radiation protection. In this respect the rock activation due to artificially produced radionuclides must

PROGRESS ON A 30 - 350 MeV NORMAL-CONDUCTING SCALING FFAG FOR PROTON THERAPY*

J.M. Garland†, R.B. Appleby‡, H. Owen and S. Tygier
University of Manchester, Manchester, M13 9PL, United Kingdom, and
The Cockcroft Institute, Warrington, WA4 4AD, United Kingdom

Abstract

We present our progress on a new design for a 30 - 350 MeV scaling FFAG for proton therapy and tomography - NORMA (NOrmal-conducting Racetrack Medical Accelerator) which allows the realisation of proton computed tomography (pCT) and utilises normal conducting magnets in both a circular and racetrack configuration which are designed using advanced optimisation algorithms developed in PyZgoubi. The ring and racetrack configurations have average circumferences of around 60 and 70 m respectively, peak magnetic fields of < 1.8 T, average orbit excursions < 50 cm and dynamic aperture calculations of > 50 mm.mrad using a novel technique. The racetrack design has a total magnet-free straight length of 4.9 m at two opposing points, designed to ease injection and extraction systems.

INTRODUCTION

The treatment of cancer using proton therapy is widely regarded as having many advantages over conventional therapies due to the more localised dose deposition in the tumour, realisable as a characteristic Bragg peak at a depth determined by the incident proton energy; around 70 - 250 MeV for human tissue treatment [1–3]. Fast, effective treatment of a tumour volume requires precise and rapid energy variation and transverse beam scanning for effective use of treatment time and localisation of dose so as to limit surrounding healthy tissue damage. Furthermore, the technique of proton computed tomography (pCT) is highly desirable clinically due to the ability to obtain real-time diagnostics on the treatment of the tumour; however pCT requires a proton energy of around 350 MeV, not currently attainable from current proton therapy centres or designs.

An FFAG (Fixed-Field Alternating-Gradient) accelerator [4] is a good choice of machine which meets these requirements as protons may be accelerated up to 350 MeV with pulse-to-pulse energy variation up to 1 kHz and variable energy extraction. The 70 - 250 MeV proton (and carbon ion), non-scaling FFAG PAMELA (Particle Accelerator for MEdicaL Applications) [5] is capable of the desired treatment regime but not pCT in the proton ring, and has potentially complicated and expensive superconducting magnets [6]. Previous studies [7] showed the possibility of inserting magnet-free straights into a ring while maintaining a suitable DA and optics. We are designing a 30 - 350 MeV scaling, proton FFAG with normal conducting magnets which has a conventional ring and a racetrack configuration to ease injection and extraction. Although our second design has only magnet-free drifts inserted, we still refer to it as a racetrack to distinguish it form the circular design. The ring design has a circumference of around 60 m and a dynamic aperture (DA) of > 60 mm.mrad, the racetrack has a circumference of around 70 m, with two 4.9 m magnet-free straight sections and a DA of > 50 mm.mrad. Both designs will have orbit shifts over the energy range of < 50 cm with peak magnetic fields <1.8 T, but relatively large sized magnets; 0.5 m aperture, 1.0 m length. However, scaling FFAGs with similar sized magnets have been constructed and successfully operated [8–10].

NORMA RING

An FDF (focusing - defocusing - focusing) triplet is being used and optimised in the NORMA design with scaling, sector-type magnets where the field in each magnet in the radial direction is defined by

$$B(r) = B_0 \left(\frac{r}{r_0}\right)^k , \qquad (1)$$

where B_0 is the magnetic field at the reference radius r_0 and k is the field index. A schematic diagram of the cell is shown in Fig. 1 where the geometric parameters are indicated. The number of cells, geometry within each cell, magnetic field strengths of the F and D magnets and the field index were optimised using specific algorithms which we developed using PyZgoubi for the optimisation of NORMA [11, 12]; some initial analytical analysis was also used in this process.

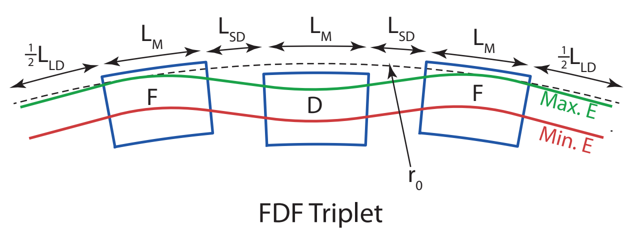

Figure 1: Geometry of the FDF triplet cell used in NORMA showing the sector-type magnets in blue, the minimum and maximum energy orbits (30 and 350 MeV) in red and green respectively and the reference radius r_0 as a dashed black line. For optimising the geometry, the free parameters were selected as the cell length L_{cell}=$2L_{LD}$+$3L_M$+$2L_{SD}$, the triplet length L_{trip}=$3L_M$+$2L_{SD}$, and the packing factor α=L_{trip} / L_{cell}.

GEM*STAR ACCELERATOR-DRIVEN SUBCRITICAL SYSTEM FOR IMPROVED SAFETY, WASTE MANAGEMENT, AND PLUTONIUM DISPOSITION

Robert Abrams†, Mary Anne Clare Cummings, Gene Flanagan,
Rolland Paul Johnson, Thomas J. Roberts, Muons, Inc, Illinois, USA
Charles Bowman, ADNA, Los Alamos, New Mexico, USA
Bruce Vogelaar, Virginia Polytechnic Institute and State University, Virginia, USA

Abstract

Operation of high-power SRF particle accelerators at two US National Laboratories allows us to consider a less-expensive nuclear reactor that operates without the need for a critical core, fuel enrichment, or reprocessing. A multipurpose reactor design that takes advantage of this new accelerator capability includes an internal spallation neutron target and high-temperature molten-salt fuel with continuous purging of volatile radioactive fission products. The reactor contains less than a critical mass and almost a million times fewer volatile radioactive fission products than conventional reactors like those at Fukushima. We describe GEM*STAR[1], a reactor that, without redesign, will burn spent nuclear fuel, natural uranium, thorium, or surplus weapons material. A first application is to burn 34 tonnes of excess weapons grade plutonium as an important step in nuclear disarmament under the 2000 Plutonium Management and Disposition Agreement[2]. The process heat generated by this W-Pu can be used for the Fischer-Tropsch conversion of natural gas and renewable carbon into 42 billion gallons of low-CO_2-footprint, drop-in, synthetic diesel fuel for the DOD.

GEM*STAR SYSTEM

The main elements of the GEM*STAR system are a particle accelerator and associated beam transport, the GEM*STAR reactor, and the ancillary facilities for utilizing the heat output for electricity generation and/or chemical processes. A block diagram of the elements is shown in Fig. 1.

*The GEM*STAR Reactor*

The heart of the GEM*STAR system is the reactor [1, 2], which consists of a graphite core matrix of tubular elements through which molten salt containing the fuel mixture circulates. As illustrated schematically in Fig. 2, pumps drive the molten salt down the periphery, up around the holding tank, and up through the graphite tubes, which act as the moderator, and back to the periphery. The molten salt level is maintained by an overflow pipe that returns the excess molten salt to the holding tank. A helium gas flow above the salt level is used to purge the volatile products from the reactor core. The accelerator beam strikes a target in the reactor to produce neutrons to control the fission rate in the reactor and maintain sub-critical operation.

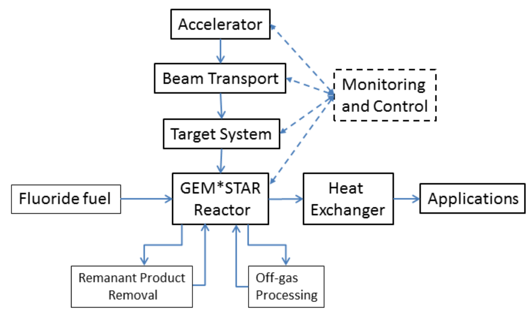

Figure 1: Block diagram showing major elements of the GEM*STAR system.

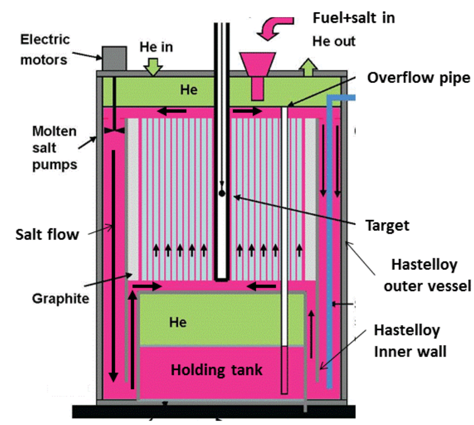

Figure 2: Cross-sectional view of GEM*STAR reactor.

The molten salt mixture is shown in magenta. Helium gas is shown in green. Secondary flow loop tubes, shown in blue, carry process heat from the core to an external heat exchanger for use by the applications. LiF salt, mixed with fluorides of plutonium, natural uranium, and thorium can be used as fuel mixtures, as well as spent nuclear fuel rods and surplus weapons material. The fuel preparation does not require MOX processing and encapsulation. Since the number of neutrons generated is independent of any particular fission chain reaction, a variety of fissile or fertile materials can be handled with one reactor design. The reactor operates in a subcritical mode, at $k_{eff} \approx 0.98$.

A MONOCHROMATIC GAMMA SOURCE WITHOUT NEUTRONS*

R.W. Garnett#, S.S. Kurennoy, L.J. Rybarcyk, and T.N. Taddeucci, LANL, Los Alamos, NM 87545

Abstract

High-energy gamma rays can be efficiently produced using the direct excitation of the 15.1-MeV level in ^{12}C via the (*p*, *p*') reaction with the threshold energy of 16.38 MeV. The threshold for neutron production via ^{12}C (*p*, *n*) is 19.66 MeV, so there is an energy window of 3.28 MeV where the 15.1-MeV photons can be produced without any direct neutrons. Thick-target yield estimates indicate that just below the neutron production threshold, the photon output is about twice that of the more well-known ^{11}B (*d*, *n*) reaction requiring 4-MeV deuterons, with the expected 15.1-MeV photon flux to be approximately $1x10^{11}$ $s^{-1}sr^{-1}$ per 1 mA of 19.6-MeV proton current on a carbon target. A compact pulsed proton accelerator capable of 10-mA or greater peak currents to drive such a gamma source will be presented. The accelerator concept is based on a 4-rod RFQ followed by compact H-mode structures with PMQ focusing.

INTRODUCTION

Conventional bremsstrahlung-based interrogation of special nuclear materials in cargo is not very efficient because its gamma energy spectrum is dominated by low-energy photons. On the contrary, 15-MeV photons are well matched to the peak of the photo-fission cross section for uranium. Such gamma rays can be efficiently produced using direct excitation of the 15.1-MeV level in the ^{12}C via (*p*, *p*') reaction that has the threshold energy of 16.38 MeV [1]. The threshold of neutron production via ^{12}C (*p*, *n*) is 19.66 MeV, so there is a window of 3.28 MeV where the 15.1-MeV photons can be produced without any direct neutrons. The thick-target yield estimates in [1] indicate that just below the neutron production threshold, the 15.1-MeV photon output is about twice that in the ^{11}B (*d*, *n*) reaction with 4-MeV deuterons (See Fig. 1).

For the latter, we estimated the 15.1-MeV photon flux as $5 \cdot 10^{10}$ $s^{-1}sr^{-1}$ per 1 mA of deuteron current [2]. Therefore, we expect a 15.1-MeV photon flux of $1 \cdot 10^{11}$ $s^{-1}sr^{-1}$ per 1 mA of 19.6-MeV protons on a carbon target – much higher than with conventional sources, and without the neutron background. Having such a monochromatic source of high-energy photons significantly reduces the total dose required for SNM interrogation in cargo. The detection efficiency also increases due to eliminated neutron background and shorter pulses.

ACCELERATOR SYSTEM

To implement the above promising approach, we need a compact system that accelerates protons with peak currents of 10s mA to 19.6 MeV. Based on our previous results [2, 3], one attractive option is a compact pulsed accelerator that consists of an RFQ followed by H-mode structures with PMQ focusing (H-PMQ). For preliminary estimates, we use results [3] where replacing the 201.25-MHz LANSCE drift-tube linac (DTL) by much more efficient H-PMQ accelerator structures [4] of the same frequency was studied. A 750-keV RFQ (~2 m) is followed by two inter-digital H-PMQ (IH-PMQ) tanks with the accelerating gradient 2.5 MV/m to bring protons to 5.4 MeV [3]. After that we switch to cross-bar H-PMQ structures (CH-PMQ); likely, three CH-PMQ tanks will be needed to accelerate protons to 19.6 MeV. The total accelerator length is estimated to be ~12 m, but can be reduced by increasing the gradient. The transverse size will be well within 1-m diameter. With peak currents below 50 mA, the highest values in designs [2, 3], the required maximum peak RF power should be less than 2.5 MW. The system is illustrated in Fig. 2 and looks feasible.

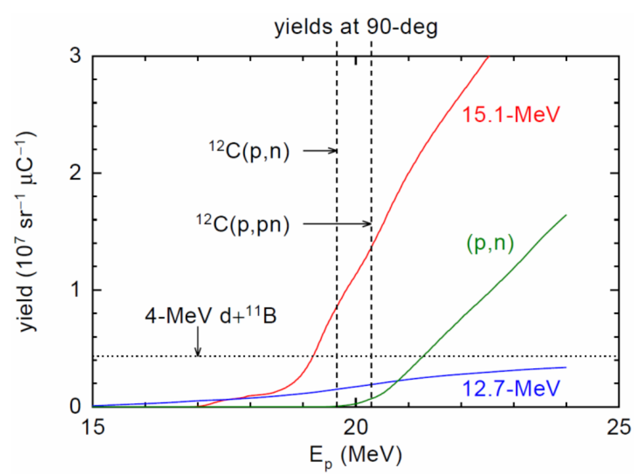

Figure 1: Thick-target yields for p+^{12}C photon and neutron production reactions.

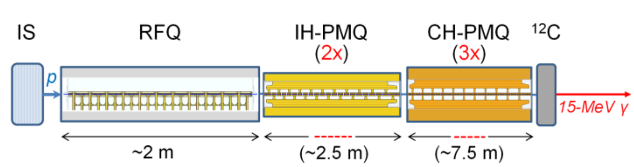

Figure 2: Accelerator scheme.

Ion Source and RFQ

Proton ion sources (IS) providing peak currents of 10s mA at duty factors up to 10-20% are readily available [5]. The IS will be connected to the RFQ entrance by a short electrostatic, low-energy beam transfer line (LEBT). The LEBT can also serve as the beam switch with on-off times ~50 ns as in the SNS front end. The 750-keV RFQ can be of either 4-vane or 4-rod type. Based on our recent

RADIOGRAPHY CAPABILITIES FOR MATTER-RADIATION INTERACTIONS IN EXTREMES*

P. L. Walstrom#, R. W. Garnett, R. L. Barber, J. A. O'Toole, T. S. Gomez, C. A. Chapman, H. R. Salazar, Los Alamos National Laboratory, Los Alamos, New Mexico 87545

Abstract

The Matter-Radiation Interactions in Extremes (MaRIE) experimental facility [1] will be used to discover and design the advanced materials needed to meet 21st century national security and energy security challenges. This new facility will provide the new tools scientists need to develop next-generation materials that will perform predictably and on-demand for currently unattainable lifetimes in extreme environments. The MaRIE facility is based on upgrades to the existing LANSCE 800-MeV proton linac and a new 12-GeV electron linac and associated X-ray FEL to provide simultaneous multiple probe beams, and new experimental areas. In addition to the high-energy photon probe beam, both electron and proton radiography capabilities will be available at the MaRIE facility. Recently, detailed radiography system studies have been performed to develop conceptual layouts of high-magnification electron and proton radiography systems that can meet the experimental requirements for the expected first experiments to be performed at the facility. A description of the radiography systems, their performance requirements, and a proposed facility layout are presented.

FACILITY MISSION

The mission need is to provide qualification, certification, and assessment of materials in the nuclear deterrent stockpile. Material interfaces, defects, and microstructure between the scales of atomic structure and the engineering continuum (the so-called mesoscale) determine time-dependent properties, from shock response to manufacturing processes to aging. Test samples will be synthesised and characterized at the mesoscale, and their dynamic behavior in time-dependent extreme conditions characterized by use of both imaging and diffractive scattering with multiple probes at multiple spatial and time scales.

FACILITY OVERVIEW

The MaRIE facility (see Fig. 1) will be built on the TA-53 site at LANL and will make use of the existing 800-MeV proton linac. New facility components include a 12-GeV electron linac, 42-keV X-ray FEL/undulator, X-ray, electron, and proton beam lines, new experimental halls, and materials fabrication/characterization facilities. X-ray, electron, and proton beams intersect in multibeam radiography areas or hutches (see Fig. 2).

walstrom@lanl.gov

12-GeV Superconducting Electron Linac

The choice of a superconducting (SC) linac was driven by the requirement of having up to 30 microbunches over a time window of up to 100 μs, which rules out high-gradient normal-conducting structures [2]. The SC linac will use the same basic 1.3-GHz cavities as planned for the European XFEL and LCLS-II. The design assumes a cavity accelerating gradient of 31.5 MV/m. The total length of the linac is 750 m, which gives it an average (real-estate) gradient of 16 MV/m.

Undulator

The undulator is a hybrid permanent magnet type with an on-axis field of 0.7 T and a period of 1.86 cm. The total undulator length is 138 m. There are 28 undulator segments and 16 FODO periods, each with a length of 8.6 m. Two of the FODO periods contain chicanes and monochromators for seeding.

FEL Undulator and X-Ray Beam Transport

In the initial stage of the facility, a single undulator/FEL will be used to produce a bright, coherent X-ray beam of up to 42 keV energy with a photon flux in excess of 2×10^{10} photons in each 30-fs pulse. Silicon kinoform lenses are used to expand the x-ray beam. Bragg scattering from crystals is used to deflect the X-ray beam at small angles of up to 5 degrees into multiple X-ray beamlines. Another set of kinoform lenses, labelled "objectives", then focus the expanded X-ray beam onto the targets with different focused spot radii, depending on the experimental requirements.

12-GeV Electron and 800-MeV Proton Radiography Systems

Proton radiography (pRad) is a mature technology, with systems operating in the USA, Germany, and Russia. Electron radiography (eRad) in the GeV range is under development [3], with proof-of-principle experiments planned for the summer of 2015 at SLAC. Both eRad and pRad have the same basic system components, but the physics of beam interaction with objects differs: ionization energy loss and multiple Coulomb scattering (MCS) are nearly the same for both eRad and pRad, but bremsstrahlung energy loss is important in eRad and negligible for pRad, and nuclear scattering is important for pRad but small for eRad. Bremsstrahlung energy loss limits 12-GeV eRad of high-Z materials (U, Pu, etc.) to thicknesses of a few millimeters or less. Object thicknesses in 800-MeV pRad are limited by MCS, dE/dx energy loss, and second-order lens chromatic aberrations. Both techniques use matching illuminating beams, point-

VARYING AMPLITUDE RASTER PATTERN FOR HIGH POWER ISOTOPE PRODUCTION TARGETS*

J. Kolski†, J. Audia, H. Bach, Y. Batygin, J. Bradley, M. Connors, J.W. Engle, E. Espinoza, E. Figueroa, M. Hall, M. Martinez, M. Nortier, D. Reass, W. Roybal, H. Watkins,
LANL, Los Alamos, NM, 87545, USA

Abstract

The Isotope Production Facility (IPF) at LANSCE [1, 2] produces medical radionuclides strontium-82 and germanium-68 by bombarding rubidium chloride and gallium metal targets respectively with a 100 MeV proton beam, 230 μA average current. Rastering the proton beam is necessary to distribute beam power deposited as heat in the target and allow for higher average beam current for isotope production. We currently use a single circle raster pattern with constant amplitude and frequency. In this paper, we demonstrate two different varying amplitude raster patterns (concentric circle and spiral) to achieve uniform target coverage and expose more target volume to beam heating. In this proof-of-principle experiment, we compare beam spot uniformity measured by irradiating films and foils for both raster patterns.

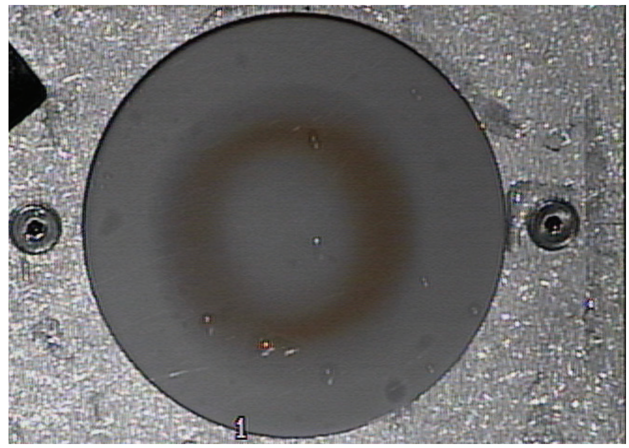

Figure 1: Beam spot at the IPF target with the single circle production raster pattern measured by film irradiation.

INTRODUCTION

A horizontal and a vertical steering magnet perform the beam rastering for IPF [3]. The steering magnets are modulated by the same frequency generator with maximum bandwidth 5 kHz. Steering magnet amplitude can be controlled separately via digital controllers. During typical production, IPF receives 625 μs long macropulses, yielding with the raster frequency ~3 raster revolutions per macropulse.

The current single circle production raster pattern with typical 15 mm radius results in the beam spot at the IPF target shown in Fig. 1. All beam heat is deposited in the thin ring and little beam hits the target center. The goal of this proof-of-principle investigation is to demonstrate that with minor modifications to existing equipment, an amplitude varying raster pattern (concentric circle or spiral) can "fill in" the target center, distributing the beam heating over more target volume, and yielding uniform target coverage.

RASTER PATTERNS

We demonstrate two different amplitude varying raster patterns: concentric circle and spiral [4, 5]. Both methods have a square root amplitude and sinusoidal frequency dependence with time, Fig. 2.

$$\begin{pmatrix} R_x \\ R_y \end{pmatrix} = A(t) \times \Phi(t) \sim \sqrt{t} \times \begin{cases} \cos(2\pi f t + \phi) \\ \sin(2\pi f t + \phi) \end{cases} \quad (1)$$

In the concentric circle method, the raster amplitude is constant for each macropulse. The amplitude changes in between macropulses, executing the square root dependence with more larger radii circles and fewer smaller radii circles. The uniform beam spot is achieved in several macropulses. Due to equipment protection considerations, we do not execute the pattern in order of radii size. Instead, we "mix up" the radii as observed in Fig. 2. In this paper, we study a concentric circle pattern with 100 different radii.

In the spiral case, the square root amplitude dependence is executed during each macropulse by spending more time at larger radii and less time at smaller radii. A macropulse-to-macropulse phase shift due to the raster frequency and the 120 Hz machine repetition rate rotates the spiral to give the uniform beam spot on target after several macropulses. Care was taken to ensure that the raster frequency was not a multiple of the 120 Hz machine repetition rate, as this would yield a zero degree macropulse-to-macropulse phase shift.

SET UP AND MEASUREMENT

We set up for this experiment with a 5 Hz repetition rate to IPF in order to achieve ~10 μA average current (for equipment protection reasons) using the production peak current, 3.4 mA. After each raster pattern was loaded into the controller, we inserted a measurement stack into the IPF target position. The measurement stack held a 0.5 mm thick polyethylene film and a 1 mm thick titanium foil. We simultaneously irradiated both film and foil with 100 macropulses of rastered beam. The plastic film image was captured with

BASELINE SCHEME FOR POLARIZATION PRESERVATION AND CONTROL IN THE MEIC ION COMPLEX*

Ya.S. Derbenev, F. Lin, V.S. Morozov, Y. Zhang, JLab, Newport News, Virginia
A.M. Kondratenko, M.A. Kondratenko, Science and Technique Laboratory Zaryad, Novosibirsk

Abstract

The scheme for preservation and control of the ion polarization in the Medium-energy Electron-Ion Collider (MEIC) has been under active development in recent years. The figure-8 configuration of the ion rings provides a unique capability to control the polarization of any ion species including deuterons by means of "weak" solenoids rotating the particle spins by small angles. Insertion of "weak" solenoids into the magnetic lattices of the booster and collider rings solves the problem of polarization preservation during acceleration of the ion beam. Universal 3D spin rotators designed on the basis of "weak" solenoids allow one to obtain any polarization orientation at an interaction point of MEIC. This paper presents the baseline scheme for polarization preservation and control in the MEIC ion complex.

INTRODUCTION

Colliders "Transparent to the Spin"

Colliders with a figure-8 topology are natural representatives of colliders "transparent to the spin". In such colliders, effect on the spin of one arc is compensated by the other arc. Thus, effect of "strong" arc fields on the spin is reduced to zero. Any spin direction repeats after a particle turn, i.e. the collider has no preferred spin direction. This means that the particles are in the region of a zero-integer spin resonance and the spin tune is zero $\nu=0$.

Colliders transparent to the spin offer a unique opportunity to efficiently control the ion polarization using small magnetic field integrals. In such a collider, any small perturbation has a strong effect on the beam polarization. To stabilize the spin direction, one must introduce additional fields into the collider's lattice, which "shift" the spin tune by a small value ($\nu << 1$) and set the necessary orientation of the polarization. "Weak" fields have essentially no effect on the beam's orbital characteristics. What especially stands out is the possibility of using weak solenoids, which do not impact the closed orbit at all. In the collider's energy range of up to 100 GeV, the field integrals of these solenoids are approximately two orders of magnitude lower than the field integrals of the spin rotators with strong fields. There is no problem with changing the fields of such solenoids during adjustment of the beam polarization direction. It becomes possible to reverse the spin in less than a second allowing for polarized beam experiments at a new precision level.

Strength of the Zero-integer Spin Resonance

The required weak field integrals are limited by the strength of the zero-integer spin resonance w_0: $\nu >> w_0$. The resonance strength is the value of the average spin field, which is determined by deviation of the trajectory from the ideal design orbit. The resonance strength consists of two parts: a coherent part arising due to additional dipole and longitudinal fields on a trajectory deviating from the design orbit and an incoherent part associated with the ions' betatron and synchrotron oscillations (beam emittances). The coherent part of the spin field is determined by linear effects and lies in the orbital plane. The incoherent part of the spin field is not present to first order in orbit deviations due to the non-resonant nature of the oscillations about the closed orbit. The coherent part of the spin field providing the main contribution to the resonance strength can be compensated by a pair of solenoids, which can be used to set any orientation and magnitude of the spin field in the collider's plane. Compensation of the coherent part of the resonance strength allows one to greatly reduce the field integrals of the control solenoids. The technique for compensation of integer resonance harmonics is well known and has been successfully utilized, for example, at the AGS [1]. Thus, figure-8 colliders allow one to take polarized beam experiments to a conceptually higher precision level.

Let us demonstrate the main advantages of spin-transparent figure-8 colliders by applying this concept to the tasks of polarization preservation and spin manipulation during experiments in the ion complex of MEIC.

ION POLARIZATION IN THE MEIC ACCELERATOR COMPLEX

In the new design, the MEIC ion complex (see Fig. 1) consists of sources for polarized light ions and non-polarized light to heavy ions, a 280 MeV pulsed SRF ion linac, an 8 GeV booster, and a medium-energy collider ring [2]. The ion collider ring is stacked vertically above the electron collider ring, and takes a vertical excursion to the plane of the electron ring for a horizontal crossing. Two interaction points of the electron and ion beams lie in the plane of the electron ring.

Abstract

Ion polarization in the Medium-energy Electron-Ion Collider (MEIC) is controlled by means of universal 3D spin rotators designed on the basis of "weak" solenoids. We use numerical calculations to demonstrate that the 3D rotators have negligible effect on the orbital properties of the ring. We present calculations of the polarization dynamics along the collider's orbit for both longitudinal and transverse polarization directions at a beam interaction point. We calculate the degree of depolarization due to the longitudinal and transverse beam emittances in case when the zero-integer spin resonance is compensated.

INTRODUCTION

Jefferson Lab presently considers an updated scheme of the MEIC electron-ion collider project with the main changes related to a switch to 3 T super-ferric magnets and an increase of the collider ring circumference to ~2.2 km [1]. The ion collider ring retains a figure-8 shape, remains transparent to the spin and, as before, allows for an efficient control of polarization of any ion species by "small" solenoids rotating the particle spins by small angles. The main element of the polarization control system is a universal 3D spin rotator designed using "weak" solenoids [2]. Below we present numerical calculations demonstrating operability of the 3D rotator in the new lattice of the MEIC ion collider ring.

3D SPIN ROTATOR IN MEIC COLLIDER

A universal 3D spin rotator consists of three modules for control of the n_x, n_y, and n_z polarization components (see Fig. 1) [2, 3].

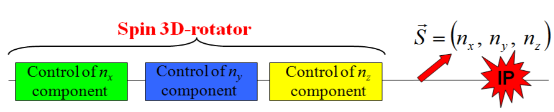

Figure 1: 3D spin rotator schematic.

Figure 2 shows the module for control of the radial polarization component n_x, which consists of two pairs of opposite-field solenoids and three vertical-field dipoles producing a fixed orbit bump. The control module for the vertical polarization component n_y is the same as that for the radial component except that the vertical-field dipoles are replaced with radial-field ones. To keep the orbit bumps fixed, the fields of the vertical- and radial-field dipoles must be ramped proportionally to the beam momentum. The module for control of the longitudinal polarization component n_z consists of a single weak solenoid.

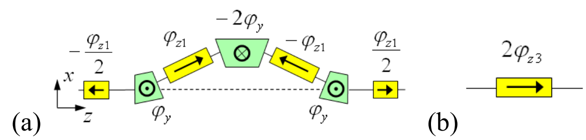

Figure 2: Modules for control of the radial n_x (a) and longitudinal n_z (b) polarization components.

Figure 3 shows schematically placement of the radial (green) and vertical (blue) dipoles as well as of the weak control solenoids (yellow) between the lattice magnets (black) of a collider's straight.

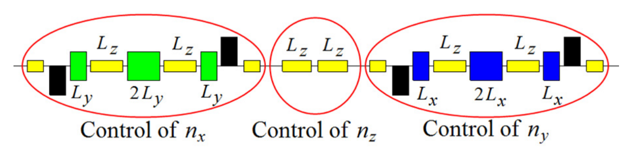

Figure 3: Placement of the 3D spin rotator elements.

The dipole and solenoid lengths are $L_x = L_y = 0.6$ m and $L_z = 2$ m, respectively. In the modules for control of the transverse polarization components, the dipoles produce a fixed orbit bump of ~18 mm in the whole momentum range. The maximum dipole field is 3 T while the field of the control solenoids does not exceed 2 T. This allows one to set the spin tune to $\nu_p = 0.01$ for protons and $\nu_d = 10^{-4}$ for deuterons and also to stabilize any polarization direction at any location in the collider during an experiment essentially with no perturbation to the collider's orbital properties.

EFFECT OF 3D SPIN ROTATOR ON THE ORBITAL BEAM PARAMETERS IN MEIC

Effect of the 3D spin rotator is calculated for multiple reversals of the beam polarization in the vertical plane (yz) of the detector during an experiment (spin flipping). Figures 4 and 5 show graphs of the solenoid fields in the n_y and n_z modules of the 3D rotator versus the angle Ψ between the spin and the beam direction for deuterons and protons. Superconducting pulsed solenoid field of 2 T can be ramped in about 1 second [4].

Abstract

We present an update on the design of the ion collider ring of the Medium-energy Electron-Ion Collider (MEIC) [1] proposed by Jefferson Lab. The design is based on the use of super-ferric magnets. It provides the necessary momentum range of 8 to 100 GeV/*c* for protons and ions, matches the electron collider ring design using PEP-II components, fits readily on the JLab site, offers a straightforward path for a future full-energy upgrade by replacing the magnets with higher-field ones in the same tunnel, and is more cost effective than using presently available current-dominated super-conducting magnets. We describe complete ion collider optics including an independently-designed modular detector region.

DESIGN OVERVIEW

The ion collider ring accelerates protons and ions from 8 to up to 100 GeV/*c* and is designed to provide luminosity above 10^{33} cm^{-2}s^{-1} in the momentum range from 20 to 100 GeV/*c*. The overall layout of the ion collider ring indicating the main components is shown in Fig. 1. The ring consists of two 261.7° arcs connected by two straight sections intersecting at an 81.7° angle. The ion collider ring's geometry is determined by the electron collider ring [2,3]. The ion arcs are composed mainly of FODO cells. The last few dipoles at either end of each arc are arranged to match the geometry of the ion collider ring. One of the straights houses an interaction region and is shaped to make a 50 mrad crossing angle with the electron beam at the interaction point. The second straight is mostly filled with FODO, however, retaining the capability of inserting a second interaction region. The overall ion ring circumference is 2153.89 m. The main building blocks of the ring are described below.

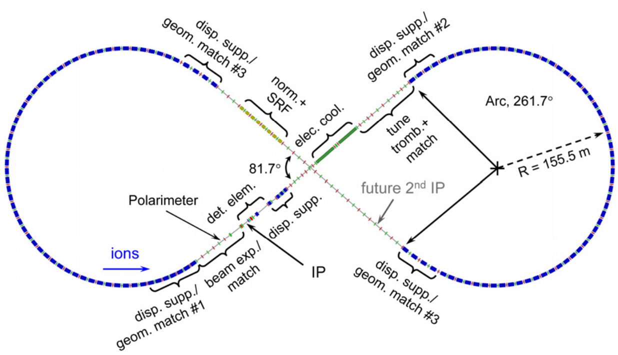

Figure 1: Layout and main components of the ion collider ring.

ARCS

The main building block of the ion arcs is a FODO cell shown in Fig. 2. It has been designed considering a balance of geometric, engineering and beam dynamical aspects. It has the same average bending radius as the electron arc. The ion FODO cell length is chosen at 22.8 m to be 1.5 times that of the electron FODO cell. Such a size allows for use of super-ferric magnets [4] up to a proton momentum of about 100 GeV/*c*. Each 8 m long dipole has a maximum field of about 3.06 T and bends the beam by about 4.2° with a bending radius of about 109.1 m.

The required magnet apertures are determined using a sum of a ±10 rms beam size at injection (including betatron and dispersive contributions), a ±1 cm closed orbit allowance, and, in case of dipoles, a plus or minus a half of the orbit arc's sagitta. To make the dipole horizontal aperture size more manageable, each dipole is implemented as two 4 m long straight pieces reducing the

PROGRESS ON OPTIMIZATION OF THE NONLINEAR BEAM DYNAMICS IN THE MEIC COLLIDER RINGS*

Y. Nosochkov†, Y. Cai, M. Sullivan, M-H. Wang, U. Wienands, SLAC, Menlo Park, CA, USA

Abstract

One of the key design features of the Medium-energy Electron-Ion Collider (MEIC) proposed by Jefferson Lab is a small beta function at the interaction point (IP) allowing one to achieve a high luminosity of up to 10^{34} cm^{-2}s^{-1}. The required strong beam focusing unavoidably causes large chromatic effects such as chromatic tune spread and beam smear at the IP, which need to be compensated. This paper reports recent progress in our development of a chromaticity correction scheme for the ion ring including optimization of dynamic aperture and momentum acceptance.

INTRODUCTION

Design of the Medium-energy Electron-Ion Collider (MEIC) [1] at Jefferson Lab is aimed at reaching high luminosity of up to 10^{34} cm^{-2}s^{-1}. The latter requires a small beam size and, therefore, small beta function (β^*) at the interaction point (IP). As a result, beta functions in the nearest to IP final focusing quadrupoles (FFQ) become very large ($\propto 1/\beta^*$) making the FFQ the main source of chromaticity in the ring. Since the FFQ linear chromaticity (i.e. first order tune shift with momentum deviation $\delta_p = \Delta p/p$) is straightforward to cancel with conventional two-family sextupoles in the ring arcs, the main concern is the large non-linear chromaticity. The latter is driven by a large perturbation of momentum dependent beta function created by the FFQ chromatic kick. This perturbation could lead to a strong non-linear momentum dependence of tune and the β^*. The increased tune spread could excite stronger effects of betatron resonances on dynamic aperture, thus limiting the momentum acceptance; and the IP chromatic beam smear would increase the effective beam size resulting in a lower luminosity. To compensate the FFQ non-linear chromaticity, a dedicated correction system is required. This paper presents a study of two correction options for the ion ring including the results of dynamic aperture optimization.

LATTICE

The MEIC ring circumference has been recently increased to $\simeq 2.2$ km [1]. This allows the re-use of the PEP-II High Energy Ring [2] components in the electron ring and the use of super-ferric magnets [3] in the ion ring. The two rings are stacked vertically in the same tunnel and have a

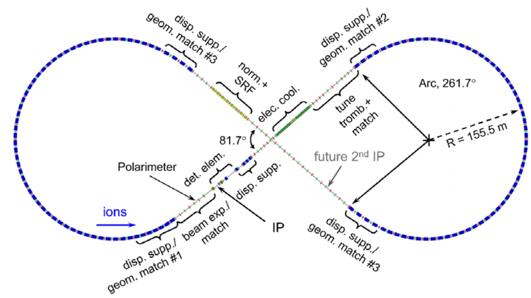

Figure 1: Top view layout of the ion ring.

figure-8 layout, as shown in Fig. 1, which optimizes preservation of the ion polarization [4]. The design collision beam energies are: 3-10 GeV for electrons, 20-100 GeV for protons, and up to 40 GeV per nucleon for ions. Each ring consists of two 90° FODO arcs and two long straight sections. One straight contains the interaction region (IR), a polarimeter, a cooling section and tune trombone, while the other FODO straight houses accelerating cavities and can be upgraded to a second IR in the future. The beams collide at 50 mrad horizontal angle at the IP.

The ion ring lattice (before chromaticity correction adjustment) is shown in Fig. 2, where the machine natural chromaticity is $\xi_{x,y} = [-101.1, -111.6]$. The two FODO arcs are the only dispersive regions suitable for the chromaticity correcting sextupoles. The IR optics is shown in Fig. 3, where $\beta^*_{x,y} = 10 \times 2$ cm corresponding to the IP rms beam size of $\sigma^*_{x,y} = 18 \times 3.6$ μm for 100 GeV protons. Due to the detector requirements, the IR optics is made asymmetric with 7 m free space downstream of IP versus 3.6 m on the upstream side. This results in a factor of 3 higher beta functions in the downstream FFQ leading to stronger chromatic perturbation. The downstream side also includes a detector spectrometer optics with a second focal point which further increases the IR chromatic asymmetry.

CHROMATICITY CORRECTION

As pointed out, the large non-linear chromaticity generated by the FFQs requires a dedicated correction. Due to the $\simeq \pi$ phase advance between the upstream and downstream FFQs their chromatic contributions add up. If not locally cancelled, the chromatic beta perturbation would propagate around the ring giving rise to large non-linear momentum dependence of the tune. A conventional solution is to use local sextupoles generating a chromatic beta wave opposite to the one from FFQ, so they cancel each other. A separate local correction is needed on each side of IP in order to avoid the IP chromatic beam smear. Desired conditions at

MATCHING INTO THE HELICAL BUNCH COALESCING CHANNEL FOR A HIGH LUMINOSITY MUON COLLIDER

D. Neuffer, K. Yonehara, C. Yoshikawa, Fermilab, Batavia, IL 60510, U.S.A.

Abstract

For high luminosity in a muon collider, muon bunches that have been cooled in the six-dimensional helical cooling channel (HCC) must be merged into a single bunch and further cooled in preparation for acceleration and transport to the collider ring. The helical bunch coalescing channel provides the most natural match from helical upstream and downstream subsystems. This work focuses on the matching from the exit of the multiple bunch HCC into the start of the helical bunch coalescing channel. The simulated helical matching section simultaneously matches the helical spatial period λ in addition to providing the necessary acceleration for efficient bunch coalescing. Previous studies assumed that the acceleration of muon bunches from p=209.15 MeV/c to 286.816 MeV/c and matching of λ from 0.5 m to 1.0 m could be accomplished with zero particle losses and zero emittance growth in the individual bunches. This study demonstrates nonzero values for both particle loss and emittance growth, and provides considerations for reducing these adverse effects to best preserve high luminosity.

INTRODUCTION

A high luminosity muon collider requires fast cooling of muons by six orders of magnitude in phase space to obtain short, intense bunches. This six-dimensional cooling is envisioned to be achieved in two stages: initial multi-bunch cooling of trains of small bunches, and single bunch cooling of a larger density bunch in preparation for the final cooling towards collision densities. The transition between multi-bunch cooling and single bunch cooling requires an intermediate bunch recombination process with minimal beam loss.

The Helical Cooling Channel (HCC) [1-4] has been proposed as a means to achieve the six-dimensional cooling of both multiple bunches of muons and single bunches of muons. The HCC allows for continuous emittance exchange for efficient cooling, with longitudinal momentum restored through RF acceleration. In this cooling scheme, muons traverse a series of helical channels, with successive sections utilizing smaller helical spatial period λ and higher RF frequency as the muon emittances are reduced. Bunch recombination to a large single bunch necessitates a return to a larger λ and corresponding lower RF frequency, and the single bunch cooling then proceeds in a similar manner, through helical channels with successively smaller λ and higher RF frequency. A helical bunch coalescing channel provides the most natural match from the upstream multi-bunch HCC to the downstream single bunch HCC and has been explored extensively [5-7] as part of the general HCC design. The helical bunch coalescing channel uses varying RF frequencies to induce an energy-time correlation in the muon bunch train. This energy-time correlation imparts relative velocities to individual bunches such that all bunches in the bunch train align in time at the end of a short drift section and can be captured into a single RF bucket. Previous studies of the helical bunch coalescing channel demonstrated particle transmission of over 90% with an RF fill factor as low as 25%, with room for optimization, but used lower RF frequencies that are no longer relevant to the system. The previous studies also excluded transition sections necessary to match the muon bunches from the exit of the upstream multi-bunch HCC to the entrance of the helical bunch coalescing channel. This work addresses the transition section required to match the muon bunches from λ = 0.5 to 1.0 m and total momentum p=209.15 MeV/c to 286.816 MeV/c in preparation for bunch merging in the helical bunch coalescing channel previously explored.

#amysy@jlab.org

TRANSITIONING TO THE HELICAL BUNCH COALESCING CHANNEL

Muons exit the upstream multi-bunch HCC with λ = 0.5 m, RF frequency of 650 MHz, and total momentum on the reference orbit of 209.15 MeV/c. This bunch coalescing method has been found to be more efficient at higher muon momentum [6]; these most recent studies assumed that the acceleration of muons to 286.816 MeV/c could be accomplished with zero emittance growth and zero beam loss. The bunch coalescing channel described in [6] also utilizes λ = 1.0 m and RF frequency of 200 MHz. This parameter mismatch necessitates a transition section to evaluate the emittance growth and particle losses induced by the matching section and to allow for an end-to-end simulation of the complete six-dimensional cooling channel. The most efficient transition section will simultaneously accelerate muons while adiabatically increasing λ. We note that the previous bunch coalescing channel was simulated using RF frequency of 200 MHz, and the bunch merge performance is expected to scale with higher RF frequency.

SIMULATION GEOMETRY

The transition section to the helical bunch coalescing channel was simulated using G4Beamline/GEANT4 [8]. RF cavities of length 5 cm were used throughout the transition section, with 60 μm thick beryllium windows

CAPTURE, ACCELERATION AND BUNCHING RF SYSTEMS FOR THE MEIC BOOSTER AND STORAGE RINGS*

S. Wang#, J. Guo, F. Lin, V. Morozov, R. Rimmer, H. Wang, Y. Zhang
Jefferson Lab, Newport News, VA 23606, USA

Abstract

The Medium-energy Electron Ion Collider (MEIC), proposed by Jefferson Lab, consists of a series of accelerators. The electron collider ring accepts electrons from CEBAF at energies from 3 to 12 GeV. Protons and ions are delivered to a booster and captured in a long bunch before being ramped and transferred to the ion collider ring. The ion collider ring accelerates a small number of long ion bunches to colliding energy before they are re-bunched into a high frequency train of very short bunches for colliding. Two sets of low frequency RF systems are needed for the long ion bunch energy ramping in the booster and ion collider ring. Another two sets of high frequency RF cavities are needed for re-bunching in the ion collider ring and compensating synchrotron radiation energy loss in the electron collider ring. The requirements from energy ramping, ion beam bunching, electron beam energy compensation, collective effects, beam loading and feedback capability, RF power capability, etc. are presented. The preliminary designs of these RF systems are presented. Concepts for the baseline cavity and RF station configurations are described, as well as some options that may allow more flexible injection and acceleration schemes.

INTRODUCTION

For the ion accelerator complex, one major change from earlier design is that only one booster exists between the source-linac system and ion collider ring [1]. In this booster, ions are captured and form a single long bunch, accumulated to the required bunch charge, and then ramped, to 8 GeV(H^+)/3.2 GeV/u(lead ion) and cooled, before being transferred to the ion collider ring. In the ion collider ring, nine long bunches are formed before being ramped to collision energy. At collision energy, the long bunches are debunched and rebunched in to 476 MHz buckets before collision with the electron bunches.

For the electron collider ring, it accepts bunch trains from CEBAF. The RF system needs to provide synchrotron radiation energy compensation and bunch longitudinal formation at different collision energies with high enough beam current, and stable operation.

CAPTURE AND RAMPING RF CAVITIES IN BOOSTER AND ION COLLIDER RING

In the ion source-linac system, ion bunch trains are accelerated to 285 MeV (proton) or 114 MeV/u (lead ions) before being delivered to the booster. Like other rapid cycling synchrotrons, the micro bunches from the linac will be accumulated in the booster ring, captured by the potential well produced by the RF field. The 8 GeV booster ring is designed to utilize multi-turn injection with combined longitudinal and transverse painting and charge exchange mechanism.

At low energy, space charge effect is the most important effect that limits the maximum available total charge in each ramping cycle. That is why a long bunch is needed in the booster in order to lower the space charge density.

During the energy ramping process in both booster and collider rings the beta of ions varies so the RF frequency needs to be variable to keep up with the revolution frequency. So, we need choose the inductance-loaded RF cavities as the ramping cavities. Because the ramping rate is limited by the super-ferric bending magnets [2], the total gap voltage needed for ramping is not high, as shown in Table 1. We chose ferrite-loaded cavities for the design for the lower cost. In the design, we assumed a linear ramping process. Design data for the ramping cavities in booster and collider ring are shown in Table 2.

Table 1: Summary of Ramping Cavity Configuration

MEIC PROTON BEAM FORMATION WITH A LOW ENERGY LINAC[#]

Yuhong Zhang*, Thomas Jefferson National Accelerator Facility, Newport News, VA USA

Abstract

The MIEC proton and ion beams are generated, accumulated, accelerated and cooled in a new green-field ion injector complex designed specifically to support its high luminosity goal. This injector consists of sources, a linac and a small booster ring. In this paper we explore feasibility of a short ion linac that injects low energy protons and ions into the booster ring.

INTRODUCTION

A polarized medium-energy electron-ion collider, MEIC, has been envisioned as a future facility at JLab beyond the 12 GeV CEBAF program [1,2]. This future collider is designed to deliver high performance including high luminosities and high polarization of both electron and light ion beams. Its luminosity concept [3] is based on a high bunch repetition rate, up to 476 MHz, which enables small emittance, short bunch length, and very strong final focusing.

The MEIC proton and ion beams are generated in a new ion injector in a green field. Recently, great efforts were made to optimize the injector design for achieving better performance and for lowering the cost. The first major change of the design is elimination of a large booster ring (3 to 20 GeV) by allowing the beams being injected directly into the collider ring from the small booster [4]. The proton extraction energy from the booster is raised to 7.9 GeV, therefore greatly easing the space charge bottleneck when the beam is injected into a full size ring (the large booster has a same circumference as the collider ring). The second major change is a proposed reduction of the linac energy by nearly 60%, leading to a large reduction of the ion linac cost. Lowering the linac energy, however, has serious impact on the process of ion beam formation, therefore, the injection scheme must be reformulated to accommodate lower injection energies and to alleviate the much stronger space charge effect. This paper reports a recent study of this topic.

MEIC ION INJECTOR

The MEIC ion injector is designed with the following major components [2]: polarized ion sources (for H^-/D^- and ^3He) and non-polarized ion sources (up to lead); a pulsed linac made of a warm front end and SRF cavities; and a single booster ring (up to 7.9 GeV). The booster ring also includes a DC electron cooler for assisting accumulation of ions and, as a part of a multi-step cooling scheme [5,6], for the initial stage of emittance reduction of all ion beams. Such DC cooling is very efficient at low energies thus it greatly improves the overall cooling rate.

Like all hadron facilities, it is a long process to form and accelerate an ion beam for collisions with an electron beam in MEIC. This process can be outlined below:

1. Eject the used beam from the collider ring, cycle the magnets;
2. Accumulate protons strip-injected from the linac to the booster ring;
3. Ramp energy to 2 GeV (the DC cooling energy);
4. Perform DC electron cooling;
5. Ramp to 7.9 GeV (the booster ejection energy);
6. Transfer the beam into the collider ring; cycle the booster ring magnets;
7. Repeat step 2 to 6 to fill the collider ring, perform electron cooling during stacking;
8. Ramp to the collision energy (20 to 100 GeV)
9. Perform bunch splitting to reach high bunch repetition rate while continuing electron cooling;
10. Resume *e-p* collisions.

Figure 1 below illustrates this beam formation process. The number of injection cycles from the booster to the collider ring depends on the linac energy. Formation of heavy ion beams in MEIC follows a similar process except it requires more injections from the booster ring.

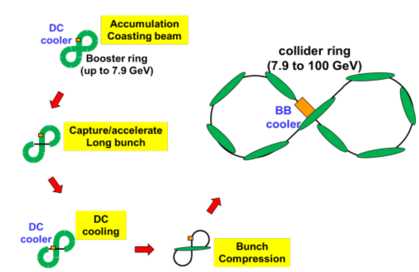

Figure 1: An illustration of the MEIC ion beam formation process. It requires multiple transfers of accumulated long bunches from the booster to the collider ring. The beam intensity is limited by the magnet apertures and the space charge effect at injection of the booster.

The MEIC ion linac is designed to accelerate protons to 285 MeV and (partially stripped) ions such as $^{208}Pb^{67+}$ to 100 MeV per nucleon [1,2,7]. Presently, we are exploring feasibility of replacing this SRF linac by a cost-effective pulsed warm RF linac (as first suggested by this author), the conceptual development is underway [8]. Alternately, lowering the linac energy could also achieve a substantial cost reduction for MEIC. One approach is installing only the warm front end and the first section of the SRF linac for the present MEIC baseline. As a result, the proton energy from the linac is 120 MeV and the lead ion energy is about 40 MeV per nucleon [7]. It is planed that extra space will be reserved for the remaining part of the SRF linac as an option of future MEIC luminosity upgrade.

INJECTION SCHEME WITH A LOW ION LINAC ENERGY

It is understood that intensity of an accumulated hadron beam in a booster ring is primarily limited by the magnet

ELECTRON COOLING STUDY FOR MEIC*

H. Zhang#, D. Douglas, Ya Derbenev, Y. Zhang, Jefferson Lab, Newport News, VA 23606, USA

Abstract

Electron cooling of the ion beams is one critical R&D to achieve high luminosities in JLab's MEIC proposal. In the present MEIC design, a multi-staged cooling scheme is adapted, which includes DC electron cooling in the booster ring and bunched beam electron cooling in the collider ring at both the injection energy and the collision energy. We explored the feasibility of using both magnetized and non-magnetized electron beam for cooling, and concluded that a magnetized electron beam is necessary. Electron cooling simulation results for the newly updated MEIC design is also presented.

INTRODUCTION

The medium energy electron ion collider (MEIC) proposed by JLab can deliver a luminosity above 10^{34} $\mathrm{cm}^{-2}\mathrm{s}^{-1}$ at a center-of-mass energy up to 65 GeV. It offers an electron energy up to 10 GeV, a proton energy up to 100 GeV, and corresponding energies per nucleon for heavy ions with the same magnetic rigidity [1]. Cooling of proton and ion beams is essential for reduction of beam emittance, suppressing the intra-beam scattering (IBS) effect thus achieving the high luminosity. The conventional electron cooling technique is chosen and a multi-stage cooing strategy has been developed.

Figure 1 shows the schematic layout of the MEIC ion complex, including a DC cooler in the booster and a bunched beam cooler in the collider ring. Since the electron cooling time is in proportion to the energy and the 6D emittance of the ion beam, it is preferred to begin the process of cooling the ion beam to the desired emittance at the lower energy. In addition, it is necessary to apply cooling during collision to maintain the emittance, otherwise the strong IBS effect will lead to a quick increase of the ion beam emittance and the luminosity will collapse. The cooling scheme for the proton beam includes the following three stages: (1) DC cooling for 2 GeV proton beam in the booster, (2) bunched beam cooling for proton beam at the injection energy (8 GeV) in the collider ring, and (3) bunched beam cooling for proton beam at the collision energy in the collider ring.

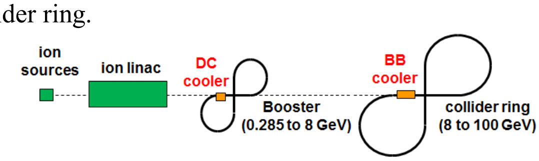

Figure 1: MEIC ion complex layout.

The technology of DC cooling is mature. A magnetized DC cooler with similar performance required by MEIC has been successfully built and commissioned at the COSY facility at Juelich [2]. The cooling by a bunched electron beam is beyond the state-of-art. The MEIC bunched beam cooler is composed of two 30 meter long cooling sections and an ERL circulator ring, which allows to repeatedly use the electron bunch tens of times. In the following we will discuss the necessity of using magnetized electron beam in the bunched beam cooler and present some simulation results.

MATCHING OF BETATRON FUNCTION IN SOLENOID

The transfer matrix of a solenoid can be written as

$$M=\begin{pmatrix} C^2 & SC/k & SC & S^2/k \\ -kSC & C^2 & -kS^2 & SC \\ -SC & -S^2/k & C^2 & SC/k \\ kS^2 & -SC & -kSC & C^2 \end{pmatrix},$$

where $k=B_0/(2B\rho)$, B_0 is the magnetic field inside the solenoid, $B\rho$ is the magnetic rigidity of the reference particle moving along the central trajectory, $C=\cos kL$, $S=\sin kL$, and L is the effective length of the solenoid [3]. Assuming the incoming beam is round with no correlation in the transverse directions, the Σ matrix of the incoming beam can be written as

$$\Sigma_i=\begin{pmatrix} \sigma_{11} & \sigma_{12} & 0 & 0 \\ \sigma_{12} & \sigma_{22} & 0 & 0 \\ 0 & 0 & \sigma_{11} & \sigma_{12} \\ 0 & 0 & \sigma_{12} & \sigma_{22} \end{pmatrix}.$$

At the exit of the solenoid, we have

$$\Sigma_f=M\Sigma_i M^T=\begin{pmatrix} \Sigma_{xf} & 0 \\ 0 & \Sigma_{yf} \end{pmatrix},$$

where M^T is the transpose of M, $\Sigma_{xf}=\Sigma_{yf}=\Sigma$ and component-wisely

$$\Sigma_{11}=C^2\sigma_{11}+\frac{2CS}{k}\sigma_{12}+\frac{S^2}{k^2}\sigma_{22},$$
$$\Sigma_{12}=\Sigma_{21}=-kSC\sigma_{11}+(C^2-S^2)\sigma_{12}+\frac{SC}{k}\sigma_{22},$$
$$\Sigma_{22}=k^2S^2\sigma_{11}-2kCS\sigma_{12}+C^2\sigma_{22}.$$

To keep the transverse bunch size constant inside the solenoid, we need to have constant β function, which means $\beta(s)=\beta$ and $\alpha(s)=0$ for $0\le s\le L$. Thus we have $\sigma_{12}=0$ and $\sigma_{22}=\varepsilon/\beta=\sigma_{11}/\beta^2$ in the solenoid. Since the transverse bunch size does not change, we have

$$\sigma_{11}=C^2\sigma_{11}+\frac{2CS}{k}\sigma_{12}+\frac{S^2}{k^2}\sigma_{22}=C^2\sigma_{11}+\frac{S^2}{k^2\beta^2}\sigma_{11}.$$

So that

$$\beta=\frac{1}{|k|}=\frac{2B\rho}{B_0}=\frac{2p}{qB_0}, \qquad (1)$$

where p, and q are momentum and the charge number of the particle. Eq. (1) is the matching condition for the transverse β function in a solenoid.

The Larmor frequency of a charged particle inside a solenoid is $\omega=Bq/\gamma m_0$, where m_0 is the mass of the

A HIGH ENERGY *e-p/A* COLLIDER BASED ON *CepC-SppC**

Yuhong Zhang#, Thomas Jefferson National Accelerator Facility, Newport News, Virginia, USA
Yuimei Peng, Institute of High Energy Physics, Chinese Academy of Science, Beijing, China

Abstract

Construction of *CepC* and *SppC*, the proposed future energy frontier circular *e+e-* and *pp* colliders in China, provides an opportunity to realize *e-p* or *e-A* collisions in a CM energy range up to 4.1 TeV. This paper presents a preliminary conceptual design of this *e-p/A* collider. The design parameters and anticipated luminosities will be given. We also discuss staging approaches to realize this collider with a low cost and at an earlier time.

INTRODUCTION

Recently, a circular *e+e-* collider (*CepC*) with a 240 GeV CM energy as a Higgs factory has been proposed at Institute of High Energy Physics (IHEP) in China. Its envisioned upgrade, a *pp* collider (*SppC*), will be built for the next energy frontier to reach 70 TeV CM energy [1]. Based on *CepC-SppC*, a multi-TeV electron-proton/ion collider, *CepC-SppC e-p/A collider* (code named *SehC* in this paper), will provide a probe (through ultra deep inelastic scatterings) that can reach unprecedentedly deep inner structure of the matters. Luminosity of the *e-p* collisions can reach middle of 10^{33}/cm^2/s [1].

DESIGN CONSIDERATIONS

An assumption of this design study is that there will be no major upgrade of *CepC* and *SppC* for realizing the *e-p/A* collisions. Thus, the *e-p/A* performance will be determined primarily by the beams that the envisioned *e+e-* and *pp* colliders could provide. The design will follow the *CepC-SppC* operational limit such as the maximum beam energies and currents, the synchrotron radiation (SR) power budget. The design will also observe limits on the parameters due to collective effects such as beam-beam interactions. However, within these limits, beam parameters such as the bunch repetition rate, bunch charges, emittance aspect ratio or crossing angles, can be altered for achieving an optimized performance.

CepC and *SppC* are two very different colliders in terms of parameters of the colliding beams. The *CepC* electron beam has 50 bunches due to a single-ring design while the *SppC* proton or ion beam has a large number of bunches varying from 3000 to 6000. This fact plus an extremely asymmetry of beam emittance aspect ratios effectively exclude the option of simultaneous operations of *e+e-* and *e-p/A* collisions in the *CepC-SppC* complex. Without this constraint, the electron beam is no longer limited to 50 bunches, it can be increased to match the bunch numbers of a proton beam from *SppC*.

Selection of the final focusing parameters for the *e-p/A* collisions is driven by the interaction region (IR) design considerations. For example, the beam spot sizes should be matched at an interaction point (IP) in order to alleviate the beam-beam effect. Nevertheless, the *CepC* lepton beam is extremely flat (the aspect ratio is as high as 333) while the *SppC* proton beam is basically round. Matching of these two beams requires very large vertical beta-star for the electron beam thus blows-up the beam-beam parameters. The operational scenario that the *e-p/A* and *e+e-* collisions will not be run simultaneously provides the opportunity to change the electron beam to a round one by utilizing the transverse optics coupling.

In the *SppC* energy regime, the synchrotron radiation and its effect on the proton or ion beam are no longer negligible. The damping time of a proton or heavy ion beam is similar or even shorter than the time of beam store. As a consequence, the proton or ion beam emittance will approach to an equilibrium value (in a balance of radiation damping and quantum excitation, and intra-beam scatterings) during the beam store. This will affect the peak luminosity as well as the integration of luminosity over one store of the beam.

The *e-p/A collider* based on *CepC-SppC* is a highly asymmetric one with an energy ratio up to 292, a highest value compared to all other *e-p/A* colliders ever been constructed or studied. The simple kinematics shows the reactant particles from collisions will go dominantly in the forward direction of the proton or ion beam. Therefore, it is expected that the forward detection of particles with extremely small scattering angles will be a critical requirement of the detector. Designing an IR to support such extreme forward detections is challenging and will require thorough studies. At the moment, as a straw-man design, we will adopt the similar final focusing parameters (beta-star β^*) of the *CepC* and *SppC* colliders respectively.

Lastly, the science programs utilizing deep inelastic scatterings as a probe usually demand experimental data collected over an energy scan. This requires the *e-p/A* collider design to be optimized over a broad energy range for both electron and proton/ion beams. In this paper, we present design parameters at a representative energy point, namely, 120 GeV electron energy and 35 TeV proton energy, the highest energies that *CepC* and *SppC* could provide. Luminosities at three other electron energies corresponding to *Z, W* and *T* processes are also given.

e-p COLLISION PARAMETERS

Table 1 below presents the nominal design parameters for the *CepC-SppC e-p* collisions. There will be only one beam in the *CepC* ring, thus the electron beam current can be doubled to 33.8 mA while still under the operational limit of 100 MW total SR power. The electron beam could have thousand bunches to match the bunch pattern

Abstract

A local crabbing scheme requires $\pi/2$ (mod π) horizontal betatron phase advances from an interaction point to the crab cavities on each side of it. However, realistic phase advances generated by sets of quadrupoles or Final Focusing Blocks (FFB), between the crab cavities located in the expanded beam regions and the IP differ slightly from $\pi/2$. To understand the effect of crabbing on the beam dynamics in this case, a simple model of the optics of the Medium Energy Electron-Ion Collider (MEIC), including local crabbing, was developed using linear matrices and studied over multiple turns (1000 passes) of both electron and proton bunches. This model was applied to determine linear-order dynamical effects of the synchro-betatron coupling induced by crabbing.

INTRODUCTION

It is a common practice to use linear models when initially designing and studying machine lattices. Then, special care needs to be taken when looking into non-linear effects in a ring (for example), to avoid higher order resonances that may rise undesirable dynamic conditions for the machine operations (i. e. beam filamentation, beam breakup, etc). Due to the high luminosity requirements imposed on the MEIC [1], stable beam operation while using crossing angle correctors [2] is of a major importance. In the present work we have reduced the entire electron and proton storage rings 6D dynamics to a simple linear map representation [3], excluding the interaction region (IR) (see Fig. 1).

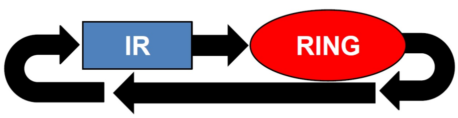

Figure 1: Conceptual sketch of the interaction region (blue) connected on its extremes by a linear map of the ring (red).

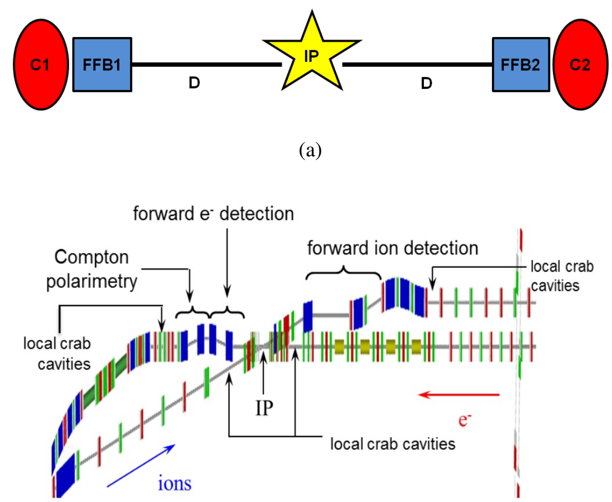
Similarly, a simplified model of a symmetric IR using linear elements in the thin lens approximation [4], such as *horizontal crab kickers*, *FFBs*, and *drifts*, was implemented for both electron and proton bunches (see Fig. 2 (a)). A more realistic layout of the current MEIC interaction region is described in Fig. 2 (b). We performed analytical calculations for the propagation of 6D Gaussian bunch distributions



(b)

END-TO-END SIMULATION OF BUNCH MERGING FOR A MUON COLLIDER

Yu Bao, Gail Hanson, University of California, Riverside, Department of Physics and Astronomy
Robert B. Palmer, Diktys Stratakis, BNL, Upton, Long Island, NY, USA

Abstract

Muon accelerator beams are commonly produced indirectly through pion decay by interaction of a charged particle beam with a target. Efficient muon capture requires the muons to be first phase-rotated by rf cavities into a train of 21 bunches with much reduced energy spread. Since luminosity is proportional to the square of the number of muons per bunch, it is crucial for a Muon Collider to use relatively few bunches with many muons per bunch. In this paper we will describe a bunch merging scheme that should achieve this goal. We present for the first time a complete end-to-end simulation of a 6D bunch merger for a Muon Collider. The 21 bunches arising from the phase-rotator, after some initial cooling, are merged in longitudinal phase space into seven bunches, which then go through seven paths with different lengths and reach the final collecting "funnel" at the same time. The final single bunch has a transverse and a longitudinal emittance that matches well with the subsequent 6D rectilinear cooling scheme.

INTRODUCTION

A high luminosity Muon Collider requires intense single muon bunches. A full scheme of a Muon Collider has been designed by the Muon Accelerator Program (MAP). In this scheme the muons are produced by a high power proton beam hitting on a target, and then they are captured and phase-rotated [1] into 21 bunches. The large initial emittance is reduced by ionization cooling, and for a high luminosity collider, the bunches need to be merged into one of each sign.

The merge concept was outlined in previous studies with preliminary simulations [2]. In this paper, we present an updated design with an end-to-end simulation using G4Beamline [3].

MERGE SCHEME

Figure 1 shows the bunch merge scheme. The incoming beam consists of 21 bunches from the output of the initial cooling channel. Each bunch has a transverse emittance (ϵ_T) of 1.3 mm and a longitudinal emittance (ϵ_L) of 1.7 mm. The 21 bunches are first merged longitudinally into seven bunches, by using radio frequency (rf) cavities with a series of rf harmonics. Then the seven bunches are transversely merged into one bunch. A kicker magnet kicks the seven bunches into seven "trombones" [4] (Only two trombones are shown in Fig. 1). Each trombone has a different arc length so that seven bunches arrive at the collecting section at the same time. A "funnel" [4] is designed to get the seven bunches close to each other to form a single bunch. In the

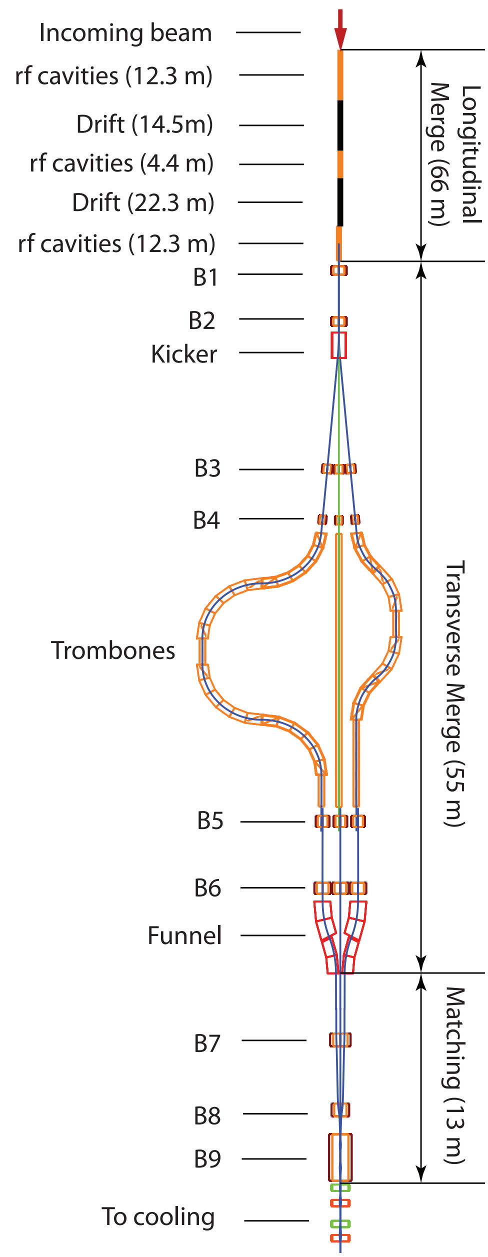

Figure 1: Merge Scheme. B1 - B9 are solenoid magnets for beam matching.

end a matching section with three solenoids will match the bunch into the post-merge cooling channel.

Longitudinal Merge

The longitudinal merge uses the rf cavities with frequencies from 108 MHz to 1950 MHz to phase-rotate the bunches

INITIAL RESULTS FROM STREAKED LOW-ENERGY ULTRA-FAST ELECTRON DIFFRACTION SYSTEM

J.J. Hartzell#, R. Agustsson, L. Faillace, A. Smirnov, S. Boucher,
RadiaBeam Technologies, Santa Monica, CA 90404, USA
P. Musumeci, E. Threlkeld, UCLA, Los Angeles, CA 90095, USA

Abstract

RadiaBeam, in collaboration with UCLA, is developing an inexpensive, low-energy, ultra-fast, streaked electron diffraction (S-UED) system which allows one to reconstruct a single ultrafast event with a single pulse of electrons using and RF deflector. The high-frequency (GHz), high voltage, phase-locked RF field in the deflector enables temporal resolution of atomic events as fine as sub-100 fs. In this paper, we present an overview of the system being developed and the initial experimental results. We also discuss the challenges based on our design of a UED system that incorporates a novel, high-resolution dielectric-loaded RF deflector and a solid-state X-band amplifier.

INTRODUCTION

Time resolved observation of atomic motion is one of the frontiers of modern science, and advancements in this area will greatly improve our understanding of many basic sciences. One technique under active development in this area is ultrafast electron diffraction (UED). UED has already been used to study solid state phase transitions [1], gas phase reactions [2], strongly coupled systems [3] and surface dynamics [4]. To improve the resolution of their UED measurements, researchers need shorter electron bunches and methods increase temporal resolution on the detected electrons. By placing an RF deflecting cavity immediately after a sample, the time-dependant, diffracted electron beam can be "streaked," transforming the temporal evolution of the diffraction pattern from the sample into a transverse image [5]. In this project, we are developing a complete S-UED system based on a dielectric loaded RF deflector and a novel solid-state power amplifier (SSPA), see Fig. 1. The system also includes the requisite electron gun, laser, magnetic optics, and imaging components.

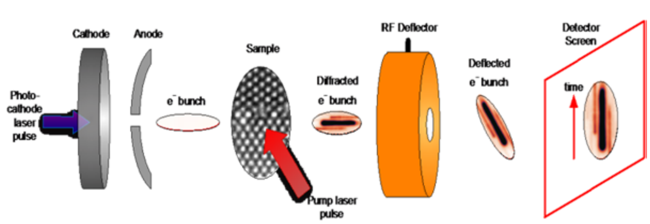

Figure 1: Overview of UED system, from photo-cathode emission on (left), through the sample, then deflector, and finally the streaked image (right).

#Hartzell@RadiaBeam.com

HARDWARE

The UED system was assembled in the Pegasus Lab at the University of California, Los Angeles. The beam line was initially installed and commissioned during fabrication of the dielectric deflector. During this time we conditioned the gun to its operating voltage and worked through the alignment procedure for the magnetic optics. The diagnostics were also tested during this time and the results were compared to earlier simulations. The important components of the system are described in further detail below.

Electron Gun

The 100 kV gun shown in Figure 2 was purchased from a Dutch company, AccTech. The HV conditioning and initial photo-beam measurements were carried out without insertion of the radio-frequency deflector in the beam-line to make the initial alignment process less difficult. Although the purchased version of the DC gun is not operable under ultra-high vacuum due to the use of elastomer O-rings, it is appropriate for our UED application which only requires vacuum of 10^{-6} Torr.

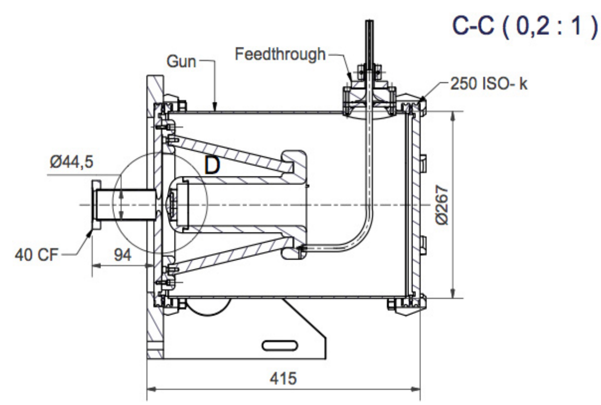

Figure 2: 100 kV electron gun employing a copper photo-cathode purchased from AccTech.

Dielectric Loaded Deflector

The deflector design was performed using the 3D code HFSS. We eventually decided to pursue a dielectric loaded structure since it saved us time and resulted in a device that was easier to manufacture than an all-copper version for such low charge. At the same time, RadiaBeam wanted to develop a medium-power (few hundred watts) RF power source using solid-state devices, and the two technologies were good compliments to each other. Figure 3 shows a 3D model of our 6 cm long

CHROMATIC EFFECTS IN LONG PERIODIC TRANSPORT CHANNELS

Vladimir N. Litvinenko, Yue Hao and Yichao Jing
Department of Physics and Astronomy, Stony Brook University, Stony Brook, NY 11794, USA
Collider-Accelerator Department, Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

Long periodic transport channels are frequently used in accelerator complexes and suggested for using in high-energy ERLs for electron-hadron colliders. Without proper chromaticity compensation, such transport channels exhibit high sensitivity to the random orbit errors causing significant emittance growth. Such emittance growth can come from both the correlated and the uncorrelated energy spread. In this paper we present results of our theoretical and numerical studies of such effects and develop a criteria for acceptable chromaticity in such channels.

