The beam will be generated by a 2.5 cells standing wave RF gun and accelerated with a conventional LIL-type structure with an operating peak accelerating gradient around 20 MV/m during the first commissioning phase. The Thomx injector linac energy will be upgraded from 50 MeV to more than 70 MeV by replacing a low gradient S-band TW section with a short high gradient S-band one.

A LAL-PMB collaboration on high gradient S-band structure research has been established in order to push the performance envelope of RF structures towards higher accelerating gradients. The program foresees the design, prototyping and high power testing of a high gradient compact S-band accelerating structure. The Thomx high gradient structure (HGS) is travelling wave, quasi constant gradient section and will operate at 2998.55 MHz (30°C in vacuum) in the 2**π**/3 mode. The section consists of five constant impedance (CI) landings with 16 identical cells plus four transition cells between the landings, in which the iris diameter decreases by 0.175 mm from one cell to another.

Before the construction of the final high gradient structure, prototypes with a reduced number of cells will be realized. The goals of these prototypes are to improve the machining of the cells and the brazing process.

The electromagnetic design of the prototypes has been performed with the codes CST MWS and HFSS. The choice of a single cell shape derives from an optimization aiming to maximize RF efficiency and minimize surface fields and modified Poynting vector at very high accelerating gradients. Such gradients can be achieved utilizing shape optimized elliptical irises, surface finish, appropriate materials and specialized fabrication procedures developed for high gradient structures.

DESIGN OPTIMIZATION AND ELECTROMAGNETIC SIMULATIONS

Traditionally, the surface electric field was long considered to be the main quantity which limits accelerating gradient because of its direct role in field emission [2]. There is clear evidence however, in data from both CLIC and NLC [3, 4] which covers structures with a wide range of RF parameters, that a simple constant surface field limit is insufficient to predict the performances of the different structures. Recently, new quantities such as the averaged power flow through the cell by the iris aperture circumference P/C [5] and the peak modified Poynting vector $S_c = \mathrm{Re}\{S\} + \mathrm{Im}\{S\}/6$ [6] have been considered to be responsible for high gradient limits.

During the design phase, the optimization of the main RF properties for the accelerating cavities (shunt impedance, accelerating gradient, group velocity, modified Poynting vector, surface fields, etc.) was carried out, by using the 3D simulation codes HFSS and CST MWS. A scan over several parameters has been performed in order to find the best combination of geometrical parameters in term of high gradient operations performance and reduced power consumption. In order to have a quantitative approach, it has been decided to find the cell geometry which minimizes the quantity η:

$$\eta \equiv \frac{P}{<E_a>^2}\cdot\frac{S_c}{<E_a>^2} = \frac{v_g}{\omega}\cdot\frac{S_c/<E_a>^2}{r/Q} \qquad (1)$$

This corresponds to having simultaneously the minimum power consumption and the minimum risk of breakdown (based on the S_c model) for a given accelerating field.

3 GHz SINGLE CELL CAVITY OPTIMIZATION DESIGN

L. Garolfi*, M. El Khaldi, LAL, Orsay, France
N. Faure, PMB-ALCEN, Peynier, France

Abstract

In order to develop a high gradient S-band electron accelerating structure, an optimized travelling wave (TW) single-cell cavity operating at the frequency of 3 GHz with $2\pi/3$ phase advance, is proposed. Starting from the well-known accelerating cells design developed by the Laboratoire de l'Accélérateur Linéaire (LAL) and the Stanford Linear Accelerator Centre (SLAC), for linear accelerators; it is possible to improve the main RF parameters, such as quality factor, shunt impedance, enhancement factor and group velocity, by choosing a suitable shape of the inner surface [1]. Even though surface electric field is being considered as the only main quantity limiting the accelerating gradient; the importance of power flow and the modified Poynting vector [2], has been highlighted from high-gradient experimental data [3]. In this context, the new field quantity (S_c) is derived from a model describing the RF breakdown trigger phenomenon wherein field emission currents from potential breakdown sites produce local pulsed heating. In particular, the modified Poynting vector takes into account both active and reactive power flow travelling along the structure. The main results presented in this paper have been carried out with the 3D electromagnetic simulation codes: High Frequency Structural Simulator solver (HFSS) and CST MICROWAVE STUDIO (CST MWS).

INTRODUCTION

ThomX is a Compton backscattering compact light source project, aiming to produce an intense flux of monochromatic X rays (40 – 90 keV) resulting from collisions between laser pulses and relativistic electron bunches. The machine consists of a 50 – 70 MeV Linac injector and a storage ring. A demonstrator was recently funded and is going to be built in the Orsay University campus. The Linac injector is composed of a RF gun and one accelerating section able to boost the energy of particles. For the first stage of the machine commissioning, a "LIL"-type accelerating section is foreseen to be lent by the SOLEIL Laboratory, as a partner of the project. This section was developed by LAL-Orsay for the pre-injector of the Large Electron Positron Collider (LEP) at CERN. In order to reach a final energy of 50 MeV, the energy gain in the section must be 45 MeV. However, the accelerator should reach higher energies in order to produce X-rays beyond 50 keV [4]. Since the maximum targeted X-ray energy is 90 keV, the Linac design should allow beam energy of 70 MeV. A LAL-PMB collaboration on high gradient S-band structure research has been established in order to advance together in this field.

* garolfi@lal.in2p3.fr

The ThomX high gradient structure is a TW quasi-constant gradient section and will operate at 2998.55 MHz (30 °C in vacuum) in the $2\pi/3$ mode. It will be fabricated by PMB in order to increase the ThomX Linac energy up to 70 MeV, with an available input power of about 20 MW. The final structure will be made of 94 accelerating cells and 2 coupling cells.

RF DESIGN OPTIMIZATION

The accelerating gradient is limited by RF breakdown in normal conducting TW structures and it has been observed to depend on many parameters including surface electric field, pulse length, power flow and group velocity [5].

For a long time, the surface electric field was considered to be the main quantity which limits accelerating gradient because of its direct role in field emission while the magnetic field was considered to be unimportant. However, as more experimental data had been taken into account, it was clear that the maximum surface electric field could not serve as an ultimate constraint in the RF design, because of its large variation in different structures. New ideas about the ratio from the input power flow to the minimum iris circumference P/C as a better constraint to be used in RF design, appeared since 2006. Although the P/C parameter fits a large fraction of experimental data, deviations were observed from geometries scaled to different frequencies.

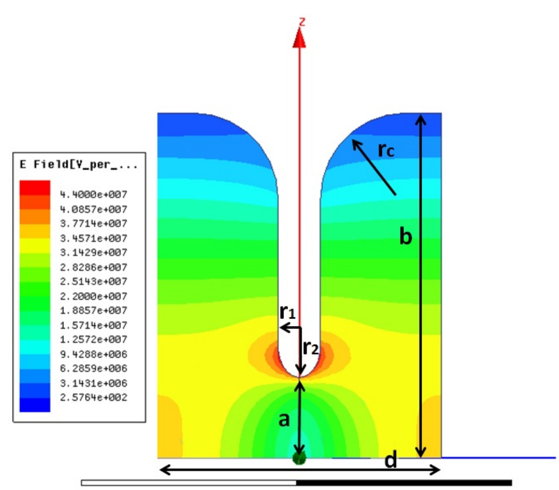

Figure 1: 2D section and electric field distribution of the half single cell.

A new model, is still based on the local complex power flow S (Poynting vector), but it also considers both a real and imaginary part of it, representing a combination of local electric and magnetic fields which sets a limit to achievable gradient.

FIRST TEST RESULTS OF THE BERLINPRO 2-CELL BOOSTER CAVITIES

A. Burrill#, W. Anders, A. Frahm, J. Knobloch, A. Neumann, Helmholtz-Zentrum Berlin, Berlin Germany
G. Ciovati, W. Clemens, P. Kneisel, L. Turlington, Jefferson Laboratory, Newport News, VA, USA

Abstract

The bERLinPro Energy Recovery Linac (ERL) is currently being built at Helmholtz-Zentrum Berlin in order to study the physics of operating a high current, 100 mA, 50 MeV ERL utilizing all SRF cavity technology. This machine will utilize three unique SRF cryomodules for the photoinjector, booster and linac cryomodules respectively. The focus of this paper will be on the cavities contained within the booster cryomodule. Here there will be three 2-cell SRF cavities, based on the original design by Cornell University, but optimized to meet the needs of the project. All of the cavity fabrication, processing and testing was carried out at Jefferson Laboratory where 4 cavities were produced and the 3 cavities with the best RF performance will be fitted with helium vessels for installation in the cryomodule. This paper will report on the test results of the cavities as measured in the vertical testing dewar at JLab after fabrication and again after outfitting with the helium vessels.

INTRODUCTION

Helmholtz-Zentrum Berlin (HZB) is building a high average current, 100 mA, Energy Recovery Linac (ERL) at the site in Adlershof, Berlin Germany. The machine is designed using all superconducting RF accelerating cavities in order to demonstrate that the operation of such a machine is possible and to allow for a study of the physics of its operation.[1, 2] The 100 mA average current will be recirculated in a single pass at an energy of 50 MeV in continuous wave (c.w.) operation as shown in figure 1. The ERL is made up of a 1.4 cell SRF photoinjector cryomodule, fitted with a normal conducting multi-alkali (CsK_2Sb) photocathode, a 3 cavity booster cryomodule, the focus of this paper, and a 3 cavity linac cryomodule. More information on the photoinjector can be found in references 3 & 4.[3, 4] The booster cryomodule is designed to accelerate the 2 MeV beam from the photoinjector to 6 MeV for insertion into the recirculation arc and the linac cryomodule. Here the beam will be further accelerated to 50 MeV to make a single pass around the machine and then decelerated to 6 MeV and sent to the beam dump.

The ERL is designed to operate in a number of different modes to fully explore the operational parameter space associated with the recirculation of a high current, low emittance 5 MW beam. In many of these operating modes there is very strong beam loading for the photoinjector and booster cavities which places stringent demands on the fundamental power couplers, a topic which has been expanded upon in other publications and will not be covered here. In short, for the 100 mA operation the photoinjector and the accelerating booster

FIRST HORIZONTAL TEST RESULTS OF THE HZB SRF PHOTOINJECTOR FOR bERLinPro

A. Burrill♦, W. Anders, A. Frahm, J. Knobloch, A. Neumann, Helmholtz-Zentrum Berlin, Berlin, Germany
G. Ciovati, W. Clemens, P. Kneisel, L. Turlington, JLAB, Newport News, VA, USA

Abstract

The bERLinPro project, a small superconducting RF (SRF) c.w. energy recovery linac (ERL) is being built at Helmholtz-Zentrum Berlin in order to develop the technology required for operation of a high current, 100 mA, 50 MeV ERL. The electron source for the accelerator is a 1.4 cell SRF photoinjector fitted with a multi-alkali photocathode. As part of the HZB photoinjector development program three different SRF photoinjectors will be fabricated and tested. The photoinjector described herein is the second cavity that has been fabricated, and the first photoinjector designed for use with a multi-alkali photocathode. The photoinjector has been built and tested at JLab and subsequently shipped to HZB for testing in the horizontal test cryostat HoBiCaT prior to installation in the photoinjector cryomodule. This cryomodule will be used to measure the photocathode operation in a dedicated experiment called GunLab, the precursor to installation in the bERLinPro hall. This paper will report on the final results of the cavity installed in the helium vessel in the vertical testing dewar at Jefferson Lab as well as the first horizontal test in HoBiCaT.

INTRODUCTION

Helmholtz-Zentrum Berlin (HZB) has set out on a program to build a superconducting RF (SRF), high average current, Energy Recovery Linac (ERL) designed to operate at an electron beam energy of 50 MeV with 100 mA average current.[1] The ERL is designed to study the physics of the operation of a high current ERL in a number of different modes. This includes operation with bunch charges ranging from a few pC to 77 pC and repetition rates that range from low repetition rate burst modes up to c.w. operation at 1.3 GHz. This wide range of operating conditions will place great demands on many of the components of the ERL, and will certainly test the limits of the SRF photoinjector.[2]

In order to help mitigate the risks associated with operation of the SRF photoinjector HZB has set out on a multi-cavity photoinjector R&D program.[3] Four different SRF photoinjectors will be built and tested in order to gain experience with different aspects of the photoinjector operation. The first two photoinjectors in the development program were designed to utilize a lead photocathode and the results of these tests can be found in references 4-7.[4-7] The first photoinjector suitable for bERLinPro, called Gun 1.0, has been fabricated by Jefferson Lab and the preliminary data reported on previously.[8] This cavity is designed to utilize an independently cooled cathode stalk which will allow for the installation of a high quantum efficiency multi-alkali, CsK_2Sb, photocathode, suitable for generation of a 100 mA electron beam. In this paper we will report on the helium vessel welding and final test results in the JLab VTA as well as the first horizontal test results obtained at HZB in the HoBiCaT horizontal test cryostat.

HELIUM VESSEL WELDING AND FINAL VERTICAL TEST RESULTS

Following the cavity fabrication at JLab the cavity was processed and tested a number of times in an attempt to achieve the required operating gradient and quality factor for bERLinPro. Due to the new cavity design and the fact that this cavity was the first article produced, several challenges were encountered and the performance after 8 vertical tests was less than desired.[8] Due to schedule constraints the decision was made to attach the helium vessel to the cavity to progress the program. The titanium helium vessel was electron beam welded to the cavity while the cavity was kept under the static vacuum to avoid contamination of the inside of the cavity during the welding process. A photograph of the cavity following the helium vessel welding is shown in figure 1, with the cut-away of the cavity inside shown in figure 2.

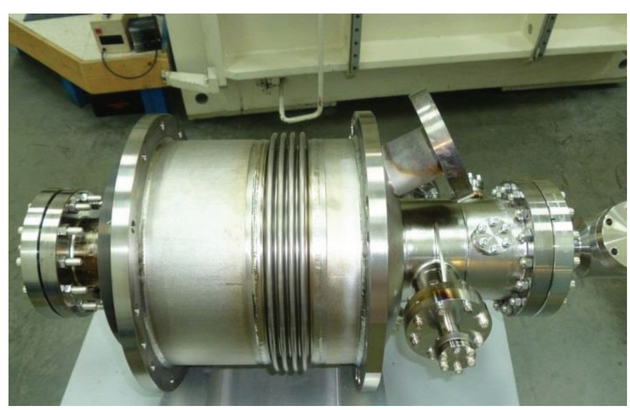

Figure 1: The SRF photoinjector for bERLinPro.

After the helium vessel welding and leak checking was complet the field flatness and frequency of the cavity were measured and found to be in very good agreement with the estimated values expected after the welding. The

HIGH-Q CAVITY OPERATION: STUDY ON THE THERMOELECTRICALLY INDUCED CONTRIBUTION TO RF SURFACE RESISTANCE

J.M. Vogt, A. Neumann, J. Knobloch, O. Kugeler, A. Velez, Helmholtz-Zentrum Berlin, Germany

Abstract

We present a study concerning the operation of a superconducting RF cavity (non-doped niobium) in horizontal testing with the focus on understanding the thermoelectrically induced contribution to the surface resistance. Starting in 2009, we suggested a means of reducing the residual resistance by warming up a cavity after initial cooldown to about 20 K and cooling it down again [1]. In subsequent studies we used this technique to manipulate the residual resistance by more than a factor of 2 [2]. We postulated that thermocurrents during cooldown generate additional trapped magnetic flux that impacts the cavity quality factor. Since several questions remained open, we present here a more extensive study including measurement of two additional passband modes of the 9-cell cavity that confirms the effect. We also discuss simulations that substantiate the claim. While the layout of the cavity LHe tank system is cylindrically symmetric, we show that the temperature dependence of the material parameters result in a non-symmetric current distribution. Hence a significant amount of magnetic flux can be generated at the RF surface resulting in an increased surface resistance [3].

SETUP

A fully equipped TESLA-type cavity welded into a titanium tank and with a TTF-3 input coupler installed was mounted horizontally inside the HoBiCaT [4] cryostat. The TESLA-type cavity reported on here received a heavy BCP (about 150 µm) prior to a 2 h bakeout at 800°C (no N_2 anneal). A light BCP etch followed the heat treatment. Before the helium tank was welded onto the cavity a quality factor of about $2 \cdot 10^{10}$ in the π mode at 2K was measured in a vertical test which corresponds to a residual resistance R_{res} of 1.2 nΩ if one assumes that the BCS resistance R_{BCS} did not change between vertical and horizontal test (fitting parameters for R_{BCS} in horizontal test are listed below).

The cavity was equipped with Cernox sensors on the helium vessel head and beam pipes near the Nb-Ti joints. Furthermore two heaters were attached, one on each beam pipe. The setup including the helium supply is sketched in Figure 1.

HoBiCaT can cool the cavity with different schemes. The cryoplant fills the helium via the filling line at the bottom left and/or the 2-phase-pipe from the top right. As discussed below, we used three different cooling schemes: The initial cooldown, the thermal cycle and the parked cooldown.

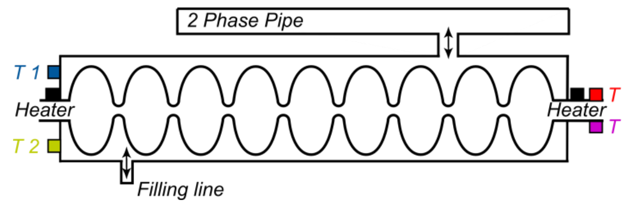

Figure 1: TESLA cavity in the LHe tank and equipped with four Cernox sensors and two heaters. The tank can be filled via the filling line and via the two phase pipe.

During the initial cooldown (whose temperature profile is shown in Figure 2a), the cavity is filled mainly via the filling line which creates a temperature gradient from its left to its right and from bottom to top. For a subsequent thermal cycle (Figure 2b), the cavity was filled via the 2-phase-pipe while the heaters were used to create a temperature difference between the cavity ends if desired. The targeted difference could be adjusted by varying the heater power. Values chosen were typical of those encountered during normal cooldowns. The "parked cooldown" (Figure 2c) from room temperature combines properties of both the initial cooldown and the thermal cycle. The cooling procedure of the initial cooldown was adapted to stop well before the sc phase transition. The cryoplant was balanced to maintain a constant temperature for 48 h. The set point was first set to 30K and then continuously lowered to 14K during this period. After all temperature sensors were clearly in equilibrium the set point was further lowered towards 1.8K and the cavity tank system transitioned with a small $\Delta T < 10$ K into the sc state.

THERMOELECTRIC EFFECT IN THE CAVITY HELIUM TANK SYSTEM

With the described setup, we investigated the hypothesis that thermoelectrically induced currents and their associated magnetic flux is responsible for the change of R_s upon thermal cycling. In the horizontal setup, the system is fabricated of two materials: Niobium (cavity) and titanium (helium tank) which create bimetal junctions. If a temperature difference is applied along the system (from left to right), a current is driven along the cavity and back through the tank. The additional temperature difference from bottom to top breaks the cylindrical symmetry of the system because the dc resistance of Nb and Ti is temperature dependent. Thus, even though mechanically the system is symmetric, the current is not and a magnetic field can be generated at the RF surface and get trapped during sc phase transition.

HOM DAMPING OPTIMIZATION DESIGN STUDIES FOR BESSY VSR CAVITIES

A.Vélez, H.W. Glock, J.Knobloch, A.Neumann, Helmholtz-Zentrum Berlin, 12489 Berlin, Germany

Abstract

The BESSY VSR project is a future upgrade of the 3rd generation BESSY II light source. By using the same "standard" user optics, simultaneously long (ca. 15ps) and short (ca. 1.5ps) bunches will be stored. Thus, SRF higher harmonic cavities of the fundamental 500 MHz at two frequencies need to be installed in the BESSY II storage ring. This work describes the optimization studies for the waveguide-based HOM dampers and the adjustable fundamental power coupler for the 1.5 GHz first SRF cavity prototype.

INTRODUCTION

Simultaneous operation of long and short pulses by BESSY VSR represents a very attractive upgrade of the conventional storage ring operation concept. As described in [1] the addition to the 500MHz signal of two higher harmonics cavities and operating at zero crossing will lead to the desired combination of compressed and long bunches. Therefore 4 new SRF cavities (2x1.5 GHz and 2x1.75 GHz) need to be designed. These cavities will operate in CW at high field levels (E_{acc} =20 MV/m). The combination of these factors with high beam current (I_b=300mA) makes the cavity design a challenging goal since stable operation must be ensured [2]. Thus special attention must be paid to the damping of high order modes (HOMs) excited by the beam that may otherwise cause coupled bunch instabilities (CBIs) [3]. In order to avoid possible CBIs a stability condition is established imposing HOM impedances to be below feedback threshold both for longitudinal and transverse modes (5e4Ω-1e7Ω/m)[4]. This paper shows the current status of the design for the first 1.5 GHz cavity with special attention devoted to the optimization of the waveguide-based HOM damping technique [5,6]. To this end, EM calculations have been performed with both Ansoft HFSS and CST Microwave Studio [7,8] in order to compute the HOM-damped cavity spectrum

WAVEGUIDE HOM-DAMPING (WG-D)

The proved efficiency of WG-D absorbers [5] offers the capability to handle high power while offering very high damping levels. In addition the WG-D close distance to the cavity shows a better performance when propagating possible trapped modes as compared to beam-pipe ferrite absorbing solutions. The present designed WG-D end-groups consist on a 2 Y-shape beam-pipe section loaded with 3 equally spaced waveguides (120°). Both input and output WG-D are shifted 60° in order to cover for different mode polarisations. The length of the waveguides is set to 400 mm ensuring enough isolation for the fundamental TM_{010} π-mode (Q_{ext}=5e10) while reducing the risk of dust contamination.

Damping Studies

In order to avoid CBIs the limit on the feedback threshold forces the model to push the limits of the damping technique. As it is well known TM modes more often present higher R/Q*Q values and therefore represent the highest risk when dealing with CBIs. However a few TE modes with impedances in the order of the present threshold limit can be found due to band superposition effects and asymmetries (with coax coupler) [4]. Therefore the damping system must be optimized in a way that both TE and TM modes can be propagated.

Two main approaches are used on the damping optimization for the cavity prototype: extended WG (HZB.x.b) and enlarged beam-pipe (HZB.2.x).

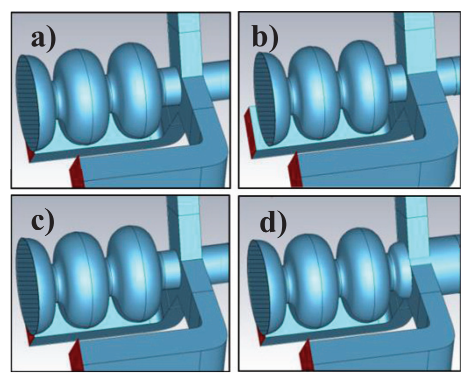

Figure 1: Layout of the two techniques applied on the optimization of the Y-shape waveguide absorbers. Extended WG-D (a~b). Enlarged beam-pipe (c~d).

In the first one, the beam-pipe diameter is equal to the iris (71mm) but the height (H) of the waveguide is increased from 50mm (HZB1a) to 60 mm (HZB1b). Therefore the propagated waveguide TE-like modes benefit from a lower cut-off (i.e f_c TE_{01}=2.50GHz) and are allowed to propagated through the WG-D. This effect is depicted in Fig 2 for the TE_{111}, TE_{011} and TE_{211} modes. However, in contrast to the enlarged beam-pipe, this approach is not as effective when damping most of the TM modes. On the other hand the enlarged beam-pipe approach benefits from the beam-pipe cut-off reduction due to the increase of its diameter (71mm~110mm). Therefore the beam-pipe cut-off for the first propagated mode is reduced to 1.65 GHz offering a great

DEVELOPMENT OF NEW MICROCONTROLLER BASED POWER SUPPLY CONTROL UNITS AT ELSA

D. Proft*, T. Perlitius and W. Hillert, ELSA, Bonn, Germany

Abstract

At the electron stretcher facility ELSA electrons are accelerated with a high ramping speed of 6 GeV/s. This leads to strong requirements on the main magnets power supplies. In particular, any synchronization errors directly result in beam tune shifts and, at worst, beam loss.

The existing thirty years old control units are now being replaced by new in-house developed versatile microcontroller based ones. These allow the application of arbitrary ramp patterns and actual value acquisition in realtime. With an ethernet interface the ramp patterns can be uploaded directly to the power supplies. The flexible design also allows usage of the module to control other power supplies, e.g. those of the orbit correction magnets.

This presentation will give details on the developed hardware design and the performance of the modules compared to the existing ones.

POWER SUPPLIES AT ELSA

ELSA is a three-stage accelerator consisting of an injector with a 20 MeV LINAC, a 1.2 GeV booster synchrotron and a so-called *stretcher ring* for post acceleration to 3.2 GeV.

One acceleration cycle is typically 6 s long. Electrons from the injector stage are accumulated in the stretcher ring at 1.2 GeV and afterwards the beam energy is increased to a maximum of 3.2 GeV within 333 ms. This yields to a ramping speed of 6 GeV/s. A typical ELSA cycle is shown in Fig. 1.

Precise timing on the energy ramp imposes high requirements on the power supplies of the main magnets. The high ramp speed corresponds to a field change of 1.8 T/s of the main dipoles and thus a change in the supplied current of 5.2 kA/s. For the other magnets, e.g. quadrupoles, the slope is lower but still in the order of 1 kA/s.

In total there are six power supplies for the main magnets[1] manufactured by HOLEC . They require an analog set point value in the range from 0 V to 10 V being proportional to the desired current as well as digital signals for slow control of the device. At the moment these are provided by 30 years old in-house developed interface cards, so-called *MACS* CPUs, which are connected to VME CPUs via HDLC and finally via ethernet to the control system.

To avoid tracking errors on the ramp all interfaces are triggered by a common hardware *ramp start* trigger.

As a vital component of the accelerator these old MACS systems are now being replaced by a new microcontroller based solution. Goals for the new design are the change

* proft@physik.uni-bonn.de

[1] dipoles, 2 quadrupole families, 2 sextupole families and extraction sextupoles

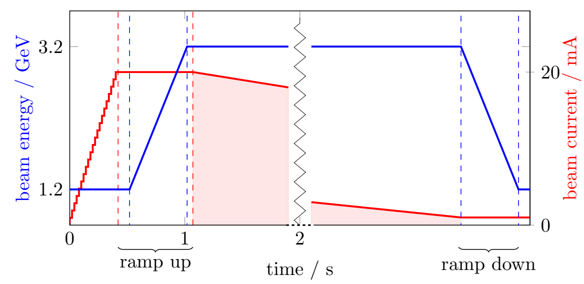

Figure 1: ELSA operation cycle consisting of accumulation, ramp up, extraction and ramp down phase.

from equidistant pre-sampled ramp patterns $I(t)$ to piecewise linear approximated ones and the ability to split the whole cycle timing into a ramp-up and ramp-down part (see Fig. 1) required for the new timing system [1].

Secondarily the new control units can be used for the corrector magnet power supplies as well [2], thus allowing to steer all magnets the same way. It also reduces tracking errors between the main magnets and the correctors on the energy ramp.

In total there are 54 corrector magnets each equipped with its own power supply. The interface is basically the same as for the main magnets except that the analog voltage is bipolar (±8 V) and the maximum current for the corrector magnets is ±8 A. Due to the high number of required power supplies it was decided to steer 4 power supplies mounted into one rack from one control unit.

HARDWARE DESIGN

Design goal for the new control units is, that all magnet power supplies can be operated with a uniform hardware module. A corresponding block diagram is shown in Fig. 2. A specialized daughter board is used to interface the different power supply's back plane connectors.

Crucial elements of the new control unit are two microcontrollers manufactured by *Atmel*. One, an *AT32UC3A1256* model is used for communication and other low priority tasks. With an attached *ethernet PHY*[2] the controller can be integrated into the existing networking infrastructure for configuration purposes and communication. Digital outputs and inputs are used for slow control of the attached power supply.

The other controller, an *ATXMEGA128A1U*, is used for real time tasks such as the output of DAC data on a regular time basis. A connected oscillator with 16 MHz and an accuracy of 30 ppm supplies the controller with a clock signal. The clock frequency is internally doubled using an

WATER-COOLED THIN WALLED BEAM PIPES OF THE FAST RAMPING STORAGE RING ELSA

P. Hänisch*, B. Neff, W. Hillert - ELSA, Bonn University, Germany

Abstract

At the Electron Stretcher Facility ELSA of Bonn University thin walled beam pipes are in use to reduce eddy current loss to a minimum. The operation of the accelerator places high demands on the beam pipes like static stress because of the inner vacuum and additional one-sided thermal stress caused by synchrotron radiation. A first generation of thin walled beam pipes had been developed and manufactured during the construction of the stretcher ring in 1985. These pipes were successfully in operating stage the following ten years. The beam pipes had a wall thickness of 0.3 mm, a length of 3 m, and a bending radius of ca. 10.5 m. Special pipes with a sideway branch for synchrotron radiation experiments have been manufactured in the same assembly dimension. In the course of an intensity upgrade, a second generation of beam pipes has been developed in 1995. To reduce the thermal stress caused by the synchrotron radiation an internal water cooling was mounted. In this contribution the design and manufacturing principles of the thin walled beam pipes with water cooling are presented.

INTRODUCTION

The Electron Stretcher Accelerator ELSA [1] is a three-stage accelerator omprising two linacs, a booster synchrotron and a fast ramping pulse stretcher ring ($2\,\mathrm{T\,s^{-1}}$). To provide the fast ramping abilities of the stretcher ring it is essential to minimize the eddy current loss in the dipole gap. Since suitable radiation resistant non-conducting curved beam pipes are extremely difficult to manufacture this is most effectively achieved by building the vacuum chambers from stainless steel and reducing their wall thickness to a minimum. This reduction is mostly limited by the static stability of the beam pipe, the manufacturing possibilities, and the costs. First thin walled beam pipes had been constructed in 1985 and were in use from 1987 to 1995 when they have been replaced by a water-cooled version to enable an intensity upgrade at ELSA. The recent assembly of a new beam pipe by the university's workshops gave reason to rework the manufacturing process, especially those of beam pipes with a sideway branch and inner water cooling.

DIPOLE STANDARD BEAM PIPE

Setting up the Oval Shape of the Beam Pipe

Feedstock for all thin walled beam pipes at ELSA are round, welded pipes made of stainless steel with a wall thickness of 0.3 mm. This source material is as well used for the production of hydraulic formed vacuum bellows or metal bellow couplings. To form the round pipe into its oval shape it is pulled over a dedicated core at its full length of approx. 3 m. The core carries stainless steel balls which are positioned in wedge profile to expand the tube sideways. In contrast to cold-drawing or pultrusion the pipe is only bent and not stretched. Therefore, the circumference of the pipe remains constant throughout the entire processing operation and the required force can be performed by hand (see Fig. 1).

* haenisch@physik.uni-bonn.de

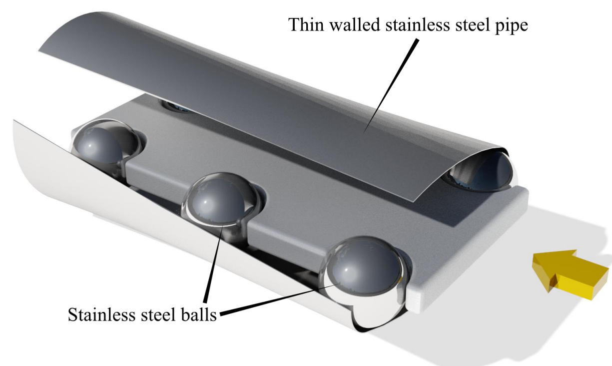

Figure 1: Schematic representation of the bending process to form the round feedstock into the required oval shape.

Mounting of the Reinforcing Ribs

In order to avoid further deformation caused by the ambient pressure on the evacuated oval pipe, it must be strengthened by additional reinforcing ribs. The design of the ribs is mostly influenced by their thickness, their maximum tolerable outer dimensions, and the distance between two adjacent ribs. Since the inner contour is determined by the oval shaped pipe and the height is limited by the size of the dipole gap, a careful minimization of the required amount of material resulted in a distance of ribs of 24 mm and a thickness of 1 mm. With an effective length of 3072 mm of each beam pipe, a considerably large number of in total 122 ribs are needed per pipe, taking into account the slightly different design of the beam pipe ends. To lower the production costs, the ribs were cut out of a stainless steel sheet using a water jet. The burr at the cut edges could be removed easily by vibratory grinding. This procedure turned out to be essential for later installation on the pipes since, in case of improper pre-treatment, burrs as well as any swarf clinging to the cut edges would cut deep marks in the thin walled pipe and could in worst case cause destruction of the entire pipe.

When mounting the ribs on the beam pipe, the pipe is fixed in a support structure to prevent it from crippling and to guide the ribs during their installation. Before mounting, fabrication tolerances of the inner rib contour have to be carefully controlled and, if necessary, adjusted. This turned out to be mandatory because only a tight fitting of the ribs

A NEW RF STATION FOR THE ELSA STRETCHER RING*

Manuel Schedler, Andreas Dieckmann, Philipp Hänisch, Wolfgang Hillert
ELSA, University of Bonn, Germany

Abstract

At the Electron Stretcher Facility ELSA of Bonn University, an increase of the maximum stored beam current from 20 mA to 200 mA is planned. The storage ring operates applying a fast energy ramp of 6 GeV/s from 1.2 GeV to 3.2 GeV and afterwards a slow extraction over a few seconds to the hadron physics experiments. The beam current is mainly limited due to missing RF power at highest energies in order to compensate for synchrotron radiation losses.

The current stretcher ring's RF station is based on a single 200 kW klystron driving two 5-cell PETRA type cavities. To achieve the desired beam current at maximum energy two additional 7-cell PETRA type cavities, drivin by a second klystron, will be installed. With this upgrade, sufficient beam lifetime for slow beam extraction will be provided and thus ensure an adequate duty cycle of the external beam current. The general setup of the new RF station as well as the changes in operation when switching from one to two stations will be presented.

THE ELECTRON STRETCHER ACCELERATOR – ELSA

ELSA is a three-stage electron accelerator. One of the two linear accelerators is used to inject an electron beam of 20 MeV into a booster synchrotron to gain an energy of typically 1.2 GeV. The beam can be accumulated and stored in the 164.4 m long stretcher ring, accelerated to a maximum energy of 3.2 GeV and, finally, slowly extracted to the hadron physics experiments using resonance extraction methods [1]. Figure 1 gives an overview of the ELSA facility including injector chain, stretcher ring and user experiments. The main operating parameters of the accelerator are summarized in Table 1.

On the fast energy ramp of typically 6 GeV/s in the stretcher ring fast changing beamloading effects lead to fast changing cavity voltages and phases. Figure 2 shows a typical post-acceleration cycle of the stretcher ring. To compensate for synchrotron radiation losses even at highest beam energies and intensities a new RF station is required. In addition, this station will allow to maintain the required overvoltage factor and lifetimes which of course have to be significantly greater than the extraction time of a few seconds to deliver a high quality and high intensity electron beam to the hadron physics experiments.

* Work supported by the DFG within the SFB/TR 16

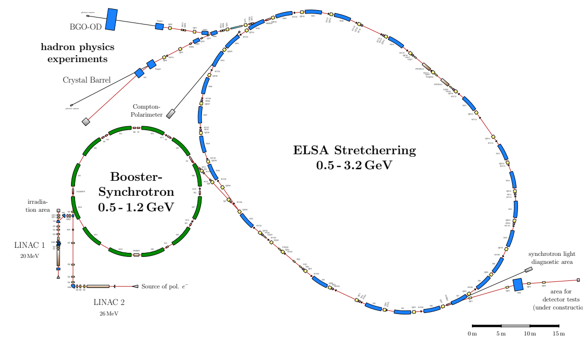

Figure 1: The Electron-Stretcher-Accelerator Facility ELSA

Table 1: Main Operating Parameters of the ELSA Stretcher Ring

Parameter	Value
Length	164.4 m
RF	499.669 MHz
Bunch spacing	2 ns
Harmonic number h	274
Filled buckets	274
Revolution frequency f_{rev}	1.8236 MHz
Beam energy E	1.2 GeV to 3.2 GeV
Beam current	20 mA to 200 mA
Ramping speed	$\leq$ 6 GeV/s
Injection rate	50 Hz
Momentum compaction factor α_c	0.0601

OVERVIEW AND SETUP OF THE NEW RF STATION

General Setup

The new RF station is based on two 7-cell PETRA type normal conducting RF cavities with a shunt impedance of 23 MΩ driven by a single klystron amplifier. The RF frequency is about 500 MHz as for the existing RF station. A magic T is used to split the amplified high power RF signal into two equivalent components in a WR1800 waveguide

ALVAREZ DTL CAVITY DESIGN FOR THE UNILAC UPGRADE

X. Du[1], A. Seibel[1,2], S. Mickat[1], L. Groening[1]
[1]GSI, Darmstadt, Germany; [2]Goethe-University, Frankfurt, Germany

Abstract

The 108.4 MHz drift tube linac (DTL) accelerator for GSI's UNLAC upgrade project is in its initial design stage using CST-MWS code. Optimization criteria for cavity design are effective shunt impedance (ZTT), transit-time factor, and electrical breakdown limit. In geometrical optimization we have aimed at increase of the energy gain in each RF gap of the DTL cells by maximizing ZTT per peak surface field with special designed tube profile. Multi-pacting probability is evaluated for one gap of typical single cell. For the beta profile design, a code based on VBA macros of CST is developed to perform cell by cell design with pre-optimized 3D tube structures. With this code several beta profile designs are presented and compared for the balance of power consumption, ZTT, tank length, and breakdown possibility of the complete cavity. The stability of the field has been taken into account and for this the crossed stem arrangement is assessed.

This paper gives a short introduction of the method, presents some important results. Possible countermeasures are discussed.

INTRODUCTION

At the existing DTL of the UNILAC five Alvarez cavities accelerate ions with an A/q of up to 8.5 from 1.4 MeV/u to 11.4 MeV/u over a total cavity length of 60 m [1]. The cavities operate at 108.4 MHz and at an rf-duty cycles of up to 30%[1].

The UNILAC upgrade intends to replace the existing Alvarez DTL with a newly designed DTL with same total length and output energy but with re-optimized shunt impedance and increased field stability. The existing Alvarez cavity tank I consists of 62 cells with tank diameter of 2 m, tube outer diameter of 200 mm, and tank length of 12 m. The designs and optimization of the new Alvarez cavities are based on the general parameters of the existing cavities.

DRIFT TUBE SHAPE DESIGN

The drift tube shape is designed to maximize the effective shunt impedance and to keep the peak electric surface field as low as possible [2]. A simplified single cell model is used for simulations with CST-microwave studio and static EM studio. The tube shape with a constant-radius corner and flat face with an angle is used at the beginning. The auto optimization tool in CST changes all parameters of the tube to obtain the best results. The parameters involved in the optimization are bore radius, drift tube face angle, drift tube corner radius, drift tube inner nose radius, drift tube outer nose radius, and drift tube flat length. But the field distribution on this tube always has a dominant maximum at certain area of the corner.

The new designed drift tube is built by a spline curve with a changing local curvature that is adjusted according to the desired surface field distribution.

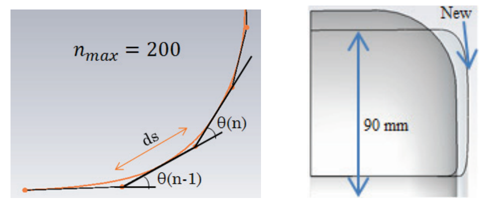

Figure 1: Spline for new tube shape design.

As shown in Fig. 1, the profile of the tube is made from steps of splines. The relationship between field distribution and curve is represented by

$$\theta(n) \xrightarrow{\text{yields}} \left.\frac{\partial^2 E_{surf}}{\partial l^2}\right|_{l=n*ds} \tag{1}$$

After the simulations, the surface field E_{surf} on the tube is evaluated. The angles of θ_n is reduced if the local field distribution is to be raised or θ_n is to be increased if the field is to be lowered. The sum of angles must be 180° such that the curve connects the inner radius to the outer radius.

With this new tube shape the surface field is uniformly distributed on the surface of the drift tube as shown in Fig. 2, keeping the maximum E_{surf} the same, while the ZTT is increased by about 12%. The tube shape is the same for all cells in one cavity for the convenience of fabrication, without discount its advantage on surface field distribution.

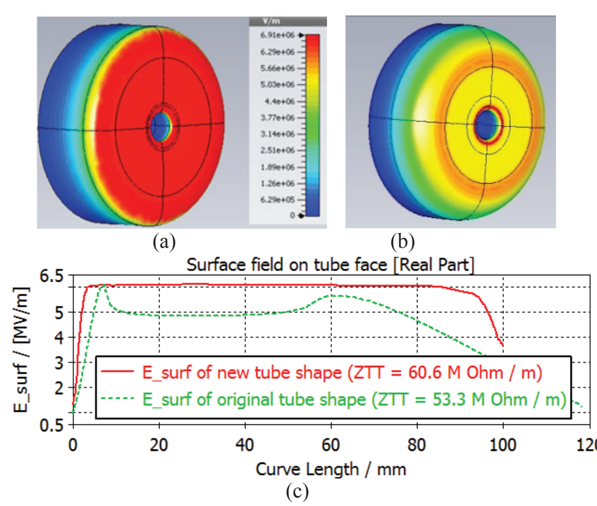

Figure 2: The surface field distribution (c) on the new tube shape (a) and on the original tube shape (b).

STATUS OF THE RING RF SYSTEMS FOR FAIR*

M. Frey, R. Balß, C. Christoph, O. Disser, G. Fleischmann, U. Hartel, P. Hülsmann, S. Jatta, A. Klaus, H.G. König, U. Laier, D.E.M. Lens, D. Mondry, K.-P. Ningel, H. Richter, S. Schäfer, C. Thielmann, T. Winnefeld, B. Zipfel, GSI, Darmstadt, Germany
K. Groß, TU Darmstadt, Darmstadt, Germany
H. Klingbeil, GSI and TU Darmstadt, Darmstadt, Germany

Abstract

For the FAIR (Facility for Antiproton and Ion Research) synchrotron SIS100 and the storage ring CR (Collector Ring), different RF cavity systems are currently being realized. In addition to the standard RF bucket generation and acceleration, these ring RF systems also allow more complex beam manipulations such as barrier bucket operation or bunch rotation in phase space. Depending on their purpose, the cavities are either loaded with ferrite material or with MA (Magnetic Alloy) ring cores. Independent of the type of cavity, a complete cavity system consists of the cavity itself, a tetrode-based power amplifier, a solid-state pre-amplifier, a supply unit including PLC (Programmable Logic Control), and an RF control system (so-called LLRF, low level RF system). In this contribution, the different systems are described, and their current status is presented.

SIS100 RF SYSTEMS

SIS100 will be the main synchrotron of the FAIR facility [1, 2]. This chapter is dedicated to the SIS100 RF systems. The mentioned RF voltages are the total peak voltages per cavity experienced by the beam.

SIS100 Accelerating System (SIS100 ACC)

The main accelerating system in SIS100, which works at harmonic number h=10, consists of 14 ferrite-loaded cavities whose parameters are shown in Table 1. The system is optimized for fast ramping and for a variety of operating modes.

Table 1: SIS100 Accelerating System (parameters for one cavity)

Parameter	Value
Frequency range	1.1-3.2 MHz
Maximum RF voltage	20 kV
Duty cycle	CW
RF power amplifier	Tetrode RS2054, single-ended
Installation length	3.0 m

For this system, the tendering process under the leadership of the FAIR GmbH* has successfully been completed. A consortium consisting of RI Research Instruments GmbH and Ampegon AG will deliver the overall system consisting of cavity, power amplifier, and power supply unit including PLC. Most parts of the LLRF system will consist of standardized GSI components. The technical design of the cavity is similar to the existing SIS18 ferrite cavities. Water cooling of the ferrite material is realized by cooling disks in-between the ring cores. A first sketch of the cavity in conceptual design phase is shown in Fig. 1.

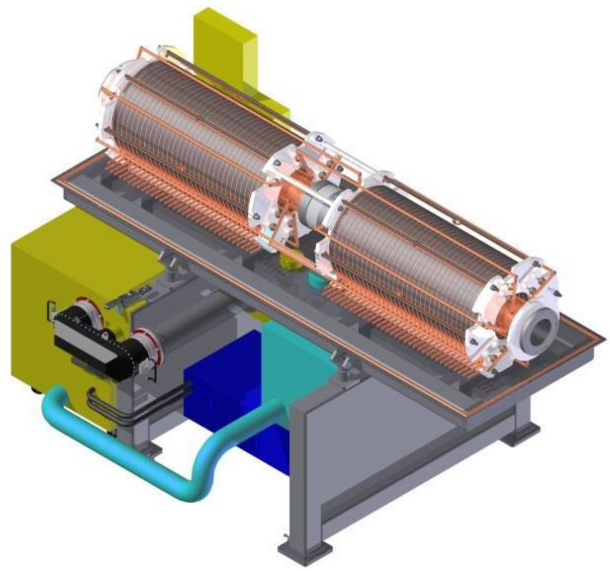

Figure 1: Conceptual design draft of SIS100 ACC cavity (image: RI Research Instruments GmbH).

In the first design phase, a specification for the ferrite ring material was agreed with the manufacturer after several ring core samples have been tested. The CDR (Conceptual Design Report) has been completed recently, the FoS (First of Series) will be delivered to GSI in 2016.

SIS100 Barrier Bucket System (SIS100 BB)

The barrier bucket system for SIS100 consists of two cavities loaded with magnetic alloy (MA) ring cores whose parameters are shown in Table 2. Each of the two cavities will create a single-sine pulse which can be shifted in time. Therefore, the beam can be captured between the two barriers (in the typical operating scenario, 8 of the 10 buckets generated by the SIS100 ACC system will be filled, and these 8 bunches will be combined to a long sausage-like bunch), and it will be pre-compressed by means of moving barriers in order to prepare the beam for final bunch rotation with the SIS100 BC system described below.

STATUS OF THE SUPER-FRS MAGNET DEVLOPMENT FOR FAIR

H. Müller, H. Leibrock, M. Winkler, P. Schnizer, E. Fischer, GSI, Darmstadt, Germany
L. Quettier, J.-E. Munoz-Garcia, Irfu, CEA, Saclay, France
L. Serio, CERN, Geneva, Switzerland

Abstract

The Super-FRS is a two-stage in-flight separator to be built next to the site of GSI, Darmstadt, Germany, as part of FAIR (Facility for Anti-proton and Ion Research). Its purpose is to create and separate rare isotope beams and to enable the mass measurement also for very short lived nuclei. Due to its three branches a wide variety of experiments can be carried out in the frame of the NUSTAR collaboration. Due to the large acceptance needed, the magnets of the Super-FRS have to have a large aperture and therefore only a superconducting solution is feasible. A superferric design with superconducting coils was chosen in which the magnetic field is shaped by an iron yoke. This paper presents the actual design status of the dipole and multipole magnets as well as the status of the development of the dedicated test facility at CERN.

INTRODUCTION

The Super-FRS is a new two-stage in-flight separator. It will be built as part of the future Facility for Antiproton and Ion Research (FAIR) in Darmstadt, Germany [1]. Due to its three branches (high-energy branch, low-energy branch, and ring branch) a wide variety of experiments will be possible [2,3]. The large acceptance required and the DC operation of the magnets led to a superconducting solution. Only the very first magnets after the target have to be built as normal conducting magnets with special radiation resistant conductor, due to the high radiation levels.

From protons to uranium all sorts of ions can be accelerated in the Super-FRS up to energies of about 1.5 GeV/u and with beam intensities of 10^{12}/s.

The general layout of the Super-FRS magnets is shown in Fig.1. Overall the Super-FRS consists out of 24 dipole magnets and 31 multiplets (containing 80 quadrupoles, 41 sextupoles, 14 steerers, and 46 octupoles).

Additional superconducting magnets are needed for the Energy Buncher in the low energy branch. These magnets are an Indian in-kind contribution to FAIR and are not treated within this paper.

MAGNET DESIGN

The magnets of Super-FRS have several common design features. Firstly, they are of so called superferric type (with the exception of the small correction magnets steerer and octupole which are made as surface coils). The magnetic field is shaped by the magnetic iron as for normal conducting magnets, but the coils of the magnet are wound with superconductors.

Secondly, the magnets have to be self-protected, i.e. they have to survive a quench without any damage even in case the quench protection system fails. Nevertheless dump resistors are foreseen for machine operation to extract as much energy as possible. The requirement of self-protected magnets leads to the use of superconductors with a high Cu/SC ratio (>9 in case of the dipoles, ~3.5 for quadrupoles and sextupoles).

Each of the magnets is powered individually and has its own pair of leads. To limit the size of the current leads and warm power cables the maximum current of the magnets have to stay below 300 A. This leads to coils wound of insulated wires rather than a cable.

The cooling of the magnets will be done by a pool boiling Helium bath. The design pressure of the Helium containers is set to 20 bars to avoid helium losses in case of quench and to be able to operate the cryogenic facility of FAIR with one common pressure.