INTRODUCTION

The subject of emittance growth resulting from non-compensated chromaticity in single pass linac focusing systems was exhaustively studied in the era of linear colliders decades ago. Some of the classical treatment can be found in [1-4] and references therein. Effects described in these papers are fully applicable to energy recovery linacs with non-compensated chromaticity, e.g. a case presented in my paper [5] where it was suggested to use a strongly chromatic lattices to improve the beam's stability in energy-recovery linacs (ERLs), or as proposed for an ERL with FFAG arcs [6]. Recently we realized, that, naturally, such lattices would exhibit a very high sensitivity to orbital errors – the effect described in details in ref. [1-4]. Such errors could, in turn, significantly increase the beam's emittance. These emittance increase can be either stationary or time-dependent – the later is determined if beam orbit is stable or is time dependent.

In this paper we briefly review a simple case when the orbit errors are random. We also use orbit correction approach described in [1-3], and applied to a long chromatic arcs, to define sensitivity to beam-position measurement (BPM) errors.

Finally, we would like to note that there is a continuing effort of finding a robust solution for chromatic FFAG arcs (which operates beams with multiple energies) using various orbit corrections scheme to avoid beam emittance growth [7].

ORBIT DISTORTION IN CROMATIC LATTICE

Let's consider a simple uncoupled motion on a arc (or straight beam-line, then $K_o=0$) comprised of periodic cells with $K_{x,y,o}(s+P)=K_{x,y,o}(s)$:

$$x''+\frac{K_x(s)}{1+\delta}x=K_o(s)-\frac{eB_y(s)}{p_oc(1+\delta)}-\frac{e\delta B_y(s)}{p_oc(1+\delta)};$$

$$y''+\frac{K_y(s)}{1+\delta}y=+\frac{e\delta B_x(s)}{p_oc(1+\delta)};\ K_o(s)\equiv\frac{1}{\rho(s)}.$$

where $\delta B_{x,y}(s)$ are field errors and $\delta=\dfrac{E-E_o}{E_o}$ is the relative energy deviation from the reference (design) energy. It is well known that within the stability range of the periodic cell, one can find periodic reference orbit

$$K_o(s+C)=K_o(s);\ B_y(s+C)=B_y(s)$$

$$\eta^\delta+\frac{K_x(s)}{1+\delta}\eta^\delta=K_o(s)-\frac{eB_y(s)}{p_oc(1+\delta)};\ \eta^\delta(s+C)=\eta^\delta(s)$$

and Courant-Snyder function fully describing transverse oscillation about the reference orbit (here we use y-direction as example):

$$\mathrm{w}_y^\delta(s+C)=\mathrm{w}_y^\delta(s+C);\ \beta_y^\delta=\left(\mathrm{w}_y^\delta\right)^2;$$

$$y=a_y\cdot\mathrm{w}_y^\delta(s)\cdot\cos\left(\psi_y^\delta(s)+\varphi_y\right);\ \frac{d\psi_y^\delta}{ds}=\frac{1}{\beta_y^\delta(s)};$$

$$y'=\begin{Bmatrix} a_y\cdot\mathrm{w}_y'^\delta(s)\cdot\cos\left(\psi_y^\delta(s)+\varphi_y\right)\\ -\dfrac{a_y}{\mathrm{w}_y^\delta(s)}\cdot\sin\left(\psi_y^\delta(s)+\varphi_y\right)\end{Bmatrix}.$$

There is well known expression for the orbit distortions caused by an arbitrary field errors. Here we rewrite it with emphasis on the energy dependence:

$$\delta y_\delta(s)=\mathrm{w}_y^\delta(s)\int_0^s\sin\left(\psi_y^\delta(s)-\psi_y^\delta(s_1)\right)\mathrm{w}_y^\delta(s_1)\frac{e\delta B_x(s_1)}{p_oc(1+\delta)}ds_1;$$

$$\delta y'_\delta(s)=\int_0^s\begin{Bmatrix}\mathrm{w}_y'^\delta(s)\sin\left(\psi_y^\delta(s)-\psi_y^\delta(s_1)\right)+\\ \dfrac{1}{\mathrm{w}_y^\delta(s)}\cos\left(\psi_y^\delta(s)-\psi_y^\delta(s_1)\right)\end{Bmatrix}\mathrm{w}_y^\delta(s_1)\frac{e\delta B_x(s_1)}{p_oc(1+\delta)}ds_1$$

which indicative of the resulting orbit dependence on particle's energy and lattice chromaticity. Naturally, similar treatment is applicable to horizontal motion:

$$\mathrm{w}_x^\delta(s+C)=\mathrm{w}_x^\delta(s+C)$$

$$x=\eta^\delta(s)+a_x\cdot\mathrm{w}_x^\delta(s)\cdot\cos\left(\psi_x^\delta(s)+\varphi_x\right)+\delta x_\delta(s)$$

$$\beta_x^\delta=\left(\mathrm{w}_x^\delta\right)^2;\frac{d\psi_x^\delta}{ds}=\frac{1}{\beta_x^\delta(s)};$$

$$\delta x_\delta(s)=-\mathrm{w}_x^\delta(s)\int_0^s\sin\left(\psi_x^\delta(s)-\psi_x^\delta(s_1)\right)\mathrm{w}_x^\delta(s_1)\frac{e\delta B_y(s_1)}{p_oc(1+\delta)}ds_1.$$

Further in the paper we will use index z both to x and y. To estimate effect of chromaticity and orbit distortions on the beam emittance

FINAL MUON EMITTANCE EXCHANGE IN VACUUM FOR A COLLIDER*

Don Summers†, John Acosta, Lucien Cremaldi, Terry Hart, Sandra Oliveros,
Lalith Perera, Wanwei Wu, University of Mississippi - Oxford, University, MS 38677, USA
David Neuffer, Fermilab, Batavia, IL 60510, USA

Abstract

We outline a plan for final muon ionization cooling with quadrupole doublets focusing onto short absorbers followed by emittance exchange in vacuum to achieve the small transverse beam sizes needed by a muon collider. A flat muon beam with a series of quadrupole doublet half cells appears to provide the strong focusing required for final cooling. Each quadrupole doublet has a low β region occupied by a dense, low Z absorber. After final cooling, normalized xyz emittances of (0.071, 0.141, 2.4) mm-rad are exchanged into (0.025, 0.025, 70) mm-rad. Thin electrostatic septa efficiently slice the bunch into 17 parts. The 17 bunches are interleaved into a 3.7 meter long train with RF deflector cavities. Snap bunch coalescence combines the muon bunch train longitudinally in a 21 GeV ring in 55 μs, one quarter of a synchrotron oscillation period. A linear long wavelength RF bucket gives each bunch a different energy causing the bunches to drift until they merge into one bunch and can be captured in a short wavelength RF bucket with a 13% muon decay loss and a packing fraction as high as 87%.

INTRODUCTION

Due to s-channel production, a muon collider [1] may be ideal for the examination of H/A Higgs scalars which could be at the 1.5 TeV/c^2 mass scale and are required in supersymmetric models [2]. But what is the status of muon cooling? As noted in Table 1, more than five orders of magnitude of muon cooling have been shown in two simulated designs [3, 4] but not quite the six orders of magnitude needed for a high luminosity muon collider. Also as can be seen in Table 1, some of the longitudinal cooling needs to be exchanged for lower transverse emittance.

A long solenoid [5] with a 14 Tesla magnetic field and a 200 MeV/c muon beam gives a betatron function of $\beta_\perp = 2p/[3.0B] = 2(200\,\text{MeV/c})/[3.0\,(14\,\text{T})] = 9.5\,\text{cm}$ and works with high pressure or liquid hydrogen absorber. The short 14 T solenoids in the final stage of the Rectilinear Cooling Channel [4] give $\beta^* = 3.1$ cm in a region of limited length, which is filled with lithium hydride absorber. To get to the lower betatron values of about 1 cm needed by a muon collider for final cooling, quadrupole doublet cells are explored herein. Table 2 gives transverse equilibrium emittances for a number of low Z materials, particularly those with high densities.

QUADRUPOLE DOUBLET COOLING

Following Feher and Strait [9] and their paper including the LHC final focus quadrupole triplet design in 1996 with a β^* of 50 cm, we look into a short quadrupole doublet for final muon cooling with a β^* of 1 cm. Focal lengths in x and y differ in the doublet. The outer two LHC quadrupoles are focusing in the first transverse dimension and defocusing in the second transverse dimension. The inner double length quadrupole is focusing in the second transverse dimension and defocusing in the first transverse dimension. The relation between β functions, focal length (L_f), and beam size is

$$\beta^* \beta_{\max} = b\, L_f^2 \quad \text{and} \quad \sigma_x = \sqrt{\epsilon_x \beta_x/(\beta\gamma)} \qquad (1)$$

where b is a fudge factor equal to 1.65 for the LHC. Thus a lower β^* leads to a larger $\beta_{\max}$ and larger bore quadrupoles.

CONSEQUENCES OF BOUNDS ON LONGITUDINAL EMITTANCE GROWTH FOR THE DESIGN OF RECIRCULATING LINEAR ACCELERATORS

J. Scott Berg, BNL*, Upton, NY 11973, USA

Abstract

Recirculating linear accelerators (RLAs) are a cost-effective method for the acceleration of muons for a muon collider in energy ranges from a couple GeV to a few 10s of GeV. Muon beams generally have longitudinal emittances that are large for the RF frequency that is used, and it is important to limit the growth of that longitudinal emittance. This has particular consequences for the arc design of the RLAs. I estimate the longitudinal emittance growth in an RLA arising from the RF nonlinearity. Given an emittance growth limitation and other design parameters, one can then compute the maximum momentum compaction in the arcs. I describe how to obtain an approximate arc design satisfying these requirements based on the deisgn in [1]. Longitudinal dynamics also determine the energy spread in the beam, and this has consequences on the transverse phase advance in the linac. This in turn has consequences for the arc design due to the need to match beta functions. I combine these considerations to discuss design parameters for the acceleration of muons for a collider in an RLA from 5 to 63 GeV.

INTRODUCTION

For the muon accelerator scenario described in [2], they envision an RLA accelerating from 5 to 63 GeV, which would accelerate beams for two stages of a Higgs factory, and would be reused for a higher energy collider with a substantially larger emittance. Important machine parameters are given in Tables 1 and 2. Details of the rationale for many of these parameters can be found in [3].

An RLA allows rapid acceleration while making multiple passes through a linac by having a beam splitter at the ends of the linac and arcs for each energy that return the beam to the linac. Having large numbers of arcs at the splitter can become a problem, particularly for large beam emittances and small energy spacings. A "dogbone" RLA geometry helps address this [4]. Bogacz [1] has described a technique to design the "droplet" arcs for this lattice; I will adopt that basic technique here.

I first discuss a generic technique to obtain a droplet arc design according to Bogacz' concept, and obtain from that an approximation to the time of flight dependence on energy in the arc. I then compute an approximation to the longitudinal emittance growth which depends on that time of flight parameter. I finally put these together to determine parameters for the RLA that will meet the requirements.

TARGET AND ORBIT FEEDBACK SIMULATIONS OF A muSR BEAMLINE AT BNL*

W. W. MacKay†, 25 Rhododendron Circle, Asheville, 28805
M. Blaskiewicz‡, W. Fischer, and P. Pile, BNL, Upton, NY 11972

Abstract

Well-polarized positive surface muons are a tool to measure the magnetic properties of materials since the precession rate of the spin can be determined from the observation of the positron directions when the muons decay. The use of the AGS complex at BNL has been explored for a muSR facility previously. Here we report simulations of a beamline with a target inside a solenoidal field, and of an orbit feedback system with single muon beam positioning monitors based on technology available today.

INTRODUCTION

Muon spin rotation, relaxation and resonance (μSR) is a powerful technique for studying local magnetic fields in samples. When a positive pion decays at rest into a positive muon, the muon has a kinetic energy of 4.119 MeV (momentum 29.792 MeV/c) and its spin is opposite to its direction (negative helicity). If the pion decays near the surface of a target the resulting muons lose little energy, and the result is a beam of muons with a narrow energy distribution and almost 100% polarization. When these positive muons are implanted in matter with a magnetic field the muons precess at a rate proportional to the local field. When the muon decays the positron momentum is preferentially along the direction of the muon spin.

In this paper, we present improvements of our previous design for a surface muon beam line at BNL [1, 2] including optimization of the target and muon capture. Also we discuss the efficacy of a possible orbit feedback section to increase the density of the muon beam for experiments.

A beam of protons with kinetic energy 1.5 GeV will be extracted from the AGS (see Fig. 1) and focused onto a thin 0.5 mm wide target. An average intensity of 10^{14} proton/s with a normalized rms emittance of 8π μm is quite achievable from the AGS. Detailed parameters of the AGS and injector chain for μSR were presented previously [1].

The tracking code G4BEAMLINE [3] has been used for most simulations of the beam line in this paper.

MUON TARGET AND CAPTURE

Pions which are produced and stop in the target will decay yielding muons which may exit the target if they are within 0.7 mm of the surface of the graphite target (see Fig. 2). Pions stopped any deeper in the target will produce muons which stop and decay inside the target leading to higher backgrounds and heating of the target and nearby beam-line elements. By making a long, horizontally thin target with the proton beam running down the length and having a waist focused at the center of the target, we can get surface muons from pions stopped near the surface with a minimum of background and heating. Fig. 3 shows a 200 mm long, 0.5 mm target, 50 mm high graphite target with a beam (noninteracting in the figure) having a $\sigma_h^* = 0.25$ mm waist. For 10^{14} protons/s simulations yield about 15×10^9 μ^+/s 0.2 mm from the target's surface. Four times as many positrons are produced, but most are outside the momentum acceptance of the beam line.

To capture the muon beam, we use a decreasing field from four solenoids placed around the target as shown in Fig. 4. A scan of the capture efficiency versus the field of the upstream solenoid (−1) shown in Fig. 5 demonstrates that capture is more efficient with a negative slope to the axial field around the target. This is reminiscent of Adiabatic Matching Devices [6] used in positron linacs. Fig. 6 shows the momentum distributions of μ^+ and e^+ at the exit of the solenoid 3.

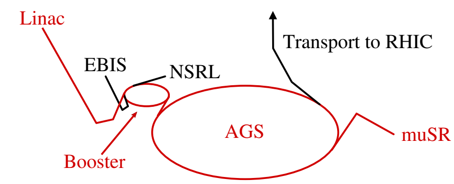

Figure 1: Schematic of the AGS complex with sections to be used for μSR shown in red.

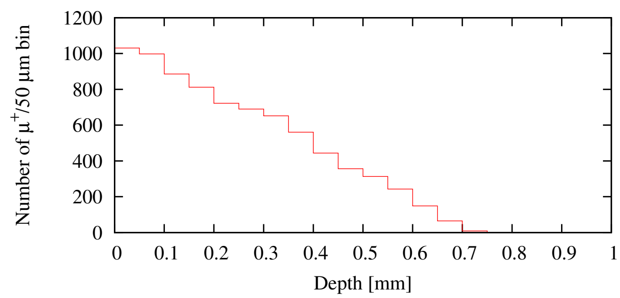

Figure 2: Number of μ^+ exiting the target from a uniform distribution of rest π^+ placed inside a thick block of graphite. No μ^+ come from a depth greater than 0.7 mm.

Figure 3: Top view of target and proton beam. The proton beam is focused onto the middle of the narrow graphite $200 \times 50 \times 0.5$ mm ($l \times h \times w$) target.

EXPERIMENTAL DEMONSTRATION OF INTERACTION REGION BEAM WAIST POSITION KNOB FOR LUMINOSITY LEVELING*

Yue Hao†, Yun Luo, Aljosa Marusic, Guillaume Robert-Demolaize, BNL, Upton, NY 11973, USA
Mei Bai, Forschungszentrum Jülich GmbH (FZJ) Institut für Kernphysik, Germany
Zhe Duan, Institute of High Energy Physics, Beijing, China
Xiaozhe Shen, SLAC, Menlo Park, CA 94025

Abstract

In this paper, we report the experimental implementation of the model-dependent control of the interaction region beam waist position (s^* knob) at Relativistic Heavy Ion Collider (RHIC). The s^* adjustment provides an alternative way of controlling the luminosity and is only known method to control the luminosity and reduce the pinch effect of the future eRHIC. In this paper, we will first demonstrate the effectiveness of the s^* knob in luminosity controlling and its application in the future electron ion collider, eRHIC, followed by the detail experimental demonstration of such knob in RHIC.

GEOMETRIC REDUCTION OF LUMINOSITY

In collider operation, it is sometimes useful to control (lower) the luminosity for one detector without affecting others. There are many methods to control the luminosity for one specific interaction point (IP), for instance, introducing offsets between two colliding beams or increasing the waist beta function of both beams at IP. It is straightforward that adjusting the location of the beta waist (s^*) can achieve the same goal.

The luminosity at one IP can be calculated from the following integral

$$L = N_1 N_2 f \int \rho_1 (x, y, s + s_0)\, \rho_2 (x, y, s - s_0)\, dxdydsds_0 \tag{1}$$

where N_1, N_2 ,ρ_1 and ρ_2 are the bunch intensities and 3-D normalized distribution functions of two colliding beam respectively, f is the bunch repetition rate. $s = (z_1 + z_2)/2$ and $s_0 = ct = (z_1 - z_2)/2$ correspond to the collision location and time of two beam slices at z_1 and z_2. We assume both beams has Gaussian distribution in all three dimensions:

$$\rho_{1/2} = \frac{1}{(2\pi)^{\frac{3}{2}} \sigma_{x,1/2}\sigma_{y,1/2}\sigma_{s,1/2}} \times \exp\left[-\frac{x^2}{2\sigma^2_{x,1/2}(s)} - \frac{y^2}{2\sigma^2_{y,1/2}(s)} - \frac{z^2}{2\sigma^2_{z,1/2}}\right] \tag{2}$$

where subscripts 1 and 2 represents two colliding beams and σ_x, σ_y and σ_z are the rms beam sizes. Including hourglass effect and the shifted s^*, the two transverse beam sizes are function of the longitudinal position:

$$\sigma_{x/y,1/2}(s) = \sigma^*_{x/y,1/2}\left(1 + \frac{\left(s - s^*_{x/y,1/2}\right)^2}{\beta^{*2}_{x/y,1/2}}\right) \tag{3}$$

where $\sigma^{*2} = \beta^*\epsilon$, β^* is the beta star located at beta waist position s^*, ϵ is the beam emittance.

The luminosity integral (Eq. 1) can be evaluated by integrate the transverse coordinates and the normalized time s_0, and reads:

$$L = \frac{N_1 N_2 f}{2\pi\sqrt{\sigma^2_{x,1} + \sigma^2_{x,2}}\sqrt{\sigma^2_{y,1} + \sigma^2_{y,2}}} G = L_0 G$$

where L_0 is the luminosity with zero length, and G is the geometric factor that reflects the reduction of hourglass effect and shifted s^*. G has the following integration form:

$$G = \int \frac{e^{-u^2} du/\sqrt{\pi}}{\sqrt{1 + \frac{(u-u^*_{x,1})^2}{t^2_{x,1}} + \frac{(u-u^*_{x,2})^2}{t^2_{x,2}}}\sqrt{1 + \frac{(u-u^*_{y,1})^2}{t^2_{y,1}} + \frac{(u-u^*_{y,2})^2}{t^2_{y,2}}}} \tag{4}$$

with

$$t^2_{x/y,1/2} = \frac{2\beta^*_{x/y,1/2}\left(\sigma^{*2}_{x/y,1} + \sigma^{*2}_{x/y,2}\right)}{\epsilon_{x/y,1/2}\left(\sigma^2_{z,1} + \sigma^2_{z,2}\right)}$$

and the scaled beta waist position s^* reads,

$$u_{x/y,1/2} = \frac{\sqrt{2} s^*_{x/y,1/2}}{\sqrt{\sigma^2_{z,1} + \sigma^2_{z,2}}}$$

where ϵ is the rms emittance. In the RHIC and its future upgrade eRHIC, both beam are designed to be round with matched rms beam size at the waist position, $\sigma^{*2}_{x/y,1/2} = \sigma_r$. The expression for $t_{x/y,1/2}$ reduces to $t_{x/y,1/2} = 2\beta^*_{x/y,1/2}/\sqrt{\sigma^2_{z,1} + \sigma^2_{z,2}}$.

USE s^* AS LUMINOSITY CONTROL KNOB

We propose to control the luminosity of one collision point by moving the waist position $s^*_{x/y}$ of one of the colliding beam. Taking RHIC beam parameter as an example, we will demonstrate the effectiveness of this method. RHIC has round beam and identical design parameters for two

POLARIZED PROTON BEAM FOR eRHIC*

H. Huang†, F. Meot, V. Ptitsyn, T. Roser, BNL, Upton, NY 11973, USA

Abstract

RHIC has provided polarized proton collisions from 31 GeV to 255 GeV in past decade. To preserve polarization through numerous depolarizing resonances over the whole accelerator chain, harmonic orbit correction, partial snakes, horizontal tune jump system and full snakes have been used. In addition, close attentions have been paid to betatron tune control, orbit control and beam line alignment. The polarization of 60% at 255 GeV has been delivered to experiments with 1.8×10^{11} bunch intensity. For the eRHIC era, the beam brightness has to be maintained to reach the desired luminosity. Since we only have one hadron ring in the eRHIC era, existing spin rotator and snakes can be converted to six snake configuration for one hadron ring. With properly arranged six snakes in RHIC and additional reduction of emittance growth in AGS, the polarization can reach 70% at 250 GeV. This paper summarizes the effort and plan to reach high polarization with small emittance for eRHIC.

INTRODUCTION

The parameters for eRHIC proton beam is 70% polarization with 3×10^{11}/bunch and 0.2 πmm-mrad normalized emittance [1]. This emittance is at store and is expected to be cooled down by coherent electron cooling(CeC) [2]. On the ramp, the emittance will be larger as delivered by AGS. The resonance strength associated with the larger emittance will be stronger. This paper will discuss how the 70% polarization can be achieved based on current status of RHIC polarized proton operation and possible snake configuration changes.

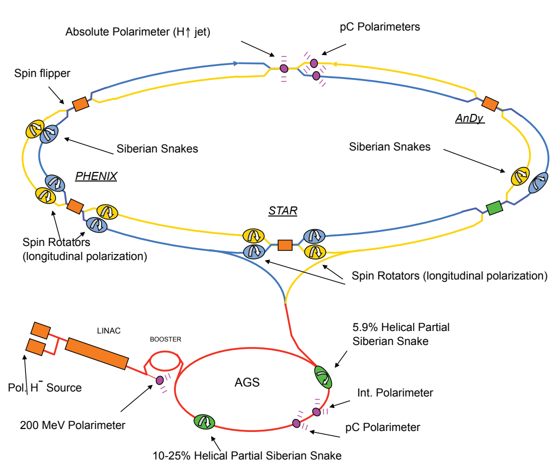

Figure 1: Layout of RHIC complex.

The current proton acceleration chain is shown in Fig. 1. High intensity and high polarization H^- is produced from the polarized proton source. The H^- beam polarization is measured at the end of 200 MeV linac as 80-82%. The beam is then strip-injected into AGS Booster. The Booster vertical tune is set high so that $0 + \nu_y$ intrinsic resonance is avoided. Two imperfection resonances are corrected by orbit harmonic correction. In the AGS, two partial Siberian snakes separated by 1/3 of the ring are used to overcome the imperfection and vertical intrinsic resonances [3]. The vertical tune on the energy ramp is mostly above 8.98, so that it is in the spin tune gap and away from the high order snake resonances. To avoid the horizontal intrinsic resonances driven by the partial snakes, a pair of pulsed quadrupoles are employed to jump cross the many weak horizontal intrinsic resonances on the ramp [4]. Two full Siberian snakes are used in each of the two RHIC rings to maintain polarization [5]. The betatron tune, coupling and orbit feedback on the energy ramp are also crucial for polarization preservation.

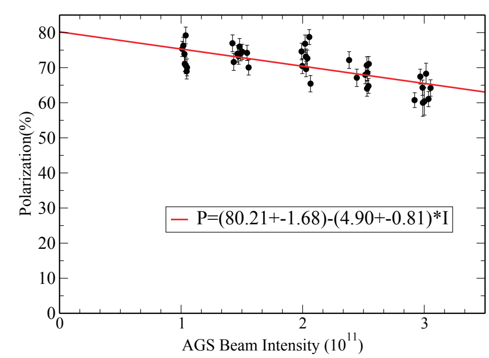

Figure 2: AGS polarization at extraction as function of bunch intensity. The polarized proton source can deliver intensity of 9×10^{11} at the Booster input. Booster scraping (both horizontal and vertical) is used to reduce the beam emittance for AGS injection. The intensity in this figure is changed by varying the Booster scraping level.

The polarization measured at the AGS extraction is shown in Fig. 2 as function of beam intensity. The intensity was reduced by Booster scraping. The polarization dependence on intensity is really dependence on emittance. As higher intensity is always associated with larger emittance, and consequently stronger depolarizing resonance resonance strength, lower polarization is expected for higher intensity. As shown in Fig. 2, the polarization at 3×10^{11} is about 65%. The AGS Ionization Profile Monitor(IPM) can measure beam emittance but the measured beam size is affected by space charge force. To mitigate the effect, the RF is turned off at flattop. The emittance reported by IPM with RF off is plotted in Fig.3. Since there is pos-

OPTICS CORRECTION FOR THE MULTI-PASS FFAG ERL MACHINE eRHIC*

C. Liu†, S. Brooks, V. Litvinenko, M. Minty, V. Ptitsyn, D. Trbojevic, BNL, Upton, NY 11973, USA

Abstract

Gradient errors in the multi-pass Fixed Field Alternating Gradient (FFAG) Energy Recovery Linac (ERL) machine, eRHIC, distort the beam orbit and therefore cause emittance increase. The localization and correction of gradient errors are essential for an effective orbit correction and emittance preservation. In this report, the methodology and simulation of optics correction for the multi-pass FFAG ERL machine eRHIC will be presented.

INTRODUCTION

Electron Relativistic Heavy Ion collider (eRHIC) is a new research tool proposed to be built at the existing RHIC facility. The design of the electron machine provides a cost-effective upgrade of RHIC for collision of electron beam with the full array of RHIC hadron beams [1]. Two circular electron accelerators with FFAG lattice are designed to be placed in RHIC tunnel to provide electron beams with top energy at 15.9 and 21.2 GeV [2]. The electron beam will be accelerated from 1.3 GeV to the top energies and energy recovered after collisions. The accelerating passes and decelerating passes in each machine go through the same vacuum chamber thanks to the small dispersion values. The beta functions of each energy differ from each other.

The deviation of the gradient from design will distort beam trajectories and the optical functions. Even though the orbit distortion can be fixed by dipole correctors, the distortion of optical functions will be detrimental for the effectiveness of orbit correction. Therefore, it would be desirable to be able to disentangle dipole errors and quadrupole errors and correct them independently. We adopted the orbit response method (ORM) [3], which has been widely applied for circular rings, and extend it for the multi-pass FFAG case to locate and correct quadrupole errors in eRHIC FFAG machines.

PROPERTIES OF THE LINEAR NON-SCALING FFAG LATTICE

In the eRHIC FFAG design, the magnets are pure focusing and defocusing quadrupoles shifted horizontally relative to a circular orbit. The field experienced by the beam is $G*x$, G is the magnet gradient, x is the horizontal beam position relative to the magnet center. The orbits of beams with different energies are plotted in Fig. 1, with respect to the circular orbit. The energy deviations are calculated with

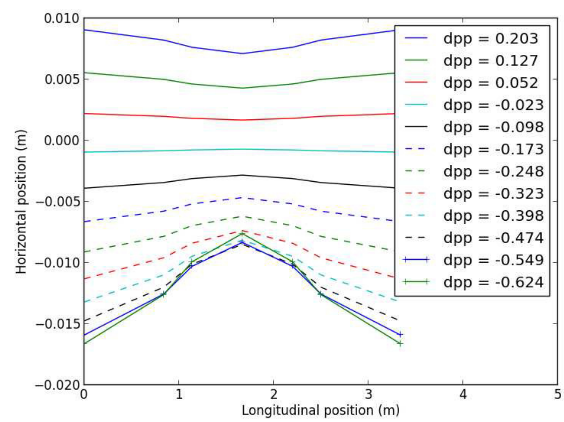

Figure 1: The orbits for beams with different energies in a single FODO cell of the FFAG lattice.

respect to 17.6 GeV. The overall horizontal offsets between beams is ∼25 mm. The beams can therefore fit in the same beam pipe. The close-together beam orbits present a challenge for beam position measurement for individual beams [4].

The beta functions in both planes are plotted in Fig. 2 and 3 for beams with different energies. The responses in terms of beam position changes are expected to be different for beams with different energies.

OPTICS CORRECTION ALGORITHM

In linear FFAG, orbit response deviation depends only on gradient errors linearly. Orbit response deviation from the model can be measured by varying dipole correctors

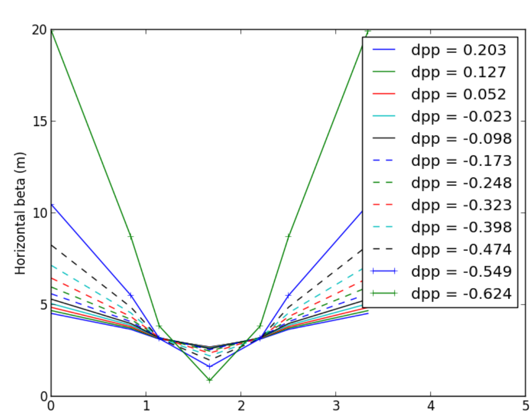

Figure 2: The horizontal beta functions for beams with different energies in a single FODO cell of the FFAG lattice.

STUDY OF ORBIT CORRECTION FOR eRHIC FFAG DESIGN*

C. Liu†, Y. Hao, V. Litvinenko, F. Meot, M. Minty, V. Ptitsyn, D. Trbojevic
BNL, Upton, NY 11973, USA

Abstract

The unique feature of the orbits in the eRHIC Fixed Field Alternating Gradient (FFAG) design is that multiple accelerating and decelerating bunches pass through the same magnets with different horizontal offsets. Therefore, it is critical for the eRHIC FFAG to correct multiple orbits in the same vacuum pipe for better spin transmission and alignment of colliding beams. In this report, the effects on orbits from multiple error sources will be studied. The orbit correction method will be described and results will be presented.

INTRODUCTION

Electron accelerators based on FFAG lattice are designed to be placed in the existing Relativistic Heavy Ion Collider (RHIC) tunnel for collision of electron and heavy ion beams [1]. The advantages of the FFAG lattice are in two aspects: the magnets are at fixed fields and there is strong focusing in the transverse planes. A machine with such lattice accepts beams over a large energy range. The dispersion function is very small ($\sim cm$) so that orbits of beams with different energies stay in the same vacuum pipe with small horizontal offsets. The orbits will be distorted differently if either the magnets are misaligned or there are magnet gradient errors. The misalignment and gradient errors in a FFAG lattice need therefore to be compensated locally to restore all the orbits to the design values. Dipole and quadrupole trims will be placed at each and every magnet center to correct the said errors. Considering the large number of magnets in the rings, a global correction scheme must detect local errors quickly and precisely. Furthermore, enough beam position monitors (BPMs) for beam position measurement is also critical to locate the errors effectively.

The lattice design has evolved much in the past year with optimization of linac size and synchrotron radiation [2, 3]. The orbit correction simulation will be presented in this paper is based on a single FFAG ring design, which accelerates electron beam from 1.9 to 10 GeV and decelerates the beam back to 1.9 GeV via energy recovery. The injected beam will be accelerated before entering the FFAG arc. Therefore, there are 9 accelerating beam passes and 8 decelerating passes through the FFAG arcs. As the beam gets accelerated, the betatron tune per FFAG cell changes from ∼0.44 to ∼0.1 in the horizontal plane and ∼0.3 to ∼0.04 in the vertical plane discretely [1].

* The work was performed under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.
† cliu1@bnl.gov

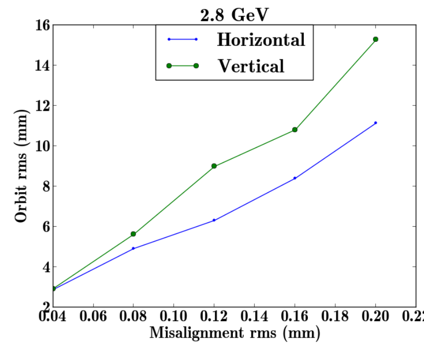

Figure 1: RMS of beam orbit distortion in eRHIC FFAG in both planes due to magnet misalignment errors, for the beam in the first pass with energy 2.8 GeV.

The measurement of beam positions is challenging for continuous bunch train with $\sim ns$ spacing between bunches. A gap in the electron beam bunch train, which coincides with the abort gap in RHIC, is necessary for ion clearing purpose. A diagnostic bunch will be put in the gap for routine monitoring of the beam positions continuously [4].

ORBIT DISTORTION DUE TO MISALIGNMENT AND GRADIENT ERROR

In the eRHIC FFAG design, the magnets are pure focusing and defocusing quadrupoles shifted horizontally in position relative to a circular orbit. The field experienced by the beam is $G * x$, G is the magnet gradient, x is the horizontal beam position relative to the magnet center.

The orbit distortion due to misalignment of magnets was studied in simulation. The orbit deviation root-mean-square (rms) in two planes for beam at $2.8GeV$ is shown in Fig. 1 for a range of misalignment rms. The same orbit distortion due to misalignment erros were studied for the other 8 beam passes. The magnification factors, the ratio between orbit rms and misalignment rms, are compared for all passes. The magnification factor decreases with beam rigidity as expected in the horizontal plane, however not in the vertical plane. Analytical calculation of the magnification factor ($\propto \frac{\sqrt{\beta_1\beta_2}}{\nu\gamma}$, β_1, β_2 are the betatron functions at the magnets and BPMs, ν is the tune per cell, γ is the Lorentz factor) confirmed the count-intuitive behavior in the vertical plane, shown in Fig. 2.

The orbit distortion due to magnet gradient errors was studied in simulation as well. The orbit rms in the horizontal plane only for beam at 2.8 GeV is shown in Fig.3 for a

END-TO-END 9-D POLARIZED BUNCH TRANSPORT IN eRHIC ENERGY-RECOVERY RECIRCULATOR, SOME ASPECTS

F. Méot, S. Brooks, V. Ptitsyn, D. Trbojevic, N. Tsoupas
Collider-Accelerator Department, BNL, Upton, NY 11973, USA

Abstract

This paper is a brief overview of some of the numerous beam and spin dynamics investigations undertaken in the framework of the design of the FFAG based electron energy recovery re-circulator ring of the eRHIC electron-ion collider project.

INTRODUCTION

A Fixed Field Alternating Gradient (FFAG) doublet-cell version of the energy recovery recirculator of the eRHIC electron-ion collider is being investigated [1]. A pair of such FFAG rings placed along RHIC recirculate the electron beam through a 1.322 GeV linac (ERL), from respectively 1.3 to 6.6 GeV (5 beams) and 7.9 to 21.2 GeV (11 beams), and back down to injection energy. A spreader and a combiner are placed at the linac ends for proper orbit and 6-D matching, including time-of-flight adjustment.

FFAG LATTICE

The second, 11 beam, 21.2 GeV ring is considered in this discussion since it produces the major SR induced particle and spin dynamics perturbations. The cell is shown in Fig. 1, there are 138 such cells in each one of the 6 eRHIC arcs. The 6 long straight sections (LSS) use that very cell, with quadrupole axes aligned. In the twelve, 17-cell, dispersion suppressors (DS) the quadrupole axes slowly shift from their distance in the arc, to zero at the LSS.

Fig. 2 shows the transverse excursion and magnetic field along orbits across the arc cell. Fig. 3 shows the energy dependence of the deviation angle and curvature radius in the two quadrupoles, and the energy dependent tunes and chromaticities.

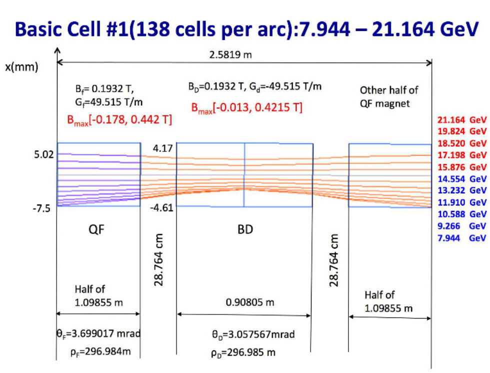

Figure 1: Arc cell in the 7.944-21.16 GeV recirculating ring.

The y-precession of the spin over the six 138-cell arcs amounts to $6 \times 138 \times a\gamma\theta_{\text{cell}} = a\gamma \times (2\pi - 0.688734)$ rad (with the difference to $a\gamma \times 2\pi$ corresponding to the contribution of the 12 DS), *i.e.*, from 18 precessions at 7.944 GeV to 48 at 21.164 GeV. ($a = 0.00116$ is the electron anomalous magnetic factor, γ the Lorentz relativistic factor).

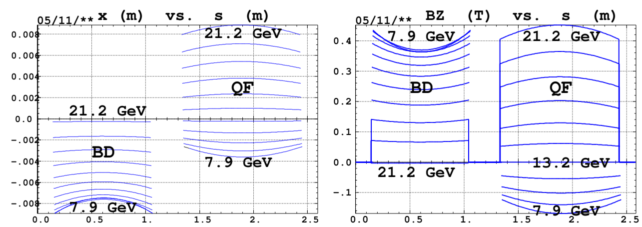

Figure 2: Transverse excursion in the quadrupole frame (hence artefact of trajectory discontinuity) (left) and hard-edged magnetic field (right), along the 11 orbits across the arc FFAG cell.

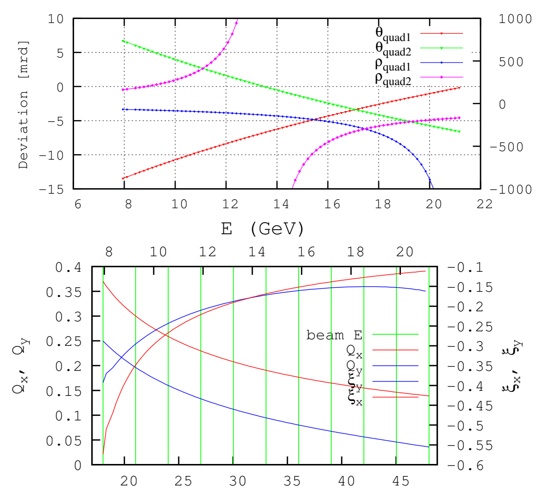

Figure 3: Top : energy dependence of deviation and curvature radius in arc cell quads. Bottom : cell tunes and chromaticities; the vertical bars materialize the 11 design energies.

SYNCHROTRON RADIATION

The SR induced energy loss relative to the the bunch centroid and the energy spread write, respectively

$$\frac{\overline{\Delta E}}{E_{\text{ref}}} = 1.9 \times 10^{-15}\,\frac{\gamma^3 \Delta\theta}{\rho},\ \frac{\sigma_E}{E_{\text{ref}}} = 3.8 \times 10^{-14}\,\frac{\gamma^{\frac{5}{2}}\sqrt{\Delta\theta}}{\rho} \tag{1}$$

with $\Delta\theta$ the arc length and $1/\rho$ the curvature, assumed constant. Taking for average radius, in the QF (focusing quad) and BD (defocusing quad) magnets respectively, $\rho_{\text{BD}} \approx \frac{s_{\text{BD}}}{\Delta\theta_{\text{BD}}}$, $\rho_{\text{QF}} \approx \frac{s_{\text{QF}}}{\Delta\theta_{\text{QF}}}$ (with s_{BD} and s_{QF} the arc lengths) and considering in addition, with l_{BD}, l_{QF} the magnet lengths, $s_{\text{BD}} \approx l_{\text{BD}}$, $s_{\text{QF}} \approx l_{\text{QF}}$, then one gets,

POLARIZATION SIMULATIONS IN THE RHIC RUN 15 LATTICE *

F. Méot, H. Huang, Y. Luo, V. Ranjbar, G. Robert-Demolaize, S. White
Collider-Accelerator Department, BNL, Upton, NY 11973, USA

Abstract

RHIC polarized proton Run 15 uses a new acceleration ramp optics, compared to RHIC Run 13 and earlier runs, in relation with electron-lens beam-beam compensation developments [1, 2]. The new optics induces different strengths in the depolarizing snake resonance sequence, from injection to top energy. As a consequence, polarization transport along the new ramp has been investigated, based on spin tracking simulations. Sample results are reported and discussed.

SIMULATED OPTICS

Main parameters of the *simplified* RHIC polarized proton optics considered for these simulations are given in Tab. 1, "Run 13" stands for the earlier optics, "Run 15" stands for the new one with betatron functions as displayed in Fig. 1. Tracking outcomes will be given for both cases,

Table 1: Optical Parameters in the Simulations

		Run 13	Run 15
Orbit length	m	3833.8452	
γ_{tr}		23	23.5
Q_x		28.685	29.68
Q_y		29.673	30.67
Q'_x		1	2.3
Q'_y		1	2.2

Axis angles (deg.)		+45, −45	

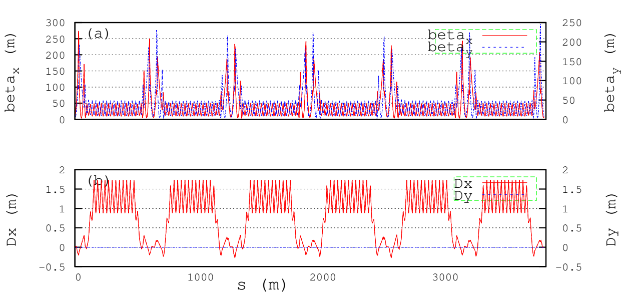

Figure 1: Betatron functions (maintained constant) in the ramp simulation, case of the new optics.

for comparison. In the simulations, optical functions are maintained unchanged over the all ramp from injection, E=23.8 GeV, to collision, E=100 GeV (total energy). The $E \approx 33$ GeV optics is taken in the "Run 15" case, the location of the strongest intrinsic depolarizing resonance, $G\gamma = 93 - Q_y$. Higher energy optics was used in the "Run 13" case, however the intrinsic reonance strengths do not change much, in spite of the varying optics, during the ramp. The resonance sequence so obtained in the 23-100 GeV range is displayed in Fig. 2, Tab. 2 gives the strengths of the strongest ones.

RESONANCE STRENGTHS

Intrinsic resonance strengths for the old and for the new optics are displayed in Fig. 2. They have been computed in the thin-lens approximation, namely,

$$\frac{J_n^{\pm}}{\sqrt{\epsilon_y/\pi}} = \frac{1+\gamma G}{4\pi}\Sigma_k \left\{ \begin{array}{l} \cos(\gamma G\alpha_k \pm \psi_{y,k})+ \\ i\,\sin(\gamma G\alpha_k \pm \psi_{y,k}) \end{array} \right\} (KL)_k \sqrt{\beta_{y,k}} \tag{1}$$

where the sum extends over the lattice quadrupoles

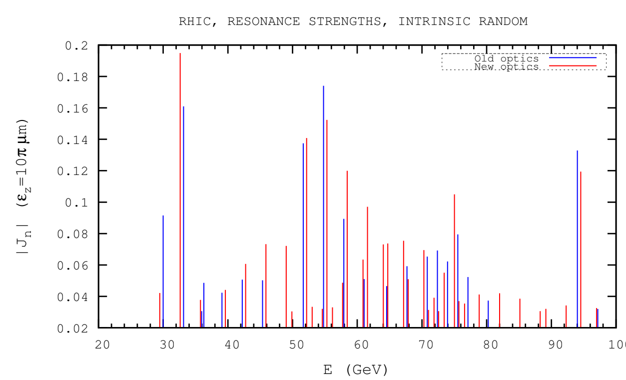

Figure 2: Resonance strengths in the simulation of the old and new optics.

9-D POLARIZED PROTON TRANSPORT IN THE MEIC "FIGURE-8" COLLIDER RING - FIRST STEPS*

F. Méot, Collider-Accelerator Department, BNL, Upton, NY 11973, USA
V.S. Morozov, JLab, Newport News, VA 23606, USA

Abstract

Spin tracking studies in the MEIC figure-8 collider ion ring are presented, based on a very preliminary design of the lattice. They provide numerical illustrations of some of the aspects of the figure-8 concept, including spin-rotator based spin control, and lay out the path towards a complete spin tracking simulation of a figure-8 ring.

INTRODUCTION

Figure 1 and Table 1 summarize the characteristics and nominal parameters of the figure-8 ring, the optical functions are shown in Fig. 2 and Fig. 3. Details can be found in [1].

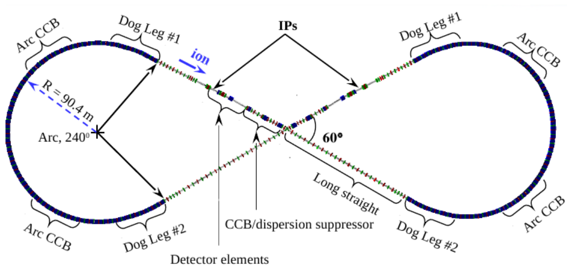

Figure 1: MEIC collider ion ring.

Table 1: Parameters of the 60 GeV MEIC Figure 8 Collider Proton Ring

transition γ		13.18

SPIN TRACKING

The present studies were done using a very preliminary design of the lattice, however not optimized for the spin dynamics and in particular not including the system intended for polarization control in MEIC. They can be viewed as simplified numerical illustrations of some of the aspects of the figure-8 concept, while laying out the path towards a complete spin tracking simulation.

The ray-tracing code Zgoubi is used in these studies [2].

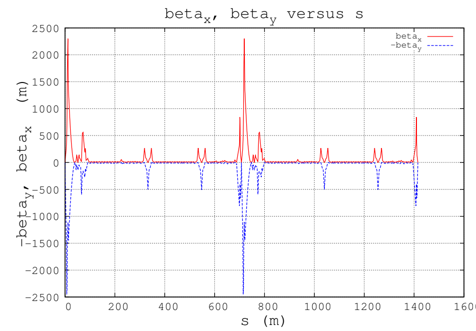

Figure 2: Betatron functions, horizontal and vertical.

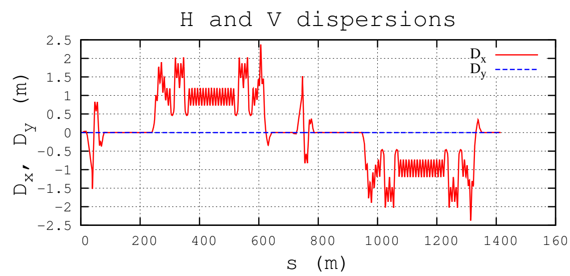

Figure 3: Dispersion functions, horizontal and vertical.

Particle with Zero Initial Coordinates

We start by tracking three particles with zero initial coordinates and with, respectively, fully longitudinal ($S_x^i = 1$), radial ($S_y^i = 1$), vertical ($S_z^i = 1$), initial spin orientation, for 200,000 turns through an ideal lattice containing no imperfections.

Figure 4-left shows the non-zero spin components of the three particles every 100 turns versus the turn number : the longitudinal spin component S_x of an initial $S_x^i = 1$ particle, the radial spin component S_y of a $S_y^i = 1$ particle, and the vertical spin component S_z of a $S_z^i = 1$ particle, all feature the same quasi-constant, quasi-unitary value vs. the turn number, as expected in a figure-8 ring. This validates the applicability of Zgoubi to this kind of study and demonstrates that it has the necessary numerical precision at least at the level of the chosen number of turns.

Effect of the Betatron Oscillations on Spin

We next launch three particles from one of the MEIC interaction points (IPs), with all three different initial spin orientations as earlier, and with initial horizontal and vertical

Abstract

This paper gives a brief overview of some aspects of the beam dynamics effects induced by the natural chromaticity in the eRHIC FFAG lattice.

INTRODUCTION

A Fixed Field Alternating Gradient (FFAG) doublet-cell version of the energy recovery recirculator of the eRHIC electron-ion collider is being investigated [1, 2, 3]. A pair of such FFAG rings placed along RHIC recirculate the electron beam through a 1.322 GeV linac (ERL), from respectively 1.3 to 6.6 GeV (5 beams) and 7.9 to 21.2 GeV (11 beams), and back down to injection energy. A spreader and a combiner are placed at the linac ends for proper orbit and 6-D matching.

SIMULATION CONDITIONS

The second, 11 beam, 21.2 GeV ring is considered in this discussion for convenience. The cell is shown in Fig. 1, there are 138 such cells in each one of the 6 eRHIC arcs. The 6 long straight sections (LSS) use that very cell, with quadrupole axes aligned. In the twelve, 17-cell, dispersion suppressors (DS) the quadrupole axes slowly shift from their distance in the arc, to zero at the LSS, in a reputedly "adiabatic" manner (details can be found in [3]).

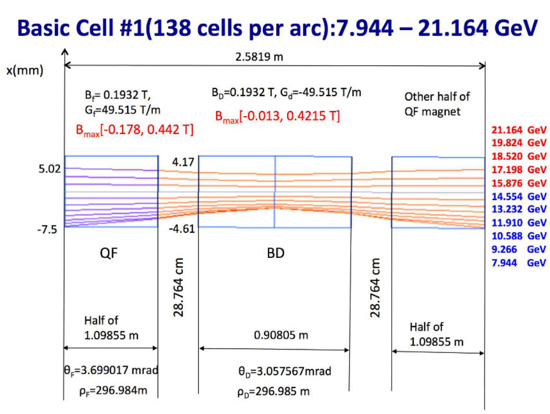

Figure 1: Arc cell in the 7.944-21.16 GeV eRHIC ERL ring [4].

Energy dependent cell tunes and chromaticities are displayed in Fig. 2. Additional details concerning the lattice and beam dynamics can be found in [5].

A complete ring is considered in the simulations discussed in the following,

$$6 \times \left[\frac{1}{2}\mathrm{LSS} - \mathrm{DS} - \mathrm{ARC} - \mathrm{DS} - \frac{1}{2}\mathrm{LSS}\right] + \mathrm{Linac}$$

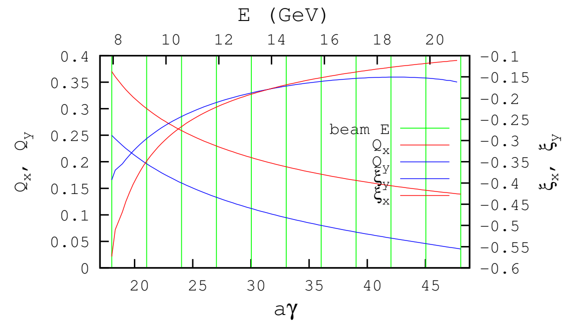

Figure 2: Energy dependence of cell tunes and chromaticities; the vertical bars materialize the 11 design energies.

The origin of the ring (the location where the bunches are injected) is taken in the middle of the LSS since the reference orbit is zero there, whatever the energy.

SR energy loss is roughly compensated at the linac : the actual energy gain is 1.322 GeV + half the energy loss at the previous pass + half the energy loss at the next pass. In particular the starting energy is 7.944 GeV + half the energy loss at pass #1.

EMITTANCE GROWTH

Due to the large chromaticity (Fig. 2), any beam misalignment results in its phase extent in phase space, following $\Delta\phi = 2\pi\xi\delta E/E$. SR for instance is an intrinsic cause since it introduces both energy spread and beam shift [5]. This SR effect is small however com-

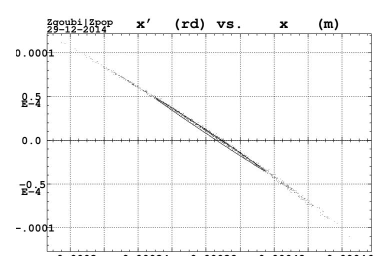

Figure 3: SR induced horizontal phase space portrait, for an initially zero 6-D emittance bunch, as acquired after an 11 GeV pass in the eRHIC ring.

pared to nominal beam emittances, it is illustrated in Fig. 3 which shows the phase-space portrait acquired by a bunch launched with zero emittances and energy spread, after a single 11 GeV pass in the eRHIC ring, assuming a very small beam misalignment in the DS regions (in the sub-millimeter range, as induced by a "lack of adiabaticity" of the adiabatic DS). Note that here we introduce a measure

INFLUENCE OF PLASMA LOADING IN A HYBRID MUON COOLING CHANNEL *

B. Freemire†, Illinois Institute of Technology, Chicago, IL 60563, USA
D. Stratakis, Brookhaven National Laboratory, Upton, NY 11973, USA
K. Yonehara, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

In a hybrid 6D cooling channel, cooling is accomplished by reducing the beam momentum through ionization energy loss in wedge absorbers and replenishing the momentum loss in the longitudinal direction with gas-filled rf cavities. While the gas acts as a buffer to prevent rf breakdown, gas ionization also occurs as the beam passes through the pressurized cavity. The resulting plasma may gain substantial energy from the rf electric field which it can transfer via collisions to the gas, an effect known as plasma loading. In this paper, we investigate the influence of plasma loading on the cooling performance of a rectilinear hybrid channel. With the aid of numerical simulations we examine the sensitivity in cooling performance and plasma loading to key parameters such as the rf gradient and gas pressure.

INTRODUCTION

A key challenge on producing intense muon beams is that they are created in a diffuse phase-space. As a result, the volume of the 6-Dimensional (6D) phase-space must be rapidly reduced via ionization cooling [1]. To reduce the transverse emittance, the beam is strongly focused with high magnetic fields and subsequently sent through an absorber material to reduce its overall momentum. Longitudinal emittance reduction is achieved by using wedge shaped absorbers and generating dispersion such that particles with higher energy pass through more material. In the aforementioned scheme, the cavities are filled with gas in order to prevent rf breakdown facilitated by multi-Tesla magnetic fields. Recently, a multi-stage tapered rectilinear channel capable for reducing the 6D emittance by at least five orders of magnitude has been designed and simulated [2, 3]. In that scheme the assumed gas pressure was 34 atm at room temperature.

An important issue in high-pressure gas filled cavities is rf power loading due to beam-induced plasma. Incident beam particles interact with dense hydrogen gas and cause significant amounts of ionization. Due to the high frequency of collisions with neutrals, electrons reach equilibrium within the picosecond time scale and move by the instantaneous external electric field. These charged particles, mainly electrons, absorb power from the electromagnetic field in the cavity. Thus subsequent beam bunches will experience a reduced electric field. This external field drop effect is reinforced by repetitive beam inflow. An experiment performed at the MuCool Test Area at Fermilab studied the formation of plasma created by a proton beam and its evolution over the course of many 805 MHz rf cycles [4]. In this paper, we investigate the influence of plasma loading on the cooling performance of a rectilinear hybrid channel.

COOLING MUON BUNCHES

The cooling scheme we consider starts with the post-phase-rotation beam [5] that yields bunch trains of muons from which we use only 21 (see Fig. 1).

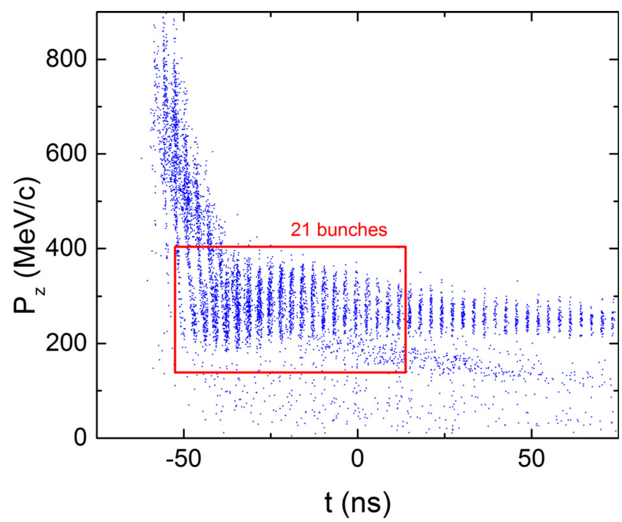

Figure 1: Longitudinal phase-space at the cooler entrance.

We consider a four-stage (A1-A4) tapered channel where each stage consists of a sequence of identical cells and the main lattice parameters are summarized in Tables 1 and 2. In all simulations the cavities are filled with gas at pressures of 34 or 100 atm at room temperature. The performance of the channel was simulated with the ICOOL code. The optimum performance for each pressure was found by using the conventional algorithm "Nelder-Mead" by scanning the rf phase, rf gradient, reference momentum, absorber length and wedge angle with the goal to maximize the beam luminosity within a given stage.

Table 1: Lattice Parameters for 34 atm

Stage	A1	A2	A3	A4
rf Freq. (MHz)	325	325	650	650
rf E (MV/m)	28.33	23.44	28.53	32.52
rf Phase (deg)	13.50	15.36	20.55	16.40
rf Length (m)	0.255	0.250	0.135	0.135

RHIC POLARIZED PROTON-PROTON OPERATION AT 100 GeV IN RUN 15*

V. Schoefer†, E.C. Abstract

The first part of RHIC Run 15 consisted of ten weeks of polarized proton on proton collisions at a beam energy of 100 GeV at two interaction points. In this paper we discuss several of the upgrades to the collider complex that allowed for improved performance. The largest effort consisted in commissioning of the electron lenses, one in each ring, which are designed to compensate one of the two beam-beam interactions experienced by the proton bunches. The e-lenses raise the per bunch intensity at which luminosity becomes beam-beam limited. A new lattice was designed to create the phase advances necessary for a beam-beam compensation with the e-lens, which also has an improved off-momentum dynamic aperture relative to previous runs. In order to take advantage of the new, higher intensity limit without suffering intensity driven emittance deterioration, other features were commissioned including a continuous transverse bunch-by-bunch damper in RHIC and a double harmonic RF cature scheme in the Booster. Other high intensity protections include improvements to the abort system and the installation of masks to intercept beam lost due to abort kicker pre-fires.

INTRODUCTION

RHIC provided polarized proton ($\vec{p}$) collisions at a beam energy of 100 GeV for ten weeks during the FY15 physics run. RHIC has a pair of spin rotators in each ring at each colliding IP that allow for collisions with an arbitrary stable spin direction at the point of collision. The run is divided here into three periods. The stable spin direction at the PHENIX experiment was kept vertical for all three periods (no spin rotation at PHENIX). The stable spin direction at STAR was oreiented longitudinally, vertically and then longitudinally again for each respective period. Figure 1 summarizes the performance relative to previous runs.

LATTICE

In order for the electron lenses to provide beam-beam compensation without exciting additional resonances, the betatron phase advances between the lenses and the proton-proton interaction need to be compensated needs to be a multiple of π. An early iteration of a lattice that met this phase advance requirement was tested (without an electron lens) in Run 13 at 255 GeV [1]. The Run 13 experience indicated that careful control of the 2/3 betatron resonance driving terms is important to preserving the transverse emittance and the beam lifetimes even at injection energy. For Run 15 a new lattice was developed [2]. The new lattice has a phase advance of π between the electron lens location and the proton-proton collision point at PHENIX. In addition, the lattice has 90 degrees betatron phase advance per cell, which produces passive compensation of the 2/3 resonance driving terms from the lattice sextupoles. Attaining the 90 degrees phase advance per FODO cell requires increasing the integer part of the tunes in each plane by 1 unit, a change from $(Q_x, Q_y) = (28.690, 29.685)$ to $(29.690, 30.685)$. The final β^* at the two proton-proton collision points is 0.85 m.

The β function at the point of each proton-electron collision is kept as large as possible (15 m) in order to prevent electron lens-driven transverse mode coupling instabilities [3].

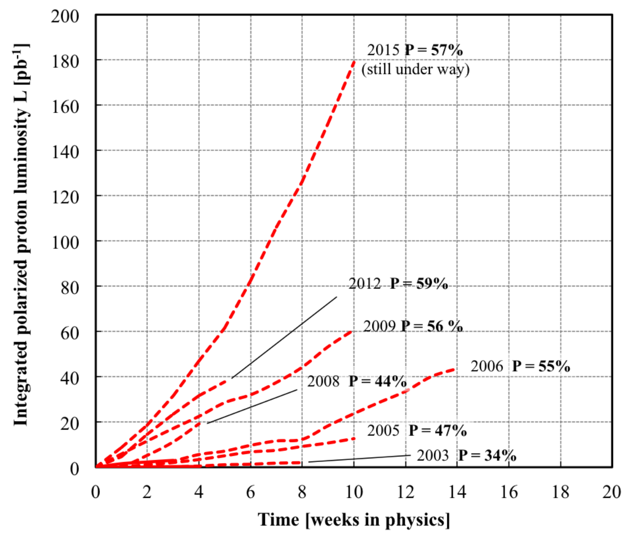

Figure 1: Integrated luminosity and polarization for all RHIC 100 GeV polarized proton runs.

Abstract

Collective beam effects, including coherent synchrotron radiation (CSR), have been studied on free-electron lasers (FELs). Here we will discuss a particular case of the CSR effects, that in energy-recovery linacs (ERLs). Special consideration is given to these machines because of their high average beam power and the architecture of the machine for energy recovery forces extreme bends. A recent study conducted on the JLab IR FEL looked at how CSR impacts both average energy and the energy spectrum of the beam. Such studies are important, both broadly, to the understanding of CSR and more specifically for a number of proposed ERL projects. A few proposed examples include the MEIC bunched beam cooler ERL design and ERL FELs for potential lithography purposes that would operate in the EUV range.

INTRODUCTION

The damaging effects of coherent synchrotron radiation (CSR) have been an area of intense research for free-electron lasers (FELs). For the very short bunches required in many FELs the very intense CSR can cause a host of problems, such as, increasing emittance and the slice energy spread, as well as, giving rise to the microbunching instability [1–4]. For energy recovery linacs (ERLs) CSR can be especially troubling due to the design of these machines. In order to recover the stored power in the beam it must be brought back through the linac. This necessitates the use of arcs composed of many dipole magnets where there is the potential for a great deal of CSR generation. ERLs could also face additional issues [5] due to very high currents that are often used in such machines, from 10 mA up to 100 mA in proposed machines. CSR remains a difficult computational problem to model due to the scaling with number of particles N as N^2 [6]. To model CSR in most accelerator simulations a 1-D model is employed that projects the transverse bunch distribution onto a line [7]. Thus far this model has shown great success in comparison with experiments [8, 9]. Since the 1-D CSR model has been so effective there is still some question as to at what point it becomes unreliable. Various 2-D and 3-D models of CSR have been developed, but to date analysis of most experiments with the 1-D model has been sufficient [10–12]. As CSR continues to be a topic of ongoing interest within the FEL community it is important to continue to perform machine studies to help better characterize its affects and to improve theory and simulation. In the first part of this paper we give an overview of a recent experiment performed on the Jefferson Lab ERL FEL driver studying CSR [13] and describe some of the key lessons learned. The second part reviews some ongoing accelerator projects for which CSR and other collective effects instabilities may be a key concern.

JLAB EXPERIMENT DESCRIPTION

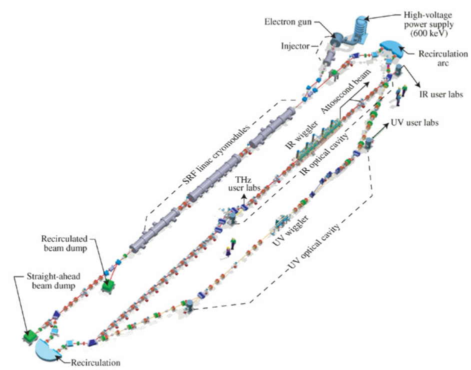

Figure 1: Layout of the JLab FEL. The IR wiggler line was used in the experiment described here.

The JLab ERL IR FEL driver [14] (Fig. 1) consists of an SRF linac that was used to accelerate the 9-MeV beam from the injector up to 135 MeV. The beam passes through the first recirculation arc which is used to provide first and second order longitudinal phase space control through the use of quadrupole and sextupole magnets placed in dispersive regions of the arc. By tuning the quadrupoles it is possible to easily manipulate the total momentum compaction (R_{56}) of the machine. Final compression of the bunch is normally performed in a standard four-dipole chicane immediately before the wiggler. This chicane also provides separation between the FEL optical components and electron beam. After passage through the wiggler (not active during the experiment) the beam passes through a THz suppression chicane [15] which serves to decompress the bunch slightly before it reaches the second recirculation arc. This decompression helps to alleviate heating on the downstream FEL optics due to CSR production in the leading dipole of the second arc. In the second arc the beam again undergoes more

Abstract

This paper presents recent observations obtained on the study of electron cloud induced instabilities and emittance growth on positron beams at the Cornell Electron-Positron Storage Ring Test Acceleartor (CesrTA), and the simulation of these phenomena under similar beam conditions using the program CMAD. Results show that the transition to large bunch oscillations ocurrs at similar electron cloud densities in experiments as well as simulations. Beam size measurements were carried out using an x-ray beam size monitor (xBSM). The spectrum of the motion of the bunches were recorded using beam position monitors. The experiment consisted of using a train of positron bunches to generate the electron cloud, and observation of a “witness bunch" at different positions behind the train. Motion of the bunches in the train were controlled using feedback, thus suppressing multi-bunch effects. This experimental set up was suitable for comparison with simulations because the simulations were carried out only to study single bunch effects.

INTRODUCTION

The CesrTA program consists of using the Cornell Electron-Positron Storage Ring as a test facility to study physics associated with linear collider damping rings [1]. One of the activities of the program was the study of the response of the positron beams to electron clouds under different conditions. This paper reports the results of experiments carried out in April 2014, along with simulations performed under similar conditions. Table 1 gives the conditions under which experiments were performed.

Table 1: CesrTA Parameters

Parameter	Value
Energy	2.085 GeV
Horizontal Emittance	2.6 nm
Vertical Emittance	20 pm
Bunch Length	10.8 mm
Bunch Spacing	14 ns
Momentum Compaction	6.8e-3
Revolution Frequency	390.1 kHz
Horizontal Tune	0.58
Vertical Tune	0.62
Synchrotron Tune	0.055

Earlier simulation studies using the program CMAD [3] were performed for CesrTA Ref [6], that showed several qualitative features also observed in the experiments. Since then, the CMAD program has undergone various improvements that has enabled better comparisons with simulations. At the same time, the method of observation underwent a change, which made it more suitable for comparison with simulations. The so called "witness bunch"(WB) method of observation consists of using a train of positrons to generate the electron cloud. The sole purpose of the train is to generate the cloud rather than for studying its response to electron clouds. The transverse motion of the bunches in the train was always well suppressed with the help of feedback. This helps eliminate multi-bunch effects. The witness bunch was placed at varying positions behind the train, and the behavior of this bunch alone was observed under different conditions. It should be noted that the witness bunches used for different measurements never existed. That is, when the observation of one of them was completed, the bunch was removed and replaced by the next one under a different condition. The instrumentation associated with performing this swap of bunches is given in Ref [7]. One of the conditions that was varied was the position of the WB behind the train, which is equivalent to varying cloud density encountered by the bunch. Other experiments on varying the chromaticity, witness bunch charge, emittance etc were attempted but the data obtained was insufficient and it was clear that a more exhaustive study is necessary to study these effects.

TUNE SHIFT ANALYSIS

The spectrum of the witness bunch was obtained by gating BPM signal from a single bunch and feeding the signal to a spectrum analyzer. The details of the instrumentation is given in [9]. These measurements provide information on tunes that are most prominent in the motion of the bunch. Figure 1 shows plots of the fractional tune vs signal amplitude, of the first bunch in the train and the witness bunch. It is assumed that the first bunch does not encounter any cloud, and thus the tune shift of the witness bunch with respect to the corresponding first bunch in the train is the electron cloud induced tune shift. These results shown had a current of 0.5mA in all the bunches (train + witness). The figure shows the tune shifts of witness bunches at positions 74 and 47, behind the 45 bunch train. The spacing between the WB and the end of the train may be computed by (WB position − no of bunches in train) × bunch-spacing. Thus WB at 47

REALIZATION OF PSEUDO SINGLE BUNCH OPERATION WITH ADJUSTABLE FREQUENCY*

C. Sun†, D. S. Robin, C. Steier, G. Portmann
Lawrence Berkeley National Laboratory, Berkeley, CA 94706, USA

Abstract

We present the concept and results of pseudo-single-bunch (PSB) operation—a new operational mode at the Advanced Light Source (ALS)—that can greatly expand the capabilities of synchrotron light sources to carry out dynamics and time-of-flight experiments. In PSB operation, a single electron bunch is displaced transversely from the other electron bunches using a short-pulse, high-repetition-rate kicker magnet. Experiments that require light emitted only from a single bunch can stop the light emitted from the other bunches using a collimator. Other beam lines will only see a small reduction in flux due to the displaced bunch. As a result, PSB allows to run timing experiments during the multibunch operation. Furthermore, the time spacing of PSB pulses can be adjusted from milliseconds to microseconds with a novel "kick-and-cancel" scheme, which can significantly alleviate complications of using high-power choppers and substantially reduce the rate of sample damage.

INTRODUCTION

A major limitation of synchrotron light sources is the ability to easily serve two classes of experiments simultaneously, namely, brightness or flux limited experiments and timing experiments. High brightness experiments require filling most of the rf buckets with electrons, thus maximizing the total current while minimizing the current per bunch. In such a multibunch filling pattern, the bunch spacing is typically only a few nanoseconds between electron bunches. On the other hand, timing experiments require longer timeing between x-ray pulses. For example, in the case of laser-pump x-ray-probe timing experiments, it is desirable to have only one x-ray pulse per laser pulse. Since such lasers operate between kHz and MHz rates, this implies a distance between pulses of ms to μs.

At the Advanced Light Source (ALS) facility, we have been exploring a new mode of operation that we call "pseudo-single-bunch" (PSB) operation, the goal of which is to allow high-flux and timing experiments to run simultaneously [1–4]. The idea behind PSB operation is to use a high-repetition (MHz)-rate, short-pulse (<100 ns) kicker [5] to vertically displace a single "camshaft" bunch relative to the bunch train. Experiments that require light emitted only from a single bunch can block the light emitted from the other bunches using a collimator with only light from the camshaft bunch reaching the experiment. The PSB timing could be at the orbital period (656 ns) or longer, depending upon how frequently the bunch is displaced.

Here we discuss the results of our studies on the PSB operational mode, especially the novel "kick-and-cancel" (KAC) scheme that can deliver a single pulse with adjustable frequency [3]. A similar idea was previously suggested [6], but to our knowledge this is the first time that it has been realized.

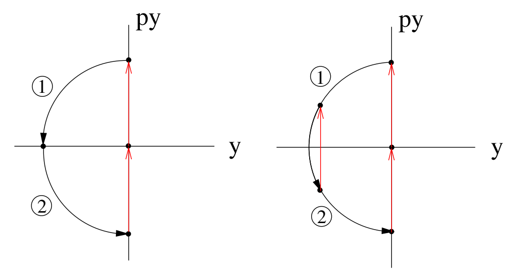

Figure 1: Illustration of the KAC scheme in the phase space at tunes 0.25 and 0.333.

KICK-AND-CANCEL (KAC) SCHEME

Working Principle

The idea of the KAC scheme is that by adjusting the ring tune and the PSB kick pattern, the camshaft bunch can first be displaced to a different orbit and then kicked back to its original one within a few turns. This KAC process can be repeated at will to create a PSB pulse with an adjustable repetition rate.

The KAC scheme can be easily understood using a normalized phase space diagram as shown in Fig. 1. In this plot, two schemes are illustrated at tune $\nu_y = 0.25$ and $\nu_y = 0.333$. For example, at tune $\nu_y = 0.25$, the camshaft bunch is first displaced to a different vertical orbit and then proceeds two turns. At the end of the second turn, the bunch has the same vertical offset but the inverse angle to the one after the first kick. At this time, if another identical kick is applied, the bunch will be put back to its original orbit. Similarly, at $\nu_y = 0.333$, three kicks and three orbital tunrs are required in order to restore the displaced orbit.

After the beam orbit is restored to the original orbit, we can wait any time of period (KAC period N) and then repeat this kick and cancel process, thus creating single-bunch pulses with adjustable repetition rates.

BENCHMARKING AND APPLICATION OF SPACE CHARGE CODES FOR RINGS

Shinji Machida*, STFC/RAL/ASTeC, Didcot, United Kingdom

Abstract

This presentation should present an overview of efforts for benchmarking and application of space charge codes for rings. After briefly recalling the historical background of the simulation efforts of space charge effects in rings, we will overview the present benchmarking efforts against experimental results.

INTRODUCTION

Benchmarking of a code in the accelerator community is usually referred to as an effort to confirm validity of a code by comparing the prediction of a code 1) with measured data, 2) with theory based on the same physics and 3) with other similar codes. In this paper, we will discuss why the benchmarking of space charge codes is important and still a challenge now.

Space charge codes using macro particles# consisting of two parts. The first part is to update macro particle coordinates as a result of space charge effects integrated in each small time step. The second part is to advance macro particle coordinates in the same time period, which is entirely determined by the external lattice elements. Separation of the two parts and alternative evaluation of them are thought to be essential in order to take into account local details of the beam envelope and the *s*-dependent space charge potential, where *s* is the direction of the beam travel. If the beam emittance in transverse and longitudinal directions evolves, the space charge potential is updated so that the calculation is self-consistent. Although the second part, which is free from space charge, can be easily symplectic, that is the essential feature for long term tracking, evaluating space charge effects is susceptible to any kinds of modelling details. It is possible that the symplectic condition is violated if we employ the Particle in Cell (PIC) method (see below) to obtain a non-smooth space charge potential. Ref. [1] further discusses the conditions of symplectic time evolution when using PIC.

The idea of evaluating the space charge potential using macro particles came from plasma physics [2]. A brute force way of calculating the space charge potential is to sum up the binary interaction among the whole macro particle ensemble (Particle Particle or PP method), but it is not efficient from the computational point. A more practical approach is to divide the configuration space using a grid and then allocate macro particles to and calculate the Coulomb potential at each grid point. This is called the Particle Mesh method or the Particle in Cell (PIC) method [3].

Whether the PP or the PIC method is employed, the number of macro particles is much less than reality, several orders of magnitude less, e.g. 10^6 macro particles to represent 10^{12} real particles, and that may introduce non-physical effects. One of them is the numerical intrabeam scattering, which causes continuous emittance blow up [4].

A different approach is to fix the space charge potential at the beginning and keep it unchanged during the tracking. This is not a self-consistent calculation. However, when the space charge effects are a small perturbation, the change of charge distribution and therefore the change of the space charge potential are negligible and the dynamics is mainly determined by the external lattice elements. In fact, space charge effects in rings are relatively small because the periodic structure excites resonances and tune is allowed only a small shift, e.g., a few per cent change in terms of tune shift, so that the approximation is well justified. The advantage is that it is free from the numerical noise which the PIC method cannot avoid and can make the whole tracking exactly symplectic. On the other hand, some kind of instabilities, such as envelope instabilities due to space charge cannot be modelled [5].

One day in the not too distance future, the same number of macro particles as real particles in rings may be tracked in simulation with space charge effects once computational power has progressed significantly. Space charge codes at present, however, have to use some approximation, often drastic one as we mention later, and the validation of codes are essential.

In this paper, we will briefly review the benchmarking efforts of space charge codes in the past. We will then overview the present activities in detail. It is interesting to see that each period places different emphasis on the benchmarking because of the accelerator projects at that time, available computational resource and theoretical understanding. We would like to note that there was a similar review paper 10 years ago [6].

BACKGROUND

In the accelerator community, the first time when a space charge simulation code for rings was used was probably in the 80s. Although space charge codes for linacs had existed earlier, codes for rings were not easy to write because the number of calculation steps was much larger so it demanded heavy computational power.

There was the demand to preserve transverse rms emittance in high energy hadron colliders and avoid luminosity deterioration. There was also the need to minimise beam loss in high intensity hadron accelerators and so allow hand-on maintenance. It was the time when Superconducting Super Collider (SSC) in the US and KAON Factory in Canada were proposed. People knew

BEAM DYNAMICS IN A HIGH FREQUENCY RFQ

A.M. Lombardi, V. A. Dimov, M. Garlasche', A. Grudiev, S. Mathot, E. Montesinos, S. Myers, M. Timmins, M. Vretenar, CERN, Geneva, Switzerland

Abstract

CERN is constructing a 750 MHz Radio Frequency Quadrupole (RFQ) which can accelerate a proton beam to 5 MeV in a length of 2 m. The beam dynamics strategic parameters have been chosen to make this RFQ a good candidate for the injector of a medical facility operating at frequency of 3 GHz . Minimising beam losses above 1 MeV, containing the RF power losses and opening the road to industrialisation have been the guidelines for an unconventional RFQ design. In this paper, the optimisation efforts, the structure design and the expected beam qualities will be detailed. The status of the construction as well as the potential for further developments will be presented.

INTRODUCTION

The office for medical application, created by the CERN director general in 2013 with the aim for CERN to become established as an important facilitator of medical physics in Europe, has -amongst others-the task of developing on-going accelerator, detector and information technologies in ways that will benefit medicine. In this framework the office has responded to the needs of several linac-based hadron-therapy projects and has created a study group for a high frequency RFQ with the aim of capitalising on the recent developments around the RFQ for the LINAC4 project, which was successfully commissioned in 2013.

Linac based proton-therapy facilities are the new generation in the field of hadron therapy machines, the main advantage with respect to the established PIMMS [1] design - being the possibility of fast energy variation (pulse-to-pulse). Typical linac-based facilities [2,3] include high-frequency, high-gradient structures resonating at the frequency of 3 GHz, equipped with Permanent Magnet Quadrupoles. Typically about 20m of accelerator are sufficient to bring the energy from 10 to 250 MeV, including a medium velocity structure up to 40 MeV and a high velocity structure up to 250 MeV. The effectiveness of accelerating non-relativistic protons with 3GHz has been demonstrated from the energy of 11 MeV [4]. It is believed that effective use from energies as low as 5 MeV is feasible. Below 5 MeV the use of 3GHz is excluded and a solution must be found for the missing link.

A HIGH FREQUENCY RFQ

The starting parameters for the RFQ design are reported in Table1. These are the working parameters used to define the layout and will be discussed in the following.

Table 1: RFQ and Source Specifications

Parameter	Value
RF Frequency	Subhar of 3GHz
Input energy	>30keV
Output Energy	5 MeV
Output Pulse Current	30 μA
Repetition frequency	200 Hz
Pulse duration	20 μsec
Transverse Emittance (100%,normalized)	0.4 (π mm-mrad)
Bunch length	±20 deg at 3 GHz
Energy spread	±35 keV
Length	Less than 2.5m

The combination of parameters as detailed in the table above calls for an unconventional RFQ design, as both the longitudinal and the transverse acceptance at 5MeV are factors smaller than the values currently obtained at this energy. Although the design of the source is outside the scope of this paper, we considered the source when defining the RFQ layout and we made sure that the challenges (emittance, extraction energy and current) were balanced between the source and the RFQ.

General Layout

In this paragraph we describe the fundamental choices that brought to the definition of the RFQ, the first one being the frequency. The choices as described here are motivated for the specific use of this RFQ in a proton therapy facility; they are not universal choices, as will be detailed in the last paragraph of this paper where other uses are proposed. The frequencies of 600, 750MHz and 1 GHz were considered: the higher the frequency the easier the frequency jump at 5 MeV but also the higher the technological jump from existing RFQs. From a purely beam-dynamics point of view the use of a higher frequency is certainly an advantage. We then compared 600 and 750 MHz on the basis of power losses consideration. The capacitance per unit length is a very weak function of the frequency, much more dependent on the ratio between the transverse radius of curvature and the average radius (ρ/r0). We can therefore assume that the capacitance is the same and we know from [5] that the power losses per meter scale like the V^2 $f^{3/2}$ where V is the vane voltage and f the frequency. For the same vane voltage the 750 MHz RFQ would use 1.4 times more power per meter, but we found out that the overall length of the RFQ would compensate for this disadvantage, and finally for the same vane voltage and same output energy the total power would be approximately the same. As the

INTERPLAY OF BEAM-BEAM, LATTICE NONLINEARITY, AND SPACE CHARGE EFFECTS IN THE SuperKEKB COLLIDER

D. Zhou*, H. Koiso, A. Morita, K. Ohmi, Y. Ohnishi, K. Oide, H. Sugimoto
KEK, 1-1 Oho, Tsukuba, Ibaraki 305-0801, Japan
Y. Zhang, IHEP, Beijing, China

Abstract

The SuperKEKB B-factory adopts nanobeam scheme for the collision, which consists of large crossing angle and very small vertical beta function at the interaction point. Simulations have revealed that the luminosity of SuperKEKB will be very sensitive to perturbations from various sources. This paper discusses various beam dynamics issues involved in the SuperKEKB collider, including beam-beam, lattice nonlinearity, and space charge effects, as well as their interplay and planned mitigations.

INTRODUCTION

The SuperKEKB is designed with the strategy of so-called nanobeam scheme, which was originally proposed by P. Raimondi for SuperB [1]. The electron and positron beams collide with a horizontal crossing angle of $\theta = 83$ mrad. The horizontal emittances are $\epsilon_{x+} = 3.2$ nm and $\epsilon_{x-} = 4.6$ nm, taking into account the intra-beam scattering effects. The beam sizes at the IP are $\sigma_{x+} = 10.1\,\mu$m and $\sigma_{x-} = 10.7\,\mu$m. The overlap area of the two beams is $\Delta s = 2\sigma_x/\theta \approx 0.25$ mm, which is about 1/20 of the nominal bunch length. Another feature of SuperKEKB is the small vertical beta function at IP, which is squeezed to be $\beta^*_{y+} = 0.27$ mm and $\beta^*_{y-} = 0.3$ mm, comparable to the overlap area Δs. The vertical emittances are assumed to be $\epsilon_{y+} = 8.64$ pm and $\epsilon_{y-} = 12.9$ pm, taking into account various intensity-dependent and -independent effects. Comparing with its predecessor, the emittances of SupkerKEKB rings are about 1/5 and 1/20, and the beta functions are about 1/40 and 1/50 of those of KEKB rings in the horizontal and vertical directions, respectively.

Since the KEKB rings, as reviewed in Refs. [2–4], have experienced many beam dynamics issues which affected the luminosity performance, it is expected that the luminosity performance of SuperKEKB will be even more sensitive to various imperfections or perturbations, such as machine errors, lattice nonlinearity, intra-beam scattering, beam-beam interaction, space charge, impedance-driven instabilities, etc. Regarding to the beam dynamics issues associated to the electron-positron colliders, there are reviews in Refs. [5–7]. The progress of next generation B-factory projects have been reviewed in Refs. [8–10], and in Ref. [11] especially the most recent status of SuperKEKB. This paper is dedicated to discussing a few beam dynamics issues which might set challenges for the future commissioning of the SuperKEKB. For more information of beam dynamics issues at SuperKEKB, such as intra-beam scattering, electron cloud effects, impedance effects, optics optimization, etc., the interested readers are directed to Refs. [12–16].

* dmzhou@post.kek.jp

BEAM DYNAMICS ISSUES

This section gives a brief overview of some important beam dynamics issues in SuperKEKB. Since most of these issues appear to be more prominent in the low energy ring (LER), we mainly use the LER for illustrations rather than the high energy ring (HER) in the following discussions.

Beam-beam Interaction

It is well accepted that the ‘sweet spot’ in the tune space for achieving highest luminosity at an electron-positron collider usually locates at an area close to half integer. To search for the best working point in the tune space, luminosity scans are performed for both LER and HER, with the fractional tunes in the range of [0.5, 0.75] and the beam currents set to design values. The tune scan results of luminosity using a weak-strong model for the LER and HER are demonstrated in Fig. 1 with scaled colours, and Fig. 2 show the relevant scans of vertical rms beam sizes. It is seen that the strong synchro-betatron resonances of $2\nu_x - N\nu_s = Integer$ exist in the nanobeam scheme. This is due to the large crossing angle chosen for the purpose of mitigating hourglass effects. Furthermore, the resonances of $\nu_x + 2\nu_y + N\nu_s = Integer$, $2\nu_y - \nu_s = Integer$, and $\nu_x - \nu_y - \nu_s = Integer$ also restrict the choice of working point. The working points have to be kept far enough from these strong resonances. In general, the luminosity is very sensitive to the vertical beam size. With higher beam energy, the electron beam in HER is more robust than the positron beam in LER with respect to the beam-beam driven synchro-betatron resonances. At present, both the main rings of the SuperKEKB are optimized with fractional tunes of [0.53, 0.57]. The working point is selected from islands isolated by the beam-beam resonance lines. But notice that the island areas might shrink when the lattice nonlinearity and machine errors strengthen those resoances [13].

Lattice Nonlinearity

For SuperKEKB, most of the unavoidable lattice nonlinearity is attributed to the interaction region resulting from the extremely small beta functions at IP and low emittances. For examples, the nonlinear terms from the drift space near IP, so called kinematic terms, and the Maxwellian fringe fields of final focus (FF) superconducting quadrupoles will become very important. The dynamic aperture (DA) lim-

MACHINE AND PERSONNEL PROTECTION FOR HIGH POWER HADRON LINACS

M. Ikegami Facility for Rare Isotope Beams, Michigan State University, MI 48824, USA

Abstract

Machine and personnel safety are increasingly important for high power hadron linacs as involved beam power increases. Design requirements and characteristic features of machine protection system and personnel protection system are reviewed for operating and proposed high power hadron linacs, such as J-PARC, SNS, FRIB, ESS, and IFMIF.

INTRODUCTION

Demand for high power hadron linacs has been increasing for various applications in recent years, which include driver for spallation neutron source, irradiation of material for fusion reactor development, and physics experiments utilizing intense secondary beams. A number of high power hadron linacs are currently under operating, construction, or planning around the world to meet this demand. Prospect for future application for an accelerator driven subcritical reactor or transmutation of nuclear waste has further motivated the pursuit of higher beam power.

Seeking higher beam power, the personnel and machine safety become increasing important as a risk of catastrophic failure has also been increased. PPS (Personnel Protection System) and MPS (Machine Protection System) are key systems to protect personnel and machine safety for accelerators. In this paper, we review design requirements and characteristic features for PPS and MPS for operating and proposed high power hadron linacs. Among a number of high power hadron linacs, we take the following five projects in this paper, namely, FRIB (Facility for Rare Isotope Beams), J-PARC (Japan Proton Accelerator Research Complex), SNS (Spallation Neutron Source), ESS (European Spallation Source), and IFMIF (International Fusion Material Irradiation Facility). For IFMIF, the linac for IFMIF/EVEDA (Engineering Validation and Engineering Design Activities) is also discussed. As summarized in Table 1, the average beam power level we discuss in this paper ranges from a few hundred kW to a several MW.

PERSONNEL PROTECTION SYSTEM

Challenges in PPS specific to high power hadron linacs are mostly related to radiation hazard mitigation. As the involved beam power is high, it can cause radiation hazard both with prompt and induced radiation.

Prompt Radiation During Normal Operation

For prompt radiation during normal operation, it is usual to control the radiation level at accessible area by shielding assuming certain amount of chronic beam loss. For example, shielding for the linac tunnel of FRIB is designed to keep the expected radiation dose rate at accessible area below 1 μSV/h assuming uniform beam loss of 1 W/m for the beam line. The goal of 1 μSv/h is deduced from the internal yearly dose limit (or ALARA goal) for radiation workers in FRIB and assumption for possible occupying hours per year. As shielding design involves radiation transport calculation, some margin is added in FRIB for its ambiguity. The beam loss assumption of 1 W/m comes from the empirical hands-on maintenance limit for proton accelerators, and we assume that we won't operate for long term with tolerating the beam loss exceeding this level. Radiation monitors connected to PPS are placed in accessible areas to monitor the radiation level, and they inhibit the beam if the radiation dose rate exceeds the assumed level. The linac itself could be operated with higher beam loss than 1 W/m, but the radiation monitor system guarantees that the radiation dose rate from chronic beam loss does not exceed the expected level. Although the dose rate limit for accessible area and assumed beam loss may be different for each facility, they share the basic strategy in their shielding design. As the dose limit is defined as an average over a period of time usually longer than one hour, fast response is not required for radiation monitor in this context.

Prompt Radiation at an Abnormal Event

However, the situation can be very different at a fault event where the dose rate can be higher by orders of magnitudes than that in normal operation. We here consider two kinds of faults. One is the worst case beam loss event where full power beam is lost at a single point. The other is beam delivery to unintended area.

Single point beam loss For the former, detailed fault analysis with radiation transport calculation is indispensable to design appropriate protection. In the case of FRIB, the most vulnerable locations to this hazard in the linac building is in the front-end area due to its unique linac layout (See Fig. 1). In FRIB, ion sources are located at the surface level and the beam is led to linac tunnel through a vertical drop. Then, the accelerated beam comes back to the vicinity of the vertical drop due to its folded layout. The dose rate around the vertical drop can be very high if we have a full power single point beam loss of the accelerated beam in the vicinity of the vertical drop. Radiation transport calculation shows that the dose rate could reach a few tens of mSv/h at the surface of the shielding block (See Fig. 2) [1]. Systematic analysis reveals that we have significant radiation dose rate only in the vicinity of four large openings in the linac building, which enables us to focus on protection around those limited areas. Our tentative internal goal for integrated dose at a single abnormal

ADVANCES IN PROTON LINAC ONLINE MODELING*

Xiaoying Pang†
Los Alamos National Laboratory, Los Alamos, NM, 87545, USA

Abstract

This paper will review current online modeling tools used for proton linacs and then focus on a new approach that marries multi-particle beam dynamics with modern GPU technology to provide pseudo real-time beam information in a control room setting. Benefits to be discussed will include fast turnaround, accurate beam quality prediction, cost efficiency, test bed for new control and operation scheme development and operator training.

INTRODUCTION

Accelerator online modeling codes are indispensable tools in proton linac control rooms. At their hearts are the online beam dynamics simulators. These simulators are developed to have direct access to real machine parameters and to be able to provide fast predictions of various beam quantities. Together with some optimization tools, they can guide accelerator operators to tune up and troubleshoot the linac systems efficiently. Existing online simulators for proton linacs are mostly developed based on the envelope model which represents a r.m.s. equivalent beam as an ellipse in phase space and uses a linear representation of the space charge force. While the envelope model enables fast response and good accuracy for beam matching and steering in most cases, it lacks the capability to simulate using real beam distributions and study a range of real-world scenarios where the beam is not a nicely formed ellipsoid or the beam intensity is high enough so that a more accurate representation of the space charge force is needed. For high power beam operations, there will be less room for operational error, therefore a more accurate multi-particle online simulator is needed to provide more realistic beam information and tuning guidance.

In the following sections, we will first review the existing online modeling tools and briefly discuss the need for a multi-particle simulator for high power beam operations. Then we will introduce the high performance simulator (HPSim) that we have been developing. Details about the design, performance and its applications will be presented.

EXISTING ONLINE MODELING TOOLS

The list of tools presented here is by no means exhaustive, but they can be considered representative of what have been used in proton linac control rooms worldwide.

TRACE2D/3D

TRACE2D and TRACE3D [1] are well-established envelope based simulation codes initially developed at LANL. TRACE2D represents a beam using phase space ellipses in the two transverse planes, while the TRACE3D has the additional capability of simulating the longitudinal beam dynamics by assuming a 3D ellipsoidal beam shape. In both cases, the beam is a r.m.s. equivalent representation and it is described as a sigma matrix whose elements are related to the Twiss or Courant-Snyder parameters. Since they only track beam through the beamline elements represented as R-matrices and only consider the linear part of the space charge force, TRACE2D/3D simulations can be very fast, which makes them perfect for accelerator online modeling. In fact, the TRACE2D is still used in the proton linac control room at the Los Alamos Neutron Science Center (LANSCE). The physics algorithms of TRACE2D/3D have been used in the development of other online modeling tools and they have been widely used to benchmark against other similar codes.

XAL Online Model

XAL is a Java development framework for accelerator applications [2]. It was first developed and tested at the Spallation Neutron Source (SNS) and has been widely adopted by several accelerator sites, not limited to proton accelerator facilities. The online modeling tools [3] of XAL can simulate not only linacs but also storage rings. It comes with a suite of tools [4] that can be very useful in accelerator tuning, i.e. PASTA [5] for warm linac RF setpoint tuning, SLACS for superconducting cavity [6] RF setpoint tuning and tools for orbit corrections, etc. Like TRACE3D, the XAL online model tracks a beam in the 6D phase space based on the envelope model and uses the linear space charge approximation.

ESS Linac Simulator

More recently, a new online beam dynamics simulator is being developed at the European Spallation Source (ESS) [7–9]. It is also an envelope model based simulator. In order to be able to simulate the 5MW beam correctly, better treatment of the RF transformation and nonlinear space charge effect have been implemented [8]. However, the nonlinear space charge effect is calculated by assuming the beam distribution is Gaussian within the 3D ellipsoid.

HIGH PERFORMANCE ONLINE MULTI-PARTICLE SIMULATOR

The common theme of the existing online simulators for proton linacs is that they are all based upon the envelope

IMPROVING THE ENERGY EFFICIENCY OF ACCELERATOR FACILITIES*

M. Seidel, PSI, Villigen, Switzerland

Abstract

New particle accelerator based research facilities tend to be much more productive, but often in coincidence with higher energy consumption. The total energy consumption of mankind is steeply rising and this is mainly caused by quickly developing countries. Some European countries decided to terminate nuclear power generation and to switch to sustainable energy production. Also the CO2 problem gives rise to new approaches for energy production and in all strategies the efficiency of utilization of electrical energy plays an important role. For the public acceptance of particle accelerator projects it is thus very important to optimize them for best utilization of electrical energy and to show these efforts to funding bodies and to the public. Within the European accelerator development program Eucard-2 [1] we organise a network EnEfficient [2] that aims at improving the energy efficiency of accelerators. In this paper we give some background information on the political situation, we describe the power flow in accelerator facilities and we give examples for developments of efficient accelerator systems, such as magnets, RF generation, heat recovery and energy management.

ENERGY – THE POLITICAL SITUATION

Over the history of mankind the consumption of energy shows a steep growth with the industrial revolution. Especially in the last few decades the growth is dramatic and many people see this development critically. Massive burning of fossil energy carriers causes high CO_2 emission, one of the causes for global warming and climate change. Nuclear power has other problems and is disputed. But even if one believes in technical advances, the development shown in Fig. 1 looks unhealthy and one might suspect that the growth rate cannot stay intact for long. The mentioned problems have caused a higher awareness on energy related issues around the world. Especially in Europe some countries try to change their energy generation schemes away from coal and nuclear power, in favour of sustainable energy production like wind and solar. In all strategies a high efficiency of electrical power utilization is of utmost importance. When a new research facility is proposed, its energy consumption is thus a critical aspect for the successful public and political acceptance. Statistical information on existing accelerator facilities can be found in [3]. In those countries with a larger fraction of renewable energies we observe also a technical impact of new energy strategies. While coal and nuclear power plants provide continuous base power, wind and sun are strongly fluctuating. Already today, spot market prices of energy vary by an order of magnitude. In extreme cases prices go even negative, when additional consumers are needed to avoid a breakdown of the grid. Energy storage systems could solve this problem. At present only limited technical solutions exist, which allow storing significant amounts of energy. As a result we observe fluctuations in availability of cheap electrical energy.

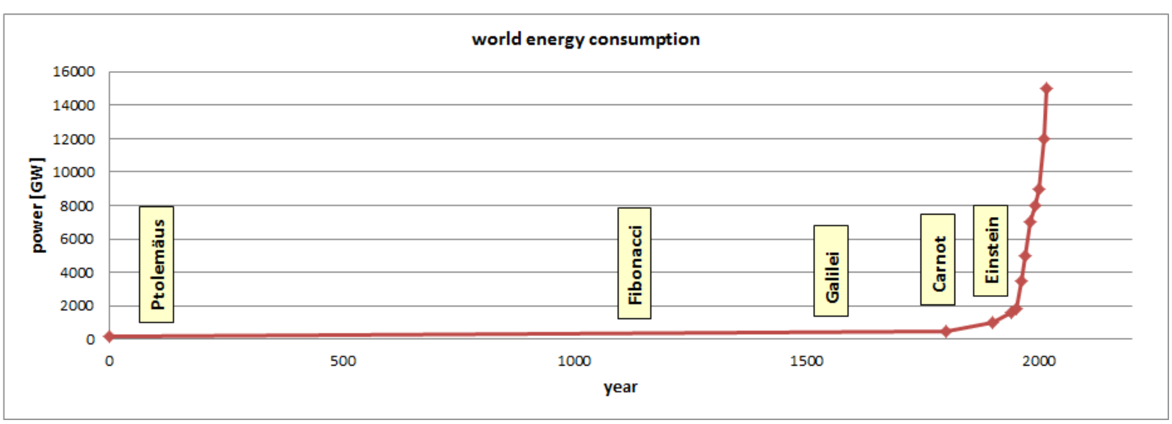

Figure 1: The world energy consumption shows a steep increase in the last 100 years. (Data before 1800 is estimated by scaling consumption in proportion to world population.)

TECHNICAL CHALLENGES OF THE LCLS-II CW X-RAY FEL*

T.O. Raubenheimer# for the LCLS-II Collaboration, SLAC, Menlo Park, CA 94025, USA

Abstract

The LCLS-II will be a CW X-ray FEL upgrade to the existing LCLS X-ray FEL at the SLAC National Accelerator Laboratory (SLAC). This paper will describe the overall layout and describe the technical challenges that the upgrade project faces.

INTRODUCTION

The LCLS-II is an X-ray Free-Electron Laser (FEL) which will upgrade the LCLS FEL at SLAC. The LCLS-II is designed to deliver photons between 200 eV and 5 keV at repetition rates as high as 1 MHz (929 kHz) using a superconducting RF linac (SCRF) linac while still providing pulses at short wavelengths and high X-ray pulse energy over the photon range of 1 to 25 keV using the existing 120 Hz copper RF (CuRF) LCLS linac.

The LCLS-II project is being constructed by a collaboration of US laboratories consisting of Argonne National Lab. (ANL), Cornell University (CU), Fermilab (FNAL), Jefferson Lab. (JLab), Lawrence Berkeley National Lab. (LBNL), and SLAC. In addition, the project has substantial assistance from the EuXFEL project as well as the other international laboratories focused on SCRF development and XFEL's.

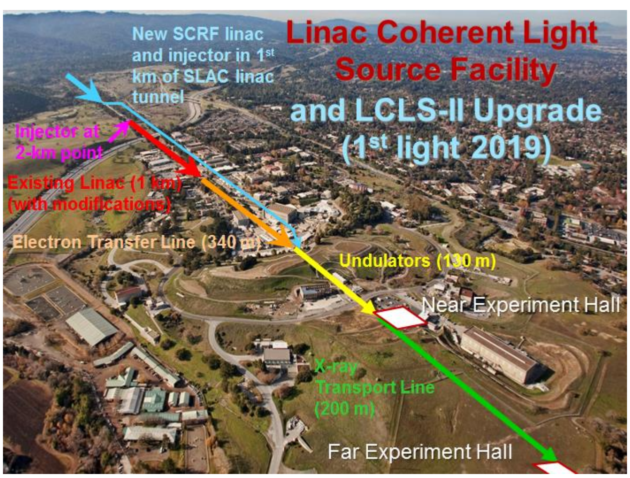

Figure 1: Schematic of the LCLS facility with the LCLS-II SCRF upgrade shown in blue.

The SCRF linac will be installed in the first third (1 km) of the SLAC linac tunnel and a bypass line will bring the high rate beam around the middle third of the existing linac and the existing LCLS CuRF linac as illustrated in Figure 1. Beams from both the CuRF and the SCRF linac will be transported to the existing LCLS Undulator Hall where, to cover the full photon-energy range, the existing LCLS fixed gap undulator will be removed and the facility will install two variable-strength (gap-tunable) undulators, one dedicated to the production of Soft X-rays (SXR Undulator) from 0.2 – 1.3 keV and one dedicated to production of Hard X-rays (HXR Undulator) from 1.0 – 25.0 keV. The facility will also allow the possibility of generating near transform-limited pulses using self-seeding as well as downstream monochromators.

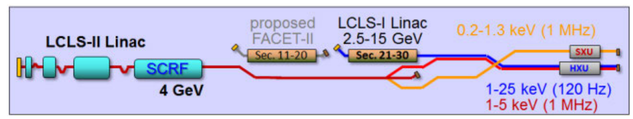

Figure 2: Schematic layout of the LCLS-II project.

As illustrated in Figure 2, the facility is constructed to either deliver high-rate beam from the SCRF linac to both the SXR and HXR undulators, or to deliver the high-rate beam to the SXR undulator and deliver beam from the existing copper CuRF linac at 120 Hz to the HXR undulator.

The LCLS-II will have the high peak brightness capability and flexibility of LCLS while also having the ability to provide MHz rate beams from a CW SCRF linac. The operating regimes are:

1. Soft X-ray photons from SASE and self-seeding between 0.2 and 1.3 keV at MHz rates, with an average X-ray power in excess of 20 Watts;
2. Hard X-ray photons from SASE between 1.0 and 5.0 keV at MHz rates with an average X-ray power in excess of 20 Watts and with the possibility of a future upgrade to self-seeding operation at energies between 1 and 4 keV;
3. Hard X-ray photons with SASE between 1 and 25 keV and self-seeding between 4 keV and 13 keV at 120 Hz, with mJ-class pulses and performance comparable to or exceeding that of LCLS.

Bunches from the SCRF linac will be directed to either the HXR or SXR with a high rate magnetic kicker that will allow independent control of the beam rate being delivered to either undulator. The SCRF linac will be intrinsically more stable than the LCLS linac and the energy stability of the electron beams is specified to be <0.01% rms which >10x more stable than that from the CuRF linac. The timing stability in the initial implementation of LCLS-II is specified to be better than 20 fs rms and is expected to be less than 10 fs rms. It is expected that the stability of the SCRF beams will be

STATUS OF THE PAL-XFEL CONSTRUCTION*

H. S. Kang, K.-W Kim, I. S. Ko, PAL, Pohang, Kyungbuk, Korea

Abstract

The PAL-XFEL, a 0.1-nm hard X-ray FEL facility consisting of a 10-GeV S-band linac, is being constructed in Pohang, South Korea. Its building construction was completed at the end of 2014. The installation of the 10-GeV linac started in January 2015 will be completed by the end of 2015 together with undulators and beam lines. The commissioning will get started in January 2016 aiming for the first lasing of hard X-ray FEL. We will report the current status, construction progress, and commissioning plans for the PAL XFEL project, including major subsystem preparations.

INTORDUCTION

The Pohang Accelerator Laboratory (PAL), Pohang, South Korea, is developing a 0.1 nm SASE based FEL, named PAL-XFEL, for high power, short pulse X-ray coherent photon sources. It is adjacent to the existing 3-rd generation light source, PLS-II, which was upgraded to a 3-GeV/400-mA/6-nm facility in 2010 (see Fig. 1). The PAL-XFEL project was started from 2011 with the five-year total budget of 400 MUSD, its building construction completed by the end of 2014, and successively the installation of linac, undulator, and beam line follows and will be completed by the end of 2015. The FEL commissioning will get started in early 2016.

The PAL-XFEL includes a 10-GeV S-band normal conducting linac, which is 700 m long and consists of a photocathode RF gun, 174 S-band accelerating structures with 50 klystron/modulators, one X-band RF system for linearization, and three bunch compressors (see Table 1). Beyond the 10-GeV linac, a 250-m long hard x-ray undulator hall follows. An experimental hall, which is 60-meters long and 16-meters wide, is located at the end of the facility. The total length of the building is 1,110 meters.

The PAL-XFEL linac is divided into four acceleration sections (L1, L2, L3, and L4), three bunch compressors (BC1, BC2, BC3), and a dogleg transport line to undulators as shown in Fig. 2 [1]. The L1 section consists of two RF units each of which is comprised with one klystron and two S-band structures, while L2 has 10, L3 has 4, and L4 has 27 RF units each of which has one klystron, four accelerating structures, and one energy doublers. A laser heater to mitigate micro-bunching instability is placed right after the injector, and an X-band cavity placed right before the BC1.

Among the available five undulator lines in the undulator halls, only two undulator lines will be prepared during the construction period of Year 2011-2105: a hard X-ray FEL line (HX1) and a soft X-ray FEL line (SX1) as shown in Fig. 2. HX1 covers the wavelength of λ=0.06 - 0.6 nm using a 4 to 10-GeV electron beam, and uses linear polarization, variable gap, out-vacuum undulators. SX1 covers the wavelength of λ = 1.0 - 4.5 nm using a 3.15-GeV electron beam.

Figure 1: Picture of construction site taken in January 2015.

Table 1: Parameters of PAL-XFEL

Linac	
FEL radiation wavelength	0.1 nm
Electron energy	10 GeV
Slice emittance	0.5 mm-mrad
Beam charge	0.2 nC
Peak current at undulator	3.0 kA
Pulse repetition rate	60 Hz
Electron source	Photo-cathode RF-gun
Linac structure	S-band normal conducting
Undulator	
Type	out-vacuum, variable gap
Length	5 m
Undulator period	2.6 cm
Undulator min. gap	8.3 mm
Vacuum chamber dimension	6.7 x 13.4 mm

To achieve the beam energy stability of below 0.02% and the arrival time jitter of 20fs for the PAL-XFEL, the linac RF parameters should be as stable as 0.03 degrees for the RF phase and 0.02% for the RF amplitude for S-band RF systems, and 0.1 degree / 0.04% for the X-band linearizer RF system. The pulse-to-pulse klystron RF stability is determined by the klystron beam voltage

COMMISSIONING AND OPERATION OF THE ARIEL ELECTRON LINAC AT TRIUMF*†

M.Marchetto, F. Ames, Z. Ang, R.A. Baartman, I. Bylinskii, Y.C. Chao, D. Dale, K. Fong, R. Iranmanesh, F. Jones, D. Kaltchev, J. Kavarskas, P. Kolb, S.R. Koscielniak, A. Koveshnikov, M. Laverty, R.E. TRIUMF, Vancouver, Canada

Abstract

ARIEL is the new TRIUMF facility for production of radioactive ion beams that will enable the delivery of three simultaneous RIB beams to the ISAC experimental stations. Two additional target stations will produce beams by using either a 50 kW proton or from 500 kW electrons via photo-fission. The electron beam driver is going to be a 50 MeV 10 mA CW superconducting electron linac. The first stage of the e-linac installation is completed and commissioning is underway. The paper will present the e-linac design characteristics, installation, commissioning strategy and current results.

INTRODUCTION

The ISAC (Isotope Separation and ACceleration) facility at TRIUMF produces rare isotope beams (RIB) using the ISOL (Isotope Separation On Lina) method. ISAC uses the TRIUMF cyclotron as driver to accelerate protons at 500 MeV up to 100 μA of current. This is presently the highest power (up to 50 kW of beam power) driver beam for an ISOL facility. It allows to produce the most intense RIB of certain species like ^{11}Li for which yield of $2.2 \cdot 10^4$ s^{-1} has been achieved. The current limitation of ISAC is that only a single RIB is available for fifteen experimental stations distributed in three areas: low, medium and high energy [1].

The ARIEL project [2] is meant to triple the RIB availability by delivering three simultaneous beams. The project consists of augmenting the present proton driver beam from the cyclotron and associated ISAC target stations with the addition of a new electron linac (e-linac) driver and a second proton beam driver from the cyclotron and associated two new target stations and low energy RIB delivery systems as illustrated in Fig. 1. The new e-linac is going to deliver 50 MeV electrons up to 10 mA for a maximum beam power on target of 0.5 MW.

A first stage of the ARIEL installation including a 30 MeV portion of the e-Linac and electron beamlines plus new ARIEL building and infrastructure is now nearing completion. The second phase encompassing the upgrade of the e-Linac to full energy, new target stations new proton beam line and low energy RIB beam lines is now under fund request adjudication.

* Funded under a contribution agreement with NRC (National Research Council Canada)
† Capital funding from CFI (Canada Foundation for Innovation)

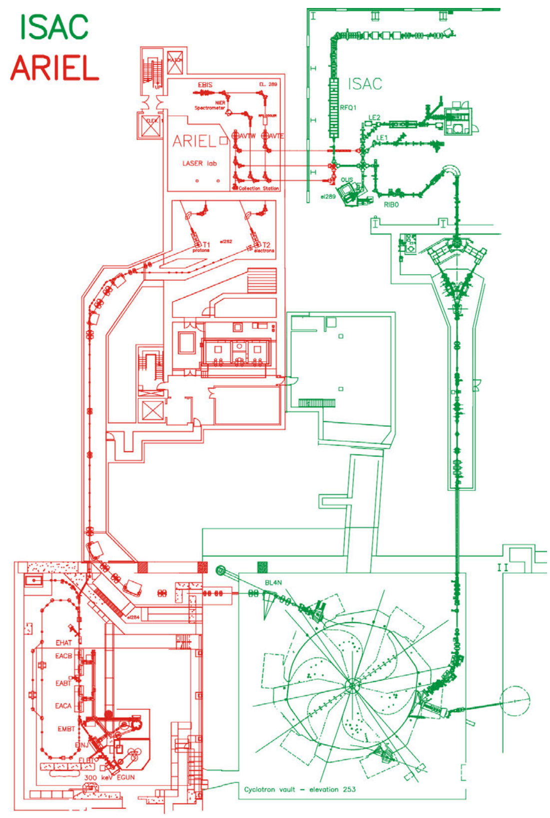

Figure 1: ISAC (green) and ARIEL (red) facilities at TRIUMF.

Accelerated electrons can be used to generate RIBs via the photo-fission process [3]. The electrons are slowed either in the target material itself or in an upstream converter material to generate bremsstrahlung radiation that produce fissions in the actinide target material. The fission production resonance is centered near an incident photon energy of 15 MeV such that the production yield saturates around an electron energy of 50 MeV. Figure 2 shows yield production comparing 10 μA, 500 MeV protons on a 25 g/cm^2 UCx target and 10 mA, 50 MeV electrons on a Hg converter and 15 g/cm^2 UCx target. The two production methods are complementary. Electrons produce more neutron rich isotopes with less isobaric contamination. A beam current of 10 mA at 50 MeV is required to produce the goal rates of 10^{13} fissions/sec in an actinide target of sufficient density. This sets the operating boundary envelope for the completed electron linac. The electron linac is housed in a pre-existing shielded former

COMPENSATING TUNE SPREAD INDUCED BY SPACE CHARGE IN BUNCHED BEAMS

Vladimir N. Litvinenko and Gang Wang
Department of Physics and Astronomy, Stony Brook University, Stony Brook, NY 11794, USA
Collider-Accelerator Department, Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

The effects of space charge play a significant role in modern-day accelerators, frequently constraining the beam parameters attainable in an accelerator or in an accelerator chain. They also can limit the luminosity of hadron colliders operating either at low energies or with sub-TeV high-brightness hadron beams. The latter is applied for strongly cooled proton and ion beams in eRHIC – the proposed future electron-ion collider at Brookhaven National Laboratory. Using an appropriate electron beam would compensate both the tune shift and the tune spread in the hadron beam in a coasting beam. But these methods cannot compensate space charge tune spread in a bunched hadron beam. In this paper we propose and evaluate a novel idea of using a co-propagating electron bunch with miss-matched longitudinal velocity to compensate the space charge induced tune-shift and tune spread.

INTRODUCTION

The paper is motivated by developing a high-energy high-luminosity electron-ion collider at Brookhaven National Laboratory called eRHIC [1] with a very short (5 cm RMS) and strongly cooled proton and ion beams with normalized transverse emittances of 0.2 mm·mrad.

Space-charge effects have been known in accelerator physics for a half of the century. There is an extensive literature [2-23] describing the effects of space charge. A nonlinear space-charge force induces an irreducible transverse tune-spread, i.e. the tune dependence on both the hadron's longitudinal position inside the bunch, z, and the amplitude of the transverse oscillations.

It is well known that space-charge effects fall as a high power of the beam's relativistic factor:

$$\Delta Q_{sc} \approx -\frac{Z^2 r_p}{A}\frac{N_o}{4\pi\beta_h^2\gamma^3\varepsilon}\frac{C}{\sqrt{2\pi}\sigma_z} \qquad (1)$$

where C is the ring's circumference, Z is the charge, and A is the atomic number of the hadron (e.g., an ion, for proton $Z=A=1$), $r_p = e^2/m_p c^2$ is the classical radius of the proton, $\gamma^2 = 1/(1-\beta^2)$ is the relativistic factor of hadron beam, N_o is number of hadrons in the bunch with an RMS bunch length of σ_z, and ε is the beam's transverse emittance.

Naturally, the maximum tune shift is experienced by the particles in the center of the beam, while the particles with large amplitude of oscillations experience a smaller value of the tune shift. The overall tune-spread is determined by its value for the center particles.

We are presenting here a strongly compressed version of our studies. Detailed description is published in full-size (24-page long) article [24].

For a round beam with equal emittances, the transverse tune shifts depend on particle's location inside the bunch as follows:

$$\delta Q_{x,y} = \delta Q_{sc}(z)\cdot f_{x,y};$$

$$\delta Q_{sc}(z) = -\frac{C}{4\pi\varepsilon}\frac{1}{\beta^2\gamma^3}\frac{Z^2 r_p}{A}\cdot\frac{N_o}{\sqrt{2\pi}\sigma_z}\cdot e^{-\frac{z^2}{2\sigma_z^2}}; \quad (2)$$

$$f_x = \left\langle \frac{2}{1+\sqrt{\beta_y/\beta_x}} \right\rangle; f_y = \left\langle \frac{2}{1+\sqrt{\beta_x/\beta_y}} \right\rangle.$$

Since the longitudinal motion of hadrons usually is very slow (e.g. $Q_s << Q_{x,y}$), the tune of the particle depends not only on the amplitudes (actions) of the transverse oscillations, but also on their longitudinal the location within the bunch.

One practically important feature of the space-charge effects is a very strong dependence on the relativistic factor, γ: $\delta Q_{sc} \propto \gamma^{-3}/(1-\gamma^{-2})$. While the power one of γ naturally comes from the increasing rigidity of the beam, the γ^{-2} comes from the effective cancelling of the forces from the electric and magnetic fields induced by the beam

$$\vec{F}_\perp = eZ\left(\vec{E}_\perp + \beta_o\left[\hat{z}\times\vec{B}_\perp\right]\right) \equiv \frac{eZ\cdot\vec{E}_\perp}{\gamma^2}. \qquad (3)$$

Several practical schemes were suggested for space-charge tune shift and tune spread compensation by colliding an electron beam with hadron beam (e.g., an electron lens), or employing an electron column induced in a residual gas [25-29]. The tune shift given by the colliding beam does not suffer from γ_h^{-2} cancelation: for round electron beam having RMS size of σ_e and the interaction length of L, the tune shift is given by the following:

$$\delta Q_{x,yel} = \frac{Z}{A\beta_h\gamma_h}\frac{r_p}{4\pi\sigma_e^2}\cdot\frac{I_e}{ec\beta_e}\left(1+\beta_e^2\right)\cdot L\left\langle\beta_{x,y}\right\rangle; (4)$$

where $\beta_e = v_e/c$ is the normalized velocity and of the electron beam.

BEAM AND SPIN DYNAMICS FOR STORAGE RING BASED EDM SEARCH*

A. Lehrach[#] on behalf of the JEDI Collaboration
Institut für Kernphysik, Forschungszentrum Jülich, 52425 Jülich, Germany
III. Physikalisches Institut B, RWTH Aachen University, 52074 Aachen, Germany
JARA-FAME (Forces and Matter Experiments)

Abstract

Full spin-tracking simulations of the entire experiment are absolutely crucial to explore the feasibility of the planned storage ring EDM (Electric Dipole Moment) experiments and to investigate systematic limitations. For a detailed study during the storage and build-up of the EDM signal, one needs to track a large sample of particles for billions of turns. In addition, benchmarking experiments have to be performed to check and to further improve the simulation tools.

INTRODUCTION

Permanent EDMs of fundamental particles violate both time invariance *T* and parity *P*. Assuming the *CPT* theorem this implies *CP* violation. The Standard Model (SM) predicts non-vanishing EDMs. Their magnitudes, however, are expected to be unobservably small with current experimental techniques. The discovery of a non-zero EDM would be a signal for new physics and could explain the matter-antimatter asymmetry observed in our Universe. Different approaches to measure EDMs of charged particles are pursued at Brookhaven National Laboratory (BNL) [1] and Forschungszentrum Jülich [2] with an ultimate goal to reach a sensitivity of 10^{-29} e·cm in a dedicated storage ring. The Jülich-based JEDI Collaboration (Jülich Electric Dipole moments Investigations) has been formed to exploit and demonstrate the feasibility of such a measurement and to perform the necessary R&D work towards the design of a dedicated storage ring [3]. As a first step R&D work at COSY is pursued. Subsequently, an EDM measurement of a charged particle will be performed at COSY with limited sensitivity. On a longer time scale, the design and construction of a dedicated storage ring will be carried out.

EXPERIMENTAL METHOD

The principle of every EDM measurement (e.g., neutral and charged particles, atoms, molecules) is the interaction of the particles' electric dipole moment with an electric field. In the center-of-mass system of a particle electric dipole moments $\vec{d}$ couple to the electric fields, whereas magnetic dipole moments $\vec{\mu}$ (MDM) couple to magnetic fields.

The spin precession in the presence of both electric and magnetic fields is given by:

$$\frac{d\vec{S}}{dt} = \vec{d} \times \vec{E}^* + \vec{\mu} \times \vec{B}^*. \qquad (1)$$

$\vec{E}^*$ and $\vec{B}^*$ denote the electric and magnetic fields in the rest frame of a particles. In case of moving particles in a circular accelerator or storage ring, the spin motion is covered by the Thomas-BMT equation and its extension for EDM:

$$\frac{d\vec{S}}{dt} = \vec{S} \times (\vec{\Omega}_{\mathrm{MDM}} + \vec{\Omega}_{\mathrm{EDM}}),$$

$$\vec{\Omega}_{\mathrm{MDM}} = \frac{q}{m}\left[G\vec{B} - \frac{\gamma G}{\gamma+1}\vec{\beta}(\vec{\beta}\cdot\vec{B}) - \left(G - \frac{1}{\gamma^2-1}\right)\frac{\vec{\beta}\times\vec{E}}{c}\right],$$

$$\vec{\Omega}_{\mathrm{EDM}} = \frac{\eta q}{2mc}\left[\vec{E} - \frac{\gamma}{\gamma+1}\vec{\beta}(\vec{\beta}\cdot\vec{E}) + c\vec{\beta}\times\vec{B}\right]. \qquad (2)$$

$\vec{S}$ in this equation denotes the spin vector in the particle rest frame in units of $\hbar$, t the time in the laboratory system. β and γ are the relativistic Lorentz factors, q and m the charge and the mass of the particle, respectively. $\vec{E}$ and $\vec{B}$ denote the electric and magnetic fields in the laboratory system. Two angular frequencies $\vec{\Omega}_{\mathrm{MDM}}$ and $\vec{\Omega}_{\mathrm{MDM}}$ are defined with respect to the momentum vector. The gyromagnetic anomaly $G=(g-2)/2$ with the Landé g-factor and η are dimensionless and related to the magnetic and electric dipole moments of the particle as follows:

$$\vec{\mu} = 2(G+1)\frac{q\hbar}{2m}\vec{S}, \vec{d} = \eta\frac{q\hbar}{2mc}\vec{S}. \qquad (3)$$

In a planar storage ring the spin precession in the horizontal plane is governed by the MDM. If an EDM exists, the spin vector will experience an additional torque. The resulting vertical spin component, proportional to the size of the EDM, will be measured by scattering the particles of the stored beam at an internal target and analyzing the azimuthal distribution of the scattered particles. A coherent buildup of the vertical polarization only takes place within the time the spins of the particle ensemble stays aligned. Since the spin tune is a function of the betatron and synchrotron amplitudes of the particles in the six-dimensional phase space, spin decoherence is caused by beam emittance and momentum

INTRA-BEAM SCATTERING EFFECTS IN ELENA*

J. Resta-López, J. R. Hunt, C. P. Welsch,
Cockcroft Institute and The University of Liverpool, UK

Abstract

Intra-Beam Scattering (IBS) is one of the main limiting processes for the performance of low energy ion storage rings, such as the Extra Low ENergy Antiproton ring (ELENA) that is being constructed at CERN. IBS effects limit the achievable equilibrium 6D beam phase space volume during the cooling process, as well as the stored beam intensity. In this contribution we analyse the IBS effects on the beam dynamics of the ELENA ring in detail. Numerical simulations using the codes BETACOOL and MAD-X have been performed to compute the beam life time and the equilibrium phase space parameters with electron cooling in the presence of IBS.

INTRODUCTION

ELENA [1] is a small synchrotron equipped with an electron cooler, which is currently being constructed at CERN to further decelerate antiprotons from the Antiproton Decelerator (AD) [2] from 5.3 MeV to 100 keV kinetic energy with a beam population of $\sim 10^7$ cooled antiprotons. Electron cooling will be used to counteract the emittance and the momentum spread blow-up caused by the deceleration process. This will increase the intensity of antiprotons delivered to the antihydrogen experiments at the AD by one to two orders of magnitude.

The ELENA cycle is schematically shown in Fig. 1. There are two cooling plateaus: the first cooling plateau lasts approximately 8 s at 35 MeV/c momentum, and the second one is applied for 2 s at 13.7 MeV/c. In both cases the cooling is applied to a coasting beam. A third cooling at 13.7 MeV/c will be applied to bunched beams prior to extraction.

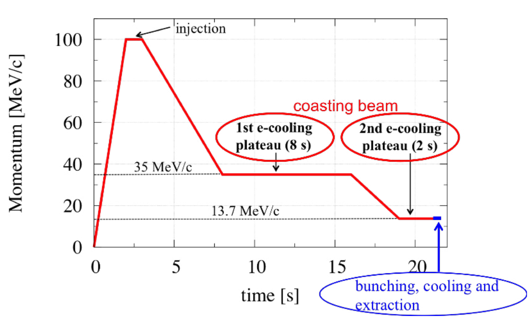

Figure 1: ELENA cycle.

A particular challenge for low energy ion storage rings, such as ELENA, is the question of achievable beam life time and stability. To address this question, we are investigating the long-term beam dynamics in ELENA considering different effects limiting the achievable phase space volume obtained under electron cooling. Among these effects, IBS and rest gas scattering are important sources of beam heating.

For ELENA with the nominal vacuum pressure $P = 3 \times 10^{-12}$ Torr, it has been estimated that the effect of rest gas scattering would be practically negligible with respect to IBS [3, 4]. Therefore, in this paper we focus mainly on the study of the IBS effects.

IBS can be defined as a beam heating effect produced by multiple small-angle Coulomb scatterings of charged particles within the accelerator beam itself. It causes an exchange of energy between the transverse and longitudinal degree of freedom, thus leading to the growth of the beam phase space dimensions. The theory of IBS is extensively described in the literature, e.g. [5–8], and many of these IBS models are implemented in the simulation code BETACOOL [9,10]. This code allows us to calculate the evolution of beam distributions in the transverse and longitudinal phase space under the action of cooling and different scattering effects, and has been successfully benchmarked against experimental data, see e.g. [11].

IBS becomes stronger when the phase space volume of the beam is reduced by cooling, thus limiting the achievable final emittances, which are determined by an equilibrium state between IBS and cooling. In the next sections we investigate the beam evolution for the two ELENA cooling plateaus in the presence of IBS.

BEAM EVOLUTION

Beam dynamics simulations are performed using the code BETACOOL [9, 10], using the nominal beam parameters and electron cooling parameters adopted from [1,12] and the ELENA ring lattice with working point $Q_x \simeq 2.3$, $Q_y \simeq 1.3$ [13] in MAD-X format [14].

The simulations are based on a Monte-Carlo method (model beam algorithm of BETACOOL), with the following conditions: 1000 modelled macroparticles; electron cooling considering a cylindrical uniform electron beam distribution with transverse temperature $k_B T_{e\perp} = 0.01$ eV and longitudinal temperature $k_B T_{e\parallel} = 0.001$ eV; the cooling friction force is computed using the Parkhomchuk's model for a magnetised electron distribution [15]; rest gas and IBS effects are also included. For the IBS, the Martini model [7] is used. More details can be found in [4].

First Cooling Plateau

Let us consider first initial Gaussian distributions with relatively large rms transverse emittances and momentum

PLANS FOR DEPLOYMENT OF HOLLOW ELECTRON LENSES AT THE LHC FOR ENHANCED BEAM COLLIMATION*

S. Redaelli, A. Bertarelli, R. Bruce, D. Perini, A. Rossi, B. Salvachua, CERN, Geneva, Switzerland
G. Stancari, A. Valishev, FNAL, Batavia, IL, USA

Abstract

Hollow electron lenses are considered as a possible means to improve the LHC beam collimation system, providing active control of halo diffusion rates and suppressing the population of transverse halos. After a very successful experience at the Tevatron, a conceptual design of a hollow e-lens optimized for the LHC was produced. Recent further studies have led to a mature preliminary technical design. In this paper, possible scenarios for the deployment of this technology at the LHC are elaborated in the context of the scheduled LHC long shutdowns until the full implementation of the HL-LHC upgrade in 2023. Possible setups of electron beam test stands at CERN and synergies with other relevant electron beam programmes are also discussed.

INTRODUCTION

The Large Hadron Collider (LHC) [1] at the European Organization for Nuclear Research (CERN) is designed to collide 7 TeV proton beams each of an unprecedented stored energy of 362 MJ. Its High-Luminosity (HL-LHC) upgrade project [2] aims at doubling the beam current while reducing by more than 30 % the beam emittance. Proton and ion beam halo cleaning in a superconducting accelerator poses obvious concerns. Even if the LHC Run I operation in 2010-2013 was successful, as stored energies up to 150 MJ were handled without accidental quenches [3,4], uncertainties apply to the extrapolations to higher energies. Various means to improve the LHC collimation performance are therefore under investigation.

Hollow electron beams can boost the performance of a collimation system through an active control of halo particles' diffusion speed and tail population. A low-energy, hollow electron beam that runs co-axially to the circulating hadron beam, over a few meters, can act on the halo particles at transverse amplitudes below that of the primary collimators, as shown in Fig. 1, without perturbing the beam core. The present multi-stage collimation system must remain in place to safely dispose of the halo particles that are resonantly driven unstable by the electron beam, possibly modulated in intensity, at smooth and tunable loss rates.

The cleaning performance of the LHC betatron collimation system has been the subject of a recent project review [5]. The Run I experience was acknowledged as very promising in view of operations at higher energy. The control of beam losses was recognized as a critical concern for future LHC upgrades. In this paper, the motivation for studying hollow e-lenses for the LHC are reviewed and the status of the present lens design for the LHC, derived from the conceptual design report in [6], is presented. In the conclusions, different plans for the possible timeline for deployment into the LHC are discussed.

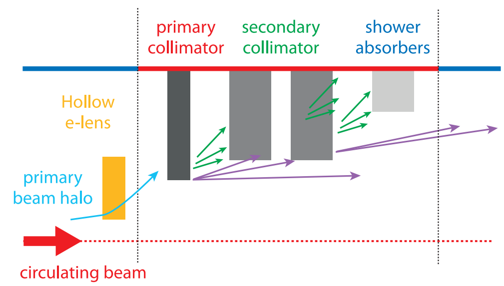

Figure 1: Scheme illustrating the conceptual integration of a hollow elens in the present collimation system hierarchy.

MOTIVATION

In 2012, the primary collimator gaps of the betatron cleaning system were as small as 2.1 mm, i.e. 4.3 betatron σ for an emittance of 3.5 μm. These settings in mm intentionally equaled the nominal settings at 7 TeV: experience could be gained operating the LHC with the tightest betatron cut. Figure 2 [7] shows the distributions of minimum lifetime recorded in high intensity fills in 2012 and compares it with what was recorded in 2011, when collimators were set at larger gaps of 5.7 σ. One can see that the beam lifetime was significantly reduced, with minimum lifetime values regularly dropping well below 1 h, whereas very few cases with lifetimes below 4 h were observed in 2011. Although extrapolations are not straightforward as the geometrical emittance will be smaller at 7 TeV, we consider the 2012 experience more representative, as also stressed in [5]. Note that beam tails at the LHC are over populated compared to nominal Gaussian distributions as they fill the entire primary collimator gaps [8]. Particularly critical are the squeeze, when the closed orbit varies in the time scale of seconds, and the preparation of squeezed beams for collisions ("adjust" mode) [7].

As an example, at 4 TeV a lifetime of 0.2 h led to peak loss rates up to 200 kW. The collimation system limit before risking plastic deformation of the jaw is 500 kW. For the 7 TeV HL-LHC, losses could reach 1 MW if similar lifetime drops were observed. So, even if upgraded cleaning performance [9] were sufficient to avoid quenches in regular operation, beam losses should be kept under control in order to avoid potential damage to the collimators.

FIRST CONSIDERATIONS ON BEAM OPTICS AND LATTICE DESIGN FOR THE FUTURE HADRON-HADRON COLLIDER FCC-HH

B. Dalena, A. Chance, J. Payet, CEA, IRFU, SACM, F-91191 Gif-Sur-Yvette
R. Alemany, B. Holzer and D. Schulte, CERN

Abstract

The main emphasis of the Future Circular Collider study is the design of a 100 TeV proton-proton collider in a new tunnel of about 100 km circumference. This paper presents the first optics design of the future hadron collider (FCC-hh). The basic layout follows a quasi-circular geometry "quasi racetrack" with 8 arcs and 8 straight sections, four of which designed as interaction points. Assuming 16 T dipole magnets, a first version of the ring geometry and magnet lattice is presented, including the optics of the foreseen high luminosity regions and of the other straight sections dedicated to the installation of injection/extraction lines, beam dump etc., and an arc structure with optimized dipole fill factor to reach the target center-of-mass energy of 100 TeV.

INTRODUCTION

Following the recommendations of the European Strategy Group, an integrated design study for accelerator projects in a global context, with emphasis on proton-proton and electron-positron high-energy frontier machines has been undertaken. The Future Circular Collider study FCC is investigating three possible storage rings options, housed in a tunnel of roughly 100 km circumference: an e^+e^- collider (FCC-ee), a hadron-hadron collider (FCC-hh), and an electron-hadron (FCC-eh) option. In order to reach the extreme high energy of the FCC-hh collider an *R&D* program on dipole magnets started with the aim of producing a field as high as 16 T. In the following we present the first considerations for the FCC-hh beam optics, taking into account the main machine parameters given in [1] as well as the geological and magnets constraints.

Layout of the FCC-hh Ring

Recently, the layout of the FCC-hh ring has converged to a "quasi racetrack" shape with 2 high luminosity interaction points (IPs) and 2 other with lower luminosity. The high luminosity operation IPs are located in Long Straight Sections LSS-PA-EXP and LSS-PG-EXP. Correspondingly, the lower luminosity IPs are located in LSS-PF[PH]-EXP (shown in Fig. 1). Two more LSS (LSS-PL[PB]-INJ) are dedicated to injection and two Extended Straight Section (ESS) are used for collimation and extraction [2]. The optics of the interaction regions are assumed to be anti-symmetric with respect to their centers. Moreover, the quadrupole is focusing at the beginning of all the long straight section and it is defocusing at the end. Four short arcs (SAR) and four long arcs (LAR) complete the layout, shown in grey and in black in Fig. 1, respectively. A first version of the optics can be found in [4]. The problem we want to handle is to compute the different parameters of the main quadrupoles and dipoles to fit with the layout and to match the arcs cells to the insertions regions. At the same time we want to explore the sensitivity of the overall lattice to these parameters.

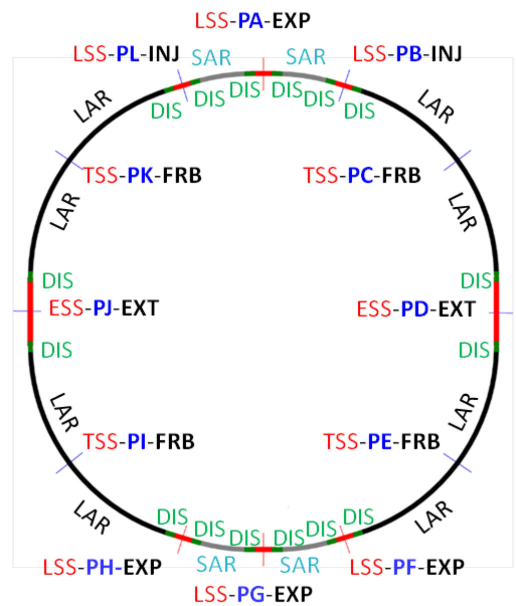

Figure 1: Layout of the FCC-hh ring.

FIRST ORDER OPTICS AND INTEGRATION WITH THE STRAIGHT SECTIONS

Some parameters of the optics are considered as fixed and other as advised. The parameters we have considered as fixed for the optimization of the baseline lattice are reported in Table 1.

Table 1: Input Parameters for the Optimization of the FCC-hh Arc Cells

Parameter	Value
center-of-mass energy	100 TeV
total ring length	100.12 km
LSS and ESS length	1.4 and 4.2 km
dipole magnetic length	14.3 m
dipole-dipole separation	1.36 m
magnet aperture radius	25 mm
sextupole magnetic length	0.5 m
quadrupole-sextupole separation	1.0 m
cell phase advance H/V	90 °

LATTICE AND ITS RELATED BEAM DYNAMICS ISSUES IN THE CEPC STORAGE RING*

H. Geng#, G. Xu, Y. Zhang, Q. Qin, S. Bai, Y. Wang, D. Wang, Y. Peng, T. Yue, Z. Duan
Institute of High Energy Physics, Beijing, China

Abstract

CEPC was proposed as an electron and positron collider ring with a circumference of 50-100km to study the Higgs boson. Since the proposal was made, the lattice design for CEPC has been carried out and a preliminary conceptual design report has been written at the end of 2014. In this paper, we will describe the philosophy and results of our lattice design. The procedure of dynamic aperture optimization will be shown. A specific issue for CEPC, the pretzel orbit, which has been found distorting the linear lattice for a considerable amount, will be examined. The ways that we are trying to correct the pretzel orbit effect and the results will be shown.

INTRODUCTION

On 4th July, CERN announced that both the ATLAS and CMS experiments had discovered a new Higgs-like boson[1-3]. Since then, many proposals had been made to build a new collider to study this new particle in detail. The linear and circular electron and positron are considered to be the most feasible one. At the end of the year 2012, the candidates of a Higgs factory, their pros and cons were compared in detail at the ICFA workshop[4,5]. It was also at this workshop, the concept of CEPC and SPPC was raised[6].

CEPC (Circular Electron and Positron Collider) was proposed as an electron and positron collider ring with a circumference of 50-100km to study the Higgs boson. The lattice design for CEPC has been carried out since the end of 2013. In about one year time, a preliminary conceptual design report has been written at the end of 2014. In this paper, we will describe the philosophy and results of our lattice design. A specific issue for CEPC, the pretzel orbit, which has been found distorting the linear lattice for a considerable amount, will be examined. The ways that we are trying to correct the pretzel orbit effect and the result will be shown. We will also discuss the saw tooth effect on the linear lattice and dynamic aperture of the ring.

LINEAR LATTICE

The layout of the ring is shown in Fig. 1. The circumference of the ring is 54km with 8 arcs and 8 straight sections. There are four IPs in the ring, IP1 and IP3 will be used for CEPC, while IP2 and IP4 will be used for SPPC. The RF sections are distributed in each straight section. At each straight section, the RF cavities will be symmetrically placed at the two ends of the section.

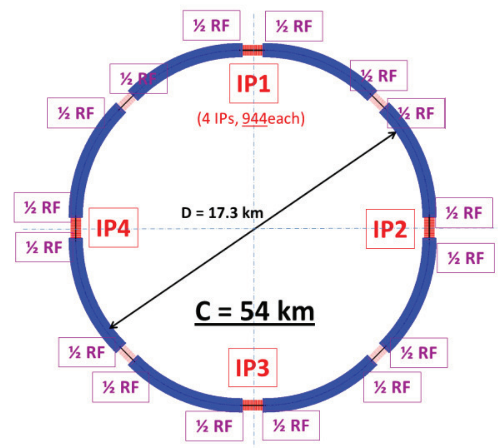

Figure 1: Layout of the CEPC storage ring.

The lattice for CEPC ring has been chosen to use the standard FODO cells with 60 degrees phase advances in both transverse planes. The FODO cell structure is chosen to have a maximum filling factor. The 60 degrees phase advance is chosen to have a relatively large beam emittance, so that a relatively longer beamstrahlung beam lifetime.

A standard FODO cell with 60 degrees phase advance is shown in Fig.2. The length of each bend is 19.6m, the length of each quadrupole is 2.0m. There is one sextupole, with a length of 0.4 m, next to each quadrupole for chromatic corrections. The distance between the sectupole and the adjacent magnet is 0.3 m, while the distance between each quadrupole and the adjacent bending magnet is 1.0 m. The total length of each cell is 47.2 m.

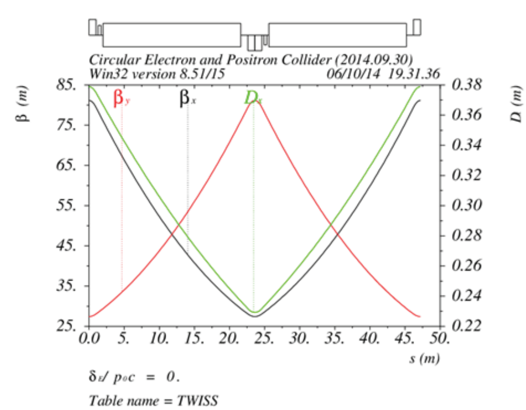

Figure 2: Beta functions and dispersion function of a standard FODO cell with 60/60 degrees phase advance in CEPC ring.

G. Ha, Department of Physics, POSTECH, Pohang, Gyeongbuk 790-784, Korea

Abstract

The commissioning of the upgraded AWA facility has been recently completed. The L-band electron gun has been fully commissioned and has been successfully operated with its Cesium Telluride photocathode at a gradient of 80 MV/m. Single bunches of up to 100 nC, and bunch trains of up to 32 bunches with a maximum total charge in the trains of 600 nC have been generated. Six pi-mode accelerating cavities bring the beam energy to 70 MeV. Initial measurements of the beam parameters have been performed. This intense beam has been used to drive wakefields in several structures, including a 26 GHz dielectric loaded power extractor, an 11.7 GHz photonic-band-gap metallic structure (PBG), and an 11.7 GHz metallic iris loaded power extractor. A second beamline provides electron bunches to probe the wakefields generated by the intense drive beam. A recent experiment has demonstrated acceleration (and deceleration) of the witness beam, in the so-called two-beam-accelerator scheme, with accelerating gradients over 40 MV/m.

AWA FACILITY

The main mission of the Argonne Wakefield Accelerator Facility (AWA) is to develop technology for future accelerator facilities. The AWA facility has been used to study and develop new types of accelerating structures based on electron beam driven wakefields. In order to carry out these studies, the facility employs a photocathode RF gun capable of generating electron beams with high bunch charges and short bunch lengths. This high intensity beam is used to excite wakefields in the structures under investigation, thus being referred to as the Drive Beam. There is a second electron beam that is used to probe the wakefields generated by the Drive Beam, and it is referred to as the Witness Beam.

The facility is also used to investigate the generation and propagation of high brightness electron beams, and to develop novel electron beam diagnostics. More recently, the facility has attracted interest from the broader scientific community, and collaborations on a wider range of topics have been fostered by the DOE-HEP stewardship initiative.

The AWA high intensity drive beam is generated by a photocathode RF gun, operating at 1.3 GHz. This one-and-a-half cell gun typically runs with 12 MW of input power, which generates an 80 MV/m electric field on its Cesium Telluride photocathode surface. Six seven-cell standing-wave π mode accelerating structures increase the energy of the beam produced by the drive gun from 8 MeV to 70 MeV.

The charge of the drive electron bunches can be easily varied from 0.1 to 100 nC, by varying the energy of the laser pulse incident on the photocathode. The high quantum efficiency of the Cs_2Te photocathode – routinely made in house and reaching over 15% QE – makes it possible to generate high charge bunches with laser pulses of relatively low energy. Thus, the laser pulse can be split into a sequence of laser pulses separated in time by one RF period, and this laser pulse train can be used to generate an electron bunch train.

The AWA laser system consists of a Spectra Physics Tsunami oscillator followed by a Spitfire regenerative amplifier and two Ti:Sapphire amplifiers (TSA 50). It produces 1.5 mJ pulses at 248 nm, with a pulse length of 2 to 8 ps FWHM and a repetition rate of up to 10 pps. A final KrF Excimer amplifier is optionally used to increase the energy per pulse to 15 mJ.

The Drive and the Witness beamlines propagate in opposite directions, and come to a common area designated beamline switchyard, where each beamline can branch out into a few beamlines and where experiments are conducted. The beamline switchyard allows wakefield experiments to be performed using either the collinear configuration, in which the drive and witness bunches travel along the same structure, or the two-beam-accelerator configuration, in which RF power is transferred from the drive beam decelerating structure to the witness beam accelerating structure, by means of a waveguide.

COMMISSIONING

The Drive beamline has been commissioned to an energy of 69 MeV, however, after a few weeks of operation, the RF window installed on one of the accelerating cavities showed signs of multipacting at full RF power. Mostly likely this was caused by some defect in the Titanium Nitride coating applied to the ceramic surface of the RF window. A couple of spare RF windows are in hand, and the defective window will be replaced soon. For now, operation of the Drive beamline has continued, but using a slightly reduced RF power level at the mentioned accelerating cavity. As a consequence, the

Abstract

Carbon Nano Tubes (CNT's) as field-emitters have been investigated for more than two decades and can produce relatively low emittance electron beams for a given cathode size. Unlike thermionic cathodes, CNT cathodes are able to produce electrons at room temperature and relatively low electric field (a few MV/m). In collaboration with FermiLab, we have recently tested CNT cathodes both with DC and RF fields. We observed a beam current close to 1A with a ~1cm^2 CNT cathode inside an L-band RF gun. Steady operation was obtained up to 650 mA and the measured current vs. surface field plot showed perfect agreement with the Fowler-Nordheim distribution.

INTRODUCTION

High-brightness electron beams are required for a number of applications, from advanced accelerators to 4th generation light sources. However, the current technology for producing such beams requires an expensive, complicated laser system to drive a photocathode in an RF gun. Furthermore, this technology is difficult to extend to very high duty cycles, as is necessary for superconducting accelerators.

Carbon nanotubes (CNTs) have been investigated [1] for more than two decades as field-emitters and can produce relatively low emittance electron beams [2] for a given cathode size, without a need of the laser. Unlike thermionic cathodes, CNT cathodes are able to produce electrons at room temperature and relatively low applied electric fields (a few MV/m). Nevertheless, they have historically either produced low currents and are prone to damage. Moreover, they are difficult to gate with conventional techniques and therefore are unable to produce short pulses.

RadiaBeam has recently tested CNT cathodes both with DC and RF fields. We have observed beam currents up to about 1A (averaged over macropulse) with a CNT cathode inside an S-band RF gun. Steady operation was observed up to 650 mA and the measured current versus surface field plot showed good agreement with the Fowler-Nordheim distribution [3, 4] (see Figure 1).

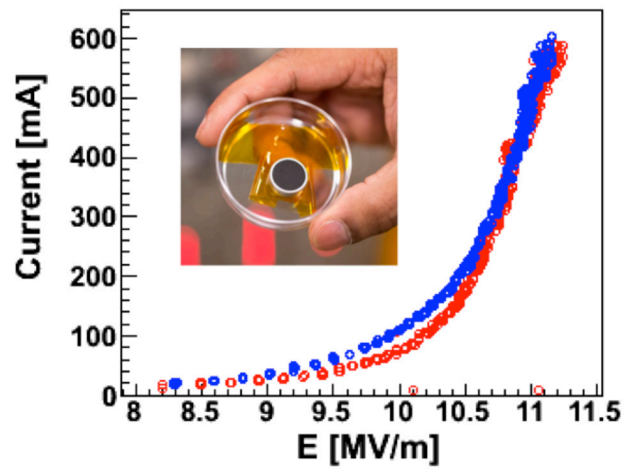

Figure 1: I-E curves. The measurements were performed with solenoids off (red) and solenoids on (blue).

DC TESTS AT RADIABEAM

Various CNT cathode samples were optimized and characterized at RadiaBeam. The cathode design as well as the whole high-voltage (HV) pulsed DC test setup were carried out according to the load-lock system for cathode insertion inside the 1.3 GHz RF gun already functioning at the HBESL facility. Eventually, two cathodes, a smaller and a bigger sample, were tested inside RF environment at Fermilab showing promising results for future applications.

Workflow

The workflow diagram that was followed for all operations is shown in Figure 2. The fabrication and cleaning of the cathode substrates were performed in-house. The CNT deposition processes, electrophoretic deposition (EPD) and chemical vapor deposition (CVD), were carried out at the California Nano-Systems Institute CNSI (UCLA) by our collaborators as well as Xintek (for the two samples used in FermiLab experiment). We then performed HV pulsed DC tests at RadiaBeam. The final RF testing took place at HBESL-FermiLab.

QUANTUM EFFICIENCY IMPROVEMENT OF POLARIZED ELECTRON SOURCE USING STRAIN COMPENSATED SUPER LATTICE PHOTOCATHODE

N. Yamamoto*, X.G. Jin, M. Yamamoto, KEK, Tsukuba, Japan
T. Miyauchi, A. Mano, M. Hosaka, Y. Takashima, Nagoya University, Aichi, Japan
Y. Takeda, Adavancd Science and Technology Foundation, Aichi, Japan

Abstract

In order to improve the quantum efficiency (QE) of the NEA-GaAs based polarized electron source. GaAs/GaAsP strain-compensated superlattice (SL) samples with thickness up to 720 nm were fabricated and a electron spin polarization (ESP) of 92 % and QE of 1.6 % were achieved at the pump laser energy of 1.59 eV for an 196nm-thickness sample. Furthermore, as results of the spin-resolved analyses, a slightly degradation of the crystalline quality for thicker thickness samples were indicated, however the effect for the beam performance was negligible up to the thickness of 720 nm. Then it is confirmed that the ESP is limited by the spin relaxation effect during electron transport in the semiconductor for the thicker thickness strain-compensated SLs.

INTRODUCTION

The GaAs-type semiconductor photocathode (PC) with a negative electron affinity (NEA) surface is used as a conventionally polarized electron source (PES). Recently, highly polarized electron beams produced by the NEA-GaAs PCs have been widely applied as a source for electron microscopes, such as a low energy electron microscopy (SPLEEM) [1] and a transmission electron microscopy (Spin-TEM) [2]. For applications in future high energy accelerators, generation of highly polarized and intense electron beam is an important technology. The International Linear Collider (ILC) requires a electron beam with > 80% electron spin polarization (ESP) and a bunch charge of 4.8 nC at the exit of the gun [3]. For the electron-ion collider at BNL, same polarization and an average current of 50 mA are required [4].