An additional requirement is a warm beam pipe.

Despite of being operated in DC mode three consecutive triangular cycles up to maximum current with a ramp up time of 120 sec have to be possible in between the different operation cycles. This cycling is necessary to always have reproducible field conditions independent from the previous setting.

The beam height in Super-FRS is at 2 m the height of the cryogenic supply was fixed to 3.3 m over ground.

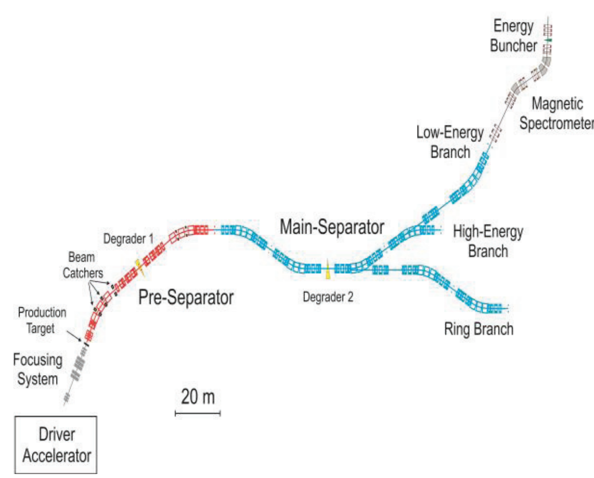

Figure 1: Magnetic Layout of Super-FRS.

SIS100 DIPOLE FIELD HARMONICS AND DYNAMIC APERTURE CALCULATIONS

C. Omet, E. Fischer, G. Franchetti, V. Kornilov, A. Mierau, C. Roux, D. Schäfer, P. Schnizer, S. Sorge, P. Spiller, K. Sugita
GSI, Darmstadt, Germany

Abstract

During the acceptance test of the First of Series (FoS) SIS100 superferric dipole magnet, detailed field measurements have been done. The harmonic coefficients have been extracted from these and dynamic aperture simulations have been done which are presented here. Furthermore, geometric precision measurement tools for the magnet have been developed to track down the field errors to geometric errors. Finally, mitigation actions have been taken to reduce these errors during manufacturing to ensure the design beam survival rate in SIS100.

SIS100 FOS DIPOLE PERFORMANCE

The SIS100 dipole magnet is a 3 m long super-ferric, curved magnet, see Fig. 1. It is the end of a successful development [1–4] and the first magnet with a high current coil made from Nuclotron cable and cooled by forced-flow 4.5 K two-phase He. It has a maximum field of 1.9 T and will be used at a very high ramp rate of up to 4 T/s in FAIR's driver synchrotron, SIS100. The gap size is 143 mm × 68 mm.

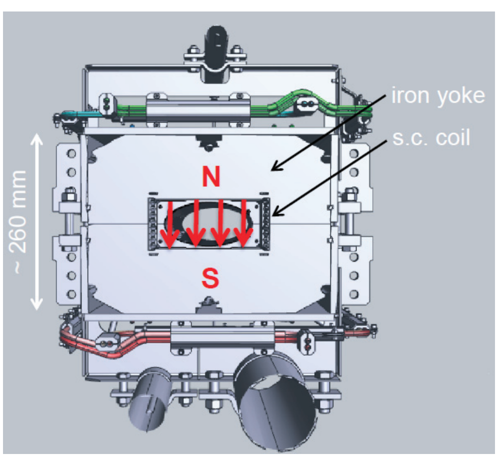

Figure 1: Cross section of the SIS100 dipole.

The First of Series (FoS) SIS100 dipole was delivered 2013 [5, 6] and has been thoroughly tested both at warm and cold conditions in the prototype test facility at GSI. Tests included electrical, geometrical, thermal checks and finally quench training and magnetic field measurements. The nominal current of 13.1 kA has been exceeded already after the second quench; even after several (8) thermal cycles, the magnet did not show a de-training behavior. AC losses at maximum ramp rate and triangular cycle have been measured to be 51 W, which is ≈30% below the calculated value and gives extra margin for the cryogenic plant of FAIR.

Beam stability during the 1 s long bunch-to-bucket injection from SIS18 into SIS100 has to be ensured. This poses a restriction onto the maximum allowable field errors of the magnets. For the dipoles, at injection field of 0.27 T (I = 1.5 kA), the good field region is 115 x 60 mm^2, where a field homogeneity of $\Delta B/B_0 \leq \pm 6 \times 10^{-4}$ is tolerated by design. Furthermore, it is important to have stable beams during middle to high energies at an up to 10 s long slow extraction plateau from SIS100 to the experiments, too.

Field Harmonics

The measurement campaign of the SIS100 dipole was based on the methods described in [7–10]. The following measurement systems were used:

- a single stretched wire system,
- a hall probe system,
- and a rotating coil probe system with transverse translated fields.

The last method allows deriving harmonics up to the 7$^{\text{th}}$ order reliably [6]. These measured data has been cross checked with a hall probe mapper and was proven to match. The analysis of these results, recalculated to a reference radius of 40 mm is shown in Fig. 2. Not allowed harmonics are larger than the allowed ones, which was somehow surprising and lead to detailed investigations of the magnet. In particular, the skew quadrupole is large.

To be useful for beam dynamics calculations, the harmonics have been re-calculated to be a valid expansion around the reference orbit, not the rotating coil probe axis.

Geometry Measurements

As for the magnet's super-ferric design, its magnetic field is dominated by the yoke's gap geometry. To track down the measured field errors to their probable root causes, the yoke geometry was measured very precisely. Therefore, special mechanical and capacitive measurement devices have been developed which are able to measure the gap height and width with a precision of ±10 µm in both warm and cold conditions. The measurements have been calibrated and cross checked with laser tracker measurements and found to be consistent.

The results of the gap height measurements along the magnet axis are shown in Fig. 3. The gap height is nonuniform along the magnet by ≈200 µm; the gap height between left and right side (parallelism) differs by ≈80 µm. As it will

EFFICIENT PULSED QUADRUPOLE *

I. Petzenhauser#, U. Blell, P. Spiller, GSI, Darmstadt, Germany
C. Tenholt, IAP, Goethe-University, Frankfurt, Germany

Abstract

In order to raise the focusing gradient in case of bunched beam lines, a pulsed quadrupole was designed. The transfer channels between synchrotrons as well as the final focusing for the target line are possible applications. The quadrupole is running in a pulsed mode, which means an immense saving of energy by avoiding standby operation. Still the high gradients demand high currents. Hence a circuit had to be developed which is able to recover a significant amount of the pulsing energy for following shots. The basic design of the electrical circuit of the quadrupole is introduced. Furthermore more energy efficient circuits are presented and the limits of adaptability are considered.

ELECTRICAL CIRCUIT

As described in detail before, a pulsed quadrupole lens was designed [1] and a prototype was built (cf. Fig. 3) to prove the feasibility of the design. While the final system is supposed to handle currents up to 400 kA, the first prototype setup should operate at ~ 30 kA.

Its electrical circuit design is sketched in Fig.1. In this prototype, a 450 µF capacitor was charged to a voltage of 4700 V and discharged, producing a current pulse of ~ 33 kA and a pulse duration (FWHM) of ~ 60 µs (cf. Fig. 2).

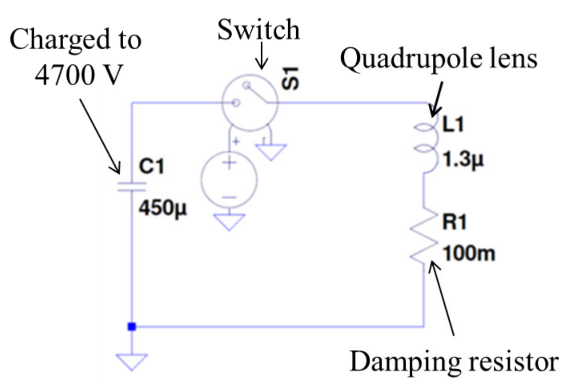

Figure 1: LTSpice[2] model of the electrical circuit of the prototype. The circuit is nearly critically damped to avoid oscillations.

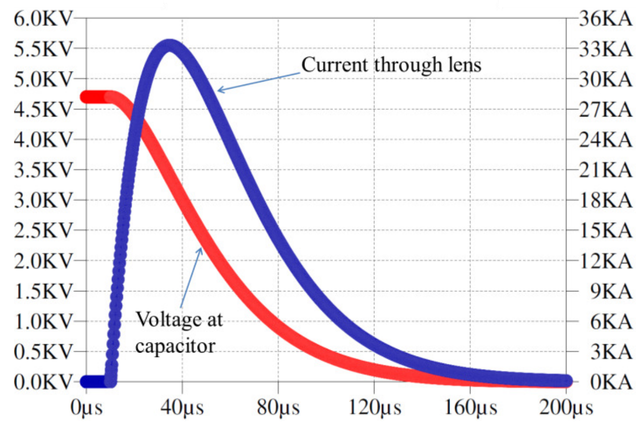

Figure 2: Pulsed current and voltage (Result of simulation in Fig. 1).

The electrical circuit presented in Fig. 1 is not suitable for a system with currents much higher than the 30 kA aimed for in this setup. Due to the damping resistance R1, a quite high voltage is required to realize high currents. For 400 kA operation, nearly 60 kV would be required. Also power dissipation (~ 16 GW at peak current) in the resistor and its cooling would be a serious issue, especially at higher repetition rates. Additionally, at 400 kA, the voltage drop across the 100 mΩ resistor would be 40 kV. Alternative electrical circuits will be discussed below. For the test circuit presented here, the resistance was a very simple possibility to damp the current critically and prevent a ringing discharge which would harm the capacitors lifetime. Due to the low repetition rate (1 shot in ~ 4 minutes) and the lower power input, cooling of the resistance was not an issue.

PROTOTYPE

To test the applicability of the design presented in [1], a prototype was built. The setup can be seen in Fig. 3. The upper part above the rectangular rack is the quadrupole lens itself. In the center of the lens is the vacuum tube. Inside the lens, this tube is made from alumina. The tube is positioned ~ 2 m above ground. Below the quadrupole lens, the pulsed power unit, i.e. capacitor, switch and damping resistor, is situated. It can be seen in more detail in Fig. 4. During operation, the rack is enclosed to prevent accidental contact with high voltage.

PROGRESS OF THE KLYSTRON AND CAVITY TEST STAND FOR THE FAIR PROTON LINAC

A. Schnase[#], E. Plechov, J. Salvatore, G. Schreiber, W. Vinzenz, GSI, Darmstadt, Germany
C. Joly, J. Lesrel, IPN Orsay, CNRS-IN2P3 Université Paris Sud, France

Abstract

In collaboration between the FAIR project, GSI, and CNRS, the IPNO lab provided the high power RF components for a cavity and klystron test stand [1]. For initial operation of the 3 MW Thales TH2181 klystron at 325.224 MHz we received a high voltage modulator from CERN Linac 4 as a loan. Here we report, how we integrated the combination of klystron, high voltage modulator, and auxiliaries to accumulate operating experience. Klystron RF operation started on a water cooled load, soon the circulator will be included and then the prototype CH cavity in the radiation shielded area will be powered. The 45 kW amplifiers for the 3 buncher structures of the FAIR proton Linac were checked at the test stand, and the results are presented here.

TRANSISTOR AMPLIFIER TEST

In autumn 2014 three 45 kW transistor amplifiers for the 3 (re-)bunchers of the Proton Linac were delivered. The alignment of the amplifiers and the RF output was improved for easier installation by replacing the standard rollers with a version that is additionally equipped with adjustable feet as shown in the bottom of Fig 1.

Figure 1: One of the 45 kW amplifiers.

We confirmed the function of the inrush-current limiter and were able to replace the 125 A mains fuses with 63 A types. This allowed us to use a 3 phase standard CEE plug, which simplifies changing of the test setup. The firmware was adjusted to the expected pulsed modes. In operation, we need a repetition rate of 4 Hz; with some margin the amplifier should work at 5 Hz and actually the amplifier can handle repetition rates of 10 Hz and higher. The required pulse length is 0.2 ms. For testing, we used 0.4 ms long pulses. Such pulse pattern is shown in Fig. 2. The amplifier bias (yellow trace) is activated 1 ms before the RF is applied. The falling edge of the green trace triggers the power measurement. The light blue trace shows the RF output.

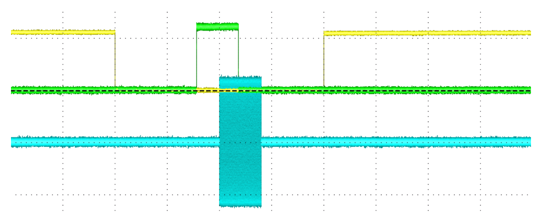

Figure 2: Amplifier test pulse pattern (0.5 ms/div).

Initial tests were conducted with a 50 Ω air cooled load at the amplifier output. The required 45 kW pulsed power was confirmed. The delay from RF-OFF command to RF-OFF was measured as less than 400 ns. From University of Frankfurt we received a compact 325 MHz test cavity structure to conduct site acceptance tests of these amplifiers under pulsed conditions driving a resonant load. This cavity was temporarily installed in a shielded area as shown in Fig. 3.

Figure 3: 325 MHz test cavity structure on support.

When discharges appear in the cavity, some power is reflected back to the amplifier. Thus we have to test the amplifier behavior not only for normal operation as shown in Fig. 4, but also for cavity conditioning.

ADVANCED MULTIPOLES AND APPROPRIATED MEASUREMENT TOOLS FOR FIELD CHARACTERIZATION OF SIS100 MAGNETS

Pierre Schnizer, Anna Mierau, Anke Gottsmann, Florian Kaether, Harald G. Weiss
Egbert Fischer, GSI, Darmstadt, Germany
Bernhard Schnizer, TU-Graz, Graz, Austria

Abstract

The heavy ion synchrotron SIS100 utilises fast ramped superconducting magnets. Describing and measuring these magnets requires advanced multipoles next to well adapted measurement techniques. We cover briefly the required theory adapted to the measurements, show which designs were available and which decisions had to be taken for measuring curved superconducting magnets. The series of SIS100 dipole magnets is going to be produced. These magnets will be measured at GSI. We present the foreseen field measurement procedure, outline the currently ongoing tests and give our calibration strategy.

INTRODUCTION

The heavy ion synchrotron SIS100 utilises fast ramped superconducting magnets [1, 2]; in particular as the vacuum chambers' inner surface is used as adsorption pump and thus has to be cold [3, 4].

These requirements led to a curved dipole with minimised aperture. The field provided within the aperture gap has to be fully understood so that today one can already forecast if the magnet's field quality will support the project targets of the high current machine.

The development of the advanced multipoles [5–7] allows describing the field within the curved beam path and the elliptic cross section of the vacuum chamber.

The required measurement devices were prepared in parallel adapted to the theoretical limitations.

THEORY

The standard description of the magnetic field for accelerator magnets is given by

$$B_y + \mathrm{i}B_x = \mathbf{B}(\mathbf{z}) = \sum_{n=1}^{\infty} \mathbf{C_n} \left(\frac{\mathbf{z}}{R_{Ref}}\right)^{n-1} \tag{1}$$

with $\mathbf{B}$ the 2D magnetic field and $\mathbf{C_n}$ the coefficient n, $z = x + \mathrm{i}y$ and R_{Ref} the reference radius. For elliptic apertures elliptic coordinates are adapted to the geometry. These coordinates (e.g. [8]) are given by

$$x + \mathrm{i}y = \mathbf{z} = e \cosh(\mathbf{w}) = e \cosh(\eta + \mathrm{i}\psi), \tag{2}$$

with x and y the Cartesian 2D coordinates, and $e = \sqrt{a^2 - b^2}$ the ellipse eccentricity. Then the field is given by

$$\mathbf{B}(\mathbf{w}) = \frac{\mathbf{E}_0}{2} + \sum_{m=1}^{\infty} \mathbf{E}_m \frac{\cosh(m\mathbf{w})}{\cosh(m\eta_0)}, \tag{3}$$

with $\mathbf{E}_m$ the elliptic coefficients and $\eta_0 = \tanh^{-1}(b/a)$.

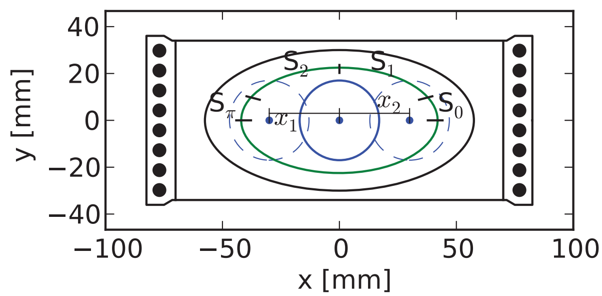

Figure 1: Rotating coil probe positions for measuring elliptic multipole coefficients. The beam aperture is indicated by a black ellipse. The green ellipse indicates the ellipse used currently in reconstruction. The blue circles indicate the area covered by the coil probe. S_0, S_1, S_2, S_π indicate the different parts where the coil probe is used. x_1 gives the offset of the coil probe measurement from the centre to the left side while x_2 gives the offset of the coil probe form the measurement to the right side. The magnet turns are indicated by the black filled circles and its inner aperture by a line.

Deduction of Equations for Error Analysis

The elliptic multipoles are derived from measurements from different positions (see Fig. 2) [5]. The coefficients $\mathbf{E_m}$ are obtained using the Fourier cosine transform

$$\mathbf{E}_m = \frac{2}{\pi} \int_0^{\pi} \mathbf{B}(\eta_0 + \mathrm{i}\psi) \cos([m]\psi)\, \mathrm{d}\psi, \tag{4}$$

with $\mathbf{B}$ the magnetic field along the ellipse, ψ the angle along the ellipse. The reconstruction is split in three parts for each coil, which finally add up to six parts as the parts which intermix have to be taken into account.

The coefficients were calculated numerically as given in [5]. An equivalent analytic expression is given below which allows deriving the influence of measurement errors.

All three coil probes will measure the same field described by some coefficients $\mathbf{C_n}$. While the coefficients obtained by the central coil probe are the $\mathbf{C_n}$, the ones obtained by the translated ones are given by

$$\mathbf{C}'_\mathbf{n} = \left[\mathcal{L}\binom{n-1}{k-1}\left(\frac{\mathbf{d_z}}{R_{Ref}}\right)^{n-k}\right]\mathbf{C_k}. \tag{5}$$

$\mathcal{L}$ indicates that this expression is an upper triangular matrix. This expression represents the so called "feed-down effect". On these set of harmonics ($\mathbf{C}^{\mathrm{r}\prime}_n$ for the coil on the right, $\mathbf{C}^{\mathrm{c}\prime}_n$

SYSTEM DESIGN FOR A DETERMINISTIC BUNCH-TO-BUCKET TRANSFER*

T. Ferrand#,TEMF, Technische Universität Darmstadt, Darmstadt, Germany
J. Bai, IAP, Goethe Universität, Frankfurt am Main, Germany

Abstract

A deterministic bunch to bucket transfer system is currently under development in the frame of the FAIR project at GSI. To achieve our accuracy and stability requirements, a set of hardware modules will be implemented. These hardware modules are expected to provide values such as the relative phase advance between the RF systems of both, the source and the target synchrotron according to an external timing system. These values are exchanged via optical fibers between different supply rooms, and the considered RF signals are re-synthesized locally. These re-synthesized signals are synchronized to enable a precise phase advance control between the synchrotrons' RF systems. The first step of the development consists in modeling the actual DDS and DSP-based LLRF environment of the SIS18 under Ptolemy-II. Measurements on real devices will be performed concurrently to the simulation. We expect to use this simulation to refine our timing expectations regarding the synchronization process and the inter-module communication protocols and design the synchronization function, which will be implemented on the hardware modules.

INTRODUCTION

As it is foreseen in the frame of the construction of the Facility for Antiproton and Ion Research (FAIR) at GSI Helmholtzzentrum für Schwerionenforschung GmbH [1], the existing SIS18 is used as a pre-accelerator for the new acceleration chain. To fulfill this task, a Bunch-to-Bucket transfer procedure is being investigated.

The SIS18 is a separated functions synchrotron designed to accelerate a variety of ions from protons to uranium with different mass over charge ratios. Two ferrite-loaded cavities in combination with three MA-loaded cavities bring the beam to the transfer flattop. The transfer is performed at harmonic number 2 (see Table 1).

Table 1: List of Beam Parameters for SIS18 at the Flattop for Uranium $^{238}U^{28+}$.

Parameters	Value
Bending field B_0	1.73 T
Magnetic Rigidity $B_0\rho_0$	18 Tm
RF frequency f_0	1.56 MHz
Circumference of the reference orbit L_0	216.72 m

*Work supported by GSI
#ferrand@temf.tu-darmstadt.de

The future SIS100 will have a maximum magnetic rigidity of 100 Tm for a reference orbit five times larger than the reference orbit of the SIS18. Injections will be performed on harmonic number 10, so that under the transfer conditions the relative bunch repartition in the SIS18 and in the SIS100 is periodical and its revolution frequency is the frequency of the SIS100 at harmonic number 1.

Independently from the applied method and from the conditions relative to the design of the different accelerators, which compose the acceleration chain, the procedure, which we refer to as synchronization consists in controlling the relative phase advance between RF signals of the SIS18 and the corresponding reference signals derived from the SIS100 RF system. The described synchronization procedure is required to ensure the capture of the bunches composing the beam extracted from the SIS18 by the RF field generated by the 14 ferrite-loaded cavities of the SIS100.

SYSTEM DESIGN

Beam Dynamics During the Synchronization

According to the circumference ratio of their reference orbits, the measured relative phase advance between corresponding RF signals of the SIS18 with respect to the SIS100 is constant. Modifying the bending field value at the transfer flattop in the SIS18 results in steering the beam on a so-called synchronization orbit, which introduces a linear variation of the relative phase advance between the corresponding RF signals of the SIS18 resp. the SIS100. According to the main synchronization scenario under development for FAIR the beam is extracted from its synchronization orbit, imposing a maximum relative radial steering during the synchronization procedure shown in Eq.1.

$$\frac{\Delta L}{L_0}=2.4\cdot 10^{-4} \qquad (1)$$

The energy matching between the two RF fields, is ensured for this maximum radial steering by modifying the bending field accordingly. The maximum frequency offset resulting from these modifications is $\Delta f = -360$ Hz.

The synchronization requirements are fulfilled periodically according to the beating frequency Δf. The transfer can be triggered within a transfer window defined by the maximum phase error expectation of ± 0.5°

HIGHER ORDER MODE PROPAGATION AND DAMPING STUDIES ON AXISYMMETRIC SUPERCONDUCTING MULTICELL RF-RESONATORS*

B.D. Isbarn†, B. Riemann, M. Sommer, T. Weis
TU Dortmund University (DELTA), Center for Synchrotron Radiation, Dortmund, Germany

Abstract

Higher order mode (HOM) propagation and damping is a major concern in feasibility studies regarding the upcoming upgrade of BESSY II, named BESSY-VSR, which involves the utilization of superconducting multicell RF-resonators in a storage ring while maintaining a reasonably high beam current typical for third generation synchrotron radiation facilities. In addition to the computation of typical figures of merit, we focus on studies of the mode propagation in axisymmetric structures. Due to the focus on axisymmetric studies we are able to use 2D codes to investigate in eigenmodes with substantialy higher frequencies than usually considered with full 3D codes in parametric studies. In this work we present preliminary studies involving mode propagation in superconducting elliptical multicell cavities.

INTRODUCTION

The upcoming BESSY II upgrade BESSY-VSR aims to provide both short and long electron bunch lengths simultaneously [1], this can be achieved through a modulation of the rf-frequency. In order to fullfill the space restrictions and field requirements the use of superconducting multicell rf-cavities is inevitable. Due to the vast intrinsic quality factors of superconducting cavities and the high beam currents of typical third generation synchrotron radiation facilities, proper higher order mode damping techniques must be implemented. A major concern for designing appropriate damping techniques is the mode propagation resp. the power flow in beam direction. We already investigated the mode propagation of a single cell spline cavity [2] using Floquet periodic boundary conditions in an earlier work [3]. To incorporate evanescent coupling and the mode propagation of normal modes we took this approach one step further and investigated in the mode propagation of a multicell cavity with varying beam tube lengths attached to the end of the multicell structure. In the following we are using the nomenclature of [4] to refer to the modes corresponding to the single cell cavity as *cavity modes* and to the modes emerging from the coupling of the single cell cavitiy into an array of cavities as *normal modes*.

NUMERICAL STUDIES

All numerical studies were performed on the 2D axisymmetric eigenvalue problem with COMSOL Multiphysics 5.0 [5]. The base cell design consisted of elliptical shaped cavities as displayed in Fig. 1 with the geometry parameters

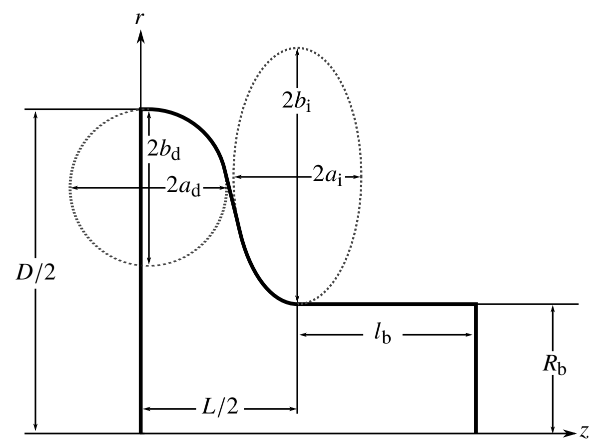

Figure 1: Geometry parameters of an elliptical cavity.

of the HZB layout [6]. These base cells were concatenated to form an array of 5 equally shaped cavities with beam tubes of length l_b attached to its ends. By restricting our scope of observation to equally shaped cells, without applying any end-cell tuning respectively optimization, we could increase the performance and therefore the observable parameter space.

Simulation Setup

In order to observe mode propagation we applied Floquet periodic boundary conditions at the ends of the attached beam tubes

$$\boldsymbol{E}_\mathrm{dst} = \boldsymbol{E}_\mathrm{src} e^{-i\boldsymbol{k}_z\cdot(\boldsymbol{r}_\mathrm{dst}-\boldsymbol{r}_\mathrm{src})}$$
$$\boldsymbol{H}_\mathrm{dst} = \boldsymbol{H}_\mathrm{src} e^{-i\boldsymbol{k}_z\cdot(\boldsymbol{r}_\mathrm{dst}-\boldsymbol{r}_\mathrm{src})}\ ,$$

where $\boldsymbol{E}_\mathrm{dst/src}$ and $\boldsymbol{H}_\mathrm{dst/src}$ represents the electric and magnetic field at the leftmost respectively rightmost port, and the wave vector $\boldsymbol{k}_z$ can be expressed as a function of the phase advance ψ and the overall length of the structure L_s

$$\boldsymbol{k}_z = \frac{\psi}{L_\mathrm{s}}\hat{z}\ .$$

All other boundaries were set to be perfect electric conductors (PEC) leading to loss-free solutions with real eigenvalues. We used the external quality factor as a figure of merit for the mode propagation, in analogy to the usual definition of the quality factor [4], described by

$$Q_\mathrm{ext} = \frac{\omega_0 U}{P_z} = \frac{\omega_0 \iiint_V \frac{1}{2}\varepsilon_0 \left|\boldsymbol{E}\right|^2 \mathrm{d}V}{\iint_A \rho_z \,\mathrm{d}A}\ .$$

FIRST CHARACTERIZATION OF A SUPERCONDUCTING UNDULATOR MOCKUP WITH THE CASPER II MAGNETIC MEASUREMENT SYSTEM

S. Gerstl#, S. Casalbuoni, N. Glamann, A. Grau, T. Holubek, D. Saez de Jauregui, R. Voutta, ANKA Synchrotron Radiation Facility, Karlsruhe Institute of Technology, Karlsruhe, Germany
C. Boffo, T. Gerhard, M. Turenne, W. Walter, Babcock Noell GmbH, Würzburg, Germany

Abstract

Superconducting insertion devices (IDs) can reach, for the same gap and period length a higher field strength compared to permanent magnet IDs. Their performance depends strongly on the magnetic field quality. While the magnetic measurements technology of permanent magnet based IDs made significant progress during the last years, for superconducting IDs similar major developments are necessary. As a part of our R&D program for superconducting insertion devices at the ANKA synchrotron radiation facility a measurement setup for conduction cooled superconducting coils with a maximum length of 2 m was built and commissioned. In the CASPER II (Characterization Setup for Phase Error Reduction) facility (see Fig. 1) the magnet coils can be trained and tested for maximum current and field quality, including the local field distribution as well as the first and second field integrals. In this paper we shortly describe the CASPER II setup and focus on the capability of this measurement device by presenting the results of a superconducting undulator mockup with a period length of 20mm.

INTRODUCTION

The performance of insertion devices (IDs) depends strongly on their magnetic field quality. It is of fundamental importance to characterize magnetic field properties of IDs accurately before installation in synchrotron light sources. While for permanent magnet IDs, commercially measuring systems exists, for the characterization of superconducting IDs they are not available. ANKA and Babcock Noell GmbH are pursuing an R&D program aiming to develop superconducting undulators (SCUs) for third and fourth generation light sources [1]. The SCUs developed and under development with BNG make use of NbTi superconducting wire and are conduction cooled. In order to characterize the magnetic field properties of these conduction cooled SCUs, the CASPER II facility has been developed at ANKA [2, 3].

The CASPER II facility is a horizontal test stand where up to 2 m long superconducting coils can be measured. The setup is cryogen free. The coils under test are put on an aluminium table in a high vacuum environment and surrounded by a shell-like structure of different temperature shields. Cooling is provided by four 2 stage cryocoolers from Sumitomo with a total cooling power of 5.5 W. An additional one stage cooler from Oerlikon is connected to the 80 K shield. In total eight 500 A current leads are installed to provide power to the main magnet and its correction coils.

For magnet training two switchable bipolar 1500 A power supplies from Bruker in conjunction with an in house designed quench detection system (built by the Institute for Data Processing and Electronics at the KIT) and a fast data acquisition system from National Instruments is available.

Figure 1: Picture of the CASPER II measurement system.

The local magnetic field perpendicular to the beam axis is measured by using 3 Hall probes, which are placed next to each other on a brass sledge. The Hall probes are placed at different horizontal positions in order to characterize a good field region of ± 10 mm. The sledge is guided by very precisely machined rails through the magnet and stepwise moved along the beam axis. To determine the position of the sledge a laser interferometer with a submircometer resolution is used. Further details can be found in Ref. [3].

For assessment of the vertical and horizontal first and second field integrals a piezo stage driven stretched wire setup is installed.

The full control and readout of the measurement system is programmed with LabView.

In this contribution we describe the CASPER II facility and its capabilities by presenting the results of the magnetic characterization of a 300 mm long prototype of the SCU20, a superconducting undulator with a period length of 20 mm under development within the collaboration between ANKA and BNG for use at the NANO beamline. An overview of the main features of the design is given in Ref. [4].

DESIGN OF A NORMAL CONDUCTING CAVITY FOR ARRIVAL TIME STABILIZATION AT FLASH*

M. Fakhari†, K. Floettmann, S. Pfeiffer, H. Schlarb, DESY, Hamburg, Germany
J. Rossbach, Uni HH, Hamburg, Germany

Abstract

It has been shown, that beam-based feedback loops stabilize the bunch arrival time in the femtoseconds range. However, further minimizing the bunch arrival time jitter requires a faster actuator that is a normal conducting cavity with higher bandwidth compared to narrow-band superconducting cavities. We present the design of a 4-cell normal conducting cavity that is going to be used in a fast beam-based feedback at free-electron laser FLASH at Hamburg. The input power will be injected to the cavity via a loop coupler from the side of the first cell. The operating frequency of the designed cavity is about 3 GHz with an adjustable bandwidth. The long range longitudinal wakefield calculation results are reported to investigate the cavity performance for multi-beam operation up to 3 MHz bunch repetition rate. The results declare that the influence of the long range wakefield on the arrival time jitter is less than 1 fs.

INTRODUCTION

The Free-Electron Laser FLASH at Hamburg provides short laser pulses to study the dynamics of molecular and chemical reaction on an atomic level. To generate the ultra short wavelength laser pulses, a high-quality electron beam is accelerated in superconducting cavities to an energy of 1.25 GeV and then sent through long magnetic undulators. The short wavelength laser light is used e.g. to study the temporal dynamics of matter typically carried out in a pump-probe arrangement, where atoms or molecules are excited by an external ultra-short pulse optical laser while their reactions are visualized using the FEL light. To achieve the required femtosecond resolution a precise regulation of bunch arrival time within a train of electron bunches is mandatory. For FEL users, it is therefore essential that the arrival time of the individual radiation pulses have a stability with a precision of a few femtoseconds only. Three superconducting accelerating modules, ACC1, ACC39 and ACC23, are being used to adjust the arrival time of the bunches [1]. However, since these modules are narrow bandwidth caused by their high quality factor, it takes a non-negligible time to stabilize the arrival time. Furthermore the final arrival time has a jitter of ± 150 fs peak to peak. Further minimizing the bunch arrival time jitter requires faster actuator, e.g. a normal conducting cavity with higher bandwidth compared to the narrow-band superconducting cavities. A normal conducting cavity is thus designed for this purpose. This cavity is going to be installed at FLASH main linac as shown in Fig. 1. Concerning the space limitation in FLASH a side coupling to this cavity is required. Since the input power of the cavity is less than 1kW it seems to be most efficient if the input power could be coupled to the cavity via a loop antenna instead of a waveguide coupler. In addition to space limits, it is more convenient to adjust the coupling constant by engaging the loop couplers. Besides, since the power supply is a solid sate amplifier with a coaxial cable as the output it would be easier to connect its output directly to a feedthrough instead of using a coaxial to waveguide converter. In this paper the designing process and the simulation results for the designed cavity are presented. The long range wakefield in the designed cavity has also been investigated to make sure that the desired arrival time resolution is achievable.

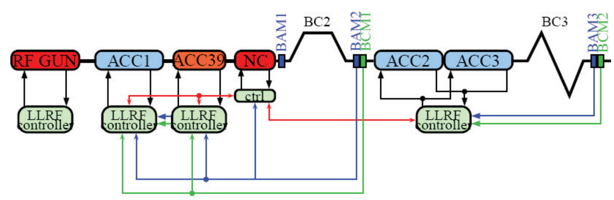

Figure 1: Place of installation of the NC cavity at FLASH

DESIGNING PROCESS

In order to design the fast feedback cavity, the arrival time deviation $\Delta t_A \approx \pm 150$ fs (peak-peak) needs to be corrected. This requires an energy correction of:

$$\Delta E = \frac{\Delta t_A \cdot c}{-R_{56}} \cdot E \approx \pm 37.5 \text{ keV} \tag{1}$$

where c is the speed of the light in free space, R_{56} is the bunch compressor parameter which is -0.18 m at FLASH-BC2, and the electron energy E is about 150 MeV. To achieve the required energy correction an accelerating voltage of $V_{acc} = \Delta E/e \approx 37.5$ kV is needed. Furthermore, a half bandwidth of 400 - 500 kHz is expected in order to make the cavity fast enough. The designed cavity is formed from four coupled pillbox cavities and has four fundamental TM_{010} normal modes which are named as 0-Mode, $\frac{\pi}{3}$-mode, $\frac{2\pi}{3}$-mode, and π-mode. These names are based on the phase shifts between adjacent cells. The operating mode is the π-mode with the frequency of 2998 MHz. After designing the cells of the cavity the most important part is to design its input coupler. By changing the coupling constant one can change the external quality factor and subsequently the bandwidth of the cavity. However, by changing the coupling constant the accelerating voltage also varies. For a cavity

DESIGN AND CHARACTERIZATION OF PERMANENT MAGNETIC SOLENOIDS FOR REGAE

M. Hachmann, K. Floettmann, F. Mayet, DESY, Hamburg, Germany
T. Gehrke, DKFZ, Heidelberg, Germany

Abstract

REGAE is a small electron linear accelerator at DESY. In order to focus short and low charged electron bunches down to a few μm permanent magnetic solenoids were designed, assembled and field measurements were done.
Due to a shortage of space close to the operation area an in-vacuum solution has been chosen. Furthermore a two-ring design made of wedges has been preferred in terms of beam dynamic issues. To keep the field quality of a piecewise built magnet still high a sorting algorithm for the wedge arrangement has been developed and used for the construction of the magnets. The magnetic field of these solenoids has been measured with high precision and has been compared to the simulated magnetic field.

INTRODUCTION

The Relativistic Electron Gun for Atomic Exploration (REGAE) is a small 5 MeV linear accelerator at DESY in Hamburg, which produces short, low emittance electron bunches. It originally was meant for temporal resolving electron diffraction experiments [1]. But two further experiments are currently planned at REGAE. First, an external injection experiment for Laser Wakefield Acceleration (LWA) [2] will be performed in the framework of the LAOLA collaboration (LAboratory fOr Laser- and beam-driven plasma Acceleration). This experiment will provide a method for the reconstruction of the electric field distribution within a linear plasma wakefield. Second one is an extension of the original experiment. A time resolving high energy Transmission Electron Microscope (TEM) will be set up.
Both experiments require strong focusing magnets inside the new target chamber at REGAE. Permanent magnetic solenoids (PMSs) can provide the needed focusing strength due to their enormous surface current density, while having compact dimensions at the same time. Since short and strong solenoids, as required for REGAE, exhibit a distinct non-linearity, the induced emittance growth is relatively large and has to be minimized as far as possible. Furthermore, the focusing strength is not adjustable and 3D in-vacuum movers are required for positioning the magnets. Due to the chosen movers a weight limitation for the magnets reveals as an additional requirement. Overcoming these difficulties PMSs are an interesting alternative when a low energy beam has to be strongly focused.

DESIGN

A strong focusing is needed to generate a small transverse beam size for the external injection experiment and for a large magnification in the transmission electron microscope.

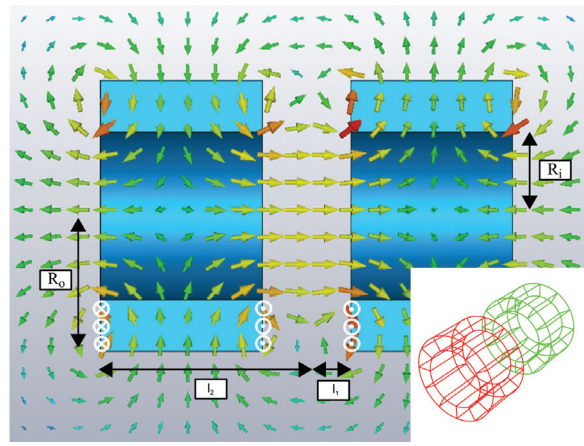

Figure 1: CST simulation of two radially magnetized rings (blue) and the conceptional wedge-based design.

This is achieved by the presented PMS design [3]. A second demand is a small emittance growth induced by the PMS. The investigations of different designs have shown that the induced emittance growth for two radially magnetized rings is considerably smaller than for an axially magnetized ring, if a weight limitation has to be applied. In the particular case at REGAE, a reduction of the emittance growth by 65% is feasible. Mimicking the magnetic field of the single axially magnetized ring with two radially magnetized rings allows for a larger influence on the field shape since a third free parameter, the distance $d = 2\,l_1$ between both rings, is introduced. The PMS dimensions (in mm) depicted in Fig. 1 are as follows $R_o = 25.4$, $R_i = 17$, $l_1 = 7.8$ and $l_2 = 44.8$ while the weight is just 0.628 kg. The focal length for a 5 MeV electron beam is ~ 0.2 m. For technical reasons radially magnetized rings need to be assembled from wedges. The imperfections of the wedges call for a sorting algorithm in order to preserve the field quality.

FIELD DESCRIPTION AND SORTING ALGORITHM

Field Model

Due to the necessity of a model which describes the resulting field of 24 wedges we developed a simple model: each wedge is described by current loops covering the surface (Fig. 2 **b**)), where each loop can be divided into four straight parts. The magnetic field can be calculated by means of *Biot-Savart's law* for a straight wire. The magnetization **M** of a wedge is defined by the direction and its magnitude which were measured by the manufacturer and can be translated into a tilt of the current loops or a variation of the current,

TIMING JITTER STUDIES FOR SUB-FS ELECTRON BUNCH GENERATION AT SINBAD

J. Zhu[#1,2], R. Assmann[1], U. Dorda[1], J. Grebenyuk[1], B. Marchetti[1]

[1] Deutsches Elektronen-Synchrotron, DESY, Hamburg, Germany
[2] Universität Hamburg, Hamburg, Germany

Abstract

Generation of ultra-short electron bunches with a few femtoseconds arrival-time jitter is the major challenge in plasma acceleration with external injection. Meanwhile, peak current stability is also one of the crucial factors for user experiments when the electron bunch is used for free-electron laser (FEL) generation. ARES (Accelerator Research Experiment at SINBAD) will consist of a compact S-band normal-conducting photo-injector providing ultra-short electron bunches of 100 MeV. We present bunch arrival-time jitter studies for two different compression schemes, velocity bunching and magnetic compression with a slit, at ARES with start-to-end simulations. Contributions from various jitter sources are quantified.

INTRODUCTION

External injection of electron bunches into laser-driven wakefield acceleration (LWFA) allows precise manipulation of the phasespace of the electron bunches and thereby provides possibilities to optimise the following acceleration and transport inside the plasma. However, the requirement on the synchronization of the electron bunch to the drive laser is rather stringent [1]. SINBAD (Short Innovative Bunches and Accelerators at DESY) is a proposed dedicated accelerator research and development facility [2]. One of the baseline experiments at SINBAD is LWFA with electron bunches generated by ARES (Accelerator Research Experiment at Sinbad) [3], which will allow the production of ultra-short bunches by velocity bunching (VB) [4] or by magnetic bunch compression (BC) with a slit [5].

In LWFA experiments, considering the general case that the cathode laser and the drive laser are different, the total timing jitter between the electron bunch and the drive laser is given by

$$\sigma_{t_{total}} \approx \sqrt{\sigma_{t_b}^2 + \sigma_{t_o}^2 + \sigma_{t_a}^2}\ , \quad (1)$$

where σ_{t_b} is the bunch arrival-time jitter (ATJ) relative to the reference, σ_{t_o} is the contribution from synchronization of the drive-laser oscillator and σ_{t_a} is the jitter of the drive-laser amplifier. The aim of this study is to quantify the term σ_{t_b} in equation (1) with different compression schemes at ARES and to identify the major jitter sources.

ANALYTICAL MODEL OF ATJ WITH MAGNETIC COMPRESSION

Considering a general case of a linac consisting of a gun and a couple of cavities powered by a single klystron, the ATJ of the electron bunch downstream of the chicane is well-known as [6]:

$$\sigma_{t_b} \approx \sqrt{\frac{R_{56}^2}{c^2}\left(\sigma_{\delta_V}^2 + \frac{h^2}{k_{rf}^2}\sigma_\phi^2 + \sigma_{\delta_B}^2\right) + \frac{\sigma_{t_0}^2}{C^2}}\ , \quad (2)$$

where R_{56} is the longitudinal dispersion of the chicane, c is the velocity of light, h is the chirp of the bunch, k_{rf} is the rf wave number, $C=1/(1+hR_{56})$ is the compression factor and σ_{δ_V}, σ_ϕ, σ_{δ_B} and σ_{t_0} are the cavity voltage jitter, the cavity phase jitter, the magnetic field jitter of the chicane and the ATJ at the gun exit respectively. However, in order to directly compress the pulse duration of the electron bunch generated at a photo-injector to sub-fs with only one compression stage, a sub-mm wide slit will be placed in the middle of the chicane at ARES. Since the slit only allows electrons with certain energies to go through, the energy jitter upstream of the chicane will almost *not* be converted into the ATJ downstream of the chicane. In this case, the bunch arrival time downstream of the chicane is given by

$$t_b \approx t_0 + t_c + \frac{s}{c}, \quad (3)$$

where t_0 is the arrival time of the bunch at the gun exit, t_c is the timing offset of the "collimated" bunch relative to the centroid of the whole bunch at the entrance of the chicane and s is the path length of the "collimated" bunch in the chicane. In this case, one can derive that the ATJ downstream of the chicane is given by

$$\sigma_{t_b} \approx \sqrt{\left(\frac{1}{hc}\right)^2 \sigma_{\delta_V}^2 + \left(\frac{1}{ck_{rf}}\right)^2 \sigma_\phi^2 + \left(\frac{R_{56}}{c}\right)^2 \sigma_{\delta_B}^2}\ . \quad (4)$$

It is obvious that equation (2) and (4) are the same in the case of full compression ($1+hR_{56}\approx 0$). Note that the ATJ at the gun exit will anyhow be fully compressed regardless of the compression factor in the case with a slit. In the meanwhile, however, the cavity phase jitter will be totally converted into the ATJ downstream of the chicane.

At ARES, two identical S-band travelling-wave structures (TWS) will be powered by their individual klystrons. In this case, one can prove that the minimum ATJ will be achieved when both TWSs are operated with the same voltage and phase, and is given by

$$\sigma_{t_b,\min} \approx \sqrt{\left(\frac{R_{56}}{c}\right)^2 \left(\sigma_{\delta_B}^2 + \frac{1}{2}\sigma_{\delta_V}^2\right) + \frac{1}{2}\left(\frac{1}{ck_{rf}}\right)^2 \sigma_\phi^2}\ . \quad (5)$$

UTILIZING GAS FILLED CAVITIES FOR THE GENERATION OF AN INTENSE MUON SOURCE*

Diktys Stratakis#, Brookhaven National Laboratory, Upton NY, USA
David V. Neuffer, Fermi National Accelerator Laboratory, Batavia IL, USA

Abstract

A key requirement for designing intense muon sources is operating rf cavities in multi-tesla magnetic fields. Recently, a proof-of-principle experiment demonstrated that an rf cavity filed with high pressure hydrogen gas could meet this goal. In this study, rigorous simulation is used to design and evaluate the performance of an intense muon source with gas filled cavities. We present a new lattice design and compare our results with conventional schemes. We detail the influence of gas pressure on the muon production rate.

INTRODUCTION

The relative immunity of muons to synchrotron radiation due to their large rest mass suggests that they may be used in place of electrons for fundamental high-energy physics research [1] as well as for various industrial and medical applications. However, the short lifetime of muons (2.2 μs in the rest frame) makes a muon beam very challenging technologically. Muons can be produced indirectly through pion decay by interaction of a multi-GeV, high-power (1-4 MW) proton beam with a stationary target. The muon yield is fractionally small, with large angle and energy dispersion. In this paper the production of pions, their decay into muons and the survival of muons during transport is studied.

MUON CAPTURE CHALLENGES

A key requirement in producing an intense muon source is that the phase space-volume of the produced beams must match the acceptance criteria of the downstream accelerators. This demands a front-end channel (the part of the facility between the target and the first linear accelerator) for manipulating the beam in transverse and longitudinal phase-space [2]. For the latter, a series of rf cavities form the resulting muon beam into strings of bunches with different energies, and then align them into nearly equal central energies by phase-rotating the beam. To reduce the volume of transverse phase-space, the bunches pass through a cooling channel, which reduces the beam's emittance using ionization cooling. The cooling channel consists of absorbers, which lower the transverse and longitudinal momentum of beam particles, and rf cavities, which restore the particle's longitudinal momentum, inside a magnetic channel. A common feature of the front-end lattices is that it requires the rf cavities to operate within strong magnetic fields that focus the muons.

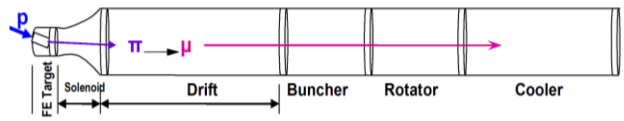

Figure 1: Schematic of the muon capture channel.

There are challenges in operating rf cavities in magnetic fields [3]. For instance, typical rf gradients in the cooling channel are 20-25 MV/m, while the magnetic field is near 2 T. Experimental and numerical studies indicated that this configuration enhances the possibility of rf breakdown. The use of rf cavities filled with high pressure hydrogen gas was proposed to overcome this difficulty. The gas not only provides the necessary momentum loss as a cooling material but also increases the breakdown gradient of the cavity. Experiments [4] have demonstrated that a breakdown gradient of 65.5 MV/m could be achieved in a 3 T magnetic field with 70 atm hydrogen gas. Here we investigate a muon capture channel which utilizes gas filled cavities and compare it's performance against the conventional vacuum channel. We examine the performance for two different pressures: One at 34 atm and one at 100 atm, both at room temperature.

SYSTEM OVERVIEW

As shown in Fig. 1, a 1 MW proton driver produces bunches with 6.75 GeV in energy. The beam is directed onto a carbon (C) target enclosed in a 20 T solenoid. The pions created are captured as they transverse a ~5 m long, tapered superconducting solenoidal magnet system, where the field profile drops adiabatically from 20 T to 2.0 T. This is followed by a drift section with a constant 2.0 T field, where the pions decay into muons, and the beam develops a time-energy correlation with a high-energy "head" and a low-energy "tail". Then the beam is bunched into a string of bunches in a "buncher" followed by "phi-E" rotator section that aligns the muon bunches to nearly equal energies (matched at 325 MHz spacing) and then cooled in 325 MHz cooling channel with LiH absorbers.

In the buncher the frequency declines along its length from cavity to cavity, starting from 490 MHz at the entrance and dropping to 365 MHz at the exit. The rf gradient gradually increases from 0 to 15 MV/m using the relation $15z/L_B$, where L_B is the buncher length. In the cooling channel the frequency further decreases from 364 to 326 MHz but the gradient remains fixed at 20 MV/m.

BAKEOUT CONCEPT FOR THE HESR AT FAIR

Heinz Jagdfeld, Norbert Bongers, Patrick Chaumet, Frank Martin Esser,
Frank Jordan, Franz Klehr, Georg Langenberg, Ulrich Pabst, Larisa Semke
Forschungszentrum Juelich, Germany

Abstract

Forschungszentrum Juelich has taken the leadership of a consortium being responsible for the design of the High-Energy Storage Ring (HESR) going to be part of the FAIR project on the GSI campus in Darmstadt in Germany. The HESR is designed for antiprotons but can be used for heavy ion experiments as well. Therefore the vacuum is expected to be 10^-10 mbar or better. To achieve this also in the curved sections where 44 bent dipole magnets with a length of around 4.5 m will be installed, NEG coated dipole chambers will be used to reach the needed pumping speed and capacity. For activation of the NEG-material a bakeout system is required. The bakeout concept including the layout of the control system and the systematization of the heater packages for all components of the vacuum system are presented. Also the special design of the heater jackets inside the dipole will be shown where the geometrical parameters are very critical and space is very limited. The results of the simulation of temperature distribution in the dipole iron are compared to temperature measurements carried out at a testbench with different layouts of the heater jackets. The final design of the dipole heater jackets will be illustrated.

DESIGN DATA OF THE VACUUM SYSTEM OF THE HESR

The High-Energy Storage Ring for Antiprotons and Heavy Ions (HESR) will have a circumference of approx. 575 m and will therefore be the second largest accelerator ring in the FAIR facility. The low-loss, undisturbed acceleration, deceleration, and storage of the antiprotons and heavy ions in the synchrotron is only possible under UHV conditions at an average residual gas pressure below 1×10^{-10} mbar, or preferably 1×10^{-12} mbar for heavy ions, and at a very low magnetic permeability of the vacuum components.

The required operating pressure can only be reached if all vacuum components are manufactured in accordance with the dedicated specifications for the UHV system. As a result, special requirements apply to the materials used and their processing.

In detail the HESR will consist of 22 vacuum sections (incl. 2 for E-Cooler, 1 for PANDA), all separated with all-metal slide valves (max. section length 45 m). In the two arcs a bakeout system and a pumping system including NEG coated chambers inside the dipoles will be installed.

For roughing at least 6 mobile pumping stations with oil-free fore pumps are foreseen.

Every section contains at least two pirani and two penning test points and one mass spectroscopy. The design data of the HESR are listed below in Table 1.

Table 1: Design Data of the HESR@FAIR

Feature	Value /Description
circumference	575 m
radius arc	r = 49,5 m
length straights	l = 132 m
nb. dipoles	44 (l = 4.2 m), 50 Tm
nb. quadrupoles	84 (l = 0.6 m)
nb. sextupoles	60 (l = 0.3 m)
experiments	SPARC, PANDA, …
cooling systems	electron cooling 2-4 resp. 8 MeV stochastic cooling 2-4 resp. 6 GHz
dipole chambers	bended with radius of 29.43 m, 8.18°, length 4.40 m, NEG coated
spec. vacuum chambers	2 for inj. kicker, 7 for stoch. cooling
av. pressure range	1×10^{-9} - 1×10^{-12} mbar at RT
beam pipe	DN93x2 mm, AISI 316LN with low hydrogen content and low permeability, electropolished
nb. pumping bodies	approx. 180, four ports each, with rf-mesh inside
nb. pumping station roughing	approx. 6 – 8, mobile design
nb. vacuum pumps	approx. 540 (IZ, TSP and NEG)
nb. slide valves	22 (24), all metal with rf-mesh
nb. high speed shutter	4

BAKEOUT CONCEPT OF THE HESR

In the curved sections 44 bent dipole magnets with a length of around 4.4 m will be installed. NEG coated dipole chambers will be used to reach the needed pumping speed and capacity (see Fig. 1).

For activation of the NEG-material a bakeout system must be installed. The bakeout concept including the layout of the control system and the systematization of the heater packages for all components of the vacuum system is shown in Fig. 2 and 3. The heater jackets for all components in the curved sections - the straight sections will not be NEG-coated and do not need a bakeout system – were combined to repetitive elements. The bakeout concept with the sequence and duration of the heating procedure as well as the switch on and off points of the vacuum pumps are shown below. The bakeout process starts with heating up the non-NEG-coated components to

LOW- AND HIGH-BETA SRF ELLIPTICAL CAVITY STIFFENING

E. Zaplatin, Forschungszentrum Juelich, Germany,
A. Kanareykin, Euclid TechLabs, Ohio, U.S.A,
V. Yakovlev, FNAL, Geneva, IL, U.S.A

Abstract

Elliptical SRF cavities are the main accelerating structures in many accelerators worldwide. Different types of external loads on the resonator walls predetermine the main working conditions of the SC cavities. The most important of them are very high electromagnetic fields that result in strong Lorentz forces and the pressure on cavity walls from the helium tank that also deforms the cavity shape. Also mechanical eigen resonances of cavities are the main source of the microphonics. To withstand any kind of external loads on the resonator walls different schemes of the cavity stiffening were applied.

In the paper we report the basic investigations of the cavity stiffening using FNAL 650 MHz beta=0.92 and 0.61 as an example. The single-cell investigation results were used as the reference to develop the ultimate scheme of the helium vessel structure to ensure the best resonator stability.

PRESSURE RESPONSE OF MID-CELL

The first step of a superconducting elliptical cavity RF design is made as a trade-off in the optimization of the cell shape between the region of high electric field and the region of high magnetic field. In practice, the cavity performance may be limited not only by the RF characteristics, but also by detuning due to the Lorentz force, bath pressure fluctuations, or microphonics. Lorentz force detuning (LFD) is of concern primarily for pulsed accelerators such as the proposed Proton Improvement Plan-II (PIP-II) at Fermilab [1]. Hence, the strategy of cavity design should include the integrated simulations of RF and mechanical properties.

For the high energy sections of SC accelerators the well-studied multiple-cell elliptic cavities are optimal. An initial investigation should be provided on middle-cell geometries. Usually the simulations are made with the cell-to-cell junction constrained by symmetry. The goal for these calculations was to understand the behaviour and trends under different stiffening options.

The response of the cavity to a pressure differential is calculated with vacuum inside the resonator and ambient pressure outside. The pressure differential changes the cavity shape and shifts the RF frequency of the accelerating mode. Inward deformation near the iris (the region of high electric field) increases the capacitance and hence reduces the frequency. Inward deformation near the equator (high magnetic field region) reduces the inductance and hence increases the frequency. Thus the effects tend to cancel one another. Although the equator region is generally more rigid than the iris region, the volume change near the equator is larger due to the larger radius.

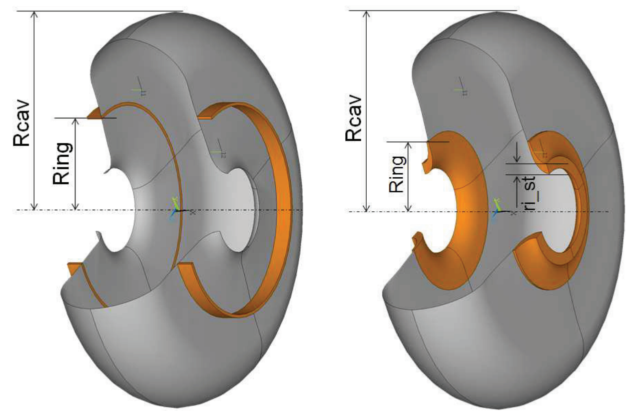

Figure 1: Elliptical mid-cell geometry (β= 0.61) with ring and iris stiffening options.

A stiffening ring position and a shape of the iris thickness can be used to change the frequency shift (Fig. 1) [2]. On the other hand the ring position also affects the Lorentz force detuning [3]. But differing from the pressure differential case the Lorentz forces at the dome region are directed outward the cavity volume. That's why the choice of the ring position is the trade-off between these two effects since their optimizations result in the different ring positions. For the pulsed accelerators like TeSLA the ring was placed to minimize primary the Lorentz force detuning (Fig. 2).

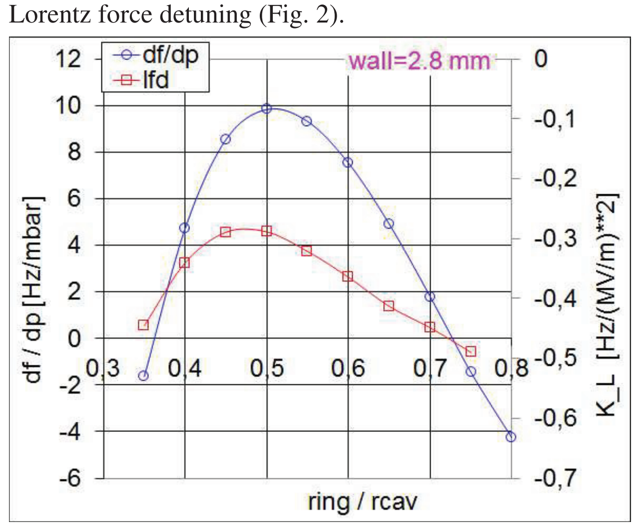

Figure 2: TeSLA mid-cell mechanical properties.

DOUBLE-CELL NOTCH FILTER FOR SRF GUN INVESTIGATIONS

E. Zaplatin, Forschungszentrum Juelich, Germany
A. Kanareykin, Euclid TechLabs, Ohio, USA
J. Knobloch, A. Neumann, Helmholtz-Zentrum Berlin, Germany
V. Yakovlev, FNAL, Geneva, IL, USA

Abstract

Some projects of SRF guns apply the design where the cathode can be easily and quickly removed. One of the disadvantages of this design is the RF power leakage from the accelerating gun cavity cells to the cathode housing that result in the excessive cathode heating. To minimize the RF power leak different kinds of choke filters are used to protect the cathode structure. These choke filters represent resonant circuits with zero input impedance and installed at the entrance of the cathode structure that shunt the cathode housing.

Still, since the choke filter frequency shift under working conditions is bigger than its bandwidth a filter tuning during assembly only in the warm stage seems insufficient and requires also fine-tuning during operation.

To eliminate the problems of the choke filter fine-tuning and hence ensure its stability during operation, a combination of the resonance choke elements can be implemented. In the paper we demonstrate advantages of the double-cell notch filter using B*ERL*inPro SRF gun cavity as an example with its simple design modifications.

CHOKE CELL GAP SIZE

First development of the SRF gun with choke-cell filter was done at FZDR [1]. The choke cell represents a cavity cell of a special shape surrounding the cathode and preventing the RF power from leaking out of the cavity. In this manner it works as a bandpass filter. The operation of the choke-cell is the same like quarter wave choke with similar S_{21}-parameter distribution [2]. An advantage of choke-cell is better possibilities for the cleaning and less probable and less stable multipactor discharge in the choke-cell. For the choke-cell structure the tuning procedure is simpler to compare with coaxial chokes and can be realized with well-developed SRF cell tuners. In HZDR and HZB [3] projects the SRF gun cavity frequency tuning is designed for the choke cell, half-cell and TESLA cells (Fig. 1). Since the half-cell and TESLA cells differ in their mechanical properties it was decided to use two separate tuning systems.

Still, caused by the narrow cathode channel and a small choke-cell gap chosen in HZDR and HZB projects, the standard buffered chemical polishing (BFP) and the high pressure rinsing (HPR) are not effective for the choke cell. This resulted in the lower quality of the surface treatment, which in its turn results in the higher probability of the electron resonance discharge (multipactor – MP), a high residual resistance and the residual impurities penetration into accelerating cells.

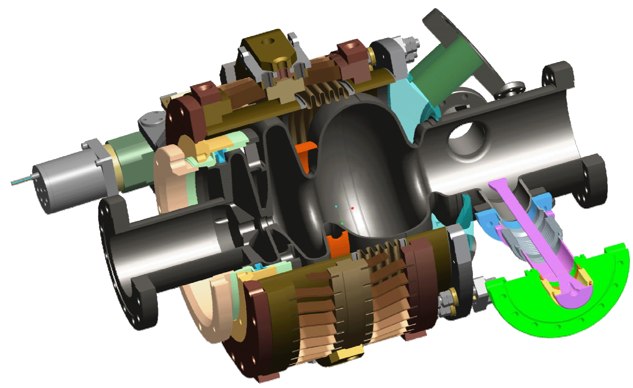

Figure 1: HZB 1.4.cell SRF gun.

To overcome the cleaning issue, the calculations have been provided to investigate the structure parameters on the choke-cell gap size. The simulation model that included half-cell, choke-cell and cathode coaxial transmission line was built using HZB SRF gun geometry (Fig. 2). The choke-cell gap size was varied from 6 mm (HZB project value) to 30 mm (full choke cell length) during simulations.

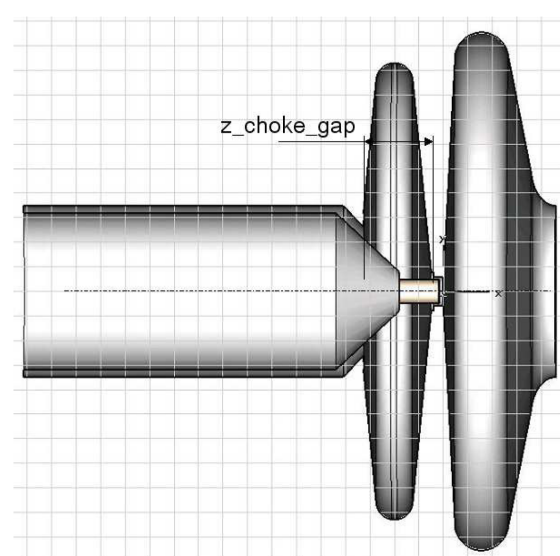

Figure 2: Choke-cell gap investigation simulation model.

MANUFACTURING AND FIRST TEST RESULTS OF EUCLID SRF CONICAL HALF-WAVE RESONATOR*

E. Zaplatin, Forschungszentrum Juelich, Germany
C. H. Boulware, T. L. Grimm, A. R. Rogacki, Niowave, Inc, Lansing, MI, USA
A. Kanareykin, Euclid TechLabs, Ohio, USA
V. Yakovlev, FNAL, Geneva, IL, USA

Abstract

Euclid TechLabs has developed a superconducting conical Half-Wave Resonator (162.5 MHz β=v/c=0.11) for the high-intensity proton accelerator complex proposed at Fermi National Accelerator Laboratory. The main objective of this project is to provide a resonator design with high mechanical stability based on an idea of the balancing cavity frequency shifts caused by external loads. A unique cavity side-tuning option has been successfully implemented. Niowave, Inc. proposed a complete cavity production procedure including preparation of technical drawings, manufacturing, processing steps and resonator high-gradient tests. During manufacturing a series of cavity and helium vessel modifications to simplify their fabrication were proposed. Following standard buffered chemical polish surface treatment and high-pressure rinse, a vertical test was carried out at Niowave's facilities.

Here we present the status of the project and the first high-gradient results.

INTRODUCTION

The conical Half-Wave Resonator (cHWR) design was reported earlier elsewhere [1-4]. The cavity RF parameters are shown in Table 1. A photo of the niobium cavity prototype being leak checked is shown in Fig. 1.

The main objective of the project was the conceptual design of the cHWR with its liquid helium vessel, minimizing the sensitivity of the resonant frequency to fluctuations in helium pressure.

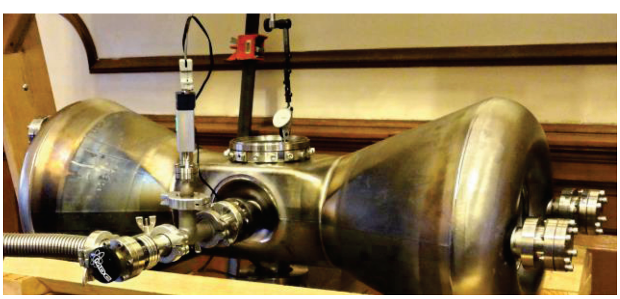

Figure 1: Modified cHWR with leak check setup.

Table 1: Conical HWR Parameters

frequency	MHz	162.5
β = v/c		0.11
R_aperture	mm	18
βλ	mm	202.94
R_cavity **)	mm	90
G	Ohm	36.36
R/Q	Ohm	119
E_{pk} / E_{acc} *)		5.1
B_{pk} / E_{acc} *)	mT/MV/m	7.1
B_{pk} / E_{pk}	mT/MV/m	1.39
tune	kHz/mm	-87
*) $L_{eff} = N_{gaps} * \beta\lambda/2$, where N_{gaps}=2 – number of gaps		
**) Cavity radius in center		

To use the outer conductor walls for cavity tuning deformations effectively, the central part of cHWR is made asymmetric with a planar surface on one side. This planar surface is used for tuning by deformation (Fig. 2).

The central resonator section optimization was made without compromising the cavity performance. The tuner ring is installed around the bellow (Fig. 2) connecting cavity and helium vessel tuning plates and provides compensation of the cavity tuning wall external pressure deformation (Fig. 3).

The side tuning procedure results in tune sensitivity up to 80 kHz/mm with acceptable stresses 350 MPa/mm and tuning pressure less than 1 kN/mm. There is nearly no dependence on the resonator frequency slow tuning.

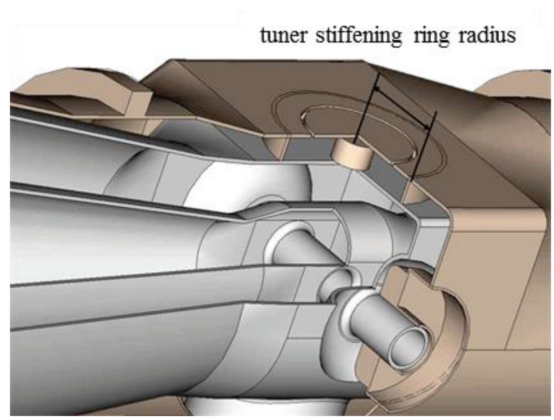

Figure 2: cHWR simulation model central part.

COMPACT IN-VACUUM QUADRUPOLES FOR A BEAM TRANSPORT SYSTEM AT A LASER WAKEFIELD ACCELERATOR*

A. Bernhard†, V. Afonso Rodriguez, J. Senger, W. Werner, C. Widmann, A.-S. Müller,
KIT, Karlsruhe, Germany

Abstract

For the transport and matching of electrons generated by a Laser Wakefield Accelerator (LWFA) a beam transport system with strong focusing magnets and a compact design is required. For the realization of such a beam transport system at the LWFA in Jena, Germany, two small series of inexpensive, modular quadrupoles were designed and built. The quadrupoles are iron-dominated electromagnets in order to keep the transport system adaptable to different energies and target parameters. To achieve the required field strength it was necessary to choose a small magnetic aperture. Therefore the magnets were designed for in-vacuum use with water-cooled coils. In this contribution the design, the realization and first field measurements of these quadrupoles are presented.

INTRODUCTION

Capturing, transporting and matching electron beams generated by Laser Wakefield Accelerators (LWFA) is a major challenge due to their significant energy spread, intrinsic divergence and pointing variance. To approach this problem experimentally one would certainly like to proceed step by step, each step involving a limited number of focusing and correcting magnets adapted to the respective experimental strategy. Such an approach, different from the situation at classical accelerators, calls for inexpensive, easy to build and easy to modify magnets providing maximal experimental flexibility.

Since the magnets, as explicated in more detail in the following section, have to be strong, compact, and adjustable to a not exactly predictable beam axis, the conventional concept of feeding a vacuum-beam pipe through the magnet gaps is discarded. Instead, the magnets should be capable of being operated in vacuum (10^{-5} mbar). At the same time it should be possible to tune the magnets on-line or to switch them off completely. Accordingly, in-vacuum electromagnets are the technology of choice.

Following these lines we designed, built and tested a set of electromagnetic in-vacuum quadrupoles and employed them in our first experimental step realizing a linear beam optics at the LWFA in Jena [1]. The basic design strategies applied can easily be transferred to higher-order multipole magnets for further experimental steps.

DESIGN REQUIREMENTS

Two small series of in-vacuum quadrupoles were realized. The magnetic and geometric design parameters for the two series are summarized in Table 1. The values for series *QG* result from an optimization with respect to the following geometric requirements and restrictions: On the one hand the large initial divergence of the beam in both transverse planes requires that the first magnets (either a doublet or a triplet) are placed as close as possible to the source and to each other. As a first approximation the focal length $f = (kl)^{-1}$ should be of the same order as the distance from the source. Here, $k = \frac{e}{p} g$ is the focusing strength, l the yoke length, g the field gradient and $\frac{e}{p}$ the beam stiffness, which is for our design beam energy of $E_0 = 120\,\mathrm{MeV}$ $\frac{e}{p} = 2.4\,\mathrm{T}^{-1}\,\mathrm{m}^{-1}$. At the same time the source-to-magnet center distance and the center-to-center distance between neighbouring magnets sets an upper limit to the full magnet length (including coils). To accommodate, on the other hand, a spectrally dispersed beam with a total dispersive beam splitting of ~ 4 mm, we chose an inscribed gap radius of 11 mm. Given this gap radius, the first estimations yielded 125 mm for the focal and 140 mm for the overall magnet length and 60 mm to 100 mm magnetic length as reasonable values. We note that for these parameters the thin lens approximation our estimation started off, is only valid in a heuristic sense.

The same basic consideration also applies to the series *QK*, however, these magnets are foreseen to be replaced by combined function quadrupole-sextupole magnets in a later experimental step. Consequently, following our design strategy of inexpensive and easy to modify magnets, the coils for series *QK* have already been designed and built for these magnets and therefore feature a sextupole geometry and a lower number of turns per coil.

Correspondingly the magnet coils for both series are laid out for being operated with standard laboratory power supplies and wound with a standard copper wire without internal cooling channel.

Table 1: Design Parameters for Two Small Series of Quadrupoles

Series	QG	QK
yoke diameter [mm]	210	203
magn. length [mm]	80	80
gap radius [mm]	11	11
turns/coil	465	412
max. operation current [A]	6	6
max. design field gradient [T/m]	39	30

MAGNET STUDIES FOR THE ACCELERATOR FLUTE AT KIT

S. Hillenbrand, A. Bernhard, M. J. Nasse, A.-S. Mueller, R. Rossmanith, R. Ruprecht, M. Sauter, S. Schott, M. Schuh, S. Schulz, M. Weber, P. Wesolowski, C. Widmann
KIT, Karlsruhe, Germany

Abstract

At KIT (Karlsruhe Institute of Technology) we are currently constructing the compact linear accelerator FLUTE (Ferninfrarot Linac Und Test Experiment). This 41 MeV machine is aimed at accelerator physics and synchrotron radiation research, using ultra-short electron bunches. The electrons are generated at a photo-cathode using picosecond long UV laser pulses. A magnetic chicane is used to compress the bunches longitudinally to a few femtoseconds [1,2].

This contribution describes both the magnet design, in particular the optimization of the chicane dipoles based on finite element method (FEM) simulations, as well as the implementation of a magnet measurement system.

INTRODUCTION

Many important questions from solid state physics to biological applications demand an analysis within a wide spectral range from THz to IR. These wavelengths are difficult to cover with high intensity using ring-based light sources. However, if the bunch length is comparable to or smaller than the desired wavelength, the electrons start to emit coherently, yielding a significant increase in flux [3].

To study bunch compression down to the fs-range, to study the influence on the generation of CSR (coherent synchrotron radiation), and to further the development of related diagnostics, a linac-based test accelerator named FLUTE (Ferninfrarot Linac Und Test Experiment) is currently under construction at KIT. The planned top-level parameters are listed in Table 1. For more information about FLUTE and the planned experiments, please refer to [1, 2] and the references therein.

Table 1: FLUTE Design Parameters

Linac Energy	41 MeV
Repetition Rate	10 Hz
Bunch Charge	1 pC - 3 nC
Pulse length	1 fs - 300 fs

To achieve the desired flexibility for experiments and the strong compression, a D-type bunch compressor is foreseen, cf. Fig. 1. As a detailed analysis of the future experiments depends on a precise description of the magnetic lattice used, OPERA [4] finite element simulations have been carried out for the chicane dipoles [5]. Particular emphasis has been put on the comparison of the calculated fringe fields with the analytical treatment used in the ASTRA [6] tracking code; and the calculation of the expected multipole components. The results are presented in the following section.

To measure the real field distribution of said magnets a measurement system featuring both a 3D Hall-probe and a stretched-wire set-up has been installed [7]. It is described in detail in the subsequent section.

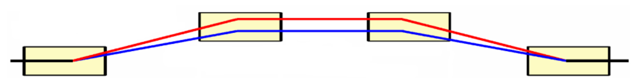

Figure 1: Schematic of a D-type bunch compressor. Particles with higher energy (blue) receive a smaller deflection in the dipole magnets (i.e. travel along a shorter path) than particles with a lower energy (red). For the correct initial energy distribution along the bunch, a bunch length compression can be achieved.

DIPOLE MAGNET DESIGN

Design Considerations

To allow maximal flexibility for future beam dynamics studies, the dipole magnets have to cover a large parameter range regarding beam energy and deflection angle, as listed in detail in Table 2. Two basic options are considered: a compact C-type and a wider, mechanically more stable H-type dipole magnet, cf. Fig. 2.

Table 2: Magnet Design Parameters

Electron beam energy	40 - 50 MeV
Deflection angle	0 - 15°
Magnetic field	0 - 120 mT
Magnet length	200 mm
Pole distance	45 mm
Transverse good field region C-type	76 mm
Transverse good field region H-type	240 mm

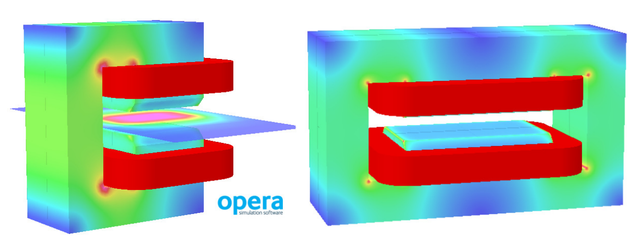

Figure 2: Possible C-type (left) and H-type (right) dipole magnet designs. The magnetic field strength within the magnet is indicated by colour map. For the C-type magnet, the magnetic field on axis is also illustrated

For the C-type magnets investigated, the transverse good field region (i.e. the area where the on-axis field does not

rx Z^¿£¡ VJ¡»pj pN–gQ£ Vp¡ “^Qj ;al ‰ ENERGY-RECOVERING SUPERCONDUCTING ACCELERATOR MESA*

F. Schlander†, K. Aulenbacher, R. Heine, D. Simon, T. Stengler
Institut für Kernphysik, Johannes Gutenberg-Universität Mainz, D-55099 Mainz, Germany

Abstract

The Mainz Energy-recovering Superconducting Accelerator MESA requires superconducting RF systems that provide sufficient energy gain of 50 MeV per turn to an electron beam. The order of two Rossendorf-type cryomodules, containing two 9-cell 1.3 GHz XFEL-like cavities each, has been placed. Besides an overview of the adaptations required for the multipass and high current beam operation of the cryomodules, details about challenges regarding the installation of the cryomodules on the premises of the Institut für Kernphysik at Universität Mainz are given.

INTRODUCTION

Superconducting Radio Frequency (SRF) is a key technology for the Mainz Energy-recovering Superconducting Accelerator MESA. The both-sided SRF main linac will provide an energy gain of 50 MeV per turn, hence 12.5 MeV per cavity, as the cryomodule of choice is the Rossendorf-type cryomodule [1] containing two 9-cell TESLA/XFEL-type cavities. The complex structure of cryomodules containing the niobium cavities and its exterior parts require adaptions to each indiviual use. So the Rossendorf-type modules will undergo modifications as described in the following section. Further on the installation of the cryomodules at their dedicated spot in the MESA caverns requires detailed planning as construction work is needed. The plans for the installation will be presented in the subsequent section, followed by an outlook.

ROSSENDORF-TYPE CRYOMODULES

The Rossendorf-type cryomodules are well-characterised and in use at HZDR for more than a decade. A picture of one of the installed modules is shown in Fig. 1. Since then smaller adaptations have been applied to the design for easier assembly and better performance by the manufacturer Research Instruments GmbH [2]. These include an improvement of the liquid nitrogen shield and the use of niobium cavities undergoing the European XFEL preparation process [3].

For the purposes of MESA some additional changes will be applied. The Higher Order Mode (HOM) couplers will contain sapphire feedthroughs, improving the thermal conductivity and thus push the thermal breakdown of the superconducting HOM coupler antenna tip to a higher performance level.

* Work supported by the German Federal Ministery of Education and Research (BMBF) and German Research Foundation (DFG) under the Cluster of Excellence "PRISMA"
† schland@uni-mainz.de

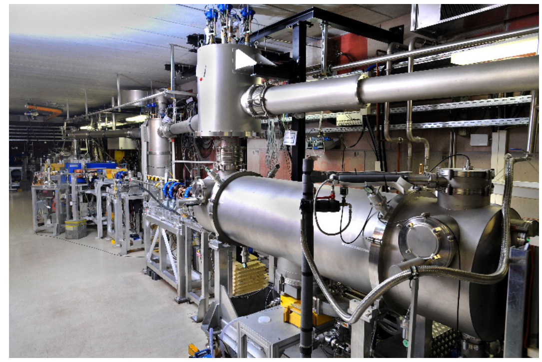

Figure 1: ELBE cryomodule (©Frank Bierstedt).

Due to the small bandwidth of the superconducting RF cavities, microphonics will be an issue for the energy recovery operation mode of MESA. To keep the frequency of the cavities under control, even for fast frequency changes, the tuner requires piezo technology which is not included in the standard Rossendorf type tuner and has to be replaced. Following from the tuner change, some redesign of the cavities' helium vessel is required. Besides the adaptations of the cryomodule, the coldboxes for the 4 K/2 K liquid helium (LHe) production including control system will also be provided, therefore only a $T = 4$ K LHe liquefier and the subatmospheric pumping units have to be provided by the institute.

SPACE CONSTRAINTS

In contrast to other projects, the facilities for MESA are already available, as they have been in use for a former experimental setup at the MAMI [4] accelerator. As these buildings are about 10 metres underground, the space foreseen is strictly limited, causing challenges in placing the lattice and all accelerator subsystems [5]. Special issues have to be faced for the cryomodules, as the current lattice places the cryomodules partially in apertures of the approx. 3 metres thick walls between the two accelerator halls MESA A/B. The front view sketch of the apertures and simplified insertions are shown in Fig. 2.

While the cryomodules itself fit into the apertures, the electric connections and the piping for the coolants will be an issue. The waveguides required for the RF supply reduce the space available for maintenance work and obstruct the passage to the end of the cryomodule which is located in the walls' aperture. Due to static reasons, a pedestal is required which will create a dead end, see Fig. 3.

In addition the cabling for RF and temperature diagnostics also hinders the transit, as the shearing forces applied might

EXPERIENCE AND DEVELOPMENTS ON THE S-BAND RF POWER SYSTEM OF THE FERMI LINAC

A. Fabris#, P. Delgiusto, F. Pribaz, N. Sodomaco, R. Umer, L. Veljak, Elettra, Trieste, Italy

Abstract

The S-band linac of FERMI, the seeded Free Electron Laser (FEL) located at the Elettra laboratory in Trieste, operates on a 24/7 basis accumulating more than 6000 hours of operation per year. The performance and operability requirements of a user facility pose stringent specifications on reliability and availability on all the systems of the machine and in particular on the RF power plants. This paper provides a review and discusses the operational experience with the S-band power plants, klystrons and modulators, operating at S-band in FERMI. Based on the satisfactory results and following return of experience, upgrades of the existing power plants are being implemented in the continuous effort of extending the operability and availability of the systems. A description of these activities and an overview of the other developments under consideration on the RF power plants are also provided.

INTRODUCTION

FERMI, the Italian seeded FEL located in Trieste, consists of two FEL lines, FEL-1 and FEL-2, covering the wavelength range between 20 and 100 nm and between 4 and 20 nm respectively. Both the two FEL lines are now open to external users [1]. The accelerator is based on a 1.5 GeV S-band linac. Fourteen 3 GHz 45 MW peak RF plants are installed to power sixteen accelerating structures, the RF gun and the three RF deflectors. Two more accelerating structures will be added at beginning of 2016 [2]. An additional power plant is installed to provide a hot-spare backup solution for the first two. This power plant is also used as a test bench for R&D purposes.

POWER PLANTS DESCRIPTION

RF power requirements for the plants are typically around 33 MW peak, with the exception of the plant that powers the gun and the low energy deflector where the needs are around 21 MW. Each power plant is composed of a 45 MW klystron and modulator. All plants are designed to operate at 50 Hz pulse repetition rate [3]. Figure 1 shows one of the RF plants.

All klystrons are TH2132A from Thales. This tube can provide up to 45 MW in pulsed mode, 4.5 µs at 100 Hz. Typical peak beam cathode voltage and current for maximum output are 310 kV and 350 A.

All modulators are line PFN type and were assembled by local companies under FERMI design. The main parameters are summarised in Table 1. The high voltage power supply is a 50 kV, 2 A capacitor charging power supply from FuG with a specified pulse-to-pulse repetition accuracy better then 100 ppm at 50 Hz. The switching element is a thyratron (CX1536X) from E2V.

#alessandro.fabris@elettra.eu

Figure 1: One of the FERMI S-band plants.

Table 1: Modulator Parameters

Parameter	Value
Maximum operating voltage	320 kV
Maximum delivered current	350 A
Repetition frequency	50 Hz
RF pulse width	4.5 µs
Risetime/falltime	< 2 µs
Pulse flatness	< ± 1 %

OPERATIONS AND STATISTICS

The RF plants are in operation continuously on a 24 hours 7/7 basis for about 6500 operating hours per year. The uptime of the entire S-band system for year 2014 has been 93 %. This comprises as well the downtime due to the other parts of the RF system such as waveguides and accelerating structures. The main sources of downtime are klystron arc discharges that amount to roughly 70 % of the total number of faults. These faults are power dependent and are randomly distributed, although three plants show a much higher arc rate.

Mean lifetime of the klystrons in operation is 32,000 hours. This value is presently assumed for spare parts management. It must be noted that this statistics is evolving and we have the two oldest klystrons that have exceeded 70,000 hours of operation. However, now these have been installed in the less demanding plants in terms of RF output. Typical failure mechanism is a too high arc rate at the operating voltage, which eventually prevents reaching or maintaining the target klystron beam parameters. Klystrons operation is continuously monitored. High voltage conditioning and heater curve

FIVE YEARS OF OPERATIONS FOR THE MAGNET POWER SUPPLIES OF FERMI

R. Visintini, Elettra Sincrotrone Trieste, Trieste, Italy

Abstract

FERMI, the FEL light source in Trieste, Italy, started its regular operation with external users in 2011. The construction of the facility began in 2008 and the commissioning of the complete system – LINAC, Undulators' chains (FEL-1 and FEL-2), photon front-end – started in 2010. On December 13, 2010 the first lasing occurred. From the Photo-injector to the electron Main Beam Dump (MBD), there are more than 400 magnets and coils, including those mounted on the accelerating sections of the LINAC and on the Undulators. With few exceptions, each magnet power supply energizes a single magnet/coil: there are about 400 magnet power supplies spanning from few tens of watt up to 42 kW. The power supplies types range from custom-made ones, to COTS (Commercial Off The Shelf), to in-house design (these accounting to 88% of the total). Almost all magnet power supplies are in use since mid-2010. During 5 years of operations, the reliability of the magnet power supplies proved to be extremely high: the downtime of FERMI operations due to magnet power supplies is very low.

INTRODUCTION

FERMI is the FEL source in operation for external users since 2011 [1] in the Elettra Research Center, in Trieste (Italy). FERMI is located extremely close to Elettra Storage Ring (SR) building: great care in planning and special low-vibration techniques were adopted not to interfere with the Users' activities on the Elettra's beamlines. FERMI is the long straight construction close to the circular Elettra SR building in Fig. 1.

Figure 1: Aerial view of FERMI and Elettra.

The civil works, carried out in about 4 years, ended in September 2010 but co-occupancy allowed the installation of the machine in parallel with the construction of the buildings and plants [2]. The commissioning started in September 2009 with the photoinjector and gun, and completed – excluding the experimental beamlines – in late 2010. The first seeded X-Ray lasing occurred on December 13, 2010 [3].

MAGNETS AND POWER SUPPLIES

The first magnet power supplies energized the gun solenoids and the injector spectrometer, starting in 2009. During 2010, about 400 more power supplies (PS) enter into operation on air- and iron-core magnets.

Design Strategies

In designing the magnet-PS combinations, we had multiple goals:

- Optimize the number of different PS for energizing the various types of magnets required by the particle physics design, taking in account the re-use of some magnets from the former LINAC to SR Transfer Line (TL) of Elettra.
- Standardize as much as possible the interface to the remote control and interlock (MPS – Machine Protection System).
- Make accurate estimations of the "contemporary factors", to define the actual power absorbed from the mains.
- Make realistic estimations of the dissipated power for the correct dimensioning of the HVAC (Heating Ventilation Air Conditioning) and water plants.

We achieved these goals through a close collaboration among the particle physics experts and the designers of the magnets, the PS, the control system, and the conventional plants. More details can be find in [4].

Power Supplies Types

The about 400 magnets and coils of FERMI belong to 37 different types, and, with few exceptions, they are individually energized. Following the optimization, the number of different PS types is 17: custom made, commercial ones (COTS – Commercial Off The Shelf) while the majority derives from an in-house design [5], as shown in Table 1.

Table 1: Types of Power Supplies

Type	# of Types	# of PS	Output [V/A]
Custom	2	4	25 – 55 / 750
COTS	12	31	15 -100 / 60 – 500
In-House	3	370	±12 - ±20 / ±5 - ±20
TOTAL	17	405

25 Hz SUB-MJ YTTERBIUM LASER SOURCE OF RF GUN FOR SUPERKEKB

X. Zhou#, T. Natsui, M. Yoshida, R. Zhang, Y. Ogawa, KEK, Tsukuba, JAPAN

Abstract

The electron beams with a charge of more than 5 nC and a normalized emittance of less than 10 μm are expected to be generated in the photocathode RF gun at the injector linac of SuperKEKB. An ytterbium (Yb)-doped fiber and Yb:YAG thin-disk hybrid laser system with a center wavelength of 259 nm and a pulse width of 20 ps is developed to obtain high peak energy pulses. As the result, more than 3 nC and 1 nC electron were generated in repetition of 25 Hz with single-bunch and double-bunch respectively.

INTRODUCTION

For injector linac of SuperKEKB project, more than 5 nC electron beams with double-bunch is expected to be generated in the photocathode RF gun. To high-current, low-emittance beams generation, the laser source with 1 mJ pulse energy, center wavelength of 259 nm and a pulse width of 20 ps are needed [1]. Especially, the broadband wavelength is required for the pulse shaping control. Therefore, a Ytterbium (Yb)-doped hybrid laser system, include an Yb-doped fiber oscillator, Yb-doped fiber amplifiers and thin-disk Yb:YAG amplifiers is developed.

For the repetition rate of electrum beam, the optional of 2 Hz, 5 Hz, 25 Hz and 50 Hz with single or double bunch were requested. Although, more than 5 nC electron with single-bunch has been generated in the 2 Hz and 5 Hz [2], when the repetition rate increases to 25 Hz, the condition of the laser amplifier system such as the thermal lens effect is changed seriously. To correspond to 25 Hz repetition rate, the laser was reformed.

LASER SYSTEM OF 25 HZ

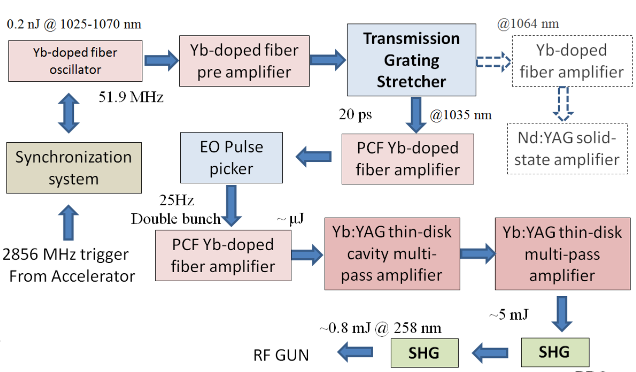

Figure 1: Layout of Laser system.

A schematic diagram of the laser setup is shown in Fig.1. The seed pulse with the pulse energy of 0.2 ns and spectrum of 1025-1070 nm was generated by an Yb-doped fiber ring oscillator. The pulse repetition is 51.9 MHz, synchronized with 2856 MHz trigger from accelerator. After an Yb fiber pre amplifier, the pulse was chirped to ~20 ps by a transmission grating stretcher with a spectral mask. An Yb-doped large-mode-area polarizing double-clad photonic crystal fiber was employed to the first amplification stage. Then, the pulse repetition rate of 25 Hz, double bunch was separated with two Electro-optic (EO) modulators. To increase the pulse energy, another Yb-doped LMA PCF was used. So the pulse was amplified to μJ-level, which was strong enough to be amplified by Yb:YAG thin-disk stage. To obtain the mJ-class pulse energy, several multi-pass amplifier stages were employed. Deep UV pulses for the photocathode are generated by using two frequency-doubling stages. High pulse energy and good stability were obtained. Finally, the pulses were injected into RF gun.

Backup of Yb Fiber Oscillator

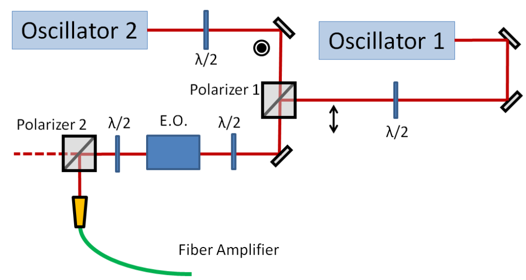

Figure 2: Selection of Oscillator.

The seed pulse was generated by a passive mode-locked oscillator with the pulse energy of 0.2 nJ at the repetition rate of 51.9 MHz (10.38*5 MHz). The spectral bandwidth is ~50 nm, from 1025 to 1070 nm. A piezoelectric transducer (PZT) is used to control the cavity length to lock the repletion rate with the 2856 MHz trigger from accelerator by a synchronization system. The mode-locked operation was stable for several months with good pulse quality and stability.

Because the oscillator is the most important part of all system, another backup oscillator was employed. As the fig.2, the two oscillators are set with cross polarizations that combine by polarizer 1. Then the EO modulator is used to change the polarization of the beams between the polarizer 1 and polarizer 2. The reflect beam of the seed pulses at polarizer 2 was chosen by the EO voltage control.

Upgrade of Yb Fiber Amplifier stages

In the fiber amplifier stages, the improvement is focus on the increase of the pulse quality. Two types amplifier was set up. For low power amplification, Yb fiber with the core diameter 4 μm same as the oscillator was used.

ENERGY DEPOSITION AND DPA IN THE SUPERCONDUCTING LINKS FOR THE HILUMI LHC PROJECT AT THE LHC INTERACTION POINTS*

A. Bignami, F. Broggi#, C. Santini[1] INFN/LASA, Segrate, Italy, [1]and Politecnico di Milano, Italy
A. Ballarino, F. Cerutti, L. S. Esposito, CERN, Geneva, Switzerland

Abstract

In the framework of the upgrade of the LHC machine, the powering of the LHC magnets foresees the removal of the power converters and distribution feedboxes from the tunnel and its location at the surface[1]. The Magnesium Diboride (MgB_2) connecting lines in the tunnel will be exposed to the debris from 7+7 TeV p-p interaction. The Superconducting (SC) Links will arrive from the surface to the tunnel near the separation dipole, at about 80 m from the Interaction Point at IP1 and IP5. The Connection Box (where the cables of the SC Links are connected to the NbTi bus bar) will be close to the beam pipe.

The debris and its effect on the MgB_2 SC links in the connection box (energy deposition and displacement per atom) are presented. The effect of thermal neutrons on the Boron consumption and the contribution of the lithium nucleus and the alpha particle on the DPA are evaluated. The results are normalized to an integrated luminosity of 3000 fb^{-1}, value that represents the LHC High Luminosity lifetime. The dose delivered to the SC Links is found to be below the damage limit. Further studies are necessary to correlate the induced displacement per atom to the superconducting properties.

INTRODUCTION

In the framework of the High Luminosity LHC project MgB_2 superconducting links delivering up to 150 kA to the magnets are being developed at CERN[1]. The links will be exposed to the radiation field of the cascades generated by the debris from the Interaction Point (IP).

The dose and DPA in the Superconducting Links (SCL) closer to the beam pipe are evaluated using a Monte Carlo code. The consumption of ^{10}B by the neutron capture reactions is considered.

THE HILUMI LHC PROJECT AND THE COLD POWERING TASK

The Large Hadron Collider (LHC) will remain the most powerful accelerator in the world for at least the next two decades. Its full exploitation is the highest priority of the European Strategy for particle physics.

To extend its discovery potential, LHC will undergo a major upgrade in the 2020s. The objective is to increase its peak luminosity (and thus collision rate) by a factor five beyond its design value and the integrated luminosity by a factor ten. The novel machine configuration, the High Luminosity LHC, will rely on a number of key innovative technologies representing exceptional technological challenges. These include among others: cutting-edge 11-12 tesla superconducting magnets; very compact with ultra-precise phase control superconducting cavities for beam rotation; new technology for beam collimation; and long high-current superconducting lines (hereafter called "links").

In the present LHC configuration, the electrical feeding of the about 1700 LHC superconducting (SC) circuits requires the transfer of more than 3 MA of current from the power converters to the magnets. Now this is done via conventional copper cables for the room temperature path between power converters and current leads, High Temperature Superconductors (HTS) or resistive currents leads for the transfer to the 4.5 K liquid helium bath.

Nb-Ti bus-bars operated in liquid helium at 4.5 K or in superfluid helium at 1.9 K provide the connection to the SC magnets. In the present LHC configuration, power converters and current leads are both located in underground areas, the first mainly in alcoves, adjacent to the machine tunnel, and the second in dedicated cryostats that are near the LHC interaction points and in line with the SC magnets.

All equipment in the tunnel is exposed to significant levels of radiation. In Fig. 1 the dose in the tunnel, normalized at 3000 fb^{-1} is shown. It is a horizontal projection and the Connection Module (CM) is behind the beam line. The CM red colour is just to evidence it and it is not related with the dose, whose level is about the same as in D1.

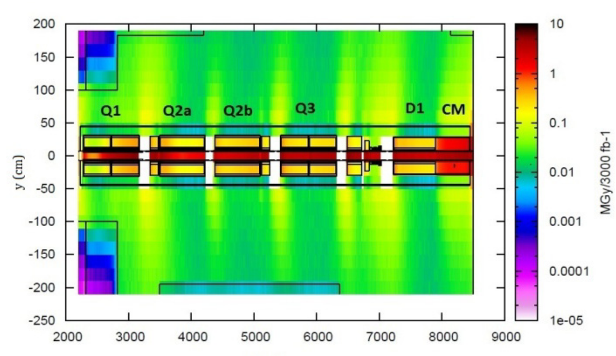

Figure 1: Dose in the insertion region of the tunnel (see text for detail) . The SCL and CM will be at about z=80 m from the IP.

For HL-LHC, the transmission of the current to the magnets is performed via SC links containing tens of cables feeding different circuits and transferring all

STUDIES ON INNOVATIVE PRODUCTION METHODS OF HOM COUPLER FOR SRF 9-CELL CAVITY

K. Nohara*, N. Kawabata, K. Miyajima, M. Shinohara,
Shinohara Press Service Co. Ltd. (SPS), Funabashi, Chiba, Japan
H. Hayano, S. Kato, T. Saeki, A. Yamamoto, M. Yamanaka
High Energy Accelerator Research Organization (KEK), Tsukuba, Ibaraki, Japan

Abstract

Pure Nb for SRF cavity bears hard workability. In addition, HOM coupler composed of cup (outer conductor) and antenna (inner conductor), a primary device of end group components, is complicated in the shape, implying much harder formability. That is why current production methods so far show serious issues in cost-effectiveness and mass-productivity. The authors have created advanced press forming methods of HOM cup and HOM antenna aiming to solve the above issues, almost resulting in satisfied quality, cost and productivity. The innovative procedures are described, remaining a bit problems to be sorted out, and further R&D works are still ongoing.