To answer these needs of future high energy accelerators, we have developed the polarized electron source for more than twenty years, and the GaAs/GaAsP strained superlattice (SL) PC was developed and demonstrated the ESP of around 90% and the quantum efficiency (QE) of 0.5% by using reflected type [5] and transmission type [6] PCs. As the NEA-type PCs have an intrinsic advantage for the beam emittance [7], high brightness beam with high ESP could be obtained [8]. However, the beam brightness is limited practically by the lack of QE value. Furthermore, to realize high intense beam required by future high energy accelerators, the QE improvement becomes important.

Recently, we have developed the strain-compensated SL PCs [9]. In the strained SL structure of conventional strained SL PCs, increasing SL layer thickness causes strain accumulation, resulting in the introduction of defects. Then the crystalline quality becomes worse and the SL thickness is limited. To overcome this problem, the use of a strain-compensated SL has been proposed. In such a structure, an opposing strain is introduced in the barrier layers to offset the strain in the quantum well layers so that no critical thickness limitation exists on the overall thickness of the SL structure and high crystalline quality is expected.

To demonstrate this effect of the strain-compensated SL PC, GaAs/GaAsP strain-compensated SL PCs have been developed and PC samples with the SL thickness from 96 to 720 nm were fabricated on the AlGaAsP buffer layer. Furthermore, in the measurements, the ESP of 92 % and the QE of 1.6 % were achieved by using the 192 nm sample [10].

In this paper, we reported the details of the GaAs/GaAsP strain-compensated SL PCs and discussed the thickness dependence of the crystalline parameter, such as an energy gap, a band width and a band split value between heavy hole and light hole bands at the valence-band maximum.

Table 1: Design Parameters of PC samples

Parameter	value
Band gap energy	1.54 eV
Cond. band Minimum width	29 meV
Heavy hole (HH) band Width	< 1 meV
Light hole (LH) band Width	29 meV
Band Split between HH and LH	75 meV

DESIGN OF STRAIN-COMPENSATED SL

GaAs/GaAsP strain-compensated SL samples were fabricated using a low-pressure metal organic vapor phase epitaxy (MOVPE) system with a vertical cold-wall quartz reactor. The 12-, 24-, 36-, 60- and 90-pair $GaAs/GaAs_{0.62}P_{0.38}$ strain-compensated SL layers were grown with on a 500-nm thick $Al_{0.1}Ga_{0.9}As_{0.81}P_{0.19}$ buffer layer and GaP substrate. The thickness of the each SL layer was 4 nm.

In the above configuration, the designed SL parameters could be calculated and shown in Table 1. The band gap energy is set to be 1.54 eV and lower than that of the buffer and substrate materials. Then the pump laser could be also irradiated the SL layers from the substrate side (transmission PC). The band width of heavy hole (HH) and Light hole (LH) minibands at the valence-band maximum are less than 1 meV and are 29 meV, respectively. The band split value between

12 GeV CEBAF TRANSVERSE EMITTANCE EVOLUTION*

T. Satogata, Y, Roblin, M. Tiefenback, and D. Turner
Jefferson Lab, Newport News, VA 23606, USA

Abstract

We present commissioning results of measurements of beam phase space evolution of the newly commissioned 12 GeV CEBAF accelerator. These measurements range over two orders of magnitude in energy for a non-equilibrium beam, from near the photocathode to the diamond bremsstrahlung target for the GlueX experiment. We also compare these measurements to modeled beam evolution, and emittance growth expectations driven by synchrotron radiation.

INTRODUCTION

The Jefferson Lab CEBAF (Continuous Electron Beam Accelerator Facility) has been upgraded to double the peak beam energy from 6 GeV to 12 GeV [1]. The 12 GeV upgrade included the addition of 10 new "C100" cryomodules (each supplying 4x the gradient of original CEBAF cryomodules), a central helium liquefier upgrade, upgraded recirculation arcs, and the addition of a new 12 GeV experimental hall, Hall D. Beam [2] and RF [3] commissioning activities have been ongoing since 2013, including optics tuning and characterization of beam parameters for the new facility.

The upgrade parameters of relevance are shown in Table 1. Though the requirements of emittance and energy spread appear to loosen between 6 GeV and 12 GeV, the 12 GeV parameters are dominated by synchrotron-radiation (SR) driven emittance growth in higher energy recirculation arcs as discussed in the remainder of this paper.

Table 1: CEBAF 6 GeV to 12 GeV Parameters

	6 GeV Operations	12 GeV Design
Emittance at max energy (geometric rms): horiz, vert	(1, 1) nm-rad	(10, 2) nm-rad
Energy spread at max energy (rms)	$2.5\text{x}10^{-5}$	Halls A-C: $5\text{x}10^{-4}$ Hall D: $5\text{x}10^{-3}$

CEBAF 12 GEV OPTICS

Theory

For a relativistic electron beam traversing a 180-degree multi-cell bend of bend radius ρ, the rms geometric (unnormalized) emittance growth and energy spread due to SR are given by [4,5]:

$$\Delta\epsilon \approx 2 \times 10^{-27} \left(\frac{\gamma^5}{\rho[\mathrm{m}]^{\,2}}\right) \langle\mathcal{H}\rangle \quad (1)$$

$$\sigma_{\mathrm{E}}^2 \approx 1.2 \times 10^{-33}\ \mathrm{GeV}^2 \left(\frac{\gamma^7}{\rho[m]^{\,2}}\right) \quad (2)$$

where the traditional curly-H function is used.

The CEBAF tunnel geometry and dipole packing fraction preclude mitigation of SR-driven emittance and energy spread growth by increasing the bend radius. However, SR-driven emittance growth can be controlled in CEBAF by reducing curly-H in high-γ arcs, similar to standard practice in current-generation synchrotron light sources. This approach was taken in the original CEBAF design to meet 6 GeV program goals [6] but was more aggressively pursued in the 12 GeV era.

Other smaller sources of emittance growth in a recirculating linac such as CEBAF are transverse nonlinearities and coupling of longitudinal RF nonlinearity to transverse motion. Magnet measurements performed during the 12 GeV upgrade indicated that transverse nonlinear fields are acceptably small. Longitudinal nonlinearities are carefully managed with bunch compression in an injection chicane with tunable M_{56}, and monitoring of linac RF cresting.

CEBAF Optics Modifications

The recirculating linac design of CEBAF requires that each separate arc is matched to each linac through separate vertical beam spreader and recombiner sections. The spreader sections also include a dispersion-free matching straight to enable arc-by-arc transverse beam envelope matching using wire scanners and matching quadrupole scans. Matching performed in these regions, and in injector matching sections, provided emittances shown in later sections of this paper.

The arcs were originally configured as achromatic, isochronous, imaging, and FODO transport systems to minimize beam size while transporting beams transparently from spreaders to recombiners. For 12 GeV commissioning, the optics were modified to double-bend achromat (DBA) cells in arcs 6-10, providing a 30-40% reduction in curly-H and projected emittance growth. An example of DBA optics for the highest energy arc (arc 10) is shown in Figure 1.

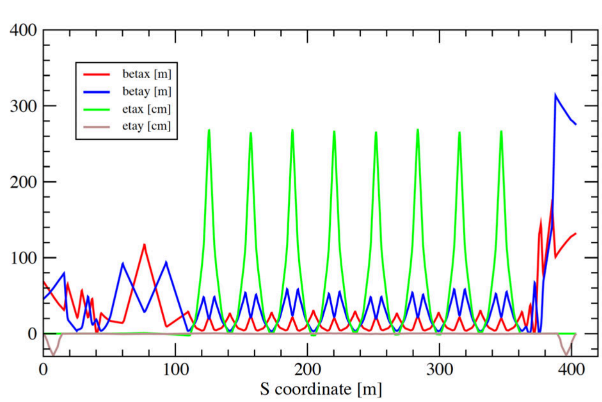

Figure 1: Arc 10 DBA optics for CEBAF SR-driven emittance growth reduction.

Abstract

The Advanced Photon Source and other existing storage ring light sources are contemplating replacing an operating storage ring with a multi-bend achromat lattice [1–6]. Existing light sources have large user communities who are greatly inconvenienced by extended shutdowns. Hence, there will be a premium placed on rapid commissioning of the new lattice. To better understand the possibilities, we undertook a survey of recent commissioning experiences at third-generation light sources. We present a summary of that survey here.

INTRODUCTION

APS, ESRF, and other existing synchrotron light source facilities are contemplating replacing their operating storage rings. Users and funding agencies insist that "dark time" is minimized. APS, for example, is targeting 12 months for removal, installation, and commissioning of a new multi-bend achromat replacement ring. Of this 12 month period, only three months are set aside for commissioning. Other facilities are facing similarly demanding constraints.

As a result, we need to determine how realistic such short commissioning intervals are. We also need to determine what factors are most likely to prevent successful commissioning in such a short time, and what steps can be taken to ensure rapid commissioning. Toward this end, we surveyed recently-commissioned light sources to understand their experience, where "recently-commissioned" was defined as within the last 10-15 years.

The survey questions were created at APS by M. Borland, L. Emery, J. Kerby, and A. Zholents. In the interest of brevity, the questions are paraphrased below. Responses directed at the survey questions were received from seven facilities, namely, ALBA, BESSY-II, DLS, PLS-II, SOLEIL, SSRF, and SPEAR3. Information was also provided by CLS. The co-authors of this paper responded to the survey for their respective facilities.

* Work supported in part by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

A potential source of confusion is that commissioning may mean different things to different people. As part of the survey, we suggested the following definition: commissioning begins when beam is first injected into the ring. It ends when the ring is capable of supporting meaningful beamline commissioning, which generally requires several conditions

1. The ring can routinely store a significant fraction of the planned initial operating current for periods of 8 hours or more.
2. The lattice and emittance are essentially at the initial design configuration and values.
3. The lifetime is workable.
4. The orbit and beam stability are workable.
5. One or more ready-to-use insertion devices are installed and available.

Respondents to the survey generally agreed with this definition. In some cases, delivery of beam to "friendly users" was considered the endpoint.

QUESTIONS AND ANSWERS

Question: How was the commissioning schedule developed? This question was intended to ask about the process for developing the commissioning schedule, but wasn't very clear and was misunderstood by several respondents. Common themes in answers included: Basing the schedule on experience at other facilities; e.g., PLS-II followed the SPEAR3 example of 6 month replacement followed by 6 month commissioning. In some cases, requirements were driven by the user community. Also mentioned were: extensive discussions among commissioning team, creation of a list of major milestones, and definition of a phased commissioning approach.

What was the scheduled duration of commissioning and how was it structured? Scheduled duration ranged between 4 and 12 months, with 6 months being the most common response (five). Other responses (one each) included 3 months, 9 months, and 12 months. Hence, in terms of planning, the 3 month commissioning period contemplated by APS is a factor of two shorter than typically contemplated.

RECENT DEVELOPMENTS ON SUPERCONDUCTING UNDULATORS AT ANKA

S. Casalbuoni*, A. Cecilia, S. Gerstl, N. Glamann, A. Grau, T. Holubek, C. Meuter, D. Saez de Jauregui, R. Voutta, ANKA, Karlsruhe Institute of Technology, Karlsruhe, Germany

Abstract

A research and development program on superconducting undulators (SCUs) is ongoing at the ANKA (ANgstrom source KArlsruhe) synchrotron at KIT. This technology is of interest to improve the spectral characteristics of the emitted photons in third and fourth generation light sources. We present here the results obtained within the ongoing collaboration with the industrial partner Babcock Noell GmbH (BNG) on NbTi conduction cooled planar devices. Investigations on the application of alternative superconductors as well as a summary of the achievements reached to precisely characterize the magnetic field properties of SCUs and to measure the beam heat load to a cold bore are also described.

INTRODUCTION

ANKA (ANgstrom source KArlsruhe) and Babcock Noell GmbH (BNG) are pursuing a research and development program aiming to developing superconducting undulators (SCUs). The collaboration is focused on conduction cooled SCUs, with coils wound using NbTi wire, and with a movable vacuum gap.

The first milestone reached within the collaboration is the successful development and operation of a full scale (1.5 m long coils) superconducting undulator with 100.5 full periods of 15 mm (SCU15) in the ANKA storage ring. The spectral characterization is being performed at the IMAGE beamline. This full scale device demonstrates for the first time that superconducting undulators generate, while in operation in a storage ring, a higher magnetic field with respect to permanent magnet undulators including cryogenic cooled ones manufactured using the best material (PrFeB) available nowadays.

As a next step the collaboration is developing SCU20, a device with 20 mm period length for the NANO beamline at ANKA. Undulator mockup coils with 20 mm period length and 300 mm long have been designed, manufactured and tested.

In the first part of this contribution we focus on the performance of the SCU15 during the first months of operation in the ANKA storage ring. In the second section, we report on the 300 mm long mockup with 20 mm period length and its calculated spectral performance inferred from the measured magnetic field. The final section describes the tools and instruments not commercially available, under development at ANKA and necessary for the development of SCUs. These instruments are needed for precise magnetic field measurements and for measuring and possibly understanding the beam heat load to a cold bore.

SCU15

ANKA and BNG designed, manufactured and tested a superconducting undulator with 15 mm period length and 100.5 full periods.

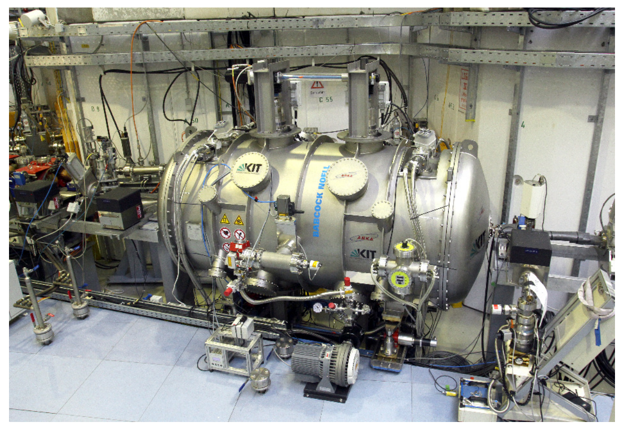

Figure 1: SCU15 installed in the ANKA storage ring.

The SCU15 has been assembled and successfully tested at BNG in summer 2014. The tests performed at BNG have been successfully repeated after transport at ANKA out of the ring. The test procedure included the cooldown, excitation, vacuum measurements and warm up of the system. Cooldown and warm up times of approximately 7 and 4 days, respectively, were achieved. The SCU15 was installed in the storage ring during the December 2014 shutdown and has been in operation with beam since the beginning of 2015 (see Fig.1).

One of the biggest challenges of the project was the development of the beam chamber (liner) which, together with the requirement for an UHV radiation-hard environment and low resistive losses [1], must open from 7 to 15 mm in operation at 10 K. Opening the vacuum gap to 15 mm is needed in the ANKA storage ring during electron beam injection and energy ramping. A movable gap might be appealing for other light sources during commissioning and/or operation, even if all other projects developing superconducting undulators in other facilities concentrate on fixed gap devices [2]. To be competitive with cryogenic permanent magnet undulators (CPMUs), high magnetic fields on axis are required; thus the coils of SCUs should be as close as possible to the beam axis, which can only be achieved by minimizing the distance between the liner and the coils. The SCU15 has

ELECTRON BEAM TRANSFER LINE FOR DEMONSTRATION OF LASER PLASMA BASED FREE ELECTRON LASER AMPLIFICATION

A. Loulergue, M. Labat, C. Evain, M. Khojoyan, W. Yang, M. E. Couprie
Synchrotron SOLEIL, Saint-Aubin, France, PhLAM/CERCLA, Villeneuve d'Ascq, France

Abstract

One direction towards compact Free Electron Lasers (FEL) is to replace the conventional linac by a laser plasma driven beam, provided proper electron beam manipulation to handle the value of the energy spread and of the divergence is done. Applying seeding techniques enables also to reduce the required undulator length. The rapidly developing LWFA are already able to generate synchrotron radiation. With an electron divergence of typically 1 mrad and an energy spread of the order of 1 %, an adequate beam manipulation through the transport to the undulator is needed for FEL amplification. A test experiment for the demonstration of FEL amplification with a LWFA is under preparation in the frame of the COXINEL ERC contract. A specific design of electron beam transfer line following different steps with strong focusing variable strength permanent magnet quadrupoles, an energy de-mixing chicane with conventional dipoles and second set of quadrupoles for further dedicated focusing in the undulator has been investigated. Beam transfer simulations and expected FEL power in the XUV will be presented.

INTRODUCTION

FEL based fourth generation light sources [1-2] presently offer femtosecond tunable radiation in the X–ray domain. Besides the preparation of additional FEL light sources for users around the world, new schemes are also under investigation. In view of the fifth generation light sources [3] several approaches are considered. One direction goes towards the improvement of FEL performance in a wide spectral range and with versatile properties and flexibility for users. Another one aims at reducing the size either by exploring further seeding and / or by replacing the conventional linear accelerator by a compact alternative one. Indeed, the rapidly developing Laser WakeField Accelerator (LWFA) [4-5] are now able to generate synchrotron radiation. With an electron divergence of typically 1 mrad and an energy spread of the order of few percent, an adequate beam manipulation through the transport to the undulator is required for FEL amplification. Different strategies have been proposed, such as a decompression chicane [6], a transverse gradient undulator [7] and lastly a dedicated chromatic matching [8-9]. The studies presented here take place in the context of the LUNEX5 (free electron Laser Using a New accelerator for the Exploitation of X-ray radiation of 5th generation) [10] collaboration, aiming at investigating the production of short, intense, coherent pulses in the 40-4 nm spectral range with a 400 MeV superconducting linac and a LWFA both connected to a single FEL for advanced seeding configurations. The LWFA has first to be qualified by the FEL application. In this frame, beam transfer simulation of longitudinal and transverse manipulation of a LWFA electron beam showing that theoretical amplification is possible, a test experiment is under preparation, with the support of different grants.

BEAM MANIPULATION

The electron different trajectories through the refocusing stage, according to their energy, span the trace phase space distribution adding the chromatic emittance. From phase space geometry, the initial divergence drastically increases this effect. The slice energy sorting of the chicane will then transfer the chromatic emittance into mismatch from slice to slice along the undulator and spoil the FEL process efficiency. Up to second order, a general quadrupole transfer using the usual TRANSPORT notation limited to the horizontal plane is given by:

$$\begin{pmatrix} x \\ xp \end{pmatrix} = \left[\begin{pmatrix} r_{11} & r_{12}=0 \\ r_{21} & r_{22} \end{pmatrix} + \delta \begin{pmatrix} r_{116} & r_{126} \\ r_{216} & r_{226}=0 \end{pmatrix} \right] \begin{pmatrix} x_0 \\ xp_0 \end{pmatrix}$$

with (x xp) the position-angle coordinates and δ the energy deviation. In addition, cancelling the chromatic term r_{226}, the 3 rms associated image momenta according to their relative energy deviation are approximated by:

$$\sigma_x^2(\delta) = r_{11}^2 \sigma_0^2 + r_{126}^2 \sigma_{xp0}^2 \delta^2$$
$$\sigma_{xxp}(\delta) = r_{126} \sigma_{xp0} \delta / r_{11}$$
$$\sigma_{xp}^2(\delta) = \sigma_{xp0}^2 / r_{11}^2$$

with the $(\sigma_{x0}\ \sigma_{xp0})$ initial rms beam size and divergence. The energy slice geometrical emittance are given by $\epsilon_0 = \sigma_{x0}\ \sigma_{xp0}$ and the total geometrical emittance integrated over the energy deviation, is given by:

$$\epsilon_t^2 = \epsilon_0^2 + \epsilon_{chrom}^2 = \epsilon_0^2 + \left(\frac{r_{126}}{r_{11}} \sigma_{xp0}^2 \sigma_\delta\right)^2$$

The second term of the right hand side is the chromatic emittance that is drastically enhanced by the initial divergence to the square.

SIMULATIONS OF ELECTRON-PROTON BEAM INTERACTION BEFORE PLASMA IN THE AWAKE EXPERIMENT

U. Dorda, R. Assmann, J. Grebenyuk, DESY, Hamburg, Germany
C. Bracco, A. Petrenko, J. Schmidt, CERN, Geneva, Switzerland

Abstract

The on-axis injection of electron bunches in the proton-driven plasma wake at the AWAKE experiment at CERN implies co-propagation of a low-energy electron beam with the long high-energy proton beam in a common beam pipe over several meters upstream of the plasma chamber. The possible effects of the proton-induced wakefields on the electron bunch phase space in the common beam pipe region may have crucial implications for subsequent electron trapping and acceleration in plasma. We present the PIC simulations with CST Studio as well as direct-beam-beam interaction simulations of the tentative common beam pipe setup and the two beam co-propagating in it.

INTRODUCTION

The AWAKE experiment is a proof-of-principle experiment that aims to utilize the 400 GeV proton beam from the SPS to drive a plasma-wake allowing to accelerate electrons from a few MeV to the GeV scale within a single plasma stage of a few meter length [1]. For this purpose a low-energy electron beam is bent onto the high-energy proton beam trajectory a few meters upstream of the plasma chamber (Figure 1) [2]. This paper reports on studies performed on the effect (wake fields and direct beam-beam interaction) of the proton beam on the electron beam over these few meters of common vacuum chamber. In this section, the common beam pipe is circular with a default diameter of d = 60 mm up to 1 m before the start of the plasma chamber where it's diameter is reduced to d = 40 mm (Assumed thickness: 2 mm, conductivity: 7.7E6 S/m). This common section is equipped with several quadrupoles allowing to focus the electron beam at the plasma entrance, corrector magnets and beam diagnostic devices [3]. In the foreseen

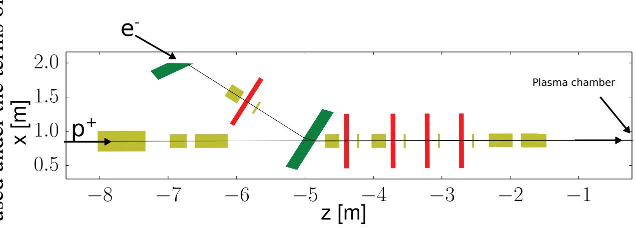

Figure 1: Sketch of the layout upstream of the plasma chamber where the high energy proton and low energy electron beam co-propagate (green: dipoles, red: quadrupoles, yellow: orbit correctors & beam diagnostic devices).

default operation scenario, the arrival of the two beams is adjusted to position the short electron beam slightly behind the center of the significantly longer proton bunch. To be on the safe side and to anticipate experimental modifications, a centered electron beam sampling the maximal direct beam-beam force was assumed. Table 1 and Figure 2 list/illustrate the proton and electron beam parameters and optics in this common section.

Table 1: Beam Parameters of the Proton and Electron Beam

Parameter	Protons	Electrons
Energy [GeV]	400	0.016
Nr of particles	3E11	1.2E9
$\epsilon_{n,xy}$ [π mm mrad]	3.5	2.0
Bunch length [1σ, mm]	120	1.2
Momentum spread [10^{-3}]	2.0	5.0
β_x [m]	7.0	1.02
β_y [m]	7.0	5.39

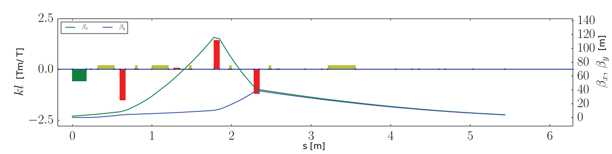

Figure 2: Electron beam optics along the common beam section. The $\beta_{x,y}$ of the proton beam is almost constant at $\approx 7m$.

WAKE FIELD STUDIES WITH CST

The "Particle In Cell" (PIC) - solver of "CST Particle Studio 2014" was used to simulate the interaction between the two beams including wake-fields taking a mock-up geometry of the vacuum chamber into account. The 6D-initial particle distributions (25000 macro-particles electrons, 50000 macro-particle protons) were externally created and imported using the "CST-particle interfaces" feature. In order to reduce the computational effort, the proton beam was cut right after the electron beam. As the two beams are launched at separate locations, the perturbations due to the non-self-consistent initialization are no issue. The fields of the magnets (dipoles and quadrupoles) were imported into CST based on ideal, hard edge models. Due to the large size of the model, special attention had to be put on the choice of mesh-parameters, where a valid compromise between computational feasibility and physical correctness had to be found. While a suitable trade-off could be found to represent the longer distance effects of the wake-fields including the interaction with the vacuum chamber, a separate code based on analytical field-formulas had to be written to study the direct beam-beam interaction at low amplitudes (see next

SIMULATIONS STUDY FOR SELF-MODULATION EXPERIMENT AT PITZ

G. Pathak*, F. Grüner, A. Martinez de la Ossa, Universität Hamburg, 22761 Hamburg, Germany
T. Mehrling, J. Osterhoff, DESY, Hamburg 22607, Germany
M. Groß, F. Stephan, DESY, Zeuthen 15738, Germany
C. Benedetti, C. B. Schroeder, LBNL, Berkeley, CA 94720, USA

Abstract

Self-modulation (SM) of proton beams in plasma has recently gained interest in context with the PWFA experiment proposed by the AWAKE collaboration at CERN. Instrumental for that experiment is the SM of a proton beam to generate bunchlets for resonant wave excitation and efficient acceleration. A fundamental understanding of the underlying physics is vital, and hence an independent experiment has been set up at the beamline of the Photo Injector Test facility at DESY, Zeuthen site (PITZ), to study the SM of electron beams in a plasma.

In this contribution we present simulation results of SM experiments at PITZ using the particle-in-cell code HiPACE. The simulation study is crucial to optimize the beam and plasma parameters for the experiment. Of particular interest is the energy modulation imprinted onto the beam by means of the generated wakefields in the plasma. With the support of simulations, the observation of this information in the experiment can be used to deduce key properties of the accelerating electric fields, such as their magnitude and their phase velocity, both of significant importance for the design of self-modulated plasma-based acceleration experiments.

INTRODUCTION

Plasma wakefield acceleration was proposed as an alternative of conventional acceleration methods due to the large accelerating fields [1]. Accelerating wakefields in excess of 50 GeV/m have been achieved in $85cm$ long plasma using a 42 GeV drive electron beam [2]. However, different stages would be required for further acceleration of electrons owing to limited drive beam energy.

Recently, it has been proposed to use short and high energetic proton beams to drive a plasma wave so as to accelerate electron beams to the TeV-energy scale in a single plasma stage [3], rather than in multiple stages, as required with electron drivers. In order to excite large amplitude plasma waves in such a scheme, the driver bunch length (L^{beam}) needs to be shorter than the plasma wavelength (λ_p). However, available proton bunches from the Super Proton Synchrotron at CERN are very long (~12 cm) in comparison with the foreseen plasma wavelength for this experiment (λ_p ~1 mm). The AWAKE experiment thus relies on the fact that a long proton bunch ($L^{beam} > \lambda_p$) is self-modulated during its propagation in the plasma, thereby being split into a train of ultra-short sub-bunches with a length on the order of λ_p, so that the plasma wave is resonantly excited [4]. The self-modulation is a result of transverse two-stream instability, occurring through the coupling of the transverse wakefield with the beam radius evolution. When a long bunch with the beam length $L^{beam} > \lambda_p$ and transverse size σ_r enters the plasma, it is radially modulated by the periodic focusing forces, and the beam density modulation ($n_b \propto \sigma_r^2$) provides feedback for the instability to grow. Consequently, this instability self modulates the long beam into ultra short bunches at the plasma wavelength scale, which resonantly drive the plasma wake. The instability is convective and grows both along the bunch (ζ) and along the plasma (z) as illustrated by the number of e-folding growths for a flat-top bunch, [4]:

$$N_{e-folding} \cong \frac{3^{3/2}}{4}\left(\nu\frac{n_{b0}m_e}{n_p M_b \gamma}\right)^{1/3}(k_p\zeta)^{1/3}(k_p z)^{2/3} \quad (1)$$

Where ω_p is the plasma frequency, $k_p = c/\omega_p$, $\nu \approx 1 - \frac{(k_p\sigma_{r0})^2}{6}$, σ_{r0} the initial bunch radius, n_{b0} the initial beam density, M_b the bunch particle mass.

The study of the self-modulation of electron beams from the Photo Injector Test Facility at DESY, Zeuthen site (PITZ) offers a unique possibility to demonstrate and optimize the self-modulation instability experimentally and to gain insight into the underlying physics of the involved processes [5]. Self-modulation in PITZ electron beam has been already shown with OSIRIS simulations [6]. The particular interest of this experiment is to see a significant modulation of the beam energy spectrum, which will be resolvable in the experiment. In the following section, results from numerical studies, aiming at the optimization of the PITZ beam and plasma parameters, are presented. Simulations on the self-modulation instability are performed using the particle-in-cell code HiPACE [7]. This code provides the possibility to import beams from the particle tracking code ASTRA [8].

SIMULATION PARAMETERS

A particle tracking code, ASTRA is used to track the beam from the RF photo-electron gun to the entrance of the plasma, $6.2m$ downstream [8]. The average energy of the bunch is $E = 22MeV$ with energy spread of $\Delta E/E = 0.1\%$. The simulation uses a moving window ($8.4mm \times 1.7mm \times 1.7mm$) that propagates at the speed of light (c), with resolution of $k_p\Delta z = 0.025$ and $k_p\Delta y = k_p\Delta x = 0.04$. Table 1 shows the beam and plasma parameters for different conditions that are used to study the self-modulations.

LASER PROPAGATION EFFECTS DURING PHOTOIONIZATION OF METER SCALE RUBIDIUM VAPOR SOURCE

J. Moody, F. Batsch, A. Joulaei, E. Öz, P. Muggli, Max Planck Institute for Physics, Munich, Germany
N. Berti, J. Kasparian, University of Geneva, Switzerland

Abstract

The baseline AWAKE experiment requires a 10 meter long plasma source with a density of 10^{15} cm^{-3} and a density uniformity of 0.2%. To produce this plasma, a temperature stabilized rubidium vapor source is photoionized by a terawatt peak power laser pulse. In this paper we describe the laser pulse evolution within the plasma source including the dispersive, diffractive, and photoionization effects on the laser pulse. These calculations will be experimentally investigated in a meter long heat pipe oven using scaled laser parameters.

INTRODUCTION

The AWAKE project is a proof of principle proton driven plasma wakefield electron accelerator experiment [1, 2], that scheduled to begin initial experiments at CERN in 2016. The experiment employs a 400 GeV proton beam from the Super Proton Synchrotron (SPS) that propagates through a 10 meter plasma to produce GeV/m wakefields via the mechanism of the self modulation instability [3–5]. The second phase of the AWAKE experiment, scheduled to begin in 2017, relies on SMI to accelerate a 15 MeV electron beam from a photoinjector and single RF booster. The electrons are injected on the axis of the proton beam 100 plasma periods behind the laser pulse that ionizes the rubidium and creates the plasma. For controlled injection of the electron beam to occur, the plasma wakefields must have a stable, well defined phase up to the longitudinal injection position, placing a requirement of 0.2% density uniformity on the plasma source.

The plasma is produced from a 10^{15}cm^{-3} rubidium vapor source. A 10 meter heat exchanger cell is being developed and built by Grant Instruments Ltd. [6]. The density of the rubidium vapor in the cell is well defined by the temperature of the device. A detailed description of the device, including density vs. temperature curves is given by E. Öz and P. Muggli [7]. The requirement of < 0.2% density stability over the device in the baseline design of the experiment is met by achieving the same level of temperature stability over the 10 meter device. Lastly, to create the plasma, the rubidium is photoionized by a 4 TW peak power laser pulse via field ionization described by Keldysh [8]. Because we are operating in a low Keldysh parameter regime in which the intensity is high and frequency low, the ionization time is much less than the laser pulse length and occurs at a laser threshold intensity of 2 TW/cm^2.

Rubidium was chosen over other Alkali metals due to it's low ionization energy of 4.2 eV and the relative technical simplicity of its use including producing the baseline vapor density at 200 degrees C and it being a solid at room temperature. The laser used to ionize the rubidium vapor was purchased from Amplitude Technologies [9]. This laser is uses and Erbium doped fiber oscillator with a central wavelength of 780 nm with a bandwidth of approximately 10 nm. The laser system is a chirped pulse amplification system that stretches the ~100 fs pulse to ~ 100 ps, amplifies it to a maximum value of 600 mJ, then recompresses the laser pulse so that it has a peak power of 4 TW at a maximum energy of 450 mJ per pulse.

To understand the laser pulse propagation we are conducting rubidium ionization experiments on a 1 m heat pipe oven and the laser to be used for the CERN experiment at Max Planck Institute for Physics (MPP). A comparative table of parameters for both the AWAKE experiment and the MPP scaled investigation are shown in Table 1.

Table 1: AWAKE and MPP Phase B Parameters

Parameter	AWAKE	MPP Phase B
Laser Pulse Energy	450 mJ	100 mJ
Rayleigh Range	5 m	35 cm
Rubidium Vapor Length	10 m	1 m

This paper describes the laser pulse propagation studies currently ongoing at MPP investigating the evolution of the pulse as it ionizes meter length scale Rubidium vapor.

DESCRIPTION OF MPP EXPERIMENT

The experiment at MPP is broken into two phases. Phase A is the study of the quasi-linear effects of the laser passing through cm scale rubidium at the baseline density of 10^{15}cm^{-3}. This length scale was chosen because the variation in the index of refraction across the bandwidth of the laser due to anomalous dispersion, $\delta n/n$ is on the order of 10^{-4}. With a wave number on the order of 10^6 m^{-1}, we expect order unit phase change across the bandwidth of the laser pulse at cm scales.

For this experiment we used a small rubidium cell with a length of 3.5 cm. This cell was heated to 200 degrees C and the density was measured using the "hook method" technique [10, 11], which employs a white light Mach-Zehnder interferometer and high resolution spectrometer. The separation of the first large distortions of the interference fringes near the D2 resonance line for rubidium acts as a diagnostic for the vapor density. An image of the cell can be seen on the left in Fig. 1.

Upon verification of the rubidium vapor density for a given temperature, 400 μJ laser pulses were propagated through

THE AWAKE, PROTON-DRIVEN PLASMA WAKEFIELD EXPERIMENT AT CERN

P. Muggli*, Max Planck Institute for Physics, Munich, Germany
for the AWAKE Collaboration

Abstract

We briefly describe the current status of the AWAKE experiment in terms of physics and experimental program.

INTRODUCTION

Plasma wakefield acceleration has made remarkable progress since it was proposed [1] and plasma wakefields were first observed [2]. In particular, very large accelerating gradient ($\sim 50\,GeV/m$) and energy gain ($\sim 42\,GeV$) where measured in a meter-scale plasma [3]. A witness electron bunch was accelerated with a narrow energy spread ($\sim$ %) and a significant energy transfer efficiency ($\sim$ 30%) [4].

The AWAKE experiment at CERN [5] aims at exploring the possibility of using a proton (p^+) bunch to drive large amplitude wakefields ($\sim\ GV/m$) in plasmas. Proton bunches are interesting because they carry large amounts for energy (kilojoules). It was shown in numerical simulations that a single LHC p^+ bunch could potentially be used to accelerate electrons to TeV scale energies, in a single plasma stage with GeV/m accelerating gradient [6].

The large momentum p^+ bunches ($\sim 400\,GeV/c$ at SPS and $\sim 7\,TeV/c$ at LHC) are long ($\sigma_z \cong 10-12\,cm$). In order to reach $\sim\ GV/m$ accelerating fields, the plasma density n_{e0} needs to be in the $10^{14}-10^{15}\,cm^{-3}$ range since their amplitude is on the order of $E_{WB} = m_e c\omega_{pe}/e$. Here $\omega_{pe} = \left(n_{e0}e^2/\epsilon_0 m_e\right)^{1/2}$ is the plasma electron (angular) frequency. At these electron plasma densities the plasma wave or wakefields wavelength ($\lambda_{pe} = 2\pi c/\omega_{pe}$) is on the order of $1\,mm$. A relativistic charged particle bunch traveling in a plasma with wakefields period much shorter than its length ($\lambda_{pe} \ll \sigma_z$) is subject to the self-modulation instability (SMI) [7].

The SMI is a transverse instability that arises from the interplay between transverse components of the plasma wakefields locally increasing (decreasing) the bunch density through focusing (defocusing), and the wakefields being driven stronger (weaker) by regions of larger (smaller) bunch density. The modulation period is $\cong \lambda_{pe}$ and the modulated bunch resonantly drives the plasma wakefields. In order to avoid another transverse instability, the current filamentation instability (CFI) [8], the bunch must be focused near the entrance of the plasma to a transverse size σ_r smaller than the cold plasma collisionless skin depth c/ω_{pe}: $\sigma_r \leq 168\,\mu m$ for n_{e0} up to $10^{15}\,cm^{-3}$.

The occurrence of the SMI can be detected by characterizing the structure of the p^+ when exiting the plasma, the corresponding plasma density modulation and the wakefields this density modulation supports through the acceleration of externally injected electrons.

Experiments will start in late 2016 with the first goal of observing and characterizing the SMI of the p^+ bunch, including seeding of the SMI, in a single, $10\,m$-long plasma. Experiments scheduled for mid 2017 will focus on the external injection of electrons into the wakefields. Acceleration from $\sim 20\,MeV$ to over $1\,GeV$ is expected. Later experiments will use two plasmas, the first one for seeding and SMI development, and the second one for acceleration. The second one can be very long thanks to the high energy of the p^+ bunch that is thus able to drive wakefields over many tens of meters [9].

PROTON BUNCH

In the AWAKE experiment, the $\sim 400\,GeV/c$, $\sigma_z \cong 12\,cm$ SPS bunch with $1-3\times10^{11}$ p^+ is focused to $\sigma_r \cong 200\,\mu m$ near the entrance of the plasma. The p^+ bunch has a low normalized emittance, $3.5\,mm-mrad$ and a small relative momentum spread of 0.35%. Its focused beta function is $\cong 5\,m$, half the plasma length.

PLASMA SOURCE

The plasma source consists of a rubidium (Rb) vapor ionized by a short ($\cong 100\,fs$) and intense laser pulse [10]. Rubidium was chosen because it has a low ionization potential ($4.177\,eV$) for its first electron and a relatively large one for the second ($27.28\,eV$). Since the appearance intensity for ionizations scales with the fourth power of the laser intensity [11], only about $1.3\times10^{11}\,W/cm^2$ are necessary to free the first electron, while a 1984 times larger intensity is required to ionize the second one. Note that in this case the p^+ beam impact or field ionization fraction is very small. Rubidium also has a relatively large ion mass, which makes the experiment less sensitive to ion motion [12]. This is important since the useful wakefields span many plasma wavelengths behind the ionizing laser pulse and the start of the wakefields. The Rb vapor with density $n_0 = 10^{14}-10^{15}\,cm^{-3}$ is created in an oil heat-exchanger and can accommodate either a very uniform constant density that may be necessary for external injection [13] or a (linear) density gradient. The density is reached at oil and vapor temperatures between 150 and 200^o C. The vapor column is $40\,mm$ in diameter and $\cong 10\,m$-long. The vapor density is measured using the hook method [14].

Since field-ionization is a threshold process, the plasma density and its uniformity are equal to those of the Rb vapor. At the densities considered here, the plasma radius needs to be everywhere at least one millimeter ($\geq c/\omega_{pe}$). Sim-

Abstract

We briefly describe some of the features of the E209 experiment at SLAC-FACET. The experiment aims at studying the physics of the self-modulation instability of long electron and positron bunches in dense plasmas. Encouraging initial results were obtained so far. Further experiments will take place soon.

INTRODUCTION

The E209 experiment at SLAC-FACET uses the well instrumented PWFA facility to study the self-modulation instability (SMI) of long charged particle bunches in m-long, dense plasmas [1]. In this context, bunches are considered as long when their duration is many periods of the electron plasma wave ($\tau \gg 2\pi/\omega_{pe} \sim n_{e0}^{-1/2}$) or their length many wavelengths of the wave ($L \gg \lambda_{pe} \sim n_{e0}^{-1/2}$). Here n_{e0} is the plasma electron density, $\omega_{pe} = \left(n_{e0}e^2/\epsilon_0 m_e\right)^{1/2}$ is the electron (angular) plasma frequency and $\lambda_{pe} = 2\pi c/\omega_{pe}$. In the FACET case the electron (e^-) or positron (e^+) bunch can be between 1.0 and 1.5 mm and the plasma density in the 10^{16} to 10^{18} cm^{-3} range ($335 \geq \lambda_{pe} \geq 34$ µm). This means that the particle bunch can be the equivalent of a few tens of plasma wavelengths long.

The SMI develops because of the positive feedback between the transverse wakefields alternating from focusing to defocusing over a plasma wavelength and the bunch density increasing/decreasing as a result. Transverse bunch slices of larger/lower density drive stronger/weaker wakefields, closing the feedback loop. The instability typically grows and saturates over a few ($5-10$) centimeters with the E209 beam and plasma parameters. The resulting periodic modulation of the bunch density due to the radial change can then resonantly drive wakefields over long plasma distances.

SMI OCCURRENCE

The occurrence of the SMI has (at least) three observable effects on the bunch.

1. The driving of wakefields leads to energy loss (and gain) by the drive bunch particles. This can in principle be measured at FACET with the imaging magnetic spectrometer that has an energy resolution on the order of 0.4% of the incoming particles energy, or better than 100 MeV around the 20 GeV bunch energy [2].
2. The transverse profile of the bunch is modified by the SMI occurrence when observed downstream of the plasma. At that location and without plasma the bunch has typically transverse Gaussian profiles with different rms sizes due to the different emittances in the horizontal and vertical planes ($\epsilon_{Nx,y} = 50, 5$ mm-mrad). When the SMI occurs the transverse profile is expected to have a focused core surrounded by a halo consisting of the defocused particles. This situation has already been observed with e^+ bunches approximately λ_{pe}-long. In this case the halo originates from the non-linear nature of the focusing fields [3]. This is observed by imaging onto a CCD camera the backward optical transition radiation (OTR) emitted by the bunch when traversing a thin titanium foil placed at 45^o with respect to the beam axis. Note that because the OTR wavelength (400-800 nm) is much shorter that the characteristic longitudinal and transverse size of the bunch, this radiation is emitted incoherently.
3. The coherent transition radiation (CTR) emitted by the bunch when traversing another thin titanium foil carries information about the bunch density modulation. Since the modulation is periodic with period $\cong \lambda_{pe}$, the wavelength spectrum of the radiation should exhibit a peak at $\cong \lambda_{pe}$. The spectrum of the radiation can be obtained using Fourier transform infrared (FTIR) spectroscopy. The CTR is sent through an interferometer and the interferometer signal recorded as a function of the delay or path length difference (PLD) between the two arms of the interferometer. The interferometer signal is then Fourier transformed and one can show that

A HIGH INTENSITY PROTON SOURCE FOR THE EUROPEAN SPALLATION SOURCE FACILITY

Luigi Celona, Luciano Allegra, Lucio Andò, Antonio Caruso, Giuseppe Castro, Francesco Chines, Giuseppe Gallo, Santo Gammino, Alberto Longhitano, Salvatore Marletta, David Mascali, Lorenzo Neri, S. Passarello, INFN/LNS, Catania, Italy
Giuseppe Torrisi, INFN/LNS, Catania; Università Mediterranea di Reggio Calabria, Reggio Calabria, Italy

Abstract

Along the last 25 years, INFN-LNS has gained a relevant role in R&D of plasma-based ion sources. The laboratory is currently involved in the construction of the Proton Source and Low Energy Beam Transport (LEBT) line for the European Spallation Source. ESS – based on a 2.0 GeV, 62.5 mA proton accelerator for neutron production – will be a fundamental instrument for research and applications. The proton source is required to produce at least 74 mA proton beam at 2.25 π.mm.mrad emittance (99% normalized), 2.86 ms pulse duration, 14 Hz repetition rate. We will illustrate the design of the source, the ongoing study of the radio frequency to plasma coupling, the result of a parametric study of the extraction system, the final layout of the LEBT – based on beam transport studies and the chopper strategy – and the first steps of the devices installation at the INFN-LNS test-bench site.

INJECTOR FOR THE ESS ACCELERATOR

The source named Proton Source for ESS (PS-ESS) (see Figure 1) was designed with a flexible magnetic system and a compact tetrode extraction system with the goal to minimize the emittance and the time needed for the maintenance operations. The ESS injector design has taken advantage of recent theoretical updates together with the new plasma diagnostics tools developed at INFN-LNS. The proton beam requirements is of 74 mA. The ability to reduce the current up to 6 mA with a precision of 2 mA, without changing the proton source conditions is reached with a six blade iris housed in the LEBT. The beam stability during the normal operations (in terms of current and emittance) shall be within ±3.5% from pulse to pulse variation and ±2% of the beam current averaged over a period of 50 us. This requirement is considered fundamental by the beam physics group, for the high energy RF cavities. The pulse duration is 2.86 ms with 14 Hz repetition rate. The requirements for the proton source and the LEBT are summarized in the Table 1. A detailed study of the beam transport in regime of space charge compensation was done and experimentally verified [1]. A chopper was designed to speed up the beam pulse rise and fall time. The final aim is to achieve a reliability better than 95% for the whole accelerator, thus meaning that the source reliability is expected to be greater than 99%.

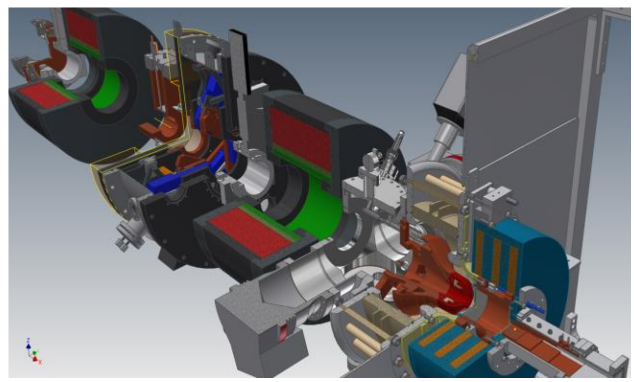

Figure 1: 3D rendering of the PS-ESS with the LEBT.

Table 1: PS-ESS Requirements

Parameters	Value
Proton current range	60-74 mA
Proton fraction	>80%
Current stability (50us averaged)	±2%
Pulse to pulse variation	±3.5%
Beam energy	70-80 ±0.1 keV
Repetition rate	1-14 Hz
Pulse length	5-2880 ±1 us
Current reduced using iris	2-74 ±1 mA
Restart after vacuum break	<32h
Restart after cold start	<16h
Emittance (99% normalized)	<2.25 π.mm.mrad
Twiss parameter α	1.02 ±20%
Twiss parameter β	.11 ±10%
Beam pulse rise and fall time	<20 us
LEBT pressure	<6e-5 mbar

PLASMA AND BEAM MODELLING

The INFN-LNS group fixed a challenging milestone for the simulation of the entire process underlying ion-beam generation. The plasma studies were performed by developing different plasma diagnostics and own code plasma modelling and to simulate the dynamics of space charge compensation (SCC), both in stationary and transient regimes. The new PIC code includes also

DESIGN OF A MICROWAVE FREQUENCY SWEEP INTERFEROMETER FOR PLASMA DENSITY MEASUREMENTS IN ECR ION SOURCES*

Abstract

Electron Cyclotron Resonance Ion Sources (ECRIS) are among the candidates to support the growing request of intense beams of multicharged ions. Their further development is related to the availability of new diagnostic tools, nowadays consisting of few types only of devices designed on purpose for such compact machines. Microwave Interferometry is a non-invasive method for plasma diagnostics and represents the best candidate for the whole plasma density measurements. Interferometry in ECR Ion Sources is a challenging task due to their compact size. The typical density range of ECR plasmas ranging from 10^{11} to about 10^{12} cm^{-3}, causes the probing beam wavelength to be in the order of few centimetres which is comparable to the chamber radius. The paper describes the design of a new microwave interferometer based on the so-called "frequency sweep" method: the density is here derived by the frequency shift of a beating signal obtained during the fast sweep of both probing and reference microwave signals; inner cavity multipaths contributions can thereby be suppressed by cleaning the spurious frequencies from the beating signal spectrum.

INTRODUCTION AND MOTIVATION

The development of microwave diagnostics is a fruitful strategy because microwaves crossing the plasma are sensitive to the entire energetic spectrum of the plasma, allowing global evaluation of the average density. In the classical scheme of a microwave Mach-Zender type interferometry, a microwave signal at frequency larger than any cutoff/resonance frequency of the plasma under investigation is splitted into two different branches: the first one is launched into the plasma, the second one is used as reference signal, propagating into a waveguide of calibrated length, as shown in Fig. 1.

The basic idea [1] is that the density can be determined from phase shift which explicitly depends on the natural plasma oscillation ω_p, i.e. the electron density, as depicted by the mathematical relation below:

$$\Delta\phi = \int_0^L \frac{\omega}{c}\left[1-\left(1-\frac{\omega_p^2}{\omega^2}\right)^{1/2}\right] dl \tag{1}$$

* Work supported by the 5^{th} National Commission of INFN (VESPRI Experiment)

where L is the plasma length along which the integral is calculated, c the speed of light, ω the probing microwave pulsation, $\omega_p^2 = \frac{n_e e^2}{m_e \epsilon_0}$ the plasma oscillation, and the other quantities are the standard fundamental physical constants. In ECRIS the measurement is greatly complicated by the mechanical constraints, which limit considerably the ratio L/λ, where L is the characteristic length of the plasma chamber, and λ is the wavelength.

In our experimental setup, typical of all ECRIS setup, the direction of the electromagnetic wave vector $\vec{k}$ is along the magnetostatic confinement field $\vec{B}_0$, then the dispersion relation of the magnetized plasma has two solutions: right-hand (R) and left-hand (L) circularly polarized waves, with the following propagation constants:

$$k_R = \frac{\omega}{c}\sqrt{1-\frac{\omega_p^2}{\omega(\omega-\omega_g)}} \tag{2}$$

$$k_L = \frac{\omega}{c}\sqrt{1-\frac{\omega_p^2}{\omega(\omega+\omega_g)}} \tag{3}$$

where $\omega_g = eB_0/m_e$ is the electron cyclotron frequency and we can assume that the collision frequency is much smaller than the microwave frequency. Without loss of generality we choose a cartesian reference system so that the z axis is parallel to $\vec{B}_0$ and to the yz plane containing the propagation constant vector $\vec{k}$ directed along $\vec{B}_0$. In this configuration the electric field vectors associated to R and L waves can be written as:

$$\vec{E}_R = (\hat{x} - i\hat{y})e^{ik_R z} \tag{4a}$$

$$\vec{E}_L = (\hat{x} + i\hat{y})e^{ik_L z} \tag{4b}$$

The sum of the two waves provides the composed wave $\vec{E}_t = \vec{E}_R + \vec{E}_L$ having the following effective constant of propagation:

$$k_{eff} = (k_R + k_L)/2$$

So, the phase shift due to the presence of the plasma is:

$$\Delta\phi = \int_0^L (k_0 - k_{eff})dL \tag{5}$$

where $k_0 = \frac{\omega}{c}$ is the free space propagation constant.

Figure 1 highlights the conceptual layout of an interferometer setup applied to small-size plasma chambers like in case

Abstract

Laser-target interaction represents a very promising field in several potential applications, from nuclear physics to medicine. On the other hand optically accelerated particle beams are characterized by some extreme features, often not suitable for several applications, as an high peak current, a poor shot-to-shot reproducibility and a wide energy and angular distribution. Therefore many efforts are currently ongoing for the development of specific beam transport devices in order to obtain controlled and reproducible output beams. In this framework, this work want to report about a transport beamline solution dedicated to laser-driven beams and made of two main sections: a quadrupole-focusing device and an energy selector system. A test beam-line consisting of prototypes has been realised at INFN-LNS (National Institute of Physics-South National Laboratories, Ct, I) and partially tested with conventional accelerated proton beams. Moreover, some of these prototypes have been already tested with laser-driven beams.
Several simulations have been also performed using the Geant4 Monte Carlo toolkit, in order to best exploit the beamline potentiality. Preliminary simulations of a transported beamline to select 5 MeV and 24 MeV proton beams are here reported.

INTRODUCTION

Nowadays, the interest in particle acceleration from ultra intense lasers is strongly growing, thanks to the huge number of potential applications and to the possibility to investigate new physics regimes and phenomena. In particular, it is becoming evident that, in the next future, laser-driven acceleration could represent a different and perhaps more effective alternative as respects to the actual conventional particle accelerators. It could bring to more compact and less expensive acceleration systems and, consequently, to a larger spread of radiation beams around the word [1]. Such reasons are stimulating the interest of many physicists for the improvement and the optimisation of the interaction regimes as well as of the overall quality of these new kinds of beams. Beyond the improvement at the laser-target interaction level, many efforts are spent for the development of specific beam transport devices. Interesting options with microlens, magnetic chicanes, quadrupoles, solenoids and radio frequency cavities are reported in literature [2], however for all these approaches, there are different crucial parameters, as the acceptance angle of the transport system that, considering the wide input divergence, limits the number of output particles. In this framework, this paper reports about a Monte Carlo study of a transport beamline solution for laser-accelerated proton beams.

TRANSPORT BEAMLINE

Ions accelerated by laser-matter interaction are characterized by high intensities, multiple species and charge states, wide energy spectrum and large energy-dependent angular distribution. Therefore, in order to make these non-conventional beams suitable for multidisciplinary applications, mainly in terms of reproducible and controlled output features, the design of specific transport elements seems to be mandatory. Bearing in mind these purposes, a transport beamline prototype has been designed and already realized at INFN-LNS. It consists of two main elements: a collecting-focusing sector and an energy selector system (ESS). Both elements have been separately tested with conventional protons up to 12 MeV, delivered by the TANDEM system of INFN-LNS and INFN-LNL. The ESS has been also tested with non-conventional beams at the Queens' University of Belfast, where the TARANIS laser system is installed [3]. Results will be reported elsewhere.
As regarding the quadrupole system, it should be able to collect, focus and pre-select in angle and energy the accelerated particles (fig. 1).

It is composed of four remotely controlled permanent quadrupoles with magnetic field gradients of 110T/m and 114T/m, 20mm bore and with lengths of 40 and 80mm, respectively [4]. This system allows to cover a wide energy operational range, from 0 up to 30MeV.
The final beam energy refinement is then obtained by means of the second transport device.

It is mainly composed of a central slit and four permanent dipoles with alternating polarity. Thanks to the magnetic field of the first two dipoles, particles with different energies are spatially separated on the radial plane. Then the central

Abstract

In order to examine the basic properties of a cryogenic C-band photocathode RF gun cavity, a 2.6-cell π-mode test cavity was fabricated in KEK. The temperature dependence of the resonant frequency and the Q-value in the cavity were measured ranging from room temperature to 21 K. The increase in the resonant frequency by the cavity cooling from 296.65 K to 21 K has been 188 kHz greater than the one estimated from the linear expansion coefficients for OFHC copper material. The unloaded Q-value of 64650 at 21 K has been in agreement with the result of the SUPERFISH calculation carried out by assuming the surface resistance of the copper material to be 3.54×10^{-3} Ω at 5712 MHz on the basis of the theory of the anomalous skin effect.

INTRODUCTION

A cryogenic C-band 2.6-cell photocathode RF gun, which operates at 20 K, is under development at Nihon University for the future possibility of use in a compact linac-driven X-ray source at KEK [1]. The cavity material is 6N8 high purity copper with the residual resistance ratio (RRR) higher than 3000, which is considered effective to suppress the RF power loss in the cavity wall significantly at low temperatures. The operating frequency of the RF gun cavity is 5712 MHz. The main specifications of the gun are listed in Table 1 [2]. In order to investigate the low-temperature properties of the cavity, a 2.6-cell π-mode test cavity was fabricated in KEK with ultra-precision machining and diffusion bonding techniques. Since it was intended to examine the effect of the high purity copper material on the low-power RF properties at 20 K, the cavity consisted of only axis-symmetric components as shown in Fig. 1 [2]. Thus, the two-dimensional code POISSON-SUPERFISH [3] was used for the design calculation of the cavity.

Table 1: Specifications for the 2.6-Cell 20 K Cryogenic Photocathode RF Gun [2]

RF frequency	5712	MHz
Source peak RF power	4	MW
Q_0	> 60000 @20 K > 11000 @298 K	
Shunt impedance	~ 550 @20 K ~ 100 @298 K	MΩ/m
Coupling coefficient	20	
Cavity length	68.2	mm
RF pulse duration	2	μs
RF pulse repetition rate	50	Hz
Maximum wall RF loss	0.73	MW
Output beam energy	3	MeV
RF duty factor	0.01	%
Maximum beam charge	0.5	nC/bunch
Laser pulse repetition rate	357	MHz
Laser pulse length	10-20	ps
Maximum beam energy	3.5	MeV

In the measurements at room temperature, the resonant frequency converted to 23.5 °C in vacuum was approximately 300 kHz lower than the designed value. The unloaded Q-value and the shunt impedance deduced from the field distribution measurement have shown good agreement with the SUPERFISH simulation [2,4].

In this paper the RF properties of the cavity measured at around 20 K are reported and compared with the predicted values from the SUPERFISH simulation and the NIST data for the linear expansion coefficients of OFHC copper [5].

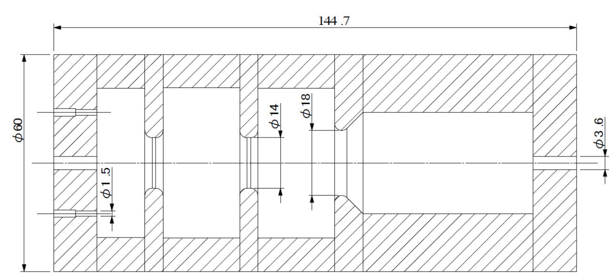

Figure 1: Cross-sectional view of the test cavity. The RF power is fed into the cavity through an antenna inserted into either hole in the left-side end plate.

EXPERIMENTAL SETUP

The experiment has been carried out using a cryogenic cooling system in KEK. The cooling system consists of a cylindrical vacuum chamber and a refrigerator unit (Daikin Industries V108C5L) installed on the top of the chamber. The test cavity has been mounted on a copper base plate with a cylindrical surface having the same radius as the outer side wall of the cavity. The base plate has been attached to the cold head of the refrigerator through a copper fitting plate and a copper block as shown in Fig. 2. Silicon thermal grease has been applied to both sides of the base plate to improve the thermal conductance between the cavity and the fitting plate. The cavity temperature has been monitored by semiconductor temperature sensors

Abstract

Based on the low-power and low-temperature RF properties of the basic 2.6-cell cavity, a new cavity with the RF input coupler was fabricated in KEK. The coupler consists of a cylindrical waveguide and a mode converter from rectangular TE_{10} to cylindrical TM_{01} mode with both the elements having been located on the accelerating cavity central axis. The structure and the dimensions of the coupler have been designed using the 3-D simulation code CST Studio. The 2.6-cell structure has been modified from the previous test cavity. The RF properties of the cylindrical part of the cavity, measured without the mode converter before finishing, were in good agreement with the result of the CST Studio calculation. However, the behaviours of the $|S_{11}|$ and the field distributions in the completed cavity have to be investigated further because of possible non-axisymmetric field in the cylindrical waveguide.

INTRODUCTION

For the future use in the compact linac-driven X-ray source at KEK [1], a cryo-cooled C-band cavity for a photocathode RF gun has been under development. The RF properties measured on the basic 2.6-cell test cavity have shown that the π-mode accelerating frequency and the unloaded Q-value at around 20 K were well predicted from the room-temperature properties [2-4]. As the next stage of the development, a new cavity equipped with an input coupler has been designed. In the new design, a coaxial coupler which had originally been assumed was not employed because of possible difficulties in the cooling of the thin central electrode. Instead, a cylindrical coupler has been designed, which consists of a cylindrical waveguide and a mode converter that converts the rectangular TE_{10} mode to the cylindrical TM_{01} mode with both of them located on the accelerating cavity central axis. The basic design of the accelerating cells has not been greatly changed from that in the first test cavity. However, the design of the third disk located next to the coupling structure, has been changed so that it has the same shape as the other disks.

The cavity has been designed using the simulation codes SUPERFISH [5] and CST Studio [6]. SUPERFISH has been used primarily for the calculation of the resonant frequency of the cylindrical parts, while the 3-D code CST Studio has been necessary for the calculation of the RF properties of the whole structure including the coupler.

The low-power test cavity was fabricated in KEK with ultra-precision machining. The results of the design simulations and the RF property measurements at room temperature are presented in this paper.

DESIGN AND SIMULATIONS

Choice of Cylindrical Coupler

From the specification of the 20-K cryo-cooled photocathode RF gun cavity, the coupling coefficient of the RF input coupler has been required to be as large as about 20 [2]. The coupler was not included in the basic 2.6-cell test cavity, just the RF cutoff cylinder being reserved temporarily as a part of the outer wall of a coaxial coupler. For a high power operation of the cavity, an efficient heat removal structure is required of the thin inner electrode of the coaxial coupler, which seems difficult to realize in the C-band low-temperature cavity.

In order to avoid the heat removal problem with the coaxial coupler, a cylindrical coupler that was employed in an X-band photocathode RF gun [7] has been designed. The cylindrical coupler has the same advantage with a coaxial coupler that, though modifications are required in the method of the cavity cooling, it is possible to locate a focusing device such as a solenoid coil centered at any position on the cavity axis.

The cross-sectional view of the cavity for the low-power test is shown in Fig. 1. In the fabrication of the cavity, high purity 6N8 copper was used for the accelerating cells and the neighboring long portion of the cylindrical waveguide.

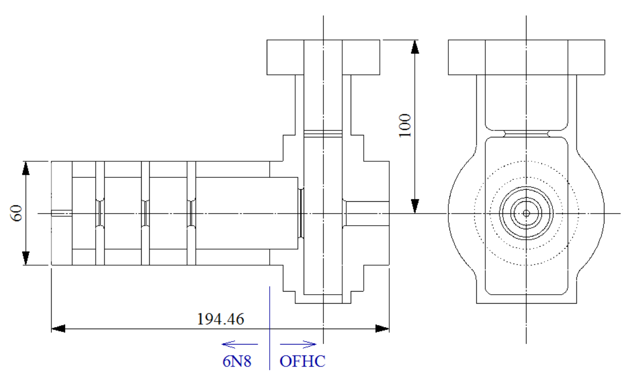

Figure 1: Cross-sectional view of the low power test cavity with the cylindrical input coupler. The hole in the left-side end plate is for the bead-pull measurement of the field.

CSKSB PHOTOCATHODE R&D WITH HIGH QUANTUM EFFICIENCY AND LONG LIFETIME

Y. Seimiya*†, M. Kuriki, A. Yokota, R. Kaku, HU/AdSM, Higashi-Hiroshima, Japan,
T. Konomi†, Inst. Molecular Sci., Aichi, Japan, M. Yamamoto, T. Miyajima, KEK, Tsukuba, Japan.

Abstract

Advanced electron linear accelerator such as Energy Recovery Linac and Free Electron Laser needs high brightness electron source. Photocathode is suitable for the high brightness requirement because some of them has low emittance and high quantum efficiency. In the photocathode, CsKSb multi-alkali photocathode has excellent features: high quantum efficiency, long lifetime, and driven by visible light, for example green laser. Therefore, the multi-alkali photocathode is considered to be one of the best candidates for the high brightness electron source of the advanced electron accelerator. We report developments of our evaporation system and results of quantum efficiency and lifetime measurement in Hiroshima University. Multi-alkali surface analyzation has being measured by ultra-violet photoemission spectroscopy to study conditions between the multi-alkali performances and the surface condition in Institute Molecular Science. We also report the status of the progress abort the study.

INTRODUCTION

Photocathode can generate a low emittance and short pulse beam by conditioning the spot size and pulse length of a laser, comparing to thermal cathode. The photocathode is essential device for high brightness electron source in advanced electron Linac such as Energy Recovery Linac (ERL) [1] or Free Electron Laser (FEL). For example, ERL requires high average current electron beam in range of 10~100mA and low emittance down to 0.1 mm.mrad.

Generally, a laser with shot wave length has lower power than that with long wave length. Multi-alkali cathode has high Quantum Efficiency (QE) about 10% and long lifetime with green laser. Green laser can be obtained easily as second harmonics of 1μm solid state laser, such as Nd:YAG or Yb:YAG. Therefore, the multi-alkali photocathode is considered to be one of the best candidates for the high brightness electron source of the advanced electron accelerator. According to a study by Cornell University, 1/e lifetime of the cathode is estimated as 30 hours with 60mA extracted current [2]. We examined the cathode performances, such as QE and the cathode lifetime, in Hiroshima University. Multi-alkali surface analyzation has also being measured by ultra-violet photoemission spectroscopy to study conditions between the multi-alkali performances and the surface condition in Institute Molecular Science (IMS). In our evaporation system, antimony(Sb), potassium(K), and cesium(Cs) are evaporated one by one in an extremely high vacuum condition, typically 4×10^{-9}Pa as a base pressure.

EVAPORATION SYSTEM

In Hiroshima University, evaporation system for multi-alkali cathode study was originally constructed. The schematic layout in the evaporation chamber is shown in Fig. 1. The multi-alkali cathode is made by the evaporation system, and its properties and performances are measured. We can extract the photo-current by a laser irradiating a substrate through a view port and QE and the cathode lifetime are measured. To monitor evaporation thickness for each materials, a quartz thickness monitor is implemented in the system. Additionally, the cathode substrate and the thickness monitor are placed symmetrically around the evaporation source to measure the thickness simultaneously during the evaporation. The evaporation source is also designed to generate the vapor symmetrically. A ceramic heater mounted behind the substrate and the substrate temperature is monitored and controlled by a thermo-coupler. For the simultaneous measurement of QE and thickness, the laser light illuminates the substrate diagonally in order to avoid interference between laser light and the substrate. The substrate made by 30mm×30mm SUS304 is used. QE map on the substrate can be obtained by scanning the laser irradiation area on the substrate with moving stage mounted on mirror. This QE mapping is performed by a green laser first, and performed by a blue laser second. The mapping is done every two hours. It takes 12 minutes to get these both QE map and laser irradiate a special point we chose during the other time of the interval, two hours. Blue laser which has about 2.3mW power and 405nm wave length and green laser which has about 0.45mW power and 532nm wave length on the substrate are used in our experiment.

Ultra-high vacuum is required during multi-alkali cathode evaporation and charge extracting from the substrate. Ion pump and NEG pump are used. Base vacuum pressure is about $10^{-8} \sim 10^{-7}$Pa during evaporation.

RESULTS

Cathode Evaporation Experiment

CsKSb cathode is made by Sb, K, and Cs evaporation in this order on the substrate. The typical process is following:

1. The substrate is heated to 600°C for heat cleaning. After that, it is cooled down and held temperature around 100°C.
2. Sb is evaporated up to a determined thickness.
3. K is evaporated up to a scheduled thickness.
4. Cs is evaporated until QE is saturated.

AN OPTIMIZATION OF ILC POSITRON SOURCE FOR ELECTRON-DRIVEN SCHEME

Y. Seimiya*, M. Kuriki, T. Takahashi, M. Urano, HU/AdSM, Higashi-Hiroshima
T. Okugi, T. Omori, M. Satoh, J. Urakawa, KEK, Tsukuba, S. Kashiwagi, Tohoku U., Sendai

Abstract

International Linear Collider is a future accelerator to find new physics behind the electroweak symmetry breaking by precise measurements of Higgs sector, Top quark, and so on. ILC has capacities to reveal new phenomena beyond Standard model, such as Supersymmetry particles and dark matters. In current design of positron source, undulator scheme is adapted as a baseline. In the scheme, positrons are generated from gamma rays through pair-creation process in Ti-alloy target. Generations of the gamma rays by the undulator radiation requires more than 130 GeV electrons. Therefore, a system demonstration of the scheme is practically difficult prior to the real construction. Consequently, it is desirable to prepare a technical backup of this undulator scheme. We study an optimization of positron source based on the conventional electron-driven scheme for ILC. In this scheme, positron beam is generated by several GeV electron beam impinging on W-Re target. Although heavy heat load and destruction of the target is a potential problem, it can be relaxed by stretching the effective pulse length to 60 ms instead of 1 ms, by a dedicated electron linac for the positron production. In this report, a start-to-end simulation of the electron-driven ILC positron source is performed. Beam-loading effect caused by multi-bunch acceleration in the standing wave RF cavity is also considered.

INTRODUCTION

International Linear Collider (ILC) is an electron and positron collider, which has a total length of 33 km ,with a center-of-mass energy of 500 GeV (first phase). ILC Technical Design Report was published in 2013 [1]. In the report, positrons are generated by undulator scheme as the baseline. In a helical undulator, polarized electron beam radiates gamma rays. The gamma rays are irradiated on a Ti (titanium) alloy target, and they are converted to polarized positrons through the pair-creation process. To obtain an enough amount of positrons, the gamma ray energy has to be more than 10 MeV, which requires a 150 GeV driving electron beam with a 10 mm undulator period. Therefore, the high-energy electron beam are shared by the gamma ray generation in the undulator and the collision with the positron. This undulator scheme has never been in operation for an accelerator, and it is difficult to demonstrate the system practically prior to the construction because more than 100 GeV electron beam is necessary as the positron driver. Therefore, a backup is desirable to reduce unknown technical risks.

The strongest candidate of the positron source as a backup is the conventional electron-driven scheme. In this conventional scheme, a several-GeV electron beam impinges on a heavy metal target. Gamma rays by Bremsstrahlung process are converted to positrons through the pair creation. In this scheme, the positrons cannot be polarized even if electron beam is polarized. According to the SLC experiments, the peak energy deposition density (PEDD) in the target should be less than 35 J/g [2–4] to avoid any damage to the target. The electron-driven positron source for the ILC was designed in Ref. [5]. In this design, a dedicated electron linac is assumed and the positron is generated in 63 ms out of 199ms which is ILC pulse interval for the collision. The generated positrons are stored on DR (Damping Ring) in 136 ms for the damping and sent to the main linac for the collision in the last 1ms. By the stretching of the beam pulse, the heat load on the target can be reduced by a factor 60. The electron-driven positron source for ILC can be accommodated in the tunnel designed for the undulator positron source, because the tunnel is wide enough. The compatibility of both schemes is one of the hottest topic in LCC (Linear Collider Collaboration). [6].

Our aim is to show that an enough number of positrons are obtained in DR acceptance by keeping PEDD less than 35 J/g under realistic parameters. By studying the yield as a function of various conditions, the design has been optimized [7]. In addition, effects caused by multi-bunch acceleration (beam-loading) and its compensation are considered in this report.

POSITRON SOURCE STRUCTURE AND REQUIREMENT

Electron-driven positron source consists of an electron driver linac, a positron production target, an AMD for transverse momentum suppression, a positron injector linac up to about 200 MeV, a chicane to remove positrons with a large momentum deviation and electrons, a positron booster up to 5.0 GeV, and an Energy Compression System (ECS) section as shown in Fig. 1. DR stored once the generated positron for the damping and the damped beam is sent to the main linac. The transverse DR acceptance (dynamic aperture) is $\gamma A_x + \gamma A_y < 0.07$ m, where γ is the Lorenz factor, and A_x and A_y are action values in the horizontal (x) and vertical (y) directions, respectively. The longitudinal acceptance is expressed as

$$\left(\frac{z}{0.035}\right)^2 + \left(\frac{\delta}{0.0075}\right)^2 < 1, \qquad (1)$$

Abstract

The ultra cold muon beam by two-photon laser resonant ionization of muonium atoms is unique way to obtain very low emittance muon beam. Its muon source is a surface muon from the muon target in MLF where one percent proton beam from J-PARC RCS is reacted. In close collaboration with the Muon Science Establishment (MUSE) at Material and Life science experimental Facility (MLF) of the Japan Proton Accelerator Research Complex (J-PARC), we are developing the reacceleration system of the ultra cold muon beam. Its optimum accelerating structure is similar to a proton accelerator in low beta part and an electron accelerator in high beta part.

Further the muon bunch is only two bunch corresponding to the bunch structure of the J-PARC RCS. Thus we are testing the dielectric transmission line accelerator based on the photoconductive switch as the alternative acceleration method..

ULTRA COLD MUON IN J-PARC MLF

The surface muon of 4 MeV from proton target is once stopped at the muon target. The muonium is thermally emitted from the target and excited by the VUV laser. The ultra cold muon generated by this method has very low emittance and become the unique probe to the material science and the elementary particle physics.

Figure 1 shows the layout of the MUSE at MLF of J-PARC. The re-acceleration of the ultra cold muon is planned to install for two lines called as U-line and H-line of total four extraction lines.

The H-line will be used for some elementary particle physics experiments including the g-2 experiment which requires 200 MeV muon beam. The U-line is used for the material science. The muon microscopy with the muon re-acceleration is planned to install at U1B area.

DEVELOPMENT OF ACCELERATOR-DRIVEN COMPACT NEUTRON SOURCES

K. Hirota*, G. Ichikawa, M. Kitaguchi, Y. Kiyanagi, H. M. Shimizu,
K. Tsuchida, A. Uritani, K. Watanabe and JCANS Collaboration,
Nagoya University, Nagoya, 464-8602, Japan

Abstract

Compact neutron sources are good tools for neutron scientist. In this paper we will present the current situation of compact accelerator-driven neutron source and the status of the facility of Nagoya University.

INTRODUCTION

Neutron is a very good probe to investigate inner structure of materials. The large neutron facilities like J-PARC MLF and SNS were constructed in decade, and ESS facility are start to construct. These large facilities are very good tools to study in academic field. However, the opportunity to use is very low, many neutron scientists use this facilities once or several a year. The beam time is less than 10 days in many case science many scientists want to use these powerful machine. The scientists require more neutron beam to study physics, chemistry and engineering.