INTRODUCTION AND TARGET

HOM coupler attached at both ends of cavity is one of indispensable devices to eliminate high order mode radio wave generated during the operation of machines to prevent lowering of accelerating voltage.

HOM coupler in Fig. 1 shows a cylindrical cup of an extremely tall body to diameter with protrusion on the flat bottom and off-center perforation followed by burring plus oblong hole on the side wall, and also an antenna demonstrating kind of unique view with a thick body, sharp corner and a large void. They are subject to EBW for assembling of HOM coupler.

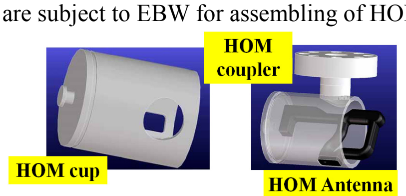

Figure 1: Schematic view of HOM coupler with cup and antenna.

From the shape and size of components, effective production methods sound quite difficult in parallel with making use of hard workable pure Nb. Now, several production methods have been implemented. However, there might be serious issues of cost-effectiveness and mass-productivity in particular.

Our final target is to invent advanced sheet plastic press-forming methods for HOM coupler i.e. HOM cup and HOM antenna aiming at realizing its satisfied function, prominent mass-productivity and drastic cost-effectiveness [1][2].

HARD WORKABLE PURE NB MATERIAL

There are close relation between material and forming, even more in tough workable pure Nb. Then, pure Nb annealed sheet (t2.8) was subject to uni-axial tension test together with commercial pure Fe sheet (t1.0) to examine both materials related to "sheet press forming" that should be most desirable due to applying plastic deformation which could make the shortest production time and extensive cost reduction available.

The diagram showing relations between applied force and displacement reveals large total elongation (λ_t) in Nb. However, the notable point is that λ_t is expressed as follows,

$$\lambda_t = \lambda_u + \lambda_\ell \qquad (1)$$

where indicated are uniform and local elongation each. It should be noted that λ_u and λ_ℓ correspond to plastic stable region (basically free from necking) and plastic unstable region (necking generation due to stress concentration), respectively. And the test results show the following relations,

$$\lambda_t(\mathrm{Nb}) > \lambda_t(\mathrm{Fe})\ ;\ \lambda_u(\mathrm{Nb}) < \lambda_u(\mathrm{Fe})\ ;\ \lambda_\ell(\mathrm{Nb}) > \lambda_\ell(\mathrm{Fe}) \qquad (2)$$

As the "ductility" is roughly equivalent to λ_u in case of press forming to avoid fracture in unstable plastic deformation, the experimental result (equation (2)) is important, namely Nb is hard workable compared with Fe. Adding, the last term of equation (2) gives rather an advantage to Nb when burring is applied. The following Ludwick's relation was proved [3],

$$\sigma = \varepsilon^n \qquad (3)$$

where σ and ε are true stress and true strain, and n is called work hardening coefficient showing hardenability of metals and alloys.

For the purpose of the conversion from the current methods to the whole plastic press forming, mechanical properties from pure Nb tensile test, and additionally observed data of Lankford's plastic strain ratio, r, at RT (Fig. 2 ; closely related to press drawability) together with popular pure Fe are useful. Further, we propose a new parametric index, ζ, which is defined and shown below using r, $\bar{r}$ (averaged r value in different directions) and Δr (indicating anisotropy of the material) [4],

$$r \equiv | r_w / r_t |, \qquad (4)$$

$$\bar{r} = \{ (r_o + r_{90}) + 2\, r_{45} \} / 4,\ \ \Delta r = \{ (r_o + r_{90}) / 2 \} - r_{45} \qquad (5)$$

$$\zeta \equiv \Delta r / \bar{r} \qquad (6)$$

where pure Nb is featured by much smaller n and ζ than pure Fe in addition to small ε_u and s_u (ultimate tensile strength). The facts are unfavorable and tough to accomplish the target [5][6].

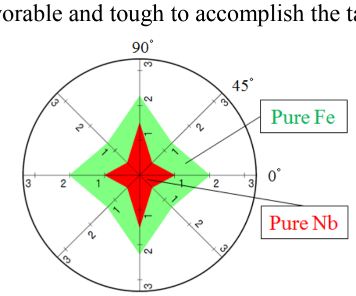

Figure 2: Plastic strain ratio, r , in different directions.

NEW PRESS DRAWING OF HOM CUP

One of points for the realization of a single process ultra-deep drawing is to strengthen the weak position of cylindrical body

MHI'S PRODUCTION ACTIVITIES OF ACCELERATOR COMPONENTS

N. Shigeoka#, S. Miura, Mitsubishi Heavy Industries, Ltd., Mihara, Hiroshima, Japan

Abstract

Mitsubishi Heavy Industries (MHI) is manufacturing various types of accelerator components. As examples of recent production activities result of a mass-production of S-band accelerating structure for PAL-XFEL and a status of series production of C-band waveguide network for SwissFEL will be reported in this paper.

INTRODUCTION

Mitsubishi Heavy Industries (MHI) has started manufacturing of accelerator components such as accelerating structures in 1960s. For example, in a field of normal conducting accelerator, in recent years, MHI had handled mass production of C-band choke-mode accelerating structures and SLED for Riken SACLA, production of DTL, SDTL (Separated DTL), ACS (Annular Coupled Structure) for JAEA/KEK J-PARC [1]. In latest years, MHI manufactured over 120 S-band accelerating structures for PAL-XFEL project [2-4] and shipment has completed in March 2015. In addition, MHI has accepted order of C-band waveguide for SwissFEL project [5] in June 2014. One set of prototype waveguide has been already delivered to PSI in December 2014 and series production is in progress now.

S-BAND ACCELERATING STRUCTURES FOR PAL-XFEL

Mass-production of the S-band 3 m long accelerating structure [6-7] started in June 2012 and finished at March 2015. Totally 120 structures has been delivered to PAL. Appearance of the structure is shown in Figure 1 and main parameters are shown in Table 1.

Result of LLRF measurement after tuning shown in Figure 2. It shows excellent performance of production.

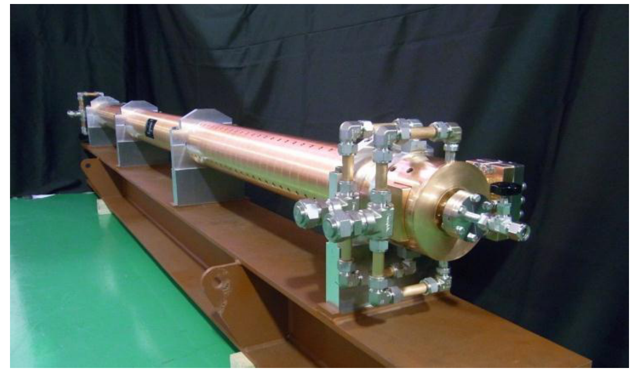

Figure 1: Appearance of the S-band accelerating structure for PAL-XFEL.

DEVELOPMENT FOR MASS PRODUCTION OF SUPERCONDUCTING CAVITY BY MHI

T.Yanagisawa#, H.Hara, K.Kanaoka, K.Okihira, K.Sennyu, Mitsubishi Heavy Industries, Ltd., Mihara, Hiroshima, Japan

Abstract

MHI's activities for superconducting accelerator are reported. MHI has supplied several 9-cell cavities for STF (R&D of ILC project at KEK) and have been considering production method for stable quality, cost reduction and mass production. Furthermore MHI had produced another shape cavities and cryomodules for several R&D projects. These activities are reported in detail.

INTRODUCTION

Mitsubishi Heavy Industries (MHI) has supplied a 1.3GHz superconducting cavity for the STF project (STF is a project at KEK to build and operate a test linac with high-gradient superconducting cavities, as a prototype of the main linac systems for ILC.) for several years [1] [2]. The cavities from MHI-12 to MHI-30 reached Eacc= 33.9MV/m on average. This average Eacc approaches the ILC target, 35MV/m. (see Table 1 and Figure 1) And we have developed new techniques for improvement of productivity and for cost reduction for ILC.

On the other hand, MHI has supplied other shape cavities and the cryomodules for KEK's superconducting projects including STF [3]. (see Figure 2) The details of cavity manufacturing techniques and cryomodule for STF are described below.

Table 1: Cavity Production List

Project	Customer	Production year	Cell-number	Quantity	Remarks
STF	KEK	2005-2015	9	30	MHI-1 to MHI-30
ERL		2009-2010	2	3	For injector of KEK c-ERL project
		2010-2011	9	2	For main ring of KEK c-ERL project
		2013-2014	1.5	1	For Superconducting RF electron gun of ERL R&D
ILC R&D	MHI	2009	9	1	[MHI-A] Deep drawing for HOM cup LBW for stiffener and flange
		2010	2	1	[MHI-B] Seamless dumbbell, Auto buffing
		2012	9	1	[MHI-C] LBW for baseplate Welding all equator line in succession
		2014	9	1	[MHI-D] Nb Gr-2 flange Welding all equator line in succession(4 cavities/1 batch)

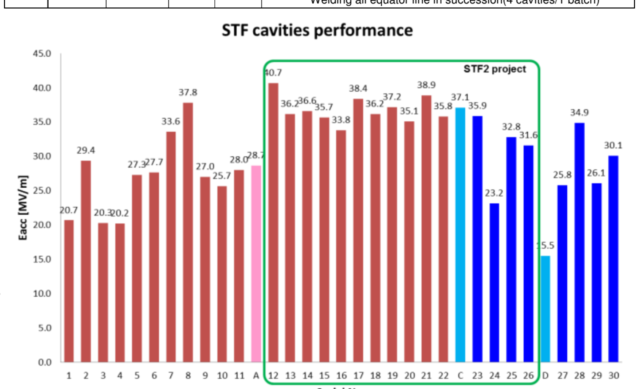

Figure 1: Performance of STF cavities.

(b) Main ring cryomodule of c-ERL at KEK

Figure 2: Cryomodules for c-ERL at KEK.

MANUFACTURING TECHNIQUES OF CAVITY

Nb Gr-2 Flange

The flanges of Cavity are generally made by Nb-Ti alloy because of the welding quality with niobium and the hardness for vacuum seal. MHI has developed to use the Niobium for cavity flanges. (see Figure 3) This way causes the reduction of number of parts and number of welding.

MHI tested three kind of niobium made by Heraeus.

- ASTM Gr-2 Nb with surface hardening treatment
- ASTM Gr-2 Nb (No treatment)
- RRR300 Nb with surface hardening treatment

After the annealing same as cavity and the thermal cycle test using liquid Nitrogen, three material flanges passed the helium leakage test. From point of view of commercial availability, ASTEM Gr-2 Nb (No treatment) was adopted.

MHI has fabricated R&D cavity (MHI-D) using niobium flanges. During vertical test at 2K, there is no leak from niobium flanges. The Eacc (π-mode) of MHI-D was 15.5 MV/m, however the Max Eacc of each cell reached 36.6 MV/m by another mode measurement. MHI confirmed that the niobium flange can be applicable to the superconducting cavities.

Abstract

We are pushing forward the development of a pulsed magnet that has a combined structure of magnet coils with a ceramic vacuum chamber, aiming to realize a small gap. The structure we are developing is that single turn air-coils are implanted along the longitudinal axis in the cylindrical ceramic chamber wall with thickness of 5 mm. The ceramic wall works for separating the vacuum from the atmosphere, as well as holding the coil structures mechanically and the electrical insulation of coils. We achieved the continuous operation over 200 days, without any failure, of current-excitation with 20 kV/7.7 kA pulse with 4 μsec width and repetition of 1Hz, using the dipole type prototype with the bore radius of 30 mm and the magnetic length of 0.3 m in 2013, while maintaining the vacuum pressure less than 10^{-6} Pa.

MERITS OF NARROW GAP MAGNET

The performances which are required in common to all pulsed magnet system are fast, strong, and high repeating pulsed magnetic field characteristics. In order to achieve these performances, there are two approaches. First one is developing a high power and high repetition pulsed power supply. Second one is reducing the power supply load as low as possible. The load reduction is an important issue. Because, if we try to achieve these performances without decreasing the load, the power supply system will have a large body size, consequently, need a huge installation space and give a restriction to the installation place of the system.

One of the best solutions to lower the power supply load is reduce the magnet pole gap. The kick angle is determined by the magnetic filed strength and field length. By the increased magnetic field with reducing the pole gap, the field length becomes shorter while keeping the kick angle the same. As a result, the coil inductance, hence the pulsed power supply load, become small. The low coil inductance is effective to achieve short pulse width and high repetition rate, in addition, to make the power supply small. The compact magnet and small power supply give the flexibility for setting position in an accelerator, making the kick efficiency optimum with the appropriate beta function value position.

Compact pulsed magnet with a narrow gap will fit to the future light source ring like generating diffraction limit synchrotron radiation [1]. Because the storage ring chamber size will be reduced in order to match the ultra low beam emittance and there is no enough space to install the pulsed magnet due to a large number of optical magnets. Additionally, it also will fit to small size storage rings that will require narrow installation spaces for these kinds of devices involving the injection kickers and correction kickers, and that have short revolution period requiring shorter pulse width.

CERAMIC CHAMBER INTEGRATION DESIGN AND THE ADVANTAGE

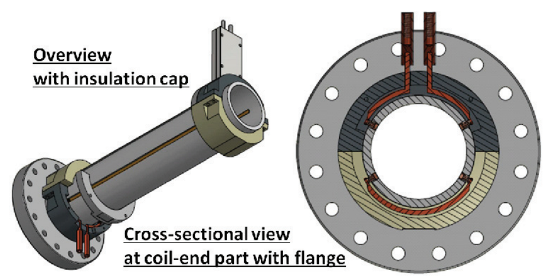

Figure 1: Design of dipole type CCIPM for the fabrication.

In an ordinary pulsed magnet, a ceramic chamber is used as a beam duct to reduce the eddy current effect for a pulsed magnetic field. Usually, the iron- or ferrite-core is set up outside of the ceramic chamber so that its magnetic poles sandwich the ceramic chamber. In this case, the distance(=magnet gap) between a magnetic pole and the beam is decided by the ceramic chamber bore radius, chamber thickness and clearance between the chamber and the pole. It is impossible to close the gap to the beam less than this restriction. On the other hand, in an air-coil type pulsed magnet, the coil is set up on the surface of the ceramic chamber so that its poles hold a ceramic chamber, or inside of the ceramic chamber like a strip-line kicker with complex supports. In the former case, the magnet gap is restricted by the ceramic chamber size. In the latter case, the complex support and coils cause an impedance unmatching of the beam wall current and increasing the chamber diameter to include the complex structures inside the chamber. To improve these insufficient aspects simultaneously, a ceramic chamber integrated type pulsed magnet was figured out.

The structure we are developing is that single turn air-coils are implanted along the longitudinal axis in the cylindrical ceramic chamber wall with thickness of 5 mm. For a dipole type magnet, four metallic bars (=coil) are totally implanted and one of bars is connected with another bars so that one pair of bars makes a coil. Implanting hole completely penetrates the chamber wall and is blocked up with the metallic bars. Figure 1 shows cross-sectional view of

PERMANENT DIPOLE MAGNET R&D FOR SPring-8-II

T. Taniuchi#, T. Aoki, K. Fukami, S. Takano, T. Watanabe, JASRI/SPring-8, Hyogo, Japan

Abstract

Permanent magnets are promising components for future light sources in point of small electric power consumption, compactness and so on. We have proposed a variable-field permanent dipole magnet and demonstrated its performance. Following the result, a prototype magnet with a longitudinal field gradient and a magnetic shunt circuit was designed. The longitudinal field gradient dipole enables a lower beam emittance and a magnetic shunt circuit improves a temperature stability of the magnetic field strength. In this paper, simulation results for this magnet are presented. The interference with magnetic fields of neighboring magnets was also investigated.

INTRODUCTION

SPring-8-II is an upgrade project of SPring-8 and a very-low emittance storage ring with a high-packing-factor lattice has been studied [1]. As a dipole magnet system of the SPring-8-II, we plan to adopt permanent dipole magnets. Permanent magnets have advantages over electromagnets in terms of electric power consumption, stability and reliability because no power supply and no cooling system are necessary.

The proposed five-bend lattice of SPring-8-II is composed of a normal bending magnet (NB) at the center of the cell and four other bending magnets with longitudinal field gradient (LGB) as shown in Fig. 1.

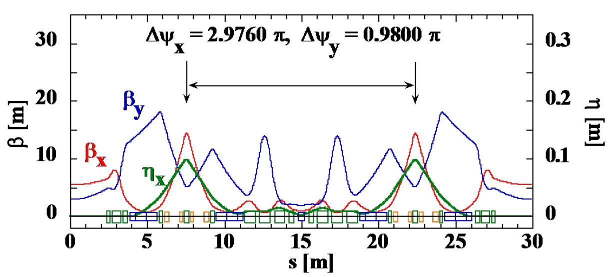

Figure 1: A unit cell of the 5-bend achromat optics for SPring-8-II.

LGB is divided into three segments and the strength of each segment is optimized to achieve a half of the emittance value with a conventional homogeneous dipole field. The major specifications of bending magnets are listed in Table 1.

We started R&D for permanent magnet dipole in 2013 and fabricated a sector magnet to verify fundamental performances [2]. Following this study, we have started a more specific design of LGB including an optimization of outer plates, magnetic shunts, field distributions, mechanical structures and so on.

#ihcuinat@spring8.or.jp

Table 1: Major specifications of permanent bending magnets.

Magnetic field [T] NB / 2 types of LGB	0.953 / 0.166, 0.296, 0.582 0.221, 0.395, 0.775
Effective length [m] NB / LGB	0.42 / 0.7, 0.7, 0.35
Gap [mm]	25
GFR [mm]	±12
Field error	5 x 10^{-4}

LONGITUDINAL GRADIENT BEND WITH OUTER PLATE

It is required to adjust magnetic field strength within a tolerable range after the fabrication, and possibly to change it in a relatively large range when the operating energy of an accelerator needs to be changed. In order to satisfy these requirements, we proposed a variable-field magnet with outer plates where the flux is intentionally leaked so that the magnetic field that beam experiences can be adjusted by moving the outer plates [2].

A configuration of LGB is shown in Fig. 2. Three outer plates are located above and below the main circuit where magnetic fluxes are leaked. A magnetic field strength of three magnets can be adjusted independently by changing the distance between the outer plate and the main circuit.

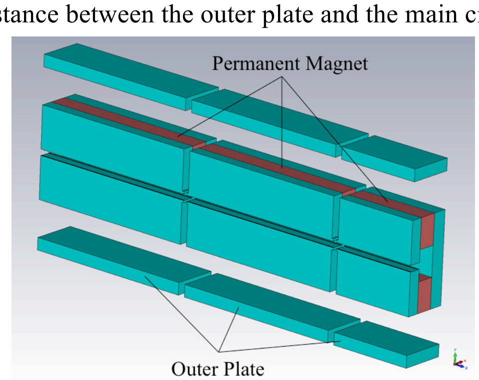

Figure 2: Longitudinal gradient bend with outer plates.

Fig. 3 shows a simulated longitudinal distribution of the magnetic field strength in an LGB for outer plate positions of 0 and 100 mm, respectively. We used CST STUDIO [3] for the magnetic field simulation. The magnetic field can be decreased below 30 percent of maximum strength at the closest position of the outer plate. A size, and a horizontal position of the outer plate will be optimized considering a tunable range and position sensitivity for the magnetic field. Alternative configurations have also been discussed such that

SUPERCONDUCTING SOLENOID PACKAGE PROTOTYPING FOR FRIB SRF LINAC*

K. Hosoyama#, K. Akai, S. Yamaguchi, KEK, Tsukuba, Japan
E. Burkhardt, K. Saito, Y. Yamazaki, FRIB, East Lansing, MI 48824, USA

Abstract

The solenoid package is consisted of a beam focusing superconducting 8 T 25 cm long solenoid coil wound by two graded NbTi SC wires and two racetrack shape X, Y-steering diploe beam corrector coils. All these coils were wound by "dry" winding. The solenoid coil was cold tested in the vertical cryostat and could reach to the design value of 8.9 T (99.5 A) without training. The full solenoid package was cold tested, including simultaneous excitation tests of all three coils, in the vertical cryostat successfully.

INTRODUCTION

KEK has more than 20 years long experience of design, fabrication, and cold test of small size 7T superconducting NbTi solenoid coils. We can utilize the existing coil winding machine and also the cryogenic facility for its cold test in KEK. A superconducting solenoid package prototyping for FRIB SRF Linac was designed, fabricated and cold tested at KEK under KEK/MSU collaboration program. The "dry" winding was used for the solenoid coil and racetrack shape steering coil winding, instead of using "wet" winding which is usually used for this size of solenoid coils. The "dry" winding has been developed and to date used for the fabrication of the small size solenoid coil in KEK.

REQUIREMENT

The required magnetic field of the solenoid package for FRIB are is 8 T with nominal operation current smaller than 100A. The operation temperature is 4.5 K and its temperature margin is +0.5 K. Inner diameter of the cold bore is larger than 4.0 cm and the solenoid coil length is 25 cm. The integrated magnetic dipole field strength for the steering coil is 0.03 Tm or larger at an operating current of 50 A. The field uniformity must be within 5% for both X and Y steering dipoles.

Table 1: Main Parameters of Coil and SC Wire

		Inner coil	Outer coil
Length	[mm]	250	250
Inner diameter	[mm]	54.25	86.25
Outer diameter	[mm]	86.5	131
Turns per layer		311	355
Layers		22	34
Dia. of bare SC wire	[mm]	0.80	0.65
Dia. of insulated SC wire	[mm]	0.75	0.70
Copper / SC		1.3	2.4
Filament diameter	[μm]	18	35
SC wire vender		Furukawa	Hitachi

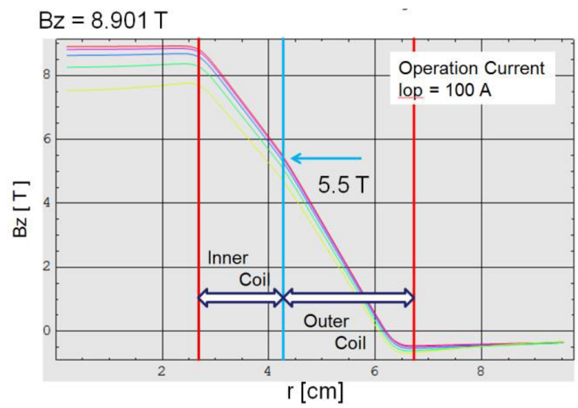

Figure 1: Magnetic Bz profile for the solenoid coil.

DESIGN OF 8T 25CM SOLENOID COIL

The main parameters of the solenoid and SC wires for inner and outer coils are summarized in Table 1. Figure 1 shows calculated Bz field profiles along radial direction for at z = 0 cm, 3 cm, 5 cm, 7 cm, 9 cm from the centre. The field uniformity inside the coil bore is very good due to the coil length is large compare to the coil inner diameter, and the field enhancement factor Bmax / B_0 is 1.0032. The self-inductance of this coil is 8.0 H.

Figure 2 shows the load line of the designed solenoid coil and critical curves (Ic) at 4.2 K and 4.5 K of the SC wire for the inner coil. The solenoid magnetic field Bz at the centre of coil reaches almost 9T at 4.2 K and 8.6 T at nominal operation temperature 4.5K over the required specification value 8T for FRIB. The solenoid has a temperature margin of 0.4 – 0.5 K

LOW LEVEL RF SYSTEMS FOR J-PARC LINAC 50-mA OPERATION

Z. Fang, K. Futatsukawa, Y. Fukui, T. Kobayashi, S. Michizono, KEK, Japan
S. Shinozaki, E. Chishiro, F. Sato, JAEA, Japan

Abstract

In the summer of 2014, lots of improvements were carried out at the J-PARC proton linac, including the ion source, the Radio Frequency Quadrupole linac (RFQ), and the medium-energy beam-transport line from the RFQ to the Drift Tube Linac (DTL) called as MEBT1. Firstly, the output beam current of the ion source was upgraded from 30 to 50 mA. Then the former 30-mA RFQ with two RF power input ports was also replaced by a newly developed 50-mA RFQ with one input port. Furthermore for the MEBT1, a new chopper cavity was developed to replace the former one, and the RF power of the solid state amplifiers for the RF cavities at the MEBT1 were upgraded; from 10 to 30 kW for both of the Buncher-1 and Buncher-2 cavities, and from 30 to 120 kW for the chopper cavity. Finally, the old scraper used as chopped-beam dump after the chopper cavity was also replaced by a new dump system using two scrapers; A new function of separating the chopped beam automatically to the two scrapers was developed by modifying the FPAG control program in the low level control systems. After those improvements, in the September 2014 the J-PARC linac was successfully upgraded for 50-mA beam operation. The details of the improvements, especially for the low level RF systems, will be reported in this paper.

INTRODUCTION

The 400-MeV proton linear accelerator at the Japan Proton Accelerator Research Complex (J-PARC) consists of 324-MHz low-β and 972-MHz high-β accelerator sections, and the J-PARC linac is operated at a repetition rate of 25 Hz with a beam pulse width of 500 μs. From October 2006 to May 2013, only the 324-MHz low-β accelerator section was in operation with beam energy of 181 MeV. In the summer of 2013, the J-PARC linac was upgraded by installing the 972-MHz high-β accelerator section, and the proton beam was successfully accelerated to 400 MeV in January 2014. Then in the summer of 2014, the upgrade of the front end of the J-PARC linac, including the ion source, RFQ, and MEBT1, were successfully carried out for the 50-mA beam operation. An outline of the RF systems and RF cavities of the upgraded J-PARC 400-MeV linac is given in Fig. 1. In the 324-MHz low-β section, there are 23 RF stations, including one RFQ, two bunchers, one chopper, three DTLs (Drift Tube Linacs), and 16 SDTLs (Separated DTLs). In the 972-MHz high-β section, there are 25 RF stations. At each station, there is one ACS (Annular Coupled Structure) cavity. Among the 25 ACS cavities, there are 2 bunchers, 21 acceleration cavities, and 2 debunchers. Therefore, for the 400-MeV J-PARC linac, there are 48 RF stations and 64 cavities in total. The length of the J-PARC linac is approximately 300 m.

UPGRADED RFQ RF SYSTEM

In the summer of 2014, the RFQ was upgraded for the 50-mA beam operation. In the former 30-mA RFQ, called as RFQ-I, there were two RF power input ports. The RF power from the klystron was divided by a high-power hybrid divider, and forwarded to the two input ports of the RFQ-I through two waveguide systems. The RFQ-I was replaced by a newly developed 50-mA RFQ, called as RFQ-III. For the RFQ-III, there is only one input port. Thus, the hybrid divider in the waveguide systems will not be used, and it was removed in the summer of 2014 for the upgraded RFQ RF system, as shown in Fig. 2. The RF power from the klystron will be directly forwarded to the RFQ cavity.

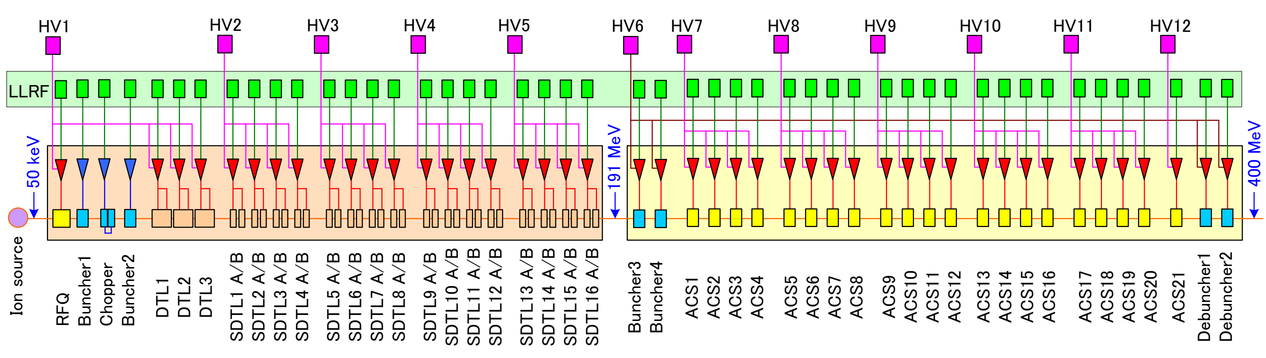

Figure 1: Outline of RF systems and RF cavities of the upgraded J-PARC 400-MeV linac.

MULTIPACTOR SIMULATIONS IN 325 MHz SUPERCONDUCTING SPOKE CAVITY FOR AN ELECTRON ACCELERATOR*

T. Kubo†, T. Saeki, KEK, High Energy Accelerator Research Organization, Tsukuba, Ibaraki, Japan
E. Cenni, Y. Iwashita, H. Tongu, Kyoto University, Uji, Kyoto, Japan
R. Hajima, M. Sawamura, Japan Atomic Energy Agency, JAEA, Tokai, Ibaraki, Japan

Abstract

To realize a compact industrial-use X-ray source with the laser-Compton scattering, a 325MHz superconducting spoke cavity for an electron accelerator operated at 4K is under development. Design-optimizations of the first prototype cavity were finished. Multipactor simulations were carried out as parts of optimization efforts. In this paper, procedures of multipactor simulations by using CST studio suite are briefly introduced. Then results of simulations and analyses to extract an optimum geometry are presented. A relation between a cavity geometry and an intensity of multipactor is also commented.

INTRODUCTION

In order to realize an industrial-use laser-Compton scattering compact X-ray source [1, 2], a superconducting cavity for electron acceleration is currently under development [3, 4]. We adopted a 325 MHz superconducting spoke cavity. The spoke cavity [5] has a small diameter around half the wavelength, namely, half a diameter of the elliptic cavity, and make it possible to reduce RF frequency, f_{RF}, with keeping its compactness. By setting $f_{\mathrm{RF}} = 325\,\mathrm{MHz}$, Bardeen-Cooper-Schrieffer (BCS) resistance ($\propto f_{\mathrm{RF}}^2$) is significantly reduced, and a cavity dissipation at 4 K nearly equals to that of 1.3 GHz elliptic cavity at 2 K.

The genetic algorithm (GA) known as a method of multi-objective optimization was used to design a spoke cavity by Sawamura et al [3, 4]. Cavities with minimized $E_{\mathrm{pk}}/E_{\mathrm{acc}}$ and $B_{\mathrm{pk}}/E_{\mathrm{acc}}$ were generated, from which geometries that maximize the achievable E_{acc} were extracted, where E_{acc}, E_{pk} and B_{pk} are the accelerating field, the peak electric-field and the peak magnetic-field, respectively. There are still degrees of freedom in the detailed design: corner radii of the end-plate and the spoke-base, and so on. Fig. 1 shows examples of geometries optimized by GA, which have similar RF characteristics, but each has different corner radius of the end-plate.

In order to finalize the detailed design, we carried out MP simulations of cavities optimized by GA and extract a model that may suppress a risk of MP as small as possible [6, 7]. In this paper, procedures and results of MP simulations are briefly summarized. Relations between cavity geometries and averaged secondary electron emission yield are also commented.

* The work is supported by Photon and Quantum Basic Research Coordinated Development Program from the Ministry of Education, Culture, Sports, Science and Technology, Japan.
† kubotaka@post.kek.jp

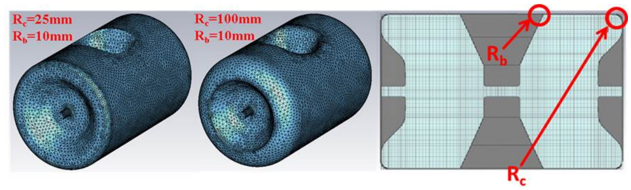

Figure 1: Examples of optimized cavity geometries. Both have optimized geometry and similar RF characteristics, but a detailed design (i.e., a corner radius of the end-plate in this example) is different from each other.

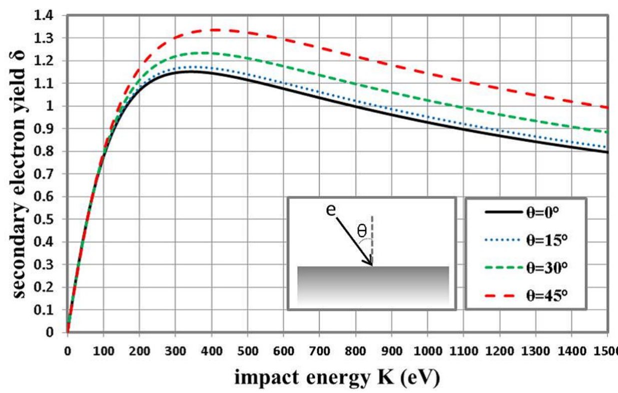

Figure 2: Furman model SEY as functions of impact energy. Each curve corresponds to an impact angle.

SIMULATION PROCEDURE

MP simulations were carried out by using CST studio suite. The procedure is as follows [7, 8, 9].

1. Calculate the electromagnetic-field distribution by using CST MW studio (MWS) Eigenmode solver.
2. Set secondary emission yield (SEY) of a cavity material on CST Particle Studio (PS) (see Fig. 2).
3. Put primary electron sources on a cavity surface. Set a number of primary electrons and their energies $O(10^3)$ and several eV, respectively.
4. Import the electromagnetic-field distribution obtained by MWS, and simulate electron-dynamics by using PS TRK solver (see Fig. 3).

The above procedure is repeated with sweeping E_{acc} and changing models.

In the step 2, we adopted the Furman model [10], in which an SEY is given as a function of the impact energy

A DISTURBANCE-OBSERVER-BASED CONTROLLER FOR LLRF SYSTEMS

F. Qiu[#], D. Arakawa, Y. Honda, H. Katagiri, T. Matsumoto, S. Michizono, T. Miura, T. Obina, KEK, Tsukuba, Ibaraki 305-0801, Japan
S. B.Wibowo, Sokendai, the Graduate University for Advanced Studies, Tsukuba, Japan

Abstract

Digital low-level radio frequency (LLRFs) systems have been developed and evaluated in the compact energy recovery linac (cERL) at KEK. The required RF stabilities are 0.1% rms in amplitude and 0.1° rms in phase. These requirements are satisfied by applying digital LLRF systems. To further enhance the control system and make it robust to disturbances such as large power supply (PS) ripples and high-intensity beams, we have designed and developed a disturbance observer (DOB)-based control method. This method utilizes the RF system model, which can be acquired using modern system identification methods. Experiments show that the proposed DOB-based controller is more effective in the presence of high disturbances compared with the conventional proportional and integral (PI) controller. In this paper, we present the preliminary results based on the experiments with DOB-based controller.

INTRODUCTION

At KEK, a 3 GeV energy recover linac (ERL) light source is proposed. For the demonstration, a compact ERL (cERL) was constructed as a prototype machine for the 3-GeV ERL project [1,2]. The cERL, which is a 1.3 GHz superconducting (SC) project, consists of an injector part and a recirculating loop part. Three two-cell cavities, called Inj. 1, Inj. 2, and Inj. 3, were installed in the injector, and two main nine-cell cavities were installed in the recirculating loop. To fulfill the required beam quality, the RF field fluctuations should be maintained at less than 0.1% (in amplitude) and 0.1° (in phase) in the cERL. Field programmable gate array (FPGA)-based digital low-level ratio frequency (LLRF) systems were developed to implement the RF field control [3].

In the LLRF systems of the cERL, disturbance signals such as 50-Hz microphonics and 300 Hz high-voltage power supply (HVPS) ripples will severely limit the performance of the LLRF systems [3]. Furthermore, during beam commissioning, the beam loading can be seen as another disturbance. In principle, these disturbance signals can be rejected or suppressed by applying high proportional and integral (PI) gains in the feedback (FB) control; however, the PI gains are limited by the loop delay. In the cERL, during the beam commissioning, we found that the PI gain is not sufficient in the presence of large disturbances. In view of this situation, we present a disturbance observer (DOB)-based approach that aims to control an LLRF system subject to large disturbances [4-5].

#qiufeng@post.kek.jp

In this paper, we first introduce the LLRF system in the cERL, and then describe the principle, design, and implementation of this DOB-based approach. Finally, preliminary results are used to compare the proposed DOB control and the previous PI control in the cERL beam commissioning.

LLRF SYSTEM

A simplified block diagram of the cERL LLRF system is shown in Fig. 1. The 1.3-GHz cavity probe signal is down-converted to a 10-MHz intermediate frequency (IF) signal. The IF signals are sampled at 80 MHz by 16-bit ADCs and then fed into the FPGA. The baseband and quadrature (I/Q) components are extracted from the IF signal with a non-IQ method. In the next stage, the I/Q signals are compared with their set values, and the errors are calculated. The errors are regulated with a PI controller and then added with a feedforward (FF) table. Finally, the combined signal is fed into the I/Q modulator via the 16-bit DACs to regenerate the 1.3-GHz RF signal. This regulated RF signal will be used to drive the high-power source, which drives the cavities [6,7].

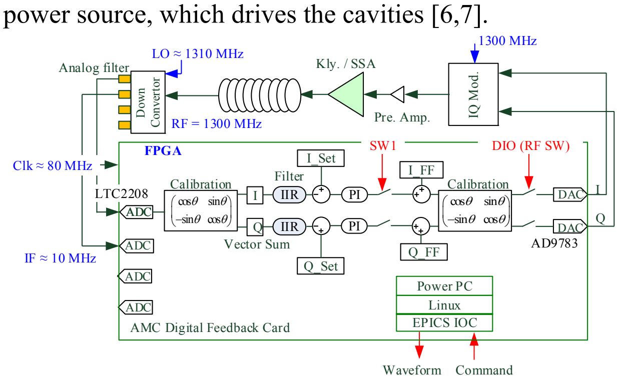

Figure 1: Schematic of the LLRF system in the cERL.

DOB CONTROL

The basic idea of DOB control is shown in Fig. 2(a) [4-5]. Here, $G_p(s)$ and $G_n(s)$ represent the transfer function of the actual plant (e.g., cavities and RF devices) and the nominal mathematical model. Signals d and d_e represent the real disturbance and the disturbance estimate, respectively. Signal *FF* represents the FF table output.

From Fig. 2(a), it is clear that the disturbance estimate d_e can be expressed by

$$d_e = (\varepsilon + d) G_p(s) G_n^{-1}(s) - \varepsilon . \qquad (1)$$

THE MAGNET AND POWER SUPPLY SYSTEM FOR THE COMPACT-ERL*

Kentaro Harada#, Tatsuya Kume, Shinya Nagahashi, Norio Nakamura,
Shogo Sakanaka, Akira Ueda, KEK, Ibaraki, Japan

Abstract

The recirculation loop of the cERL (compact Energy Recovery LINAC) was constructed in 2013. In this paper, we show the magnet and the power supply system for the recirculation loop of the cERL. The recirculation loop consists of the eight main bending magnets at the arc section, sixty quadrupole magnets and ten small bending magnets for the three chicanes of the injection, extraction and circumference adjuster. The four power supplies are used for the chicane bending magnets, sixty for the quadrupoles, forty-eight for the horizontal correctors, and thirty-three for the vertical correctors. The EPICS (Experimental Physics and Industrial Control System) was adopted to control these power supplies.

INTRODUCTION

The cERL (compact Energy Recovery LINAC[1-3]) consists of the injector, merger, recirculation loop, extraction chicane, and the beam dump. The photocathode electron gun generates the electron beam. The beam goes to the recirculation loop after the acceleration by the injector cavities through the merger chicane. The main linac cavities accelerates the beam to about 20 MeV. After the recirculation loop, the main linac decelerate the beam to about 3 MeV. Finally the beam dump catches the "used" beam after the extraction chicane. In this paper, we show the magnet and power supply system of the cERL.

MAGNETS

The layouts of the magnets of the cERL are show in Fig. 1. For the magnet names in the figure, "B.."s are the bending magnets, "Q.." quadrupole magnets. "ZH.."s are the horizontal correctors and "ZV.." the vertical correctors. The all correctors at the recirculation path are the correction coils of the bending and quadrupole magnets. The four sextupoles for the bunch compression and restoration will be installed at the arc section in this summer of 2015. The parameters are shown in Table 1.

Bending Magnets

The bending angle of the main bending magnet at the arc sections (BMIF and BMIR in Fig. 1) are 45 degree. The parameters are shown in Table 1. The eight sector type magnets are connected to one power supply. The path of the magnetic power cable was fixed in order to avoid the large solenoidal loop. The picture of the magnet is shown in Fig. 2(a).

The magnetic core consists of the lamination of the silicon steel. The edge of the magnetic core was cut in order to form the sector shape after the lamination. The magnetic cables of 200 mm^2 cross section was used for the full energy operation of 245 MeV (800 A). With 20 MeV operation, the magnetic current is about 50 A and the capacity of the present power supply is 100 A/40 V. All bending magnets have the correction coils of fifty turns for the horizontal corrector. The hollow conductor was used for the main coil in order to 800 A operation. However, no water cooling was required for present 20 MeV operation.

The two ready-made bipolar power supplies of ±10 A/±40 V were used for the five small bending magnets of the merger chicane (Fig. 3(a)); the one connected to BMAG3-5 and the other BMAG1-2. (For the beam operation, the unipolar type power supplies were sufficient.) For the recirculation beam, the turn numbers of the coils of BMAG3-5 are adjusted to achieve the local bump orbit. For the injection beam, the edge angle of BMAG2 is fixed to eliminate the dispersion function at the entrance of the recirculation loop. The correction coils of these magnets are used for the precise adjustment of the

Abstract

A 5-year research program on the development of superconducting spoke cavities for electron accelerators has been funded by MEXT, Japan since 2013. The purpose of our program is establishing design and fabrication processes of superconducting spoke cavity optimized for compact X-ray sources based on laser Compton scattering. The spoke cavity is expected to realize a compact industrial-use X-ray source with a reasonable cost and easy operation. We have chosen a cavity frequency at 325 MHz due to possible operation at 4 K and carried out cavity shape optimization in terms of electromagnetic and mechanical properties. Production of press-forming dies is also in progress. In this paper, we present overview and up-to-date status of the research program.

INTRODUCTION

Laser Compton scattered (LCS) X-ray sources are now widely explored as an important application of advanced accelerators, since they can produce high-brightness energy-tunable X-ray beams with a compact footprint [1,2]. Such LCS X-ray sources can be realized with any type of electron accelerator: RF linacs, racetrack microtrons, storage rings, and energy-recovery linacs.

A photon flux from LCS sources is proportional to the frequency and density of electron and laser beams at the collision. Spectral brightness is proportional to electron beam brightness. Thus, electron beams of high-average current and small emittance are preferable for high-flux and high-brightness LCS sources. In this sense, we consider the energy-recovery linac is suitable for LCS sources.

A 5-year research program has been established to develop fundamental technologies for a compact high-brightness LCS X-ray source. In the research program, we are developing superconducting spoke cavities for future LCS X-ray sources.

Spoke cavity was originally invented for acceleration of protons and ions (v/c<1), but it can also be applied to electron accelerators (v/c=1) with minor modification of cavity shape [3,4]. We suggest the spoke cavity realizes a compact industrial-use X-ray source with a reasonable cost and easy operation because of the following reasons: (1) with the same cavity radius, the resonant frequency of spoke cavities is almost half of elliptical cavities. As a result, 4-K operation becomes a practical solution by choosing a resonant frequency below 500 MHz. (2) Spoke cavities have small microphonic detuning thanks to their mechanical stiffness and unique electromagnetic property, the resonant frequency depending mainly on the spoke length. This small frequency fluctuation contributes to the reduction of RF source capacity for ERL operation. (3) the spoke cavities accommodate power couplers and HOM couplers at the side region, thus the multiple spoke cavities can be installed with a better packing factor than elliptical cavities that require couplers on the beam pipe. (4) cell coupling of spoke cavity is stronger than that of elliptical cavity. With the strong cell coupling, we can easily adjust the field flatness along a multi-cell (multi-spoke) structure.

In this paper, we describe the status of spoke cavity development program in Japan.

PROPOSED X-RAY SOURCE

The proposed X-ray source is based on an ERL and a laser enhancement cavity similar to the LCS source recently demonstrated at the Compact ERL (cERL) [5]. As seen in Table 1, the targeting goal of the project is to realize the collision of megawatt-class electron and laser beams for a high-flux and high-brightness X-rays. Average brightness expected in the LCS source is comparable to 10-keV X-rays from a bending magnet at KEK-PF (2.5 GeV, 400 mA). The X-ray flux and brightness are reduced by duty factor, if we operate the LCS source at a burst mode (1 ms x 10 Hz for example) for saving the machine construction and running cost.

Table 1: Parameters of the Proposed X-Ray Source

E-bean			
Energy / current	25 MeV / 30 mA	Norm. emittance	1 mm-mrad
Laser			
Wave-length	1 μm	Stored power	1 MW
LCS			
Repetition	325 MHz	Flux (100%BW)	1×10^{14} ph/s
Collision spot	20 μm (rms)	Average Brightness	3×10^{14} (c.u.)
X-ray	10 keV

Abstract

We have been developing magnets utilizing high-temperature superconducting (HTS) wires for this decade. We built three model magnets, a mirror coil for an ECR ion source, a set of coils for a scanning magnet and a super-ferric dipole magnet to generate magnetic field of 3 T. They were excited with AC/pulse currents as well as DC currents. Recently we fabricated a cylindrical magnet for a practical use which polarizes ultracold neutrons (UCN). The field strength at the center is higher than 3.5 T which is required to fully polarize 210 neV neutrons. The magnet was used to polarized UCN generated by the RCNP-KEK superthermal UCN source. One dipole magnet is under fabrication, which is used as a switching magnet after the RCNP ring cyclotron and is planned to be excited by pulse currents. It becomes possible to deliver beams to two experimental halls by time sharing.

INTRODUCTION

High-temperature superconductor (HTS) materials were discovered in 1986 [1] for the first time. Significant efforts have been continued for the development of new and improved conductor materials [2] and it became possible to manufacture relatively long HTS wires of the first generation [3]. Today, many researches are ongoing to establish a reliable production process of the second generation HTS wires and their applications. Although many prototype devices using HTS wires have been developed, so far these applications have been rather limited in accelerators and beam line facilities [4].

At the Research Center for Nuclear Physics (RCNP) of Osaka University, we have investigated the performance of HTS wires applied for magnets excited by alternating current (AC) as well as direct current (DC) for ten years. We have fabricated four types of magnets. They are a cylindrical magnet [5], a scanning magnet with race-track shape coils [6], a super-ferric dipole magnet [7] and a solenoid like magnet consisting of double pan cakes [8]. The coil of the dipole magnet has a negative curvature and the magnet successfully generated the field higher than 3 T at operating temperature of 20 K. First three magnets are toy models, but the last one is actually used to polarize ultracold neutron (UCN). Based on the successful application, we are now constructing a HTS switching magnet to make a time sharing of beams from the RCNP ring cyclotron. We selected a commercially available first-generation HTS wire supplied by Sumitom Electric Industries, Ltd [9].

Designs and preliminary results of performance tests of fabricated magnets are summarized in this paper.

SCANNING MAGNET

A two-dimensional scanning magnet was fabricated to model a compact beam scanning system. The size of the irradiation field is 200 mm by 200 mm for 230 MeV protons at the distance of 1.25 m from the magnet center. The required magnetic field length is 0.185Tm. The scanning magnet consists of two sets of two racetrack-type coils. Each coil is built by stacking three double pancakes. The design parameters are summarized in Table 1. Figure 1 shows a photograph of one coil.

Table 1: Design Parameters of the HTS Scanning Magnet

Coils	Iner size	B_x: 150mm x 300mm.
		B_y: 150mm x 380mm
	Separation	70mm
	Maximum Field	0.6T
	# of tturns	420 x 2 for each B_x and B_y
	Winding	3 Double pancakes/coil
	Inductance/coil	B_x: 75mH, B_y: 92mH
	Temperature	20K
	Rated current	200A
Cryostat	Cooling power	45W at 20K, 53W at 80K

NEW INJECTION BUMP POWER SUPPLY OF THE J-PARC RCS*

T. Takayanagi#, N. Hayashi, T. Ueno, K. Horino, K.Okabe, K. Kinsho, J-PARC, Japan
JAEA, Tokai-Mura, Naka-Gun, Ibaraki-Ken, Japan
Y. Irie, KEK, Ibaraki-Ken, Japan

Abstract

The new injection bump power supply for the shift bump (SB) magnet of the beam injection sub-systems at the J-PARC (Japan Proton Accelerator Research Complex) [1] 3-GeV RCS (Rapid Cycling Synchrotron) [2] has been developed and manufactured. The power capacity of the new power supply was more than doubled with the injection beam energy upgrading of the LIANC (Linear Accelerator) from 181 MeV to 400 MeV [3]. Furthermore, the low ripple noise on the output current was required to prevent the resonance of the RF shield loop at the ceramic duct with the excitation magnetic field [4]. The power supply newly adopted a capacitor commutation method to form the trapezoid waveform pattern (bump waveform). This paper reports characteristic about the new power supply.

INTRODUCTION

The new power supply for the injection SB-magnet, which is one of the beam injection sub-systems of the 3-GeV RCS in the J-PARC, has been developed and manufactured with the injection beam energy upgrading of the LINAC from 181 MeV to 400 MeV. The power supply capacity increases about twice the 181 MeV specifications. The previous SB power supply adapted the IGBT (Insulated Gated Bipolar Transistor) chopping system of the main circuit, which produces the continuous current ripple noise due to the switching [5]. However, the ripple noise on the output current had been resonated with the RF shield loop on the ceramics duct in the SB-magnet, resulting in a forced beam oscillation at the injection stage [4]. The circuit configuration of the new power supply has been changed to the capacitor commutation method using the charging and discharging circuits. This system forms the trapezoid waveform pattern (bump waveform) at 25 Hz repetition with only three times switching per pulse. Therefore, the current ripple noise caused by the switching was reduced considerably.

The SB power supply is comprised of the 16 banks in parallel. The 1 bank includes 12 rise-fall units (Rf-unit) and 2 flat-top units (Ft-unit), which produces an output current of 2 kA and an output voltage of 12 kV. So the maximum output current and output voltage are 32 kA and 12 kV, respectively. By controlling the capacitor voltage and the gate timing of the changeover switch in each unit individually, the power supply can produce an arbitrary waveform which has different rise-fall time and flat-top time duration with high accuracy. The RCS provides a high intensity beam for the MLF (Material and Life Science Experimental Facility) and MR (50-GeV Main Ring) in a time-sharing mode. The bump system changes the output current to meet the demand of different painting areas for the MLF and MR beams [6]. This paper summarizes the design and the experimental results of the new power supply.

*tomohiro.takayanagi@j-parc.jp

OVER VIEW OF THE POWER SUPPLY

Basic Circuit

The power supply is comprised of two kinds of unit. One is the Rf-unit that produces the peak voltage controlling the rise-fall time of the bump waveform. Another is the Ft-unit that maintains the flatness and duration at the flat-top. The basic circuit of the two units is the same, whose schematic view is shown in Fig. 1. The DC charger charges the main electrolytic capacitor C and the switching device of the IGBT defines each operation mode, which is the powering, regeneration and free-wheeling. The model of the bump waveform and the relationship between each unit and each operation mode are shown in Fig. 2 and Table 1. The peak current is determined by setting each DC charger parameter for the charging voltage of the capacitor and the duration of the rise-fall and flat-top is determined by the switching in a predetermined timing of each operation mode.

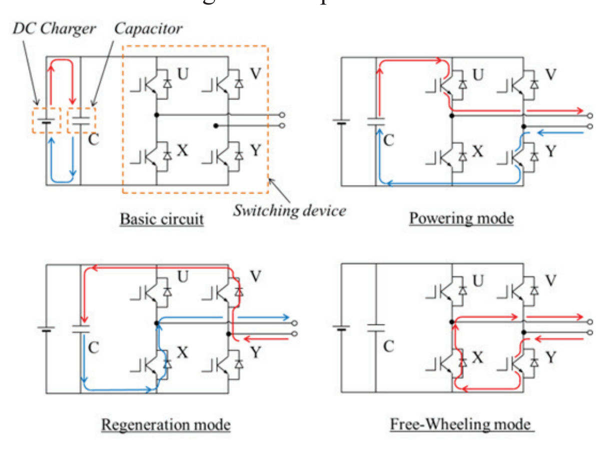

Figure 1: Base circuit of the unit.

Power Supply Construction

The schematic view of the 1 bank is shown in Fig. 3. The 1 bank is comprised of 12 Rf-units and 2 Ft-units, where all units are connected in series with the midpoint earth. The Rf-unit has two chopper stages connected in series. The capacitor unit is composed by 8 capacitors of 24 mF and the composite capacitance is 48 mF per one DC charger. The Ft-unit has two chopper stages with different charging voltages in order to change the output

DEGASSING OF KICKER MAGNET BY IN-SITU BAKE-OUT METHOD

J. Kamiya[#], N. Ogiwara, Y. Hikichi, M. Kinsho
JAEA/J-PARC, Shirakata Shirane 2-4, Tokai, Naka, Ibaraki, Japan
N. Miki, T. Yanagibashi
NAT, Muramatsu 3129-45, Tokai, Naka, Ibaraki, Japan

Abstract

New method of in-situ degassing of the kicker magnet in the beam line has been developed. The heater and heat shielding panels are installed in the vacuum chamber in this method. The heater was designed considering the maintainability. The graphite was selected as the heater and the high melting point metals were used as the reflectors just near the heater. The thermal analysis and the temperature measurement with the designed heater was performed. The ideal temperature distribution for the degassing of the kicker magnet was obtained. The outgassing of the graphite during rising the temperature was measured. The result showed that the outgassing was extremely suppressed by the first heating. This means the outgassing of the graphite heater was negligible as long as it is used in the beam line without exposure to the air.

INTRODUCTION

The usual way to reduce outgassing from a device in vacuum is to heat up a whole vacuum chamber containing the device. However, the situation, where this method can be applied, is limited due to the heat expansion of the chamber. Especially in accelerators, where the vacuum chambers are connected with nearby beam pipes, this normal bake-out method may not be applied. If a heat source and heat shields are appropriately installed inside the chamber, heat flux is directed to the device. Therefore the device can be baked out without raising the temperature of the vacuum chamber.

One candidate for such bake-out method to be applied is kicker magnets in J-PARC 3GeV synchrotron (RCS), which are installed in large vacuum chambers. The role of the kicker magnets is to extract an accelerated 3 GeV proton beam to a downstream beam transport line [1]. The voltage of 30 kV is applied from the power supply to the magnets in order to generate the magnetic field whose rise time is about 300 ns. The kicker magnets are installed in vacuum to prevent the discharge by such high voltage. The kicker magnet mainly consists of Ni-Zn ferrite cores, aluminium electrode plates. The total outgassing rate of the materials is large due to the large surface area. Therefore it is very important to develop a degassing method for the kicker magnets in the beam line because the vacuum quality may become poor after repeated exposures to air for the maintenances. The main outgassing component is water vapour [2]. Therefore the bake-out temperature should be above 100 °C, which is the typical desorption temperature of water vapour from the general surface. In the RCS beam line, 3 and 5 kicker magnets are located in vacuum chambers, whose length is 3 and 5 m, respectively. It is undesirable to use a normal baking method like baking the vacuum chamber of the kicker magnets because the large heat expansion of the vacuum chamber, which will be ~5 mm with a temperature rise of 100 ^{o}C for a chamber of 5 m length, will break nearby equipment such as alumina ceramics pipes. By applying the bake-out method, which is mentioned at the beginning of this chapter, only the kicker magnet is heated without raising the temperature of the vacuum chamber. So far, we performed the operability assessment of the new degassing method by the calculation with a simple model and the principal experiments using the R&D kicker magnet, which have the same structure as the production kicker magnets in RCS [3]. As a result, the ferrite cores were heated up above 100 °C while keeping the temperature rise of the vacuum chamber less than 20 °C. One of the technical issues was the design of the heater, which has a good maintainability. In this report, first, we will show the design and concept of the newly developed heater. Next, the temperature distribution of the kicker magnet and the vacuum chamber using the new heater is also presented. Finally, the vacuum characteristic of the heater material is reported.

DESIGN OF THE HEATER

Any heater is possible to be damaged eventually. Thus the exchange of the heater should be easily performed. The vacuum chambers for the kicker magnets in the RCS beam line has ports with flanges under each kicker magnets. The heater was designed to be inserted from the port. Therefore, the size of the heater should be less than the inner diameter of the port (ϕ 130 mm). In the previous calculation, it was known that about 1000 W is needed for the heater to rise the temperature of ferrite sufficiently above 100 °C [3]. When the 1000 W is supplied to the heater with about 100 mm diameter, the heater temperature would be more than 1000 °C. We selected graphite as the heater material, which meets such requirement. The physical properties of the selected graphite are summarized in Table 1. In addition to the suitable electrical resistivity, the high mechanical strength is the reason of choice. Figure 1 shows the appearance of the heater. The design was performed with checking the temperature distribution of the heater by the thermal analysis. In the analysis, about the heat transfer from the each material surface, the radiation was taken account for the vacuum side, while the natural convection was considered for the atmospheric side, The result of the thermal analysis when 1000 W was supplied to the

Abstract

Superconducting accelerating cavities used in high-energy accelerators can generate high electric fields of several 10 MV/m by supplying radio frequency waves (RF) with frequencies matched with resonant frequencies of the cavities. Generally, frequencies of input RFs are fixed, and resonant frequencies of cavities that are fluctuated by Lorentz force detuning and Microphonics are corrected by feedbacks of cavity frequency tuners and input RF power. Now, we aim to develop the cavity frequency tracking type RF control system where the frequency of input RF is not fixed and consistently modulated to match the varying resonant frequency of the cavity. In KEK (Tsukuba, Japan), we are developing SRF-TEM that is a new type of transmission electron microscope using special-shaped superconducting cavity. By applying our new RF control system to the SRF-TEM, it is expected to obtain stable accelerating fields so that we can acquire good spatial resolution. In this presentation, we will explain the required stabilities of accelerating fields for SRF-TEM and the feasibility of SRF-TEM in the case of applying the cavity frequency tracking type RF control system.

WHAT IS SRF-TEM?

In material science, biology and other science regions, electron microscopes (EMs) are often used to observe sub-nanometer world. There are two kinds of EMs; transmission EMs (TEMs) and Scanning EMs (SEMs). TEMs are more suitable when insides of specimens are targets of studies. Past TEMs use electrostatic acceleration to give kinetic energy to electron beams. Therefore there has been a limit of accelerating energy because of discharge problems. The highest voltage of TEM is 3 MV which has been achieved in Osaka Univ. in Japan [1]. Now we are developing a new type of TEM called SRF-TEM, which applies high energy accelerator technologies; SRF cavities and photo-cathode DC electron gun. It will overcome the limit of accelerating energy so that thicker specimens could be observed. It will help to study the materials, for example, high temperature superconducting matters and magnetic materials and so on. SRF-TEM has other advantages; downsizing facilities, micro-second temporal resolution, less damages to biological samples and the potential for world's best spatial resolution.

* higashi@icepp.s.u-tokyo.ac.jp

CHROMATIC ABERRATION AND SPATIAL RESOLUTION OF TEMS

We could acquire higher energy than 3 MeV for TEMs easily employing RF acceleration with a superconducting cavity. However there is a problem to consider in advance of practical development; degradation of spatial resolution due to increase of chromatic aberration. Spatial resolution of TEMs is determined by following three factors; diffraction aberration, spherical aberration and chromatic aberration. Chromatic aberration occurs due to an energy spread ΔE of an electron beam so that focal lengths of beams are different. A conventional TEMs has low energy dispersion of $O(10^{-6})$. However RF acceleration of our SRF-TEM makes it larger by its sinusoidal electric fields. Therefore the chromatic aberration mainly determines the spatial resolution of SRF-TEM. Figure 1 shows the relation between the energy dispersion and the spatial resolution of our prototype SRF-TEM which accelerating energy is 300 kV. Note that the declination of the spatial resolution is saturated below 1.0×10^{-5} in the energy dispersion. This is because the chromatic aberration r_c is determined by

$$r_c = \alpha C_c \sqrt{\left(\frac{\Delta E}{E}\right)^2 + 4\left(\frac{\Delta J}{J}\right)^2} \tag{1}$$

,where α is the maximum angle of incident beam into the objective lens, C_c is the chromatic aberration constant, $\Delta J/J$ is the current stability of objective lens, which is 1.0×10^{-5} so that even if the energy dispersion is lowered

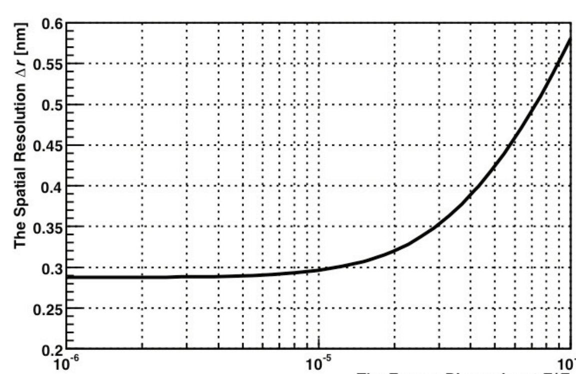

Figure 1: The relation of energy dispersion and the spatial resolution.

THE MAGNETIC MEASUREMENT FOR LOW MAGNETIC FIELD STABILITY OF DIPOLE MAGNET FOR CEPC*

#Z.Zhang, F.Chen, B.Yin, H.Geng
Institute of High Energy Physics, CAS, Beijing 100049, China

Abstract

The CEPC (Circular Electron Positron Collider) project is in the pre-research stage. When the beam energy of booster is 120GeV, the magnetic field of deflection magnet is 640 G. In order to save funds for scientific research, we are ready to select the injection energy for 6 GeV, this corresponds to a magnetic field about 32 Gs. In such a low magnetic field, the effects of earth's magnetic field and ambient temperature variations cannot be ignored. In this paper, first written the collection procedures for magnetic field value and ambient temperature values by Labview software, then used a one-dimensional probe to measure the background magnetic field for three directions (Bx, By, Bz) and the value of the ambient temperature values, the time of data collection for each direction are more than 24 hours (every minute collecting a set of values). Finally, plus the different currents (3A, 6A.. 15A) to the dipole magnet, the time of measured and the data collected by over 24 hours. Based on the results of the analysis of large amounts of data, summarized and analyzed the effect of Earth's magnetic field and ambient temperature for dipole magnet in a low magnetic field.

INTRODUCTION

The Circular Electron Positron Collider (CEPC) is a long-term collider project, which will be divided into two phases. The first phase will construct a circular electron-positron collider in a tunnel with a circumference of 50 – 70 km, and detectors installed at two interaction points. The machine is expected to collide electron and positron beams at the center-of-mass energy of 240 – 250 GeV, with an instantaneous luminosity of 2×1034 $cm^{-2} s^{-1}$. The baseline design considers a single ring in a 50/70 km tunnel and electron/positron beams following a pretzelled orbit in the ring[1]. The accelerator parameters have been calculated and shown in Table 1.

Table 1: The Accelerator Parameters

Accelerator Parameters			
Beam energy[E](Gev)	120	**Lorentz factor[γ]**	234834.66
Circum Ference [C](km)	53.6	**Revolution period[T0](s)**	1.79×10^{-4}

When the beam energy of booster is 120GeV, the magnetic field of deflection magnet is 640 G. In order to save funds for scientific research, we are ready to select the injection energy for 6 GeV, this corresponds to a magnetic field about 32 Gs. In such a low magnetic field, the effects of earth's magnetic field and ambient temperature variations cannot be ignored.

According to the physical requirements of this experiment, first, a new program of measurement has been written by Labview software.Second, the preparation for hardware, the device of measurement and collimation. The device about measurement includes the Hall-probe measurement facility, the power supply and the dipole magnet; the device of collimation includes theodolite, level and collimation target.

THE DESCRIPTION OF PROGRAM

The Tesla meter is via RS-232 serial port to communicate with the computer. The main program consists of several parts, the serial port is defined, write, read, close, data acquisition (temperature and magnetic field values).The main structure of the program is the while loop and conditional structures.The the front panel of the program is shown in Fig. 1.

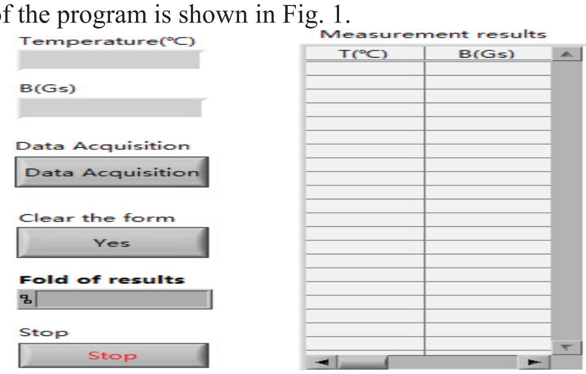

Figure 1: The front panel of the program.

THE DESCRIPTION OF HALL-PROBE MEASUREMENT FACILITY

The Hall-Probe measurement facility is a 3-axises mot ion bench. The movement of 3-axises(x, y and z) can be o perated by computer. The positioning accuracy of x, y and z axis is ±0.001mm and the positioning repeatability accu racy is ±0.01mm. In addition, this machine can be also us ed to adjust the rotation and pitch adjustment probe ensur e that the probe can measure the magnetic field perpendic ular to enter the area of the magnet, so that the total is a fi ve-dimentional adjustment system. The Teslameter and H all probe are produced by Group3 Led. The sensitive of th e MPT-141 Hall Probe is 1×0.5(mm).

PROGRESS ON THE CSNS POWER SUPPLY SYSTEM

Xin Qi, Institute of High Energy Physics, Chinese Academy of Sciences
P.O. Box 918, Beijing, 100049, China

Abstract

The 1.6 GeV proton synchrotron proposed in the CSNS Project is a 25 Hz rapid-cycling synchrotron (RCS) with injection energy of 80 MeV. Beam power is aimed to 100 kW at 1.6 GeV. The power supply system consists of seven subsystems. Those power supplies have three operation modes: DC mode, AC plus DC mode and programmable pulse mode. This paper will introduce the Power Supply System status in recent years.

INTRODUCTION

The CSNS is designed to accelerate proton beam pulses to 1.6 GeV at 25 Hz repetition rate, striking a solid metal target to produce spallation neutrons. The accelerator provides a beam power of 100 kW on the target in the first phase. It will be upgraded to 500 kW beam power at the same repetition rate and same output energy in the second phase. This project has started construction in September 2011, and plans to complete the first phase in March 2018.

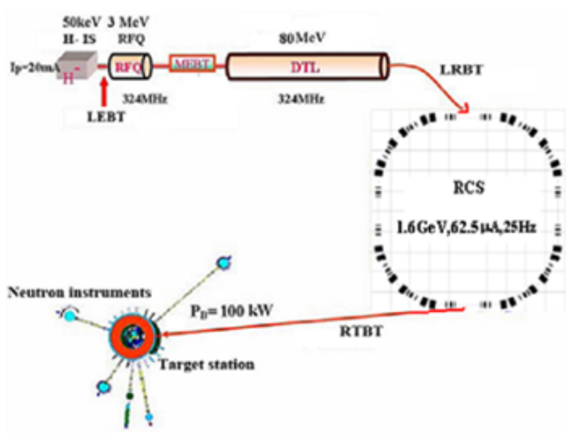

Figure 1: The structure diagram of CSNS.

Figure 1 shows the structure diagram of the CSNS. An ion source produces a peak current of 25 mA H- beam. RFQ linac bunches and accelerates it to 3 MeV. DTL linac raises the beam energy to 80 MeV. After H- beam is converted to proton beam via a stripping foil, RCS accumulates and accelerates the proton beam to 1.6 GeV before extracting it to the target. The Power Supply System consists of the LEBT, MEBT, DTL, LRBT, injection and extraction system, RCS and RTBT Power Supplies. All of them are Digital Power supply. Figure 2 shows the Digital Power Control Module (DPSCM), which is specially designed for CSNS. There is only one FPGA fulfilling the fully-digital control, and the design principle of system on a programmable chip (SOPC) has been implemented [1].

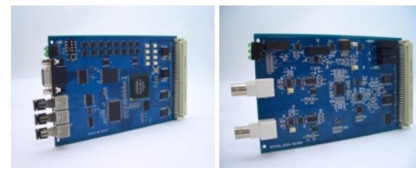

Figure 2: The DPSCM for CSNS Power Supply.

Table 1: Technical Specifications of DC PS

Number(sets)	239
Output Current(A)	10~1700
Output Voltage(V)	5~220
Output Power(Kw)	0.1~73
Stability(24 hours)	100ppm/500ppm
Ripple	≤ 0.01%

DC MAGNET POWER SUPPLY

Table 1 shows the technical specifications of CSNS DC magnet PS. Depending on the power level, this kind of PS has different topology. For the power less than 10 kW, the topology uses the DC/DC half-bridge or full-bridge switch PS; for the power less than 100 kW, the topology uses the Chopper.

In the past year, most of them have completed the production, testing and installation. Now the PS for LEBT and MEBT has worked for beam commissioning.

POWER SUPPLIES FOR RCS

In order to avoid drawing a large reactive power from the a.c. lines, the "White Circuit" type resonant network was adopted widely as the structure of the magnet power supply system of the rapid cycle synchrotron. There are two kinds of resonance configurations: the parallel resonance (PR) and the series resonance (SR) [2]. Usually, dipole magnets adopt the PR network because of the huge power variation and quadrupole magnets adopt the SR network. Considering the convenient machine repair and the controllability of magnet current, all magnets will adopt the SR network in the CSNS Project.

There are totally 24 dipole magnets and 48 quadrupole magnets, which consist of six families. Each magnet is connected in series to the others of its type, and is excited independently by the power supply system.

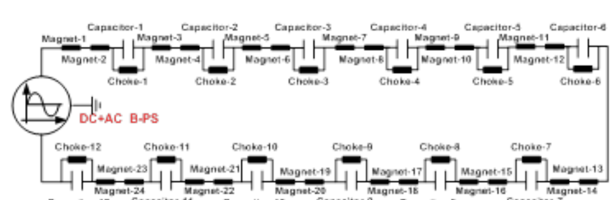

Figure 3: Resonant network of the RCS Dipole PS.

RESEARCH DEVELOPMENT OF HIGN PRECISION INSTALLATION AND ALIGNMENT SYSTEM FOR HEPS*

Lei Wu#, Chunhua Li, Xiaolong Wang, Suying Chen, Haijing Wang, Huamin Qu
IHEP, Beijing, China

Abstract

High Energy Photon Source (HEPS) is a proposed 6 GeV third generation light source with high brightness and ultra-low emittance. Because the measurement error of the traditional optical survey method in the girder and magnet installation can't meet the tight alignment tolerance, the installation and alignment will not only rely on laser tracker and some other optical survey instruments. So HEPS is developing the research of high precision installation and alignment system which is consists of the design of auto-tuning girder based on beam alignment and research of vibrating wire alignment system based on magnetic measurement. This paper introduces the research development of installation and alignment system in storage ring of HEPS.

INTRODUCTION

HEPS will be a 5 GeV, 1296 meters circumference third generation synchrotron radiation facility with ultra emittance and extremely high brightness. The emittance will be better than 0.1nm·rad. The storage ring is a 48 cell 7BA lattice. Fig.1 is one of 48 typical cells. In order to install the magnets easily, the adjacent quadrupole magnets, sextupole magnets and the corrector will use a common multipole support girder. Blue block represents quadrupole magnets and green block represents sextupole magnets. The multipole support girder is designed 3.8 meters [1]

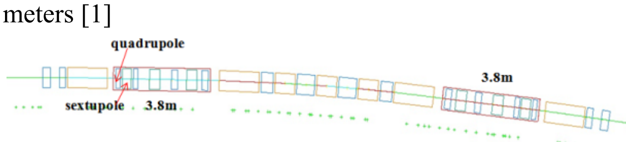

Figure 1: One of 48 typical cells.

Table 1: HEPS Alignment Tolerance

Tolerances	Magnet to Magnet	Girder to Girder
Horizontal	±0.03mm	±0.05mm
Vertical	±0.03mm	±0.05mm
Beam direction	±0.5mm	±0.5mm
Roll angle	±0.2mrad	±0.2mrad

*Work supported by HEPS project
#wulei@ihep.ac.cn

Table 1 shows the alignment tolerance in HEPS. It is difficult to achieve the required accuracy using the traditional optical survey. So vibrating wire alignment technique is considered to meet the tolerance ±0.03mm between magnet to magnet on a multipole girder. And auto-tuning girder can help to achieve the tolerance ±0.05mm between girder to girder.

AUTO-TUNING GIRDER

All girders in the storage ring will automatically adjust when the accelerator is running by monitoring the beams. The natural frequency of the auto-tuning girder should better than 30Hz. And the dynamic state of the auto-tuning girder must be stable. The high precision auto-tuning girder is based on the cam mover mechanism. The similar scheme has been used in Swiss Light Source [2], Taiwan Photon Source [3] and in some other facilities. The eccentric circle cam mover had demonstrated good resolution and good performance in the facilities which have used motorized adjusting mechanism. The design parameters of the auto-tuning girder for HEPS are in Table 2.

Table 2: Design Parameter of Auto-tuning Girder

Design parameter	Design value
Girder size(L×W)	3.8m×0.8m
Cam load	2.5t
Cam eccentric offset	7mm
Cam adjust range	X (-8.7mm~9.4mm) Y (-11.8mm~10.4mm)

Fig.2 is the schematic distribution of the girder supports and the location of the cam mover mechanisms. This eight girder supports distribute along the girder and form four groups of groove mounted mutually perpendicular. This can make full use of the adjust range of this 8 cam mover mechanisms.

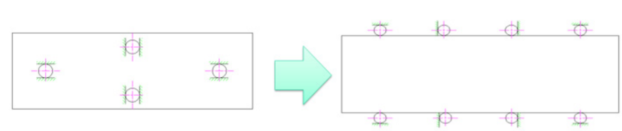

Figure 2: Distribution of girder supports and cam mover mechanisms.

In the storage ring, adjust the position of the girder is by adjusting the origin position of coordinate system. The adjustment process is divided into two steps. Firstly,

MATERAL TEST OF PROTON BEAM WINDOW FOR CSNS

Haijing Wang#, Donghui Zhu, Huamin Qu, Ling Kang, Lei Wu
IHEP, Beijing, China

Abstract

The proton beam window (PBW) is one of the key devices of China Spallation Neutron Source (CSNS). Material selection of PBW is of particular importance. A5083-O was chosen in the previous work, and recently the material tests are done. The tests show the material has good microstructure, physical and mechanical performance. Creep lifetime is analyzed based on the creep test. All the experiments show the selected material is qualified.

INTRODUCTION

The PBW is one of the key devices of CSNS. It is located at the boundary of transport line and target, separating the high vacuum in the accelerator and helium atmosphere in the Helium Vessel. The material selection of the window is important. The heat dissipation, mechanical properties, scattering effect on proton beam, lifetime and so on should be considered. A single-double layered PBW was proposed for CSNS with the beam power of 100 kW in our previous work. A5083-O was chosen as the PBW material mainly for its low effect on beam, and allowable thermal and mechanical properties [1].

As the window is important to the CSNS project, the material should be tested before the window manufactured. The PBW suffers thermal increase because of the energy deposition. And under the comprehensive effects of temperature, boundary fixation, pressure from helium and cooling water and so on, there will be stress and deformation of the window. Generally, the creep temperature of materials is about 30-50% of melting temperature [2]. The working temperature of the window is 73 °C, about the 40% of the melting temperature, then the creep effect should be verified. The material tests contain chemical components, microstructure, physical properties, tensile experiments and creep experiments.

CHEMICAL COMPONENTS

Chemical components are tested by optical emission spectrometric analysis method. There are three samples from different locations and plates. Compared with the standards of GB/T 7999-2007, the materials are all up to standard.

MICROSTRUCTURE

The microstructure is inspected by metalloscope. The results show that the material microstructure is fiber texture. The procedure should be hot rolling and then homogenizing annealing. The plates are annealed completely, and have no defects such as slag inclusion, air hole or loosen. Figure 1 presents the microstructure.

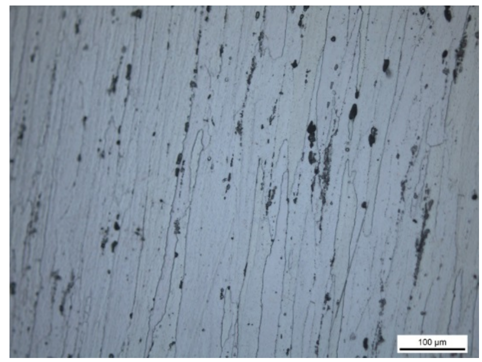

Figure 1: Microstructure (200×).

PHYSICAL PROPERTIES

The physical properties tested conclude density, coefficient of thermal conductivity, coefficient of thermal expansion, Poisson's ratio, modulus of elasticity and heat capacity, of which the results are showed in Table 1. All these items are tested from three samples from different locations and plates. And the results are the average values of each items separately. All these parameters will affect the thermal and structural conditions of the window, and are necessary for finite element analysis by ANSYS.

Table 1: Results of Physical Properties

Item	Results
Density ($g \cdot cm^{-3}$)	2.66
Coefficient of thermal conductivity ($W \cdot (m \cdot °C)^{-1}$)	119.7
Coefficient of thermal expansion ($10^{-6} \cdot °C^{-1}$)	24.2
Poisson's ratio	0.32
Modulus of elasticity (GPa)	70.3
Heat capacity ($J \cdot (kg \cdot °C)^{-1}$)	901

TENSILE PROPERTIES

The tensile properties should be estimated to make sure the window can work normally. There are two types of tensile experiments, at room temperature and high temperature separately.

DESIGN AND THERMAL ANALYSIS OF ADS BEAM STOP

Minxian Li, Jianli Wang, Lei Wu, IHEP, Beijing, China

Abstract

ADS beam stop is an important device which required for the commissioning and accelerator tests of Accelerator Driven Sub-critical System (ADS), it is used to stop the beam which power is about 100kW and consume energy of the beam. This paper will present a triangular prism structure of the ADS beam stop, its mechanical design is described in detail, and there are numerous grooves and ribs in the cooling plates which is the core component of the beam stop. The thermal analysis is performed and its result proves that the triangular prism structure meet the design requirement.

INTRODUCTION

The China Accelerator Driven Sub-critical System(C-ADS) program is an important strategic research for solving nuclear waste and nuclear fuel problems. The Institute of High Energy Physics (IHEP) is responsible for Injector I which based on 325MHz RFQ and spoke cavities [1]. The driven accelerator works with an average beam current of 10mA. The ADS beam stop is an important terminal device of accelerator which used to stop the beam and consume energy of the beam, as no target is planned for the accelerated beam, so the ADS beam stop is required for the commissioning and accelerator tests. Table 1 Shows some design parameters of ADS beam stop.

Table 1: Design Parameters of ADS Beam Stop

Item	Result
Beam power	100kW
Beam current	10mA
Beam energy	10MeV
Beam diameter	200mm
Design water pressure	10kg/cm^2
Water velocity	2m/s
Water temperature	20°C
Vacuum pressure	6.67×10^6 MPa
Vacuum leak rate	2.67×10^3 MPa· m^3/s

MECHANICAL DESIGN

Material and Structure Choice

As the temperature, thermal gradients, and stress field in the beam stop material are directly dependant on the power density profile [2], therefore, it is an effective means by reducing the power density. The reduction of this power density is achieved by defocusing the beam to increase its size and by using a very low incidence angle in the beam stop thus maximizing the material surface area hit by the beam [3]. So the beam, which has a circular cross profile, is expanded to diameter 200mm at the beam stop entrance. In addition, use a smaller angle in order to increase the material surface area hit by the beam is another mean to reduce the power density. The Oxygen-free Copper (OFC) is chosen for the main material of the core component because of its thermal properties and activation criteria.

The triangular prism structure is used for the beam stop (Figure 1), the material surface area hit by the beam is changed with the angle of the two OFC plates, the angle of the two OFC plates should be properly chosen, avoiding large angle, which would produce high power density, and too small angle, which would increase the overall length of the beam stop. Besides, this structure is more convenient for processing.

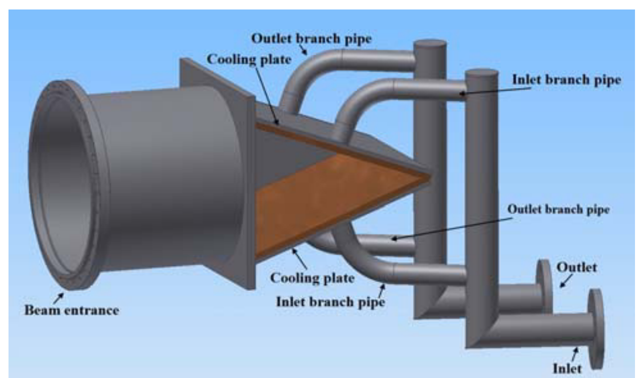

Figure 1: The structure of the ADS beam stop.

Cooling System

Due to the heat flux (or the power density) is very high, water is chosen as coolant of the cooling system. There are a number of long grooves (Figure 2&3) and ribs in the back of the OFC plates which opposite to the beam hit surface. The cooling water flow through the long groove from one side to another side, in this process, the heat exchange is performed and the heat is taken away by cooling water. The coolant channel geometry is chosen to provide adequate velocity in the high power density zone, avoiding high values, which would produce vibrations and material erosion, and too low values, which would not provide enough heat transfer [3]. Therefore, as a matter of past experience and calculation, the cooling water enters at a high velocity (2m/s), and the water pressure is 10kg/cm2.

ANALYSIS OF THE ELECTROMAGNETIC FIELD IN THE COUPLER OF NORMAL TEMPERATURE TRAVELLING-WAVE ACCELERATING TUBE

X. He#, M. Hou, G. Shu, Key Laboratory of Particle Acceleration Physics and Technology, Institute of High Energy Physics, Chinese Academy of Science, Beijing, China

Abstract

With the developed requirement of the beam quality in modern accelerators, rapid development of all kinds of accelerating structures with different frequencies and materials have been achieved. However, the normal temperature travelling-wave (TW) accelerating structures which are widely used in Free Electron Laser (FEL) are still indispensable. For reducing the beam emittance, it is very important to optimize the symmetry of the high-order electromagnetic field in the coupler of such accelerating structures. In this paper, the symmetry of the electromagnetic field in TW accelerator couplers using different coupling mechanisms was analysed. A lot of design optimization as well as the result analysis work has been done for the three kinds of commonly used waveguide-coupled TW accelerating structures: single-feed electrical-coupling, dual-feed electrical-coupling using magic tee in feeding waveguide and dual-feed magnetic-coupling using J-type feeding waveguide. Finally, basing on lots of simulation results and the performances during the fabrication, measurement and RF conditioning of these three kinds of structures, the J-type racetrack coupler type is regarded as the best choice.

INTRODUCTION

The SLAC-type normal temperature travelling-wave accelerating structure is widely used in the large high-energy electron linear accelerators all over the world. The rotational-symmetrical cylindrical cavity or the racetrack cavity is usually used as the input coupler for this kind of accelerating structure. The rotational symmetry of the cylindrical cavity is affected by the introduction of the coupling hole of the cavity, which results in an asymmetry of the electromagnetic field within the envelope of the beam and then degrades the beam quality by increasing the beam emittance. By using the dual-feed accelerating structure instead of the single-feed, the symmetry of the electromagnetic field of the cylindrical cavity is improved, however, along the vertical direction of the two symmetrical coupling holes in the dual-feed cylindrical cavity, the symmetry is still affected. For further improving the symmetry of the electromagnetic field within the envelope of the beam, the racetrack cavity is adopted by elongating the cylindrical cavity along the vertical direction of the two coupling holes.

The research work concerning the improvement of the symmetry of electromagnetic field in the racetrack cavity comparing to the cylindrical cavity has been done in some articles [1]. However, all of them are focused only on one of the coupling mechanism, or only on the symmetry of electrical field. On the basis of considering several kinds of coupling mechanisms, the comprehensive analysis and compare work for the symmetry of electromagnetic field between the cylindrical and racetrack cavity has been done and some inferences has been given here.

STRUCTURE OF THE COUPLING CAVITIES

For better analysing the improvement of the symmetry of electromagnetic field in the racetrack cavity, three commonly used coupling mechanisms (numbered as coupling mechanism 1 to 3 in sequence) are chosen: the single-feed electrical-coupling (central frequency 2998 MHz), the dual-feed electrical-coupling using magic tee in feeding waveguide (central frequency 2856 MHz) and the dual-feed magnetic-coupling using J-type feeding waveguide (central frequency 2856 MHz). The structures of them are shown in Fig. 1a and the difference between the racetrack cavity and the cylindrical cavity is shown in Fig. 1b.

RF MODULATION STUDIES ON THE S BAND PULSE COMPRESSOR

G. Shu[#], F. Zhao, S. Pei, Key Laboratory of Particle Acceleration Physics and Technology, Institue of High Energy Physics, Chinese Academy of Science, Beijing, China

Abstract

An S band SLED-type pulse compressor has been manufactured by IHEP to challenge the 100 MW maximum input power, which means the peak power around the coupling irises is about 500 MW at the phase reversal time. In order to deal with the breakdown problem, the dual side-wall coupling irises model was used. To further improve the reliability at very high power, RF phase modulation (PM) with flat-top output is considered. By using the CST Microwave Studio (MWS) transient solver, a new method was developed to simulate the time response of the pulse compressor. In addition, the theoretical and experimental results of the PM theory are also presented in this paper.

INTRODUCTION

The SLED-type pulse compressors play an important role in the linear accelerators to increase the efficiency of the klystron RF power. An S band SLED-type pulse compressor has been manufactured by IHEP to challenge 100 MW input peak power. At just one compressed pulse time (usually equal to the filling time of the travelling wave accelerating structure) from the incident RF pulse end, the incoming pulse phase is reversed 180^{o} by the PSK (phase shift keying) switcher, the output peak power will reach 500 MW. The extreme high power leads to the sparking phenomena around the SLED coupling irises and the first several accelerating cells.

A significant reduction of the electric fields near the irises had been achieved by adopting dual side-wall coupling irises model. High power test results show that the maximum input power can reach 85 MW. To further improve the high power reliability, the amplitude modulation (AM) and phase modulation (PM) of the SLED was considered to obtain the flat-top output. For AM, the input power is slowly increased to compensate the damped radiation power of the storage cavities during the pulse compressed interval. Due to the non-linear input/output characteristics of the klystron at high power, AM can't be implemented in the saturation regime [1]. For PM, the incoming RF pulse phase can be manipulated with a constant amplitude, thus the PM is a more feasible option.

THEORY AND SIMULATIONS

Figure 1 shows the equivalent circuit model of the SLED. The energy storage cavity can be regarded as an oscillating circuit. The voltage source refers to the RF generator.

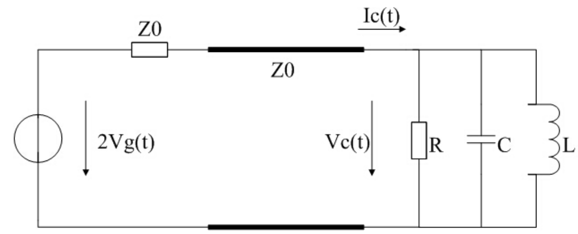

Figure 1: Equivalent circuit model of the SLED.

According to the Kirchhoff's law, the following differential equation can be obtained (dots mean derivatives with respect to time) [2][3].

$$\mathrm{Vr} + \tau\dot{\mathrm{Vr}} = \Gamma\mathrm{Vg} - \tau\dot{\mathrm{Vg}}, \quad (1)$$

where Vg is the equivalent complex voltage of the SLED input while Vr is the output. $\tau = 2Q_l/\omega_c$ is the filling time of the storage cavity, Q_l and ω_c are the loaded Q and the resonant angular frequency. Γ is the reflection coefficient and can be defined as $(\beta-1)/(\beta+1)$ with β the coupling factor.

The RF power is fed into the SLED at time t_0, the input has a phase jump with a step φ_0 (generally much less than 180^{o}) at time t_1, then the phase is increased continuously until the RF pulse ends at t_2. The phase modulation based upon the differential Eq. (1) is carried out during $t_1 \leq t < t_2$, then a compressed pulse with constant amplitude can be acquired.

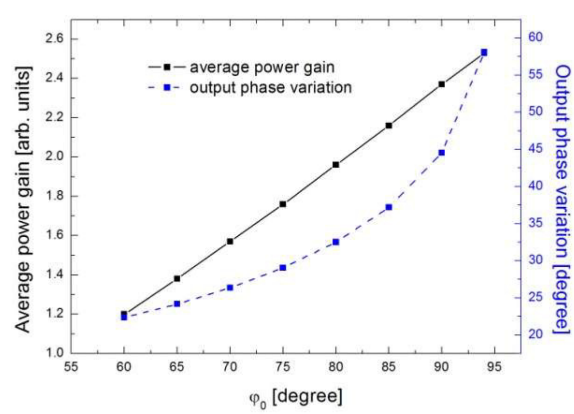

Figure 2: Dependence of the average power gain and the output phase variation on the phase jump step φ_0.

Figure 2 shows the dependence of the average power gain and the output phase variation on the phase jump step φ_0. The average power gain is proportional to φ_0, while the output phase variation increases with φ_0 as well. For the time duration $t_1 \leq t < t_2$, the output phase experiences a large variation. As we all know, the

CATHODE STALK OPTIMIZATION FOR A 325 MHz SUPERCONDUCTING QWR ELECTRON GUN*

P.L Fan†, F Zhu, S.W Quan, L Lin, Y.M Li, K.X Liu
Institute of Heavy Ion Physics, Peking University, Beijing 100871, China

Abstract

The structure of cathode stalk is very important for the performance of a superconducting QWR (Quarter Wave Resonator) electron gun. With improper design, RF power dissipation on the surface of cathode stalk and its surrounding tube can lead to a serious decrease of quality factor for superconducting QWR injector. We present here an optimized design of the cathode stalk for the 325 MHz superconducting QWR gun and special considerations are taken to minimize the power dissipation. The details of microwave simulation, beam dynamic simulation of the cavity with cathode stalks in different length, diameter and position are presented in this paper.

INTRODUCTION

An appropriate source is very important for the success of the proposed energy recovery linac (ERL) and high average power free-electron lasers (FELs). The superconducting radio frequency (SRF) electron guns offer great promise of very bright beams for use in electron injectors. QWR is compact at low RF frequency compared to elliptical cavity and its long wavelength allows to produce long electron bunches for which space charge effects can be minimized. Because of these potential benefits, projects of QWR electron gun have been developed at Naval Postgraduate School (NPS) [1], the University of Wisconsin [2] and Brookhaven National Laboratory (BNL) [3]. A 325MHz QWR electron gun has also been proposed at Peking University for obtaining higher beam current than the present DC-SRF gun.

One of the main problems of the SRF injectors is that a cathode inserted into the superconducting gun cavity causes worse performance of the SRF cavity. Usually we use a cantilevered stalk, not shorted directly to the cavity, to support the cathode in the desired position. This design has a singular flaw that the cathode stalk becomes an RF transmission line allowing RF energy to flow down it as a coaxial waveguide. As we know, any RF power pulled from the cavity degrades gun performance. This problem has been predicted in the Rossendorf gun [4] and Brookhaven SRF gun [5]. Both of them were designed to incorporate an RF choke to prevent the RF power flowing down the cathode stalk. The DC-SRF [6] gun in Peking University also offers an effective way to solve this problem, which combining a Pierce gun with a superconducting cavity. As to the QWR gun, its reentrant structure determines that a choke filter or a Pierce gun is not a good choice. So the design of the cathode stalk in QWRs is very important, the test in NPS shows that the quality factor of cavity with cathode stalk can be an order of magnitude smaller than that of the virgin cavity. We do some research on the design of the cathode stalk aiming to reduce the RF power dissipation on the cathode stalk on the basic of the 325MHz QWR electron gun.

325 MHz QWR ELECTRON GUN

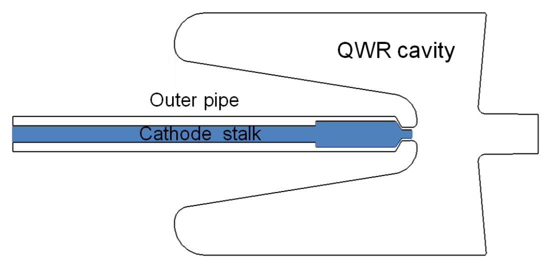

Figure 1: The schematic of 325MHz QWR cavity and the cantilevered cathode stalk.

The 325MHz QWR gun cavity design is given in reference [7], the simulation of the electromagnetic field of the QWR cavity was carried out with the Superfish code [8]. When the average accelerating electric field E_{acc}=20 MV/m, the stored energy of the cavity U=4.67 J and the cavity's intrinsic quality factor Q_0=1.536 $\times 10^9$ (T=4 K), the dissipated power in the cavity walls is given by

$$P_c = \frac{\omega_0 U}{Q_0} = 6.2\,\mathrm{W} \tag{1}$$

Here, we defined the RF power dissipation on the cathode surface and the outer pipe inner surface as P_d, that is

$$P_d = \frac{R_s}{2}\int_{A_1+A_2} H^2 da \tag{2}$$

Here, Rs is the surface resistance. We choose copper as the material of stalk because of its lower resistivity. A_1 and A_2 are the area of the cathode stalk surface and the area of the outer pipe inner surface, respectively. The QWR cavity and the cantilevered cathode stalk are shown in Figure 1.We define the quality factor which considering the RF power dissipation on the cathode surface and the surrounding tube inner surface as $Q_0^{'}$, which is defined as

$$Q_0^{'} = \frac{\omega_0 U}{P_c + P_d} \tag{3}$$

THE CATHODE STALK

Just like the input coupler, the cathode stalk and the outer pipe form a RF transmission line. We consider the case

DEVELOPMENT OF DC-SRF INJECTOR AT PEKING UNIVERSITY*

Jiankui Hao, Shenwen Quan, Lin Lin, Liwen Feng, Fang Wang, Feng Zhu, Senlin Huang, Zhiwen Wang, Xiaodong Wen, Peiliang Fan, Kexin Liu#, Huamu Xie, Kui Zhao, Jiaer Chen
Institute of Heavy Ion Physics & State Key Laboratory of Nuclear Physics and Technology, Peking University, Beijing, China

Abstract

DC-SRF electron injector, which combines a DC Pierce gun and a 3.5-cell 1.3 GHz superconducting cavity in a cryomodule, has been developed at Peking University. Based on the improvements of beam line, LLRF system and 2K cryogenic system, stable operation of the DC-SRF injector has been carried out recently. Electron beams with 3.4 MeV energy and the currents of ~1mA in a macro-pulse mode was obtained. As the first application of this DC-SRF injector, THz radiation produced with a 10 period undulator was also detected. The description of the experiment process and results will be presented in this paper.

INTRODUCTION

To obtain electron beams with high average current and low emittance, superconducting radiofrequency (SRF) photocathode guns, which combine the high brightness of normal conducting RF photocathode guns with the advantage of CW operation of superconducting RF cavities, have been developed in many laboratories worldwide [1, 2]. For HZDR SRF photoinjector, the SRF cavity is a 3.5-cell TESLA type cavity and there is a center hole on the back wall of the half-cell for Cs_2Te photocathode installation, which is in normal conducting. An attached choke filter made of pure niobium was designed to protect RF power leak towards the cathode support system from a vacuum gap between the cavity and the photocathode [3]. This SRF injector has been in operation since 2008[4] and was used for FEL operation recently [5]. A 704 MHz half-cell cavity SRF gun with a double quarter wave choke joint cathode insert was constructed at BNL and K2CsSb was chosen as cathode material [6]. The RF conditioning has been carried out [7] and the beam test is underway.

DC-SRF injector was first proposed by Peking University in 2001 [8]. It combines a DC Pierce gun and a superconducting cavity. The feasibility of DC-SRF injector was demonstrated by the prototype injector with a 1.5-cell TESLA type superconducting cavity in 2004 [9]. An upgraded DC-SRF injector with a 3.5-cell large grain niobium cavity was then designed and constructed [10]. Conditioning of the DC-SRF photoinjector has been started since the 2K cryogenic system has been in operation in 2011 [11]. Based on a series of improvements on drive laser, photocathode, low level RF (LLRF) control system and beam diagnostic devices, electron beam with a current of mA level has been obtained at long-term stable operation. In this paper, the improvements, beam experiments and results of the DC-SRF photoinjector are described.

DC-SRF INJECTOR

Figure 1 shows the schematic view of the upgraded DC-SRF photoinjector. The cryomodule consists of the DC pierce gun, 3.5-cell superconducting cavity, helium vessel, liquid nitrogen shield, input power coupler, tuner and auxiliary systems.

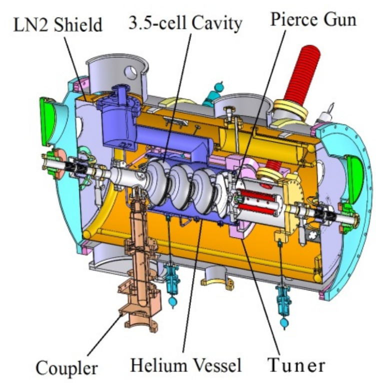

Figure 1: Schematic view of the DC-SRF photoinjector.