One of the solution to solve this situation is constructing Compact Accelerator-driven Neutron Source(CANS). The CANS has some merit comparing with large neutron facilities. The constructing cost is lower than larger facilities. The opportunity to use neutron beam is so frequently. All devices from accelerator to detectors are able to handle by ourselves, that is very good for student education. The amount of radiation is smaller than that of the large-scale facilities. Unfortunately the emitted total neutron is much lower than large facilities and it is not suitable for the measurement of statistics-dominant. We can use these CANS for BNCT(Boron Neutron Capture therapy), neutron imaging, device development and so on. In this paper we will present the current situation of CANS and the status of the facility of Nagoya University.

l Q–“¡ p l ZQl Q¡ ; “ap l

There are some methods for generating neutrons. In general, the emitted neutron flux has following relation,

$$NeutronFlux = I_{beam} \times Eff_n \times Eff_{Mod} \quad (1)$$
$$I_{beam} = I_{peak} \times (Duty) \quad (2)$$

where, I_{beam} is an intensity of accelerated beam, Eff_n, and Eff_{Mod} are efficiency of neutron emission and moderation, I_{peak} is a peak current of accelerated beam, duty denotes duty cycle of accelerator.

Fission reaction is using at research reactor, and spallation reaction is using at large neutron facilities like J-PARC, SNS, and ISIS. These two methods have good neutron emission efficiency. Photonuclear reaction and low energy proton (or deuteron) reaction are using at compact neutron sources. The other neutron emission methods are fusion reaction and radioisotope. These two methods are lower neutron flux than the other methods in the laboratory use.

In CANS, neutron emission efficiency is not so high and neutron flux is lower than that of large facilities. In order to compensate the neutron flux, these reactions require the incident beam intensity. One solution is increase duty ratio by using cyclotron or electro static accelerator. However, it is not suitable for the case of pulse imaging method, which need neutron TOF(time of flight) information. In this case, we have to try to increase the peak current by using linear accelerator. In these way, we have to select the suitable acceleration beam properties.

The incident beam energy is also important for CANS. High incident beam energy increasing the accelerator and radiation shield size, and also increase the construction cost. On the other side, the low energy beam decrease the neutron emission efficiency. The relation between incident beam energy and neutron emission is written in elsewhere [1]. The selection of beam energy and target should be carried out carefully. In less than 2 MeV region, the deuteron beam is only useful for CANS. But the moderation efficiency in eq. (1) is not so good because of the emitted neutron average energy is more than one MeV. In 2 - 5MeV region, proton beam and Li target is suitable for CANS, however Li target is difficult to use, and second solution is Be target [2]. In more than 5 MeV region, Be target is suitable [3].

NUANS

Nagoya University Accelerator-driven Neutron Source (NUANS) is constructing at Nagoya, Japan. The aim of this neutron source is the evaluation test machine about Li target for BNCT. In general, the total neutron emission needs 10^{13} n/sec for BNCT use. We are planning to achieve this number by using high duty machine, DC beam accelerator. An electrostatic accelerator, dynamitron and an ECR ion source are using for the incident proton beam injector. The proton beam energy and DC beam current are 2.8 MeV and 15 mA, respectively. The accelerator is doing the final test at production factory and shipping within few month.

The Li target and epi-thermal moderator are also important components for neutron source. We select the emboss structured target [4] and MgF_2 neutron moderator for NUANS.

Mitsuhiro Fukuda, Shunpei Morinobu, Osaka University RCNP, Osaka, Japan

Abstract

A new DC muon beam line has been constructed at RCNP, Osaka University. The MuSIC, which has the highest muon production efficiency using superconducting solenoidal magnets, has successfully demonstrated to provide a 3 x 10^8 [μ+/s/μA]. In 2014, the solenoidal magnets of the MuSIC were extended by a new beam line with normal conducting magnets. The new beamline consists of beam slits, quadrupole magnets, bending magnets and a DC separator. This new beamline is designed for muon experiments such as μSR experiments and muonic X-ray measurements. To study the performance of the beams provided by the beamline , a beam test was done in December 2014 and February 2015. In this paper, a detail design of MuSIC including the new beamline and result of the beam test are written.

INTRODUCTION

The MuSIC is a high intensity muon beam facility at RCNP, Osaka University (Figure 1). The proton beam is provided by the RCNP's ring cyclotron. The proton beam power is 400 W. The MuSIC achieves a muon yield of 10^8 [μ+/s/μA]. Compared with that, the the Paul Sherrer Institute (PSI) achieve a same muon yield with 1.3 MW proton beam. This shows that the muon production efficiency of the MuSIC is over 1000 times higher than that of PSI. The MuSIC has two features.

Pion Capture System

The pion capture system is a system involves a pion capture solenoid and a 36∘ curved transport solenoid. Protons enter the pion capture solenoid and hit a graphite target. Pions produced from protons are captured by a magnetic field of the pion capture solenoid and the 36∘ curved transport solenoid transport these pions. Pions decay to muons while transported.

MuSIC M1 Beam Line

MuSIC M1 Beam Line has SLITs(SL), Staring Magnets(STH), Quadrupole Magnets(QM), Bending Magnets(BM) and a DC separator(SR). Particles transported by the 36° curved transport solenoid enter the MuSIC M1 Beam Line. While passing through the beam line, focused muons with uniform momentum are taken out.

PION CAPTURE SYSTEM

The construction of the pion capture system was completed in 2009. In 2010 measurement proved that the Mu-

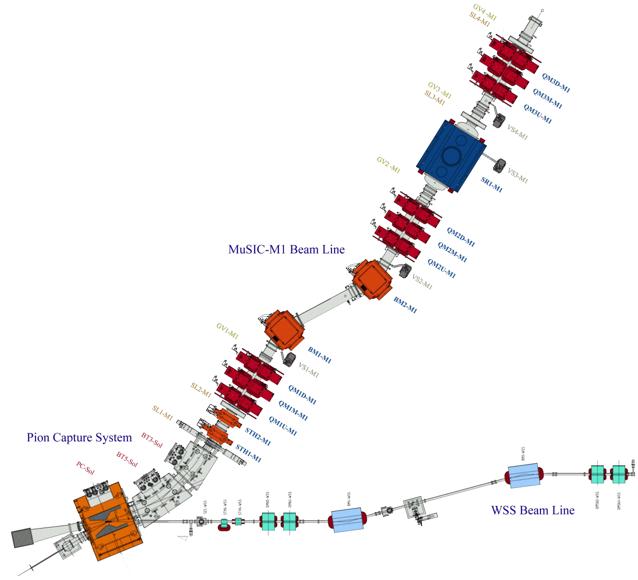

Figure 1: Layout of MuSIC.

SIC achieves about 10^8 [μ/s/μA] muon production efficiency. This is 1000 times higher than that of PSI and TRIUMF. The details are described in this section.

Features

A special structure of the pion capture system is enable the MuSIC to achieve a high muon production efficiency. In the case of the conventional muon beam facility, the neutron facility uses same proton beam line. So the structure of muon beam facility should be like Figure 2 (left. The target is thin and the pion capture solenoid is set beside the target. In contrast, the MuSIC can use full proton beam. Figure 2 (right) shows the structure of the MuSIC pion capture system. A 200 mm thick graphite target stops the protons, so a large mount of pions are produced. Pions are captured by the pion capture solenoid surrounding the graphite target over a large solid angle. It makes pion production and capture efficiency higher. Pions captured by the pion capture solenoid are transported by the 36° curved transport solenoid and decay to muons. A 2 T solenoid magnet and a 0.04 T dipole magnet select muon charge and momentum. Thus the MuSIC obtains a high muon production efficiency.

G4beamline

G4beamline is a simulator based on Geant4 [1]. The MuSIC structure from the graphite target to the 36° curved transport solenoid were described by G4beamline. 392 MeV

Abstract

Muon acceleration is beyond our experiences. It enables us to measure the muon anomalous magnetic moment with an accuracy of 0.1 ppm and search for electric dipole moment with a sensitivity of $10^{-21}\mathrm{e}\cdot\mathrm{cm}$ to explore beyond Standard Model of elementary particle physics. We are developing a linac dedicated to the muon acceleration and planning to try the muon acceleration by utilizing slow negative muonium production. This paper described status of these developments.

INTRODUCTION

Though the discovery of Higgs at LHC completed the particles predicted in Standard Model (SM) of elementary particle physics, some observations such as dark matter existence indicate new physics beyond SM at some energy scale or interaction scale. One of the clues for new physics is anomaly of the muon anomalous magnetic moment $(g-2)_\mu$; There is a $\sim 3\ \sigma$ discrepancy between the SM prediction and the experimental value measured by E821 with a precision of 0.54 ppm [1]. Measurement with higher precision (0.1 ppm) is necessary to confirm this anomaly.

It should be also mentioned that measurements up to now rely on the technique of the magic momentum. Because the muon beam generated from the secondary pions in flight has large emittance, focusing with electric field in addition to the magnetic field is necessary in storage ring. The anomalous spin precision vector of muon is written by

$$\vec{\omega} = -\frac{e}{m}\left[a_\mu\vec{B} - (a_\mu - \frac{1}{\gamma^2-1})\frac{\vec{\beta}\times\vec{E}}{c} + \frac{\eta}{2}(\vec{\beta}\times\vec{B} + \frac{\vec{E}}{c})\right] \quad (1)$$

where e is elementary charge, m is muon mass, a_μ is anomalous magnetic moment, γ is the Lorentz Factor, β is the ratio of particle velocity to the speed of light c, and η is electric dipole moment. The second term depending on the electric field is eliminated when the muon momentum is 3.094 GeV/c, so called magic momentum. Measurement with a new method should be surveyed for verification of the $(g-2)_\mu$ anomaly.

The muon electric dipole moment (EDM) is also sensitive to new physics because it is strongly suppressed in SM (10^{-38} e·cm), and violates CP symmetry assuming the CPT theorem. In addition to that, there is a possibility that anomaly of $(g-2)_\mu$ can be explained by finite EDM with an order of 10^{-20} e·cm [2], whereas current direct limit is 1.9×10^{-19} e·cm [3].

The E34 experiment [4] aims to measure $(g-2)_\mu$ with a precision of 0.1 ppm and search for EDM with a sensitivity to 10^{-21} e·cm by utilizing high intensity proton beam at J-PARC and newly developed novel technique of the ultra-cold muon beam. Figure 1 shows the experimental setup. The experiment utilizes the proton beam from the 3 GeV Synchrotron ring to Materials and Life Science facility (MLF). The proton beam is injected to the graphite target. The generated surface muons are extracted to one of the muon beamline of H-line. Surface muons stop in the muonium (μ^+e^-, Mu) production target of the silica aerogel and then form thermal muoniums. The paired electron in the muonium is knocked out by laser and thermal muon (3 keV/c) is generated. Then the muon is accelerated up to 300 MeV/c and injected to the storage ring supplying 3 T. The decay positron is detected by the silicon strip tracker and the spin precession frequency is obtained from variation of counting rate of the decay positron.

Thanks to the ultra-cold beam ($\sigma_{pT}/p = 10^{-5}$) where p_T is the transverse momentum of the beam particles, the electric focusing is not necessary anymore. Eq. 1 becomes

$$\vec{\omega} = -\frac{e}{m}\left[a_\mu\vec{B} + \frac{\eta}{2}(\vec{\beta}\times\vec{B})\right] \quad (2)$$

Because the anomalous magnetic moment and EDM are perpendicular each other, these can be measured simultaneously.

One of the milestones for the experiment is verification of the muon acceleration from thermal energy to 212 MeV, which is the first case in the world. This paper describes status of developments of the muon accelerator and the first experimental verification of the muon acceleration. Other developments can be found elsewhere [5–7].

DEVELOPMENTS FOR THE MUON LINEAR ACCELERATOR

To suppress muon loss in the acceleration, the muon should be accelerated in a sufficiently short period. To realize the fast acceleration, a linac dedicated to the muon is being developed. Since velocity (β) of a muon largely varies during acceleration, several types of RF cavities should be adopted to realize sufficiently effective acceleration along with β. Three types of cavities are adopted: inter-digital H-mode (IH) for low β (< 0.27), disk and washer (DAW) for middle β ($0.27 < \beta < 0.7$), and disk loaded structure for high β ($0.7 < \beta$) section.

DEVELOPMENT OF A C-BAND RF GUN WITH A CONIFEROUS-TREE-TYPE CARBON NANOSTRUCTURE FIELD EMISSION CATHODE*

Y. Taira, H. Kato, R. Kuroda, H. Toyokawa, AIST, Tsukuba, Japan

Abstract

Recently, coniferous formed carbon nano-structure (CCNS) as a field emission cold cathode has been developed. Tips of it have a nanometer-size tubular structure that becomes thicker on the substrate side. Owing to this configuration, the CCNS is considered to be more stable in high electric fields than carbon nanotubes. Characteristic of the field emission of the CCNS under an electrostatic field was revealed in the previous study. We have developed a C-band RF gun to reveal characteristic for a RF field. An important quantity for the field emission cathode which is called field enhancement factor was measured as 894 ± 54 by applying the electric field from 20 to 30 MV/m. This value is lower than that obtained by an electrostatic field up to 7.4 MV/m. Reduction of the enhancement factor was due to the destruction of tips of the CCNS by a high electric field.

INTRODUCTION

We have fabricated a C-band RF gun which used a field emission cathode of coniferous-tree-type carbon nano-structure (CCNS) cathode. Aim of it is a development of a tabletop size high-energy x-ray source and a terahertz radiation source.

If a wavelength of emitted radiation is longer than a bunch length of an electron beam, each radiation is coherently enhanced. Terahertz radiation is coherently enhanced by using the sub-picosecond electron beam. Electrons are emitted only in the restricted phase by the field emission. This characteristic is suitable for the generation of the short pulsed electron beam. Generation of the short pulsed electron beam in the range from sub-picosecond to picosecond is usually achieved by a photocathode and a short-pulsed laser system. If the picosecond electron beam can be generated via a field emission, it contributes to a miniaturization of the equipment.

We use the CCNS as a field emission cathode. Appearance of the CCNS cathode is shown in Fig. 1. The CCNS is deposited on a stainless steel substrate with the diameter of 6 mm by plasma-enhanced chemical vapor deposition. A detailed method is described in Ref. [1]. The CCNS has a following structure, which a graphene sheet composed of carbon has a coniferous form, and the tip has a nanometer-size tubular structure that becomes thicker on the substrate side [1]. A lot of studies concerning the field emission characteristics of carbon nanotubes (CNT) are carried out. CNT is a uniform diameter from the substrate side to the tip. On the other hand, the CCNS has the similar tip shape as CNT and becomes thicker towards the substrate side. Owing to this structure, the CCNS is considered to be more stable in high electric fields than CNT. In the previous study using the electrostatic field, it was found that a field emission current was 1.6 mA at the electric field of 7.4 MV/m, current density was 200 mA/cm^2, and field enhancement factor was 1562 [1]. In this proceedings, we report the first measurement of the field emission properties of the CCNS under the RF field.

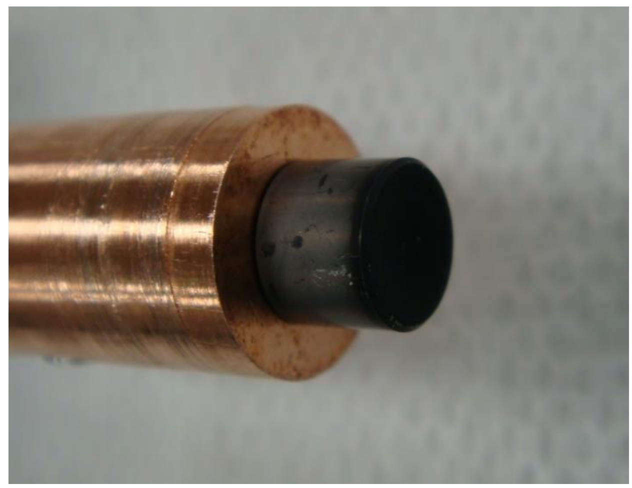

Figure 1: Appearance of CCNS cathode. The diameter of the CCNS is 6 mm.

C-BAND RF GUN

Appearance of the C-band RF gun is shown in Fig. 2. The detailed structure is described in Ref. [2]. This C-band RF gun is a single cell cavity, which the radius and length are 21.6 mm and 16.1 mm, respectively. RF power is inputted from a magnetron (New Japan Radio Co., Ltd. M1602). A four-port circulator, a directional coupler, and a pressurization window are connected between the magnetron and the C-band RF gun. Forward and reflected

Abstract

An laser ion source which produces bunched ion beam is proposed to enhance an acceleration efficiency of ion accelerator front end with RFQ linac. To demonstrate a production of an initially bunched ion beam, H_2 gas was ionized by short pulse laser in an RF electric field. As a result, ions captured by the RF field were observed by an ion probe.

INTRODUCTION

RFQ (Radio Frequency Quadrupole) linac [1] has been the essential component of ion accelerator front ends for tens of years[2]. Since ordinary ion sources provide DC (unbunched) ion beam, the function of RFQ includes not only acceleration and radial focusing but also adiabatic bunching. Therefore, conventional RFQ consists of three or four sections; radial matching section, (shaper section), bunching section, and accelerating section[3]. At the bunching section, the beam is bunched adiabatically by longitudinal RF electric field. However, satisfying the adiabatic condition, the vane modulation and synchronous phase rise gradually to the values for accelerating section. Therefore, bunching section takes lengthy part of RFQ tank, where the longitudinal field contribute almost only for bunching and not for acceleration. Hence the accelerating efficiency along the entire RFQ tank decreases.

If the beam is already bunched at the entrance of RFQ, bunching section is not needed and beam can be accelerated along the whole part of RFQ tank. Then, the accelerating efficiency of RFQ can be improved. For production of such a bunched beam, laser plasma induced by short pulse laser has promising potential. The ions in the plasma produced by short pulse laser are supposed to have also short pulse structure. If the bunch of the short pulse ions can be captured by RF bucket at the laser interaction region before an expansion of plasma, the production of short pulse bunch can be achieved and direct injection of the bunched ion beam into RFQ can be realized. The schematic image of the front end with direct injection of bunched ions into RFQ is shown in Fig.1. This scheme is similar to the RF gun, while the electrons are replaced with the ions.

In this paper, an experiment to demonstrate the capturing of laser-induced ions in RF bucket is described.

EXPERIMENT

To demonstrate the capturing of ions produced with a short pulse laser by RF electric field, H_2 gas was irradiated

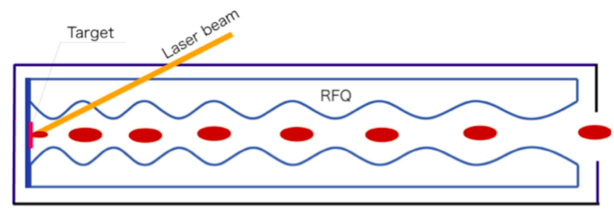

Figure 1: Schematic image of RFQ with initially-bunched ion beams.

by short pulse laser in an accelerating gap of an RF resonator and the accelerated charged particle was detected by a probe electrode. The layout of experimental equipments is shown in Fig.2. In this section, the component used in this experiment is described. The experiments were performed in a vacuum chamber with a pressure of 0.02 Pa.

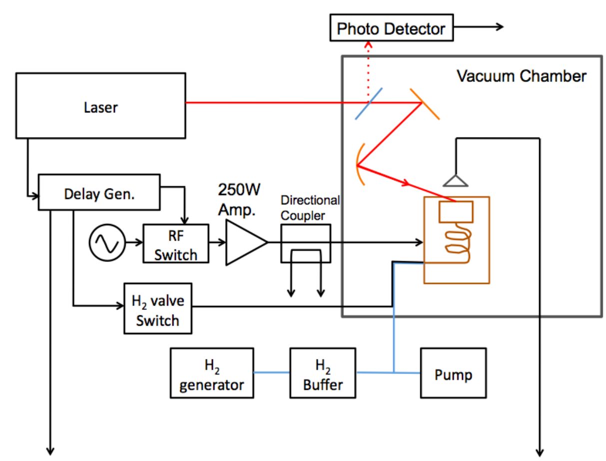

Figure 2: Image of Experimental Layout.

Laser

The experiment was performed with a terawatt 40-fs Ti:sapphire laser system in Institute for Chemical Research, Kyoto University. A laser pulse energy was tuned between 30 μJ and 100 μJ and a repetition rate of laser pulse was up to 5 Hz. The laser pulse was focused to a spot with 11 μm diameter by an off-axis parabolic mirror. The laser power density at the interacting point is $10^{14} \sim 10^{15}$ W/cm^2. The Rayleigh length of laser at interacting point is nearly 1 mm.

RF Resonator

To generate the longitudinal RF electric field, RF resonator was prepared. The frequency of the resonator is chosen as 53.3MHz, so that the ions with heavy masses com-

LOADING OF A PLASMA-WAKEFIELD ACCELERATOR SECTION DRIVEN BY A SELF-MODULATED PROTON BUNCH

V. K. Berglyd Olsen*, E. Adli, University of Oslo, Norway
P. Muggli, Max Planck Institute for Physics, Munich, Germany
L. D. Amorim, J. M. Vieira, Instituto Superior Technico, Lisbon, Portugal

Abstract

We investigate beam loading of a plasma wake driven by a self-modulated proton beam using particle-in-cell simulations for phase III of the AWAKE project. We address the case of injection after the proton beam has already experienced self-modulation in a previous plasma. Optimal parameters for the injected electron bunch in terms of initial beam energy and beam charge density are investigated and evaluated in terms of witness bunch energy and energy spread. An approximate modulated proton beam is emulated in order to reduce computation time in these simulations.

INTRODUCTION

The AWAKE experiment [1] is a proof-of-principle demonstration of acceleration of an electron bunch to the TeV energy range in a single plasma section, using a proton bunch driver [2].

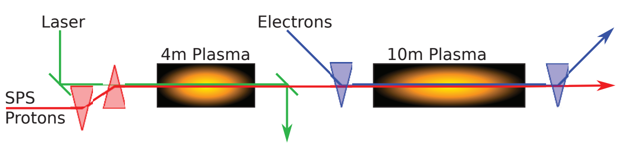

Figure 1: Simplified set-up of AWAKE Phase III. A long proton bunch experiences the SMI in a short plasma cell. The electron bunch is injected before the second plasma cell.

The AWAKE experiment proposes using a proton driver at 400 GeV, delivered by the SPS. The experiment is currently under construction at CERN, scheduled to start in late 2016. The SPS proton bunch is too long to generate a sufficiently strong wakefield [3]. A usable drive bunch needs to be close to the plasma wavelength λ_p in length; however, producing a short enough proton bunch is technically difficult.

The plasma wavelength and frequency are given by

$$\lambda_p = \frac{2\pi c}{\omega_p}, \quad \omega_p = \sqrt{\frac{N_p e^2}{m_e \varepsilon_0}}, \tag{1}$$

where N_p is the plasma electron density, e is the elementary charge, m_e is the electron mass and ε_0 is the vacuum permittivity.

A proton bunch with $\sigma_{z,0} k_p \gg 1$, where $\sigma_{z,0}$ is the initial length of the bunch, will under certain conditions develop a self-modulation instability (SMI) when it travels through a plasma [4]. The proton bunch will then develop into a train of micro bunches with a period on the order of λ_p.

In phase I of the AWAKE experiment the SMI of the proton bunch will be studied. In phase II, the proton wake will be studied using a long, externally injected electron bunch that will sample all phases of the wake. In phase III, acceleration of a short bunch in the wake of an already self-modulated proton beam will be studied, as illustrated in Fig. 1. In this paper we study the beam quality of a short electron bunch accelerated by an SMI proton wake in preparation for phase III of AWAKE.

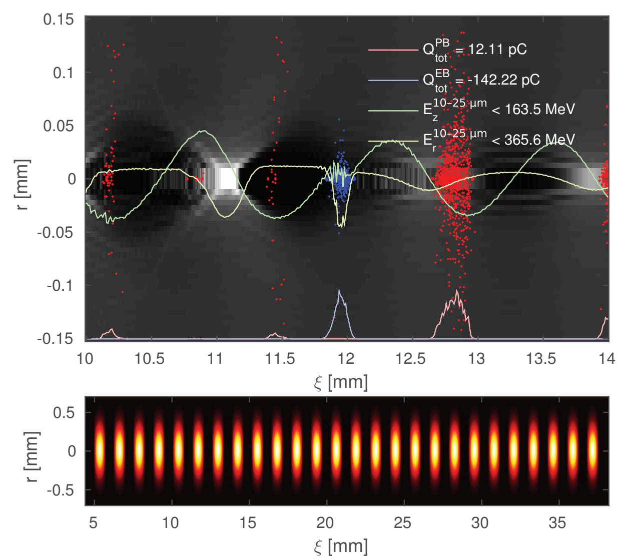

Figure 2: **Top:** An example showing the structure of the plasma electrons (grey) with a projection of the proton beam (red) and the electron bunch (blue) density on the bottom. The E_z (green) and E_r (yellow) fields have been overlayed on the plot. Shown is also a sample of electron (blue) and proton (red) macro particles. **Bottom:** An example of a pre-modulated proton drive beam at $t = 0$ plotted in terms of charge density.

SIMULATION SET-UP

All simulations in this paper have been performed using OSIRIS, a three-dimensional, relativistic, particle-in-cell code for modelling plasma based accelerators [5].

The parameter scans presented have all been run on a small scale test case with a shorter proton drive beam than AWAKE specifications. We simulate here only the second plasma stage in Fig. 1, assuming a pre-modulated proton beam profile with charge density function

$$\rho_{p^+}(\xi) = A\left[\frac{1}{2\sqrt{2}} + \cos\left(k_p\xi - \mu_1\right)\right] e^{-r^2/2\sigma_r}, \tag{2}$$

GAS FLOW INFLUENCE ON NEGATIVE HYDROGEN ION GENERATION WITHIN THE MICROWAVE-DRIVEN NEGATIVE ION SOURCE*

Shixiang Peng#, Yuan Xu, Zhang Tao, Haitao Ren, Jingfeng Zhang, Jie Zhao, Zhiyu Guo and Jia'er Chen,
SKLNPT & IHIP, School of Physics, Peking University, Beijing 100871, China
Ailin Zhang, School of Physics, UCAS, Beijing 100049, China

Abstract

H^- ion was generated through two processes within a volume Cs- free source. The density of molecule hydrogen gas will impact on the electron temperature within the primary discharge chamber that will influence the population of vibrational excited H_2^*. Within the extraction region, the interaction between molecule hydrogen and H^- ion will is cause the dissociation of negative ion. To better understand the gas flow influence on H^- ion generation within a volume negative ion source, a new Cs-free volume microwave-driven H- source body with two gas inlets was developed at Peking University (PKU). Experiment on gas flow and gas pressure distribution within the plasma chamber was carried out with this source body. In the meantime a two dimensional (2D) model for gas flow was developed. Details will be presented in this paper.

INTRODUCTION

The 2.45 GHz electron cyclotron resonance (ECR) ion source has been developed at many labs.[1, 2] This kind of ion source is widely used mainly for high current single charge state positive ions (H^+, D^+, He^+, O^+ etc.) generation which shows great performances in high stability, high reliability, easy maintenance and long lifetime. Recently, reliable negative hydrogen ion sources are also demanded in many high current facilities because H^- ion has significant advantages in beam transmission or injection into synchrotron. [3] H^- ion source is a kind of ion source which needs a lot of theoretical and experimental work. Among all kinds of H^- ion source, Penning ion source and the volume ion source operating with Cs are regarded as promising candidates, also ECR source is promising to generate H^-.[4] Since 2012, a 2.45 GHz microwave-driven H^- ion source without using Cs was designed at PKU. This ion source was intended to generate more than 10 mA H^- for the injector of SPRESA facility in China at the beginning. [5, 6]. Recently, a 35 mA H^- beam with 10% duty factor and a 16.5mA CW H^- beam at 35 keV have been produced with this source. However, just like Prof. Horst Klein said at 20 ICFA Workshop summary, "The ion sources, and especially the H^- sources, are still somewhat a black magic". [4] Many factors, such as electron density and temperature, molecule hydrogen gas distribution, etc., will influence the generation of H- ions [7]. To better understand the processes within a volume H- source, a series of experiments were carried out on the impaction of gas distribution. A 2D simulation was performance to study the pressure distribution with different inlets. More simulated and experimental results will be reported in this paper.

EXPERIMENT SETUP

Experiment was done on a compact permanent magnets 2.45 GHz microwave- driven Cs- free volume H^- source developed at PKU. The Schematic diagram is plotted in Fig.1. Its outside dimension is Φ116 mm×124 mm. Detail was described in Ref. 8. 2.45 GHz microwave is feed into discharge chamber through three-layer Al_2O_3 microwave window to heat the electrons confined by ECR resonance magnetic field.

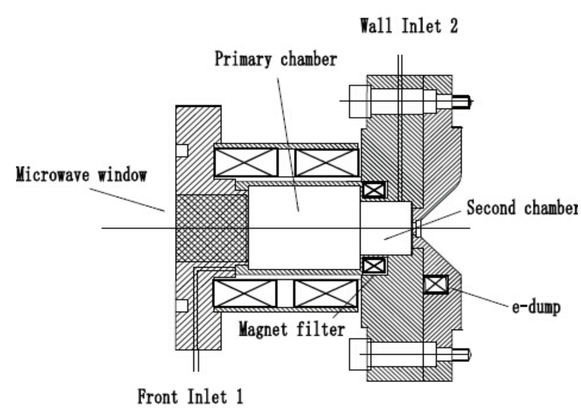

Figure 1: Schematic diagram of microwave-driven negative ion source.

As mention in Ref. 9, two processes will happen within this volume source. First, energetic electrons that heated by microwave will impact with hydrogen molecular to generate amount of vibrationally excited H_2^* in the primary discharge chamber. Then, H_2^* will interact with slow electrons in the second chamber to produce H^- ions. A magnetic filter field, which has a high diffusion constant only for slow electrons (<1 eV), is applied between primary and second discharge chamber to lower the electron temperature in the second chamber and prevent fragile H^- ions from being destructed by fast electrons.

The measurements in Ref. 10 & 11 show that T_e will decrease with operation pressure increasing in ECR ion source because the energy transfer between fast electrons and other particles will be enhanced with higher pressure which means high particle density in the chamber. Therefore, it is important to keep a relative higher pressure in the ion source especially in the second

NUMERICAL SIMULATION ON EMITTANCE GROWTH CAUSED BY ROUGHNESS OF A METALLIC PHOTOCATHODE

Z. Zhang, C. Tang*, Tsinghua University, Beijing 100084, China

Abstract

The roughness of a photocathode could lead to an additional uncorrelated divergence of the emitted electrons and therefore to an increased thermal emittance. The randomness of the real-life photocathode surface makes it unrealistic to perform typical beam dynamics simulation to study the roughness emittance growth. We develope a numerical simulation code based on the point spread function (PSF) and an estimated form of electric field distribution on an arbitrary gently undulating surface to deal with the problem. The simulation result shows that the emittance growth factor is 1.04, which is much smaller than expected (1.5 ~ 2).

INTRODUCTION

Photocathodes are widely integrated in large particle sources. The quantum efficiency (QE) and intrinsic emittance determine the quality of the photocathode. D. Dowell gives formulas [1] to predict the QE and thermal emittance of a metallic smooth surface photocathode by using a simplified three-step model [2]:

$$\mathrm{QE}(\omega) \approx \frac{1-R(\omega)}{1+\dfrac{\lambda_{\mathrm{opt}}}{\lambda_{e-e}(\omega)}} \frac{(\hbar\omega-\phi_{\mathrm{eff}})^2}{8\phi_{\mathrm{eff}}(E_F+\phi_{\mathrm{eff}})}$$

$$\varepsilon_{n,x} = \sigma_x\sqrt{\frac{\hbar\omega-\phi_{\mathrm{eff}}}{3mc^2}}$$

Formula for QE agrees well with the experiments, while the emittance measured by some labs appeared to be two times larger than predicted [3,4]. It's widely believed that the differ between the experiment and analysis is caused by surface roughness of the photocathode.

Typical beam dynamics simulations require the electric field distribution in the simulation region as well as the initial particle samples. However it's hard to acquire on an arbitrary photocathode surface due to the computer memory and CPU limitation.

In this paper, we developed a numerical simulation code based on the point spread function (PSF) and an estimated form of electric field distribution on an arbitrary gently undulating surface to deal with the issues.

PRINCIPLES OF THE SIMULATION

Generation of the Initial Particle Samples

The keypoint of initial samples generation is how one include the emission angle diffusion introduced by the surface roughness, which is also known as "slope effect" [5,6]. This can be done in at least two ways:

1. Employ the similar three-step model as discussed in [1] and use the Monte Carlo method. Considering the emission process as shown in Fig. 1. One photon injected into a gentle slope on the bulk metal photocathode, travelling a distance of s along $-z$ direction, then absorbed by an electron of energy E, went towards surface with a direction angle (θ', ϕ') relative to the normal of the slope (the slope angle is θ) without scattering and finally escaped from the surface.

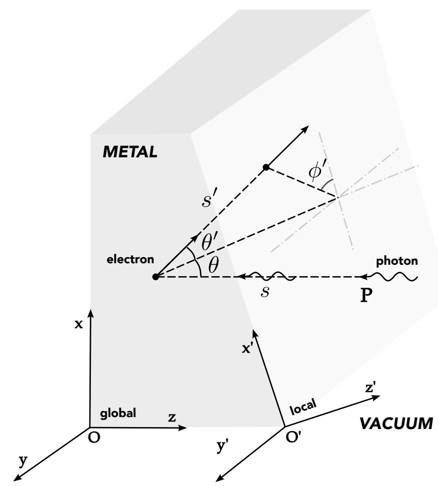

Figure 1: The schematic plot for the bulk photoemission on a part of a rough metallic cathode. The definitions of coordinates and variables are labeled in the plot.

The idea is to generate $s \sim \mathrm{Exp}(\lambda)$, $E \sim U(E_{\mathrm{F}}-\hbar\omega, E_{\mathrm{F}})$, $\theta' \sim U(0,\pi/2)$, $\phi' \sim U(0,2\pi)$, where $1/\lambda = 1/\lambda_{\mathrm{opt}} + 1/\bar{\lambda}_{\mathrm{e\text{-}e}}$, then apply the filter condition $(E+\hbar\omega)\cos^2\theta' \geq \phi_{\mathrm{eff}}$ to eliminate samples that cannot escape. All definitions of the parameters above are in consistence with [1]. However the sampling efficiency of this simple method is very low due to the fact that the QE of metal is usually $\sim 10^{-4}$.

2. Employ the point spread function (PSF) of the photocathode. In general, the PSF describes the response of an imaging system to a point source or point object. For photocathode, the PSF describes the response of a photocathode to a point laser source. With the PSF of photocathode, one could generate the samples without large loss (to be specified, our sampling pass rate is around 1/6, which will be explained later), therefore we choose the second sampling method.

The generalized momentum PSF For typical photoemission on metallic cathode, it's safe to ignore the dependence between electron momentum distribution and incident

A COMPACT MULTIPLY CHARGED ION SOURCE FOR HADRONTHERAPY FACILITY

L. Celona[#], L. Andò, G. Castro, F. Chines, S. Gammino, O. Leonardi, D. Mascali, L. Neri, D. Nicolosi, F. Noto, F. Romano, INFN/LNS, Catania, Italy
G. Ciavola, CNAO Foundation, Milan; INFN/LNS, Catania, Italy
G. Torrisi, INFN/LNS, Catania; Universitá Mediterranea di Reggio Calabria, Reggio Calabria, Italy

Abstract

The ion sources for accelerators devoted to medical applications must provide intense ion beams, with high reproducibility, stability and brightness. AISHa (Advanced Ion Source for Hadrontherapy) is a compact ECRIS whose hybrid magnetic system consists of a permanent Halbach-type hexapole magnet and a set of independently energized superconducting coils. These coils will be enclosed in a compact cryostat with two cryocoolers for LHe-free operation. The microwave injection system has been designed for maximizing the beam quality through a fine frequency tuning within the 17.3-18.4 GHz band which is possible by using an innovative variable frequency klystron. The introduction of an integrated oven will allow the production of metal ions beams with relatively high intensity for light ions. “Accel-decel” extraction system will be used. The LEBT line will consist of a solenoid and a 90° dipole for ions selection. Two diagnostic boxes, made of Faraday cups, beam wires and slits, will allow the characterization the beam. Moreover, a system of scintillating screens and CCD cameras, placed after the solenoid will allow the investigation of the Frequency Tuning Effect (FTE) on the source performances.

INTRODUCTION

The AISHa ion source has been designed by taking into account the typical requirements of hospital-based facilities, where the minimization of the mean time between failures (MTBF) is a key point together with the maintenance operations which should be fast and easy. Therefore, a so called 3rd generation ECR ion source is not suitable, being quite complex for unskilled operators.

The new AISHa source is designed to be an intermediate step between the 2nd generation ECRIS, unable to provide the requested current and/or brightness and the 3rd generation ECRIS, too complex and expensive. It is intended to be a multipurpose device, operating at 18 GHz, in order to achieve higher plasma densities. It should provide enough versatility for future needs of the hadrontherapy, including the ability to run at larger microwave power to produce different species and highly charged ion beams and to be upgraded to higher frequency than 18 GHz. These demands implies also the simplification of all ancillary systems including an oven for metallic ion beams, which permits the production of new beam for hadrontherapy and for other applications. The source characteristics are described in Table 1.

The AISHa source is funded within the framework of the program of Sicilian Government named PO FESR 2007-2013 and a pool of Sicilian SME is associated with INFN for this project. The source is potentially interesting for any hadrontheraphy center using heavy ions.

Table 1: AISHa Source Characteristics

Parameters	Dimension
Radial Field (max)	1.3 T
Axial Field (INJ/MID/EXTR)	2.6 T /0.4 T / 1.7 T
Operating Frequency	18 GHz (TFH)
Operating Power	1.5 kW (1.5 kW)
Extraction Voltage (max)	40 kV
Chamber diameter / length	ø= 92 mm / 357 mm
Warm bore diameter / thickness	274.00 mm / 22 mm
Weight	600 Kg

MECHANICAL DESIGN

The plasma chamber will be stainless steel made and it is designed to operate at a maximum power rate of 2 kW by using a multi-channel water-cooling system. The insulation will be adapted to 40 kV operation by means of a 20 mm thick Glass Fiber/Carbon Fiber tube surrounding the hexapole, keeping superconducting magnets and yoke at ground potential. The movable extraction system will permit to adapt the AISHa source to other facilities (e.g. the high voltage platform for INFN-LNL).

A new type of DC-break has been designed to permit reliable operation up to 50 kV.

The layout of the source is shown in Fig. 1.

In the development of this new source some mechanical improvements have been introduced, in particular for the hexapole containment chamber and for the plasma chamber.

CsK_2Sb GROWTH STUDIES, TOWARDS HIGH QUANTUM EFFICIENCY AND SMOOTH SURFACES*

S. Schubert, H. Padmore, J. Wong, LBNL, Berkeley, CA 94720, USA
Z. Ding, M. Gaowei, E. Muller, J. Sinsheimer, J. Smedley, BNL, Upton, NY 11973, USA
J. Xie, ANL, Lemont, IL 60439, USA
J. Kuehn, HZB, Berlin, Germany

Abstract

The properties of CsK_2Sb, make this material an ideal candidate as photocathode for electron injector use. Producing photocathodes with quantum efficiencies of 5 % and greater at 532 nm poses no challenge, nevertheless the traditional growth mechanisms, which are based on a sequential deposition of Antimony, Potassium and Cesium at a range of temperatures up to 150°C yield a rough surface with a rms roughness in the range of 25 nm, determined by AFM [1]. Surface roughness in this region impacts the emittance. Whereas thermal sequential deposition gives a roughness on the order of the film thickness, for high gradient accelerators, we need a roughness on the order of 1 nm in order to preserve low emittance.

Studies are performed to optimize roughness. Various growth procedures are exploited and the resulting samples' surface roughness compared.

INTRODUCTION

Within the last years multi-alkali-antimonides have been a targeted material for use as photocathode for high brightness, high repetition rate and low emittance injector applications.

Their high quantum efficiency (q.e.) in the visible region and fast response time make alkali-antimonies prime candidates. The group of interest includes K_3Sb, Cs_3Sb and a number of multi-alkali antimonide materials like CsK_2Sb and $(Cs)Na_2KSb$, which exhibit q.e. of >5% at 532 nm wavelength.

These materials have been used in photomultiplier tubes for several decades [2], but little is known about the detailed chemistry of these materials during synthesis. Therefore adapting this technology and transfer it into production of reproducible and reliable photocathodes for the use in photoinjectors are still ongoing.

In an effort to understand the growth procedure and reaction mechanism and finally it's influence on the photocathode behavior, in-situ growth measurements are undertaken.

Nondestructive X-ray measurements are utilized to analyze the growth and morphology of alkali-antimonies. A number of experimental techniques are being used simultaneously. Information about film thickness, roughness, crystallinity and composition are being recorded and complimented by photocurrent (phc) measurements during deposition and spectral response measurements after growth. This paper will give a short comparative analysis on tested growth methods and their resulting surface roughnesses as determined by X-ray reflectivity (XRR) for CsK_2Sb photocathodes.

* Work supported by by U.S. DoE, under KC0407-ALSJNT-I0013, and the German BMBF, Helmholtz-Association and Land Berlin. NSLS was supported by DOE DE-AC02-98CH10886, CHESS is supported by NSF & NIH/NIGMS via NSF DMR-1332208.

EXPERIMENTAL

Wide angle X-ray diffraction (WAXD), X-ray scattering measurements and X-ray fluorescence (XRF) are performed in-situ during growth. After growth measurements include spectral response curves in the range from 200 - 800 nm and X-ray diffraction (XRD) measurement to verify crystallinity and composition of the crystalline phases.

Experiments are carried out at the Cornell High Energy Synchrotron Source (CHESS) at beam line G3, measurements are conducted at photon energies in the range of 9.8 keV to 11.26 keV. Two Pilatus 100K detectors are used to record the X-ray data. A Vortex-detector is positioned approx. 18 cm from the sample recording the fluorescence data. The active range of the detector starts at 2.5 keV, allowing for a reasonable detection of the K signal at 3.3 keV.

The materials are grown in a UHV system with a base pressure of $2{\cdot}10^{-10}$Torr or below. Water and Oxygen partial pressures are in the low 10^{-12} Torr range.

Sb is deposited from PtSb beads and Alkali metals from Alvatec or SAES getter sources. The deposition rate is held around 0.2 Å/s.

The photocurrent is monitored during the growth, a bias voltage of 20 V is applied and using a 5 mW green laser to illuminate the sample.

Further information about the setup can be found elsewhere [3].

The roughness and thickness data presented here are determined by Parratt's recursion, after extracting the XRR intensity from the raw images [4].

Si(100) and MgO(001) are used as substrates. The Si substrates are cleaned in aceton, followed by isopropyl-alcohol and as a last step dipped in HF and stored in DI water until transferred to the UHV system, which could take 10 min - 2 days.

MgO substrates were dipped in DI water. Both materials are blown dry with Nitrogen prior to mounting in the UHV chamber. Then the substrates are heated to 500°C for 1- 5h, after which they are cooled down to the respected deposition temperature.

During deposition the substrate is usually held at 100°C.

CHARACTERIZATION OF LASER-PLASMA ACCELERATED ELECTRON BEAM FOR A COMPACT STORAGE RING*

Seong Hee Park#, Yong-Ho Cha, Young Uk Jeong, Jeongsang Jo, Ha Na Kim, Kyung Nam Kim, Kitae Lee, Woojae Ryu, Jae Sung Shinn, Nikolay Vinokurov[1,2], [1]KAERI, Daejon, Korea, [2]BINP SB RAS, Novosibirsk, Russia

Abstract

A compact radiation source can be utilized by an electron beam from a Laser-plasma acceleration combined with localized shielding in a small laboratory. The stability of synchrotron radiation in wavelength and power depends on the shot-to-shot jitters of the energy and charge of an electron beam, which is strongly influenced by the plasma density of target and the jitters of a laser beam. With the 30 TW fs laser in KAERI, the optimization for generating the electron beam have done using the different shape of gas nozzle. We also present the pointing stability of the laser-accelerated electron beams.

INTRODUCTIONS

Laser-plasma electron acceleration has been attracted for high energy injectors, synchrotron radiation, XFEL, and so on, for a decade. The energy of laser-accelerated electrons is recorded over 4.2 GeV[1] and the energy spread is down to 1%. It is dramatically rapid developments in quality of electron beam generated by laser plasma interaction since the success of quasi-monochromatic electron beam generation in early 2000s. The more stable operation and/or the better quality of electron beams have been developed, the more diverse applications has been suggested and studied.

As like the conventional electron accelerators, there are many applications using it. The property of ultrashort pulse and compactness in radiation shielding can be strong advantages of newly developed applications. We can also consider it as an injector for storage ring such as an ultimate storage ring, which is recently under development to reduce the emittance. In aspect of compactness, we can develop as radiation sources using tens of TW laser system. Tens of TW laser system can be used for the generation of tens to hundreds of MeV electron beams, by either reducing the laser intensity or increasing the interaction length with plasma. We may use simple gas target, capillary discharge plasma, or possibly laser evaporated plasma using metal target.

Usage of metal target has been suggested for a compact storage ring using Laser-accelerated electron beam [2], in order to keep high vacuum inside storage ring. With gas targets, the injector should be separated by thin window to keep high vacuum inside the storage ring. However, laser induced plasma will generate small amount of plasma enough for laser acceleration, even in few mm long plasma density. Under the WCI Program, KERI and KAERI are developing the Laser-induced electron acceleration using the solid target.

To utilize Laser-accelerated electron beam as an injector, more detail studies for reliability are required. The pointing jitter of electron beam is recently done with KAERI 30TW laser system using the gas target. Optimization study of electron beam generation depending on laser and plasma density can apply to the case of solid target except exponentially decreasing plasma density along the vertical direction.

EXPERIMENTAL SET-UP

A 30 TW Ti:sapphire laser system at KAERI has been developed to utilize for laser-induced particle accelerations. Using total pumping energy of 4 J from two 2nd harmonic Nd:YAG lasers, the energy of 1.1 J is achieved with three staged amplifiers. The limitation of laser energy is mainly due to the limited size of gratings presently installed. New set of gratings including the compression chamber should be required to increase the laser power. After compression, the energy at target chamber is 60% of 1.1 J with pulse duration of 25 fs, yielding a 25-TW peak power.

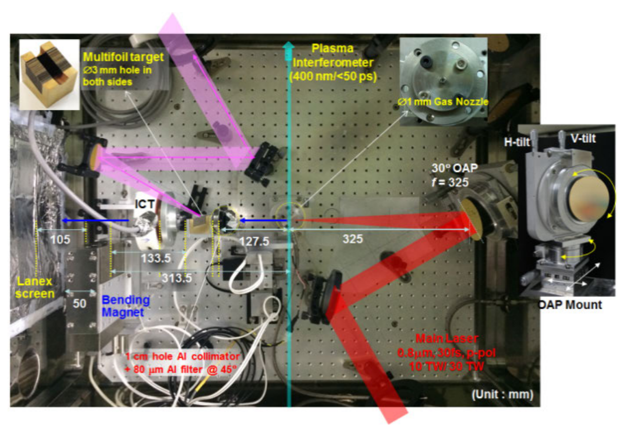

Figure 1: Layout of Experimental set-up

The laser beam was focused on a helium gas jet target using an off-axis parabola (OAP) mirror with a focal length of 326 mm. To vary the size of focal spot and the Rayleigh range, an iris is placed at the entrance to the target chamber and the laser pulse passing through the iris

HIGH-CHARGE-SHORT-BUNCH OPERATION POSSIBILITY AT ARGONNE WAKEFIELD ACCELERATOR FACILITY

Gwanghui Ha, Moohyun Cho, Won Namkung, POSTECH, Pohang, Gyeongbuk 790-784, KOREA
Wei Gai, Kwang-Je Kim, John Gorham Power, Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

The Argonne Wakefield Accelerator (AWA) drive RF photoinjector linac was designed to generate a 75 MeV high charge bunch train of up to 100 nC per bunch. Recently we installed a double dog-leg type emittance exchange beam line and studies are now underway of two options to use a part of this beamline for the bunch compression. In one option, we introduce a chicane and in the other we use a single dog-leg. Simulations have been carried out to find the minimum bunch length for a range of charges (1- 40 nC) and the emittance growth due to coherent synchrotron radiation. We present GPT simulation results to show the high-charge-short-bunch operation possibilities at the AWA facility.

DOWNSTREAM BEAM LINE OF ARGONNE WAKEFIELD ACCELERATOR

The Argonne Wakefield Accelerator (AWA) has two main beam lines that are used to generate a drive beam and a witness beam for the demonstration of two beam acceleration (TBA) [1]. The drive linac consists of an L-band photocathode gun followed by six RF accelerating cavities to generate a 75 MeV beam. The main experimental beamline exits a straight from the dirve linac into two device under test areas with a spectrometer at the end. Recently, we installed a double dog-leg emittance exchange (EEX) beam line that has two identical dog-legs [2].

We are comparing two options for adding a magnetic bunch compressor to the AWA facility (Fig. 1): a chicane vs a dog-leg compressor. The first option, the chicane, adds a dipole to the straight ahead beamline while the second option, the dog-leg compressor, uses the first dog-leg of the EEX beamline. In the rest of paper, we present the results of the bunch compression achieved and the corresponding emittance growth for these beamlines

BUNCH COMPRESSION AND EMITTANCE GROWTH

A strong bunch compression is predominantly limited by the emittance growth in both the chicane and the single dog-leg (path “A” and path “B” in Fig. 1). Our GPT simulations include a 3D space-charge routine [3] and 1D CSR routine [4]. Table 1 shows the parameters of the EEX beam line and the incoming beam parameters at the AWA. The incoming beam energy was varied while the linac phase was changed to control the longitudinal chirp. We simulated incoming charges of {1, 5, 10, 20, 30 and 40 nC} with the gun launch phase set to 50 deg (maximum energy) and a fixed laser pulse length of 8 ps FWHM. These are the nominal operation parameters for the AWA drive gun.

Table 1: Beam Line Specification

Beam line parameters	**Value**	**Unit**
Bending angle	20	deg
Drift length in the dog-leg	2.0	m
Drift length between two dog-leg	1.5	m

Abstract

A program is under development at Argonne National Laboratory to use an emittance exchange (EEX) beamline to perform longitudinal bunch shaping (LBS). The double dog-leg EEX beamline was recently installed at the Argonne Wakefield Accelerator (AWA) and the goals of the proof-of-principle experiment are to demonstrate LBS and characterize its deformations from the ideal shape due to higher-order and collective effects. The LBS beamline at the AWA consists of insert-able transverse masks mounted on an actuator and four quadrupoles (to manipulate the transverse phase space) before the EEX beamline, which consists of two identical dog-legs and a deflecting cavity. The mask and input beam parameters are varied during the experiment to explore the shaping capability and clarify the deformation sources and their mitigation. Progress on the commissioning of the LBS beamline, initial experimental data and benchmarks to GPT [1] simulations will be presented.

EMITTANCE EXCHANGE BEAMLINE AT ARGONNE WAKEFIELD ACCELERATOR FACILITY

The emittance exchange (EEX) is an attractive tool to manipulate the phase space because of its unique characteristics [2]. In the EEX beam line, the entire longitudinal beam properties at the downstream are governed only by the upstream transverse properties. This characteristic can be applied to generate an arbitrary current profile for many applications [3]. The Argonne Wakefield Accelerator (AWA) is planning to demonstrate longitudinal bunch shaping (LBS) using EEX [4,5]. The EEX beam line was installed at the downstream of the AWA drive beam line last year and experiments have started this year. The EEX experiment at the AWA will take place in three stages: (1) EEX demonstration, (2) LBS demonstration, and (3) deformation study. Recently, we successfully finished the stage (1) and we present the experiment results here.

There are several different varieties of EEX beam lines [2,6,7], and the AWA installed the double dog-leg EEX beam line for the initial study. This beam line consists of four rectangular dipole magnets which make two identical dog-legs and one transverse deflecting cavity (TDC) as shown in Fig. 1. The linear transport matrix for the beam coordinate $X = [x, x', z, \delta]$ with $1 + \kappa\eta = 0$ condition is

$$R = \begin{bmatrix} 0 & L_c/3 & \kappa L_s & \eta + \kappa\xi L_s \\ 0 & 0 & \kappa & \kappa\xi \\ \kappa\xi & \eta + \kappa\xi L_s & L_c\kappa^2\xi/6 & L_c^2\kappa^2\xi^2/6 \\ \kappa & \kappa\xi L_s & L_c\kappa^2/6 & L_c\kappa^2\xi/6 \end{bmatrix}, \quad (1)$$

where L_s is $L + L_{bc} + L_c/3$, L is $(2L_b\cos\alpha + L_{bb})/\cos^2\alpha$, η is $(2L_b\cos^2\alpha - 2L_b\cos\alpha - L_{bb}\sin^2\alpha)/(\sin\alpha\cos^2\alpha)$, ξ is $(L_{bb}\sin^3\alpha + 2L_b\sin\alpha - 2\alpha L_b\cos^2\alpha)/(\sin\alpha\cos^2\alpha)$, α is the bending angle, L_b is the length of the dipole magnet, L_{bb} is the distance between dipoles, L_{bc} is the distance between the dipole and the TDC. L_c is the length of the TDC, and $\kappa\,(=\frac{eV}{E}\frac{2\pi}{\lambda})$ is the deflecting cavity kick strength [4,8].

The beam line parameters (Table 1) were chosen to simultaneously insure compatibility with the existing AWA facility and satisfy EEX requirements. The dispersion created by the dog-leg was large enough for the TDC [8]. The charge of the bunch at the entrance of the exchanger was set to 5 nC such that the charge after

BEAM-DRIVEN TERAHERTZ SOURCE BASED ON OPEN ENDED WAVEGUIDE WITH A DIELECTRIC LAYER: RIGOROUS APPROACH*

Sergey N. Galyamin†, Andrey V. Tyukhtin, Aleksandra A. Grigoreva, Viktor V. Vorobev
St. Petersburg State University, Physical Faculty, St. Petersburg, 198504, Russia

Abstract

Terahertz frequency radiation (0.1-10 THz) is a promising tool for a number of scientific and practical applications. One promising scheme to obtain powerful and efficient THz emission is usage of beam-driven dielectric loaded structures [1]. Recently we have considered the problem where the microbunched ultrarelativistic charge exits the open end of a cylindrical waveguide with a dielectric layer and produces THz waves in a form of Cherenkov radiation [2]. To investigate the applicability of utilized approximations, we analyze here the case of orthogonal end of a waveguide with continuous filling. However, presented rigorous approach can be generalized for waveguide with vacuum channel. We use the combination of Wiener-Hopf technique and tailoring technique. The infinite linear system for magnitudes of reflected waveguide modes is obtained and solved numerically. We present typical field distributions over the aperture and typical radiation patterns in the Fraunhofer zone.

THEORY AND ANALYTICAL RESULTS

Convenient rigorous method for investigation of radiation from open-ended plane dielectrically loaded waveguides has been developed several decades ago [3]. Here we generalize this approach for the case of cylindrical geometry. At the current stage, we consider in detail the case of continuous filling, which is relatively simple. In the sequel, we plan to apply the developed technique for layered waveguide.

Consider a semi-infinite cylindrical waveguide with radius a filled with a dielectric ($\varepsilon > 1$) (Fig. 1). We suppose that single TM_{0l} waveguide mode incidents the orthogonal open end (cylindrical frame ρ, φ, z is used):

$$\left\{ H_{\omega\varphi}^{(i)}, E_{\omega\rho}^{(i)} \right\} = \left\{ 1, k_{zl} c (\omega\varepsilon)^{-1} \right\} J_1(\rho j_{0l}/a) e^{i k_{zl} z}, \quad (1)$$

$$E_{\omega z}^{(i)} = N J_0(\rho j_{0l}/a) e^{i k_{zl} z}, \quad N = ic(\omega\varepsilon)^{-1} j_{0l}/a, \quad (2)$$

where $J_0(j_{0l}) = 0$, $k_{zl} = \sqrt{k_0^2 \varepsilon - j_{0l}^2 a^{-2}}$, $\operatorname{Im} k_{zl} > 0$, $k_0 = \omega/c$. The reflected field in the area $z < 0$, $\sqrt{x^2+y^2} = \rho < a$ is decomposed into a series of waveguide modes propagating in opposite direction:

$$E_{\omega z}^{(r)} = \sum\nolimits_{m=1}^{\infty} N_m J_0(\rho j_{0m}/a) e^{-i k_{zm} z}, \quad (3)$$

where N_m are unknown "reflection coefficients" that should be determined. The vacuum area is divided into two subareas (1) and (2) (see Fig. 1), where the field is described by Helmholtz equation:

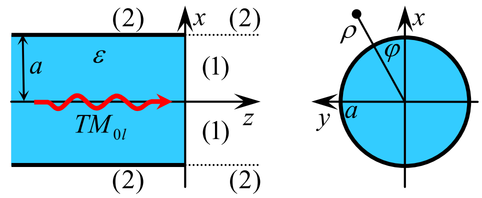

Figure 1: Geometry of the problem.

$$\left(\partial^2/\partial z^2 + \partial^2/\partial\rho^2 + \rho^{-1}\partial/\partial\rho + k_0^2 \right) E_{\omega z}^{(1,2)} = 0. \quad (4)$$

We introduce functions $\Psi_{\pm}(\rho,\alpha)$ (hereafter subscripts $\pm$ mean that function is holomorphic and have no zeros for $\operatorname{Im}\alpha > 0$ and $\operatorname{Im}\alpha < 0$, correspondingly):

$$\Psi_{+}^{(1,2)}(\rho,\alpha) = (2\pi)^{-1} \int_0^{\infty} dz E_{\omega z}^{(1,2)}(\rho,z) e^{i\alpha z}, \quad (5)$$

$$\Psi_{-}^{(2)}(\rho,\alpha) = (2\pi)^{-1} \int_{-\infty}^{0} dz E_{\omega z}^{(2)}(\rho,z) e^{i\alpha z}. \quad (6)$$

From (4) we obtain

$$\left(\frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial}{\partial\rho} + \kappa^2 \right) \left\{ \begin{matrix} \Psi_{+}^{(1)} \\ \Psi_{-}^{(2)} + \Psi_{+}^{(2)} \end{matrix} \right\} = \left\{ \begin{matrix} F^{(1)} \\ 0 \end{matrix} \right\}, \quad (7)$$

$$F^{(1)} = (2\pi)^{-1} \partial E_{\omega z}^{(1)}/\partial z \Big|_{z=+0} - (2\pi)^{-1} i\alpha E_{\omega z}^{(1)} \Big|_{z=+0}, \quad (8)$$

where $\kappa = \sqrt{k_0^2 - \alpha^2}$, $\operatorname{Im}\kappa > 0$. Function $F^{(1)}$ is determined using continuity of $\partial E_{\omega\rho}/\partial\rho \sim \partial E_{\omega z}/\partial z$ and jump of $E_{\omega z}$ at $z = 0$, in the issue we obtain:

$$\Psi_{+}^{(1)} = C_1 J_0(\rho\kappa) + \Psi_p^{(1)}, \quad \Psi_{-}^{(2)} + \Psi_{+}^{(2)} = C_2 H_0^{(1)}(\rho\kappa), \quad (9)$$

$$\Psi_p^{(1)}(\rho,\alpha) = \frac{i}{2\pi} \left[\frac{k_{zl} - \alpha\varepsilon}{\kappa^2 - j_{0l}^2 a^{-2}} J_0\left(\frac{\rho j_{0l}}{a}\right) - \sum_{m=1}^{\infty} N_m \frac{k_{zm} + \alpha\varepsilon}{\kappa^2 - j_{0m}^2 a^{-2}} J_0\left(\frac{\rho j_{0m}}{a}\right) \right], \quad (10)$$

where $C_{1,2}$ are unknown coefficients. Utilizing $E_{\omega z} = 0$ for $\rho = a$, $z < 0$ and continuity of $E_{\omega z}$ and $\partial E_{\omega z}/\partial\rho \sim (\partial^2/\partial z^2 + k_0^2) H_{\omega\varphi}$ for $\rho = a$, $z > 0$, we obtain the following relation

$$\frac{\partial \Psi_{+}^{(2)}(a,\alpha)}{\partial a} = \frac{-\kappa J_1(a\kappa)}{J_0(a\kappa)} \Psi_{+}^{(2)}(a,\alpha) + \frac{\partial \Psi_p^{(1)}(a,\alpha)}{\partial a} \quad (11)$$

and Wiener-Hopf equation for $\Psi_{+}^{(2)}(a,\alpha)$:

MODE TRANSFORMATION IN WAVEGUIDE WITH TRANSVERSAL BOUNDARY BETWEEN VACUUM AND PARTIALLY DIELECTRIC AREA*

A.A. Grigoreva †, A.V. Tyukhtin ‡, T.Yu. Alekhina, S.N. Galyamin,
Saint-Petersburg State University, Physical Faculty, Russia

Abstract

We consider the mode transformation in a circular waveguide with a transversal boundary between a vacuum part and a part with a cylindrical dielectric layer and a vacuum channel. It is assumed that an incident mode can be both propagating and evanescent. Analysis is carried out with the using the mode decomposition technique. Numerical algorithm for calculating the mode transformation at an arbitrary channel radius is also developed. Typical dependences for the reflection and transmission coefficients on the channel radius are presented and discussed.

INTRODUCTION

We study the electromagnetic field in a circular waveguide which consists of two semi infinite parts: one of them has a cylindrical dielectric layer and a vacuum channel, and the other does not have any filling. Such a problem is of interest, for example, for new perspective method of generation of terahertz radiation from an electron bunch in a dielectric loaded structure [1–3]. It is important to consider the field of the bunch flying into the vacuum part of the waveguide. Earlier this problem was considered for the case when the vacuum channel is absent [4, 5]. It is obvious that the principal modifications in the reflected and transmitted fields take place in the presence of the vacuum channel due to the effect of the mode transformation.

Another sample is the wakefield acceleration technique in the dielectric waveguide structures [6, 7]. The generation of the wakefield occurs at some distance after a driver flying into the dielectric part of waveguide. Analysis of process of the wakefield formation is essential for this application. This process is also interesting as well for development of the method of measurement of particle energy with applying the dielectric loaded waveguide [8, 9].

These examples show that both of the problem, when the bunch enters into the partially dielectric area, and the problem, when the bunch flies out of this, are of interest for applications. Such problems can be analyzed by means of an expansion of the incident field into a series of waveguide modes. Here we consider the case of a single incident mode. Note that such a problem statement is conventional in the waveguide theory and has an essential independent importance.

THE CASE OF THE MODE FALLING FROM THE VACUUM PART

First, we assume that the left part of the waveguide ($z < 0$) is filled up with a medium having permittivity ε_c and permeability μ_c. The right part of the waveguide consists of a channel and a dielectric layer described by ε_c, μ_c and ε_d, μ_d respectively (Fig. 1). Initially we assume that media are dissipative that is Im $\varepsilon_{c,d} > 0$ for positive frequencies (these values will be tended to zero at numerical calculations). Both of the media are isotropic, homogeneous and nondispersive. We suppose that the z-axis coincides with the waveguide axis, and the transversal boundary is placed at $z = 0$. The incident field is one of the TM_{0i} mode which can be both propagating and evanescent.

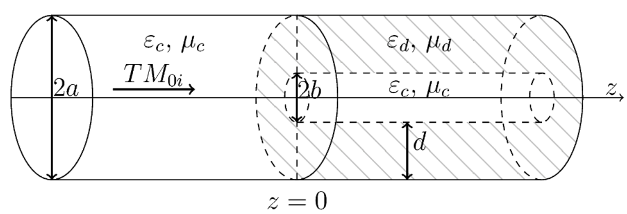

Figure 1: The problem geometry in the case of the mode falling from the vacuum part.

The solution is carried out by cross-linking method. This method presupposes that reflected and transmitted fields are presented as a series of eigenmodes. In order to obtain the equation for the excitation coefficients of the modes of reflected and transmitted fields, we use the continuity conditions for the tangential components of the field at the transversal boundary. After some transformation we obtain a system containing an infinite number of linear algebraic equations. For calculations, we consider the system of finite size. It is possible because the most of the modes are evanescent and they exponentially decrease with the distance from the boarder.

In general case, this matrix system is analytically unsolvable. However, in two dedicated cases (a narrow channel, $b \ll a$, and a thin dielectric layer, $d = (a - b) \ll a$) some approximate results can be obtained.

A Narrow Channel

The approximation for eigenvalues in the dielectric waveguide with a narrow channel ($b \ll a$) can be obtained using the iteration technique. One can see that eigenvalues don't have linear terms. In a similar way, the system of

Abstract

The AWAKE project at CERN is planned to study proton driven plasma wakefield acceleration. The proton beam from the SPS will be used in order to drive wakefields in a 10 m long Rubidium plasma cell. In the first phase of this experiment, scheduled in 2016, the self-modulation of the proton beam in the plasma will be studied in detail, while in the second phase an external electron beam will be injected into the plasma wakefield to probe the acceleration process. The installation of AWAKE in the former CNGS experimental area and the required optics flexibility define the tight boundary conditions to be fulfilled by the electron beam line design. The transport of low energy (10-20 MeV) bunches of $1.25{\cdot}10^9$ electrons and the synchronous copropagation with much higher intensity proton bunches ($3{\cdot}10^{11}$) determines several technological and operational challenges for the magnets and the beam diagnostics. The current status of the electron line layout and the associated equipment are presented in this paper.

INTRODUCTION

The AWAKE project at CERN will be the first experiment world wide to test plasma wakefield acceleration using a high energy (400 GeV) proton drive beam [1]. The first phase in 2016 will be focused on the study of the self-modulation instability of the drive bunch as described in [2]. In the second phase of the AWAKE project in 2017 the plasma wakefields will be probed with an externally injected electron beam.

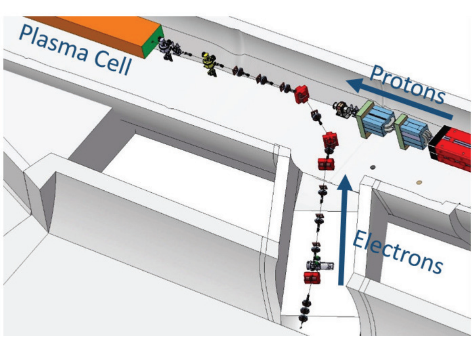

Figure 1: View of the AWAKE electron transfer line.

First studies on the electron transfer line have been presented in [3]. The bunch of $1.2{\cdot}10^9$ electrons will be produced by the PHIN electron gun, which will be recuperated from the CTF3 facility [4] with an output momentum of 5 MeV/c and accelerated to 10-20 MeV/c by a linac booster. The source will be located in a room adjacent to the proton gallery. From there the electron beam will be raised to the height of the proton line, where the two beams will be merged in a common beam line and injected into the plasma following the "on-axis" concept [3]. The general layout of the transfer line is shown in Fig. 1. The baseline parameters of the injected electron beam are summarized in Table 1. With these parameters, the capture efficiency of the electrons in the wakefields has been studied in [5].

Table 1: Electron Beam Parameters

Parameter	Value
Momentum [MeV/c]	10 - 20
Electrons/bunch	$1.2{\cdot}10^9$
Rep. rate [Hz]	10
Bunch length (z) [ps (mm)]	4 (1.2)
Relative momentum spread $\Delta p/p$ [%]	0.5
Emittance (r.m.s. norm.) [mm mrad]	2

ELECTRON BEAM LINE LAYOUT

Following the accelerator of the electron gun, a quadrupole triplet will match the beam into the transfer line. This 15 m long line will consist of three parts. After the matching triplet, two dipoles with a deflection angle of ±18° form an achromatic dog-leg to raise the beam by 1.16 m up to the level of the proton line with a slope of 20%. At this level two horizontal dipoles of ~32° bend the beam towards the proton line. The merging dipole is tilted by 3.2° to match the electron beam axis with the proton one, which has a slope 5.66% in the CNGS tunnel. The final part is the common beam line where the electrons and the protons share the same vacuum chamber and the electrons are focused by an independently powered quadrupole triplet to be captured in the plasma wakefield.

In total eleven quadrupoles will be distributed along the line to control the beta function and the dispersion of the beam. Their evolution along the transfer line is shown in Fig. 2 for the horizontal (x) and vertical (y) plane. The dispersion in y cannot be closed due to the general slope of the proton line and the plasma cell, but still crosses zero at the focal point. With this optics the experimental requirements are fulfilled with a 1σ bunch size at the nominal focal point of 228.1 μm in x and 226.04 μm in y as shown in Table 2.

GENERATION AND RADIATION OF PHz RING-LIKE ELECTRON-PULSE TRAIN

Fu-Han Chao [2], Chia-Hsiang Chen [1,3], Yen-Chieh Huang [1,2], Ping J. Chou[2,3]

[1]Institute of Photonics Technologies/Department of Electrical Engineering, National Tsing Hua University, Hsinchu 30013, Taiwan

[2]Department of Physics, National Tsing Hua University, Hsinchu 30013, Taiwan

[3]National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract

In this paper, we propose a multi-ring structured photocathode to emit a set of longitudinally packed electron rings with a bunching frequency of 1 PHz during particle acceleration. We also present in this paper the beam dynamics and radiation of the structured electron-pulse train.

INTRODUCTION

In an electron radiation device, the constructive interference of the radiation fields from a periodic electron-pulse train [1] can rapidly increase the spectral radiation power at the fundamental or harmonics of the pulse frequency.

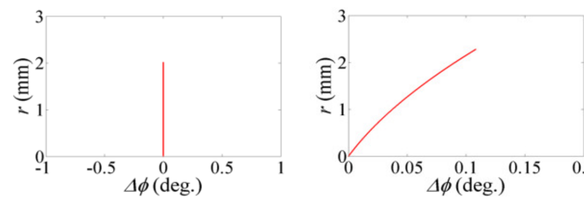
To generate radiation in the EUV or X-ray spectrum, the required pulse frequency of the electron beam should be few tens or even few hundreds of PHz. The repetition rate of electron pulses generated from an ordinary RF photoinjector is usually at 10-100 Hz, which is far below that for efficient EUV or X-ray radiation.

In this paper, we propose a technique to generate a PHz ring-like electron-pulse train from an RF photoinjector with a structured photocathode. Our study using the ASTRA simulation code confirms that a PHz 3-D electron-pulse train can be generated from a photoinjector with an excellent bunching factor [1].

In this paper, we also study the interference of the radiation fields of a 3-D structured electron-pulse train.

BUNCH DISTORTION DURING ACCELERATION

Since the acceleration fields in the RF cavities of a photoinjector or a Linac are radially dependent [2], the transit time of an electron in an accelerator is dependent on its radial position in the accelerator. We have investigated the evolution of ultra-short electron bunches in an RF photoinjector by using the particle tracking codes, PARMELA and ASTRA, and found that the different transit time of the electrons can distort the electron bunch during acceleration [3]. When the space charge effects are insignificant, the transit time of the electron is only influenced by its radial position in the cavity. A delta-function like layer of electrons in the longitudinal direction allows us to exploit the impulse response of the accelerator system for bunch distortion during particle acceleration. Fig. 1(a) shows a delta-function input beam of an RF photoinjector and Fig. 1(b) shows the impulse response at the injector exit simulated by PARMELA, where r is the radial position and $\Delta\phi$ is the acceleration phase of the electron. To plot Fig. 1, the peak acceleration field in the 1.6 cell, S-band photoinjector is 80MeV/m.



(a) (b)

GENERATION AND ACCELERATION OF PHz RING-LIKE ELECTRON-PULSE TRAIN

The impulse response of the accelerator reveals a transverse-to-longitudinal relation of the accelerated electron bunch. With a specified transverse-to-longitudinal relation of particles for an accelerator, it is possible to modulate the longitudinal density of an accelerated electron beam by properly modulating the transverse electron density at the cathode. To reduce the azimuthal bunch distortion resulting from the space charge force, we implement a cylindrically symmetric transverse density modulation for the electrons at cathode. A multi-ring structure can be used for generating such a symmetrically distributed electron bunch, as shown in Fig. 2(a). The transverse bunch profile consists of a set of concentric particle rings laid in the plane of the cathode, as shown in Fig. 2(b). After being accelerated by the radially dependent RF field, the electron rings with different radiuses are separated and become an electron-pulse train in the longitudinal direction, as shown in Fig. 2(c). The longitudinal distances between the accelerated electron rings are affected by the initial radius of and the total charge in each electron ring.

The flux of electrons emitted at the cathode depends on the driver laser power and the material of the cathode. Fabricating a series of concentric metal rings on a dielectric coated cathode or vice versa is a way to spatially modulate the electron density and generate ring-like electron micro-bunches. Such a multi-ring-structured cathode, as shown in Fig. 2(a), can be manufactured by electron beam lithographic patterning. It is possible to

PLANS FOR A LINEAR PAUL TRAP AT RUTHERFORD APPLETON LABORATORY

D.J. Kelliher*, S. Machida, C. Plostinar, C.R. Prior,
STFC Rutherford Appleton Laboratory, ASTeC
S.L. Sheehy,
JAI, Oxford & STFC Rutherford Appleton Laboratory, ASTeC

Abstract

For over a decade, Linear Paul Traps (LPT) have been used in the study of accelerator beam dynamics. LPT studies exploit the similarity of the Hamiltonian with that of a beam in a quadrupole channel while having advantages in the flexibility of parameter choice, compactness and low cost. In collaboration with Hiroshima University, LPT research planned at STFC Rutherford Appleton Laboratory (RAL) in the UK aims to investigate a range of topics including resonance crossing, halo formation, long-term stability studies and space charge effects. Initially, a conventional quadrupole-based LPT will be built at RAL and used for a variety of experiments. In parallel, a design for a more advanced LPT that incorporates higher order multipoles will be pursued and later constructed. This multipole trap will allow non-linear lattice elements to be simulated and so broaden considerably the range of experiments that can be conducted. These will include the investigation of resonance crossing in non-linear lattices, a more detailed study of halo formation and the effect of detuning with amplitude. In this paper we report on progress made in the project to date and future plans.