The designed DC voltage of Pierce gun is 90 kV. The surface electric field on the cathode is almost 5 MV/m and the peak electric field is lower than 13 MV/m. Simulations show that the electron beam experiences a focusing force when it leaves the cathode and is defocused around the anode [10]. The anode, which is also a part of the 3.5-cell cavity, is made of single crystal niobium in order to avoid the effect of the welding seam on the DC field distribution. The 3.5-cell large grain niobium superconducting cavity comprises three TESLA type cells and a special designed half-cell. The accelerating gradient of the cavity reaches 23.5 MV/m and the intrinsic quality factor Q_0 is higher than 1.2×10^{10} in vertical test [10]. The simulation shows that space charge effect of the electron beam is still remarkable due to the relatively low energy gained from the DC voltage. The gap between the Pierce gun and the 3.5-cell cavity should be as short as possible to prevent the beam from diverging too much due to space charge effect before it enters the high field area in the cavity. On the other hand, the RF field and DC static field infiltrating into each other should be suppressed. The length of connecting beam pipe between the DC anode and the half-cell of the cavity is 17 mm. The magnet field shielding of the DC-SRF injector is provided by the vacuum vessel, which is made of high pure iron plate with the thickness of 12 mm. The residual magnetic field in the

A C-BAND DEFLECTING CAVITY DESIGN FOR HIGH-PRECISION BUNCH LENGTH MEASUREMENT*

Xiaopeng Jiang[a,b,#], Jiaru Shi[a,b], Ping Wang[a,b], Huaibi Chen[a,b]
[a] Department of Engineering Physics, Tsinghua University, Beijing 100084, PR China
[b] Key Laboratory of Particle and Radiation Imaging of Ministry of Education , Tsinghua University, Beijing 100084, PR China

Abstract

A standing wave RF deflecting structure has been designed as a tool for high-precision bunch length measurement. This 3-cell deflecting cavity is designed to operate at a frequency of 5.712GHz. In this paper, the RF design and thermal analysis of the deflecting cavity are introduced. We study the electromagnetic field distribution inside the cavity. The coupler design is also discussed. And the beam dynamics simulation is shown.

INTRODUCTION

RF deflecting cavities have been widely used in the characterization of the longitudinal and transverse phase space in ultra-short electron beams [1]. Recently an ultrafast electron source with femtosecond-level is used for diffraction and imaging system [2]. The main parameters of the bunch are given below (Table 1). A C-band deflecting cavity is designed for high-precision measurement of the bunch length.

Table 1: Beam Parameters

Parameters	Value
Electron beam energy (MeV)	2
Transverse beam size (mm)	0.5
Longitudinal beam size(fs)	20

In the second section of the paper, the design of the deflector is discussed including the structure design, electromagnetic field characterization, beam dynamics and the coupler design. Thermal simulation calculated by CST is shown in the third part.

RF DEFLECTOR DESIGN

The required transverse deflecting voltage V_T=1MV can be, achieved by both traveling wave (TW) and standing wave (SW) structures [1]. In our case, we choose a 3-cell SW structure operated at a frequency of 5.712GHz. The 3D-model draw by CST is shown in Figure 1.

Model Design

The main part of the model is composed of several cylinders. The radius of the cell is determined by both the frequency and flatness of the magnet field [3]. The working mode is TM_{110} mode and π-mode. Length of the middle cell is given by [3]:

$$l = \frac{\lambda}{2} = \frac{\pi c}{\omega_0}. \tag{1}$$

where λ and ω_0 are the wavelength and angular frequency of the microwave, c is the speed of light, l is the length of the middle cell which include half of the gap between middle cell and end cell each side. Meanwhile, the length of the end cell is determined by beam dynamics which is discussed later in this paper.

In order to make sure the polarization direction not changed while two cell coupled, two end cells are slotted on the edges which are perpendicular to the direction we put the coupler.

According to the discussion above, the dimensions of the cavity is shown in table 2.

Table 2: Dimensions of the RF Cavity

Dimensions	Value(mm)
Radius of middle cell	30.85
Length of middle cell	21.49
Radius of end cells	30.61
Length of end cells	10.93
Gap between cells	4.76
Radius of beam pipe	8
Radius of slots	3.5

Abstract

The localized high electric field enhancement or low work function is the trigger for strong field emission, which however has yet been well experimentally studied. Using an L-band photocathode gun test stand at Argonne Wakefield Accelerator Facility (AWA), we've constructed an imaging beam line to observe field emission current from predefined emitters on cathode. Preliminary experiment results are present. Future plan is discussed.

INTRODUCTION

Field emission (a.k.a. dark current) plays an important role in development of high gradient rf devices [1]. Elimination of sharp edges and achievement of smooth surface finishing in fabrication to alleviate the field emission is a standard practice to avoid rf breakdowns in operation of high gradient accelerating structures. Field emission has been well explained by the Fowler-Nordheim formula with quantum mechanism [1, 2], which is governed by three independent parameters, the local field enhancement factor β, the emitter area Ae, and the work function φ.

Strong field emission observed in high gradient devices is dominated by emitters with high β or low φ [1, 3]. Previous dc studies by field emission scanning microscopy (FESM) [4] and tunnelling atomic force microscopy (TUNA) [5] have revealed different types of emitters, such as particulates, surface protrusion, grooves with trapped contaminants, grain boundary, etc. However, to the best of the authors' knowledge, no systematic study to exactly locate emitters in rf devices has been carried out yet.

Locating field emitters in rf devices might help understand the fundamental mechanism of field emission. Moreover, if the rf breakdown spot can be identified simultaneously, it will also help reveal the relationship between field emission and breakdown.

IMAGING PRINCIPLE

The gun used in this study is a 1.3 GHz L-band single cell photocathode gun with mountable cathode [6]. With 2 MW input power, the electric field on the flat cathode (noted as $E_{cathode}$) can reach 70~100 MV/m depending on the cathode position.

* jshao@anl.gov
# jingchg@anl.gov

A modified version of ASTRA code [7] is used to simulate the emission from the cathode as well as to track their movement to the downstream of the beam line. Due to the difficulties of accurately obtaining initial conditions, we've simulated the worst possible scenario (less constraint) of field emission on the cathode surface. In the simulation, we've assumed that 1) the initial kinetic energy of dark current is constant, 7 eV (Fermi energy of Cu), which is the maximum value of the real energy distribution [8]; 2) the emission angle follows uniform distribution over the entire 360° range; 3) the temporal structure of the emitted current is approximated by Gaussian distribution [9]; 4) space charge and mirror effect are not included; 5) $E_{cathode}$ is 100 MV/m and β is 80; 6) the radius of emitter is 0.

Dark current can be emitted over 180° rf phase, resulting a wide energy spread and complicated beam dynamics. Although there is a sharp peak with the highest energy gain, the rms energy spread is ~300 keV as illustrated in Fig. 1. The trajectory of electrons emitted from the same position but different phases will be completely different, causing blurred images at downstream after acceleration by the gun, as shown in Fig. 2(a) and (b).

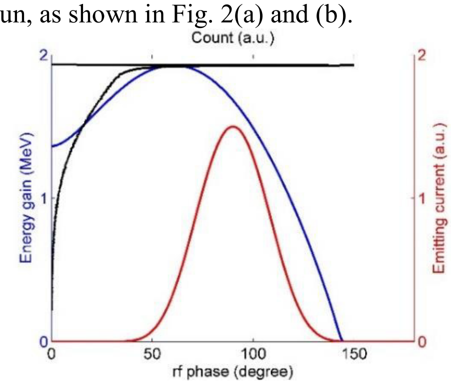

Figure 1: Energy gain (blue) and emitting current (red) at different rf phases and energy distribution (black).

To form a clear image, a straight-forward idea is to select electrons only from narrow phase band (or with narrow energy spread) and block others as shown in Fig. 2(c). This can be achieved by a solenoid (noted as the imaging solenoid) whose focusing depends on beam energy (thin lens approximation [10]):

$$\frac{1}{f} = \left(\frac{q}{2mc\beta\gamma}\right)^2 \int_l B^2 dz \qquad (1)$$

where f is the focusing length; m, q, cβ, and γ are mass, charge, speed and Lorentz factor of the particle; B and l

Abstract

A pin cathode has been used to study the influence of stored energy on field emission in an L-band rf gun. The stored energy was tuned by adjusting the recess of the cathode in order to obtain the same electric field on the cathode tip. At same electric field, we have observed very strong correlation of dark current with stored energy, where five times enhancement of dark current was obtained with the stored energy increased by three fold. Beam dynamics study reveals that the correlation is not from the beam transmission. We'll present the experiment results as well the possible mechanisms about the phenomena.

INTRODUCTION

Field emission (i.e. dark current) plays an important role in high gradient rf devices. Generally, it's very harmful and can cause rf breakdown. It needs to be suppressed to achieve high gradient accelerating structures [1]. Dark current has been well explained by the Fowler-Nordheim formula with quantum mechanism [1, 2], which is governed by three independent parameters, the local field enhancement factor β, the emitter area Ae, and the work function φ. When φ is taken as its nominal value, β and Ae are usually inconsistent with surface analysis [3]. Moreover, they have a very large diversity from different accelerators with similar peak electric field but different frequency, group velocity and so on [1]. This might imply that the field emission might not be a completely local phenomenon, which could also relate with global parameters of a system.

Recent study in which two pins were attached to a WR90 waveguide has revealed that rf breakdown depends strongly on the net rf power flow through the waveguide [4]. As dark current is highly related to rf breakdown, we are motivated to exam its dependence on the net power flow or stored energy in a standing wave cavity. In this paper, dark current dependence on input power/ stored energy is studied with a standing wave rf photocathode gun with mountable cathode.

EXPERIMENTAL SETUP

The experiment has been carried out on an L-band photocathode gun test stand at Argonne Wakefield Accelerator Facility (AWA), illustrated in Fig. 1. The forward and reflected rf power, and the field of the gun are monitored. A Faraday cup right at the exit of the gun measures the field emission current. Besides, a dark current imaging system is located downstream to index dark current emitters, which consists of a solenoid, a collimator, trim magnets, and YAG screens [5, 6].

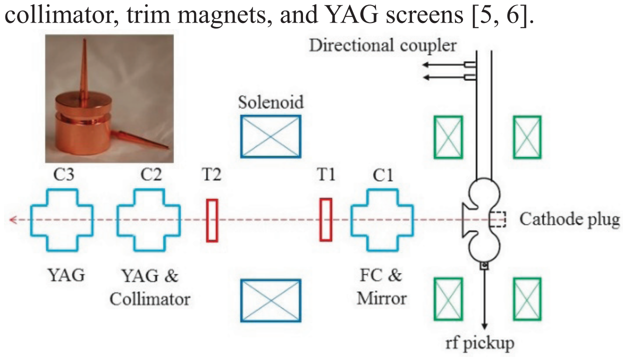

Figure 1: Layout of the L-band test stand. Inset: pin cathodes designed and fabricated in SLAC.

Pin cathodes are used to maintain the highest field in the gun to govern the field emission in the experiment. The field on the tip is at least four times higher than any other place of the gun. The copper pin cathode is 0.8 inch long with a R0.02 inch hemisphere tip as shown in inset of Fig.1.

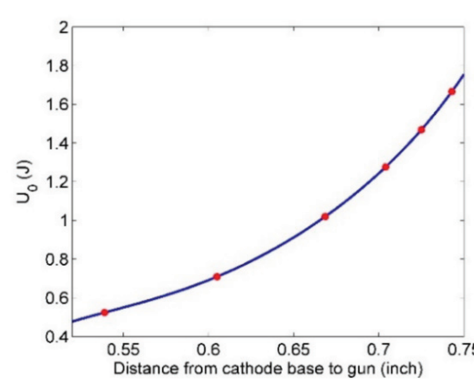

Figure 2: The stored energy at peak field of 625 MV/m vs the cathode positions from simulation, where the red points corresponds the different test sets.

Abstract

We report the experiment design and preliminary results on high power RF generation at W-band based on coherent wakefields from the metallic periodic structure of 91 GHz PETS (power extraction and transfer structure), excited by intense electron beam at the Argonne Wakefield Accelerator (AWA) facility. The recently output RF power is 0.7 MW, with 67 MeV, 1.4 nC single electron beam going through the structure. The RF pulse length is 3.4 ns. We measure the energy loss of electron beam as reference to the RF generation, which agrees well with the simulation results. Next run is to increase the output RF power with higher charge and to excite coherent wakefields with electron bunch train. The output RF peak power is expected to be ~100 MW and the electrical field gradient can reach up to 400 MV/m, with RF pulse duration adjustable from few ns to 30 ns when excited with 5~10 nC charge in a single bunch and up to 32 sub bunches in total.

INTRODUCTION

High power and high frequency RF generation benefits high energy and compact accelerator, and is also important for high gradient and breakdown study [1].

We use a copper periodic structure with wakefields frequency of 91 GHz as a PETS (power extraction and transfer structure) to transfer energy of ultra-relativistic electron beam into the RF radiation. Preliminary experiment has been conducted at the Argonne Wakefield Accelerator (AWA) drive beam line. Experimental results demonstrate the mean energy loss is 1.6 MeV of the 1.4 nC electron single bunch, corresponding to RF power generation of 0.66 MW.

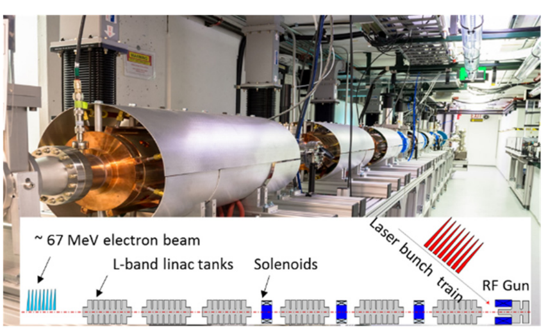

Figure 1: Layout of AWA drive beam line.

Since wakefields will be enhanced coherently when excited by bunch train with proper bunch spacing. We design the experiment aimed at 100 MW level RF generation at 91 GHz for the next run based on intense 1.3 GHz electron bunch train at AWA, with 5~10 nC charge in single bunch and up to 32 sub bunches in total.

The upgraded AWA drive beam line consists of a 1.3 GHz RF photocathode gun and 6 RF cavities [2], which has the capability to generate intense charged electron beam of 67 MeV, with picosecond RMS bunch length. AWA is designed to work at two modes of operation. In single-bunch mode, a high charge (up to 100 nC) bunch is generated. While in bunch-train mode, a laser bunch train illuminates the high current photocathode to generate an electron beam distributed up to 32 sub-bunches, with 1.3 GHz (769 ps) spacing. The electron bunch train will deliver up to ~ 1000 nC total charge. The layout of AWA is shown in Fig. 1.

ANALYSIS OF WAKEFIELD EXCITED BY BUNCH TRAIN

Two copper plates with periodic grooves make up the W-band structure, which is similar to Valery Dolgashev's 100 GHz structure [3]. We design two couplers on both end of the structure for bench test purpose and getting RF band pass. As shown in Fig. 2. We can choose the frequency by adjusting the gap between the two plates, when the gap 2a = 0.94 mm, the phase velocity is matched to the particle velocity at 91 GHz, thus wakefields interacts strongly with the on-axis bunch. The dimensions of the periodic groove in x/y/z direction are all about 1 mm, the total length of the structure L is 12.3 cm. The relative group velocity $\beta_g = \frac{v_g}{c} = 0.1$ and the loss factor is $\kappa_L = 13.3 MV/m/nC$.

Abstract

A photocathode RF gun is being developed in Tsinghua University. We measure the single cell frequency and the cell-cell coupling coefficient by a detuning method with high accuracy. This note presents the principle of the method and several examples.

INTRODUCTION

The 1.6 cell photocathode S-band gun has been used as the electron sources with high beam quality for many years. A lot of scientific research programs benefit from this type of photocathode RF gun, such as the compact x-ray source in Tsinghua University [1] and the LCLS in SLAC [2].

The achievement of a photocathode RF gun with good performance needs careful measurements and tunings of the RF cavities. However as is known the half cell of a photocathode RF gun makes the measurements of the RF properties difficult because of the cathode with no beam pipe. We can measure the full cell frequency by detuning the half cell. But if we want to obtain the frequency with high accuracy we have to detune the half cell by a large amount, which risk damaging the surface of the cathode [3]. The cell-cell coupling coefficient in photocathode RF gun is another very important parameter which influence the frequencies of both 0-mode and π-mode as well as the field balance [4]. Ref [4] give a full description of the tuning procedure for a photocathode gun, which can be used to calculate the cell-cell coupling coefficient with no approximation. However we have to measure the frequencies of the 0-mode and the π-mode, the quality factors and shunt impedances of the full cell and the half cell and the field balance for eventually calculating the cell-cell coupling coefficient.

In this paper we introduce a simple method to measure the frequencies of the full cell and the half cell and the cell-cell coupling coefficient. Only a small extra metal stick is used to detune the half-cell by a small amount. We start from the equivalent RLC circuit of the RF gun. Then we design a simplified model to show how we measure the RF gun.

BASICS OF MEASUREMENT

We can analysis an RF structure by the method of equivalent RLC circuit. The equivalent RLC circuit of the RF gun is shown in the Fig. 1. The two cells are coupled by the equivalent capacitor C. The two cells of the RF gun is different from each other. So they have different equivalent capacitors and Inductors.

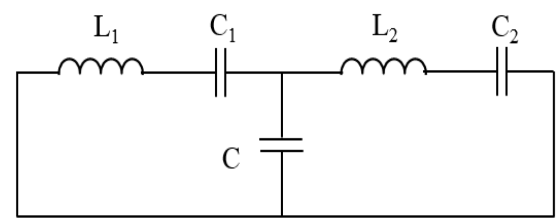

Figure 1: The equivalent RLC circuit.

We can easily obtain the relationship of the frequencies with cell-cell coupling coefficient [3]:

$$\frac{\left(f^2\right)^2}{f_h^2 \cdot f_f^2} - \left(\frac{1}{f_h^2} + \frac{1}{f_f^2}\right) \cdot f^2 + 1 - \frac{k^2}{4} = 0 \quad (1)$$

Here f is the frequency of the operating mode. The f_h and the f_f are the resonant frequencies of the half cell and the full cell. The solutions of equation (1) are the frequencies of the 0-mode and the π-mode. We can get:

$$f_0^2 + f_\pi^2 = f_h^2 + f_f^2 = x \quad (2)$$

$$f_0^2 \cdot f_\pi^2 = \left(1 - \frac{k^2}{4}\right) \cdot f_h^2 \cdot f_f^2 = y \quad (3)$$

We define two new variables x and y here. During the experiment we use a small metal stick to detune the half-cell through a laser port. So we change the frequency of the half cell while keeping the frequency of the full cell unchanged. The relationship between x and y are given:

$$y = \left(1 - \frac{k^2}{4}\right) \cdot f_f^2 \cdot x - \left(1 - \frac{k^2}{4}\right) \cdot f_f^4 = ax - b \quad (4)$$

Both of the variable x and y vary with the amount of the detuning and they have a simple linear relationship. We can easily obtain the slope and intercept of the straight

[3]CERN, Geneva, Switzerland

Abstract

With the aim to test prototype accelerating structures for CLIC at high-gradient, new klystron-based, X-band high power test stands are being built at CERN. These tests stands are referred to as Xboxes with Xbox1 and Xbox2 being already operational. Stainless steel loads are placed in the end of the Xbox-1 system to absorb the remaining power which comes out of the accelerating structure. Power information is important and needs to be measured precisely. A new power measuring method based on calorimetry is proposed independent from RF measurements subject to frequent calibration. The principles of the method and simulations are presented and the results of actual experimentation are used to validate the method. The results show calorimetric measurement is feasible method and have a good precision at this power level.

INTRODUCTION

X-boxes are X-band klystron-based high power test stands at CERN. They provide a peak power on the 50~100 MW range which generates a field gradient of about 100 MV/m in the prototype structures for the CLIC project [1]. The flexible and instrumented test stands provide important data for fundamental high-gradient studies including not only initial energy version of CLIC study but also X-band based XFEL linacs and medical linacs [2]. Xbox-1 has now been operated for over two years with the goal of conditioning and operating CLIC prototype accelerating structures. The preliminary results can be found in [3].

Stainless steel RF loads are placed in the end of Xbox-1 to absorb the remaining power which comes out of the testing structures. Power information is important for the data processing in operation and needs to be measured precisely. In order to achieve this goal, a new power measuring method based on calorimetry is proposed independent from RF measurements subject to frequent calibration.

This report describes the concept and principles of the calorimetric power measuring method. Simulation works and experimental set-up are also presented. The calorimetric power measuring experiment was done during the new CPI klystron's commissioning in Xbox-1 in 2014. The experimental results are used to validate the method and show that calorimetric measurement is a feasible method with good precision at this power level.

*wuxw12@mails.tsinghua.edu.cn

CONCEPT OF CALORIMETRIC POWER MEASUREMENT

The RF power coming out of the accelerating structures in Xbox-1 is fed into stainless steel RF loads. RF power was transformed into heat energy which will be taken away by the water cooling system in the load. In ideal situation, the RF input power should be equal as the heat energy taken away by the cooling water. The heat energy can be expressed as follows:

$$P = c \cdot \dot{m} \cdot \Delta T \, . \qquad (1)$$

P is the heat power absorbed by the cooling water. c is the specific heat capacity of water. $\dot{m}$ is the total mass flow rate of the water cooling system. ΔT is the temperature difference between input flow and output flow. The quantities $\dot{m}$ and ΔT can be measured by flowmeters which are attached to the water cooling system of the RF load. We can obtain input RF power by measuring these parameters in experiment and calculating heat power by the formula above. In order to avoid heat dissipation into ambient environment and improve measurement's accuracy, the loads are covered by heat insulation jackets.

SIMULATION OF THE LOAD

Before carrying out the experimental study of calorimetric power measurement, simulations of the RF load are needed for knowing electromagnetic and thermal properties of the system.

Basic Information of the Load

The stainless steel RF load used in Xbox-1 is double-band SS430 dry RF load, as shown in Fig. 1. The load is designed to be working at frequencies of 11.994 GHz and 11.424 GHz respectively [4]. It is made of magnetic stainless steel SS430 and consists of five functional parts which are shown in Fig. 2.

DESIGN AND RESEARCH OF SECONDARY ELECTRON EMISSION TEST EQUIPMENT WITH LOW ELECTRON ENERGY*

Yanhui Xu, Jie Wang, Bo Zhang, Le Fan, Xiangtao Pei, Yuanzhi Hong, Wei Wei, Yong Wang#,
National Synchrotron Radiation Laboratory, University of Science and Technology of China,
HeFei, AnHui 230029 China

Abstract

In particle accelerators, the secondary electrons resulting from the interaction between particles and vacuum chamber have a great impact on beam quality. Especially for positron, proton and heavy ion accelerators, massive electrons lead to electron cloud, which affects the stability, energy, emittance and beam life adversely. We have studied the secondary electron emission (SEE) of metal used for accelerators. A secondary electron emission measurement system with low electron energy has been designed and used to measure the SEE yield of metal and non-evaporable getter materials. With the equipment, we have obtained the characteristic of the SEE yield of stainless steel and oxygen free copper (OFC).

INTRODUCTION

The research of secondary electron emission has attracted great interest over the past many years [1-10]. In accelerator area, obtaining high quality beam is a main target. Under bombardment of massive particles, surface of vacuum chamber excites the secondary electrons, which affects beam quality, like stability, energy, emittance and beam life. For the reason above, measuring the secondary electron yield (SEY) of different materials is extremely critical and important. Finally, we intend to find low SEY materials used for accelerators.

Nowadays, most research institutes have measured SEY by reforming expensive SEM (scanning electron microscope) and AES (Auger Electron Spectroscopy) apparatus [2]. So we decided to design an independent secondary electron emission measurement equipment with low electron energy.

In this article, the basis for the design and some test of secondary electron emission measurement system with low electron energy was introduced.

TESTING PRINCIPLES

The secondary electron yield measurement principle is shown in Fig.1. I_p is the incident current, which causes the secondary electron emission from the surface material and I_s is the secondary electron current intensity. I_p and I_s are in opposite direction and I_t is the current flowing through the sample and is the sum of I_s and I_p. The secondary electron yield (σ) is the ratio of the secondary electron current and incident current. If I_p and I_t have been measured, we can obtain SEY value by the following formula:

$$\sigma = 1 - I_t / I_p \quad (1).$$

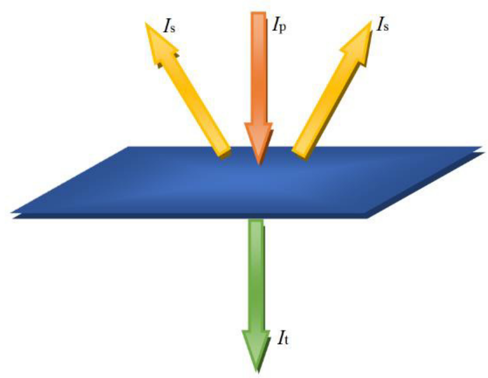

Figure 1: The SEY measurement principle.

There are two common methods of measurement: RP (Retarding Potential) method and ZR (Zero Retard) method. RP method can only measure vertical incident electron, because the electric field of sample bias in the case of oblique incidence will change the direction of the incident electron motion, so some incident electrons will not get to the sample surface. The sample is grounded with the method of ZR, and the bias voltage of the electron gun falls from zero to -300 V where the space charge effect appears, which is the main disadvantage of this method. In this mode, the incident current is changed with the increase of accelerating voltage, so both I_p and I_t need to be measured and recorded, then SEY value can be calculated by formula(1).

In further research, incident current I_p can be measured by a Faraday cup, which can reduce the irradiation time of the electron gun to the sample surface, so the charge accumulation of the sample surface will be less and the result accuracy will be improved. The schematic diagram of the Faraday cup is shown in Fig.2. Elastic scattering electrons from the surface will scatter to test indoor wall and produce secondary electrons, and these secondary electrons will cause a certain extent error to the measurement of I_s if reaching the sample surface. In order to eliminate this impact, some negative bias is applied on the samples.

OPTIMIZATION DESIGN OF Ti CATHODE IN CERAMIC PIPE FILM COATING BASED ON THE SIMULATION RESULTS OF CST*

Jie Wang, Yanhui Xu, Bo Zhang, Wei Wei, Le Fan, Xiangtao Pei, Yuanzhi Hong, Yong Wang#,
National Synchrotron Radiation Laboratory，University of Science and Technology of China, HeFei, AnHui 230029, China

Abstract

The injection chamber at Hefei Light Source II (HLS II) consists of four ceramic vacuum chambers whose inner surface were coated with TiN thin film. The cross section of ceramic pipes is special racetrack structure. In order to improve the uniformity of the film, the structure of the cathode Ti plate needed to be optimized. In this article, CST PARTICLE STUDIO™ software had been used to simulate the influence of different target structure on discharge electric field distribution and electrons trajectories. Furthermore, the reliability of the simulation were analysed compared with the experimental results. Also, we put forward the optimization design of Ti cathode structure which could satisfy the requirement of uniformity of the thin film.

INTRODUCTION

TiN thin film causes great interest because of its low secondary electron yield (SEY), good electrical conductivity, stability of performance, ability to block hydrogen permeation, etc. [1-3]. TiN film deposition methods include DC magnetron sputtering, DC sputtering, hollow cathode discharge ion plating (HCD-IP) [4], RF sputtering et al. In general, the substrates are mainly flat plates, stainless steel cylindrical pipe [5], and ceramic vacuum chamber [6]. However, for some irregular type ducts, such as the racetrack type (Fig. 1) ceramic chamber in accelerators, the shape of the ceramic pipe will induce new and considerable technological difficulties for the uniformity of TiN coating which is important for vacuum performance and beam stability in the pipe.

Ceramic vacuum chamber is the key equipment of the electron storage ring injection system which was made of 99.9% pure alumina. The electrons injection chamber at Hefei Light Source II (HLS II) consists of four ceramic vacuum chambers whose inner surface are coated with thin conductive metal film, and the length of each vacuum chamber was 350 mm. Typically TiN or Ti are chosen while the sheet resistance of the film should be 0.3-0.8 Ω/sq. It was an extremely valuable research that how to get uniform TiN film which has high quality and meets the requirements of the physical design of the storage ring, such as mitigating the electron cloud instability [7]. This article mainly focuses on optimization design of Ti cathode in ceramic pipe which based on the simulation results of CST.

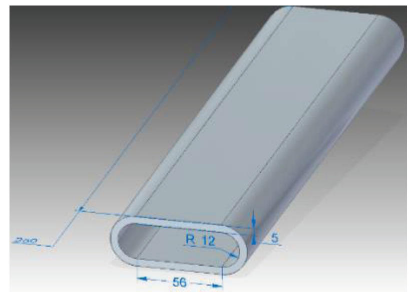

Figure1: A diagram of a ceramic vacuum pipe.

APPARATUS AND METHODS

Coating System

The TiN films are deposited onto the interior wall of ceramic vacuum pipe which is shown in Fig. 1, using DC magnetron sputtering method. The deposition system which is shown in Fig. 2 consists of observation window, 300 l/s turbo molecular pump, DC power supply, vacuum gauge, vacuum chamber and gas flow control system. Argon gas and nitrogen are introduced into the sputtering system through an adjustable leak valve. The typical sputtering parameters are: ~ -600 V cathode voltage, 5×10^{-1} torr gas pressure, 2:1 nitrogen and argon gas flow ratio, 200 Gauss magnetic field strength and 0.5 A sputtering current.

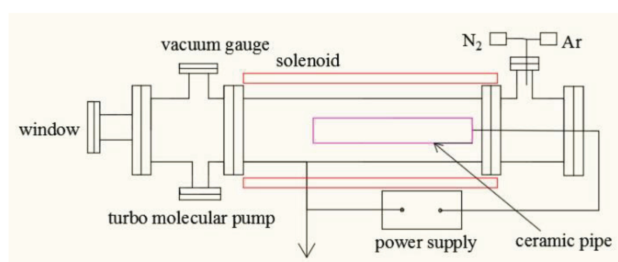

Figure 2: Schematic diagram of DC sputtering coating system.

TiN Coatings

Thickness was measured by use of a Sirion 200 Schottky field scanning electron microscope (SEM). Fig. 3 shows the cross-sectional and surface SEM morphology of specimen TiN film. It can be seen that the TiN film has a columnar structure which are mostly perpendicular to the film surface.

VACUUM SYSTEM OF THE STORAGE RING OF HLS-II

Yong Wang#, Xiangtao Pei, Wei Wei, Bo Zhang, Le Fan, Yuanzhi Hong, Jie Wang, National Synchrotron Radiation Laboratory，University of Science and Technology of China, HeFei, AnHui 230029 China

Abstract

HLS storage-ring has been operated for more than twenty-five years. In 2014 we began to upgrade the machine, which is called HLS-II. The emittance is reduced to 40 nmrad, five insertion devices are added and the injection energy increases to 800MeV. Now the machine commissioning has already been completed. The typical life time is 300 mins at 300mA, 800MeV. The average pressure of static and dynamic vacuum are below 2×10-8 Pa and 1.2×10-7 Pa respectively. The design, installation and commissioning of the vacuum system of the storage ring are detailedly stated in this paper.

INTRODUCTION

The 800MeV electron storage ring of the National Synchrotron Radiation Laboratory (NSRL) is a dedicated VUV and soft X-ray synchrotron radiation light source. The construction of NSRL facility began on November, 1983 and was completed in 1989. HLS comprises of 200 MeV injector, 800 MeV storage ring, 12 beamlines and 15 experimental stations by 2010. In order to supply synchrotron light with higher brightness and stability to the users, the upgrading project of HLS has been carried out during 2010-2014. The main changes of the new HLS (HLS-II) include: The energy of the injector increases to 800 MeV, so the electrons can be injected to the storage ring with full energy. The lattice of the storage ring was changed from TBA to DBA. The beam emittance decreased to 40 nmrad. A group of multifunctional sextuple magnets are employed and thus the long and short straight section are both lengthened. Five insertion devices were installed in the storage ring.

A VACUUM SYSTEM OF STORAGE

The storage ring's circumference is 63.66 meters. The main vacuum pipes are made of 316LN stainless steel by welding. The section is octagonal as shown in Fig. 1. To reduce surface degassing and magnetic permeability induced by welding, the chambers are baked at 900 °C in the vacuum furnace. After this treatment, vacuum chambers of the total leak rate, outgassing rate and magnetic permeability are below 2×10^{-8} Pa L/s , 2×10^{-11} Pa L/s cm^2 and 1.02 respectively, which meet the design requirements. Considering the convenience of installing, commissioning and maintenance, 3 RF-shielded all-metal gate valves are used to separate the storage ring into three cells. 20 UHV gauges are distributed in the storage ring to monitor the vacuum and also for interlock protection system.

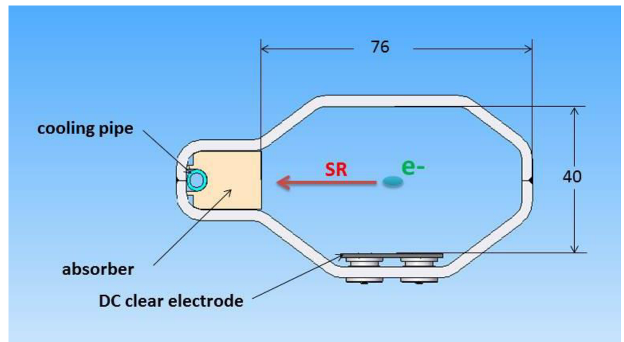

Figure 1: The section of the main vacuum pipe.

Because of the low electron energy, the deflection angle of the dipole magnet is relatively large, so the synchrotron light can hardly be absorbed by a lumped photon absorber. To ensure thermal stability of the vacuum pipes and reduce photon stimulated desorption, water-cooled absorbers made of oxygen-free copper which can protect the inner surface of the dipole magnet pipe from being hit by the synchrotron light, are arranged in the pipes along the beam direction and near the light outlet, as shown in Fig. 2. The absorbers in the pipes also act as supports and simplify the design of vacuum pipes.

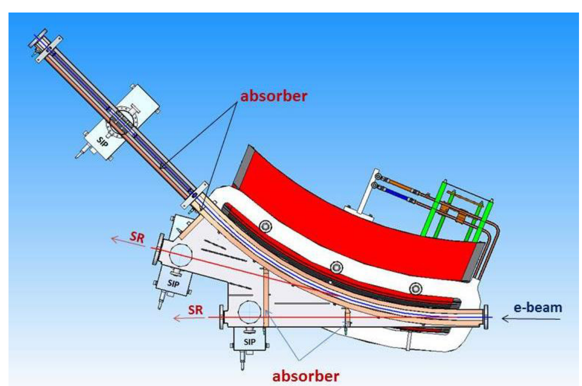

Figure 2: A standard segment of the storage ring.

18 RF-Shielded bellows are adopted to eliminate the machining and installing errors, deformation induced by temperature difference, and for the smooth transition of chambers with different sections. The bellows are machined by welding with high stability. Considering the smooth transition of chambers and high frequency contact resistance, the RF shield is achieved by using shield fingers. Shield fingers (Cu-Be) which bridge the gap between neighbouring flanges inside the welding bellows.

EXPLORATION OF MULTI-FOLD SYMMETRY ELEMENT-LOADED SUPERCONDUCTING RADIO FREQUENCY STRUCTURE FOR RELIABLE ACCELERATION OF LOW- & MEDIUM-BETA ION SPECIES

Shichun Huang[#, 1,2], R.L. Geng[3]
[1] IMP, CAS, Lanzhou 730000, China
[2] UCAS, Beijing 100049, China
[3] JLAB, Newport News, VA 23606, USA

Abstract

Reliable acceleration of low- to medium-beta proton or heavy ion species is needed for future high current superconducting radio frequency (SRF) accelerators. Due to the high-*Q* nature of an SRF resonator, it is sensitive to many factors such as electron loading (from either the accelerated beam or from parasitic field emitted electrons), mechanical vibration, and liquid helium bath pressure fluctuation etc. To increase the stability against those factors, a mechanically strong and stable RF structure is desirable. Guided by this consideration, multi-fold symmetry element-loaded SRF structures (MFSEL), cylindrical tanks with multiple (n>=3) rod-shaped radial elements, are being explored. The top goal of its optimization is to improve mechanical stability. A natural consequence of this structure is a lowered ratio of the peak surface electromagnetic field to the acceleration gradient as compared to the traditional spoke cavity. A disadvantage of this new structure is an increased size for a fixed resonant frequency and optimal beta. This paper describes the optimization of the electro-magnetic (EM) design and preliminary mechanical analysis for such structures.

INTRODUCTION

SRF acceleration has become an enabling technology and many SRF accelerators are under construction or proposed world-wide for research in fundamental sciences and applications of society importance. TEM-type cavity structures, such as Quarter Wave Resonator (QWR), Half Wave Resonator (HWR) and spoke cavities [1] are usually chosen for accelerating protons or heavy ion species at low and medium beta (beta=v/c). Future heavy ion colliders such as MEIC [2], HIAF [3] are examples of proposed heavy ion machines that require SRF acceleration. A particular accelerating structure has its advantages and disadvantages over others in terms of mechanical (such as susceptibility to environmental vibrations and liquid helium pressure fluctuations), RF (such as peak surface electric and magnetic fields), and cryogenics (such as dynamic heat load). The consideration of high stability and high performance drives this present effort of exploring a mechanically strong and stable RF structure. For MFSEL structures, cylindrical tanks with multiple (n>=3) rod-shaped radial elements (see Fig. 1) were investigated as a starting point. The 3D computer simulation codes CST MWS and ANSYS were used to study electromagnetic and mechanical parameters, respectively. This paper provides the preliminary results of these types of structures.

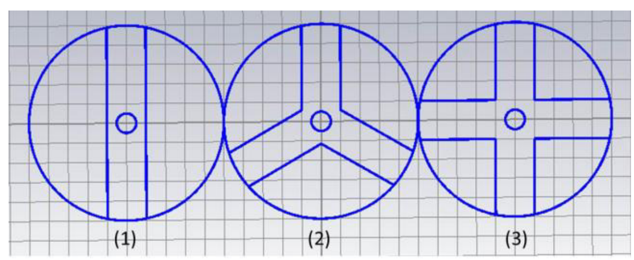

Figure 1:The general schematic of single-spoke structure (1) and MFSEL structure; three-fold (2) and four-fold (3).

EM DESIGN

The EM design of a multi(n=3,4)-fold symmetry element-loaded structure is to be compared with a baseline structure designed for high intensity proton acceleration in the framework of accelerator-driven system efforts at IMP [4] The baseline structure is a single spoke cavity with a beta = 0.32 and a frequency of 325 MHz. The MFSEL was originally proposed for muon acceleration [5]. More recently, similar structures were studied [6]. Figure 2 shows the side-cut view of a three-fold (TFSEL) symmetry element-loaded RF structure, with geometric dimensions as used in the numerical optimization. The geometric dimensions of the four-fold (FFSEL) symmetry element-loaded RF structure are similar to that of the TFSEL structure.

HARMONIC RESONANT KICKER DESIGN FOR THE MEIC ELECTRON CIRCULAR COOLER RING*

Y. Huang#, IMP, CAS, Lanzhou 730000, China & UCAS, Beijing 100049, China
H. Wang, R.A. Rimmer, S. Wang, JLab, Newport News, VA 23606, USA

Abstract

Bunched-beam electron cooling of the high-energy ion beam emittance may be a crucial technology for the proposed Medium energy Electron Ion Collider (MEIC) to achieve its design luminosity. A critical component is a fast kicker system in the Circular Ring (CR) that periodically switches electron bunches in and out of the ring from and to the driver Energy Recovery Linac (ERL). Compared to a conventional strip-line type kicker, a quarter wave resonator (QWR) based deflecting structure has a much higher shunt impedance and so requires much less RF power. The cavity has been designed to resonate simultaneously at many harmonic modes that are integer multiples of the fundamental mode. In this way the resulting waveform will kick only a subset of the circulating bunches. In this paper, analytical shunt impedance optimization, the electromagnetic simulations of this type of cavity, as well as tuner and coupler concept designs to produce 5 odd and 5 even harmonics of 47.63MHz will be presented, in order to kick every 10^{th} bunch in a 476.3 MHz bunch train.

INTRODUCTION

Cooling of ion beams is critical in delivering high luminosities for the proposed MEIC [1].The present MEIC design utilizes a scheme of multi-stage cooling. In the booster, a DC cooler is used to assist accumulation of injected positive ions and reduce the beam emittance at the low energy. In the ion collider ring, an electron cooler utilizing high energy bunched beam will be responsible for cooling the medium energy ions to suppress intra-beam scattering (IBS) and maintain emittance during collisions. Two critical accelerator technologies in the bunched beam electron cooler are an ERL and a circulator ring (CR) to reduce the current and power of the cooling electron beam from the source and linac. As illustrated by the schematic drawing in Fig. 1, electron bunches are accelerated in an SRF linac, and then kicked into a closed ring that includes part of the ion collider storage ring. In this ring, electron bunches will be merged with the ions, and continuously cool the ion bunches in a long cooling channel, and then return to the linac for energy recovery after 25turns in the CR. In the present MEIC baseline design, the collision frequency is 476.3MHz, thus the repetition frequency of the electron bunches is 476.3MHz in CR and 19.052MHz in the ERL. A critical component in this scheme is a fast kicker system in the CR that periodically switches electron bunches in and out of the ring from and to the driver ERL. When the electron bunches are kicked into the CR (476.3MHz), every bunch in the ERL (19.052MHz) is kicked; when kicked out, every 25^{th} bunch is kicked and other 24 bunches are, ideally, undisturbed. The electron energy is 55MeV, assuming the kick angle is 0.001 rad, thus the kick voltage needed would be 55 kV. In the first R&D design, we just consider kicking every 10^{th} bunch in order to simplify the problem. The kick voltage pulse and bunch distance scheme is shown in Fig. 2 (red).

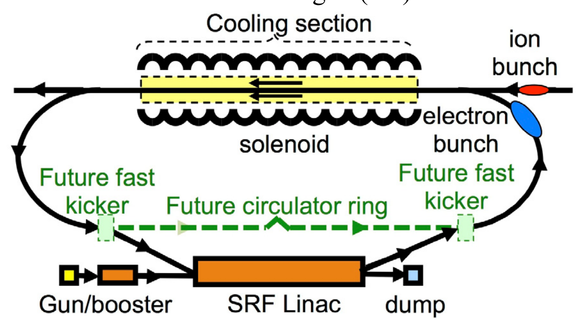

Figure 1: A schematic drawing of a bunched beam cooler based on an ERL, with bypass circulator ring connection in green.

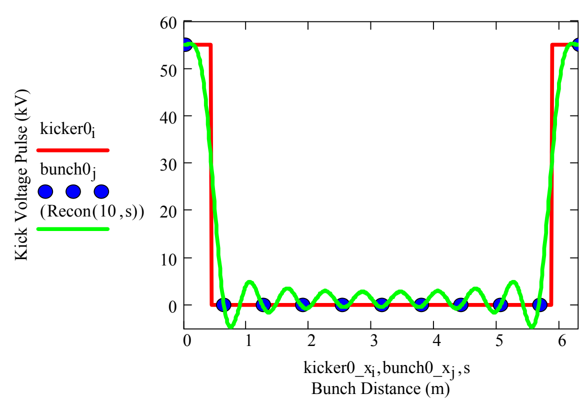

Figure 2: Ideal kicker voltage pulse (red) and bunch train scheme (blue) to kick every 10^{th} bunch, and the reconstructed kicker pulse with the first 10 harmonic modes (green).

GENERATION OF KICK VOLTAGE WITH FINITE HARMONIC MODES

The periodical kick voltage pulse can be described mathematically as a Fourier series expansion in compact trigonometric form [2]:

$$V_t = V_0 + \sum_{n=1}^{\infty} V_n \cos(n\omega_0 t + \varphi_n) \qquad (1)$$

Where V_t is the total kick voltage, the constant term V_0 represents a DC offset, ω_0 is bunch repetition frequency

DEVELOPMENT OF NON-RESONANT PERTURBING METHOD FOR TUNING TRAVELING WAVE DEFLECTING STRUCTURES

Jianhao Tan, Dechun Tong, Qiang Gu, Wencheng Fang, Zhentang Zhao*, SINAP, CAS, China

Abstract

For traveling wave accelerating structures, the tuning method assisted by bead pull technique based on non-resonant perturbation field distribution measurement has been widely applied. The method is also suitable for deflecting structures, but some key considerations of the field components of HEM11 mode and the selection of bead are discussed. A cage type of perturbing object has been made and applied on non-resonant perturbation measurements. The measurements on an S-band traveling wave deflecting structure are presented.

INTRODUCTION

Non-resonant perturbing method has been widely used on accelerating structure for field distribution measurement and guiding tuning procedure. For the purpose of tuning deflecting structure, non-resonant perturbing technology has been developed and applied for field distribution measurement in deflecting structure. As described in ref [1], non-perturbation method, which make the field measurement procedure fast, especially for long-period structure, and it uses direct measurements of the field distribution in the structure. For measurement and tuning travelling wave deflecting structure, the bead pull measurement based on non-resonant perturbation theory has been developed and will be applied.

NON-RESONANT PERTURBATION THEORY

According to the non-resonant perturbation theory [2], the reflection coefficients are measured at the input port of the structure in the absence of the perturbation object and in its presence. When the perturbing bead moves along a line from input port to output port, the magnitude and phase distribution of the electromagnetic field could be collected, which could be applied to get the information for tuning of the structure after the post-processing.

In non-resonant perturbation theory, the reflection coefficient and the field distribution in the structure have the relationship as follows:

$$2P_i(\Gamma_p - \Gamma_a) = -j\omega(k_e E_a^2 - k_m H_a^2) \tag{1}$$

Where Γ_p and Γ_a are the reflection coefficients in the input port in the presence and absence of the perturbing object, respectively. Ea and Ha are the complex vectors of the electric and magnetic field at the position of the bead in the structure, respectively. It is well known that, for traveling wave accelerating structure, the TM01 mode is used for beam acceleration, and the electric field EZ is the unique field component on axis. Then Eq. 1 becomes scalar equation, name as Eq. 2

$$\Delta S_{11} = S_{11p} - S_{11a} = \frac{-j\omega k_e}{P_i} E_z^2 = K_{ez} E_z^2 \tag{2}$$

Where ΔS_{11p} and ΔS_{11a} are reflection coefficients in the presence and absence of perturbation object, respectively, acquired from the NetWork Analyzer. $E_Z(z)$ is the electric field on axis, as the perturbing object goes through the structure along z, it is obvious that the amplitude of E_Z is proportional to the square root of the amplitude of ΔS_{11}, and the phase of E_Z is the half of the phase of ΔS_{11}, the information of measuring for tuning is collected.

For a deflecting structure, the operating mode is HEM11, which is a hybrid of TE11 and TM11 mode [3], and the field components have been calculated in [4]. Then Eq. 1 becomes a complicated equation, named as Eq. 3

$$\Delta S_{11} = \textstyle\sum_{i=x,y,z} (K_{ei} E_i^2 - K_{mi} H_i^2) \tag{3}$$

Where E_i and H_i are electric and magnetic field in different directions, respectively, K_i is defined as form factor of perturbing object. Further consideration, Eq. 3 can be expressed as,

$$\begin{aligned}\Delta S_{11} = \sum &[(K_{ei}|E_i^2|\cos 2\varphi_i + j|E_i^2|\sin 2\varphi_i) \\ &- (K_{mi}|H_i^2| + j|H_i^2|\sin 2\varphi_i)]\end{aligned} \tag{4}$$

Where φ_i and Ψ_i are the phase of electric and magnetic field. Eq. 4 indicate that, it is a multi-element complex equation, becomes difficult and complicated for measuring and guiding tuning multi-cell deflecting structure. A fast and reliable method for measurement is desperately needed.

In the travelling wave structure, the magnitude of E_Y and H_X nearly homogeneous on the axis cell by cell, but the positions of E_Y and H_X at their maximum are iris center and cavity center, respectively. For other four field components, except E_Z exist in coupler cavity, the distribution of E_Z, E_X, H_Y, and H_Z could be ignored in the structure on axis. Figure 1 shows the magnitude and phase distribution of E_Y and H_X along z. The magnitude and phase distribution in Figure 1(b) and (c), comparing with schematic drawing of structure in Figure 1(a), indicate that the electric field E_Y has maximum magnitude and flat phase shift in the iris center, on the contrary, H_X in the cavity center.

PRELIMINARY MECHANICAL DESIGN OF CERAMIC PIPE FILM COATING EQUIPMENT AT HEFEI LIGHT SOURCE II *

Jie Wang†, Yanhui Xu, Bo Zhang, Wei Wei, Le Fan, Xiangtao Pei, Yuanzhi Hong, Yong Wang#,
National Synchrotron Radiation Laboratory， University of Science and Technology of China, HeFei, AnHui 230029 China
Jiadong Lu†, School of Automation, Northwestern Polytechnical University, Xi'an, Shanxi 710072 China

Abstract

Ceramic vacuum chambers are important components of the injection chamber at Hefei Light Source II (HLS II). The length of each Ceramic vacuum chamber is 350 mm and their inner surface is coated with TiN thin film whose properties are low secondary electron yield (SEY), good electrical conductivity, stability of performance, ability to block hydrogen permeation. Considering that the cross section of Ceramic pipe is racetrack structure, Ti plate was chose as the cathode to improve TiN thin film deposition rate. Meanwhile, the authors designed a motor drive magnetron sputtering film coating equipment to obtain uniform TiN film.

INTRODUCTION

Ten years ago, ceramic chambers and ferrite kicker magnets were developed in HLS injection system and the inner surface of the ceramic chambers was coated with 0.1 ohm/square metallic Mo layers to meet the requirements of both the penetration of pulse magnetic field and small beam coupling impedance [1]. Now TiN or Ti are chosen as the metal coating material of the ceramic vacuum chamber in HLS II [2-6]. Furthermore, for the purpose of improvement of the deformation and uniformity of the thickness, Ling-Hui Wu et al. designed and fabricated a ceramic chamber using Ti films [7]. However, for some irregular type ducts, such as the racetrack type (Fig. 1) ceramic chamber in accelerators, the shape of the ceramic pipe will induce new and considerable technological difficulties for the uniformity of TiN coating which is important for the vacuum and beam stability in the pipes of storage ring.

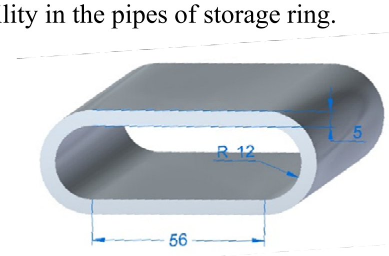

Figure1: A diagram of a ceramic vacuum pipe.

APPARATUS AND METHODS

Coating System

The TiN films are deposited onto the interior wall of ceramic vacuum pipe which is described in Fig. 1. The cross-section of shaped ceramic vacuum chambers in the system is a special type of racetrack with a small aperture. The schematic diagram of DC magnetron sputtering coating system which mainly consisted of vacuum gauge, solenoid, cathode, gas flow control system, power supply, 300 l/s turbo molecular pump and ceramic pipe, was shown in Fig. 2.

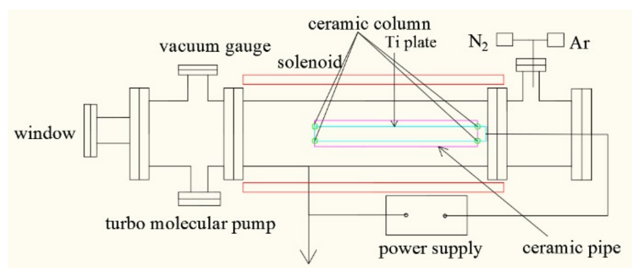

Figure 2: Schematic diagram of DC magnetron sputtering coating system.

The Uniformity of TiN Film and Electric Field Distribution

The electrostatic solver of CST software was used to simulate the electric field distribution in the case of ceramic pillars as cathode brace, during glow discharge. In this simulation, the voltage of the cathode plate and ceramic pillars was -680 V and 0 V respectively. In Fig. 3, the location of green arrow is the position of the ceramic pillars. According to the scale on the right side of Fig. 3, the electric displacement vector on the position of four ceramic pillars is two times higher than that on both ends of Ti cathode plate and also higher than other parts of the ceramic pipe. The electric field distortion caused that film thickness near the ceramic pillars is greater than the one on other parts, which also can be seen from Fig. 4. Therefore, the results of the simulation basically matched experimental results.

TESTING PROCEDURES FOR FAST FREQUENCY TUNERS OF XFEL CAVITIES

K. Przygoda#, J. Branlard, O. Hensler, H. Schlarb, C. Schmidt, DESY, Hamburg, Germany
K. Kasprzak, IFJ-PAN, Cracov, Poland
W. Cichalewski, T. Pozniak, DMCS, Lodz, Poland

Abstract

The XFEL accelerator will be equipped with 100 accelerating modules. Each accelerating module will host 8 superconducting cavities. Every single cavity will be equipped with a mechanical tuner. Coarse tuning will be supported by a step motor. A fine tuning will be handled by double piezoelectric elements installed inside a single mechanical support, providing actuator and sensor functionality or redundancy. Before the main linac installation, all its subcomponents need to be tested and verified. The AMTF (Accelerator Module Test Facility) has been built at DESY to test all XFEL cryomodules. In total 1600 piezos need to be tested. Test procedures for fast frequency tuners have been developed to check their basic performance in cryogenic conditions (tuning range, acting and sensing abilities). High level applications have been first developed and next adopted to perform fully automated tests including report generation and data base storage. After the successful completion of the acceptance tests, the cryomodules will be prepared for tunnel installation.

INTRODUCTION

The 36 accelerating modules equipped with 1.3 GHz superconducting (SC) resonant cavities have been delivered to DESY since February 2014. The 26 (including 3 pre-series) cryomodules have been tested using AMTF test stand. The AMTF test stand has been equipped with 3 independent RF stations supported by cryogenic subcomponents, RF waveguide distributions and RF sources. The each RF station has been installed with LLRF control system based on MTCA.4 technology [1].

The pre-series and a few of first regular series of XFEL modules have been fully tested with both piezo tuners installed per single cavity including: DC scans, LFD compensation and microphonics measurement. The rest of the tests of regular XFEL 1.3 GHz modules have been reduced mainly due to time limitation (e.g. to train operators, limited space at storage buffer, sharing resources with 3 GHz modules) and technical problems (broken couplers, RF source problems, cabling issues).

The piezo DC scans have been proposed for checking not only the typical tuning range foreseen for the Saclay II model of the piezo tuner but also locating piezo looseness (mechanical mistake during piezo assembly), shorts on the cables and inside connectors or mistakes in cabling pinout (reversed piezo polarity). The acceptance criterion for piezo tuning range has been agreed to not be less than 850 Hz of cavity absolute static detuning value.

Lorentz force detuning (LFD) compensation can play crucial role not only for regular operation at high RF gradient conditions (above 30 MV/m) but also to evaluate the quench limit conditions for each cavity per accelerating module [2]. The actuator functionality of supporting piezo elements applied for each cavity has been checked. The LFD factor has been measured for each cavity for both middle (between 10 and 15 MV/m) and high gradient (between 19 and 30 MV/m) operating conditions. The acceptance test threshold has been initially set to be below 10 Hz of static and dynamic detuning values and next relaxed due to time constraints foreseen for the tests (less than 50 Hz).

The sensor functionality of each piezo element has been evaluated to study the main sources of the mechanical vibrations that can additionally modulate resonance frequency of the cavity. The dominated frequency component for all tested cavities has been located at 50 Hz (see Fig. 1).

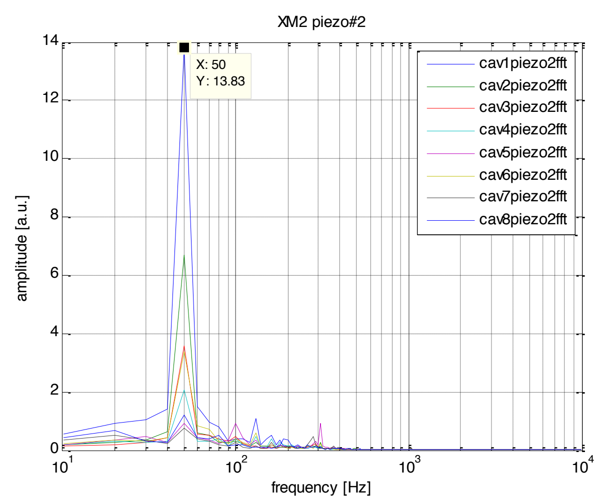

Figure 1: Microphonics measurement at XM-2 module.

Due to limited time the test procedure has been excluded from the regular tests.

LLRF CONTROL

The single RF station at AMTF has been installed together with LLRF control system designed according to MTCA.4 standard. The LLRF control system has been packed inside 9U, 12-slot crate equipped with cooling units, redundant power supply (PS), MTCA Carrier Hub (MCH), CPU and HDD, Advanced Mezzanine Card backplane (AMCB). In addition, the crate is equipped

AUTOMATED QUENCH LIMIT TEST PROCEDURE FOR SERIAL PRODUCTION OF XFEL RF CAVITIES

Karol Kasprzak, Daniel Konwisorz, Krzysztof Krzysik, Szymon Myalski, Jacek Swierblewski, Katarzyna Turaj, Mateusz Wiencek, Agnieszka Zwozniak, IFJ PAN, Krakow, Poland
Denis Kostin, Konrad Przygoda, DESY, Hamburg, Germany

Abstract

In the Accelerator Module Test Facility (AMTF) at DESY in Hamburg RF cavities and accelerating cryomodules are tested for the European X-ray Free Electron Laser (XFEL). Measurements are done by team of physicists, engineers and technicians from The Henryk Niewodniczanski Institute of Nuclear Physics Polish Academy of Sciences in Krakow, Poland, as a part of Polish in-kind contribution to XFEL. The testing procedures providing information about maximum available gradient and heat loads measurement are performed for the high gradients (up to 31MV/m). During these tests the cavity deformation caused by the Lorentz force is compensated by piezo (fast) tuners. For this purpose automated high level software was developed. This paper describes a method used to tune automatically the cavities during the RF tests. It was validated with the XFEL cryomodules. This improvement was implemented into the testing software and it is successfully used for testing of serial production cavities.

INTRODUCTION

In the Accelerator Module Test Facility (AMTF) at DESY in Hamburg serial-production accelerating cryomodules for the European X-ray Free Electron Laser (XFEL) are tested. Currently (status 28 April 2015) 28 out of 101 modules have been tested. The two vital acceptance measurements for them are called: flat top and heat loads [1, 2].

From RF point of view, during these measurements, it is critical to automatically regulate RF fields inside the cavities. It is essential for the time schedule as well as for the precision of the measurement. This is done by the high level feedback controller that regulates step (slow) motor and piezo actuators. The software is written in LabVIEW (see Fig. 1) . It was validated and successfully used for cryomodules testing.

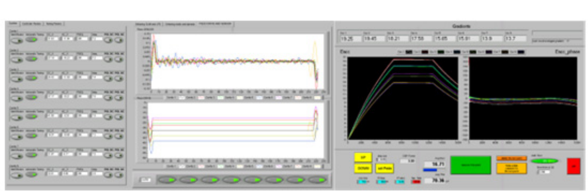

Figure 1: The controller software (left) and test software (right) during the heat loads measurement of the cryomodule XM33.

TESTING PROCEDURE

Flat Top Measurement

The aim of the flat top measurement is to obtain the following cavity parameters:

a) gradient when field emission is started – is visible on the X-ray detectors
b) (if possible) gradient when radiation starts exceeding 10^{-2} mGy/min
c) the maximum gradient (0.5 MV/m less than the quench, measured up to 31 MV/m)
d) power measured for the maximum gradient

31 MV/m is the gradient equivalent to maximum power for the single cavity, which will be available in the XFEL tunnel with respect to the planned klystron power (10 MW), losses in the waveguide system and power distribution. Single klystron will supply 4 cryomodules (in sum 32 cavities).

Also during this measurement the operating gradient is obtained as the minimum value from:

a) gradient when radiation starts exceeding 10^{-2} mGy/min
b) the maximum gradient
c) gradient when temperature measured on the input power coupler rises rapidly
d) gradient when input power coupler vacuum rises rapidly

Heat Loads Measurement

The aim of the heat loads measurement is to evaluate thermal loads during normal XFEL cryomodule operation. From the RF point of view, this procedure is done by changing power distribution in the waveguides. Values saved during flat top measurement are used as reference. As a result the cavities gradients used during heat loads measurement are limited by:

- operating gradient taken from the flat top measurement or
- 23.6 MV/m (XFEL goal gradient)

Furthermore, the waveguide power distribution during the AMTF measurements is paired, which means that the same power is set to the neighboring cavities. This determines the chosen gradient as the weakest from the cavity pair (1-2, 3-4, 5-6, 7-8).

MICROPHONIC DISTURBANCES PREDICTION AND COMPENSATION IN PULSED SUPERCONDUCTING ACCELERATORS

R. Rybaniec*, L.J. Opalski, ISE WUT, Warsaw, Poland
V. Ayvazyan, L. Butkowski, S. Pfeiffer, K. Przygoda, H. Schlarb, Ch. Schmidt
DESY, Hamburg, Germany

Abstract

Accelerators are affected by the cavities detuning variation caused by external mechanical disturbances (microphonics). The paper presents microphonics estimation and prediction methods applicable for superconducting accelerators operating in pulsed mode. A mathematical model is built using the estimates of detuning during previous RF pulses. The model can be used for predictions of disturbances for the future time step and setup of the fast tuners accordingly. The proposed method was successfully verified with measurements conducted at the FLASH linac.

INTRODUCTION

Located at DESY, FLASH and currently constructed XFEL [1] are examples of the Linear Particle Accelerators (linacs) built using superconducting technology. Those linacs operate in pulsed mode regime. Because of the high operating gradients reaching up to 40 MV/m, during the pulse, RF cavities are detuned by the magnetic field pressure phenomena. In a RF cavity, electromagnetic field induces surface current and surface charges on the wall of the cavity. Interaction of the surface currents with a standing wave inside cavity generates a pressure, which mechanically deforms the cavity and as a consequence detunes it from the nominal frequency. In the literature it is known as Lorentz force detuning (LFD).

Another source of the detuning is caused by external mechanical forces acting on the RF cavities called microphonics. In opposite to the Lorentz force detuning, microphonics are generally not synchronized to the RF operation. Some sources of the microphonics are the helium plant, ground motions and man made machinery [2]. Pulsed mode operation at FLASH consists of the approx. 1.3 ms RF pulses with a repetition rate of 10 Hz. Time during the RF pulse is insufficient to measure the microphonic disturbance and compensate for it during the same pulse.

Due to a very high quality factor of superconducting cavities, detuning decreases the power transferred from the RF system. This reduces the RF system efficiency and also makes controlling stability of the accelerating gradient more difficult. In a situation where a high power amplifier is shared between many cavities, accelerating field control becomes more complicated, because detuning affects each cavity separately.

Conceptually (Fig. 1) it is possible to compensate for microphonics by predicting its level based on the information

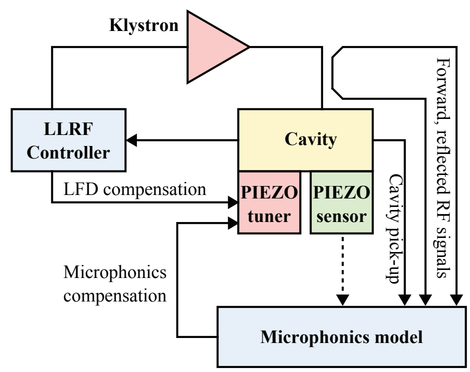

Figure 1: Block diagram of the proposed microphonics compensation method for a linac operating in pulsed mode.

from previous pulses. To enable this, a microphonics model has to be build during an operation of a facility. Possible information sources are RF signals during the pulse and (optionally) piezo sensors output in the time between the pulses. Piezo actuator can be used for fast tuning of the cavity based on the knowledge from the model, in the similar way as it is used for Lorentz force detuning compensation. This could decrease the amount of microphonic disturbances affecting the cavity.

In the paper a first implementation of this concept is evaluated. In the first attempt a simple auto-regressive (AR) model for the microphonics is used. Disturbances are estimated using the detuning computed from the RF signals. The method was validated with the open-loop measurements at the FLASH linac. First results show potential reduction of the detuning caused by microphonic disturbances in the accelerators operating in a pulsed mode.

MICROPHONIC DISTURBANCES ESTIMATION AND PREDICTION

During an operation of the facility, detuning of SRF cavities can be computed [3] using RF signals. This is accomplished with the first order cavity model [4]:

$$\frac{d\mathbf{V_c}}{dt} + (\omega_{1/2} - j\Delta\omega)\mathbf{V_c} = K_g \cdot \mathbf{V_g},$$

where $\mathbf{V_c}$ - cavity pick-up signal, $\omega_{1/2}$ - half-bandwidth of the cavity, $\Delta\omega$ - detuning and $K_g \cdot \mathbf{V_g}$ - is the calibrated generator voltage, calculated from the forward and reflected power signals. After separation of the real (I) and imaginary (Q) parts of the complex numbers, detuning can be

THE FABRICATION OF PROTOTYPE NORMAL CONDUCTING REBUNCHER FOR THE MEBT IN RISP

Hye-Jin Kim*, Myung Ook Hyun, Bum-Sik Park
RISP, Institute of Basic Science, Daejeon, Korea

Abstract

The Medium Energy Beam Transport (MEBT) system of RAON consists of several quadrupole magnets for controlling the transverse beam parameter at the entrance of the low energy linac, three normal-conducting (NC) re-bunchers to match the longitudinal beam ellipse into the acceptance of the low energy linac and several diagnostic devices. The NC QWR re-buncher, which has a frequency of 81.25 MHz, a geometric beta factor of 0.032, and an effective length of 24 cm, has been fabricated and tested to demonstrate the frequency tuning by using slug tuner, power transmission and reflection with low input power, and pulsed high power transmission with cooling channels. In this presentation, we show the design and fabrication criteria for the high power, ~ 10 kW, re-buncher and its test results.

INTRODUCTION

The Medium Energy Beam Transport(MEBT) line system, which is located between the RFQ and the SCL, requires matching of the optical parameters in the transverse plane and removal of the unaccelerated ion beams from the RFQ. It also includes beam diagnostic devices to measure and control the beam quality and Twiss parameter at the entrance of the linac during a beam operation [1,2]. In our designed MEBT line, three normal-conducting re-bunchers with 81.25 MHz (β_g = 0.032) quarter wave resonators (QWRs) and eight room-temperature quadrupole magnets were chosen for the beam bunching, beam transport and matching. Strip-line beam position monitors, current monitors, a bunch length monitor, beam collimators and steering magnets are also installed in the MEBT line. The designed MEBT line can accept and control the transverse and the longitudinal distributions of several beams such as the 500 keV/u ^{238}U beam, the 500 keV proton beam, and the 500 keV/u ^{18}Ar beam [3].

ELECTROMAGNETIC AND MECHANICAL DESIGN

Two gap normal conducting 81.25 MHz quarter wave resonators (QWRs) were chosen to provide enough electric field for matching of the longitudinal phase space distribution from the RFQ into the linac [4]. The gap distance of the cavity is 5.9 cm that is consistent with the velocity of the ion beam. Based on the particle tracking simulation, the requirement of the peak electric field on the beam axis is about 3 MV/m to control the longitudinal phase space distribution and to remove the un-accelerated beams [5].

* hjkim87@ibs.re.kr

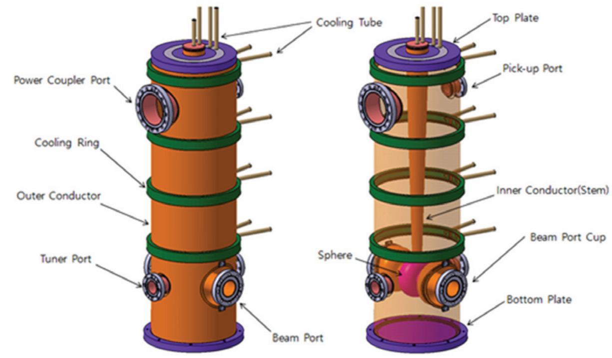

Figure 1: Drawing of the QWR cavity in MEBT of RAON.

As shown in Fig. 1, the bore radius of the beam pipe of the QWR cavity is 5 cm to minimize the uncontrolled beam loss. It was limited by the shunt impedance for getting a high acceleration field. The internal structure, such as shape of the stem, center sphere, and beam port, is optimized to decrease the surface electric field which strongly related with the heat loss from the QWR cavity. The electromagnetic design of the cavity is performed by using code CST-MWS and the electric field along the beam axis is shown in Fig. 2 [6].

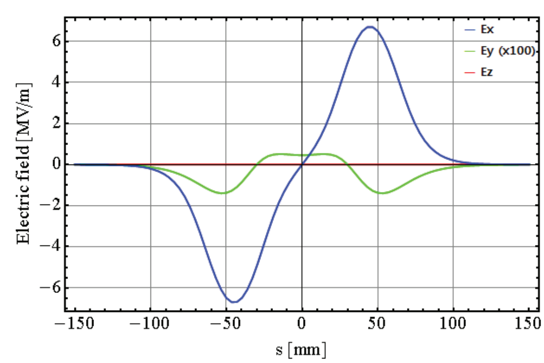

Figure 2: Electric field profile along the beam axis.

It has the electric field component on the vertical direction which can cause the orbit steering due to the structural asymmetry of the QWR cavity. The field strength, however, is small enough to ignore the orbit displacement at the entrance of the linac. It was confirmed by the tracking simulation.

The cooling of the QWR cavity is most significant factor for the mechanical design of the high power normal-conducting structure since the almost power, ~ 10 kW, is converted as the heat on the surface of the QWR cavity. The drawing for the cooling channels is shown in Fig. 3.

In order to suppress the heat up to 15 kW since the calculated power loss was to be about 10 kW for the electric field of 3 MV/m on the beam axis, the QWR cavity was produced

ELECTRON EMISSION FROM SURFACE ROUGHNESS ON CAVITY IN LOW TEMPERATURE*

Heetae Kim[1], Yong Sik Chang[2], Gunn-Tae Park[1], Hyuk Jin Cha[1], Suk Choi[1], Wookang Kim[1,#]
[1]Rare Isotope Science Project, Institute for Basic Science, Daejeon 305-811, Republic of Korea
[2]Department of e-Business, Hanshin University, Osan, Kyungki 447-791, Republic of Korea

Abstract

Electron emission phenomenon from surface roughness on cavity is investigated. The distribution of the electric field from the surface roughness can be obtained on cavity surface. The field emission is calculated from the electric field distribution. The generalized electron emission from electric field and temperature effect is also calculated on the surface roughness of the cavity.

INTRODUCTION

When a body is heated, it generates thermal radiation. Blackbody radiation is used to measure the temperature of the heated body for all range of temperature. Size effect of thermal radiation [1-3] and the effective temperature for non-uniform temperature distribution were investigated [4-6]. Ionization efficiency of helium gas was investigated as a function of pressure and applied voltage with the use of a tungsten tip [7]. Unified theory of field and thermionic emission was constructed with a free electron gas model [8]. Properties of the thermal radiation from arbitrary fractional dimension were investigated [9]. Sheet resistance of graphene grown on different surface roughness of Cu films was measured [10].

In this research, we show total electron emission which includes electric field effect, temperature effect, and surface roughness effect on cavity. General electron emission is introduced and electron emission can be limited with a resistor. Effect of surface roughness causes the increased fractional dimension and focused electric field. Total electron emission can be calculated from thermionic and field emission.

GENERAL ELECTRON EMISSION

Electrons can be generated from heating, electric field, and UV light. Electron current density from thermionic emission, field emission and UV light can be expressed as

$$J = J_{therm} + J_{field} + J_{UV} \ , \tag{1}$$

where J_{therm}, J_{field} and J_{UV} represent the current density of thermionic emission, field emission, and UV, respectively.

Electrons come out of the metal when they get enough thermal energy to overcome the work function. The current density of thermionic emission is

$$J_{therm} = \frac{4\pi mek_B^{\ 2}}{h^3} T^2 e^{-\Phi_w / k_B T} \ , \tag{2}$$

where Φ_w is the work function, h is the Planck constant, m is the electron mass and k_B is the Boltzmann constant. Electrons make thermionic emission when they have higher energy than work function.

Electrons come out of the metal to which strong electric field is applied. Electron current density of field emission for zero-temperature approximation is

$$J_{field} = \frac{e}{2\pi h} \frac{\sqrt{E_F}}{(\Phi_w + E_F)\sqrt{\Phi_w}} F^2 e^{-4k\Phi_w^{\ 3/2}/3F} \ , \tag{3}$$

where $k = \sqrt{\frac{8\pi^2 m}{h^2}}$ is electron wave number and F is the electric field. This is the well-known Fowler-Nordheim equation.

LIMITATION OF ELECTRON EMISSION

Electron emission can be limited by applying a

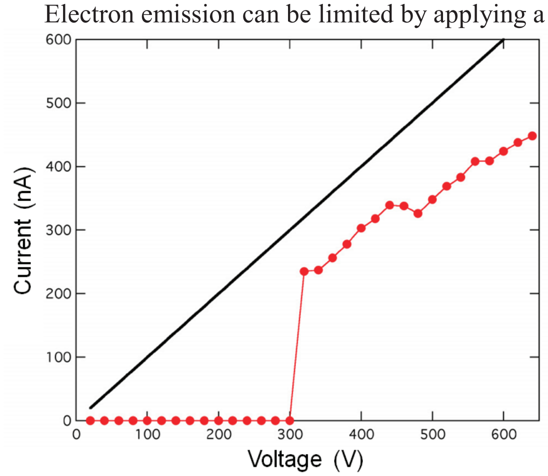

Figure 1: Current measurement is shown as a function of applied voltage.

resistor. The resistor having 1 G ohm is connected to carbon nanotubes. Carbon nanotubes are connected with an electrode by using epoxy. Electron collector is made of copper and the chamber is being pumped. Fig. 1 shows the electron current as a function of applied voltage. The

QWR AND HWR CRYOMODULES FOR HEAVY ION ACCELERATOR RAON *

W.K. Kim, M.K. Lee, Y. K. Kim, G. T. Park, H.J. Cha, H.J. Kim, H. Kim#
Rare Isotope Science Project, Institute for Basic Science, Daejeon 305-811, Republic of Korea

Abstract

The accelerator called RAON has five kinds of cryomodules such as QWR, HWR1, HWR2, SSR1 and SSR2. The QWR and HWR1 cryomodules are designed and fabricated. The cryomodules will be operated at 2 K and 4 K in order to operate the superconducting cavities. The static heat load of the system was analytically computed for each configuration. The functional requirement of the cryomodules and the static heat load measurement of the QWR and HWR1 cryomodules are presented in this research.

INTRODUCTION

The accelerator called RAON which accelerates beam to 200 MeV/u has five kinds of cryomodules such as QWR, HWR1, HWR2, SSR1 and SSR2. The cryomodule of QWR and HWR1 cryomodules are designed and fabricated. The cryomodules will be operated with liquid helium of 2 K and 4 K in order to operate the superconducting cavities. Liquid helium above 2.172 K is normal fluid and liquid helium below 2.172 K is called superfluid. Superfluid properties of liquid helium are well-known and properties of superfluid fog were intensively investigated [1-4]. Blackbody radiation is changed due to size effect [5, 6]. The effective temperature for non-uniform temperature distribution was studied [7-9] and the thermal radiation from arbitrary fractional dimension was investigated [10]. The main role of the cryomodules is to minimize heat leak and heat generation, to supply cryogenic fluid and to align beam through superconducting cavities. The static heat load of the system was analytically computed for each configuration.

In this research, we show the fabrication design and static heat load measurement for QWR and HWR1 cryomodules.

CRYOMODULES

The cryomodule has Mu-metal magnetic shield to reduce earth's magnetic field by less than 10 mG. The crymododule consists of thermal shield of 40 K, intercepts and strong-back made of invar to align the cavity. The SCL11 section accelerates beam from 0.5 to 2.7 MeV/u. Table 1 shows the summary of SCL1 cryomodules for RAON. QWR cryomodule has one cavity, HWR1 has two cavities and HWR2 has four cavities. The length of QWR cryomodule is 450 mm, that of HWR1 cryomodule is 1,400 mm and that of HWR2 cryomodule is 2,720 mm. The SCL11 consists of 22 quarter wave resonators and SCL12 consists of 32 half wave resonators.

Table 1: Summary of SCL1 Cryomodules for RAON

SCL	Cavity	No. of cavity in CM	No. of CM	CM length (mm)
SCL11	QWR	1	22	450
SCL12	HWR	2	13	1,400
		4	19	2,720

Functional requirements of cryomodule are shown in Table 2. Cavity alignment is mainly changed by pumping chambers and cool-down process. Air pressure outside of cryomodule and thermal contraction due to cool-down process make alignment change. The alignment requirement is important for beam dynamics. Vacuum of cavity and chamber is required to reduce the heat load in cryomodule operation.

Table 2: Functional Requirements of Cryomodule

Note	Conditions	Requirement
Cavity alignment	X, Y	±0.25 mm
	Z	± 0.5 mm
	Tilt	± 0.1 °
Vacuum	Chamber	~10^{-5} torr
Vacuum	Cavity	~10^{-7} torr
System pressure rating	Reservoir 4.5 K pipe 40 K pipe	4 bar 20 bar 20 bar

EXPERIMENT

The main roles of cryomodules are to maintain operating condition of superconducting cavities and to keep alignment of beam line. High vacuum and thermal insulation are required for the cryomodules to maintain the operating temperature of superconducting cavities. A detailed conceptual design is performed to fabricate cryomodules. The stiffness of the strong back is designed sufficiently to make device alignment to remain within

Abstract

The RF amplifier of 100 kW (CW) at 165MHz has been studied for a Radio Frequency Quadruple (RFQ). The RFQ as a linear accelerator will be used for low energy beam section of KBSI accelerator system in order to accelerate and focus the ion beam up to 500keV/u [1]. An RF amplifier is composed of a drive, an intermediate, and a final amplifier stage with power supplies. The intermediate amplifier (IPA) of 5 kW is designed with solid state amplifier modules, and the final amplifier is designed with a tetrode tube. The high voltage power supply for the tetrode provides the fine regulation of 15 kV at 10 A. The RF amplifier is operated by program logic controller (PLC) with interlocks, and a low level RF control for RFQ accelerator. This paper describes the present design study on the 100 kW RF amplifier.

INTRODUCTION

The RF amplifier of 100 kW is composed of a Final Power Amplifier (FPA) of a tetrode TH781, IPA of 5kW with SSPA and a PLC control system. Main component of FPA is a tetrode amplifier: Thales tube TH781 and a resonant input/output cavity TH18781E [2].

Figure 1 shows the block diagram of high power RF amplifier including 6-1/8" coaxial transmission lines such as circulator, loads, directional coupler, and an RFQ.

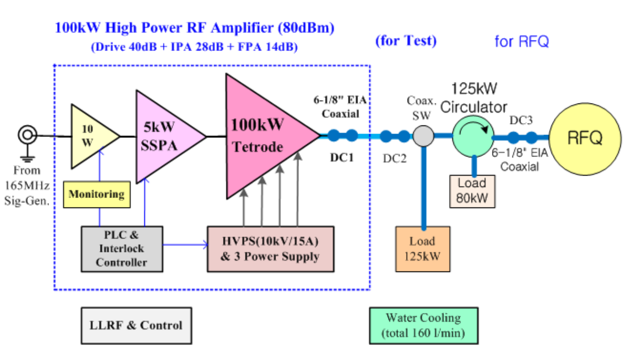

Figure 1: block diagram of RF amplifier for RFQ.

Main power supply is for the anode of 10 kV/15 A to get 100 kW RF output. The others are grids and heater power supplies. The PLC controls the amplifier including power supplies and manages interlocks. Table 1 shows design parameters of the amplifier.

Table 1: Design Parameter of Amplifier for RFQ

Specification	Value	Details
Frequency	165 MHz	Synthesizer
Bandwidth	± 0.8 MHz	-1 dBc
Amp. Stability	< ± 0.2 %	Close loop
Phase Stability	< ± 0.2 degree	Close loop
Operating mode	Continuous	or Pulse mode
Transmission Lines	6-1/8" EIA w/ Circulator	100 kW CW 150 kW peak
Interlock time	less than 2 us	fast, wired

FINAL AMPLIFIER

The final amplifying stage is based on the TH781 tetrode fabricated by Thales. The 100 kW/165 MHz amplifier with vacuum tube has advantages for high power up to 300 kW and cheaper than SSPAs. TH781 is only a tetrode for high power application at 165MHz and has been tested to other projects of IHEP, LANL and IFMIF (International Fusion Materials Irradiation Facility) [3][4][5]. Some power supplies including a high voltage anode supply are needed for operating the tetrode. Table 2 shows specification of power supplies and option items for the FPA of 100 kW RF output.

Table 2: Power supplies and accessories of FPA

Items	Specification	Details
Anode P/S	10kV / 15A	controlled
Screen Grid P/S	1200V / 0.7A	< ± 0.1 %
Control Grid P/S	-350V / 0.9A	< ± 0.1 %
Filament P/S	10V / 375A	DC or AC
Resonant Cavity	Input / Output	TH 18781E
HV Filter	< -50dBc	Option

HIGH POWER KLYSTRON AMPLIFIERS FOR THE PLS AND PLS-II STORAGE RING *

M.H. Chun†, I.H. Yu. Y. Joo, I.S. Park, Y. Sohn and H.J. Park
Pohang Accelerator Laboratory (PAL), Pohang, 790-834, Korea

Abstract

The RF system of the Pohang Light Source-II (PLS-II) storage ring is operating at the 3.0 GeV/340 mA with three superconducting RF (SRF) cavities. PLS-II RF system was upgraded to 3.0 GeV/400 mA(max.) beam storage from 2.5 GeV/ 200mA of PLS. Each high power RF (HPRF) station is composed of a 300 kW klystron with power supplies, transmission components including a 350 kW circulator and load, and water cooling system. The klystrons are generally operated as a RF power source with high gain amplification for RF system of light sources. This paper describes the present operation status of 300 kW klystron amplifier and experiences of the former PLS 75 kW klystron amplifiers as well as RF system.

INTRODUCTION

The PLS-II machine of 3.0GeV is the upgraded third synchrotron light source from PLS of 2.5GeV. PLS-II has a full energy Linac and a storage ring. The PLS RF system was five independent RF stations. Each station was consisted of a modified 75kW klystron amplifier, a circulator, a single-cell normal conducting RF cavity with precise controlled water cooling system, all connected by 6-1/8" coaxial transmission lines and analogue type low level RF system [1][2]. But the upgraded PLS-II RF system in 2015 is operating for beam current of 340mA with three superconducting RF cavities supplied RF power through WR1800 waveguides from three 300kW klystron amplifiers with high voltage power supplies, and digital type LLRF control system [3]. Figure 1 shows the block diagram of PLS-II RF system with 300kW klystron amplifiers.

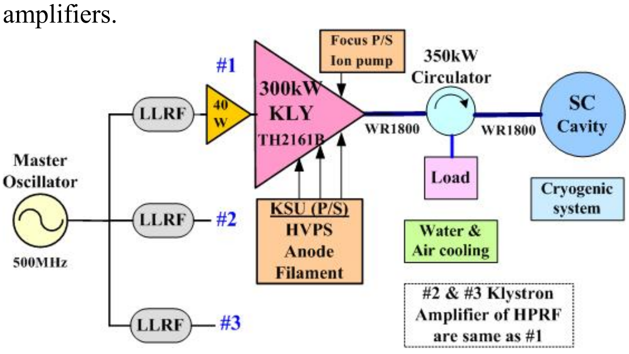

Figure 1: Klystron Amplifier at PLS-II RF system.

Also table 1 shows comparison of main parameters for PLS and PLS-II storage ring.

Table 1: Comparison of PLS and PLS-II

Specification	PLS(~2010)	PLS-II(2015)
Energy/Current	2.5GeV/200mA	3.0GeV/400mA
Emittance	18.9 nm-rad	5.8 nm-rad
Circumference	280.56 m	281.82 m
Total RF Power	200 kW	480 kW
RF Frequency	500.082MHz	499.964MHz
RF Power Sources	75kWx5	300kWx3
RF Voltage/Cavity	1.6MV, 4 NC	4.8MV, 3 SC

KLYSTRONS AS RF SOURCES

Klystrons have been used as RF sources for almost particle accelerators because of high power capacity and efficiency. Three 300kW high power klystron amplifiers are operating for PLS-II and some 60~75kW klystrons were used for PLS RF system. The TH2161B klystrons are operating some light sources such as SLS, IHEP, CLS, SSRF, TPS and NSLS-II storage rings. Table 2 shows comparison of klystron parameters: TH2161B of 300kW for PLS-II and K3773BCD of 75kW for PLS storage ring RF system [4].

Table 2: Comparison of CW Klystrons

Specification	TH2161B	K3773BCD
Frequency (B/W)	500MHz(2MHz)	470~860MHz (7MHz)
RF output (CW)	310 kW(max)	75 kW(max)
Beam V/I (peak)	54kV/9.5A	26.5kV/6.3A
Gain/Efficiency	40dB / 60%	35dB / 45%
μ-Perveance	1.62	2.00
Cavities	5 Integrated	4 External
Maker	Thales (France)	EEV (UK)

K3773BCD klystron was originally manufactured for UHF-TV transmitter application, and to be modified to CW operation for light sources. Similar UHF-TV klystrons of K3672BCD and K3775BCD are still operating at Elettra and Bessy-II [5].

RF ACCELERATING VOLTAGE OF PLS-II SUPERCONDUCTING RF SYSTEM FOR STABLE TOP-UP OPERATION WITH BEAM CURRENT OF 400 mA

Youngdo Joo#, Myung-Hwan Chun, In Soo Park, In-Ha Yu, Taekyun Ha, Ilmoon Hwang, Byung-Joon Lee, Younguk Sohn
Accelerator Division, Pohang Accelerator Laboratory, POSTECH, Pohang, Gyeongbuk, Korea

Abstract

During the beam store test up to 400 mA in the storage ring, it was observed that the vacuum pressure around the RF window of the superconducting cavity rapidly increases over the interlock level limiting the availability of the maximum beam current storing. We investigated the cause of the window vacuum pressure increment by studying the changes in the electric field distribution at the superconducting cavity and waveguide according to the beam current. An equivalent physical modeling was developed using a finite -difference time domain (FDTD) simulation and it revealed that the electric field amplitude at the RF window is exponentially increased as the beam current increases, thus this high electric field amplitude causes a RF breakdown at the RF window.

INTRODUCTION

As the RF accelerating voltage increases, the energy acceptance increases, as a result, the injection efficiency becomes higher. However, the energy acceptance of 2.5% is already sufficient for the injection efficiency of the PLS-II SR [1,2]. Therefore, the effect of the RF accelerating voltage higher than 3.6 MV on the injection efficiency is saturated. The Touschek lifetime keeps increasing until the RF accelerating voltage reaches about 3.6 MV, but it gets lower for the RF accelerating voltage higher than 3.6 MV. The longitudinal bunch length becomes shorter as the RF accelerating voltage increases as shown in Fig. 1(a). The shorter bunch can cause the problem of ion instability due to the short bunch interacting more strongly with the impedance of the vacuum chamber, enhancing outgassing in some local points. For an instance, the loss factor of the SC cavity taper section in the PLS-II SR is calculated and shown in Fig. 1(b). When the RF accelerating voltage increases from 3.6 MV to 5.0 MV, the beam bunch length is reduced by 17.5% and the loss factor is enlarged by 26.4%. This enlarged loss factor means that more power loss due to the wake-field occurs at the taper section increasing the surface temperature and vacuum pressure. . Therefore, it is recommended that the total RF accelerating voltage be kept at around 3.6 MV.

#ydjoo77@postech.ac.kr

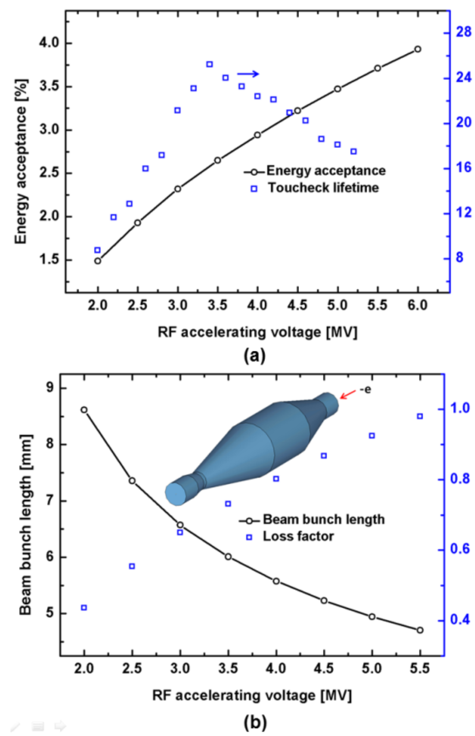

Figure 1: (a) Calculated energy acceptance and Touschek lifetime and (b) the beam bunch length and the loss factor of the PLS-II SC taper section. The three-dimensional modeling of the SC taper section is shown in the inset.

BEAM STORING MACHINE STUDY

The measured forward power, reflect power and window vacuum pressure from Fig. 2(a) are plotted to the beam current domain and shown in Fig. 2 together with the calculated beam power, forward power and reflect power of SC2 with the RF accelerating voltage of 1.2 MV. The calculated and measured powers are well matched until the beam current reaches 235 mA. However, the measured powers become unstable and show difference from calculated powers when the current is higher than 235 mA. Both the forward power and the reflect power are larger than those calculated. That means that the coupling ratio of the cavity is changed. When the beam current is dumped, it reaches 259 mA due to the window vacuum high interlock. The unpredictable changes in the coupling ratio and the rapid increment of window vacuum pressure strongly suggest that the changes in the electric field distribution must be examined at and around the ceramic window in the beam current domain.

TECHNICAL OVERVIEW OF BUNCH COMPRESSOR SYSTEM FOR PAL XFEL

H.G. Lee, D.H. Na, S.B. Lee, B.G. Oh, Y.J. Seo, H.S. Suh, Y.G. Jung, D.E. Kim, K.H. Park, H.S. Kang, K.W. Kim
Pohang Accelerator Laboratory, POSTECH, Korea

Abstract

Pohang Accelerator Laboratory(PAL) is developing a SASE X-ray Free Electron Laser based on 10 GeV linear accelerator. Bunch compressor (BC) systems are developed to be used for the linear accelerator tunnel. It consists of three(BC1, BC2, BC3_H) hard X-ray line and one(BC3_S) soft X-ray line. BC systems are composed of four dipole magnets, three quadrupole magnet, BPM and collimator. The support system is based on an asymmetric four-dipole magnet chicane in which asymmetry and variable R_{56}. can be optimized. This flexibility is achieved by allowing the middle two dipole magnets to move transversely. In this paper, we describe the design of the stages used for precise movement of the bunch compressor magnets and associated diagnostics components.

INTRODUCTION

A bunch compressor support system has been fabricated and tested for the PAL XFEL. The machine of the PAL XFEL consists of four main sections: the linear accelerator, the hard x-ray undulator hall, the soft x-ray undulator hall and the experimental area. The accelerator, schematically shown in Figure 1, comprises the gun, the laser heater, four accelerating sections groups (L1–L4), four bunch compressors (BC1, BC2, BC3_H and BC3_S) and the spreader. The physics design of the magnetic bunch compressor is based on an asymmetric four-dipole chicane configuration [1]. The BC purpose is to reduce the electron bunch length, thus increasing the peak current, taking advantage of the beam correlated energy spread. Due to the accelerating process, there is an inherent longitudinal energy spread in the electron bunch. Passing through four bending magnets chicane, the path length is energy dependent and the electron bunch is compressed. At each bend, the electron bunch head delays with respect to the tail. Mounting high homogeneity magnetic field dipoles and having diagnostic devices centre on the beam at each chicane position are the main advantages of the movable chicane.

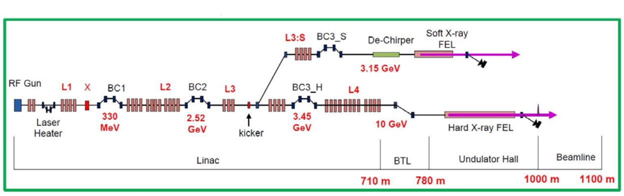

Figure 1: The schematic layout of the 3-BC lattice.

BUNCH COMPRESSOR OVERVIEW

The BC support system, shown in Figure 2 and Table 1, consist of four dipole magnets (DM), two tweak quadrupole magnets and a skew quadrupole magnet, two corrector magnets, BPM, collimator, screen and CSR monitor. The position of such diagnostic devices remains fixed with respect to the central dipoles.

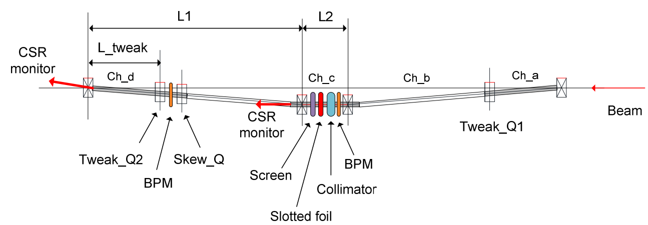

Figure 2: Layout of the BC support system.

Table 1: Major Parameters of the BC Support System

	BC1	BC2	BC3_H	BC3_S
Dipole angle , deg	4.9	3.0	1.7	1.7
Dipole length , m	0.2	0.7	0.7	0.7
L1 , m	4.4845	7.1905	7.597	6.397
L2 , m	1.2	1.8	1.8	1.8
L_tweak , m	1.146	1.3483	2.349	1.349
Aperture diameter of Tweak Quad, mm	44 (Q11)	44 (Q11)	44 (Q11)	44 (Q11)

The support systems of BC are composed of two fixed support and a moving support. The two central dipoles are mounted on a moving support that can have up to 627.0 mm motion orthogonal to the beam axis. A servo motor provides movement to the central stage and a linear encoder controls its exact position. The position accuracy of dipoles is within 50 μm.

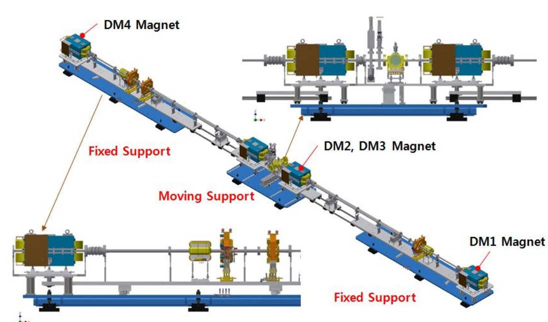

Figure 3: 3D modelling of BC support system.

400 mA BEAM STORE WITH SUPERCONDUCTING RF CAVITIES AT PLS-II*

Younguk Sohn#, Myung-Hwan Chun, Taekyun Ha, Mansu Hong, Youngdo Joo, Heung-Sik Kang, Hyung-Gyun Kim, Kyung Ryul Kim, Tae-Yeon Lee, Chong-Do Park, Hong-Jib Park, In Soo Park, Seunghwan Shin, In-Ha Yu, Jong Cheol Yun, PAL, Pohang, Korea

Abstract

Three superconducting RF cavities were commissioned with electron beam in way of one by one during the last 3 years, and now PLS-II is in user service on the way of beam current to 400mA, the target of PLS-II. The cavities and cryomodules were prepared with SRF standard technology and procedures, then vertical test, windows conditioning, cryogenic test in each cryomodule, horizontal power test, conditioning, and commissioning without and with beam at PLS-II tunnel by collaboration with industries. All the cavities showed stable performances as good as not-observing any RF instability from cavities, couplers and windows up to 400 mA beam store, but observing several cavity quenches and minor vacuum bursts by abrupt power with control and human errors. The initial beam current for user run were recorded as 150 mA with one cavity, 280 mA with two cavities and 320 mA with three cavities. The 400 mA beam was also achieved with two cavities by decay mode and also with three cavities by top-up mode. The stabilities of RF amplitude and phase are good enough not to induce beam instabilities.

INTRODUCTION

The PLS-II of which is the upgraded light source from former PLS is mainly to increase the number of ID beamlines by changing magnet arrangement from double bend achromat lattice (DBA) to triple bend achromat lattice (TBA) [1], so that 20 ID beamlines are afforded at PLS-II. Also the upgrade machine is to provide higher brightness of photon beam, order of two through increasing electron beam energy and stored beam current, as 3 GeV and 400 mA, respectively.

The RF system of PLS-II should be high capacity of RF power and free from cavity higher mode (HOM) instabilities. The RF system must compensate the energy loss as much as 1024 keV and 200 keV from 24 bending magnets and 20 insertion devices, respectively. So the RF system must afford to provide 550 kW RF power properly for additional broad band loss from the SR structures and no coupled bunch instabilities (CBI) should be shown to 400 mA beam current by installing HOM free cavities. A superconducting RF (SRF) system is chosen to meet such a requirement, described above.

The baseline design [2] is a three-independent RF station, of which each RF cavity has its own power amplifier, transmission system, and a LLRF. With 3 SRF cavities, the design Vacc and forward RF power per each cavity are lower than their specification, which has been contributed to reduce cavity abnormality and to increase the lifetime of ceramic window and also of high power amplifier.

The 3 SRF stations were installed one by one during last 4 years as first 3 normal conducting cavities in 2011 and they were replaced with one SC cavity, then two more SC cavities during following two years. It is strategy to make time for operator to be familiar to SRF system, meanwhile for machine to be conditioned gradually by low synchrotron energy. Even though these consideration, we suffered from a lot of troubles such as vacuum bursts at RF window, cavity quenches from bad RF power control resulted to violent He evaporation and He refrigerator trip by poor protection and many human error by LLRF in the first 3 months. The trial and errors during beginning 3 months contributed to the performance normalization. First of all, we improved the listed trouble makers such as LLRF, interlock system between RF source and cavities, electric power control of He refrigerator. Also, we setup maintenance procedures as cavity partial warmup and pulse conditioning cavity and window before start of every user-run.