INTRODUCTION

In a linear Paul trap an rf electric field confines a non-neutral plasma transversely. The quadrupole symmetry of the electrodes focus and defocus the plasma in analogy with a bunch in a FODO channel. Longitudinally the plasma is trapped in a potential well created by applying DC voltages to end cap electrodes. The secular frequency of the plasma, equivalent to the cell tune in an accelerator, can be adjusted by varying either the frequency or voltage applied to the rf electrodes. Following a period of plasma confinement in which an experiment is performed, the plasma is extracted by lowering one of the DC voltages and sent to an external diagnostic.

For over a decade LPTs have been used in the study of accelerator beam dynamics both at Hiroshima University, Japan [1], [2] and at Princeton University, USA [3], [4]. At RAL, plans are advanced for the construction of an LPT based on the S-POD device at Hiroshima. As in S-POD, the device will consist of segmented cylindrical rod electrodes and the plasma (typically Argon) will be ionised in-situ using an electron gun. Diagnostics will include a Faraday cup to measure the total number of ions and an MCP (Multi Channel Plate) screen imaged with a CCD camera (Fig.1).

Although initially a linear quadrupole trap will be constructed, the design should allow for the possibility of installing additional electrodes at a later date in order to add an octopole component. This would allow an investigation of halo formation in which the octopole term plays an important role [5]. It would also facilitate a study of detuning with amplitude during resonance crossing and when on-resonance in an extension of earlier work [6]. A more extensive list of proposed experiments can be found in ref. [7].

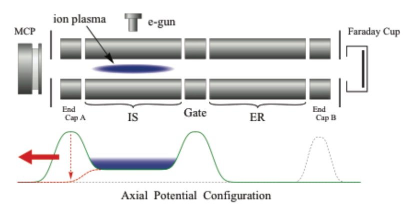

Figure 1: Schematic of S-POD showing the five segments used to create two trapping regions (IS: ion source region, ER: experimental region), and below, the potential well established by the DC voltages. As indicated by the arrows, by lowering the voltage applied to one set of end cap electrodes, the plasma moves towards an external diagnostic. The trap is about 20 cm in length and is operated at 1 MHz. Image courtesy of H. Okamoto and his group.

QUADRUPOLE TRAP DESIGN

Basic Design Parameters

The potential in the transverse plane in a LPT with quadrupole symmetry is given by

$$\Phi(x,y,t) = (U - V_0\cos(ft))\left(\frac{x^2 - y^2}{2r_0^2}\right) \tag{1}$$

where U is the DC potential applied to the end cap electrodes, V_0 is the rf voltage of frequency f and r_0 is the trap radius (i.e the radius that inscribes the trap electrodes). Making the following transformations

$$a_x = a_y = \frac{4qU}{mr_0^2 f^2}$$
$$q_x = -q_y = \frac{2qV_0}{mr_0^2 f^2}$$
$$\xi = ft/2$$

PROGRESS ON THE DESIGN OF THE RACETRACK FFAG DECAY RING FOR NUSTORM

J.-B. Lagrange*, J. Pasternak, Imperial College London, UK
R. B. Appleby, J. M. Garland, H. Owen, S. Tygier,
Cockcroft Institute and Manchester University, UK
Y. Mori, Kyoto University, Japan

Abstract

The neutrino beam produced from muons decaying in a storage ring would be an ideal tool for precise neutrino cross section measurements and search for sterile neutrinos due to its precisely known flavour content and spectrum. In the proposed nuSTORM facility pions would be directly injected into a storage ring, where circulating muon beam would be captured. The racetrack FFAG (Fixed Field Alternating Gradient) option for nuSTORM decay ring offers a very good performance due to a large dynamic and momentum acceptance. Machine parameters, linear optics design, beam dynamics and injection system for nuSTORM FFAG ring are discussed in this paper.

INTRODUCTION

Using a muon decay to produce a neutrino beam with a defined spectrum and flux composition is a well-established idea. This concept was developed into the Neutrino Factory facility proposal, which was then addressed in several dedicated research and development studies culminating in the International Design Study for the Neutrino Factory (IDS-NF) [1]. The Neutrino Factory consists of a high power proton driver, the output of which is directed towards a pion production target; a decay channel, where the muon beam is formed; the muon front end, where the beam is prepared for the acceleration and the muon accelerator to boost the energy to the required value. The muon beam is then injected into the decay ring, one of the straight sections pointing towards near and far detectors and producing ν beams for both interaction and oscillation physics. Although it has been shown that such a facility will be superior in its discovery potential with respect to a conventional neutrino beam facility based on pion decay, it requires the construction of many new accelerator components, which do not exist at present.

In order to allow for the start of neutrino physics experiments based on muon decay using conventional accelerator technology, the neutrinos from STORed Muon beam (nuSTORM) project was proposed [2]. In nuSTORM high energy pions produced at the target are directly injected into the ring after passing through a short transfer line equipped with a chicane to select charge of the beam. Once in the ring, decaying pions will form the muon beam. A fraction of the muon beam with energy lower than the injected parent pions will be stored in the ring and a fraction with similar or larger energy will be extracted with a mirror system of the injection at the end of the long straight section to avoid activation in the arc. They may also be used for accelerator research and development studies for future muon accelerators.

As the flux intensity is one of key elements for a successful neutrino experiment, it is proposed to push the momentum acceptance of the ring to ±8% or even ±16%. Although the design based on the standard accelerator lattice with separated function magnets has been proposed [3], the design based on scaling FFAG lattice is being developed in parallel. The scaling FFAG technology allows to have zero chromaticity with large dynamical acceptance, which enables large momentum spread of the beam with low losses by avoiding the dangerous resonances. This paper describes the update of the racetrack FFAG (RFFAG) ring design for nuSTORM.

RING DESIGN

Triplet Cell in the Straight Section

The RFFAG ring design consists of long straight sections pointing towards neutrino detectors, where the majority of the pions will decay into muons and along which the neutrino beam will be formed firstly from the pion decay and secondly from the muon decay. Both signals can be separated by the detector timing information. The ring contains also compact arcs in order to achieve a large neutrino beam production efficiency minimizing the size of the ring and the associated cost. An RFFAG design was proposed previously [4], but further study of neutrino production from pion decays presented interest in long baseline scenarios. This scenario is incompatible with any scallop of the beam in the production straight. In the previous design, the long straight part of the ring was made of doublet cells, where the beam had a scallop of ±12 mrad for more than 90% of the production straight. This solution can thus no longer be used if long baseline scenario are to be considered. Doublet cells were used in order to minimize the magnet packing factor to limit the cost, and to limit the betatron function beating in the arc. However, a careful choice of straight FFAG triplet can be used to have a similar betatron function beating in the arc, while keeping a low packing factor. A triplet with long drift space has the advantage to allow the beam to be guided without any scallop for most of the production straight, giving possibility to long baseline studies.

THE ALIGNMENT OF THE MICE TRACKER DETECTORS*

M. A. Uchida†, Imperial College London, UK
for the MICE collaboration

Abstract

The Muon Ionization Cooling experiment (MICE) has been designed to demonstrate the reduction of the phase-space volume (cooling) occupied by a muon beam using the ionization-cooling technique. This demonstration will be an important step in establishing the feasibility of muon accelerators for particle physics. The emittance of the beam will be measured before and after the cooling cell using a solenoidal spectrometer. Each spectrometer will be instrumented with a high-precision scintillating-fibre tracking detector (Tracker). The Trackers will be immersed in a uniform magnetic field of 4 T and will measure the normalised emittance reduction with a precision of 0.1%. A thorough knowledge of the alignment of the Trackers is essential for this accuracy to be achieved. The Trackers are aligned: mechanically inside the spectrometer solenoids, with respect to the MICE experimental hall, to one another, and to the magnetic and beam axes. These methods are described here.

INTRODUCTION

The Muon Ionization Cooling Experiment (MICE), in preparation at the Rutherford Appleton Laboratory in the UK, aims to demonstrate ionization cooling for the first time. Ionization cooling is the process of reducing the beam emittance (phase space) while maintaining the longitudinal momentum of the beam. Muons are produced with a large emittance, which must be condensed before acceleration. Muon beams are produced at the front end of a Neutrino Factory (NF) [1] with an emittance of 15–20 mm.rad, which must be reduced to 2–5 mm.rad. A Muon Collider [2] requires further cooling, reducing the emittance to 0.4 mm.rad in the transverse plane, and 1 mm.rad in the longitudinal plane. Due to the short muon lifetime, synchrotron radiation and stochastic cooling techniques are unsuitable for muon beams, and hence ionization cooling is the only process that can efficiently reduce the emittance of a muon beam within its lifetime.

The MICE experiment shown in Figure 1 will pass a muon beam through a low-Z material (absorber), where the muons lose both longitudinal and transverse momentum through ionization energy loss. A proportion of the lost longitudinal momentum is then restored using accelerating RF cavities that follow the absorber. Along with this cooling, however, there is a heating effect produced as a result of multiple scattering through the system, therefore, the net cooling is a balance between these two effects. This is described in Eq. 1, where the first term on the right hand side represents the cooling effect and the second term the heating effect:

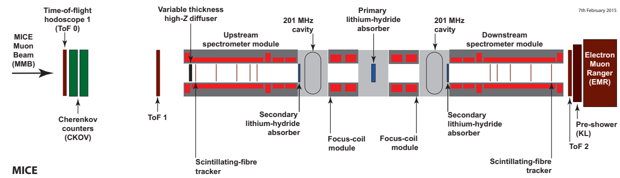

Figure 1: Schematic of the International Muon ionization Cooling Experiment (MICE), with the beam entering from the left.

$$\frac{d\epsilon_n}{ds} \sim -\frac{1}{\beta^2}\left\langle\frac{dE_\mu}{ds}\right\rangle\frac{\epsilon_n}{E_\mu} + \frac{1}{\beta^3}\frac{\beta_\perp(0.014\text{GeV})^2}{2E_\mu m_\mu L_R} \quad (1)$$

$\frac{d\epsilon_n}{ds}$ is the rate of change of normalised-emittance within the absorber; β, E_μ and m_μ the ratio of the muon velocity to the speed of light, muon energy, and mass respectively; $\beta_\perp$ is the lattice betatron function at the absorber; and L_R is the radiation length of the absorber material.

MICE aims to reduce the normalised emittance of the muon beam by a few percent and to measure the reduction with a precision of 0.1%. To do this each muon will be measured individually by an upstream and downstream high precision scintillating fibre tracking detector (Tracker). The Trackers are contained within super-conducting spectrometer solenoids (SSs) which produce a uniform 4 T field. The muon beamline has been commissioned and the beams produced have been shown by direct measurement with MICE particle detectors to be adequate for cooling measurements. The beam was experimentally studied paying particular attention to the rate, particle composition and emittance; the Trackers are built, fully tested, installed and are undergoing commissioning and calibration. MICE is surrounded by a partial return yoke (PRY) so as to minimise any stray magnetic field from the experiment.

MICE Step IV, shown in Figure 2 will begin data taking this year [3]. It will test the full system but without RF cavities to re-accelerate the beam (and will have only one absorber). Step IV can reduce normalised beam emittance but it will not restore longitudinal momentum and so it will not allow for a demonstration of sustainable cooling.

The final stage (see Figure 1), the Demonstration of Ionization Cooling will include the RF cavities and additional absorber modules and its construction is scheduled for completion in 2017.

DEVELOPMENT OF A SPECTROMETER FOR PROTON DRIVEN PLASMA WAKEFIELD ACCELERATED ELECTRONS AT AWAKE

L. Deacon, S. Jolly, F. Keeble, M. Wing*, UCL, London, United Kingdom
B. Biskup†, E. Bravin, A. Petrenko, CERN, Geneva, Switzerland

Abstract

The AWAKE experiment is to be constructed at the CERN Neutrinos to Gran Sasso facility (CNGS). This will be the first experiment to demonstrate proton-driven plasma wakefield acceleration. The 400 GeV proton beam from the CERN SPS will excite a wakefield in a plasma cell several meters in length. To observe the plasma wakefield, electrons of 10–20 MeV will be injected into the wakefield following the head of the proton beam. Simulations indicate that electrons will be accelerated to GeV energies by the plasma wakefield. The AWAKE spectrometer is intended to measure both the peak energy and energy spread of these accelerated electrons. Improvements to the baseline design are presented, with an alternative dipole magnet and quadrupole focussing, with the resulting energy resolution calculated for various scenarios. The signal to background ratio due to the interaction of the SPS protons with upstream beam line components is calculated, and CCD camera location, shielding and light transport are considered.

INTRODUCTION

Proton bunches are the most promising drivers of wakefields to accelerate electrons to the TeV energy scale in a single stage. An experimental program at CERN — the AWAKE experiment [1, 2] — has been launched to study in detail the important physical processes and to demonstrate proton-driven plasma wakefield acceleration.

AWAKE will be the first proton-driven plasma wakefield experiment world-wide and will be installed in the CERN Neutrinos to Gran Sasso facility [3]. An electron witness beam will be injected into the plasma to observe the effects of the proton-driven plasma wakefield: plasma simulations indicate electrons will be accelerated to GeV energies [4]. In order to measure the energy spectrum of the witness electrons, a magnetic spectrometer will be installed downstream of the exit of the plasma cell. The design of the spectrometer was outlined in [5]. This paper will present the updated spectrometer design along with estimated energy resolution for various quadrupole and magnet settings.

SPECTROMETER DESIGN

Dipole Magnet

As a change to the previous design [6], a smaller, lighter and more efficient C-shaped magnet (HB4) was considered as an alternative to the window-shaped dipole (MBPS). The energy measurement uncertainties were also compared (see

* and DESY, Hamburg, Germany and University of Hamburg, Germany
† and Czech Technical University, Prague, Czech Republic

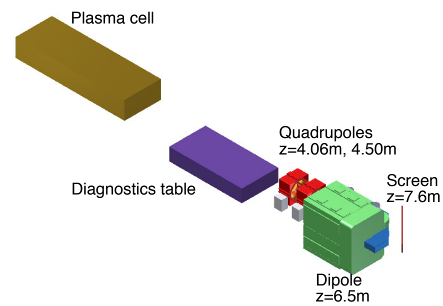

Figure 1: A 3D CAD image of the spectrometer system annotated with distances along the z direction from the exit of the plasma cell to the magnetic centres of magnets, and the centre of the scintillator screen.

Resolution below). It was finally decided to change the design and to use magnet HB4 instead of MBPS since HB4 has sufficient field strength and field width (see Table 1), and similar resolution to MBPS.

Table 1: Comparison Between Window-shaped Dipole MBPS and C-shaped Dipole HB4 [7].

Dipole	MBPS	HB4
Weight	15 t	8.5 t
Power consumption	60 kW	24 kW cycled
Integrated field	1.9 Tm	1.6 T cycled
Max. mag. field	1.65 T	1.5 T cycled
Hor. aper.	52 cm	32 cm
Vert. aper.	11 cm	8 cm
Iron length	1 m	1 m

Field maps and measurements Field measurements have been carried out [7] on the HB4 field at the magnetic centre and the integrated field has been measured along a line parallel to the z-axis running through the magnetic centre. Three dimensional field maps [8] calculated using the OPERA simulation software at various field strengths show agreement with the measurements to within 2-3% (Table 2), with fields calculated for 100 A, 170 A, 540 A and 650 A.

The measurable energy range can be set by changing the magnet current. The simulation results giving the currents and corresponding ranges are shown in Table 3. The magnet current can, of course, be set to intermediate values.

TIME DOMAIN SIMULATIONS OF DETUNED ACCELERATING CAVITIES FOR TWO BEAM APPLICATIONS

L.R. Carver*, R.M. Jones, School of Physics and Astronomy, University of Manchester & The Cockcroft Institute of Science and Technology, Daresbury, UK

Abstract

A multi-harmonic accelerating cavity that has its fundamental and harmonic mode frequency detuned away from the bunch repetition frequency could provide the basis for a beam driven wakefield accelerator with high transformer ratios. The excitation of multiple harmonic eigenmodes will allow high gradients to be achieved without encouraging the onset of rf breakdown or pulsed surface heating. This accelerating cavity will be introduced, and time domain simulations verifying the theory will be shown.

INTRODUCTION

Cavities that have their fundamental accelerating mode frequency detuned away from the bunch repetition frequency could form the basis of a high gradient collinear two beam accelerator structure with high transformer ratios [1]. The field that is excited by the high current drive beam undergoes a phase shift that arises from the detuning, and the cavity can be designed such that the drive bunches are being decelerated by the steady state field. High transformer ratios can be achieved by interleaving the drive beam with a low current test beam, such that the test bunches are being accelerated as they traverse the cavity chain. A cavity of this design would remove the need for the Power Extraction Transfer System (PETS) found in the CLIC design [2].

A multi-harmonic cavity that operates at high gradients could act as an alternative cavity design for CLIC. Cavities of this type have unconventional surface electric and magnetic field profiles that can potentially lower the surface field emission and/or pulsed surface heating without compromising the accelerating gradient [3]. Two particular phenomena found in multi-harmonic cavities provide the main motivation for their use: (a) the anode-cathode effect, which can be found in an asymmetric multi-harmonic cavity that relies on fields pointing into one wall (cathode-like) to be significantly smaller than fields pointing away (anode-like) from the same wall. This effect will raise the work function barrier to supress field and secondary emission, and (b) a reduction in the surface heating by lowering the average $H_{||}^2$ along the surface.

Both of these concepts can be combined to give a cavity that is capable of operating at high gradients with reduced damage from pulsed surface heating, while maintaining high transformer ratios and collinear acceleration. This paper will verify some of the fundamental principles introduced here by time domain simulations. First, the transformer ratio and the surface fields will be verified for a single mode cavity. Then a third harmonic cavity structure will be introduced and similar comparisons presented that show the pulsed surface heating reduction.

SINGLE MODE SIMULATIONS

A three cell π-mode standing wave cavity was designed with a fundamental frequency of 11.7292 GHz and the conductivity of the cavity walls was adjusted to give a quality factor of 500. The field in the cavity is excited by a traversing high current drive bunch, but the field undergoes a phase shift given by [4]

$$\tan\phi = -2Q\delta \tag{1}$$

where Q is the cavity quality factor, $\delta = (f_c - f_d)/f_c$ is the magnitude of the detuning, f_c is the cavity frequency and f_d is the drive bunch repetition frequency. For test bunch offsets of $t = \pi/2$, it emerges that $T = -2Q\delta$. Therefore, when exciting this cavity with a train of bunches with repetition frequency $f_d = 11.9942$ GHz, there is an anticipated transformer ratio $T = 22.59$. It can be shown that when considering the test bunch excited field, the transformer ratio is given by [1]

$$T = \frac{\varsigma - 2Q\delta}{1 + 2Q\delta\varsigma}, \tag{2}$$

where ς is the modified current ratio given by $\varsigma = \Theta_T I_T/\Theta_D I_D$ where $\Theta_{T,D}$ is the transit time factor and $I_{T,D}$ are the currents of the drive and test bunches respectively [5]. Here, both bunches traversing the cavity have $\beta \approx 1$. The cavity was excited by a train of 1 pC bunches with $\sigma_z = 4$ mm using ACE3P [6]. A bunch repetition frequency of 5.9971 GHz was employed (CLIC rf frequency, every other bucket filled) such that a Gaussian distribution of width $5\sigma_z$ did not result in any overlapping in the tails. Field monitors were placed along the cavity axis, and the bunch train continually excited fields in the cavity until steady state was reached. The steady state surface fields were then extracted.

To calculate the transformer ratio of a specific mode, only the fields from that mode should be considered. Therefore, a frequency filter was applied to the E_z field from each field monitor, such that the higher orer modes were excluded. The transformer ratio was calculated by determining the time offset of the drive bunches through the steady state field. The definition $T = \frac{\Delta W_T}{\Delta W_D}$ was used, where $\Delta W_{T,D}$ refers to the energy gained by a test bunch and the energy lost by the drive bunch respectively. The cavity Q and f_c were determined from the E_z profile from the probe at the center of the middle cell. The arrival time of each drive bunch at this probe was calculated and the field that the drive bunch

EMITTANCE GROWTH IN A PLASMA WAKEFIELD ACCELERATOR

O. Mete*, K. Hanahoe, G. Xia, The University of Manchester, Manchester, UK
The Cockcroft Institute, Sci-Tech Daresbury, Warrington, UK
M. Labiche, Nuclear Physics Group, STFC Daresbury Laboratory, Sci-Tech Daresbury, Warrington, UK

Abstract

The interaction of the witness beam with the surrounding plasma particles and wakefields was studied. The implications of the elastic scattering process on beam emittance and, emittance evolution under the focusing and acceleration provided by plasma wakefields were discussed. Simulations results from GEANT4 are presented in this paper.

INTRODUCTION

The next generation of particle physics colliders will need to supplement pp collisions with e^+e^- and ep collisions to deliver precision and to address QCD research needs. Generally each successor collider should push the limits of the energy frontier further.

Plasma accelerators have made tremendous progress in the last few decades since the inception of the idea from Tajima and Dawson [1]. Nowadays, laser wakefield accelerators (LWFA) can achieve MeV-GeV level, electrons through millimetre to centimetre plasma cells [2–6]. Electron beam driven plasma wakefield acceleration (PWFA) has demonstrated energy doubling for an ultra relativistic 42 GeV electron beam in a metre long plasma structure [7]. The accelerating gradients measured in these experiments can be in the range of 10-100 GeV/m, which are 3-4 orders of magnitude larger than that in today's conventional RF-based particle accelerators.

Towards the realisation of a collider scheme based on plasma wakefield acceleration, challenges and issues must be explored.

EMITTANCE GROWTH DUE TO COULOMB SCATTERING

Under the conditions where a beam travels in the vacuum with a constant acceleration, emittance decreases with increasing energy according to the conservation of the area in the phase space given by Louville's theorem. This phenomenon is known as adiabatic damping. However, if the particles in the beam encounter a medium of gas or plasma, emittance diffusion occurs through scattering and competes against the adiabatic damping as suggested in Eq.1 [8];

$$\Delta\epsilon = \frac{F}{2\gamma\prime}\left[\sqrt{\gamma_f} - \sqrt{\gamma_i}\right], \qquad (1)$$

where $\gamma\prime$ is the rate of change of the acceleration, γ_f and γ_i are the final and initial beam energies, respectively. F is written as,

$$F = 2\pi r_e^2 n\left[\frac{-\pi\sigma_0^2 mc^2}{\lambda_p eE_{z0}cos(\phi)}\right]^{1/2} ln\left(\frac{\lambda_D}{R}\right), \qquad (2)$$

where r_e is the classical electron radius, m is the mass of the electron; n is the number of scattering centres, σ_0 is the initial beam size interacting with the scattering medium. The constant accelerating field is given as $E_{z0}sin(\phi)$.

Minimum and maximum scattering angles are determined through uncertainty in the momentum of the incident particle, p, (Eq.3) and the impact parameter, b.

$$\theta = \frac{\Delta p}{p}, \qquad (3)$$

the quantum mechanical limit $\Delta p\, b \geq \hbar$ applies resulting in Eq.4, where $\hbar$ is the reduced Planck constant,

$$\theta_{min,\,max} = \frac{\hbar}{p\, b_{max,min}}. \qquad (4)$$

The maximum impact parameter, b_{max}, comes from the shielding effect of the atomic electrons for a linear plasma wakefield. In a fully ionised plasma this will correspond to the Debye length, shown in Eq.5, where ϵ_0 is the electric permitivity of vacuum, k_B is the Boltzmann constant, T_e is the temperature of the plasma electrons, n_e is the number of electrons in the plasma and e is the charge of an electron:

$$\lambda_D = \sqrt{\frac{\epsilon_0 k_B T_e}{n_e e^2}}. \qquad (5)$$

The Debye length is the distance over which the potential of the nucleus is reduced to $1/e$ of its maximum value within a plasma due to the screening effect of the surrounding plasma electrons. For the nonlinear (bubble or blow-out) regime, where number density of the drive bunch is larger than the plasma, the maximum impact factor corresponds to the radius of the ion cavity [9].

The minimum impact parameter can be related to the effective Coulomb radius of the nucleus, R. The extrema of the scattering angle can be rewritten as in Eq.6.

$$\theta_{min} = \frac{\hbar}{p\lambda_D},\ \theta_{max} = \frac{\hbar}{pR} \qquad (6)$$

MONTE CARLO SIMULATIONS

The above theory can be examined by comparing it with the results from a Monte Carlo code which can simulate the particle-matter interactions such as GEANT4 [10, 11]. A particular scenario was simulated where an electron beam with given parameters, under constant acceleration and focusing, travels through a defined gas column undergoing only elastic Coulomb scattering. An example wake field of a 250 MeV proton drive beam is shown in Fig.1 within the simulation window of a few plasma periods. This result from

Abstract

PARS (Plasma Acceleration Research Station) is an electron beam driven plasma wakefield acceleration test stand proposed for VELA/CLARA facility in Daresbury Laboratory. In order to optimise various operational configurations, 2D numerical studies were performed by using VSIM for a range of parameters such as bunch length, radius, plasma density and positioning of the bunches with respect to each other for the two-beam acceleration scheme. In this paper, some of these numerical studies and considered measurement methods are presented.

INTRODUCTION

PARS experimental station is planned on the soon-to-be-built VELA/CLARA beam line in the Daresbury Laboratories as shown in Fig. 1 [1,2]. PARS will receive an 250 MeV electron beam with a flexible parameter range. This will allow the station to conduct wide range systematic studies on electron driven plasma wakefield acceleration. Program aims to explore single and two-beam operation. The former aims to study maximum achievable accelerating gradient and head-to-tail acceleration with a single electron bunch. Whereas the latter aims to demonstrate the acceleration of a witness or trailing bunch. Numerical studies reported in this paper were performed by using VSim [3].

SINGLE BUNCH ACCELERATION

The maximum achievable accelerating gradient was studied for different bunch length and radius values between 30 − 75 μm and 20 − 100 μm, respectively, considering a 250 MeV electron bunch with a charge of 250 pC. Higher wakefields of 1 − 3 GV/m for a tightly focused drive beam (20μm), and 200 − 300 MV/m for more realistic beam sizes are possible within the bunch length range between 30 − 75 μm (Fig. 2). The achieved field gradient is proportional to the plasma density and after a certain density it scales inversely proportional to the squared bunch length as predicted by the linear theory Eq. 1,

$$E = 240(MV/m)\left(\frac{N}{4\times 10^{10}}\right)\left(\frac{0.6}{\sigma_z(mm)}\right)^2 \qquad (1)$$

* oznur.mete@manchester.ac.uk

where N is the density of background plasma electrons and σ_z is the bunch length. A realistic case of 50 μm bunch length and 100 μm bunch radius which yields 300 MV/m gradient for single bunch propagated 4.5 mm at a plasma density of $5\times 10^{21}\ m^{-3}$ was selected for further studies in this paper.

TWO-BUNCH ACCELERATION

A two-beam scenario was simulated using the baseline case detailed above. A second bunch of same sizes but with a certain fraction of the drive bunch charge was initially placed half a plasma wavelength ($\lambda_p/2$) behind the centre of the driver bunch. The maximum energy gain and the minimum energy spread of the trailing bunch was found to occur between ($\lambda_p/2 - 40$) μm and ($\lambda_p/2 - 20$) μm behind the driver bunch as shown in Fig. 3. The initial two beam configuration shown in Fig. 4(a) was tracked along a 0.5 m long plasma column. Figure4(b) shows the beam profiles evolved after 0.45 m reaching an energy of 315 MeV with a 10% energy spread. Energy spread control is under study through beam loading and bunch profile manipulation. A “fish-bone” structure starts forming in the driver bunch and both bunches are transversely focused where there is no significant bunch length change. 2D field distribution for the two-beam case is given in Fig. 5 with accelerating blue region and decelerating red region. Plasma wakefields consist of co-existing transverse and longitudinal fields as they are induced due to the motion of the plasma electrons in both directions. The transverse field accompanying the above longitudinal field is shown in Fig. 6(a) as a 2D intensity map. The transverse fields generally have a comparable field strength to the longitudinal fields (Fig. 6(b)) and they might act as focusing fields depending on the phase of the trailing bunch.

BEAM LOADING WITH TWO BUNCHES

It has been observed that in the presence of a second bunch the resulting field in the region is modified by the self electromagnetic field of this bunch. This phenomena is similar to the “beam loading” in the RF cavities. The position of the second beam can be adjusted so that the beam loading effect can be used, in favour of the scheme, in a way to reduce the energy spread on the second bunch by adjusting the field gradient across it. Such a scan was performed by moving the trailing bunch around its initial location at $\lambda_p/2$. Effect of the beam loading on controlling the energy

LOW ENERGY BEAM TRACKING UNDER SCATTERING FOR A COLD ELECTRON SOURCE IN MANCHESTER

R.B. Appleby*†, W. Bertsche§, M. Harvey¶, M. Jones, B. Kyle, O. Mete†, A. Murray¶, G. Xia†,
The University of Manchester, Manchester, M13 9PL, United Kingdom

Abstract

High quality electron beams, with high spatial and temporal resolution, have an important use in electron diffraction experiments to probe and study the constituents of matter. A cold electron source is being developed based on electron ionisation from an atom cloud trapped by using AC magneto-optical methods in the University of Manchester. The technique will produce bunches of electrons well suited for high precision and single shot electron diffraction. In this paper issues of modelling at low energies for this state of art electron source with very low energy spread are presented, with a focus on newly developed tools to model the scattering in the meshes used to support the extraction electric fields. The dependence on emittance growth on mesh wire thickness is studied.

INTRODUCTION

Electron diffraction experiments are an integral part of many fields of research, including crystallography, spectroscopy and investigations into chemical bonding. As these fields progress, there is an ever-increasing need for electron beams with better spatial and temporal resolution, requiring investigation into novel methods of increasing beam quality. The AC-MOT, currently being developed at Manchester, promises to deliver low-emittance and low temperature beams through the cooling of the electron source using magneto-optical trapping [1, 2]. It offers advantages over conventional magneto-optical trapping techniques through the AC magnetic field, such that there are no residual fields due to eddy currents persisting after the trapping cycle has ended. As such, the trajectories of electrons extracted from the AC-MOT are unaffected by stray external fields resulting in a more reliable electron source with potentially higher beam quality. We present in this paper newly developed tools to study particle transport and scattering in the Manchester-Cockcroft Institute experiment and show results of simulations conducted to model the extraction process from the AC-MOT. In this work several codes have been employed, namely CST [3], for modelling the experimental region and calculating the electric fields used for electron extraction; General Particle Tracer [4], for simulation of particle trajectories in drift spaces; and Geant4 [5, 6], for determining emittance growth due to scattering. Note that some preliminary calculations have been performed with FLUKA [7] but are not described in this paper. We outline an assessment of the extraction configuration which is being built and make the first look at the impact of mesh scattering on the transported electrons.

EXTRACTION REGION LAYOUT

The atoms in the MOT are ionised and the electrons are extracted using a series of electrostatic electrodes towards the diagnostic section (or later an electron diffraction experiment or injection into a FEL). A full description of the AC-MOT in this experiment can be found in [1]. After passing through the grounded MOT field coils, the electrons pass through three electrodes connected to 5 kV power supplies, which provide the extraction fields. An electrode is constructed of a stainless steel ring covered with a fine mesh, designed to support the fields but allow electron transmission. The three electrodes are followed by the Microchannel Plate (MCP) detector, with its front plate biased at 200 V. The electrode arrangement is shown in Fig. 1.

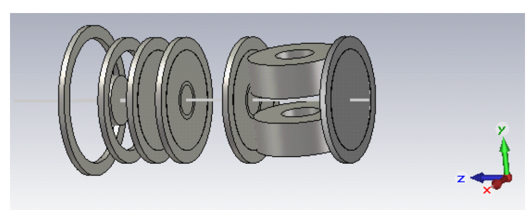

Figure 1: The layout of the extraction region, showing the extraction electrodes.

The need to accelerate and extract the electrons before the bunch is rapidly expanded by space-charge forces means the extraction voltages need to be high. The MOT coils are grounded and the voltage plates are positioned to provide a strong electric field over the MOT region and subsequent transport of the electrons towards the MCP is performed in a drift region delimited by the first and second electrodes, both held at 5 kV. A third plate very close to the second plate is held at 2 kV and provides a retarding electric field to slow the electrons down in a short time before the MCP to provide optimum MCP efficiency. The fast extraction configuration gives a strong field across the MOT, resulting in a larger energy spread than the penetrating field configuration described in [2]. Figure 2 shows the voltages applied to the plates and the resulting potential, computed using the electrostatic modelling tools of CST-Microwave Studio [3].

INVESTIGATIONS INTO DIELECTRIC LASER-DRIVEN ACCELERATORS USING THE CST AND VSIM SIMULATION CODES*

Y. Wei#, C.P. Welsch, Cockcroft Institute and University of Liverpool, UK
G. Xia, O. Mete, K. Hanahoe, Cockcroft Institute and University of Manchester, UK
J.D.A. Smith, Tech-X UK Ltd, Sci-Tech Daresbury, Warrington, UK

Abstract

Dielectric laser-driven accelerators (DLAs) based on gratings structures have received a lot of interests due to its high acceleration gradient up to GV/m and mature lithographic techniques for fabrication. This paper presents detailed numerical studies into the acceleration of relativistic and non-relativistic electrons in double gratings silica structures. The optimization of these structures with regards to maximum acceleration efficiency for different spatial harmonics is discussed. Simulations were carried out using the commercial CST and VSim simulation codes and results from both codes are shown in comparison.

INTRODUCTION

Dielectric laser-driven accelerators (DLA) have good potential to become a strong candidate for future electron accelerators. Due to a higher damage threshold than metals, these dielectric microstructures can support accelerating fields higher than what can be achieved in conventional accelerators. This can increase the acceleration gradients up to GV/m. An experiment has successfully demonstrated acceleration of relativistic electrons with an accelerating gradient of 250 MV/m in a fused silica double grating structure [1] and the acceleration of non-relativistic 28 keV electrons with a gradient of 25 MeV/m in a single grating structure was also observed [2].

This paper investigates dielectric laser-driven acceleration of electrons in a double grating structure exploiting the different spatial harmonics excited by the diffraction of the incident laser. The double grating structure was originally proposed by Plettner [3] and is shown in Figure 1. Each grating pillar adds a phase shift with respect to the adjacent vacuum space, which produces a longitudinally periodic oscillating electric field in the centre of the vacuum channel. Optimization studies into these structures by parameter variation studies have already been performed with the aim to increase the acceleration efficiency for highly relativistic electrons [4,5]. Here, we consider also the non-relativistic case where electrons are injected at an energy of 25 keV, corresponding to β=0.3, where β=v/c, v the electron velocity and c the speed of light. Different spatial harmonics were considered using the CST [6] and VSim [7] simulation codes to identify the optimum acceleration efficiency and comparing simulation results.

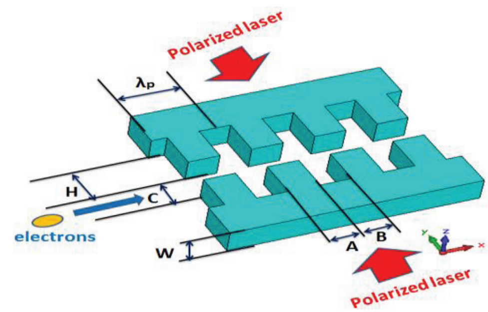

Figure 1. Schematics of a dielectric grating structure.

ACCELERATION OF HIGHLY RELATIVISTIC ELECTRONS

When a double grating structure is driven by two TM polarized laser beams from opposite sides, the diffraction of the incident laser at the grating excites different spatial harmonics which can all be used in principle to accelerate the electrons, see Figure 2.

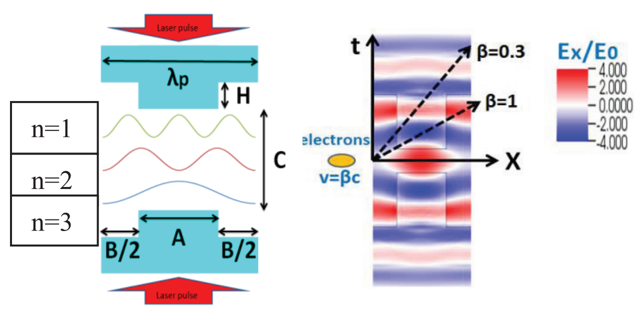

Figure 2. Illustration of the first, second and third spatial harmonics for the case that one grating period is illuminated by laser from two sides.

In the simulations an incoming plane wave with a wavelength of λ_0=1,550 nm was used to excite the grating structure from two sides. Silica (SiO_2, refractive index n=1.528) was chosen as grating material due to its good properties in terms of transparency and field damage threshold. Figure 3 shows the acceleration efficiency for different structure parameters for a grating period of λ_p = 1,550 nm. With an increase of the vacuum channel width C, the acceleration efficiency η gradually decreases, as can be seen in Figure 3(a). Figure 3(b) shows that the maximum acceleration efficiency can be achieved when the pillar height H=0.87λ_p. For further optimization the pillar ratio A/λ_p was varied and Figure 3(c) shows the resulting optimum acceleration efficiency of 0.25 and 0.26 as computed by VSim and CST, respectively.

RF CONDITIONING OF THE PHOTO-CATHODE RF GUN AT THE ADVANCED PHOTON SOURCE – NWA RF MEASUREMENTS*

T.L. Smith, N. DiMonte, A. Nassiri, Y. Sun, A. Zholents
ANL, Argonne, IL 60439, USA

Abstract

A new S-band photo-cathode (PC) gun was recently installed and RF conditioned at the Advanced Photon Source (APS) Injector Test-stand (ITS) at Argonne National Lab (ANL). The APS PC gun is a LCLS type gun fabricated at SLAC [1]. The PC gun was delivered to the APS in October 2013 and installed in the APS ITS in December 2013. At ANL, we developed a new method of fast detection and mitigation of the gun's internal arcs during the RF conditioning process to protect the gun from arc damage and to RF condition more efficiently. Here, we report the results of RF measurements for the PC gun and an Auto-Restart method for high power RF conditioning.

INTRODUCTION

RF measurements performed on the gun at the APS before installation confirmed the measurements made at SLAC before the gun was shipped to ANL. After the gun was fully RF conditioned and photo-electron beam commissioned in the ITS, the gun was baked to improve vacuum and then installed into the APS linac tunnel in August 2014 (Figure 1).

During the PC gun conditioning at the APS, three different protection systems were used to disable RF in order to prevent gun damage that could be caused by sustained or continuous arcing: 1) vacuum pressure interlock, 2) reflected RF power interlock, and 3) arc detector interlock. Arcing is a common phenomenon during RF conditioning and typically it is not required to disable the RF on every single random arc, however, it is prudent to disable the RF on all sustained arcs. A new Auto-Restart method has been developed that limits the number of arcs associated with the PC gun, which is interlocked to both the RF reflected power (~4µs trip) and the arc detector (~3µs trip) systems. During Auto-Restart, both protective systems will shut off RF to the gun every time there is a reflected power or an arc detected. The Auto-Restart scripts will turn the RF back on automatically in < 20ms if it is a single-arc event and not a sustained arc. With the APS linac operating at a maximum of 30 Hz repetition rate, the RF will turn back on easily before the next RF pulse. The Auto-Restart system is "fail-safe" in that if the Auto-Restart script would quit working, both protective circuits are hard-wire interlocked and the RF would trip off at the next arc event and will remain off.

PC GUN OVERVIEW AND MEASUREMENT RESULTS

The photo-cathode RF gun and its magnets are identical to the LCLS gun system. The 1.6 cell S-band RF gun has dual RF feeds to mitigate the dipole field [1]. The basic requirements from the RF gun design include ~15MHz mode separation between the zero and π modes, 120 MV/m accelerating gradient on axis, and a cavity quality factor Q0 > 11500 [2]. The gun and focusing magnets are critical in order to generate high-brightness beams. After gun conditioning in the ITS, the gun and the solenoid assembly were baked for five days at 150ºC in order to improve the gun base pressure. The PC gun and its beam line components were installed in the APS linac tunnel in August 2014 after completion of the bake. The vacuum conditions of the PC gun after linac installation are gun cathode cell (cold cathode gauge) = 7 x 10^{-9} Torr and gun waveguide = 2 x 10^{-10} Torr.

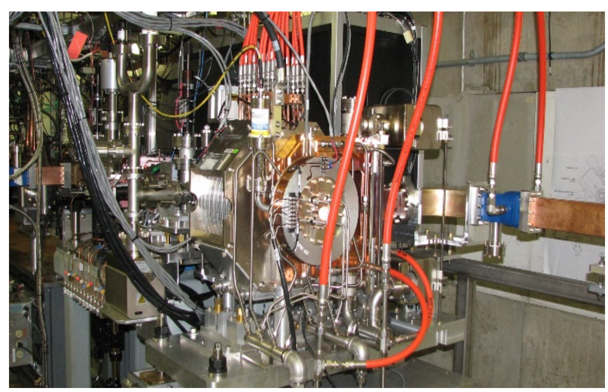

Figure 1: PC Gun Installed in the APS Linac Tunnel.

Initial network analyzer measurements were completed at SLAC, including bead drop measurements. Upon receiving the gun at the APS, RF measurements were performed using a closed water system to control the gun temperature such that the π-mode frequency was set to 2856.0 MHz. Resonant frequencies of the zero and π modes, quality factors, and coupling coefficients were made using a network analyzer. The gun body temperature was varied by ± 4ºC and the above measurements were repeated.

Unloaded Q, External Q and Loaded Q were measured using the Impedance Method [3]. To characterize the PC gun before installation, the following measurements were performed (see Table 1).

Abstract

The Micro-Accelerator Platform (MAP), an optical-scale dielectric laser accelerator (DLA) based on a planar resonant structure that was developed at UCLA, has been tested experimentally. Successful acceleration was observed after a series of experimental runs at SLAC's NLCTA facility, in which the input laser power was well below the predicted breakdown limit. Though acceleration gradients were modest (<50 MeV/m), these are the first proof-of-principle results for a resonant DLA structure. We present more detailed results and some implications for future work.

INTRODUCTION

Dielectric Laser Accelerators (DLAs) have the potential to operate with high (~GV/m) acceleration gradients, and represent a path toward extremely compact colliders and industrial accelerator technology [1]. DLA devices are optical-scale microstructures that can be fabricated on wafers via methods developed for the microchip industry, and powered using fiber lasers, which afford very high repetition rates in compact packages. These devices are naturally suited to a novel length and time scale, producing sub-fs, sub-μm and sub-pC bunches at MHz repetition rates.

Experimentally, advanced accelerators are at the proof-of-principle stage [2], with performance metrics including total energy gain, maximum acceleration gradient, and peak field strength. We report here on a series of experimental tests of the Micro-Accelerator Platform (MAP), a resonant DLA based on a slab-symmetric structure. As a resonant (rather than near-field) device, the MAP is distinct from other DLAs [1].

STRUCTURE AND FABRICATION

Theoretical analysis and many fabrication details of the MAP have been described in previous work [3,4]. In brief, the MAP is a slab-symmetric (planar) resonant structure constructed from a pair of partial Bragg reflectors (DBRs), which surround an accelerating gap. Laser power is coupled into the structure through a transmissive diffraction grating placed atop one of the surfaces, which serves to enforce a synchronous accelerating mode within the gap.

Potential dielectric materials used for fabrication are limited to a small class of oxides having high breakdown thresholds, high transparency, and good uniformity. The MAP is constructed on a fused silica substrate, with the DBRs made from alternating layers of hafnia and zirconia for maximum contrast. The MAP structures as built measured 1.0 ± 0.1 mm in length and 1.00 ± 0.01 mm in thickness, with a transverse area of 3.3 mm, comprising 1250 optical periods.

An error tolerance budget was established via simulation, tracking mode quality and resonant frequency shift. The main tolerance constraint is not the mode quality itself, but the need to maintain the resonant frequency within 25 THz. The most restrictive tolerances, on the boundary layers in the Bragg reflectors, are on the order of ±1 nm; and are at state-of-the-art, for many processes.

In practice, dozens to hundreds of half-structures were fabricated at once, diced, then bonded in pairs. Each structure was checked for quality both visually and optically. We note that bonding the structure halves, and determining the exact gap height, are significant technological challenges.

PROTON INJECTION INTO THE FERMILAB INTEGRABLE OPTICS TEST ACCELERATOR (IOTA)*

E.J. Prebys, S. Antipov, H. Piekarz, A. Valishev, Fermilab, Batavia, IL 60510, USA

Abstract

The Integrable Optics Test Accelerator (IOTA) is an experimental synchrotron being built at Fermilab to test the concept of non-linear "integrable optics". These optics are based on a lattice including non-linear elements that satisfies particular conditions on the Hamiltonian. The resulting particle motion is predicted to be stable but without a unique tune. The system is therefore insensitive to resonant instabilities and can in principle store very intense beams, with space charge tune shifts larger than those which are possible in conventional linear synchrotrons. The ring will initially be tested with pencil electron beams, but this poster describes the ultimate plan to install a 2.5 MeV RFQ to inject protons, which will produce tune shifts on the order of unity. Technical details will be presented, as well as simulations of protons in the ring.

INTRODUCTION

Table 1: HINS Parameters for IOTA

Parameter	Value	Unit
Particle type	proton	-
Kinetic Energy	2.5	MeV
Momentum	68.5	MeV/c
β	.073	-
Rigidity	.23	T-m
RF structure	325	MHz
Current	8	mA
Circumference	39.97	m
Total Protons	9.1×10^{10}	-
RMS Emittance (un-normalized)	4	π-mm-mrad
Tune shift	-.51$\times B$	-
Pulse rate	<1	Hz
Pulse length	1.77	μsec

All particle optics to date have been based on linear magnetic systems of quadrupoles and dipoles. Higher order multipoles are treated perturbatively, and generally lead to instabilities if they are large enough. It has long been known that very specific conditions can produce stable orbits in non-linear magnetic systems [1] [2]; however, it was not until fairly recently that specific magnetic lattices were proposed that satisfy these conditions [3]. Such systems have stable orbits, but not unique tunes. They are therefore extremely insensitive to harmonic instabilities, thereby allowing the storage of beams with intensitities beyond those which would otherwise be limited by space charge tune shift.

* Work supported by the United States Department of Energy under Contract No. DE-AC02-07CH11359

The Integrable Optics Test Accelerator (IOTA) at Fermilab is being built to test this concept, and is described in detail elsewhere [4]. Initial tests will use a 150 MeV electron beam from the Advanced Superconducting Test Acceleratator (ASTA) facility at Fermilab [6]. By varying initial conditions, this electron beam can be used to probe the optical space of the ring; however, since the space charge effects on the electron beam will be negligible, it will not serve as a direct test of the inherent stability.

As a next step, we therefore plan to reuse the 2.5 MeV RFQ, which was built for Fermilab's High Intensity Neutrino Source (HINS) program [5]. This RFQ became available when the lab chose to focus instead on a CW ion source for its high intensity program.

DESIGN

IOTA

Figure 1 shows the IOTA ring. The ring is essentially an ordinary lattice with two straight sections to accommodate the non-linear elements for the proposed optical tests. A straight section is also provided for optical stochastic cooling tests, which are separate from the non-linear optics program.

Initial tests of the IOTA ring will use the 150 MeV electron beam from the ASTA test facility. This facility was built primarily to test 1.3 GHz cryomodules, of the sort that could be used for a linear electron collider. It is also used to support an electon-based R&D program. In the figure, the elecron beam is seen entering from the upper left. A system of dipoles can selectively direct the electron beam to the IOTA ring, a beam dump, or potentially other electron experiments.

Because space charge is not an issue for an electron beam of this energy, the non-linear optics will be probed by varying the initial position and trajectory of the beam and observing the orbit.

HINS RFQ

The High Intensity Neutrino Source (HINS) program began as R&D to develop the front end of an 8 GeV proton linac, which was being considered as an upgrade the the Fermilab accelerator complex (the so-called "Project X") [7]. To this end, a 2.5 MeV RFQ was built, with the goal of producing a beam up to several mA, with a duty factor of 1%. This was followed by a bunching cavity and a series of spoke resonators, with the goal of ultimately accelerating the beam to 10 MeV.

The source consists of a 50 kV filament proton source, capable of delivering 8 mA. The RFQ itself is a four vane

THE SINUOUS TARGET

R. Zwaska, FNAL, Batavia, IL 60510, USA

Abstract

We report on the concept for a target material comprised of a multitude of interlaced wires of small dimension. This target material concept is primarily directed at high-power neutrino targets where the thermal shock is large due to small beam sizes and short durations; it also has applications to other high-power targets, particularly where the energy deposition is great or a high surface area is preferred. This approach ameliorates the problem of thermal shock by engineering a material with high strength on the micro-scale, but a very low modulus of elasticity on the meso-scale. The low modulus of elasticity is achieved by constructing the material of spring-like wire segments much smaller than the beam dimension. The intrinsic bends of the wires will allow them to absorb the strain of thermal shock with minimal stress. Furthermore, the interlaced nature of the wires provides containment of any segment that might become loose. We will discuss the progress on studies of analogue materials and fabrication techniques for sinuous target materials.

INTRODUCTION

We propose to generate a new, engineered material for use in high-power accelerator targets. This material will be composed of a multitude of interlaced wires, or rills, of small dimension. The rills will be made of a thermal-shock resistant material, but will not be subject to stress accumulation due to their small size. The intrinsic bends of the wires will allow them to absorb the strain of thermal shock with minimal stress. The solid bulk of this material will have a dramatically reduced modulus of elasticity than the bare material, greatly improving its resistance to thermal shock. Furthermore, the interlaced nature of the wires provides containment of any segment that might become loose.

This material could accommodate dramatically higher beam powers without breaking itself to pieces because it is strong on the micro-scale, but resilient and flexible on the meso-scale. The challenges will be fabricating this material and devising a cooling scheme.

BACKGROUND

A high-power target is an integral part of a neutrino beam, muon beam, and areas outside HEP such as neutron and rare isotope sources. The target rests in the center of the entire facility; it is within the target that the majority of the transformation occurs from an intense proton (or other species) beam produced by the accelerator, to a beam of unstable or rare particles suitable for experimentation. The target is a singular item, being small on the scale of other beam components. Yet, it bears the brunt of thermal, mechanical, and radiation effects [1].

Intense beam facilities operate targets at the edge of their capability [2]. Frequently, the intensity of a facility is limited by the target, or compromises are made in efficiency to make the target more survivable. Extending the capability of targets is central to building the next generations of all these facilities.

The key novelty of the sinuous approach is to engineer a material's properties to make it more survivable. We capitalize on a counter-intuitive fact: a stronger material is often inferior as a target material.

The actual factor we are interested in is the stiffness of the material which often goes hand-in-hand with strength. Particularly, we are concerned with a material's modulus of elasticity (or bulk or Young's modulus). This factor is crucial as it is what causes material to break under the influence of beam (short of melting). As a beam passes through the material, its energy deposition is thermalized producing a very rapid temperature rise correlated to the spatial intensity of the beam. The beam necessarily has a non-uniform profile, leading to uneven heating of the material. The material will attempt to expand at a local level in response to the heat, but cooler areas will resist this change. The difference in expansions must be equalized through the application of stress to compress or expand the material. That stress, S, is directly correlated to the length difference to be corrected (strain, ϵ) and the bulk modulus, K: $S = K \times \epsilon$. If this stress exceeds the yield strength of the material, it will start to fail. This is a predominant design requirement for targets and other significant mechanical components. Figures of merit have been designed using these and other parameters to evaluate the suitability of various target materials [3].

Unfortunately, for most materials strength is directly proportional to the bulk modulus: a strong material will be stiff. We desire a material with high intrinsic strength on the micro-scale, but very flexible: having a low bulk modulus. The most straightforward way to achieve this is to make the material into a spring. Then, to build a bulk, these springs can be overlaid and combined to build up a material that is nearly uniform on the meso-scale of the proton beam. The temperature-induced strain on this material will be negligible to its ability to expand, and strains will be non-existent.

There are further advantages of the small scale of the primary material. The cross-section will be so small that the heating will be uniform on the length scales of the material, so it will simply expand uniformly at the micro-scale. Stress waves will be inhibited as they also depend on non-uniform heating and propagation through a bulk: any waves would simply travel along the wires. The material can also be made more resistant to radiation damage effects as the lattice dislocations in a material attempt to migrate through the bulk until reaching a grain boundary, and further to the exterior of the material. As this material will be much smaller, the

Abstract

Muon-based accelerators have the potential to enable facilities at both the Intensity and the Energy Frontiers. Muon storage rings can serve as high precision neutrino sources, and a muon collider is an ideal technology for a TeV or multi-TeV collider. Progress in muon accelerator designs has advanced steadily in recent years. In regard to 6D muon cooling, detailed and realistic designs now exist that provide more than 5 order-of-magnitude emittance reduction. Furthermore, detector performance studies indicate that with suitable pixelation and timing resolution, backgrounds in the collider detectors can be significantly reduced thus enabling high quality physics results. Thanks to these and other advances in design & simulation of muon systems, technology development, and systems demonstrations, muon storage-ring-based neutrino sources and a muon collider appear more feasible than ever before. A muon collider is now arguably among the most compelling approaches to a multi-TeV lepton collider. This paper summarizes the current status of design concepts for muon-based accelerators for neutrino factories and a muon collider.

INTRODUCTION

It has been more than 3 decades since muon colliders and muon storage rings were proposed [1-3]. Interest in muon colliders increased significantly following the observation that ionization cooling could be used to rapidly cool muon beams. Several workshops were held in the 1980s and 1990s, and in 1997 the Muon Collider Collaboration was formed, which later became the Neutrino Factory and Muon Collider Collaboration (NFMCC). By the late 1990's muon collider and neutrino factory design efforts were well-established worldwide. In 2007 the International Design Study for a Neutrino Factory (IDS-NF) was initiated. In 2011, muon R&D in the United States was consolidated into a single entity, the Muon Accelerator Program (MAP) [4].

The purpose of MAP is to perform R&D in muon accelerator technologies and to perform design & simulation to demonstrate the *feasibility* of concepts for neutrino factories and muon colliders. In the short time that MAP has existed there have been many accomplishments that have significantly changed our understanding of technology limits and design concepts for muon accelerators.

Particularly noteworthy is the situation regarding RF breakdown in magnetic fields, as is needed in ionization cooling systems. At the time MAP was initiated there was significant concern that RF cavities could not operate at sufficiently high magnetic fields while maintaining high gradients. Under MAP this phenomena has been understood and several solutions demonstrated. Careful cavity design has been shown to limit gradient loss with increasing magnetic field. Beryllium has been shown to have almost no damage due to breakdown compared with copper. Experiments at the Fermilab MuCool Test Area (MTA) have demonstrated that using cavities filled with high-pressure gas can prevent this breakdown, and that this is a viable technology for muon cooling systems [5].

Under MAP design studies have been carried out hand-in-hand with technology R&D, because for the designs to be credible they need to take account of technology limits. Though MAP has not involved detailed engineering studies, the designs studies have been performed with an awareness of gradient limits, space requirements for hardware, etc.

At this conference, more than 60 papers have been submitted on muon accelerator designs and technologies. Very many of these were submitted by MAP researchers. The following highlights some key accomplishments under MAP in design concepts for muon-based accelerators for neutrino factories and muon colliders.

DESIGN OVERVIEW

The MAP design & simulation effort included neutrino factories (short baseline and long baseline) and muon colliders. The Muon Accelerator Staging Study (MASS) developed a staged approach that bridged the Intensity Frontier and the Energy Frontier [6,7]. An important aspect is that each stage is both a facility for doing physics and an R&D facility for the next stage.

The staging begins with nuSTORM [8], a short-baseline neutrino facility that could be built with existing technology. Experiments done at nuSTORM could settle the sterile neutrino debate, and could provide precise neutrino cross-section measurements needed for long-baseline experiments like DUNE. In nuSTORM, pions would be injected into a decay ring with long straights where they would decay into muons that would be stored, and whose decays would produce a precision neutrino beam. The remaining non-decayed pion beam would be directed at a beam dump that would provide beam to an R&D platform on muon cooling.

RF PLASMA-BASED ION SOURCE MODELING ON UNSTRUCTURED MESHES *

S. A. Veitzer†, Tech-X Corporation, Boulder, CO, 80303 USA
K. R.C. Beckwith, Tech-X Corporation, Boulder, CO, 80303 USA
M. Kundrapu, Tech-X Corporation, Boulder, CO, 80303 USA

Abstract

Ion source performance for accelerators and industrial applications can be improved through detailed numerical modeling and simulation. There are a number of technical complexities with developing robust models, including a natural separation of important time scales (rf, electron and ion motion), inclusion of plasma chemistry, and surface effects such as secondary electron emission and sputtering. Due to these computational requirements, it is typically difficult to simulate ion sources with PIC codes.

An alternative is to use fluid-based codes coupled with electromagnetics in order to model ion sources. These types of models can simulate plasma evolution and rf-driven flows while maintaining good performance. We show here recent results on modeling the H- ion source for the Spallation Neutron Source (SNS) at Oak Ridge National Laboratory (ORNL) using the fluid plasma modeling code USim. We present new meshing capabilities for generating and parallelizing unstructured computational meshes that have increased our parallel code performance and enabled us to model inductively coupled plasmas for long periods of operation.

ION SOURCE MODELING CHALLENGES

Ion sources are used in a large variety of research and industrial applications, including front-end uses for particle accelerators. A large class of sources produce ions through inductive coupling of rf energy with a plasma. For example, the internal antenna H- source currently in use, and the next-generation external antenna source at the Spallation Neutron Source (SNS) are both inductively coupled sources.

Accurate numerical models of ion sources can provide insights into techniques for both predicting source performance, as well as optimizing design features and understanding failure mechanisms and failure mitigation. However, in these kinds of systems there are typically physical processes that are operating on different spatial and temporal scales, which makes developing models that are both accurate and can be executed in a reasonable amount of time difficult. For instance, to explicitly capture the physics of plasma motion, a model must resolve the Debye length of the plasma over device lengths of many tens of cm, and resolve rf frequencies of tens of MHz over many hundreds or thousands of rf periods. In addition, ion motions are thousands of times slower than electron motions due to mass differences. The result is that numerical models require solving coupled equations on large physical domains with a very large number of computational cells, short time steps, and long duration simulations.

Due to the computational requirements, it is typically not possible to execute straight-forward explicit Particle-In-Cell (PIC) models for ion sources. Alternatively, models that ease time step restrictions over PIC models, such as fully implicit PIC models for both fields and particles (e.g. divergence-preserving ADI methods), some electrostatic methods, and fluid models that do not explicitly resolve electron motions, such as various magnetohydrodynamic (MHD) models can give results that are accurate and computationally efficient.

For PIC and fluid models, plasma and particle motions and electromagnetic and hydrodynamic fields are solved for on a computational grid, or mesh, that covers the domain of the simulation. Algorithms to efficiently solve these equations have been developed over the last 50 years and this continues to be an active area of research. Algorithms for solvers differ depending on the kind of mesh that is being used. For instance, on a structured mesh such as a uniform Cartesian mesh, one may employ the Yee algorithm in a Finite Difference Time Domain solver to compute electromagnetic fields to 2^{nd}-order accuracy. However, on an unstructured mesh, where mesh elements are comprised of tetrahedrons and hexahedrons, finite element or finite volume solvers are needed to gain 2^{nd}-order accuracy. Parallel computing, in the form of domain decomposition, is required to be able to model ion sources using any of the types of models described above. This is because in order to resolve the smallest physical processes, models can consist of meshes that have tens of millions of computational cells or more, meaning that the memory required to perform the computations are too large to fit into memory on a single computer, even with multiple cores. Parallel computation on large domain-decomposed meshes can provide sufficient performance in time-domain codes. Coupling distributed parallelism with reduced physical models that do not explicitly follow electron motions make it possible to simulate inductively coupled ion sources accurately while still being computationally efficient enough to perform long timescale simulations in a reasonable amount of wall-clock time.

INTERACTION OF A VOLUMETRIC METAMATERIAL STRUCTURE WITH AN ELECTRON BEAM

X. Lu, M. A. Shapiro, R. J. Temkin, MIT, Cambridge, MA 02139, USA

Abstract

A volumetric metallic metamaterial structure with a cubic unit cell is introduced. The unit cells can naturally fill all of space without additional substrates or waveguides. The structure can support a negative longitudinal electric mode that can couple to an electron beam. The dispersion characteristics of the unit cell are modeled by the effective medium theory with spatial dispersion. The theory also predicts the correct resonant frequencies of the emitted radiation excited by an electron beam traversing the structure. In the wakefield simulations, a backward radiation pattern is observed. The proposed metamaterial can be applied to beam diagnostics and wakefield acceleration.

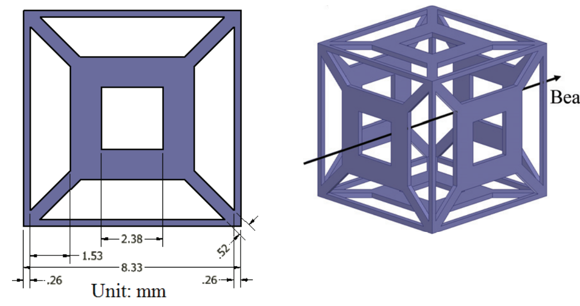
INTRODUCTION

Metamaterials (MTMs) generally refer to subwavelength structures engineered to have exotic electromagnetic features. The resonator type [1] and the transmission line type [2] structures are developed as the negative refractive index MTMs for applications in electromagnetic cloaking, antenna design and microstrip lines, etc. However, the interaction of the MTMs with an electron beam is a new area of research and differs from the study of passive microwave devices where the planar MTM design is often adopted. The planar unit cells, like the split ring resonators, require supporting dielectric substrates, which will suffer from breakdown in the face of high power. Besides, electromagnetic fields are concentrated on the planar plates, so when an electron beam needs to be arranged in the structure, a reasonable spacing must be preserved between the beam and the planar structure, and the decreased field intensity at the beam location restricts the achievement of a large coupling impedance. These difficulties call for the design of a real 3D MTM unit cell. It should fill the space automatically, so we can study the fields in a bulk structure stimulated by the electron beam in a clean environment without the complexity arising from additional substrates or supporting parts.

In this paper, we will present the design of such a 3D MTM unit cell design. We will also introduce an analytical modeling technique, the effective medium theory with spatial dispersion. Radiation features and a possible application for wakefield acceleration will also be discussed.

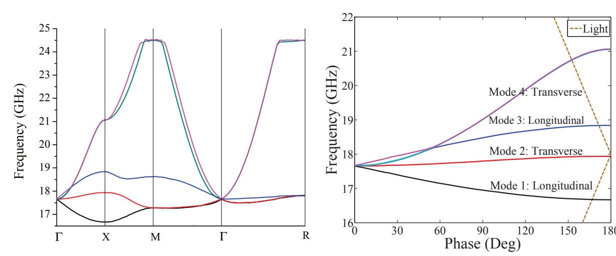
DESIGN AND CHARACTERIZATION OF THE UNIT CELL

The unit cell is an all-metal coupled-cavity cubic crystal with beam holes and coupling slots. The structure design is shown in Fig. 1. The design frequency is 17 GHz, and the coupling slots through which the electromagnetic waves are coupled is about one tenth of the wavelength in size.



(a) (b)

Figure 1: Unit cell geometry. (a) Face view. The thickness of each face is 0.26mm. (b) 3D view. In later sections we will put an electron beam on the axis.



(a) (b)

Figure 2: Brillouin diagram of the unit cell. (a) Different regions in the first Brillouin zone. (b) $\Gamma - X$ region dispersion showing intersection with the light line.

We use both numerical simulation and analytical modeling to study the dispersion relations of the unit cell.

Numerical Simulation

The HFSS Eigenmode Solver is used to calculate the dispersion curves in the first Brillouin zone, as shown in Fig. 2. The high symmetry points for a simple cubic lattice are $\Gamma(0,0,0)$, $X(\pi/p,0,0)$, $M(\pi/p,\pi/p,0)$ and $R(\pi/p,\pi/p,\pi/p)$, where p is the period of the unit cell. We design the geometry to have a balanced structure with all the modes having the same cut-off frequency at the Γ point.

In the $\Gamma - X$ region, there are four modes. Among them, Mode 1 and Mode 3 are longitudinal, so they will couple strongly to an electron beam; Mode 2 and Mode 4 are transverse. The synchronized frequencies of the light line and the longitudinal modes are 16.7 GHz and 18.8 GHz, and the phase advance per cell is near 180°. Mode 1 can couple to the electron beam better than Mode 3, since in one unit cell Mode 1 has a field in the same direction, while Mode 3 has it in the opposite directions, as illustrated in Fig. 3.

HIGH-GRADIENT TESTING OF METALLIC PHOTONIC BAND-GAP (PBG) AND DISC-LOADED WAVEGUIDE (DLWG) STRUCTURES AT 17 GHz*

B. J. Munroe†, J. X. Zhang, M. A. Shapiro, R. J. Temkin, MIT PSFC, Cambridge, MA 02139, USA

Abstract

Photonic Band-gap (PBG) structures continue to be a promising area of research for future accelerator structures. Previous experiments at 11 GHz have demonstrated that PBG structures can operate at high gradient and low breakdown probability, provided that pulsed heating is controlled. A metallic single-cell standing-wave PBG structure has been tested at 17 GHz at MIT to investigate how breakdown probability scales with frequency in these structures. A single-cell standing-wave disc-loaded waveguide (DLWG) was also tested at MIT as a reference structure. The PBG structure achieved greater than 90 MV/m gradient at 100 ns pulse length and a breakdown probability of 1.1×10^{-1} /pulse/m. The DLWG structure achieved 90 MV/m gradient at 100 ns pulse length and a breakdown probability of 1.2×10^{-1} /pulse/m, the same as the PBG structure within experimental error. These tests were conducted at the MIT structure test stand, and represent the first long-pulse breakdown testing of accelerator structures above X-Band.

INTRODUCTION

Photonic band-gap (PBG) structures, which use a lattice of metallic or dielectric rods to confine an accelerator mode while damping higher-order modes (HOMs), are a topic of ongoing experimental and theoretical work [1–5]. Previous experimental work has demonstrated successful acceleration using a traveling-wave PBG structure [1] as well as suppression of wakefields [4, 6]. More recent work by MIT and SLAC National Accelerator Lab has shown that metallic PBG structures can operate at high gradient and low breakdown probability, achieving gradients of greater than 100 MV/m with a breakdown probability of less than 10^{-3} per pulse per meter of structure [5].

In order to compare breakdown performance as a function of frequency, two standing wave high-gradient structures have been designed and fabricated for breakdown testing at 17 GHz at MIT. A round-rod PBG structure (MIT-PBG), for direct comparison to the PBG-R structure tested at 11 GHz, and a disc-loaded waveguide structure (MIT-DLWG), to serve as a reference for structure performance at 17 GHz, have been tested. The PBG and DLWG designs are electrically very similar to the structures tested at SLAC, although the mechanical designs of both structures are modified to use a clamped, as opposed to brazed, assembly. Each structure consists of one coupling cell on each side of central high-gradient cell; power is provided axially in the TM_{01}-mode through a mode launcher provided by SLAC National Accelerator Lab. A model of the PBG structure tested at MIT is shown in Fig. 1; the DLWG structure differs only in the center cell pieces. The details of the structure design can be found in [7].

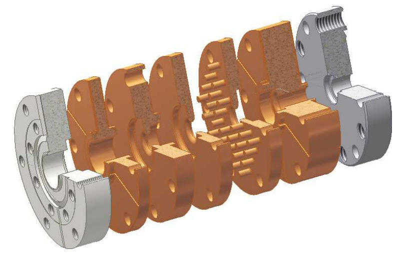

Figure 1: Expanded three quarter section view of the solid model of the 17 GHz PBG structure, showing two coupling cells and central PBG cell. Power is coupled in from the left.

EXPERIMENTAL SETUP

The standing-wave structure test stand at MIT is powered by a 25 MW traveling-wave relativistic klystron designed by Haimson Research Corporation (HRC) and coupled to the test stand through a 4.4 dB hybrid, also from HRC. The test stand is instrumented with incident and reflected power detection via a directional coupler, current monitors both upstream and downstream to detect dark current and breakdown electrons, and an optical diagnostic to look for light emission during breakdowns. In addition to these dedicated diagnostics the pressure in the chamber, which is vacuum-isolated from the rest of the rf system, can be monitored using the chamber ion pump.

The incident and reflected rf power signals are detected using Hewlett Packard HP 8473B low-barrier Schottky diodes coupled into at LeCroy LT264M oscilloscope. The diode traces are recorded by the associated computer system and used to calculate the gradient and peak surface temperature rise in the structure, which are calibrated using HFSS simulations and vector network analyzer measurements. The upstream and downstream current monitors are both composed of copper plates isolated from the body of the mode launcher and structure, respectively. The current monitor signals are used both to monitor the dark current during normal operation and to detect breakdown events. Breakdowns to be detected as a binary signal; if the current monitor signal goes off-scale, then a breakdown is determined to have occurred.

DESIGN AND HIGH-POWER TESTING OF A HYBRID PHOTONIC BAND-GAP (PBG) ACCELERATOR STRUCTURE AT 17 GHz*

JieXi Zhang†, Alan M. Cook, Brian J. Munroe, Michael A. Shapiro, Richard J. Temkin, Haoran Xu,
MIT PSFC, Cambridge, MA 02139, USA

Abstract

An overmoded hybrid Photonic Band Gap (HPBG) structure used as an accelerator cavity has been theoretically designed and high power tested at 17.1 GHz. The HPBG structure consists of a triangular lattice of dielectric (sapphire) and metallic (copper) rods. Due to the frequency selectivity, the hybrid PBG cavity can be operated in a TM_{02} mode. The maximum surface fields are on the triple point of the innermost row of the sapphire rods. The relatively high value of the surface fields resulted in a high breakdown rate (BDR) at a low gradient in the HPBG structure. Breakdown damage on the triple point edge and the metallization of copper onto the sapphire surface have been observed in the post-testing images. An improved HPBG design, that reduces the peak fields, has been developed. It will be built and tested in an effort to improve the HPBG performance.

INTRODUCTION

A periodic photonic structure, whose dispersion relation has photonic band gaps (PBG), can be applied to accelerators due to its frequency selectivity [1]. A traveling-wave (TW) multi-cell metallic PBG structure has demonstrated successful acceleration of electrons with a gradient of 35 MV/m [2]. Standing-wave (SW) metallic PBG (MPBG) structures have been studied with high power to investigate the breakdown rate at both SLAC and MIT [3–6].

A dielectric PBG structure has been theoretically studied [7]. A sapphire rod structure was previously built and cold tested but not tested at high power [8]. A hybrid PBG structure using both dielectric (sapphire) and metallic (copper) rods to form the triangular lattice array for an accelerator cavity was presented by this author [9]. The dielectric band gap map was calculated using HFSS. Since the dielectric band gap map has no cut off frequency, an overmoded operation with the TM_{02} mode confined in a defect cavity can be chosen by adjusting the lattice ratio a/b, where a is the radius of the dielectric rod and b is the lattice constant. This helps in the design of the geometry for a high frequency of 17 GHz. The defect is formed by removing the first four rows of sapphire rods. Metallic rods are added on the outermost row to increase the reflection, thus increasing the quality factor Q of the accelerating mode. Different rod patterns can be arranged by removing rods to increase the azimuthal uniformity of the TM_{02} mode and damp the higher-order-modes (HOMs). Cold test showing a single resonance at the right frequency has demonstrated the overmoded excitation.

† zhangjx@mit.edu

In this paper, the design and the results of the high power testing of our first HPBG structure will be described. Post-test images will show some damage on both the dielectric and the metallic materials. An improved HPBG design to reduce the peak surface fields will be discussed.

EXPERIMENTAL DESIGN

To conveniently and comparably test the high power properties of a specific cavity, SLAC has developed a procedure of testing a single-cell, Standing-Wave cavity with two side cavities to concentrate the high field in the central test cavity [10]. The PBG structures tested at MIT follow the same design concept with a clamped assembly and scaled dimensions to match the resonant frequency of 17.14 GHz of the Haimson Research Corporation (HRC) klystron. Figure 1 shows the 3D model of the HPBG structure used in the SW test stand. A mode launcher is used to convert the rectangular waveguide mode to the input fundamental TM_{01} mode. The c-axis of each sapphire rod is aligned parallel to the longitudinal axis of the accelerator cavity. The birefringence of the sapphire gives a permittivity $\varepsilon_r = [9.398, 9.398, 11.587]$. The lattice parameters are a rod radius $a = 1.58$ mm and a rod spacing $b = 4.48$ mm. The length of the sapphire rods is 11.68 mm. Rods are inserted into copper plates with an insertion depth $d = 3$ mm. Fillets with a radius of $R_{fil} = 2.25$ mm are added on the triple point (the point where sapphire, copper and vacuum meet) of the six innermost rods to reduce the strong surface fields. The radius of the coupling iris is adjusted to obtain a critical coupling. The symmetry of the structure and the TM_{02} mode allows the simulation of the entire 360-degree structure with a 30-degree wedge. The final simulation result of S_{11} is shown in Figure 2. The resonant frequency f_0 and the quality factor Q_L are listed in Table 1. To compare, Figure 2 and Table 1 show results

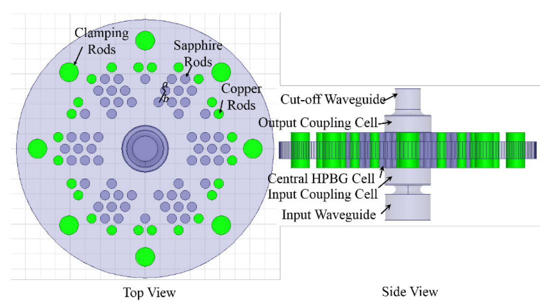

Figure 1: The SW model of the HPBG structure in the 3D simulation. Sapphire rods are shown in dark purple and metal rods in green.

BEAM-PLASMA EFFECTS IN MUON IONIZATION COOLING LATTICES*

J. Ellison, P. Snopok, Illinois Institute of Technology, Chicago, IL 60616, USA

Abstract

New computational tools are essential for accurate modeling and simulation of the next generation of muon based accelerator experiments. One of the crucial physics processes specific to muon accelerators that has not yet been implemented in any current simulation code is beam induced plasma effect in liquid, solid, and gaseous absorbers. We report here on the progress of developing the required simulation tools and applying them to study the properties of plasma and its effects on the beam in muon ionization cooling channels.

INTRODUCTION

Though muon accelerator simulation codes have been steadily improving over the years, there is still much room for improvement. Many single-particle processes and collective effects in vacuum and matter, such as space charge, beam-beam effects, plasma effects from ionized electrons and ions, etc. have not been studied thoroughly or implemented. In order to ensure proper accuracy of simulations, these effects have to be either deemed negligible or taken into account.

Ionization cooling is a method by which the overall emittance of a muon beam can be reduced. A beam is sent through a material, losing momentum as they ionize electrons, and reducing its overall emittance. By reaccelerating the beam through RF cavities, the longitudinal momentum is restored and any lost energy is regained (Fig. 1).

Muons will ionize material as they travel through absorbers. This can generate a plasma, and it is the interaction of the muon beam with the generated plasma that is studied here. Beam-plasma interaction is not taken into account currently in a majority of muon accelerator simulation codes. This can be needed when simulating ionization cooling and high-pressure gas-filled RF (HPRF) cavities.

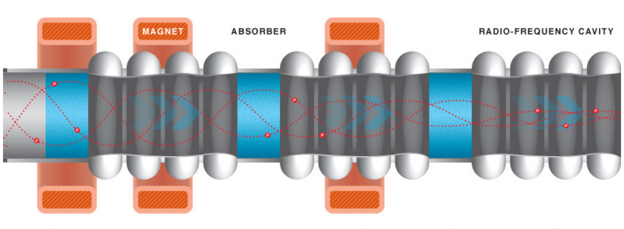

Figure 1: A diagram of ionization cooling. In each cell, absorbers reduce the transverse and longitudinal momentum of the muon beam, and RF cavities reaccelerate in the longitudinal direction only, reducing the overall emittance of the beam.

* Work supported by the U.S. Department of Energy.

The plasma effects have been studied by plasma physicists, but has not been studied extensively from a beam physics point of view. The plasma has been shown to not disrupt the beam or make it blow up [1]. For ionization cooling purposes, beam-plasma effects may have a large impact on the cooling rates for both charges of muon. Essentially, the head of a bunch sees a material with different properties than the tail of the bunch. Ionization rates vary from material to material so the effects may be more prominent in some materials than others.

QUALITATIVE SIMULATIONS

After several simulation packages were considered, the one found to best suit our needs was WARP [2]. WARP is an extensively developed particle in cell (PIC) simulation code designed to simulate charged particle beams with high space-charge intensity. A dense Gaussian beam of muons ($N = 10^{12}$, $p = 200$ MeV/c) was sent through a solenoidal magnetic field ($B = 5.46$ T) and Hydrogen gas (180 atm) with ionization and space-charge effects turned on only (scattering and straggling were not implemented).

The first simulation was without ionization effects turned on in order to have a baseline reference case. The second simulation added a plasma at each simulation step in the form of a thin cylinder of the beam radius containing the total number of plasma electrons (and ions) that were calculated to be created each step. The third simulation used a built-in ionization module of WARP that, given a cross section and density, would place an electron-ion pair at their creation point.

The number of secondaries generated in a single step can be calculated from the Bethe Equation [3] and is given by the following equation:

$$N_s = \left\langle \frac{dE}{dx} \right\rangle \frac{\rho}{W_i} \times d_s, \tag{1}$$

where N_s is the number of particles generated per step, d_s is the step length, $\left\langle \frac{dE}{dx} \right\rangle$ is the mean rate of energy loss by the muons, W_i is the average energy to produce an ion pair, and ρ is the mass density of the medium.

The cross section (σ) for a single particle in the beam is given by

$$R = nv\sigma, \tag{2}$$

where R is the rate of the reaction, v is the velocity of the beam, n is the number density of target particles. That leads to the cross section formula

$$\sigma = \left\langle \frac{dE}{dx} \right\rangle \frac{1}{W_i} \frac{\rho}{\rho_n}, \tag{3}$$

where ρ is the mass density of the absorber and ρ_n is the atomic density of the absorber.

Abstract

Ionization cooling is a method to reduce the emittance of a beam through the use of absorbers, rf cavities, and strong solenoids for focusing, arranged into a condensed lattice. By tuning lattice parameters, it is possible to construct a staged cooling channel in which the beam emittance is always considerably greater than the minimum value. In the late stages of the cooling channel, space charge effects can become a significant obstacle to further emittance reduction once the beam becomes sufficiently condensed. A method has been implemented in COSY Infinity, a beam dynamics simulation and analysis code, which efficiently and accurately calculates the self-fields of all particles on each other based on a variant of the Fast Multipole Method (FMM). In this paper, we present simulations of a muon ionization cooling channel performed in COSY, utilizing the FMM, benchmarked against G4beamline, a standard code for muon beam analysis, in order to investigate the significance of space charge effects.

OVERVIEW OF IONIZATION COOLING

In the area of high energy colliders, using leptons has a significant advantage over hadrons due to hadron collisions being inefficient and complicated by secondary quark interactions. A muon collider could be used for high energy studies of lepton collisions without the limitations on energy due to synchrotron radiation. The muon beam is produced by sending protons through a target, producing pions which in turn decay into muons with a large momentum spread. In order to be accelerated, the six-dimensional (6D) phase space volume of the muon beam must be reduced for injection into a storage ring. Ionization cooling is currently the only feasible method for cooling the beam within a muon lifetime of 2.2 μs. In order for a full 6D ionization cooling experiment to be constructed, a baseline lattice design has to be studied and selected based on detailed simulations [1].

Emittance Reduction

For the reduction of transverse emittance, the beam is strongly focused with magnetic fields and subsequently passed through an absorber material to reduce overall momentum. The beam's longitudinal momentum is restored in RF cavities which results in a net reduction in transverse emittance. The change in the transverse emittance is described by:

$$\frac{d\varepsilon_n}{ds} = -\frac{1}{\beta^2}\frac{dE_\mu}{ds}\frac{\varepsilon_n}{E_\mu} + \frac{1}{\beta^3}\frac{\beta_T E_s^2}{2E_\mu m_\mu c^2 L_R},$$

$$\varepsilon_{n,min} = \frac{\beta_T E_s^2}{2\beta m_\mu c^2 L_R \left|\frac{dE_\mu}{ds}\right|},$$

where ε_n is the normalized transverse emittance, c is the speed of light, and $\beta = v/c$, E_μ, m_μ are the muon velocity, energy, and mass. The transverse betatron function within the absorber is β_T, dE_μ/ds is the energy loss per unit length in the absorber, L_R is the radiation length of the absorber material, and E_s is the characteristic scattering energy. The top equation describes the effects of cooling (first term) and heating (second term), and when the cooling rate equals the heating rate, we can find the minimum normalized transverse (or equilibrium) emittance ($\varepsilon_{n,min}$) for a given absorber material and focusing field.

To maximize cooling, materials with low Z and large radiation length (such as LH_2, LiH) are used in order to minimize multiple scattering. A high gradient RF field and high absorber density, the combination of which determines the energy loss per unit length dE_μ/ds, are used along with solenoids arranged such that there is strong focusing at absorbers, thus small β_T. Cooling typically occurs around a muon momentum of 200 MeV/c, where the curvature of the Bethe-Bloch function (to determine absorber dE_μ/ds) is favorable. The cooling channel is tapered into stages in order to vary the solenoid focusing, RF frequency and gradient, and geometry such that the minimum normalized emittance decreases with the beam [2–4].

The longitudinal momentum spread is reduced using the concept of emittance exchange. This process involves applying a magnetic field to create dispersion in the beam at wedge shaped absorbers, such that particles with higher energy pass through more material than those with lower energy, resulting in an overall reduction in the energy spread of the beam. The cooling process is essentially a transfer of emittance from the longitudinal to transverse direction combined with transverse ionization cooling for emittance reduction in all six dimensions.

SPACE CHARGE

One of the challenges presented in muon cooing channels is that as the size of the beam is reduced, Coulomb repulsion in the beam limits further emittance reduction. To investigate the effect of space charge, a method has been implemented in COSY INFINITY [5] to achieve efficient and accurate calculation of the interparticle Coulomb forces based on variants of the Fast Multipole Method (FMM). This method divides an arbitrary charge distribution into small boxes with a hierarchical structure. It then computes the multipole expansions and local expansions of charges far from the observer to achieve a computational efficiency that scales with the number of particles, N, and computational errors scaling with a high power of the expansion order. The FMM algorithm is especially suited for beam dynamics sim-

THE ADVANCEMENT OF COOLING ABSORBERS IN COSY INFINITY*

J. Kunz, P. Snopok†, Illinois Institute of Technology, Chicago, IL 60616, USA
M. Berz, K. Makino, Michigan State University, East Lansing, MI 48824, USA

Abstract

COSY Infinity is an arbitrary-order beam dynamics simulation and analysis code. It can determine high-order transfer maps of combinations of particle optical elements of arbitrary field configurations. For precision modeling, design, and optimization of next-generation muon beam facilities, its features make it a very attractive code. New features are being developed for inclusion in COSY to follow the distribution of charged particles through matter. To study in detail some of the properties of muons passing through material, the transfer map approach alone is not sufficient. The interplay of beam optics and atomic processes must be studied by a hybrid transfer map–Monte-Carlo approach in which transfer map methods describe the average behavior of the particles in the accelerator channel including energy loss, and Monte-Carlo methods are used to provide small corrections to the predictions of the transfer map accounting for the stochastic nature of scattering and straggling of particles. The advantage of the new approach is that it is very efficient in that the vast majority of the dynamics is represented by fast application of the high-order transfer map of an entire element and accumulated stochastic effects as well as possible particle decay. The gains in speed are expected to simplify the optimization of muon cooling channels which are usually very computationally demanding due to the need to repeatedly run large numbers of particles through large numbers of configurations. Progress on the development of the required algorithms is reported.

INTRODUCTION

Muons are tertiary production particles (protons → pions → muons) and high-intensity collection requires a large initial phase space volume. The resultant spray of muons must be amassed, focused, and accelerated well within the muon lifetime (2.2 μs in the rest frame). The only technique fast enough to reduce the beam size within the muon lifetime is ionization cooling. When muons traverse a material, both the longitudinal and transverse momentum components shrink due to ionization. The energy is then restored in the longitudinal direction only, leading to an overall reduction in the transverse beam size (cooling). In order to achieve cooling in the longitudinal direction, emittance exchange is used, usually involving wedge-shaped absorbers. For some applications such as a high-energy high-luminosity muon collider, cooling needs to be very aggressive: six-dimensional emittance reduction over six orders of magnitude is required to reach design goals.

† psnopok@iit.edu

In order to carefully simulate the effect of the absorbers on the beam, one needs to take into account both deterministic and stochastic effects in the ionization energy loss. The deterministic effects in the form of the Bethe-Bloch formula with various theoretical and experimental corrections fit well into the transfer map methods approach, where the effect of the lattice on the particles is evaluated first by producing the so-called transfer map, and then is applied to a given initial distribution of particles. The arbitrary-order simulation code COSY Infinity [1] is a key representative of transfer map codes. COSY was chosen because of its built-in optomization tools, speed, its ability to produce high-order transfer maps, and its ability to control individual aberrations.

However, to take into account stochastic effects the transfer map paradigm needs to be augmented by implementing the corrections from stochastic effects directly into the fabric of COSY. Some of the fundamental ideas of the process were presented in [2] in application to quadrupole cooling channels, but the approximations used were fairly basic. In this work, a more rigorous theoretical approach is presented along with the resulting valiation.

STOCHASTIC PROCESSES

The stochastic processes of interest are straggling (fluctuation about a mean energy loss), angular scattering, transverse position corrections, and time-of-flight corrections (corresponding to the longitudinal position correction). The general outline to simulate these four beam properties will be discussed and benchmarked against two other beamline simulation codes, ICOOL [3] and G4Beamline [4], and (in the case of angular scattering) against experimental data [5]. The simulation followed the beam properties cited in [5], which were a pencil beam with an iinitial momentum of 172 MeV/c through 109 mm of liquid hydrogen (LH) with cylindrical geometry. The step sizes for ICOOL and G4Beamline were chosen to be a modest 1 mm in order to ensure a quality simulation. The step size for COSY was chosen as the entire cell (109 mm), since its algorithms are largely insensitive to step sizes, as will be shown later.

Straggling (Figure 1)

As the momentum range of interest is 50–400 MeV/c through low-Z materials, only ionization effects contribute to the mean energy loss. As such, Landau theory accurately describes the energy loss spectra, having the form [6]

$$f(\lambda) = \frac{1}{\xi} \cdot \frac{1}{2\pi i} \int_{c+i\infty}^{c-i\infty} \exp(x \ln x + \lambda x) dx,$$

where $\xi \propto Z\rho L/\beta^2 A$, and $\lambda \propto dE/\xi - \beta^2 - \ln\xi$. Here, Z, A, and ρ are the material parameters of charge, atomic mass,

ACOUSTIC BREAKDOWN LOCALIZATION IN RF CAVITIES*

P. Lane, P. Snopok,† Y. Torun, Illinois Institute of Technology, Chicago, IL 60616, USA
E. Behnke, I. Levine, Indiana University South Bend, South Bend, IN 46634, USA
D. Peterson, Fermilab, Batavia, IL 60510, USA

Abstract

Current designs for muon cooling channels require high-gradient RF cavities to be placed in solenoidal magnetic fields in order to contain muons with large transverse emittances. It has been found that doing so reduces the threshold at which RF cavity breakdown occurs. To aid the effort to study RF cavity breakdown in magnetic fields it would be helpful to have a diagnostic tool which can detect breakdown and localize the source of the breakdown inside the cavity. We report here on acoustic simulations and comparisons with experimental acoustic data of breakdown from several RF cavities. Included in this analysis are our most recent results from attempting to localize breakdown using these data.

INTRODUCTION

Muon beams are desired for use in future particle physics experiments. Muon colliders could compliment hadron machines like the LHC without the need for prohibitively long accelerators that are proposed for electron-positron machines such as the ILC or CLIC. Neutrino physics would also benefit from having a neutrino factory which generates a neutrino beam from the decay of muons.

The main challenge with using muons for colliders and neutrino factories is creating tight muon beams. Muons are created from the decay of pions which themselves come from proton collisions with fixed targets. The resultant spray of muons must be collected, focused, and accelerated well within the muon lifetime (2.2 μs in the rest frame). The only feasible method that has been conceived for reducing the beam size prior to accelerating it is ionization cooling [1].

Ionization cooling uses low-Z materials as energy absorbers to reduce the overall momentum of muons. The muons are then subjected to electric fields which accelerate them only along the beam axis. To corral the muons as they are cooled transversely, strong solenoidal magnetic fields are used [1]. Unfortunately it has been found that the maximum accelerating gradient a cavity can produce without breaking down is significantly reduced in the presence of strong magnetic fields [2].

In order to improve the performance of accelerating cavities in strong magnetic fields, it would be useful to have a diagnostic tool that would indicate where breakdown sparks are occurring without having to shutdown the experiment and open the cavity to inspect damage. Acoustic data has been collected on the Muon Ionization Cooling Experiment's (MICE) 201.25 MHz RF cavity and the Modular Cavity at the MuCool Test Area (MTA) at Fermilab. We have demonstrated the feasibility of acoustic localization of breakdown spark sources with other cavities, and we present here experimental and simulation results as well as our path forward towards the goal of acoustic localization of breakdown.

† psnopok@iit.edu

EXPERIMENTAL SETUP

The experimental setup for the MICE 201.25 MHz cavity at the MuCool Test Area (MTA) at Fermilab was previously described in detail [3]. Additional details on previous cavity setups was also previously presented [4]. Since then we have instrumented a newly built, cylindrical cavity, the Modular Cavity, with 10 passive, piezoelectric microphones. These microphones are nearly identical to those on the MICE cavity, with the main difference being added strain relief for the cable where it attaches to the microhpone housing. Four are placed on each end plate. The remaining two were placed on the underside of the waveguide. An additional variable gain amplifier box was installed in the MTA experiment hall for these new microphones. Connections to our DAQ system were simplified by the existance of enough spare capacity that no rearrangement of MICE cavity connections was necessary. Finally, our LabVIEW software has been rewritten for stability and to be easily configurable for multiple cavity setups.

EXPERIMENTAL RESULTS

MICE Cavity

The MICE cavity was run at the end of last year in no magnetic field. The signals are characterized by large spikes at the beginning that correspond with the RF pulse followed by oscillations that have an amplitude less than a volt (Fig. 1). This is true for both spark and non-spark signals, making it difficult to tell the difference on visual inspection between the two. Given that our experience with previous cavities shows a much larger response from spark than from normal RF pulse noise (referred to as the RF hammer), it was thought that the microphones might have been ruined during the cavity bakeout in preparation for evacuation. After the Fall running completed the Cu end plates on the MICE cavity were removed along with the 12 microphones attached to them (leaving 12 on the main body at a constant radius of 41 *cm*). We took the opportunity to test the microphones again by tapping on the cavity with a makeshift hammer that triggers the DAQ on contact with the cavity's conductive surface. All but two microphones were behaving normally. Since this cavity dissipates much more energy than previous cavities it was assumed that the acoustics in general would be much louder. We have put considerably more effort towards

SIMULATION OF LASER PULSE DRIVEN TERAHERTZ GENERATION IN INHOMOGENEOUS PLASMAS*

Chenlong Miao#, IREAP, University of Maryland, College Park 20740, USA
John P. Palastro, Naval Research Laboratory, Washington DC 20375, USA
Thomas M. Antonsen, IREAP, University of Maryland, College Park 20740, USA

Abstract

Intense, short laser pulses propagating through inhomogeneous plasma can ponderomotively drive THz radiation. Here we consider a transition radiation mechanism (TRM) for THz generation as a laser pulse crosses a plasma boundary. Full format PIC simulations and theoretical analysis are conducted demonstrating that TRM results in low frequency, broad band, coherent THz radiation. The effect of a density ramp is also considered and shown to enhance the radiated energy.

INTRODUCTION

Electromagnetic terahertz radiation (THz) spans frequencies from 300 GHz to 20 THz. A wide variety of THz applications [1] include spectroscopy, remote detection, and medical and biological imaging. Intense THz pulses can be generated at large scale accelerator facilities via synchrotron or transition radiation, but the size and cost of such facilities are prohibitive for widespread use. This motivates the development of small-scale table top terahertz sources.

Existing small-scale terahertz sources are based on laser-solid interaction and are limited to μJ/pulse levels [2]. This has led to the consideration of laser-plasma based THz generation schemes. Examples include the transition radiation of a laser accelerated electron beam passing from plasma to vacuum producing energies in excess of 100 μJ/pulse [3], and radiation produced during two-color laser pulses gas ionization[4]. Here, with a combination of theory and simulation, we investigate a mechanism of ponderomotively driven THz radiation, which offers the possibility of high conversion of optical pulse energy to THz.

The mechanism occurs as a laser pulse crosses a plasma boundary [5] and is analogous to transition radiation emitted by charged particle beams. The THz radiation resulting from this transition radiation mechanism (TRM) is characterized by conical emission and a broad spectrum with the maximum frequency occurring near the plasma frequency [6].

The THz generation mechanism is simulated using the full format PIC simulation TurboWAVE [7], with the goal of increasing the conversion of optical energy to THz radiation. A range of laser pulse and plasma parameters is considered. We conduct the simulations in the lab frame with a finite sized plasma target illuminated by a laser pulse incident from the left, as shown in Fig. 1 for the case of a sharp boundary, uniform plasma. To investigate the power radiated from the plasma, we calculate the Poynting flux through the prescribed surfaces outside the plasma region. These represent the forward, backward and lateral radiation from the plasma.

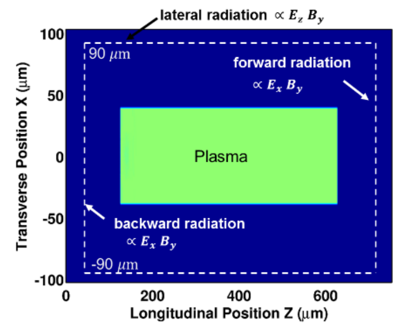

Figure 1: Diagnostic box outside the plasma channel. The Poynting flux through each surface is calculated.

TRANSITION RADIATION MECHANISM

We first consider a uniform plasma with sharp step boundaries as illustrated in Fig. 2. The plasma is 500 μm long and 90 μm wide with a density of $n = 2.8\times10^{18}\,cm^{-3}$. When the laser pulse crosses the vacuum-plasma boundary, it drives ponderomotive currents that produce radiation with frequencies near the plasma frequency.

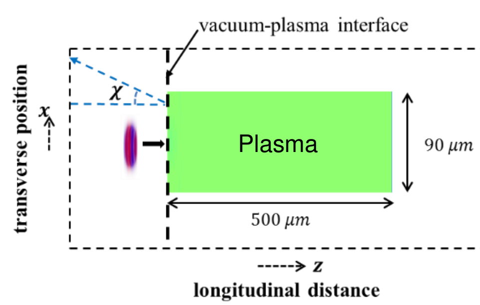

Figure 2: Diagram of simulation set up for transition radiation at the vacuum plasma boundary.

Following Ref. 5, a formula can be derived for the radiated energy per unit frequency (ω) and length (recall the simulations have 2D planar symmetry) across the left diagnostic boundary shown in Fig. 2.

$$\frac{dW_L}{d\omega} = \frac{L}{|\omega|}\frac{\omega_{p0}^2}{\omega_0^2}\frac{k_p^2}{\pi^{3/2}}\frac{a_0^2}{4}U_L\int_0^1 dy\,\frac{y^2\sqrt{1-y^2}\times\exp\left[-\frac{\omega^2}{2c^2}\left(L^2+R_L^2\left(1-y^2\right)\right)\right]}{\left|\varepsilon(\omega)\,y+\sqrt{y^2-\omega_{p0}^2/\omega^2}\right|^2}\,. \quad (1)$$

CONSIDERATIONS FOR AN EFFICIENT TERAHERTZ-DRIVEN ELECTRON GUN *

F. Lemery[1], P. Piot[1,2]
[1] Department of Physics and Northern Illinois Center for Accelerator & Detector Development, Northern Illinois University DeKalb, IL 60115, USA
[2] Accelerator Physics Center, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

We investigate a dispersion-controlled-acceleration scheme of low-energy electrons to mitigate phase slipping using a tapered dielectric lined waveguide (DLW). Our approach matches the velocity of an electron being accelerated in a slab-symmetric structure in a constant electric field. We also present first experimental results of a THz pulse propagating in a slab-symmetric DLW.

INTRODUCTION

Although conventional electron sources are often used to investigate the performance of advanced acceleration concepts [1], their adaptation to serve as an injector for an optimized advanced accelerator remains challenging. Instead several groups have developed short-pulse electron sources, e.g., based on dielectric grating [2], free-space THz streaking [3, 4], or the proposed optically driven dielectric-waveguide sources [5]. Unfortunately, electron sources using an optical wave are typically limited in the charge they can produce since space charge is predominant at low energy and needs to be mitigated. For instance at $\lambda_{acc} = 800$ nm, a typical bunch length of a few nm would be required which would result in peak current, $Qc/(2\pi\lambda_{acc} \geq 6$ kA for a 1 pC bunch charge (here c is the light velocity). Alternatively, using a THz pulse with λ_{acc}=100 μm would result in a peak current on the order of 50 A (taking $\sigma_z \simeq 10^{-2}\lambda_{acc} \simeq 1$ μm). The latter value is consistent with values typically achieved in conventional photoinjectors, see Ref. [6] for example. Likewise, the trade-off between electron bunch length and charge could enable the production of higher charge (up to 100 pC) in exchange for longer bunches.

Recently, the development of efficient (2%) laser-based THz sources (300 GHz) has opened the path to the development of THz-driven linacs [7–10]. In this scheme, a radially-polarized THz pulse is co-propagated with an electron bunch in a dielectric-lined waveguide (DLW) with optimized geometry; THz pulses with mJ energies can support accelerating fields on the order of GV/m. The THz-pulse is also matched to the structure thereby mitigating possible excitation of spurious modes (e.g. dipole modes often excited in beam-driven schemes dielectric-wakefield acceleration [11]. This technique would work well at relativistic energies as the electron has a velocity close to the phase velocity of the THz pulse and the particle-wave slippage is negligible over the considered interaction lengths. In contrast, using a THz pulse to accelerate an electron bunch from rest, as recently demonstrated for the free-space case in Ref. [10], is prone to large phase-slippage effects that significantly alter the maximum energy achievable.

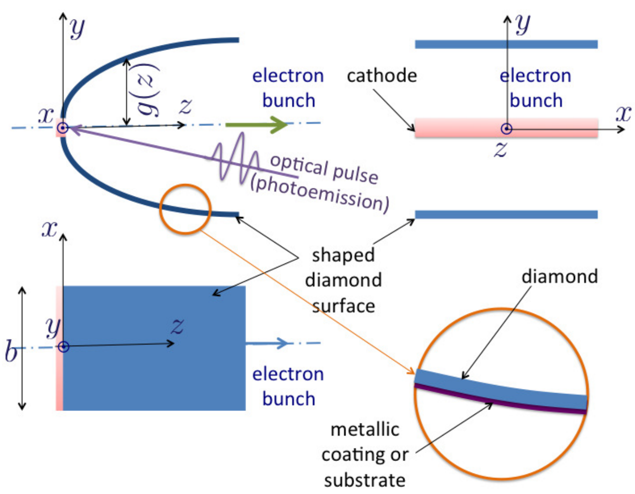

Figure 1: Section, top view and side view (respectively on top, bottom left and top right) of the proposed "THz gun" electron source.

This paper presents some preliminary considerations toward the development of a THz-driven electron source with some attempt to keep phase-slippage effects under control. A conceptual schematic of this low-energy electron source, henceforth dubbed "THz-gun", appears in Fig. 1: two thin dielectric surfaces deposited on a metallic substrate (or free-standing with metalized outer surfaces) are faced to each other.

DISPERSION-CONTROLLED ACCELERATION

The rate of phase slippage between an electromagnetic travelling wave with axial field $E_z(z,t) = E_0 \sin(\omega t - kz + \psi_0)$ (where ω and k are respectively the wave's frequency and wavector) and a particle with Lorentz factor γ is given by $d\psi/dz = \alpha k \sin(\psi)$ where $\psi = \psi(z,t) \equiv \omega t - kz + \psi_0$ (with ψ_0 being the injection phase), and $\alpha \equiv eE_0/(kmc^2)$ is

A COMPACT X-RAY SOURCE BASED ON A LOW-ENERGY BEAM-DRIVEN WAKEFIELD ACCELERATOR*

F. Lemery[1], D. Mihalcea[1], K. Chouffani[2] and P. Piot[1,3]
[1] Department of Physics, Northern Illinois Center for Accelerator & Detector Development, Northern Illinois University DeKalb, IL 60115, USA
[2] Idaho Accelerator Center, Pocatello, ID 83201, USA
[3] Accelerator Physics Center, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

Accelerator-based X-ray sources have led to many scientific discoveries. Yet, their limited availability in large national laboratory settings due to the required infrastructure is a major limitation to their disseminations to a larger user community. In this contribution we explore the use of a low-energy electron beam produced out of a photoinjector coupled to a pair of dielectric structure to produce a higher energy (10-20 MeV) beam via a beam-driven acceleration scheme. The accelerated beam can then be used to produce X-rays via inverse Compton scattering.

INTRODUCTION

Modern accelerator-based X-ray sources have led to a wave of scientific advancements in various fields. Their inception relies primarily on energetic electrons which are manipulated to radiate either via undulators or inverse Compton scattering (ICS). In both radiation mechanisms the photon energy $O(\gamma^2)$, therefore an increase in the beam energy is significant. Recently, compact X-ray sources based on X-band RF technology has been proposed [1]. Likewise an X-ray source utilizing laser-plasma wakefield accelerator have been demonstrated [2]. Finally, most recently the possible use of a THz pulse to accelerate electron bunches have been put forward [3] and tested [4]. These solutions, although appealing, are either costly (X-band technology) and/or require the use of high-power lasers currently operating at low repetition rates.

A possible alternative to increase the beam energy is to rely on collinear beam driven acceleration using high-impedance media such as dielectric lined waveguides (DLW) – for dielectric-wakefield acceleration (DWFA) – or plasmas – for wakefield acceleration (PWFA). In collinear beam-driven schemes, a "drive" bunch is used to drive the wakefield in the medium while a properly delayed "witness" bunch at the proper phase is accelerated. The longitudinal wakefield produced by the drive bunch is given by

$$E(z) = \int_{-\infty}^{z} G(z-\zeta)S(\zeta)d\zeta, \quad (1)$$

where $G(z-\zeta) = 2\kappa\cos(k\zeta)$ is the longitudinal Green's function, κ the loss factor, and $k = \frac{2\pi}{\lambda}$ with λ being the wavelength of the mode supported by the medium. Additionally, in a DLW the maximum field strength generally scales as $E_+ \propto \Lambda(z)a^{-2}$ where a is the inner radius of the DLW and $\Lambda(z)$ is the longitudinal charge density. An essential figure of merit associated to beam-driven acceleration is the transformer ratio $\mathcal{R} = |E_+^{(m)}/E_-^{(m)}|$ where the superscript "m" refers to the maximum amplitude of the accelerating (E_+) or decelerating field (E_-), which describes the efficiency of the energy transfer of the drive bunch to the wake.

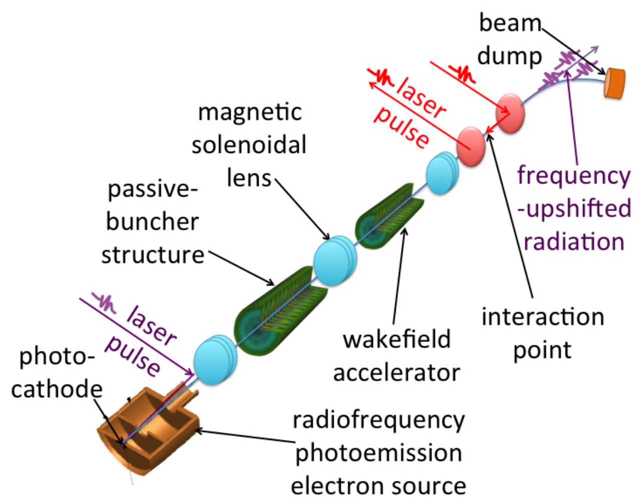

Figure 1: Overview of the compact source scheme: a photoinjected electron bunch passes through a series of DLWs for cascaded acceleration,the resulting high energy electrons are used with a laser to generate inverse Compton scattering.

Two practical challenges emerge for beam-driven acceleration at low energy. First, the geometric emittance associated to a low-energy photoinjected electron bunch sets an upper limit on the inner radius a and length L of the DLW structure. Second, the scheme relies on the production of a high-peak-current electron bunch along with the formation of a witness bunch.

To address some of these challenges, we propose an accelerator setup diagrammed in Fig. 1 based on a "cascaded acceleration" scheme. A high-quality electron bunch is produced in an RF gun and focused into a DLW structure (DLW1). The structure passively bunches the beam which

Abstract

Atomic channels in crystals are known to consist of 10 – 100 V/Å potential barriers capable of guiding and collimating a high energy beam and continuously focused acceleration with exceptionally high gradients (TeV/m). However, channels in natural crystals are only angstrom-size and physically vulnerable to high energy interactions. Carbon-based nano-crystals such as carbon-nanotubes (CNTs) and graphenes have a large degree of dimensional flexibility and thermo-mechanical strength, which could be suitable for channeling acceleration of MW beams. Nano-channels of the synthetic crystals can accept a few orders of magnitude larger phase-space volume of channeled particles with much higher thermal tolerance than natural crystals. Our particle-in-cell simulations with 100 μm long effective CNT model indicated that a beam-driven self-acceleration produces 1 – 2 % net energy gain in the quasi-linear regime (off-resonance beam-plasma coupling, $n_p = 1000\ n_b$) with ASTA 50 MeV injector beam parameters. This paper presents current status of CNT-channeling acceleration experiment planned at the Advanced Superconducting Test Accelerator (ASTA) in Fermilab.

INTRODUCTION

Shock waves in an ionized plasma media, excited by relativistic particles, have been of great interest on account of their promise to offer extremely high acceleration gradients of G (max. gradient) = $m_e c\omega_p/e \approx 96 \times n_0^{1/2}$ [V/m], where $\omega_p = (4\pi n_p e^2/m_e)^{1/2}$ is the electron plasma frequency and n_p is the ambient plasma density of [cm^{-3}], m_e and e are the electron mass and charge, respectively, and c is the speed of light in vacuum. However, a practically obtainable plasma density (n_p) in ionized gas is limited to below ~ 10^{24} m^{-3}, which in principle corresponds to wakefields up to ~ 100 GV/m [1, 2], and it is realistically very difficult to create a stable gas plasma with a charge density beyond this limit. Metallic crystals are the naturally existing dense plasma media completely full with a large number of conduction electrons available for the wakefield interactions. The density of charge carriers (conduction electrons) in solids $n_0 = \sim 10^{26} – 10^{29}$ m^{-3} is significantly higher than what was considered above in gaseous plasma, and correspondingly the wakefield strength of conduction electrons in solids, if excited, can possibly reach 10 TV/m in principle.

The channels between atomic lattices or lattice planes aligned in a crystal orientation of natural crystals like silicon or germanium are sparse spaces with relatively low electron densities. Charged particles, injected into a crystal orientation of a mono-crystalline (homogeneous and isotropic) target material, undergo much lower nucleus and electron scatterings. The idea of accelerating charged particles in solids along major crystallographic directions was suggested by several scientists such as Pisen Chen, Robert Noble, Richard Carrigan, and Toshiki Tajima in the 1980's and 1990's [3–6] for the possible advantage that periodically aligned electrostatic potentials in crystal lattices are capable of providing a channeling effect [7–9] in combination with low emittance determined by an Ångström-scale aperture of the atomic "tubes". The basic concepts of atomic accelerator with short pulse driving sources like high power lasers or ultra-short bunches have been considered theoretically. However, the idea has never been demonstrated by experiment or simulation due to the extremely tight interaction condition of the Angstrom-size atomic channels in natural crystals and the complexity of electron dynamics in solid-plasma.

NANOTUBES FOR CHANNELING

Carbon nanotubes (CNTs) are a synthetic nanostructure, which is a roll of a graphene sheet, and its tube diameter can be easily increased up to sub-micron by optimizing fabrication processes (chemical vapor deposition, CVD). For channeling applications of high power beams, carbon nanostructures have various advantages over crystals [10]. Particles are normally de-channeled when the transverse forces are larger than the maximal electric field acting on channeled particles from crystal atoms, which is described by the critical angle. The dechanneling rate is significantly reduced and the beam acceptance is increased by the large size of the channels, e.g., a 100 nm wide CNT channel has larger acceptance than a silicon channel by three orders of magnitude. If the channel size is increased from angstroms to nanometers, the maximally reachable acceleration gradient would be lowered from ~ 100 TeV/m to ~ 1 TeV/m due to the decrease of effective plasma charge density. However, the nanotube channels still provide sufficiently large transverse and longitudinal fields in the range of TV/m. For the crystal channels in angstrom scale, the lattice dissociation time of atomic

OPTIMAL POSITRON-BEAM EXCITED PLASMA WAKEFIELDS IN HOLLOW AND ION-WAKE CHANNELS

Aakash A. Sahai *, Thomas C. Katsouleas
Dept of Electrical Engineering, Duke University, Durham, NC, 27708 USA

Abstract

A positron-beam interacting with the plasma electrons drives radial suck-in, in contrast to an electron-beam driven blow-out in the over-dense regime, $n_b > n_0$. In a homogeneous plasma, the electrons are radially sucked-in from all the different radii. The electrons collapsing from different radii do not simultaneously compress on-axis driving weak fields. A hollow-channel allows electrons from its channel-radius to collapse simultaneously exciting coherent fields [1]. We analyze the optimal channel radius. Additionally, the low ion density in the hollow allows a larger region with focusing phase. We have shown the formation of an ion-wake channel behind a blow-out electron bubble-wake. Here we explore positron acceleration in the over-dense regime comparing an optimal hollow-plasma channel to the ion-wake channel [2]. The condition for optimal hollow-channel radius is also compared. We also address the effects of a non-ideal ion-wake channel on positron-beam excited fields.

INTRODUCTION

Acceleration of positron beams is a major challenge for developing a collider using plasma-based acceleration techniques. Hollow-channel plasma is required for a collider-level plasma-based positron acceleration [1]. However, no analysis has been done to study the scaling laws of the hollow-channel properties based upon the positron beam properties. Similarly, the preparation of hollow-channels with properties suited for positron acceleration is still an ongoing research. In this paper we present a preliminary analysis of the scaling laws and application of the ion-wake channel for positron-beam driven wakefield acceleration. The ion-wake channel is a cylindrical soliton left behind in the plasma by a bubble wake train [2]. Studies of processes behind the plasma acceleration structures also helps in our understanding of the repetition-rate of the plasma colliders [4].

Positron beam interacts with a homogeneous plasma (density, n_0) unlike an ultrashort electron beam (peak density, n_{be}, radius, r_{be}). The plasma electrons see the repulsive force of the electron beam space-charge and are blown-out radially, $\frac{\mathrm{d}^2}{\mathrm{d}\xi^2}r = \frac{1}{r}\frac{1}{2\pi\beta_b^2}\frac{n_{be}(\xi)}{n_0}\pi\left(\frac{r_{be}(\xi)}{c/\omega_{pe}}\right)^2$ (at a fixed $\xi = c\beta_b t - z$, where $\omega_{pe} = \sqrt{\frac{4\pi n_0 e^2}{m_e}}$ and $\frac{c}{\omega_{pe}}$ is the plasma skin-depth). We look for radial plasma-electron dynamics at time t, just behind the current location of the drive-beam propagating at $c\beta_b$. This is done using an appropriate coordinate ξ such that the current longitudinal beam location is $c\beta_b t$ and $c\beta_b t - z$ is longitudinally behind the beam. The electrons coherently collapse back to the axis under the influence of the plasma ion restoring force; executing cylindrical plasma oscillations and driving a large on-axis longitudinal wakefield. The regions where the electrons are in the blow-out phase, unshielded plasma ions are left behind; quite conveniently exciting the focussing-phase of the transverse fields for an electron beam.

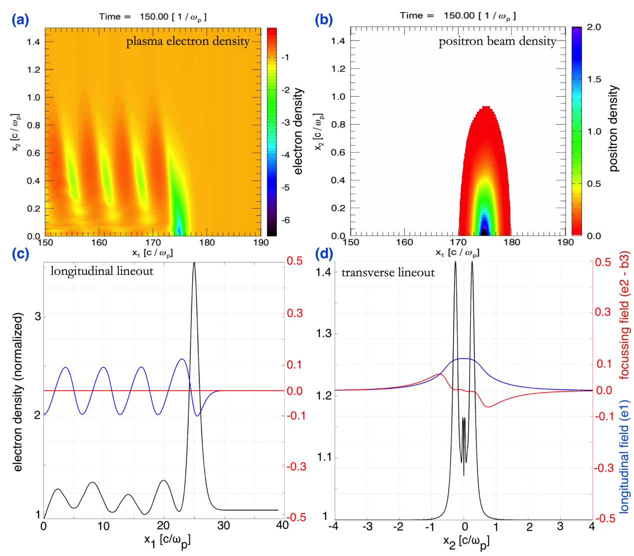

Figure 1: Positron-beam driven wakefields in a homogeneous plasma (a) electron density in 2D cylindrical space at $t = 150\omega_{pe}^{-1}$ (b) positron-beam in 2D cylindrical space (c) on-axis longitudinal (x_1) line-out: electron density (black), longitudinal field (blue), focussing field (red) (d) transverse (x_2) line-out at the peak longitudinal field.

The space-charge of an ultrashort positron beam (n_{bp}, r_{bp}), on the contrary, sucks in the plasma electrons and they collapse to the axis, $\frac{\mathrm{d}^2}{\mathrm{d}\xi^2}r = -\frac{1}{r}\frac{1}{2\pi\beta_b^2}\frac{n_{bp}(\xi)}{n_0}\pi\left(\frac{r_{bp}(\xi)}{c/\omega_{pe}}\right)^2$. However, there are 2 major problems with the suck-in wakefields in a homogeneous plasma. (i) The plasma electrons are sucked-in from different radii; with the radially closer ones experiencing a larger force and radially farther ones a smaller force (it is interesting to contrast this with an electron beam interacting with the plasma electrons). So, the collapse to the axis is not coherent and different rings of electrons arrive at different times. Due to the lack of optimal on-axis electron compression the wakefields are weak (note the on-axis compression in Fig. 1(a)). (ii) When the sucked-in electrons execute radial oscillations, the regions where the electrons are not in the on-axis compression phase has excess unshielded ions. The regions with ions are de-focussing for positrons (positrons to be accelerated are aligned to be

PHOTOINJECTOR IMPROVEMENT AND CONTROL BY SURFACE ACOUSTIC WAVES*

A. Afanasev[1,2], C. Korman[2], R.P. Johnson[1]
[1]Muons, Inc., Batavia, IL, USA
[2]The George Washington University, Washington, DC, USA

Abstract

A new technique is being developed to enhance the efficiency of photocathodes used for electron sources in order to improve emission capabilities of electron sources, such as bunch charge and average current. The proposed technique is based on the use of surface acoustical waves (SAW) generated on the piezoelectric surface of a GaAs photocathode. The generation of SAW on piezoelectric substrates is known to produce strong piezoelectric fields that propagate on the surface of the material. These fields can significantly suppress recombination effects and result in enhanced quantum efficiency of photoemission. Experimental measurements of photoemission quantum efficiency are planned on semiconductors used as photocathode materials (e.g., GaAs) in presence of SAW with varied parameters. The experimental results will be used as input for physics modeling that will provide a basis for the design of operational SAW-enhanced photocathodes. The improved quantum efficiency and parameter control expected from the use of SAW will be useful for electron sources in particle accelerators as well as for commercialization in other fields, such as electron microscopy.

MOTIVATION

An experiment [1] reported strikingly long lifetimes of photo-excited electrons in a GaAs sample in the presence of piezoelectric fields induced by SAW. In this experiment, electrons and holes were photo-generated by a 5 µm diameter laser spot and were transported towards a semi-transparent metal strip, at which electron–hole recombination was induced by screening out SAW. The key observation relevant for potential applications for polarized electron sources is that spin polarization of the electrons during transport was preserved, at a distance of hundreds of microns. An observed increase of electron diffusion length with minimized de-polarization effects is an important motivation for our study. The advantages provided by the use of piezoelectric fields are not only limited to applications of SAW. Realization of piezoelectric fields in nano-scale devices has recently led to the development of the entire field of *piezotronics* and *piezophototronics* [2] that results from three-way coupling of piezoelectricity, photonic excitation, and semiconductor transport, leading to enhanced performance of photovoltaic cells and photon detectors.

*E-mail: afanas@gwu.edu

It is our main objective to demonstrate the effects of piezoelectric fields, via SAW application, on photocathode performance. To the best of our knowledge, such an effect was never demonstrated before.

GENERATION OF SAW

SAW are presently a basis of a well-established technology used in multiple applications, primarily in SAW devices associated with electronic circuits. The telecommunications industry is probably the largest consumer of SAW devices, with an estimated 3 billion acoustic wave filters used per year [3]. In most applications SAW are generated (and detected) using a piezoelectric effect, namely, conversion of electrical energy into mechanical energy and vice versa. This is accomplished through the use of Interdigital Transducers (IDT) placed on a piezoelectric substrate, as shown in Fig. 1. An AC voltage, typically with frequencies up to 1 GHz, is applied to the IDT, resulting in one or more SAW propagating with the speed of sound v_{SAW}. The spacing λ of the structure on the IDT defines the wave number of each of the SAW, $k=2\pi/\lambda$. SAW are deformations of the crystal lattice that produce a periodic modulation of the electric charge and potential in piezoelectric semiconductors, such as GaAs (Fig.1).

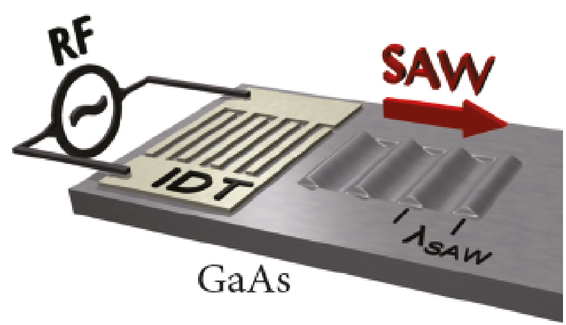

Figure 1: Generation of SAW on a piezoelectric substrate with an interdigital transducer (IDT) powered by an RF-source.

Typical values of the parameters related to experiments of interest [1,4] are frequency f = 840 MHz, wavelength λsaw = 3.4 µm, and speed $v_{SAW} \approx 3$ km/s. More formally, SAW are acoustic phonons with a linear dispersion relation between energy and wave vector, and their eigenmodes are described by the theory of elasticity. For a homogeneous medium, the three bulk elastic

DIELECTRIC WAKEFIELD ACCELERATOR EXPERIMENTS AT ATF*

D. Shchegolkov#, E. Simakov, LANL, Los Alamos, NM 87545, USA
S. Antipov, Euclid TechLabs, Bolingbrook, IL 60440, USA
M. Fedurin, BNL, Upton, NY 11973, USA

Abstract

Dielectric wakefield acceleration (DWA) presents us with means to achieve the accelerating gradient high above the limits of conventional accelerators. In a typical DWA scheme a higher energy lower charge main bunch is accelerated in the wakefield produced by a preceding lower energy higher charge drive bunch inside of a hollow metal-encapsulated dielectric tube. To make use of as much energy of the drive bunch as possible, it is highly important that all parts of it decelerate uniformly. Close to uniform drive bunch deceleration can be achieved if its current is properly shaped.

At Accelerator Test Facility (ATF) at BNL we shaped the current of a chirped electron beam with an adjustable mask placed inside of the highly dispersive region in the magnetic dogleg. We passed the shaped beam current through a quartz tube and observed the beam particles' energy modulation at the tube's output with a spectrometer. By tuning the mask we were able to control the beam energy modulation and thus the wakefield profile in the tube.

INTRODUCTION

Dielectric wakefield accelerators are formed by one or several coaxial dielectric layers surrounded by metal cladding (Fig. 1). Wakefields in dielectric structures may reach gradients on the order of 10 GV/m [1] with 100 MV/m demonstrated in multiple experiments. They also have the remarkable property that the wakefield's axial electric field is transversely uniform due to the fact that the relativistic drive beam and the subsequent wakefield travel very nearly at the speed of light. As we noticed previously [2, 3], these unique properties may allow the use of DWAs as high gradient high brightness accelerators for X-ray free electron lasers.

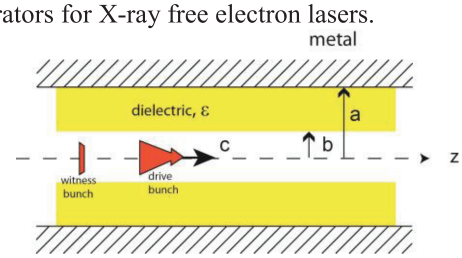

Figure 1: Schematic of the DWA.

An important parameter of each accelerator is its energy transfer efficiency. In case of the DWA it has to do with the transformer ratio (TR), which is the ratio of the accelerating field acting on the main bunch to the maximum deceleration field inside of the drive bunch. For the same accelerating gradient higher TR wakefield will ensure longer use of the drive bunch due to its smaller and more uniform deceleration. For any finite length longitudinally symmetric bunch the TR can never exceed 2 [4]. An enhanced TR can be achieved with a ramped beam or a ramp-profiled bunch train [4]. Recently a double triangular (DT) beam current was proposed [5]:

$$I(t) = \begin{cases} I_0 \cdot f \cdot t, & 0 \le t < \dfrac{1}{4f}; \\ I_0 \cdot \left(f \cdot t - \dfrac{1}{2\pi} \right), & \dfrac{1}{4f} \le t < T. \end{cases}$$

In the above formula, f is the frequency of a single mode accelerator, T – the total bunch duration, t – time, I_0 – a constant with units of current. In a single mode approximation the DT current produces strictly uniform deceleration of the drive bunch except for its very beginning part (Fig. 2). In reality, due to the finite thickness of the dielectric tube, more than one mode is exited; as a result, the TR is generally reduced (Fig. 2). For very long DT drive bunches the TR becomes proportional to the bunch length expressed in wavelengths of the induced wakefield radiation and thus the TR can be made very large.

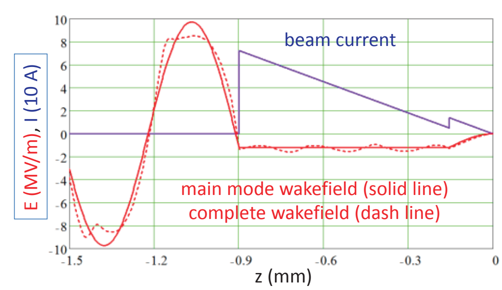

Figure 2: DT current and its wakefield in the tube chosen for the experiment: a=550 μm, b=400 μm, ε=3.8.

Even though the DT bunch has no steep rising edges, it is still difficult to produce with all the features in subpicosecond scale required for the accelerator operation at 300 GHz or higher frequencies.

At ATF we used an indirect method of current modulation employing a transverse DT beam mask [6]. The mask was made adjustable to compensate for beam parameters which were hard to control. An energy chirped beam was shaped with the mask, passed through a metal encapsulated quartz tube and visualized on a spectrometer. We tuned the mask and observed the beam energy change on the spectrometer. The idea of the experiment was that if the beam has a right DT shape then its picture on the spectrometer incurs minimum changes

SIMULATION STUDIES OF BBU SUPPRESSION METHODS AND ACCEPTABLE TOLERANCES IN DIELECTRIC WAKEFIELD ACCELERATORS*

D. Shchegolkov#, E. Simakov, LANL, Los Alamos, NM 87545, USA
A. Zholents, ANL, Argonne, IL 60439, USA

Abstract

The advantage of dielectric wakefield accelerators (DWAs) is the ability to achieve accelerating gradients well above the limits of conventional accelerators. However DWAs will also produce high transverse wakefields if the beam propagates off-center, which grow even faster than the accelerating gradient when the width of the beam channel is decreased. It is highly important to suppress single beam breakup (BBU) instability in order for the beam to propagate long enough so that a reasonable amount of energy (e.g., 80%) from the drive bunch is extracted. In addition bending of the dielectric channel has a similar effect to off-center steering of the beam with the required tolerances on the channel straightness typically in a few micron range. For both rectangular and circular dielectric lined waveguides we use a FODO lattice with a tapered strength for suppression of BBU. We impose initial energy chirp on the drive beam to make use of the BNS damping. We change rectangular waveguide orientation by 90 degrees with a small step to make use of the quadrupole wakefield focusing. These and other techniques and tolerance requirements are discussed and simulation results are presented in this paper.

INTRODUCTION

Accelerating gradients as high as several GV/m have been demonstrated in short dielectric tubes fed by electron beams [1]. However, when it comes to staging, a problem of high transverse wakefields arises. Narrowing of the dielectric tube results in higher accelerating gradient which is generally in inverse proportion to the tube radius squared. However the transverse wakefields grow even faster in inverse proportion to the tube radius cubed [2]. Consequently smaller tube size causes premature BBU that will lower the accelerator efficiency and the maximum achievable energy due to the beam loss. More efficient use of the drive bunch can be obtained if the BBU instability is effectively suppressed.

SIMULATIONS IN ELEGANT

DWA modelling was performed in Elegant to study ideas and configurations for their effectiveness in fighting BBU [3]. Even though Elegant [4] is considered as a primarily transfer matrix type of an accelerator code, it has all the necessary capabilities to fully account for different particle energies in beamline elements (including quadrupole magnets) with momentum kicks. This is especially important as the drive and the witness bunches in the DWA may have different particle energies by as much as several orders. We implemented both longitudinal and transverse wakefields (dipole and quadrupole) in Elegant by supplying their Green's functions as a table of time dependent values in a separate input file.

BUNCH SHAPES FOR HIGH TRANSFORMER RATIO

To achieve high efficiency in a DWA a drive bunch with a ramped current which creates a high transformer ratio wakefield (HTRW) has to be used [5]. The wake of a ramped bunch has a uniform decelerating field acting on the whole drive bunch except only for a small part of it at the beginning, where the field is lower. It was suggested to use a specific double triangular (DT) current to excite the HTRW [6, 7]. Any HTRW is also associated with near linear growth of the transverse deflection force towards the tail of the drive bunch, which in turn linearly increases with the beam offset from the tube's axis. It makes the tail of the drive bunch most susceptible to the BBU. The main longitudinal and dipole wakefield modes have close frequencies, but their Green's functions are 90° out of phase with the longitudinal gradient reaching the peak value right behind the drive charge and the transverse gradient reaching its peak value a quarter wavelength downstream.

BBU SUPPRESSION

The well-established way to confine the charged particle beam is to use a FODO lattice consisting of magnetic quadrupoles of alternating polarity. The period of the FODO lattice has to be much smaller than the typical length of instability's growth. At the same time, smaller periods require higher magnetic gradient to provide adequate focusing. If quadrupoles are too strong, there is an overfocusing. So the quadrupoles need to be strong enough to have pronounced focusing effect, but not too strong to cause instability. As the drive beam loses energy the magnetic strength of the FODO lattice needs to be tapered to keep it optimal for the particles in the tail of the drive bunch which are most susceptible to the BBU (Fig. 1).

The FODO suppression of the BBU instability is not very efficiency as is. The reason for that is that once the beam has an off-center shift, it will oscillate in the FODO

EXPERIMENTAL STUDY OF WAKEFIELDS IN AN X-BAND PHOTONIC BAND GAP ACCELERATING STRUCTURE*

Evgenya I. Simakov#, Sergey Arsenyev, Cynthia Buechler, Randall L. Edwards, and William Romero, Los Alamos National Laboratory, Los Alamos, NM 87545, USA
Manoel Conde, Gwanhui Ha, John Power, and Eric Wisniewski, Argonne National Laboratory, Argonne, IL 60439, USA
Chunguan Jing, Euclid Techlabs, LLC, Solon, OH 44139, USA

Abstract

We designed an experiment to conduct a detailed investigation of higher order mode spectrum in a room-temperature traveling-wave photonic band gap (PBG) accelerating structure at 11.7 GHz. It has been long recognized that PBG structures have great potential in reducing long-range wakefields in accelerators. The first ever demonstration of acceleration in room-temperature PBG structures was conducted at MIT in 2005. Since then, the importance of that device has been recognized by many research institutions. However, the full experimental characterization of the wakefield spectrum in a beam test has not been performed to date. The Argonne Wakefield Accelerator (AWA) test facility at the Argonne National Laboratory represents a perfect site where this evaluation could be conducted with a single high charge electron bunch and with a train of bunches. Here we describe fabrication and tuning of PBG cells, the final cold-test of the traveling-wave accelerating structure, and the results of the beam testing at AWA.

INTRODUCTION

The next generation of linear colliders with multi-hundred GeV to TeV beam energies pushes the frontiers of the current beam physics and technology with the goal of obtaining high luminosity of the beam and avoiding bunch to bunch beam breakup. Thus, the accelerating cavities for the future linear colliders must be selective with respect to the operating mode, and higher order mode (HOM) wakefields that affect the quality of the beam must be suppressed. Photonic Band Gap [1] (PBG) cavities have the unique potential to filter out HOM power and greatly reduce wakefields. A PBG structure or simply, photonic crystal, represents a periodic lattice of macroscopic components (e.g., rods), metallic, dielectric or both. For accelerator applications, two-dimensional PBG resonators based on arrays of metal rods are commonly employed. The first ever demonstration of acceleration in a PBG resonator was conducted at Massachusetts Institute of Technology (MIT) in 2005 [2]. Since then, the importance of PBG structures for accelerators has been recognized by many research institutions worldwide.

Two attempts to experimentally study wakefields in PBG accelerators were conducted to date, but were incomplete [3,4]. At this point, the full experimental characterization of the wakefield spectrum in a traveling-wave PBG accelerator is overdue.

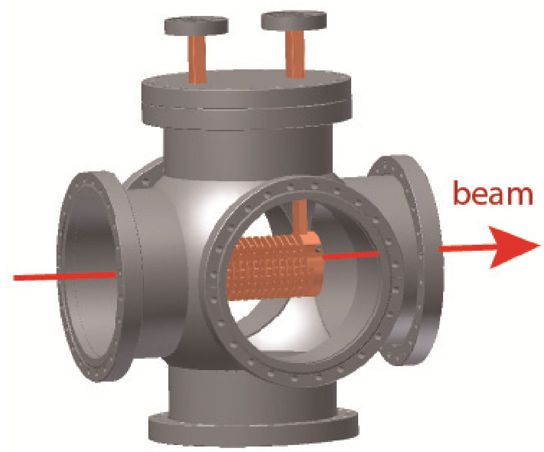

Figure 1: A 16-cell traveling-wave PBG accelerator structure with two waveguide couplers installed in a vacuum chamber for the wakefield tests.

DOE HEP funded a project at Los Alamos National Laboratory (LANL) to conduct the experimental characterization of the wakefield spectrum of a traveling-wave PBG accelerator structure. We put together an 11.7 GHz $2\pi/3$-mode accelerating structure of 16 PBG cells, installed it at the Argonne Wakefield Accelerator (AWA), passed an electron beam through the structure (as shown in Figure 1) and recorded the full traveling-wave (TW) wakefield spectrum.

DESIGN OF 11.7 GHz TW PBG ACCELERATOR

We designed a 16-cell traveling-wave $2\pi/3$-mode PBG accelerator structure with characteristics similar to the 6-cell MIT PBG structure [2]. The PBG accelerator was designed at the frequency of 11.7 GHz, which is 9 times the frequency of the AWA (1.3 GHz). The exact dimensions and the accelerator characteristics of the structure are summarized in Table 1.

PARTICLE PRODUCTION OF A GRAPHITE TARGET SYSTEM FOR THE INTENSITY FRONTIER*

X. Ding,† UCLA, Los Angeles, CA 90095, USA
H.G. Kirk, Brookhaven National Laboratory, Upton, NY 11973, USA
K.T. McDonald, Princeton University, Princeton, NJ 08544, USA

Abstract

A solid graphite target system is considered for an intense muon and/or neutrino source in support of physics at the intensity frontier. We previously optimized the geometric parameters of the beam and target to maximize particle production at low energies by incoming protons with kinetic energy of 6.75 GeV and an rms geometric emittance of 5 mm-mrad using the MARS15(2014) code. In this study, we ran MARS15 with ROOT-based geometry and also considered a mercury-jet target as an upgrade option. The optimization was extended to focused proton beams with transverse emittances from 5 to 50 mm-mrad, showing that the particle production decreases slowly with increasing emittance. We also studied beam-dump configurations to suppress the rate of undesirable high-energy secondary particles in the beam.

INTRODUCTION

Neutrino-physics and muon-physics at the intensity frontier require the greatest possible beam intensities of neutrinos and muons. The target scenario for the present study is to use a 6.75-GeV proton driver with beam power of 1 MW [1] interacting with a graphite target in the so-called 20to2T5m4PDL target system configuration, as shown in Fig. 1.

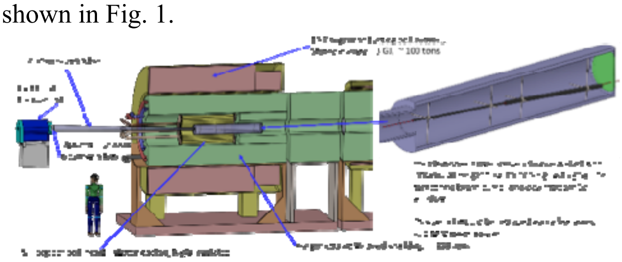

Figure 1: Layout of the 20to2T5m4PDL Target System configuration.

Figure 2 shows that the axial magnetic field for configuration 20to2T5m4PDL tapers adiabatically over 5 m from 20 T around the target to 2 T in the rest of Front End [2]. The inner radius of superconducting coils (SC) in the region surrounding the graphite target is 120 cm to permit sufficient internal tungsten shielding for a 10-year operational lifetime of the SC coils against radiation damage [3]. The first 50 m of the magnetic channel of the Front End is sketched in Fig. 3.

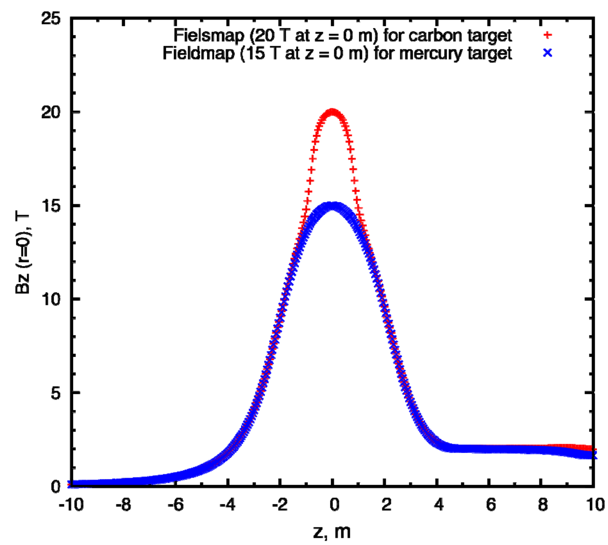

Figure 2: Axial magnetic field of the 20to2T5m4PDL (red dots) and 15to2T5m4PDL (blue dots) Front-End channels. The center of the target is at $z = 0$.

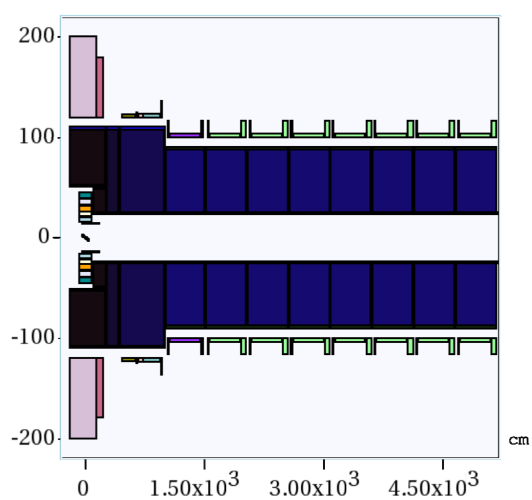

Figure 3: Schematic of the 20to2T5m4PDL Target System configuration, for $-2 < z < 50$ m.

The graphite-target, and graphite-beam-dump, rods are inside a double-walled stainless-steel containment vessel, with downstream Be windows, shown at the right of Fig. 1. These rods are radiation cooled, and the containment vessel is cooled by He-gas flow between its double walls. The outer cylinder extends over $-46 < z < 170$ cm, with outer radius $r = 15$ cm. The inner cylinder extends over $-45 < z < 169$ cm, with inner radius $r = 14$ cm. The

HIGH RELIABILITY, LONG LIFETIME, CONTINUOUS WAVE H- ION SOURCE

Preston J. Barrows, University of Wisconsin - Madison, WI 53706, USA
Gabriel E. Becerra, Phoenix Nuclear Labs LLC, WI 53713, USA

Abstract

Phoenix Nuclear Labs (PNL) is developing a high-current, long-lifetime negative hydrogen (H-) ion source in partnership with Fermilab as part of an ion beam injector for future Intensity Frontier particle accelerators. In this application, continuous output with long lifetime and high reliability and efficiency are critical. Existing ion sources at Fermilab rely on plasma-facing electrodes and are limited to lifetimes of a few hundred hours, while requiring relatively high gas loads on downstream components. PNL's H- ion source uses an electrodeless microwave plasma generator which has been extensively developed in PNL's positive ion source systems, demonstrating 1000+ hours of operation and >99

INTRODUCTION

Ion sources are critical for a wide range of applications including basic science research, medical applications, and semiconductor production. In many cases, the performance and reliability of very large, complex, and expensive systems is limited by the performance and reliability of the ion source, which often represents a relatively small part of the total system in terms of size and cost. Thus, advances in ion source technologies can lead to drastic improvements in system performance relatively quickly. However, ion sources are complex devices that often suffer from reliability issues when pushed to high currents, as is often demanded by the rest of the system.

Lifetime and reliability issues can be troublesome for ion sources, and this can be especially true for negative hydrogen (H-) sources. Nonetheless, negative ion sources are still commonly used across a broad range of applications due to the fact that, for many applications, downstream system components require negative rather than positive ions. In this project, a new type of ion source that can produce high DC current output (up to 15 mA) and has a long lifetime (up to several months) has been designed. It is understood that the near term DoE need for such a source is to serve as an ion beam injector into future Intensity Frontier particle accelerators that are under development at Fermi National Lab and other DoE labs.

Intensity Frontier accelerators are next generation basic science research accelerators which include GeV-scale linacs able to operate at higher current levels than have ever been achieved at this energy level.

The leading H- ion source candidate that is currently under consideration by the Fermilab design team has a lifetime of a few hundred hours. This lifetime decreases further when operated at full power (15 mA). Furthermore, the source has high power requirements (15 kW) and high gas load

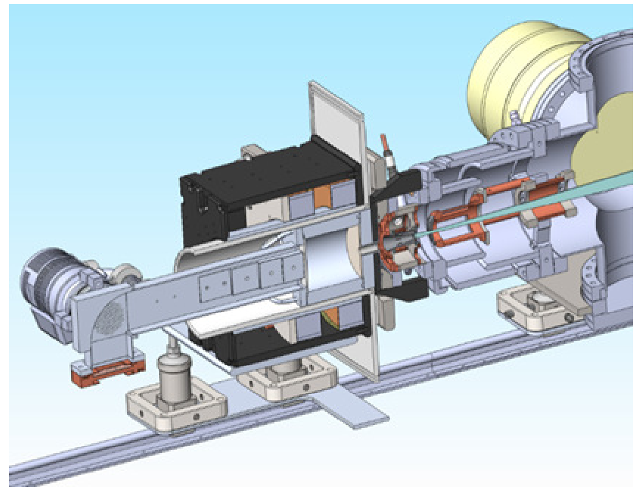

Figure 1: Cross-sectional view of negative ion source beamline.

(18-20 SCCM) on the downstream vacuum components. Though ion sources are cheap on the scale of large research accelerators, if a more reliable H- source is not developed the results of the entire project could be in jeopardy.

In this project, a modified 2.45 GHz microwave proton source has been evaluated as a generator of atomic hydrogen that will be used for surface production of H- ions. A cesiated surface converter is located between the proton source and the H- extraction region. In the extraction region, electrostatic lenses produce a low energy H- ion beam. Diagnostics developed in this work monitor neutral atomic hydrogen particle energy and flux, along with electron temperature and density near the extractor. A design for H- beam formation in a reduced plasma density environment has been developed. It is particularly important to reduce high temperature electron density in the converter region. Thus, the two ion source chambers (neutral production and H- conversion) are separated by a tunable magnetic dipole field.

DESCRIPTION

Phoenix Nuclear Labs (PNL) has developed a design for a negative hydrogen ion source. The device is driven by a plasma chamber that produces energetic electrons, positive hydrogen ions, and neutral hydrogen atoms. The particles generated by the plasma are filtered by a transverse magnetic field, which preferentially removes energetic electrons while allowing fast neutrals to pass. These neutrals are directed to a surface converter and produce the desired negative hydrogen ions, which are then extracted into a low energy beam using

Abstract

Recent experimental demonstrations of dielectric laser-driven accelerator structures offer a path to the miniaturisation of accelerators. In order to accelerate particles to higher energies using a staged sequence of accelerating structures, integrating compatible micrometre-scale transverse deflecting structures into these accelerators is necessary. Using simulations, the present work outlines the design and optimisation of a fused-silica laser-driven grating deflecting structure for relativistic electron beams. Implications for device fabrication and experiments are outlined.

INTRODUCTION

The design of conventional particle accelerators is motivated by the Lorentz force, with magnetic fields for the efficient deflection of high energy particles. However, the possibility of transverse electric field gradient of the order 1 GV m^{-1} bypasses the need for magnetic fields for deflecting beams, and opens new options and length scales for accelerator design.

Recent experimental demonstrations of dielectric laser acceleration with electric fields exceeding 300 MeV m^{-1} are presented in Refs. [1–3]. Using ultrafast laser pulses of the order of 100 fs, this can be extended to electric field gradients of 1 GV m^{-1} [4].

The present work outlines electromagnetic simulations of a laser-driven dielectric deflecting structure. An experiment is proposed to demonstrate laser-driven dielectric deflecting structures with relativistic electron beams in a compact undulator.

THEORY

The theory of dielectric grating deflecting structures for relativistic electron beams is described in the previous work of Plettner, et al. [5–7]. Several key parameters can be used to compare dielectric accelerators of differing geometry. The accelerating gradient, denoted by G_0 is given by [8],

$$G_0 = \frac{q}{\lambda} \int_0^{\lambda} E_z[z(t), t] dz, \tag{1}$$

where q is the particle charge, λ is the laser wavelength, and the electric field E_z represents the electric field in the direction of travel of the electron. Similarly, a deflecting field can be denoted by D_0, defined by,

$$D_0 = \frac{q}{\lambda} \int_0^{\lambda} \left[\Big(E_x[z(t), t] - cB_y[z(t), t] \Big)^2 + \Big(E_y[z(t), t] + cB_x[z(t), t] \Big)^2 \right]^{\frac{1}{2}} dz, \tag{2}$$

where the electric and magnetic fields of the laser are decomposed into the directions x and y of Fig. 1.

The purpose of the dielectric grating structure is to generate periodic, local oscillations to the incident the electric field. The amplitude of the electric field therefore varies within the structure, with the maximum electric field anywhere in the structure defined as E_{max}. The maximum electric field in the structure determines the maximum incident electric field that the structure will sustain without damage.

One can define the field enhancement factor of a structure as $\eta = E_{\mathrm{max}}/E_0$ [9]. Hence, the acceleration factor f_A (denoted by Plettner, et al. as the damage factor [8]) is given by,

$$f_A = \frac{G_0}{E_{\mathrm{max}}}, \tag{3}$$

and the deflection factor by [9]

$$f_D = \frac{D_0}{E_{\mathrm{max}}}. \tag{4}$$

Given a material with a known damage threshold electric field E_{dam}, the structure accelerating and deflecting fields can be scaled based upon the incident electric field E_0.

STRUCTURE AND LASER

The geometry of the structure simulated in the present work is presented in Fig. 1 below. The structure coordinates are defined in rectangular Cartesian coordinates, with the electron beam propagating in the z direction. The grating is rotated at an angle α about the y axis.

The structure is assumed to be illuminated by a single plane wave source of wavelength λ, propagating with wavevector k in the $-y$ direction, linear polarisation axis perpendicular to the grating and incident electric field E_0. Assuming a relativistic electron beam ($v \approx c$), the grating period in the direction of the electron beam trajectory should satisfy $\lambda_p = \lambda \cos\alpha$ [5].

At the photon wavelength of interest $\lambda = 800$ nm, the index of refraction of fused silica is approximately $n = 1.5$, and the relative permittivity $\varepsilon_r = n^2 = 2.25$ [10].

A NEW ACCELERATING MODE IN A SILICON WOODPILE STRUCTURE AND ITS HIGH-EFFICIENCY POWER COUPLER DESIGN*

Z.R. Wu#, C.H. Lee, C.K. Ng, K.P. Wootton, R.J. England
SLAC National Accelerator Lab, Menlo Park, CA 94555, USA

Abstract

Silicon woodpile photonic crystals provide a base structure that can be used to build a three-dimensional dielectric waveguide system for high-gradient laser-driven acceleration. A new woodpile waveguide design that hosts a phase synchronous, centrally confined accelerating mode with ideal Gaussian transverse profile is proposed. Comparing with previously discovered silicon woodpile accelerating modes, this mode shows advantages in better beam loading and higher achievable acceleration gradient. Several travelling-wave coupler design schemes developed for multi-cell RF cavity accelerators are adapted to the woodpile accelerator coupler design based on this new accelerating mode. A forward-wave-coupled, highly efficient silicon woodpile accelerator is achieved. Simulation shows high efficiency of over 70% of the drive laser power coupled to this fundamental woodpile accelerating mode, with less than 15% backward wave excitation. The estimated acceleration gradient, when the coupler structure is driven at the damage threshold fluence of silicon at its operating 1.506 um wavelength, can reach roughly 185 MV/m.

INTRODUCTION

Laser driven dielectric photonic bandgap (PBG) accelerating structures have drawn great interest due to the potential ~ GeV/m accelerating gradient and mature high-power, high-efficiency lasers as driving sources [1-3]. The Woodpile structure in particular provides three dimensional EM field confinement and manipulation, and has been shown to exhibit TM-like modes in the defect waveguide to support electron acceleration [4, 5]. Individual rods in the structure discretize the spatial dielectric distribution; therefore offer required degrees of freedom for mode control and building various coupling and focusing elements. The structure, if made of silicon, could potentially be well suited into standard photolithography process, and fabricated on a single wafer as an on-chip accelerator.

The woodpile structure is an arrangement of high-index dielectric scatters in a low-index background material (e.g. air), following a "woodpile" formation. The schematic in Fig. 1 Inset shows a woodpile accelerating waveguide design first proposed in [4]. The base lattice consists of rectangular silicon rods stacked layer-by-layer, whose collective scattering of light exhibits a three-dimensional photonic band gap. The structure possesses mirror symmetry about the XZ plane, permitting a symmetric monopole mode for acceleration. This mode is confined to the open and roughly rectangular channel, as marked by the red break line in Fig. 1 Inset, and it propagates in the z direction. The accelerator waveguide channel is $7h$ tall and $3a$-w wide along its two transverse directions, with definition of dimensions w, h, and a illustrated in the figure. Speed-of-light synchronous TM-like mode is present with this waveguide channel design. An integrated on-chip WPS accelerator is conceptually visualized in Fig. 1. An input laser pulse is split into different branches of silicon-on-insulator (SOI) waveguides, represented by solid black channels in the layout, to power multiple stages of woodpile accelerators (meshed cells in the layout). The SOI waveguides are basically silicon slabs sitting atop lower-refractive-index materials, which confine laser light mostly within the silicon by total internal reflection. Control of the flow of the laser power can be realized via splitters and couplers built upon these SOI waveguides [5]. Electrons traversing through the accelerator channel in the WPS waveguide get a kick at each accelerating cell by the laser field, and accelerate. Each accelerator stage contains a woodpile waveguide loop cavity in order to recycle the laser energy and enhance optical-to-beam efficiency, as the rectangular loops in the layout illustrate.

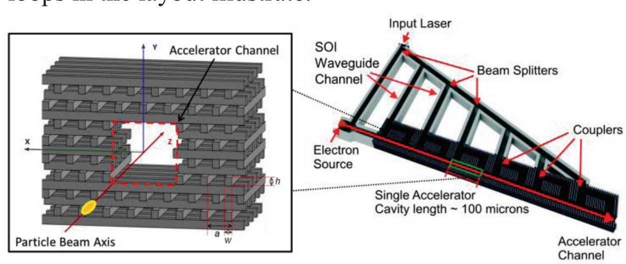

Figure 1: Conceptual schematic of an on-chip woodpile accelerator consisting of multiple accelerator cavities. Inset: Layout of a woodpile accelerator waveguide section supporting speed-of-light accelerating mode. Courtesy of Christopher McGuinness and Benjamin Cowan [4, 6].

A NEW ACCELERATING MODE

Several Accelerating waveguide designs based on silicon woodpile structure have been proposed before [4, 6]. By adjusting the waveguide aperture size and details at the interface between silicon and the channel wall, modal profile as well as phase/group velocities of the accelerating modes can be fine-tuned [6]. As an example, plotted in Fig. 2, Left is a propagating TM-mode with large longitudinal electric field component for

MUON TRACKING STUDIES IN A SKEW PARAMETRIC RESONANCE IONIZATION COOLING CHANNEL

Abstract

Skew Parametric-resonance Ionization Cooling (SPIC) is an extension of the Parametric-resonance Ionization Cooling (PIC) framework that has previously been explored as the final 6D cooling stage of a high-luminosity muon collider. The addition of skew quadrupoles to the PIC magnetic focusing channel induces coupled dynamic behavior of the beam that is radially periodic. The periodicity of the radial motion allows for the avoidance of unwanted resonances in the horizontal and vertical transverse planes, while still providing periodic locations at which ionization cooling components can be implemented. A first practical implementation of the magnetic field components required in the SPIC channel is modeled in MADX. Dynamic features of the coupled correlated optics with and without induced parametric resonance are presented and discussed.

INTRODUCTION

The limit on the minimum achievable emittance in muon ionization cooling comes from the equilibrium between the cooling process and multiple Coulomb scattering in the absorber material. The concept of Parametric-resonance Ionization Cooling (PIC) is to push this limit by an order of magnitude in each transverse dimension by focusing the muon beam very strongly in both planes at thin absorber plates. This creates a large angular spread of the beam at the absorber locations, which is then cooled to its equilibrium value resulting in greatly reduced transverse emittances. Achieving adequately strong focusing using conventional magnetic optics would require unrealistically strong magnetic fields. Instead, PIC relies on a resonant process to provide the necessary focusing. A parametric resonance is induced in a cooling channel, causing focusing of the beam with the period of the channel's free oscillations. To attain simultaneous focusing in both planes at regular locations, the horizontal and vertical betatron oscillation periods must be commensurate with each other and with the channel's period. A magnetic channel possessing such optical properties, called a Twin helix channel, has been successfully developed and simulated [1].

Another important condition necessary for implementation of PIC is compensation of the beam smear from one focal point to another, to a degree where it is small compared to the focused beam size. Since the angular spread at the focal point is on the order of 100 mrad rms while the beam size is a fraction of a mm, this can be quite challenging. To mitigate this problem, the Twin helix channel was designed using continuous helical fields eliminating fringe-field effects. Significant progress has been made on compensation of aberrations using helical multipole fields [1]. However, multipole fields in combination with correlated optics introduce another serious problem, namely, non-linear resonances causing loss of dynamical stability.

To illustrate this problem, consider the Hamiltonian term of a continuous harmonically-varying octupole field $H_{oct} = n_{oct}\,(6x^2y^2 - x^4 - y^4)/4$ where $n_{oct} \sim \cos(2\pi mz/L)$ is the normalized octupole strength, m is an integer, z is the longitudinal coordinate, L is the channel period length, $x \sim \cos(2\pi\nu_x z/L)$ and $y \sim \cos(2\pi\nu_y z/L)$ are the horizontal and vertical transverse betatron coordinates, respectively, and ν_x and ν_y are the horizontal and vertical betatron tunes, respectively. Multiple octupole harmonics are needed in a cooling channel to compensate spherical aberrations. However, as can be clearly seen from the Hamiltonian, with our choice of betatron tunes of $\nu_x = 0.25$ and $\nu_y = 0.5$, any octupole harmonic m causes resonances in both planes. Dispersion further complicates the resonance structure. Selecting different betatron tunes does not help; as long as the betatron periods are integer multiples of the channel period as required by PIC, multipole fields will tend to cause non-linear resonance. This makes it difficult to find a set of multipoles sufficient for aberration compensation that does not cause beam instabilities.

To overcome this problem, we developed the concept of Skew PIC (SPIC). We introduce coupling in a cooling channel in such a way that the point to point focusing needed for PIC is preserved but the canonical betatron tunes are shifted from their resonant values, i.e. the canonical phase advances in the two planes are shifted from $m\pi$ values. A simple way to think of it is that the beam is azimuthally rotated between consecutive focal points. This moves the dispersion and betatron motion away from non-linear resonances. It also offers a number of other benefits: (a) it allows for control of the dispersion size for chromatic compensation; (b) it reduces the dimensionality of the aberration compensation problem to just the radial dimension and therefore reduces the number of required compensating multipoles; (c) it equates the parametric resonance rates in the two planes, and therefore only one resonance harmonic is needed; (d) it equates the two cooling decrements in the two transverse dimensions. In this paper, we present a design of a SPIC channel and first results of dynamics studies in this channel.

INTENSE MUON BEAMS FROM THE CSNS SPALLATION TARGET

Yu Bao*, Gail Hanson,
Dept. of Physics and Astronomy, University of California, Riverside, CA, USA

Abstract

Intense muon beams are useful for a wide range of physics experiments. Currently most of the muon beams are produced by protons hitting thin targets sitting upstream of spallation neutron targets. The intensity of the muons is greatly limited by the small thickness of the muon targets, which are intended to have minimum impact on the proton beams. When the majority of the proton beam hits the spallation target, a large number of pions/muons are produced. After being captured in a solenoidal magnetic field, a high intensity muon beam can be produced. In this paper we take the Chinese Spallation Neutron Source (CSNS) target as an example and investigate the production of high intensity muon beams. Two possibilities are presented in this paper: an upstream collection of surface muons and a downstream collection of pions which is followed by a decay and compress channel to obtain a high intensity muon beam. Simulations show both methods can reach high intensities which could significantly increase the statistics of many experiments.

INTRODUCTION

When protons hitting spallation targets, a large number of pions are produced along with the neutrons. Such pions can be collected to produce high intensity muon beams in decay channels. Such muon beams can be injected into storage rings for neutrino studies. They can also be used for rare-decay researches if their energies are reduced by rf cavities. When the pions decay on the surface of the target, a highly polarized, mono-energy muon beam can be produced, which is called "surface muon". Such surface muon beams can be used for the next generation μSR applications, muonium spectroscopy, as well as searches for muon rare decays.

In this paper we investigate the production of pions and muons on the Chinese Spallation Neutron Source (CSNS) target [1]. In order to have minimum impact on the neutron production, we outline two possible ways of collecting the pions and muons: collecting surface muons from upstream of the target and collecting pions from downstream of the target. We present the collecting efficiency depending on various solenoidal magnet settings. Simulation results show that with reasonable settings the collecting efficiency for the surface muons and the pions can reach $1.3 \times 10^{-5} \mu^+/proton$ and $5 \times 10^{-3} \pi^+/proton$ respectively. Based on the 500 kW proton driver with an energy of 1.6 GeV, a surface muon beam of $6.5 \times 10^{10} \mu^+/s$ and a pion beam of $2.5 \times 10^{13} \pi^+/s$ can be reached at the end of the collecting solenoid. Such a surface muon intensity is on the same level as the planned HiMB project [2] at Paul Scherrer Institute (PSI).

* baoyubaoyu@gmail.com

For the collected pions downstream, we implement the front end [3] concept of the Neutrino Factory/Muon Collider to compress the momentum spread, and then decelerate the muons from pion decay to low energy so that they can be used for various experiments. Preliminary simulations based on G4beamline show a muon rate of $2 \times 10^{12} \mu^+/s$ can be reached with muon momentum lower than 75 MeV/c. Such an intense muon beam can significantly increase the statistics of many muon experiments such as Mu2e [4], Mu3e [2], etc.

COLLECTING SCHEME

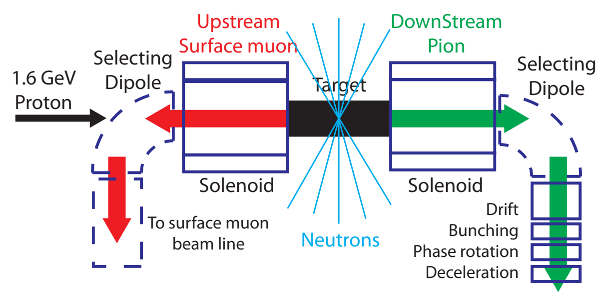

Figure 1: Scheme of collecting the surface muons upstream of the target and collecting the pions downstream.

Figure 1 shows the collecting scheme. The proton source has an rms size of 80 mm × 30 mm on the target. The geometry of the tungsten target is 170 mm in width, 70 mm in height and 570 mm in length. We put collecting solenoids upstream and downstream to focus the muons and pions that are produced in the target. In this way we minimize the influence on the neutron beams. Selecting dipoles can be implemented to guide the beams to further beam lines. In this paper we focus on the collecting efficiency of various settings of the collecting solenoids and implement the front end concept of the Neutrino Factory/Muon Collider to compress the muon momentum spread.

SURFACE MUONS

Figure 2 shows the momentum distribution of the surface muons on the upstream surface of the target. The spectrum has a peak at 28 MeV/c with a sharp cut at high momentum, representing the muons that decay right on the surface of the target. The stopped pions that decay inside but close to the surface of the target produce the muons with lower momentum. The higher momenta muons are produced by the pions that decay in flight. The production efficiency of the surface muons (p < 30 MeV/c) is $3.6 \times 10^{-5} \mu^+/proton$ on the target surface.

SIMULATIONS OF FIELD-EMISSION ELECTRON BEAMS FROM CNT CATHODES IN RF PHOTOINJECTORS

D. Mihalcea, Northern Illinois University, DeKalb, IL 60115, USA
L. Faillace, Radiabeam Technologies LLC, Santa Monica, CA 90404, USA

P. Piot, Northern Illinois University, DeKalb, IL 60115, USA and Fermilab, Batavia, IL 60510, USA

Abstract

Average field emission currents of up to 700 mA were produced by Carbon Nano Tube (CNT) cathodes in a 1.3 GHz RF gun at Fermilab High Brightness Electron Source Lab. (HBESL). The CNT cathodes were manufactured at Xintek and tested under DC conditions at RadiaBeam. The electron beam intensity as well as the other beam properties are directly related to the time-dependent electric field at the cathode and the geometry of the RF gun. This report focuses on simulations of the electron beam generated through field-emission and the results are compared with experimental measurements. These simulations were performed with the time-dependent Particle In Cell (PIC) code WARP.

INTRODUCTION

To increase the power of the Free Electron Laser (FEL) to megawatt-level the injectors must be upgraded such that they could provide ampere level of average electron beam current [1]. Alternatively, low beam charge (picocoulomb-level) and extremely low emittance (10^{-10} m) are desirable to build compact ultra high brightness X-ray sources [2, 3].

Cathodes with deposited Field-Emitters (FE's) were extensively studied during the last decade and are proven to have some obvious advantages compared with the more standard photoemission or thermoionic cathodes. First of all there is no need for additional expensive components to extract the electrons from cathode: lasers (photoemission) and heating systems (thermoionic). In the case of FE's the electrons are extracted by an external electric field through quantum tunneling. The local electric field E at the surface of the FE is typically much larger than the applied electric field E_a by a factor β (enhancement factor) dependant on FE geometry. The current density of the electron beam is given by Fowler-Nordheim (FN) formula: $j = aE^2 exp\left(-\frac{b}{E}\right)$ where constants $a = \frac{1.42\times10^{-6}}{\Phi} exp\left(\frac{10.4}{\sqrt{\Phi}}\right)$ and $b = -6.56 \times 10^{-9}\Phi^{3/2}$ depend on cathode material through the work function Φ (in units of eV) [4] and E ($= \beta E_a$) is the external electric field at the surface of the FE.

Large effective emitting area combined with large enhancement factor are key elements to design efficient FE cathodes. In the recent years Carbon Nano Tubes (CNT's) proved to be promising FE candidates. CNT's are cylindrical single-wall or multi-wall nanostructures which can be deposited on the surface of a metallic cathode. They have extremely low electrical resistivity and are very robust at high temperature. Due to small diameter (1-50 nm) and high aspect ratio ($\sim$ 1000) the enhancement factor is high (typically several hundreds).

To maintain the simplicity of the injector it is desirable that the external applied electric field produced by the standard RF system, needed anyway to further accelerate the beam, is enough to produce the desired beam intensity. In this contribution we show that cathodes deposited with multi-wall randomly oriented CNT's can produce ampere-level beam currents when they are simply exposed to the fields inside a standard RF gun.

EXPERIMENTAL SETUP

The testing of the CNT FE cathodes was carried out at Fermilab High Brightness Electron Source Lab (HBESL) and described in [5]. The schematic top-view of the injector relevant components is shown in Fig. 1. The main component of this injector (normally used as a photoinjector) consists of a 1.5-cell resonant RF gun operated at 1.3 GHz. The RF power is provided by a 2 MW klystron in macropulses with adjustable duration and 0.5 Hz repetition rate. The typical macropulse duration for these experiments was chosen at 40 μs to compromise between achieving maximum charge in he bunch train and avoiding any significant energy depletion inside the gun due to beam loading. The peak field at the cathode can reach about 35 MV/m.

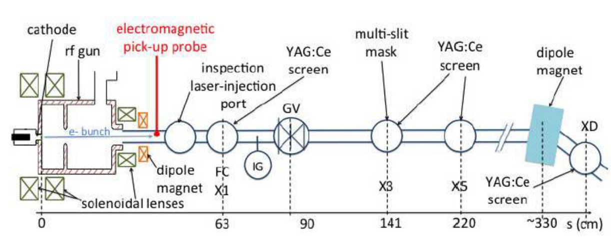

Figure 1: Simplified schematic top-view layout of HBESL injector.

The RF gun is embedded in the external magnetic field created by three solenoids to control the transverse size of the electron beam and to partially compensate the emittance growth. The beam current is measured with a Fara-

THE TWO BEAM ACCELERATION STAGING EXPERIMENT AT ARGONNE WAKEFIELD ACCELERATOR FACILITY*

J. Shi, Tsinghua University, Beijing, China

Abstract

Staging, defined as the accelerated bunch in a wakefield accelerator continues to gain energy from sequential drive bunches, is one of the most critical technologies, yet be demonstrated, required to achieve high energy. Using the Two Beam Acceleration (TBA) beamline at Argonne Wakefield Accelerator (AWA) facility, we will perform a staging experiment using two X-band TBA units. The experiment is planned to conduct in steps. We report on the most recent progress.

STAGING EXPERIMENT AT AWA

Linear colliders based on two-beam wakefield acceleration have a modular design [1]. A fundamental requirement of two beam wakefield acceleration that has yet to be demonstrated is the staging of sequential accelerating modules. For a successful staging demonstration two key issues need to be addressed: drive beam separation and the timing between wakefields from different stages and the accelerated (witness) beam.

In many approaches a fast deflector is required to direct beams from a drive bunch train into separate power extractor units feeding sequential accelerating stages for a witness beam. In the case of an L-band driver at the AWA the drive beam spacing is 50 ns. Stripline kickers or RF deflecting cavities can be used as fast deflectors on this time scale. We propose to use a standard strip line kicker for this proposal.

Another important issue for a staging demonstration is ability to synchronize the witness beam with the wakes generated in different stages. The solution considered up to now has been to bend the drive beam, which raised questions about the energy loss and beam degradation caused by coherent synchrotron radiation. Here we propose a new design based on the time delay of RF pulses in different stages with respect to the witness beam. This approach eliminates the need to bend a high charge beam 180 degrees. For the design of the RF delay line one has to consider two factors: line length and attenuation.

Demonstration of wakefield acceleration staging is the next big step towards validation of the approach as a whole. It proves that wakefield acceleration is indeed possible in a modular way. Once staging is demonstrated one can achieve TeV energies by stacking these modules. This approach allows for length reduction of the accelerator, as wakefield acceleration yields a high gradient operation in a short pulse mode.

Technical Approach

Most of wakefield collider concepts relied on bending the drive beams out of the drive train into the power extractor units to catch the appropriate phase of the witness beam. We are trying to avoid the need for a 180° arc in the drive beamline because coherent synchrotron radiation and its effects on the drive beam become a concern. Figure 1 shows a two beam acceleration concept with an RF delay substituting for the 180° bend. There are two types of staging when relevant to this concept.

- Each module is driven by its own drive beam or a drive bunch train. Separate modules need to be synchronized to accelerate the main beam (Figure 1); this process is called inter-module staging. Spacing between the drive beams, L_b, relates to the geometrical spacing between modules, L ($L_b=2L$) for synchronization to occur. A fast kicker is used to direct the drive beam to its respective module.
- There are numbers of power extractor – accelerator pairs inside a single module. This is done to extract as much energy out of the drive beam as possible. These units also have to be synchronized representing an intra-module staging. In our design the drive beam enters the last (from the main (witness, accelerated) beam point of view) power extractor (the m^{th}) in each module. The generated rf is transported through a longer rf waveguide which provides a delay time t_{dm}. The delay time of the rf transport line in the $(m\text{-}1)^{th}$ TBA pair is $t_{d(m-1)}$. At the exit of the power extractor #1, drive beam is dumped after exhausting most of its energy. At the moment when the rf from the 1st power extractor fills the 1st accelerating structure, the main beam is launched. Because the rf filling time for each accelerating structure is the same, if we assume the rf delay of the transport line in the first TBA pair t_{d1}=0, then $t_{d2}=2L_s/c$, $t_{dm}=2\times(m\text{-}1)\times L_s/c$, where m is the number of structures in each module and L_s is the length of a single structure. Besides the timing in RF delay lines between separate power extractors we need to address the issue of possible RF losses.

Experimental Plan

As the first step towards demonstration of complete staging, a simplified staging experiment was proposed, which includes one power extractor–accelerator pair for

Abstract

Using optical electromagnetic fields in dielectric microstructures, we can realize higher-energy accelerator systems in a more compact, low-cost form than the current state-of-the-art. Dielectric, laser-driven accelerators (DLA) have recently been demonstrated using fused silica structures to achieve about an order-of-magnitude increase in accelerating gradient over conventional RF structures. We leverage higher damage thresholds of silicon over metals and extensive micromachining capability to fabricate structures capable of electron acceleration. Our monolithic structure, the buried grating, consists of a grating formed on either side of a long channel via a deep reactive ion etch (DRIE). The grating imposes a phase profile on an incoming laser pulse such that an electron experiences a net change in energy over the course of each optical cycle. This results in acceleration (or deceleration) as electrons travel down the channel. We have designed and fabricated such structures and begun testing at the SLAC National Accelerator Laboratory. We report on the progress toward demonstration of acceleration in these structures driven at 2 um wavelength.

INTRODUCTION

Dielectric laser-driven accelerators (DLA) hold promise as an advanced accelerator technology capable of reducing system size and cost. Dielectric materials can have significantly higher damage thresholds at optical wavelengths than metals, allowing for the generation of close to 100 times greater acceleration gradients, in the GV/m range [1]. This, combined with the smaller structure, matched to optical wavelengths at the micron or submicron scale, in principle can drive the miniaturization of accelerator systems. By leveraging decades of photolithography and micromachining technology development, these types of structures can be produced on a large scale for relatively small cost. Driving with commercially available lasers rather that klystrons compounds these size and cost benefits.

Several dielectric accelerator structures have been proposed [2–5], but the grating accelerator [6] is the most successfully demonstrated to date. Subrelativistic electrons have been accelerated in fused silica and silicon Smith-Purcell gratings [7, 8] and relativistic electron acceleration has been demonstrated in a fused silica dual grating structure [9]. A silicon grating-based structure for the acceleration of relativisitic electrons, the buried grating, has also been proposed [10].

Grating DLAs use a laser incident normal to an electron beam with the field polarized in the direction of electron motion. The phase front of the laser is modulated by the grating and then incident on the electron beam travels through vacuum near the grating. This modulated phase breaks the temporal symmetry of a planar wavefront and results in a net acceleration or deceleration, depending on the position of the electron along a grating period. Short-pulse lasers are used to achieve high peak fields in the structure, and therefore high accelerating gradients.

Here we present the progress made toward demonstration of the silicon buried grating structure proposed in [10].

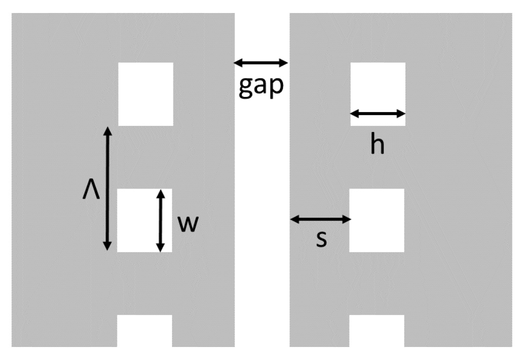

Figure 1: Illustration of parameters used in the design and simulation of buried grating structures.

DESIGN AND FABRICATION

Like previously demonstrated grating DLAs, the buried grating consists a phase grating adjacent to a vacuum region. The grating period is chosen such that the longitudinal component of the field (in the direction of electron travel) always produces an acceleration force. For phase matching the alternating acceleration field, we want the electron to traverse one grating period in one optical cycle, leading to the condition on the grating period of

$$\Lambda = \beta\lambda \tag{1}$$

CATHODE PERFORMANCE DURING TWO BEAM OPERATION OF THE HIGH CURRENT HIGH POLARIZATION ELECTRON GUN FOR eRHIC*

O. Rahman†, I. Ben-Zvi, C. Degen, D.M. Gassner, R. Lambiase,A. Pikin, T. Rao, B. Sheehy, J. Skaritka, E. Wang, BNL, Upton, NY 11973, USA J. Pietz, M. Ackeret, Transfer Engineering and Manufacturing, Inc, Fremont, CA 94539, USA
C. Yeckel, R. Miller, E. Dobrin, K. Thompson, Stangenes Industries, Palo Alto, CA 94303,USA

Abstract

Two electron beams from two activated bulk GaAs photocathodes were successfully combined during the recent beam test of the High Current High Polarization Electron gun for eRHIC. The beam test took place in Stangenes Industries in Palo Alto, CA, where the cathodes were placed in diagonally opposite locations inside the high voltage shroud.

No significant cross talking between the cathodes were found for the pertinent vacuum and low average current operation, which is very promising towards combining multiple beams for higher average current. This paper describes the cathode preparation, transport and cathode performance in the gun for the combining test, including the QE and lifetimes of the photocathodes at various steps of the experiment.

INTRODUCTION

The future Electron Ion Collider requires a high average current high polarization electron source. The average current requirement is 50 mA whereas the maximum average current demonstrated at other polarized electron sources is 4 mA. One very promising idea to obtain the high average current requirement is to combine multiple electron beams on to one axis by using a rotating magnetic field [1]. The key assumption in this proposal is that the operation of one cathode does not affect the lifetime of another cathode in the same vicinity. Therefore, based on the idea of combining multiple beams, a specialized DC electron gun has been designed at Brookhaven National Lab.

EXPERIMENTAL SETUP

For the low current proof of principle test in CA, the gun set up was simplified and is shown in figure 1. The major simplification being the absence of "Depressed collector" [2]. A Faraday cup, biased to 500 V, replaced the Depressed collector. The main goal of this test was to generate low current electron beams from two activated bulk GaAs situated radially opposite ends of the high voltage shroud. The maximum current from the cathodes were limited by a 2.88 G Ω current limiting resistor in series with the gun and a hard HV barrier at approximately 14 KV. Since two cathodes were to be operated at a very low repetition rate, the combiner magnet was essentially in a switch on-off mode. [3]

Cathode Preparation Chamber and Transfer Line

The cathode preparation chamber and it's performance was described in the proceedings of PAC'13 [4]. In order to transport activated GaAs from the cathode preparation chamber to the gun, a transport line in between the gun and preparation chamber was installed. A custom made magnetic manipulator, manufactured by Transfer Engineering and Manufacturing, Freemont, CA [5], was attached to the other side of the preparation chamber.

PROGRESS ON THE STUDY OF DIRECT LASER ELECTRON ACCELERATION IN DENSITY-MODULATED PLASMA WAVEGUIDES *

M.-W. Lin, B. W. Morgan, and I. Jovanovic†, Department of Mechanical and Nuclear Engineering, The Pennsylvania State University, University Park, PA 16802, U.S.A.

Abstract

Direct laser acceleration of electrons can be achieved by utilizing the axial field of a guided, radially polarized laser pulse in a density-modulated plasma waveguide. When a short fs electron bunch is injected together with the drive laser pulse, our particle-in-cell simulations show that the electrostatic field, arising from plasma electrons perturbed by the laser ponderomotive force, increases the transverse divergence of the bunch electrons. Simulations are performed to study the method in which a precursor electron bunch is introduced prior to the main accelerated bunch. The precursor induces a focusing electrostatic field in the background plasma, which can considerably reduce the transverse expansion of the accelerated electrons. Based on the ignitor-heater scheme, density-modulated plasma waveguides are produced in experiments with high-Z gas targets and used to test the guiding of laser pulses. Supersonic gas jet nozzles for producing gas targets are simulated, designed, and then fabricated via additive manufacturing. Surface quality of the nozzles is evaluated via computed tomography.

INTRODUCTION

By guiding a radially polarized laser pulse in a density-modulated plasma waveguide, a large axial acceleration gradient on the order of tens of GV/m can be produced and used for direct laser acceleration (DLA) of electrons over an extended distance [1, 2]. The plasma waveguide extends the acceleration distance and the density modulation provides the quasi-phase matching (QPM) condition to improve the DLA efficiency. However, in addition to interacting with the laser fields, the injected bunch electrons also experience the nonlinear laser ponderomotive force and the electrostatic force from the resulting density variation of the background plasma electrons. The donut-shaped ponderomotive force of a radially polarized pulse pushes the plasma electrons to concentrate at the axis, which produces a transverse electrostatic force that can significantly defocus the electrons of a fs bunch after DLA [3].

In this study, we simulated the DLA scheme in which an additional precursor electron bunch is injected at a proper time prior to the main accelerated electron bunch. The precursor induces a focusing electrostatic field in the background plasma that can be used to considerably reduce the final transverse expansion of the accelerated electron bunch [4]. An all-optical method was experimentally implemented to produce density-modulated plasma channels with Ar gas target, which can be applied to realize the QPM of DLA. Next, micrometer-scale supersonic gas jet nozzles were designed and simulated for generating uniform gas density profiles needed for plasma waveguide production. Additive manufacturing techniques were applied to produce the nozzles.

DLA WITH A PRECURSOR

We carried out 3-D PIC simulations of DLA by the simulation framework VORPAL. Figure 1(a)-(c) summarizes the definition for the laser pulse for driving DLA and the 2.1-mm long plasma waveguide composed of alternating waveguide and neutral hydrogen sections that provide the necessary QPM condition. The waveguide sections have

PHASE SPACE DENSITY AS A MEASURE OF COOLING PERFORMANCE FOR THE INTERNATIONAL MUON IONIZATION COOLING EXPERIMENT

J. Scott Berg, BNL*, Upton, NY 11973, USA

Abstract

The International Muon Ionization Cooling Experiment (MICE) [1] is an experiment to demonstrate ionization cooling of a muon beam in a beamline that shares characteristics with one that might be used for a muon collider or neutrino factory. I describe a way to quantify cooling performance by examining the phase space density of muons, and determining how much that density increases. This contrasts with the more common methods that rely on the covariance matrix and compute emittances from that. I discuss why a direct measure of phase space density might be preferable to a covariance matrix method. I apply this technique to an early proposal for the MICE final step beamline. I discuss how matching impacts the measured performance.

INTRODUCTION

The analysis of the MICE particle trajectories must provide a numerical measure of the cooling performance, and must ensure that this performance measure is unbiased. To provide an example of a potential difficulty, I first examine two possible measures of cooling performance; the first is an increase in the phase space density

$$N_f \epsilon_{6i}/(N_i \epsilon_{6f}) \tag{1}$$

where the i subscripts refer to the initial distribution, the f subscripts to the final distribution, N refers to the number of particles, and ϵ_6 refers to the 6-D phase space emittance, defined to be the square root of the determinant of the 6-D second moment matrix. A different measure could be the luminosity increase:

$$N_f^2\sqrt{\epsilon_{6i}}/(N_i^2\sqrt{\epsilon_{6f}}) \tag{2}$$

This is generally a stronger condition than the increase in phase space density, but may be a more appropriate measure for a muon collider as it measures the eventual increase luminosity one might expect (though there are arguments for a different contribution from the longitudinal emittance).

I use an early version [2] of the MICE final step lattice. The design parameters are given in Tables 1–3. There are two 201.25 MHz cavities with a gradient of 16 MV/m, a length of 434.62 mm, centered at ±281.81 mm. The beam distribution will always be launched from −4050 mm and analyzed at +4050 mm. The beam has a total momentum of 200 MeV/c, and I only consider transverse dimensions. Simulations are performed using ICOOL [3].

To illustrate the potential difficulties I perform a simple simulation: I launch a beam with a Gaussian distribution in transverse phase space, matched to the 4.14565 T solenoid field at the launch point, including its angular momentum, with a given normalized emittance. I then compute the normalized emittance at the end using

$$\sqrt{\sigma_{xx}\sigma_{p_xp_x}\sigma_{yy}\sigma_{p_yp_y}} - \sigma_{xp_x}\sigma_{yp_y} - L^2/4 \tag{3}$$
$$L = \sigma_{xp_y} - \sigma_{yp_x} \tag{4}$$

where σ_{ij} are the corresponding elements of the second order moment matrix. I then use Eq. (1) to compute the increase in phase space density. Figures 1 and 2 show the results. Whether one sees cooling or not depends on the choice of the initial emittance, and there is no clear reason to choose one emittance over another. For small emittances,

CONCEPTUAL DESIGN OF A QUADRUPOLE MAGNET FOR eRHIC*

H. Witte†, J. S. Berg, Brookhaven National Laboratory, Upton, NY, USA

Abstract

eRHIC is a proposed upgrade to the existing Relativistic Heavy Ion Collider (RHIC) hadron facility at Brookhaven National Laboratory, which would allow collisions of up to 21 GeV polarized electrons with a variety of species from the existing RHIC accelerator.

eRHIC employs an Energy Recovery Linac (ERL) and an FFAG lattice for the arcs. The arcs require open-midplane quadrupole magnets of up to 30 T/m gradient of good field quality.

In this paper we explore initial quadrupole magnet design concepts based on permanent magnetic material which allow to modify the gradient during operation.

INTRODUCTION

To discover and understand the emergent phenomena of Quantum Chromodynamics the eRHIC facility is presently being designed. eRHIC adds an electron accelerator to the existing proton accelerator called RHIC (Relativistic Heavy Ion Collider). eRHIC would be an unprecedented facility for Nuclear Physics to study QCD; it is planned to collide unpolarized and 80% polarized electrons (6.6–15.9 GeV) with up to 70% polarized protons (25-250 GeV). The center of mass energy range is 30–145 GeV.

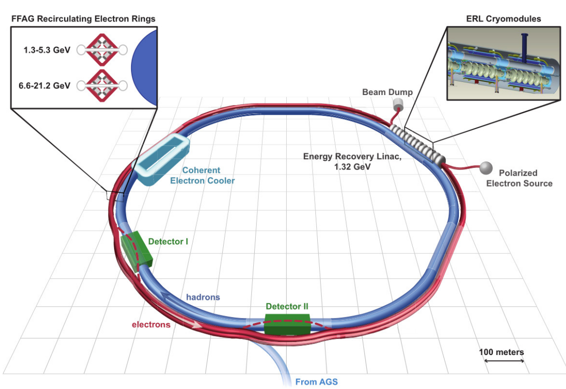

Figure 1: The layout of the eRHIC accelerator.

It was decided to employ the fixed-field alternating gradient (FFAG) accelerator concept for eRHIC. It is planned to add two FFAG rings to the RHIC tunnel for up to 16 beams. The targeted luminosity is $> 10^{33}$ cm^{-2} s^{-1}; plans exist to increase the hadron beam intensity, which would increase the luminosity to $> 10^{34}$ cm^{-2} s^{-1}. Collisions with Au and He are also planned. Figure 1 shows an overview of the facility.

† hwitte@bnl.gov

MAGNET REQUIREMENTS AND CONCEPT

The FFAG lattice requires quadrupole magnets with a gradient strength of up to 28 T/m in a good field region of ±17 mm. The required gradient quality is 1×10^{-3}. In addition to this the poles are not allowed to penetrate the area around the midplane. The open-midplane (±7 mm) is required because of synchrotron radiation.

One design choice is to use permanent magnets. This is possible as the magnets are not required to sweep. The use of permanent magnets allows to dispense with expensive power supplies in the RHIC tunnel, which also greatly simplifies cabling.

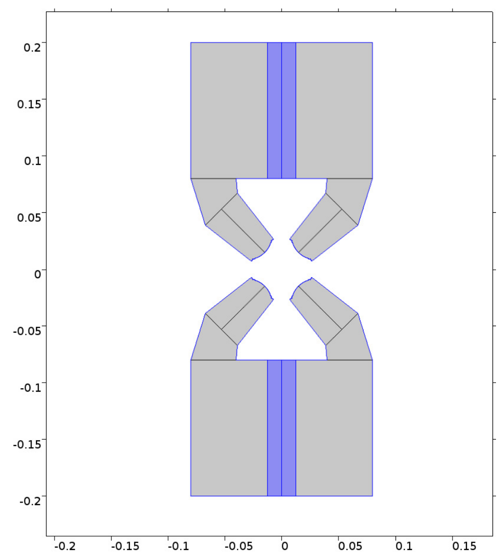

Figure 2: Magnet geometry. The permanent magnetic material is shown in blue.

We envisage NdFeB permanent magnetic material with a remanent magnetic field of about 1.1 T for this design. NdFeB is sufficiently radiation hard provided the grade chosen is relatively low. Studies are underway to demonstrate this.

The geometry of the permanent magnetic material is chosen so that the operating point of the permanent magnet is close to the energetic maximum. Figure 2 shows the general geometry of the quadrupole; the permanent magnets are shown in blue. The total cross-sectional area of the permanent magnets is 60 cm^2 and the height of each block about 12 cm.

The starting point for the initial design of the quadrupole are Tanabe's equations for quadrupoles [1]. The equations below are used to obtain approximate coordinates for the

PARTIAL RETURN YOKE FOR MICE STEP IV AND FINAL STEP*

H. Witte†, S. Plate, J. S. Berg, Brookhaven National Laboratory, Upton, NY, USA
J. Tarrant, STFC Rutherford Appleton Laboratory, Didcot, UK
A. Bross, Fermilab, Batavia, IL, USA

Abstract

This paper reports on the progress of the design and construction of a retro-fitted return yoke for the international Muon Ionization Cooling Experiment (MICE). MICE is a proof-of-principle experiment aiming to demonstrate ionization cooling experimentally.

In earlier studies we outlined how a partial return yoke can be used to mitigate stray magnetic field in the experimental hall; we report on the progress of the construction of the partial return yoke for MICE Step IV.

We also discuss an extension of the Partial Return Yoke for the final step of MICE; we show simulation results of the expected performance.

INTRODUCTION

Ionization cooling has been discussed for a long time for applications where particles need to be accelerated quickly. Ionization cooling so far has never been demonstrated experimentally; MICE is an experiment which is presently constructed at the Rutherford Appleton laboratory in the UK to demonstrate this for the first time [1].

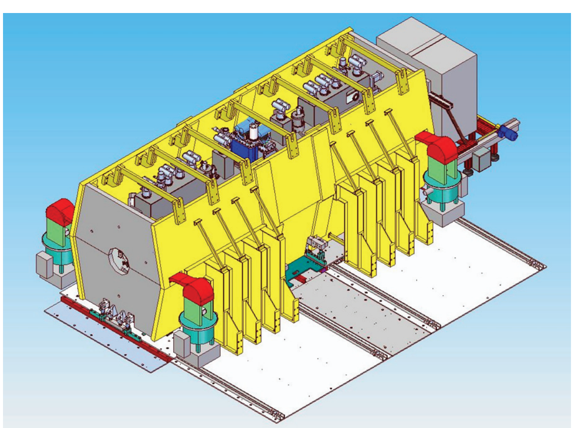

Figure 1: The MICE Partial Return Yoke.

At the time of writing MICE Step IV is under construction, which consists of 12 superconducting solenoids. Recently it was discovered that the MICE solenoids produce a substantial stray magnetic field, which can be problematic for equipment in the MICE hall.

To mitigate this risk the concept of the so-called Partial Return Yoke (PRY) was developed. The MICE PRY is a retro-fitted return yoke, which partially encloses MICE. Figure 1 shows the PRY surrounding the MICE solenoids in Step IV configuration.

In earlier papers we have described the concept, the expected shielding performance and the engineering [2–4]. This paper reports on the progress of construction, which includes magnetic testing of the low-carbon steel for the yoke and required adjustments of the MICE coil currents. The paper concludes with a concept of the extension of the PRY for the final step of MICE.

MATERIAL

For the MICE PRY a low carbon steel (C content $< 0.010\%$) was chosen because of the high saturation value in combination with a high relative magnetic permeability. The design of the PRY was carried out with magnetization curves supplied by the manufacturer. About 60 metric tons of 10 cm thick plate material was obtained; from each heat samples were taken.

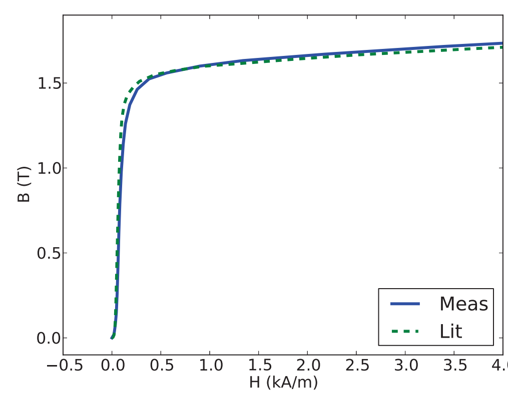

Figure 2: Comparison of the measured and literature magnetization curves of the MICE PRY low carbon steel.

The magnetization curves of the samples were measured by a commercial supplier; it was found that very little difference was observed between the different heats. Figure 2 shows the measured data in comparison to the initially used literature values and Fig. 3 the calculated relative magnetic permeability. As shown in the figures, there is a small variation of the material properties at small magnetic fields. At the operating point of the MICE PRY, which is indicated by the dashed line in Fig. 3, the measured permeability agrees well with the expected value. Simulations show that the differences in material properties lead to a change of the stray magnetic field in the MICE hall by about 1 Gauss (0.1 mT).

THE PROGRESS OF FUNNELLING GUN HIGH VOLTAGE CONDITION AND BEAM TEST

E. Wang#, I. Ben-Zvi, D.M. Gassner, R. Lambiase, W. Meng, O. Rahman, A. Pikin, T. Rao, B. Sheehy, J. Skaritka ,BNL, Upton, NY 11973, USA

C. Yeckel, R. Miller, E. Dobrin, K. Thompson, Stangenes Industries, Palo Alto, CA 94303,USA

Abstract

A prototype of a high average current polarized electron funneling gun as an eRHIC injector has been built at BNL. The gun was assembled and tested at Stangenes Incorporated. Two beams were generated from two GaAs photocathodes and combined by a switched combiner field. We observed the combined beams on a YAG crystal and measured the photocurrent by a Faraday cup. The gun has been shipped to Stony Brook University and is being tested there. In this paper we will describe the major components of the gun and recent beam test results. High voltage conditioning is discussed as well.

INTRODUCTION

In order to construct a future electron ion collider with high luminosity, a high average current and high bunch charge polarized electron source is under R&D at Brookhaven National Laboratory. Currently, the highest average current of polarized electron source was 4 mA achieved at JLab. The cathode lifetime is limited by ion back bombardment. To obtain average current of 50 mA and increase the lifetime, enlarging the photocathode emission area is a straight forward method. However, there are technical difficulties to get uniform photoemission and polarization from large superlattice GaAs photocathode. Uniform electrical field on the large cathode is another challenge as well. Alternatively, we developed a DC gun with multiple cathodes. Funneling the multiple electron bunches generated from several photocathodes to a single common axis could increase the total average current and single-cathode-lifetime. Here, we have to assume the individual cathode performance will not be affected by the rest of cathodes. The first step of the R&D program is proof of this principle.

The gun and beam parameters for eRHIC were described in reference [1]. To carry out the proof of principle test in a short time, we simplified the gun setup and started test with lower current to meet radiation limits. Our first gun conditioning and beam combining test was carried out at Stangenes Industries. Two beams were emitted from two cathodes positioned radially opposite to each other and combined by a switched combiner magnet. Beam current, cathode QE and lifetime was measured.

* Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.
# wange@bnl.gov

GUN SETUP

The detailed gun design with beam optics was described earlier [2]. The depressed collector was replaced by a faraday cup which placed at the end of the beam line. It was biased to 500V to eliminate the secondary electron and back-scattering electrons. A pico-ammeter was connected in series to the Faraday cup. A fixed YAG crystal monitor was placed between the combiner magnet and Faraday cup for monitoring the beam profile and beam position. The YAG crystal has a hole at the centre which allows the beam pass through and reaches the Faraday cup. Figure 1 is the schematic layout of funnelling gun in this first beam test.

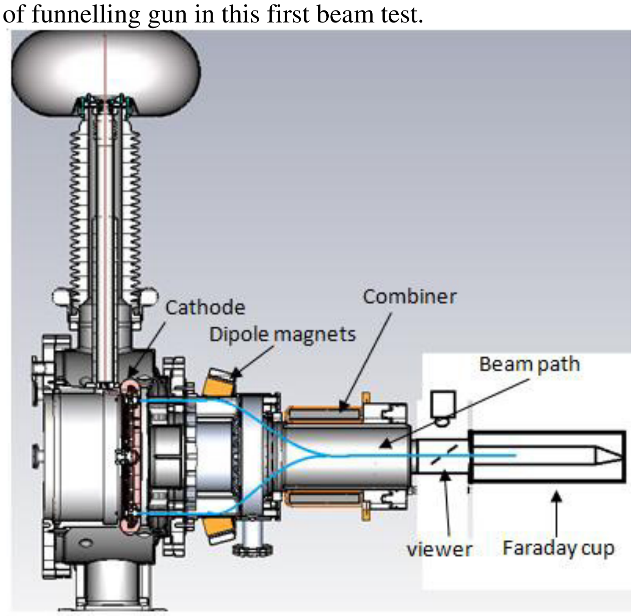

Figure 1: The schematic layout of the funnelling gun with beam measurement instruments

Two dipole magnets and combiner magnets were placed downstream of anode. The combiner was designed to have 20 coils with Sine distribution of the current. In our first beam test, it was simplified to six pairs of coils with constant current and driven by single power supply. Figure 2 shows the field distribution of measured magnetic field compared with the designed ideal field.

Abstract

The Australian Synchrotron Light Source has been operating successfully since 2007 and in top-up mode since 2012, while additionally being gradually upgraded to reach a beam availability exceeding 99 %. Considering the ageing of the equipment, effort is required in order to maintain the reliability at this level. The proposed upgrade of the linac with a SLED cavity has been chosen to mitigate the risks of single point of failure and lack of spare parts. The linac is normally fed from two independent klystrons to reach 100 MeV beam energy, and can be operated in single (SBM) or multi-bunch mode (MBM). The SLED cavity upgrade will allow remote selection of single klystron operation in SBM and possibly limited MBM without degradation of beam energy and reduce down time in case of a klystron failure. The proposal for the SLED cavity upgrade is shown and the linac designs are detailed.

INTRODUCTION

The injector comprises a 100 MeV linac and a 3 GeV booster to enable full energy beam injection into the storage ring. The injector was upgraded later from decay to top-up mode operation to keep the storage ring at 200 mA current. Top-up has been continually running since then with an MBM injection of 0.5 mA every few minutes compared to a reinjection every 12 hours in decay mode.

Alongside top-up came the need to improve reliability and mean down time for the entire facility. Improvements on the injector were more cost effective to target mean down time due to the increase in wear on the system, single point of failure and the limited lifespan of devices such as the electron tubes. Improvements on the linac were necessary with two klystrons required for operation, and a failure could take weeks, depending on missing critical spare parts. The waveguide radio frequency (RF) distribution system for the linac was modified in the first stage in 2010, to test single klystron operation to power the whole linac; albeit at a reduced final beam energy. Booster injection was successful, but booster ramping remained unsolved as a lack of control in fine field adjustments at low energy levels from below 100 MeV. The increase in klystron trips operating at higher power levels was also not satisfactory. The next stage is to add a SLED cavity to overcome the current deficiencies. This paper will outline the proposed upgrade and benefits.

LINAC OVERVIEW

General Specifications

The 100 MeV 3 GHz linac structure is made of a 90 keV thermionic electron gun (GUN), a 500 MHz subharmonic prebuncher unit (SPB), preliminimary buncher (PBU), final buncher (FBU), and two 5 m accelerating structures. The structures are powered by two 35 MW pulsed klystrons supplied from a pulse forming network (PFN). The low level electronics include two pulsed 400W S band amplifiers to drive the klystrons, and two 500W UHF amplifiers for the GUN and SPB. The linac is based on the SLS/DLS design and was delivered by Research Instruments, formerly ACCEL, the modulators subcontracted to PPT-Ampegon, and the waveguide to SPINNER. The linac overview is shown in Figure 1, a summary of the general specifications listed in Table 1 and more details referenced to [1].

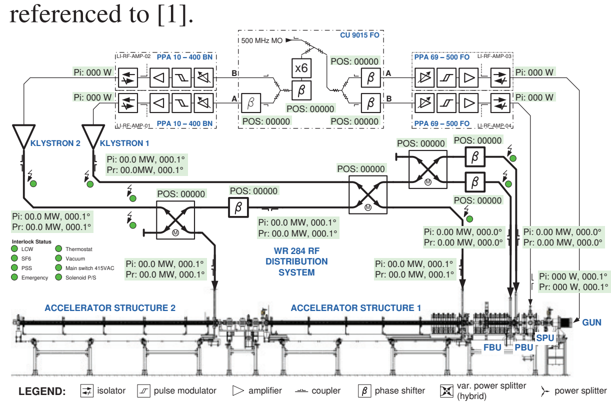

Figure 1: Linac overview.

Table 1: Linac Specifications

Quantity	Specification
Beam Energy	100 MeV
RF Frequency	2.997 GHz
Repetition rate	1 Hz
RMS Emittance	50 π mm mrad
Single/Multi-bunch pulse length	2/150 ns
Single/Multi-bunch pulse charge	> 0.5/4 nC

RF Distribution

The RF power from the two klystrons is transmitted and distributed across the SF6 pressurised WR284 waveguide distribution system. The first klystron feeds power to the PBU, FBU and first accelerating structure, with two successive variable power dividers used to distribute the correct amount of power to each section. The second klystron feeds the power to the second

THE BEAM CHOPPER POWER CONVERTER FOR MEDAUSTRON: SAFETY BY DESIGN AND DEVELOPMENT

T. Stadlbauer, R. Filippini, X. German, F. Osmic, P. Urschütz
EBG MedAustron, Wr. Neustadt, Austria
M.J. Barnes, T. Kramer, CERN, Geneva, Switzerland
M. Beerwald, U. Dirksen, Poynting GmbH, Dortmund, Germany

Abstract

MedAustron is the Austrian centre for hadron therapy and non-clinical research. The beam chopper system is an essential component for patient safety in specific hazardous situations as well as for beam delivery from the synchrotron to the irradiation rooms. This paper presents the results from the development phase and the commissioning of the MedAustron beam chopper system. Details will be given on the design, the risk management, the test and the verification of the chopper power converter (PKC).

SYSTEM DESCRIPTION

System Architecture

The beam chopper system is shown in Fig 1. It consists of one PKC, four kicker magnets (MKC [1], [2]) connected in series and a dump block, located in the high energy beam transfer line (HEBT).

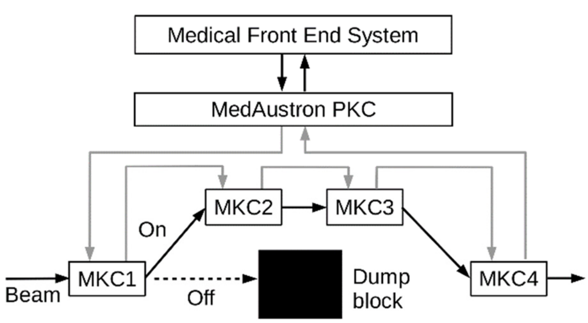

Figure 1: Schematic of the HEBT beam chopper system.

Functioning Principles

The beam chopper in the MedAustron Particle Therapy Accelerator (MAPTA) allows switching the beam in the irradiation room on and off. It performs two functions: 1) it contributes to deliver the beam into the irradiation rooms and 2) protects the patient from specific hazardous scenarios in case of faults. The system is designed to switch off the beam in less than 250 µs (Fig. 2), both in nominal and single fault condition. The beam chopper receives the set points, which are contained in the treatment file, from the accelerator control system (ACS) and is triggered by the Medical Front End (MF) system. If the chopper is switched on, the beam passes from the synchrotron through the chopper chicane in the HEBT to the irradiation room where the patient is treated. In case of detected faults in MAPTA, the chopper is commanded to switch off the beam; the safe state for the patient.

Nominal current	100 A – 630 A
Magnet maximum B-field	136 mT
Maximum output voltage (pulsed)	1500 V
Voltage (DC)	60 V
Repetition rate (max.)	20 Hz
Rise and fall time (max.)	250 µs
Dimension in mm	800 x 800 x 2000
Weight	700 kg

Figure 2: System parameters of PKC SVM-630A manufactured by Poynting GmbH.

REALISATION AND DEVELOPMENT

Design Requirements Specification

The design requirement document was the reference for the beam chopper development, in addition to the quality targets, the test concepts, the applicable standards and the time plan. The specification of the design requirements was structured in order to facilitate the generation of test cases. The preliminary design report, including prototype test, was followed by the definitive design report which concluded the development phase at Poynting GmbH.

Risk Management

The risk assessment of the PKC was carried out according to the MedAustron risk management guidelines in agreement with the EN ISO 14971 standard [3]. The following points were addressed: 1) identification of hazards and categories at risk, 2) compliance with applicable safety standards and 3) risk assessment and evaluation. The hazards analysis identified the situations at risk for the patient during irradiation and for the personnel during service. The risk assessment and evaluation for the PKC was performed by a failure mode, effects and criticality analysis (FMECA) according to IEC 60812 [4]. The FMECA considered the design of the PKC in three stages. The first stage was the preliminary design where the conceptual design was examined; the second stage was the definitive design and the third stage the as-built design. The close collaboration of all involved

VACUUM SYSTEM DESIGN FOR THE SIRIUS STORAGE RING

R.M. Seraphim, O.R. Bagnato, R.O. Ferraz, H.G. Filho, G.R. Gomes, M. Nardin, R.F. Oliveira, B. M. Ramos, T.M. Rocha, A.R.D. Rodrigues, M.B. Silva, LNLS, Campinas, Brazil

Abstract

Sirius is a 3 GeV 4th generation light source under construction by the Brazilian Synchrotron Light Laboratory (LNLS). Sirius will have a low emittance storage ring, 0.28 nm.rad, based on 20 cells of a highly compact lattice – 5 bend achromat (5BA). This lattice concept leaves very little space for components and therefore requires narrow vacuum chambers with tight mechanical tolerances. Most of the storage ring vacuum chambers will be made of oxygen-free silver bearing (OFS) copper and have a circular cross section with inner diameter of 24 mm and a wall thickness of 1 mm. Unused synchrotron radiation will be distributed along the water cooled walls of the chambers. Due to the small conductance of the chambers, vacuum pumping will be based on distributed concept and then non-evaporable getter (NEG) coating will be extensively used, with more than 95% of the chambers being coated. In this paper, we present an overview of the storage ring vacuum system and the fabrication approach for some components.

INTRODUCTION

In order to reduce the horizontal emittance to sub-nm.rad value, the Sirius storage ring will be based on a 5-bend achromat (5BA) lattice [1], with a circumference of 518 m comprising 20 achromat cells, 10 straight sections of 7 m and 10 straight sections of 6 m.

The compact lattice of the storage ring leaves very little space for components and therefore requires narrow vacuum chambers. For this reason, the storage ring will base vacuum pumping mainly on NEG coatings.

The vacuum chambers will be made of OFS copper. The high electrical conductivity of this material minimizes the impact on the machine's impedance, while its thermal conductivity makes it a suitable choice to absorb unused synchrotron radiation. Also, OFS copper has good resistance to softening at the NEG activation temperature of 200°C.

LNLS NEG COATING FACILITY

Since all the vacuum chambers will have small vacuum conductance, on account of their narrow cross section, NEG coatings will be extensively used. The host lab of Sirius, LNLS, has signed a license agreement with CERN to develop the coating technology in Brazil. Moreover, LNLS has designed and built its own NEG coating facility to produce the vacuum chambers (Fig. 1). The current facility allows LNLS to produce coatings according to standards determined by CERN – offering the ability to coat vacuum chambers up to 3.2 m long and 450 mm in diameter.

Figure 1: NEG coating facility at LNLS.

THE STORAGE RING VACUUM SYSTEM

One achromat cell of the storage ring vacuum system is illustrated in Fig. 2. Each cell comprises 18 chambers, 2 crotch absorbers with radiation extraction ports and 1 pumping chamber to install an additional ion pump.

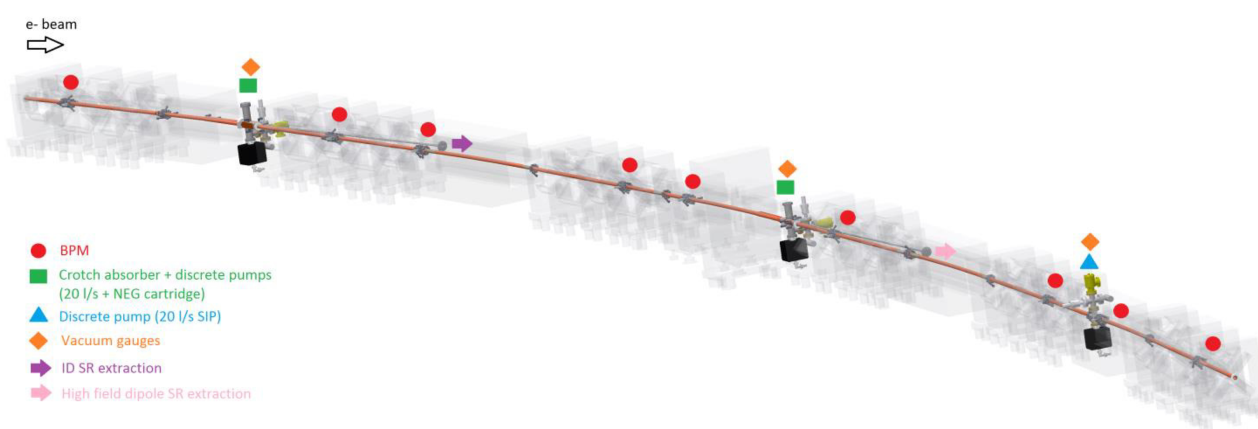

Figure 2: Vacuum system layout for one achromat cell.

A 250 Hz AC SCAN MAGNET FOR HIGH-POWER RADIOISOTOPE PRODUCTION AND BNCT APPLICATIONS*

M.P. Dehnel, D.E. Potkins, T.M. Stewart, A. Kilbourne-Quirk, S. Tranfo, J. Chu, C. Hollinger
D-Pace, Inc., Nelson, BC, Canada
C. Philpott, Buckley Systems Ltd, Auckland, New Zealand

Abstract

This paper describes the proto-type magnet measurement results for a compact (212 mm effective length) yet large gap (97 mm) ambient air-cooled laminated AC scan magnet. A large aperture is essential for machine safety in radioisotope production, and Boron Neutron Capture Therapy (BNCT) applications with steady-state beam power up to 50 kW [1]. Rose shim and Purcell filter techniques are examined for improved transverse field flatness. The measured magnetic field and frequency response curves through a range from (250 Gauss, 70 Hertz) to (25 Gauss, 250 Hertz) are given for the case of an air-gap, SS316 beampipe, and SS316 bellows. Measured transverse and longitudinal magnetic field curves are also given. A model of the frequency response of the magnet was created and validated against measured data. The model simplifies power supply selection and maps effects of system natural frequency on the magnetic field. Tests were conducted with and without a resistor in parallel with the magnet coils. Lastly, an algorithm for a flat-topped square raster scanned beam intensity distribution is given.

FIELD MEASUREMENTS & IMPROVEMENTS

D-Pace has developed an AC Scan Magnet for high-power (tens of kW) single-pass beamlines for radioisotope production and BNCT applications. For these applications a short device is required (350 mm insertion length, and 212 mm magnetic effective length) with a large gap (97 mm), so excess space is provided transverse to beams up to 40 mm in diameter to provide clearance between the beam extents and the beam pipe. For high power beams, a small percentage of beamspill would melt beam pipe walls in a catastrophic manner. A good-field region transverse to the beam is achieved with our nominal design where the field is flat to within ±1% within ±20 mm of the beam axis, refer to Figure 1.

Modelling of Rose shims and Purcell filters with Infolytica's Gemini code, as illustrated in Figure 2, resulted in a magnetic field flat to within ±0.25% within ±20 mm of the beam axis. The modelling of several shim and filter designs were undertaken, and the results shown here were the best achieved for a 97 mm gap.

Figures 3 & 4 illustrate the measurement of the magnetic field for the case of (a) an air-gap, (b) 1.6 mm wall SS316 beam tube, and (c) 0.4 mm wall SS316 formed bellows. These measurements were undertaken to determine any degradation to magnetic field resulting from eddy currents in the SS316 tube or bellows material.

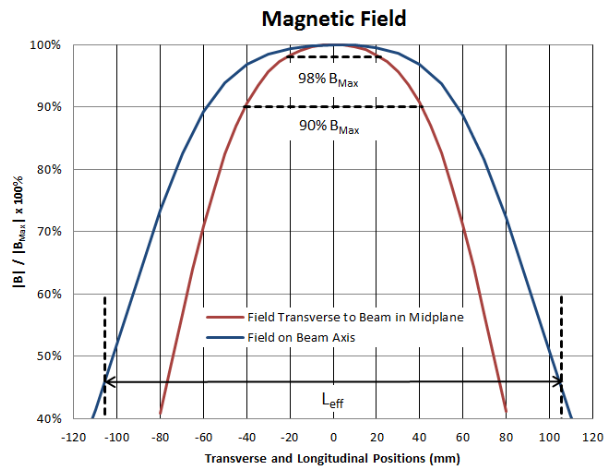

Figure 1: Measured normalized magnetic field transverse to the beam axis, and along the beam axis.

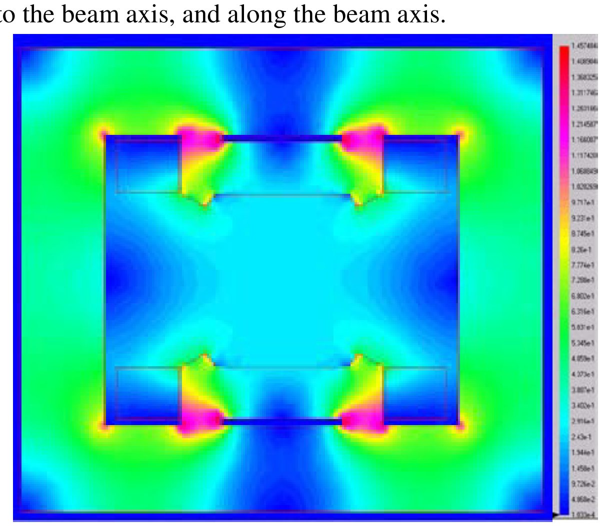

Figure 2: Magnetic field in Tesla. Each Rose shim is a triangle with base 20 mm in horizontal plane and height 8 mm at a point ¾ along the base. Each Purcell filter is an absence of C1010 material, centred at the pole base, 4 mm in height by 72 mm in width.

PARTICULARITIES OF THE ARIEL E-LINAC CRYOGENIC SYSTEM

I. Bylinskii, G. Hodgson, D. Kishi, S. Koscielniak, A. Koveshnikov, R. Laxdal, R. Nagimov, D. Yosifov, TRIUMF, Vancouver, Canada

Abstract

The Advanced Rare IsotopE Laboratory (ARIEL) is a major expansion of the Isotope Separation and Acceleration (ISAC) facility at TRIUMF [1]. A key part of the ARIEL project is a 10 mA 50 MeV continuous-wave superconducting radiofrequency (SRF) electron linear accelerator (e-linac). The 1.3 GHz SRF cavities are cooled by liquid helium (LHe) at 2 K [2]. The 4 K-2 K LHe transition is achieved onboard of each cryomodule by the cryoinsert containing counterflow heat exchanger augmented with JT-valve [3]. Air Liquide LHe cryoplant provides 4 K LHe to cryomodules. After successful commissioning of the cryoplant, 2 K sub-atmospheric (SA) system and cryomodules, the ultimate integration test confirmed stable operation of two cryomodules comprising two 9-cell SRF cavities. Particularities of this cryogenic system include conservative design of the oil removal system, original design heat exchanger in the SA pumping system, hermetic SA pumps, inline full SA flow purifier, multipurpose recovery/purification compressor, modular LHe distribution system, top-loaded design cryomodules, and overall radiation resistant design. The paper presents details of these features as well as integration tests results.

INTRODUCTION

The TRIUMF ten year plan (2010-2020) seeks to triple the laboratory nuclear physics scientific output by the additional of two new rare isotope beam (RIB) sources. These sources will supply the three existing experimental areas at the ISAC research facility which presently shares a single "driver" proton beam line (BL2A) for RIB production - resulting in under-utilization of experimental potential. The plan foresees a 50 MeV and 10 mA e-linac. Its major components are a 300 keV electron gun, 10 MeV injector cryomodule (ICM) with one 9-cell Nb elliptical cavity, and two 20 MeV accelerator cryomodules (ACM) each containing two 9-cell Nb elliptical cavities. The cavity frequency (1.3 GHz), type (9-cell elliptical), and operating temperature (2 K) have been chosen to benefit from the two decades of development, at the TESLA Test Facility.

For both budgetary and resource allocation reasons the e-linac project is planned in two phases. The first stage, ARIEL phase-I, includes two cryomodules (ICM and ACM #1). A third cryomodule will be added in ARIEL phase-II. The architecture of the ARIEL cryogenic system is shown in Figure 1.

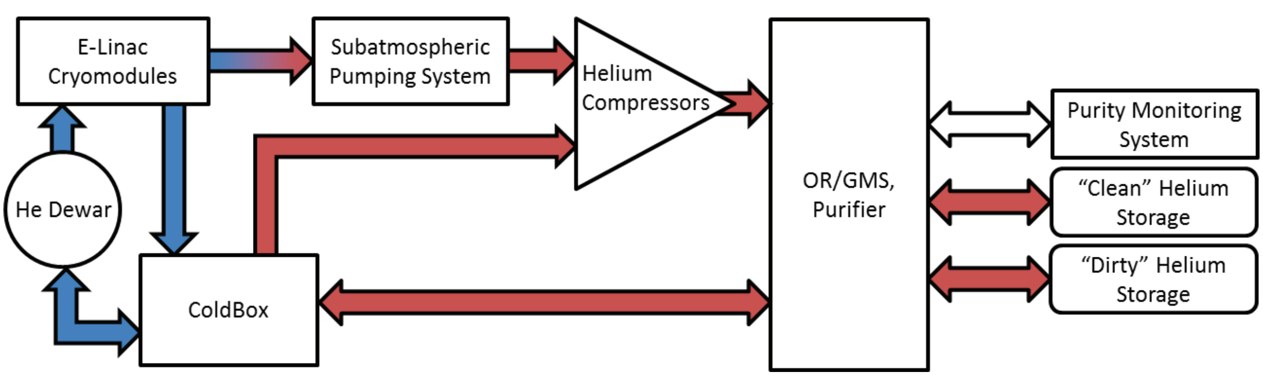

Figure 1: Architecture of the e-linac cryogenic system.

COMPRESSION AND GAS HANDLING

Compression Station

The compression station contains two Kaeser oil-flooded screw-type compressors (Figure 2). The main compression unit (Kaeser FSD571SFC) has 112 g/s capacity at the nominal discharge pressure of 14.5 bar(a). In addition, a smaller air-cooled recovery/purification compressor is installed. This unit (Kaeser CSD85) provides 15 g/s flow rate and is used for a dual purpose. In the event of a power failure the compressor uses power from an emergency power generator to recover all helium boil-off. During regular operation, this same compressor handles the entire throughput of the sub-atmospheric pumps when cryomodules are at full RF load. This helium flow can then be cleaned of impurities by passing through the purifier. This compressor is equipped with dedicated oil-removal and gas management system (OR/GMS). Additionally, this compressor will be used as a purification compressor, moving helium inventory through the purifier from the 'dirty' storage tank (to be installed as a part of ARIEL phase-II upgrade) to the 'clean' storage tank.

Oil Removal and Purification Systems

Oil removal system shall remove any oil vapors or oil aerosol particles from the process gas. The size of the

EXPERIMENTAL STUDY OF MULTIPACTOR SUPPRESSION IN DIELECTRIC MATERIALS

M. EL Khaldi, W. Kaabi
LAL, ORSAY, France

Abstract

A novel coaxial resonator to investigate two-surface multipactor discharges on metal and dielectric surfaces in the gap region under vacuum conditions (~10^{-8} mbar) has been developed and tested. The resonator is ~ 100 mm in length with an outer diameter of ~ 60 mm (internal dimensions). A pulsed RF source delivers up to 30 W average power over a wide frequency range 650-900 MHz to the RF resonator. The incident and reflected RF signals are monitored by calibrated RF diodes. An electron probe provides temporal measurements of the multipacting electron current with respect to the RF pulses. In this paper we compare and contrast the results from the RF power tests of the alumina (97.6% Al_2O_3) and quartz samples without a coating, "the non-coated samples" and the Alumina and quartz samples with a TiN coating in order to evaluate a home made sputtered titanium nitride (TiN) thin layers as a Multipactor suppressor. The effectiveness of this method is presented and discussed in the paper.

INTRODUCTION

A multipactor discharge is a phenomenon in which electrons impact one or more material surfaces in resonance with an alternating electric field [1]. Two main conditions must be met in order to develop a multipactor discharge between two material surfaces. First, electrons traversing the gap must impact the electrode near the time the E-field reverses the direction. Second, electrons must impact the surface with enough energy to create electron multiplication by secondary emission, i.e. δ (E) $\geq$1. The discharge is sustained by the population of electrons that remain in phase with the RF electric field. Because the discharge is sustained by secondary electrons, multipactor discharges typically occur under vacuum conditions.

Multipactor discharges are considered detrimental to RF systems in most applications. The discharges can cause vacuum window failure, limit the delivery of RF power, detune resonant cavities, damage high power RF sources, and cause a local pressure rise due to the desorption of surface gases [2]. As mentioned, multipactor (MP) is often an undesirable phenomenon, and avoidance can be critical in the operation of certain systems, it can be avoided in several ways. A general cure against multipacting is to avoid the resonant conditions by either a proper choice of the geometry of the device [3, 4] or by coating the critical areas with a material with a lower secondary yield [5,6]. This way the effect of multipacting can be significantly reduced, but very often the MP phenomenon cannot be removed. Titanium nitride (TiN) coating is used as a proven anti-multipacting coating for dielectric-loaded accelerating (DLA) structures, and RF vacuum windows. Several experimental investigations have been performed at DESY and LAL-Orsay, aimed at reducing secondary electron emission and multipactor effects by TiN layers generation on dielectric or metal surfaces [7, 8].

We propose here an experiment facility for investigating two-surface multipactor discharges on dielectric and metal surfaces. The compact apparatus consists of a RF coaxial resonator in a high vacuum system (~ 10^{-8} mbar). The RF resonator is ~ 100 mm in length with an outer diameter of ~ 60 mm (internal dimensions), powered with a pulsed RF source delivering up to 30W average power. These experiments were successful in identifying multipacting and allowed us the evaluation of a homemade sputtered titanium nitride (TiN) thin layers as a Multipactor suppressor.

TiN COATING TECHNOLOGY

The presence of a dielectric window on a high power RF line has in fact a strong influence on the multipactor phenomenon, a resonant electron discharge that is strongly limiting for the RF components performances. The most important method to reduce the multipactor is to decrease the secondary emission yield of the dielectric window and the dielectric-loaded accelerating structures (DLA). Due to its low secondary electron emission coefficient, TiN thin film is used as a multipactor suppressor coating on RF ceramic coupler windows. For this purpose, a reactive DC magnetron sputtering bench has been developed at LAL-Orsay with the collaboration of the consortium Ferrara Ricerche-Italie in the frame of CARE program (Figure 1).

Within the sputtering process gas ions out of a plasma are accelerated towards a target consisting of the material to be deposited. Material is detached ('sputtered') from the target and afterwards deposited on a substrate in the vicinity. The process is realized in a closed recipient, which is pumped down to a vacuum base pressure ~ 10^{-8} mbar before deposition starts (Figure 1).

In the both sides of vacuum chamber, the machine is equipped with a 10 inch titanium disc target of high quality (grade2, minimum 99.7 % Ti). Two rotary magnet packs are placed just behind the targets to increase plasma density at their surface, and thus improve sputtering yield. Two power supplies are used to fix both target bias. A special rotating sample holder was designed to allow uniform deposition on the samples made of different materials and had different sizes and shapes. The machine allows also the RF etching of the substrate, a pretreatment step in order to remove particle contamination, as it is not possible to clean a ceramic (alumina) with solvent due to

RF DESIGN OF A HIGH GRADIENT S-BAND TRAVELLING WAVE ACCELERATING STRUCTURE FOR THOMX LINAC

M. EL Khaldi, L. Garolfi
LAL, ORSAY, France

Abstract

There is growing demand from the industrial and research communities for high gradient, compact RF accelerating structures. The Thomx high gradient structure (HGS) is travelling wave (TW), quasi constant gradient section and will operate at 2998.55 MHz (30°C in vacuum) in the 2**π**/3 mode. The optimization of the cell shape (Electromagnetic design) has been carried out with the codes HFSS and CST MWS, in order to improve the main RF characteristics of the cavity such as shunt impedance, accelerating gradient, group velocity, modified Poynting vector, surface fields, etc. Prototypes with a reduced number of cells have been designed. For an input power of about 20 MW, EM simulation results show that an average accelerating gradient of 28MV/m is achieved which corresponds to a peak accelerating gradient of 35 MV/m, a peak surface gradient of 44 MV/m and peak modified Poynting vector S_{cmax} of 0.24 MW/mm^2.

INTRODUCTION

ThomX is a Compton source project in the range of the hard X rays (45/90 keV). The machine is composed of a 50-70 MeV injector Linac and a storage ring where an electron bunch collides with a laser pulse accumulated in a Fabry-Perot resonator. The final goal is to provide an X-rays average flux of $10^{11}/10^{13}$ ph/s. The emitted flux will be characterized by a dedicated X-ray line. Different users are partners in the ThomX project [1], especially in the area of medical science and cultural heritage. Their main goal will be the transfer of all the experimental techniques developed on big synchrotron rings to these more compact and flexible machines. The ThomX project has recently been funded and will be located on the Orsay University campus.