Then, the beam current with two SC cavities by top-up mode in 2013 was 120 mA at beginning of user run to 280 mA at last run. During the machine study, 400 mA beam current was touched during several ten minute, but it couldn't go on due to vacuum burst. Also we tried to increase beam current with one more SC cavity installation in 2014. Even with frequent partial warmup and pulse conditioning, the window vacuum burst still one of trouble for high beam current. It was overcome with deep study of relationship between RF forward power, reflected power and window dissipation heat [3]. With these result, stable 400 mA beam current with top-up mode was achieved during 2 hours in machine study.

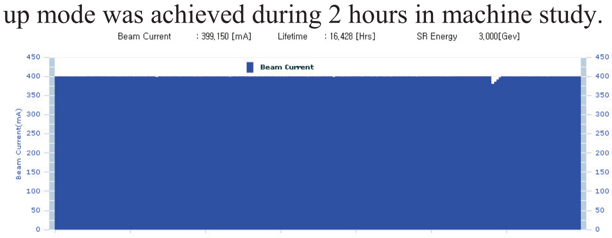

Figure 1 : Achievement of 400 mA top-up mode.

In 2nd half year of user run, beam current increased in run by run, 300 mA, 320 mA and 350 mA. At 350 mA operation, we couldn't provide stable user beam due to the vacuum interlock from the in-vacuum undulators.

THE RF STABILITY OF PLS-II STORAGE RING RF SYSTEM

I.H. Yu, Y.D. Joo, Y. Sohn, M.H. Chun, I.S. Park, H.J. Park, M.H. Chung, H.G. Kim, H.S. Kang, Pohang Accelerator Laboratory, Pohang, Korea
Y.S. Lee, Department of Energy Science, Sungkyunkwan University, Suwon, Korea

Abstract

The RF system for the Pohang Light Source (PLS) storage ring was greatly upgraded for PLS-II project of 400 mA, 3.0 GeV from 200 mA, 2.5 GeV. Three superconducting RF cavities with each 300 kW maximum klystron amplifier were commissioned with electron beam in way of one by one during the last 3 years for beam current of 400 mA to until March 2014. The RF system is designed to provide stable beam through precise RF phase and amplitude requirements to be less than 0.3% in amplitude and 0.3° in phase deviations. This paper describes the RF system configuration, design details and test results.

INTRODUCTION

The final quantitative goal of PLS-II is a top-up user-service operation with beam current of 400 mA to be completed by the end of 2014. The RF accelerating voltage of PLS-II RF system was set to 4.8 MV(1.6 MV/cavity), which was estimated using the maximum available beam current that works as a function of RF voltage, and the top-up operation test with the beam current of 400 mA was successfully carried out. The PLS-II has increased the beam energy from 2.5 GeV to 3 GeV; the number of IDs has been increased by a factor of two (20 IDs); and the beam current has been increased from 190 mA to 400 mA. The beam emittance has been reduced to below 10 nm while retaining the existing PLS tunnel as well as the existing injection system [1].

The radio-frequency (RF) system of the electron SR for the light source generates a sufficient RF accelerating voltage and transfers RF power to the electron beam to compensate for the beam energy loss due to synchrotron radiation from the bending magnets and IDs. Three superconducting RF systems are installed in the PLS-II storage ring.

The schematic diagram of a RF station in PLS-II storage ring is shown in Fig. 1. The PLS-II RF system consists of five major components: (1) low level RF control system(LLRF) with EPIC IOC, (2) a continuous wave (CW) klystron with a rated output power of 300 kW at the frequency of about 500 MHz, (3) a 300 kW circulator which isolates the klystron to protect the klystron form reflection power from cavity, (4) a 300 kW water cooling ferrite load which terminates the RF power by converting the RF power to thermal loss at the ferrite panel, and (5) a CESR-B type cryomodule produced by RI (former ACCEL).

The RF power generated by klystron is incident to the superconducting cavity (SC) through WR1800 waveguide, the ceramic RF vacuum window and the RF coupler to build a RF field at the SC RF cavity. The LLRF system gets the amplitude and phase information of the RF field from the signal at the cavity RF pickup and keeps the RF field stable by controlling the amplitude and phase of forward power in the presence of various external noises such as beam loading effect, mechanical vibrations, changes in the electrical length of the waveguide between the klystron and the cavity, and the pressure fluctuation in the Liquid He vessel [2].

Each cavity consists of a cell elliptical type. The cavities are tuned to 500MHz, and individually controlled by a mechanical stepper motor with tuner. Each cavity is powered and controlled by a single klystron and LLRF system. The klystrons produce 300 kW Maximum. The RF controls use a traditional heterodyne scheme and digital down conversion at an intermediate frequency (50 MHz). Each cavity field and resonance control PI algorithm is contained in two FPGAs. One FPGA is in the field control chassis (FCC manufactured by JLAB RF Group), controlling a single cavity. The resonance control chassis contains the other and controls three cavities simultaneously. Controls and interfaces for the most of RF system devices are provided through EPICS [3].

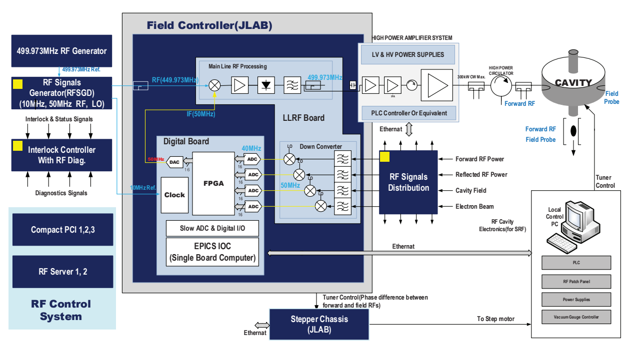

Figure 1: The schematic diagram of the RF station for PLS-II Storage Ring.

RF SIGNALS MEASUREMENT & FEEDBAK CONTROL HARDWARE

Each cavity is controlled by a single LLRF system, called here FCC. an FCC contains five fast ADC channels (receivers), although one receiver channel has no heterodyning frontend in order to direct sample 10 MHz external clock reference. All RF signals, once down-converted and digitized, are processed in an FPGA. The FCC requires an external 20 dBm LO (450 MHz) and external 3 dBm clock reference (10 MHz). The clock system has a programmable digital PLL and can work with different references as well as produce assorted sampling frequencies. A fast DAC channel produce 50

IOT USE AS A POWER SOURCE FOR A LINEAR ACCELERATING STRUCTURE

E. Savin, S. Matsievskiy, N. Sobenin, I. Sokolov, NRNU MEPhI, Moscow, Russia
A. Zavadtsev, LLC « Nano Invest », Moscow, Russia

Abstract

Nowadays the interest of using compact and high efficiency power sources called Inductive Output Tubes (IOT) [1] for feeding accelerating structures with the required pulsed power around 1MW is increasing. In this article results of the beam dynamics and geometry calculations for the L-band IOT S-band IOT and accelerator-generator hybrid module are presented. Different concepts of the cavity have been proposed, but the most efficient has been chosen. The layout of the generator cell with biperiodic buncher cells has been investigated. The hybrid structure composed from the generator cell and the compact SW accelerating section is proposed.

THE GOAL

The goal of the research is to find optimal geometry of the generator cells, output and injection systems for different types of the linear accelerators.

L-BAND PROTON LINEAR ACCELERATOR HYBRID STRUCTURE

Accelerating section consists from washers-diaphragms accelerating structure working on TH_{020} mode at 991 MHz frequency [2]. The idea is to create TH_{020} cavity designed for the same purpose as a klystron output cavity with six beam tubes (Fig. 1). Together with accelerating section they create the hybrid structure working on quasi $\pi/2$ mode [3] where connecting waveguide is a coupling cavity (Fig. 2).

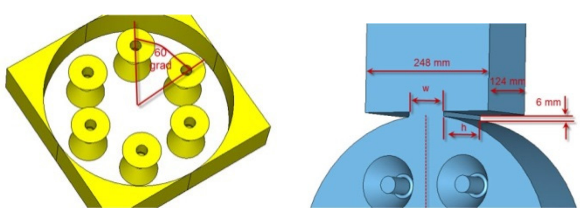

Figure 1: Generator cell geometry.

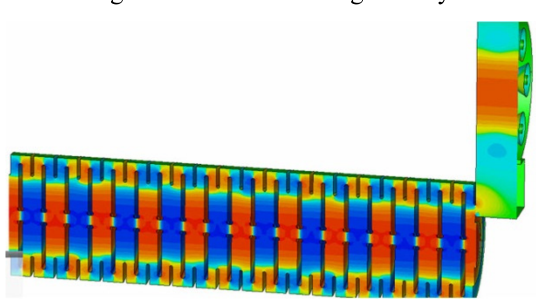

Figure 2: Generator-accelerator hybrid structure.

IOT DESIGN

Next geometries are designed on 2856 MHz working frequency regarding for the uncovered researches for the S-band IOTs. Geometry parameters were varied to achieve maximum output power [4] from the generator cell while inputting there six 5A (pulse) modulated electron beams (Fig. 3).

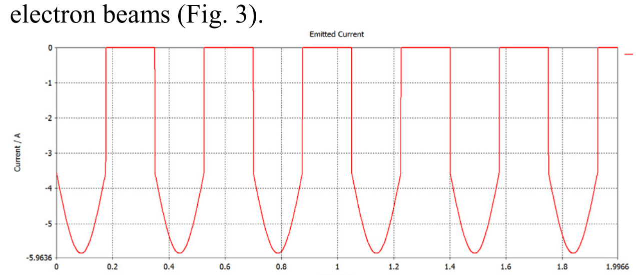

Figure 3: Emitted current from the one cathode.

TH_{020} Pillbox Cavity

TH_{020} wave type consists from two electric field maximums – one in the middle of the cavity and other one (radial) on the perimeter, thus we can put beam pipes in this maximum (Fig. 4).

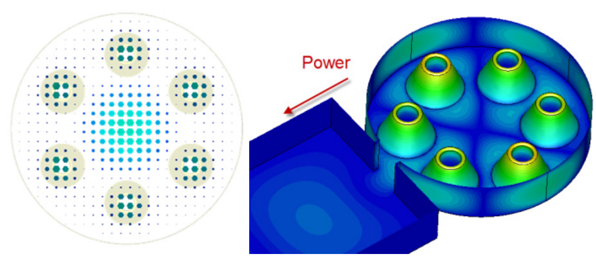

Figure 4: TH_{020} wave in resonator and the power output waveguide.

Maximum power level was reached by varying the beam gap and over coupling between generator cell and the output design by changing the window width w (Fig. 5). In every geometry variations the operating frequency was tuned to 2856 to match with injected beam frequency.

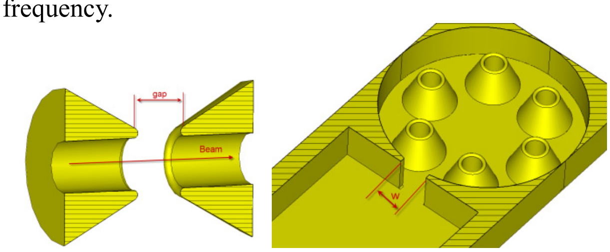

Figure 5: Generator parameters to adjust.

COMPASSION OF HIGHER ORDER MODES DAMPING TECHNIQUES FOR SUPERCONDUCTING 9-CELL STRUCTURE

Ya.V. Shashkov, N.P. Sobenin, A.Mitrofanov, National Research Nuclear University MEPhI (Moscow Engineering Physics Institute), Moscow, Russia
V. Zvyagintsev, TRIUMF, Canada's National Laboratory for Particle and Nuclear Physics, Vancouver, BC, Canada

Abstract

Modern types of accelerators, such as Energy recovery linacs, require low values of higher order modes (HOM) Q_{ext}. In accelerators with high current HOM could lead to high losses for the modes excitation, beam instability and beam break up. HOM couplers and waveguides are often used in such structures for HOM damping. Unfortunately they could lead to a violation of the axial symmetry of the accelerating field and negatively affect the beam emittance. Also these devices are subject for multipactor discharge and could be difficult in maintaining and fabrication. In this paper we examine several ways of HOM damping with ridged, fluted and corrugated drift tubes which are devoid of the above-mentioned drawbacks. The influence of the parameters of the drift tube on the HOM damping and on the parameters of the fundamental wave were analyzed.

INITIAL DESIGN

As a reference point for simulations 9-cell 1300 MHz superconducting accelerating cavity (Fig. 1a) [1] was analyzed. In order to estimate efficiency of HOM damping in such structure electrodynamic characteristics (EDC) [2] were calculated for the structure without couplers but with ideal load boundary conditions on at the end of drift tubes. EDC of operating mode presented in Table 1.

In order to estimate HOM frequency range dispersion characteristics (Fig. 1b) for TM_{010} modes and HOMs were plotted. The most dangerous HOMs for the structure are dipole modes TE_{111}, TM_{110}; quadrupole modes TE_{211} and TM_{210} and monopole mode TM_{011}. Line $\beta_{phase} = 1$ is also presented on the graph. Intersection points of dispersion characteristics with $\beta\text{-}_{phase} = 1$ line (synchronous point) represent modes with the highest interaction between particles and modes and requires additional attention. External Q-factor Q_{ext} and shunt impedance R_{sh} for HOMs and operational mode presented on the Fig 2 and 3. Q_{ext} values were calculated in CST Microwave Studio [3].

Comparison of the results with similar structures [4] showed that Q_{ext} for operating mode is nearly the same, for dipole modes it is three orders higher, 4-5 orders higher for quadrupole modes and for 2nd monopole HOM its two times higher.

SUPPRESSION OF HIGHER ORDER MODES IN AN ARRAY OF CAVITIES USING WAVEGUIDES*

Ya.V. Shashkov, N.P. Sobenin, NRNU MEPhI, Moscow, Russia
M.M. Zobov, LNF-INFN, Frascati (Rome), Italy

Abstract

In the frameworks of the High Luminosity LHC upgrade program an application of additional harmonic cavities operating at multiplies of the main RF system frequency of 400 MHz is currently under discussion. A structure consisting of two 800 MHz single cell superconducting cavities with grooved beam pipes coupled by drift tubes has been suggested for implementation. However, it is desirable to increase the number of single cells installed in one cryomodule in order to decrease the number of transitions between "warm" and "cold" parts of the collider vacuum chamber. Unfortunately it can lead to the appearance of higher order modes (HOM) trapped between the cavities. In order to solve this problem the methods of HOM damping with rectangular waveguides connected to the drift tubes were investigated and compared. In this paper we describe the results obtained for arrays of 2, 4 and 8 cavities.

INTRODUCTION

The Large Hadron Collider luminosity upgrade (HL-LHC) [1] project considers a possible implementation of harmonic cavities in addition to the main accelerating cavities working at 400 MHz to increase or to shorten bunches. In order to achieve the desired results a combination of the existing main RF cavities and harmonic cavities operating at 800 MHz is being studied. One of the main goals of the design of cavity is to fulfill strict HOM damping requirements. Several techniques for HOM damping such as beam pipe grooves, fluted beam pipes, ridged beam pipes etc. have been suggested, investigated and compared.

It is desirable to combine more cavities in a single cryostat in order to avoid multiple transitions between cryogenic and "warm" areas. However, connecting several cavities in a chain can create parasitic HOM that may affect the stability of circulating beams and lead to excessive power loss. The methods of HOM damping with rectangular and ridged waveguides attached to the beam pipes, usage of fluted and ridged beam pipes, as well as combinations of these methods have been considered and compared in order to solve this problem.

*Work is supported by Ministry of Education and Science grant 3.245.2014/г и and by the EU FP7 HiLumi LHC - Grant Agreement 284404.

SINGLE CELL

An initial design of the harmonic cavity was obtained by scaling (reducing) all the sizes of the LHC accelerating cavity operating at 400 MHz by a factor of 2 (Fig. 1) [2]. HOM damping is carried out with four couplers: two dipole and two broadband couplers. Unfortunately those couplers have some drawbacks including: violation of the cylindrical symmetry of the electromagnetic field in the structure which gives rise to the transverse component of the electric field (kick-factor), the complexity of the installation of robust power coupler on the same pipe with HOM couplers and possibility of multipacting discharges. That's why several alternatives HOM damping techniques have been investigated (Fig 2-4) [3].

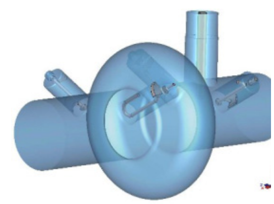

Figure 1: Accelerating cavity.

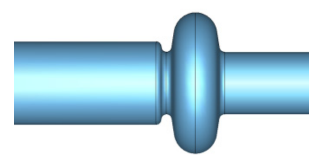

Figure 2: Cavity with grooved beam pipes.

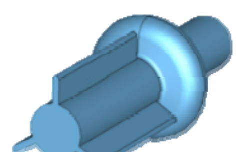

Figure 3: Structure with 3 flutes.

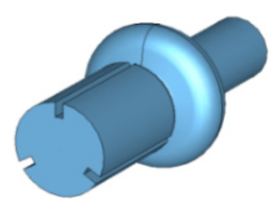

Figure 4: Structure with ridged beam pipe.

The frequency of dipole HOMs lies below the cut-off frequency of the TE_{11} wave and therefore cannot propagate along the drift tube in the structure shown in Fig. 1. The main feature of structures from Fig. 2-4 is that the HOMs frequencies become lower than the beam pipe cut-off frequency which allows [4] providing damping with a load placed in the drift tube outside the cryomodule. The results of wakefield simulations conducted with ABCI code [5] and CST [6] has clearly demonstrated that in these structures we managed to obtain a truly "single mode" cavity. We should not expect multibunch instabilities since the wake field decays completely at the distance of 15-25 m that corresponds to the actual bunch separation of 50 ns in LHC. The results obtained for single cell structures with grooved, fluted and ridged beam pipes are similar. In all the structures Q_{ext} are below 100 for all HOMs (except for a few modes

CALIBRATION OF THE ACCELERATION VOLTAGE OF SIX NORMAL CONDUCTING CAVITIES AT ALBA

B. Bravo, A.Salom, J. Ocampo, U.Iriso, J.Marcos, P.Solans, F. Pérez, CELLS, Cerdanyola del Vallès

Abstract

ALBA is a 3GeVsynchrotron light source located in Barcelona and operating with users since May 2012.The ALBA storage ring uses six room temperature cavities; each one fed by combining two 80kW IOTs amplifiers at 499.654 MHz.

An accurate calibration of the RF voltage is required for the right adjustment of the RF phase with respect the beam. In addition, since the ALBA the ring accommodates several RF cavities, these may not be optimally phased with respect to each other, complicating the calculation of the total RF voltage. In this paper, the steps to calibrate the accelerating voltage of the SR will be presented and different methodologies to cross-check these calibrations.

INTRODUCTION

ALBA is a 3 GeV, 400 mA, 3rd generation Synchrotron Light Source in Cerdanyola, Barcelona, Spain, operating with users since May 2012.

The RF System, formed out of six RF plants, provides up to 3.6 MV of effective voltage and restores up to 540 kW of power to the electron beam. A cavity combiner add the power of two 80 kW IOTs to produce the more than 150 kW needed for each DAMPY cavity, a normal conducting HOM damped cavity developed by BESSY and based in the EU design cavity [1].

The total RF voltage seen by the beam depends on the relative RF phase between cavities which means that it is important to properly adjust RF field phase of each cavity with respect to the beam. To optimize the performance of the system, the RF voltage and phase of each cavity is controlled independently via a digital low level RF (DLLRF) [2].

OPERATION WITH SEVERAL RF CAVITIES

When several cavities are in operation the net accelerating voltage per turn is:

$$V_{acc} = \left|\overline{V_{cav,1}}\right| \sin(\phi_{s,1}) + \left|\overline{V_{cav,2}}\right| \sin(\phi_{s,2}) + \ldots, \quad (1)$$

where $\phi_{s,i}$ is the RF phase respect to the beam of each cavity.

The total effective voltage can be represented as the vector sum of the cavity voltage of each RF station:

$$\overline{V_{eff}} = \overline{V_{cav,1}} + \overline{V_{cav,2}} + \overline{V_{cav,3}} + \ldots \quad (2)$$

If the RF phase of the cavities with respect the beam is not the same the $\left|\overline{V_{eff}}\right|$ is reduced, as shown in figure 1 and 2.

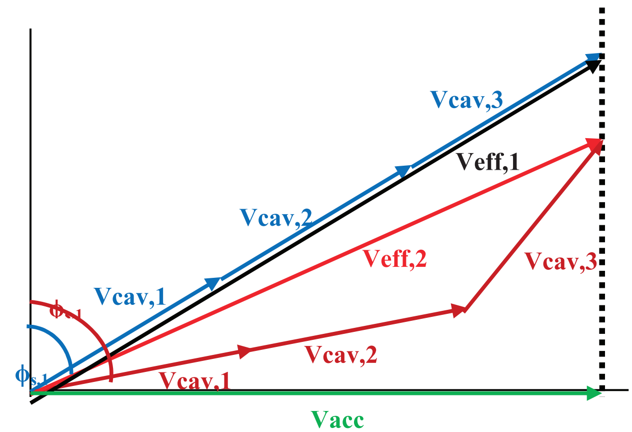

Figure 1: The effective voltage, Veff,1, is the sum vector of three cavity voltage in phase and Veff,2 is the sum when two cavities are in phase and one not $\phi_{s,1} = \phi_{s,2} \neq \phi_{s,3}$.

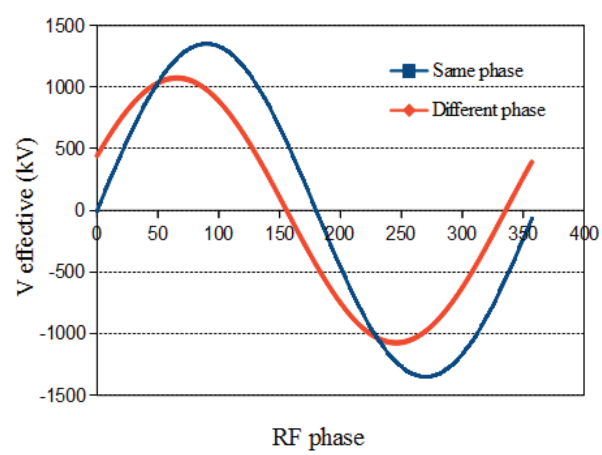

Figure 2: $\overline{V_{eff}}$ when RF phases between the three cavities are the same and when $\phi_1 = \phi_2 \neq \phi_3 = \phi_1 + 80$.

RF CALIBRATIONS

Forward and Reflected Power

RF power in the transmission lines is measured by means of directional couplers, device that couples a small amount of the power flowing through the line, in a given direction, towards one port.

A PINGER MAGNET SYSTEM FOR THE ALBA SYNCHROTRON LIGHT SOURCE

M. Pont, N. Ayala, G. Benedetti, M. Carla, Z. Marti, R. Nuñez
ALBA-CELLS, 08290 Cerdanyola del Vallès, Spain

Abstract

A pinger magnet system consisting of two short kickers, one for each transversal plane, has been recently commissioned at the ALBA Synchrotron Light Source. The kickers excite large betatron oscillations on the electron beam in order to probe the linear and non-linear beam dynamics regime together with the turn by turn capabilities of the BPMs. The kickers are mounted around a single Ti coated ceramic vacuum chamber, have a length of 0.3 m each and provide a half sine pulse with an approximate pulse length of 1.5 us at an amplitude of 1.60 mrad in the horizontal plane and 1.15 mrad in the vertical plane. The pulser unit is based on solid state technology. This report summarises the steps followed from its design until its installation, electric and magnetic characterisation in the laboratory, and the first results with beam.

INTRODUCTION

To probe the non-linear regime of beam dynamics, a pair of pinger magnets have been designed, built in house and installed in the ALBA storage ring.

A single electron train will be kicked transversally by means of the pinger magnets, resulting in the excitation of betatron oscillations around the reference orbit. If the kick is strong enough the oscillations can reach the boundary of the non-linear region where the magnetic fields of the optics exhibits strong non-linearities.

The evolution of the dynamics of the electron train is then sampled; turn after turn, by beam position monitors (BPM). The pulse width must be such that the electron beam is kicked only once, all through the dynamic range of the pinger magnets. Beam dynamic results from the first studies performed with the pinger magnets are reported also in this conference [1,2] and the analysis of the impedance change due to the installation of the pinger magnets has also been evaluated [3].

MAGNETS SPECIFICATIONS

The maximum kick to be provided by the pinger magnets to the electron beam was specified as 1.60 mrad in the horizontal plane and 1.15 mrad in the vertical plane by the Beam Dynamics group. Under these kicks the dynamic aperture can be probed up to the physical limits of the vacuum chamber. The pinger magnets have been installed in a short straight section where the beta functions are 9.17 m and 5.14 m in the horizontal and vertical plane respectively. The pulse width is required to be smaller than twice the revolution time (896 ns) and the goal was to stay below 1.5 us for the whole range.

DESIGN OF THE MAGNETS

The design of the magnets is based on a window shaped magnet made with ferrites, CMD5055, from Ceramic Magnetic Ltd and a single turn coil. The main magnets parameters are presented in Table 1.

Table 1 Main Magnets Parameters

Parameter	Units	HOR	VER
Gap	mm	38	94
Ferrite length	mm	300	300
Max kick	mrad	1.60	1.15
Max field	T	0.053	0.038
Intensity	A	1614	2869
L_{magnet}	uH	1.00	0.16

The magnets have been installed around an existing ceramic chamber with inner dimensions 24x80 mm and a length of 780 mm, as shown in Figure 1.

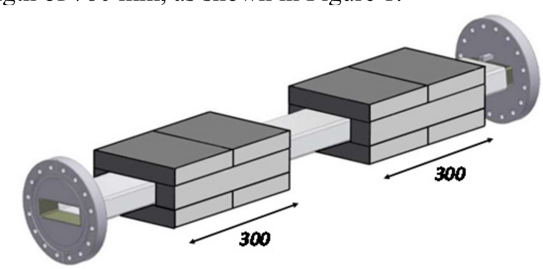

Figure 1: Installation of the magnets around the ceramic vacuum tube. Ferrite length in mm.

The chamber has a 0.4 μm Ti coating, which allows the circulation of the image current and it is thin enough not to generate significant eddy currents which might distort the magnetic pulse [4]. This ceramic chamber is the same that has been used for the ALBA storage ring injection kickers. Figure 2 shows the cross section of both magnets.

Magnetic simulations have been performed with OPERA-2d to ensure that the ferrites do not saturate. A field homogeneity of $\pm 5\cdot 10^{-4}$ has been achieved over ±25 mm. Figure 3 shows the magnetic field lines as obtained with OPERA-2d [5].

DESIGN OF A SUPERCONDUCTING GANTRY CRYOSTAT

Cristian Bontoiu*, Jose Sanchez-Segovia, FABIS, Spain
Rafael Berjillos, Javier Perez Bermejo, TTI, Spain
Ismael Martel, Univ. of Huelva, Spain

Abstract

The University of Huelva in collaboration with the Andalusian Foundation for Health Research (FABIS) [1] and the TTI Company [2] is currently involved in developing and assembling a prototype for a compact superconducting proton gantry with the goal to generate a business case within the narrow niche of hadron therapy. While main beam characteristics are reported in [3], this article presents the current status of the engineering design for the cryostat and beam steering system. An account for the mechanical deformations due to magnetic forces and weight is also presented.

INTRODUCTION

Beam dynamics studies have shown that protons of 175 MeV±20% kinetic energy can be handled and delivered at the target using a simple gantry made of two arcs of radius 2.5 m with 90° and 180° respectively, as shown in Fig. 1.

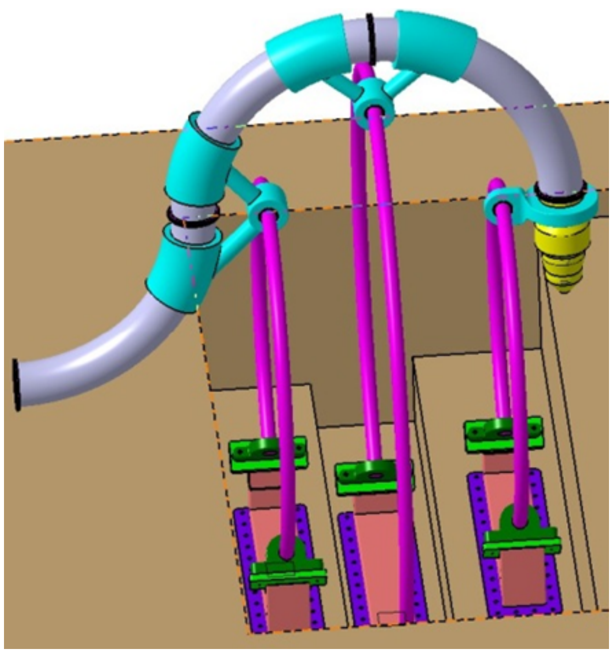

Figure 1: Overview of the gantry and its beam steering system installed on three support rings.

Within a preliminary design carried out in Catia [4] the gantry is installed on three rings which both take the load and constrain its motion within the plane defined by the isocentre. The main problems to be addressed for the cryostat are:

- mechanical support which cam minimize the deformations and stress due to the mass of the cryostat, coolant and magnets;
- rotation mechanism to enable a 270° excursion around the isocentre;
- technical solution for the junction between the rotating gantry arm and the fixed accelerator line to enable transfer of coolant and vacuum pumping;
- design of the support collars for the SC coils;

* cbontoiu@gmail.com

ASSEMBLY

The SC cryostat accommodates 36 combined-function magnets made of one one-layer quadrupole coils assembled on the top of one-layer dipole coils, their collars (clamps) and special channels for the coolant and vacuum insulation. In a simplified view as shown by Fig. 2 the cold liquid helium enters at 4 K through a coaxial pipe and fills the channel near the collars at hydrostatic pressure.

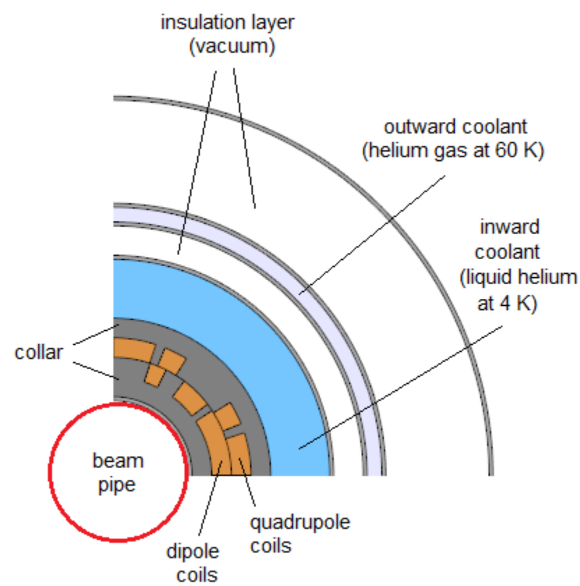

Figure 2: Sketch of the transverse layers to be considered for cryogenic cooling of the gantry.

As the SC coils trigger phase transition of helium from liquid to gas, bubbles accumulate at the highest point of the cryostat from where they can pass into a return coaxial channel through valves. These valves are distributed around the cryostat circumference and open synchronized with its motion only if they are at the highest altitude within some error margin. With rising vapour pressure the gas is pushed towards a larger coaxial port installed at the junction between the beam line and the gantry. There is a layer of vacuum between the liquid and gas helium layers and another one surrounding them in order to reduce heat transfer. Technical implementation of these ideas can be seen in Fig. 3 with the main components:

A NEW RF LABORATORY FOR DEVELOPING ACCELERATOR CAVITIES AT THE UNIVERSITY OF HUELVA

I. Martel, D. Gordo-Yáñez, A. K. Orduz, C. Bontiu, J. Dueñas, J. Sanchez-Segovia
University of Huelva, E-21071, Huelva, Spain

Abstract

The University of Huelva is presently involved in R&D projects for developing RF accelerator cavities. Two types of cavities are presently under design, a prototype of room temperature RFQ injector and a quarter-wave resonator for high intensity heavy-ion linear accelerators. The laboratory is equipped with dedicated test-bench for RF measurements, which includes high-power RF generators, network analyzer, amplifiers and power meters. A clean room is also available having a dedicated space for high-precision mechanical metrology and cavity mounting, together with a vertical cryostat for superconducting cavity test.

INTRODUCTION

Heavy-ion accelerators are the cornerstones of nuclear physics research. As our knowledge of subatomic degrees of freedom has increased during the last decade, new physics phenomena have emerged that require the construction of high intensity heavy-ion beams, with heavy-ion beam intensities of several milliamps on target.

A number of facilities are presently in construction around the world (ESS-Sweden, FRIB-USA, SPIRAL2-France) with will be soon operating and recognized as leading international research infrastructures. The need of high intensity beams demands however an important technological effort in developing high field RF accelerating cavities.

The main interest of implementation of a Radio-Frequency RF Laboratory at University of Huelva is to test the performance of RF cavity prototypes, allowing for improving the electromagnetic and thermo-mechanical design, mainly focused on heavy ion accelerators.

RF LABORATORY

The RF laboratory is complementary to a cryostat system foreseen for testing superconducting cavities. Main equipment of the lab is listed below:

- Agilent CX N9000A spectrum analyzer.
- Agilent 53181A, Frequency counter
- Rhode and Swartz Network analyzer 9k-6GHz
- 3 kW power-amplifier from DB-Elettronica
- Analog RF signal generator MXG N5181AEP from Keysight Technologies.

Figure 1: Bead pull system and cold model of RFQ in aluminium.

The lab is also equipped with a remotely operated beam pull system for field measurements (Fig. 1). The clean room is close to the test cryostat where superconducting cavities can be tested at T=4.5ºK. The space dedicated to the clean room has been prepared for assembly and testing of both particle detector systems and RF cavity systems. Total surface is of 50 m^2, divided in three main areas (Fig. 2):

- An over-pressurized area for entry of personnel and equipments of 20 m^2 (SAS).
- An ISO8 area of 30 m^2 containing a metrology system for quality control of mechanical elements.
- An ISO5 area of 4 m^2 has been prepared for special system assembly and manipulation.

The associated auxiliary equipment has been installed in a separate area of 18 m^2 close by the research complex.

First RF Tests

First activity of the lab has been dedicated to build and test a cold model (aluminium) of a RFQ cavity with design goal of 75.25 MHz, a representative working frequency of superconducting heavy-ion linacs. We have chosen an octagonal shaped cavity of 500 mm length (see Fig. 1), where four-vanes can be fixed using screws to the

RAMI OPTIMIZATION-ORIENTED DESIGN FOR THE LIPAC RF POWER SYSTEM

M. Weber, D. Regidor, C. de la Morena, P. Mendez, J.M. Arroyo, I. Kirpitchev, J. Molla, A. Ibarra
Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas, CIEMAT, Madrid, Spain

Abstract

The Linear IFMIF Prototype Accelerator (LIPAc) is currently under construction in Rokkasho (Japan). LIPAc will generate a continuous wave (CW) 9 MeV deuteron beam at 125 mA. It will serve to validate the final IFMIF accelerator concept and technologies. The radiofrequency (RF) power system is being integrated by CIEMAT (Spain) in collaboration with its partner companies and European institutes. LIPAc RF Power System design has been performed aiming high reliability, high availability and easy maintainability to address one of the most important requirements for IFMIF. The target of LIPAc tests is to validate the technologies and designs for the final phase of IFMIF. Several improvements in reliability, availability and maintainability have been implemented in the LIPAc RF Power System. These improvements are based on both, new technologies and new maintenance philosophy. The results of their first tests are shown in this paper.

INTRODUCTION

IFMIF will irradiate fusion structural materials under similar energy spectrum to the Fusion Neutron energy spectrum in order to test them under inner fusion reactor conditions. The data obtained from IFMIF are required for the building of the future DEMOnstration Fusion Reactor. Any delay in the IFMIF Program would directly delay the Fusion Program and the commercial application of Nuclear Fusion Energy.

Achieving the required dpa on the materials pivots on two parameters: deuteron current at the accelerator and irradiation time. Since IFMIF deuteron current is foreseen to be the maximum reasonably achievable (125mA per accelerator), the only way to speed up the program is by increasing the availability.

The RF Power System is the main active system of the accelerator. It is one of the largest systems and shares interfaces with most of the Accelerator Systems. Consequently, its availability highly impacts on the IFMIF's overall availability. An EFDA Report on technological options for the IFMIF RF Power System [1] was presented in 2007, assessing the use of solid state power amplifiers instead of tetrode based amplifiers. This report concluded that in the near future it would be advisable to develop a solid state alternative for the IFMIF amplifiers to take advantage of the inherent solid state availability characteristics. However, this technology was not ready for the LIPAc project due to the still low power MOSFET technology available in 2007.

Taking that into account, the first IFMIF RAMI (Reliability, Availability, Maintainability and Inspectability) studies [2] proposed a new availability target for the RF Power System for improving overall IFMIF availability: it should reach 98.2%. Two strategies have been followed for this purpose:

1. Improvements in the tetrode based LIPAc RF System.
2. Improvements in the solid state technology for a better performance and tighter fitting to this application.

LIPAc was then considered as a validating test bench for new proposals and new technologies devoted to improve the RF Power System availability.

AVAILABILITY FACTORS

All the developed improvements have been proposed following a RAMI optimization-oriented methodology. It consists of the continuous and iterated interaction between designers and RAMI engineers aiming at an enhanced availability. Since maximum operation time is defined by the characteristics of the critical components of the beam line, the RF Power System availability can be directly related to MDT (Mean Down Time). Two are the main MDT factors in which RF Power System can be improved:

1. MTBF (Mean Time Between Failures), which is mainly related to the reliability of the system.
2. MTTR (Mean Time To Repair), which is mainly related to the maintainability of the system.

THE LIPAC TETRODE BASED RF MODULE

Due to the high number of RF power chains at IFMIF (104), their high power levels (<220 kW each) and the high number of components required by the tetrode technology, the IFMIF RF power system reference design would have shown an unacceptable availability from the IFMIF's point of view.

An innovative solution was proposed in order to improve the availability: The RF Module [3]. This is a structure containing two complete RF chains, as shown in Fig. 1. All the components of both RF chains (except the HVPS) are on board. This daring design was developed by CIEMAT and its partner companies INDRA SISTEMAS and SEVEN SOLUTIONS. The full power tests of the amplifier demonstrated its capabilities, exceeding the foreseen. The achieved gain after the fine tuning is 25.4dB showing very high anode efficiency (73% at final amplifier). With 230kW CW RF output, the

HIGH POWER TESTING OF THE FIRST RE-BUNCHER CAVITY FOR LIPAC*

F. Toral#, C. de la Morena, D. Gavela, I. Podadera, D. Regidor, M. Weber, CIEMAT, Madrid
B. Bravo, R. Fos, J.R. Ocampo, F. Pérez, A. Salom, P. Solans, CELLS, Cerdanyola del Vallès

Abstract

Two re-buncher cavities will be installed at the Medium Energy Beam Transport (MEBT) of the LIPAc accelerator, presently being built at Rokkasho (Japan). They are IH-type cavities with 5 gaps and will provide an effective voltage of 350 kV at 175 MHz for deuterons at 5 MeV. The first prototype has been designed at CIEMAT and built by the Spanish industry. The high power tests and RF conditioning have been successfully performed at the ALBA/CELLS RF laboratory. A solid state power amplifier, which has been developed by CIEMAT and its partner companies at Spain for the LIPAc RF System, has been used for the tests. The cavity has shown a performance according to calculations, regarding the dissipated power, peak temperatures and coupling factor. RF conditioning was started with a duty cycle of 3%, which was increased gradually till continuous wave (CW), which is the nominal working mode in LIPAc.

INTRODUCTION

Two re-buncher cavities will be installed in the MEBT line [1], as part of the Spanish contribution to LIPAc. Electromagnetic and mechanical simulations led to a design based on a 5-gap IH-type cavity providing a 350 kV effective voltage at 175 MHz [2]. The first of the two cavities has been manufactured and tested with low power [3]. Last step to validate this cavity is the high power test.

EXPERIMENTAL SETUP

The high power test of the re-buncher prototype was performed at CELLS RF laboratory. It is equipped with a bunker with a useful surface about 15 m^2. Ancillary equipment (cooling, power, instrumentation) is available to ease the test of different cavity configurations.

Two vacuum pumps (one ionic and one turbomolecular) were installed at the CF160 ports on both sides of the cavity. A cold cathode gauge was installed at the beam pipe port, to measure the vacuum level as close as possible to the region with higher electric field, that is, the drift tubes. It was connected through a 100 mm long pipe to avoid the influence of the RF fields. A RGA analyser was installed at the other beam pipe port. An arc detector was also present (Fig. 1).

Six PT100 sensors were located at the expected hottest spots at the cavity, according to FEM simulations: one on each endplate, in front of the nearest stem; on the input coupler; two at the top part of the main body and the last one at the bottom, close to the central stems base.

The mechanical performance of the tuners was checked: position of limit switches and movement accuracy were within specifications. One tuner is manual and its initial position was set to get the nominal resonant frequency when the motorized one is at midpoint. The automatic tuner was powered using the ALBA standard driver for step motors, which also manages the limit switches.

The cooling was designed with a pressure drop of 2.3 bar for a flow of 31 l/min: four parallel channels, two with 12 l/min and other two with 3.5 l/min. However, a pressure drop of 3.8 bar was measured for a flow of 27.8 l/min, likely due to underestimated pressure drops at the cross section steps and elbows. The valves present in each parallel channel were used to balance the pressure drops accordingly. This regime was kept during the conditioning and shown to be enough.

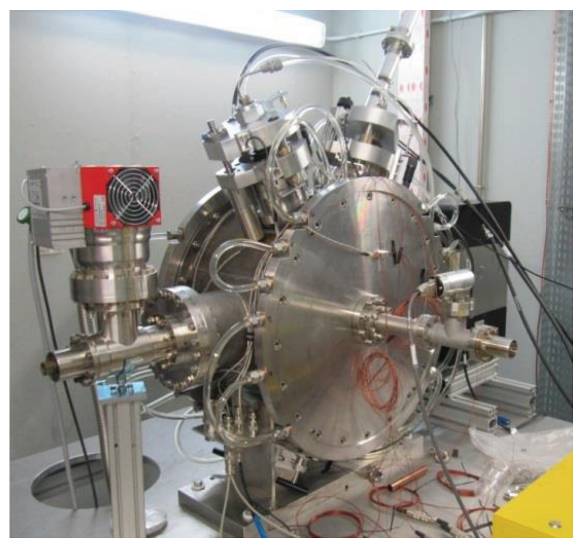

Figure 1: Test bench.

A solid state power amplifier (SSPA) [4] manufactured by BTESA (Spain) under CIEMAT specifications was used for the conditioning. It consists of ten parallel modules, each able to provide up to 2 kW. The low level RF system developed by CELLS/CIEMAT was used for the conditioning test bench, because all the local interlocks were already integrated: vacuum gauge, arc detector, reflected power, SSPA, temperatures, cooling flow, tuner limit switches and others. The enhanced low level RF system to be used in LIPAC has been developed by CIEMAT in collaboration with SevenSolutions (Spain).

CALCULATION AND DESIGN OF A RF CAVITY FOR A NOVEL COMPACT SUPERCONDUCTING CYCLOTRON FOR RADIOISOTOPE PRODUCTION (AMIT)*

D. Gavela#, J. Calero, L. García-Tabarés, A. Guirao, D. Obradors-Campos, C. Oliver, J.M. Pérez Morales, I. Podadera, F. Toral, CIEMAT, Madrid, Spain

Abstract

The AMIT (Advanced Molecular Imaging Techniques) cyclotron will be a 8.5 MeV, 10 μA, CW, H^- accelerator for the purpose of radioisotope production. It includes a superconducting, weak focusing, 4 T magnet, which allows for a small extraction radius and a compact design. The RF cavity design has to deal with challenging requirements: high electric fields created by the required accelerating voltage (60 kV), a narrow aperture of the magnet leading to high capacitances and thermal losses, and a requirement for a small overall size of the cavity. A quarter wave resonator with one dee (two acceleration gaps) design was chosen. Calculations with numerical codes such as HFSS and ANSYS have been performed to compute the main RF parameters and the stresses and deformations of the cavity due to the power losses and vacuum operation. Finally, the fluid dynamics of the cooling circuits have been carefully studied.

INTRODUCTION

Positron-emission tomography (PET) is a broadly used technique around the world for biomedical human imaging. Therefore, there is a high and increasing demand for positron emitter isotopes. The most effective PET isotopes (like ^{11}C or ^{18}F) have a short half-life (20 min and 2 h, respectively). Low energy cyclotrons (below 15 MeV) are the most widely used devices for their production. There is a growing interest in developing compact, light and cheap cyclotrons, capable of running at a small facility and producing the isotopes close to the patient, reducing the transport inconveniences and the loss of activity of the isotopes.

Spanish AMIT collaboration aims at producing a compact cyclotron for production of ^{11}C and ^{18}F isotopes. It will accelerate 10 μA of H^- ions to 8.5 MeV. It includes a superconducting, weak focusing, 4 T magnet.

CONCEPTUAL DESIGN

Table 1 summarizes the technical specifications of the cavity. Since AMIT cyclotron is of classical type, the magnet air gap has uniform height. Its RF cavity configuration is based on the typical 180 degree dee, at the end of a quarter wave coaxial resonator. The weak focusing limits the number of particle turns before the beam is lost. This imposes, for the required final energy, a minimum of 60 kV per gap, according beam dynamics simulations [1].

Other configurations have been studied trying to reduce RF power losses. That dissipation is due to the currents necessary to charge the capacitance between the dee and the vacuum chamber wall. A 90 degree dee features half the capacitance, that is, half of the charging currents, one quarter of the initial power losses. However, the nominal frequency should be doubled, which would yield the same original power losses for the same gap voltage. Furthermore, the phase shift is doubled, so the gap voltage should be increased to reach the same output beam energy according with beam dynamics simulations, resulting in additional RF power losses.

Two 90 degree dees do not allow decreasing the gap voltage and consequently the power losses, because the phase shift is doubled with the frequency, arising similar problems than the single 90 degree dee configuration. Furthermore, this layout is hardly compatible with the space necessary for the instrumentation and beam extraction [2].

Table 1: Cavity Technical Specifications

Frequency	60 MHz
Gap voltage	60 kV
Magnet air gap	74 x 280 mm
Maximum beam extraction radius	115 mm
Maximum beam axial excursion	± 6 mm
Tuning range	± 140 kHz

The aim is to keep the peak electric field below 1.5 times Kilpatrick criterion, that is, below 14.2 MV/m, at all the parts except the puller. The peak temperature shall be below 60ºC to keep moderate thermal emission of electrons and increase of copper resistivity due to heating.

ELECTROMAGNETIC CALCULATIONS

Ansys (including the high frequency electromagnetic package HFSS), has been used to perform the RF simulations [3]. Firstly, a static electric model was used to optimize the central region geometry. Eigenmode HFSS analysis was performed afterwards to achieve the resonance and to get the field maps. Finally, both input power coupler and pickup probe were designed using the HFSS DrivenModal analysis.

TRANSVERSE IMPEDANCE MEASUREMENTS AND DC BREAKDOWN TESTS ON THE FIRST STRIPLINE KICKER PROTOTYPE FOR THE CLIC DAMPING RINGS*

C. Belver-Aguilar, IFIC (CSIC-UV), Valencia, Spain
A. Faus-Golfe, IFIC (CSIC-UV) and LAL, Université Paris-Sud, Orsay, France
F. Toral, CIEMAT, Madrid, Spain
M.J. Barnes, H. Day, CERN, Geneva, Switzerland

Abstract

A first stripline kicker prototype for beam extraction from the CLIC Damping Rings (DRs) has been designed at IFIC and CIEMAT, with excellent field homogeneity, good power transmission and low beam coupling impedance. The prototype has been built by the company Trinos Vacuum Projects, and laboratory tests and measurements have been carried out at CERN to characterize, without beam, the electromagnetic response of the striplines. In this paper, we present the measurements of the transverse beam coupling impedance, using the coaxial wire method, and a comparison with simulations. Furthermore, results of DC breakdown tests, using High Voltage (HV) power supplies, are also reported.

TRANSVERSE BEAM COUPLING IMPEDANCE MEASUREMENTS

Measurements in the laboratory, without beam, are important to characterize the electromagnetic response of the striplines, and compare the results of the measurements with the electromagnetic simulations. The measurements carried out in this first prototype have been the following: (1) power reflection through the striplines, (2) longitudinal beam coupling impedance, and (3) transverse beam coupling impedance. In addition, DC breakdown tests have been carried out. In this paper, results for the transverse beam coupling impedance, as well as for the DC breakdown tests will be presented.

For transverse beam coupling measurements, two techniques are commonly used: (1) the two wire method, or (2) the moving single wire method [1,2]. The two wire method consists of inserting two wires in the striplines aperture, and driving them with opposite phase RF waves. With this method, the dipolar component of the transverse impedance is calculated, whereas with the moving single wire method the total transverse impedance (dipolar and quadrupolar components) is measured. The setup for the two measurements is shown in Fig. 1. The results of these measurements have been compared with CST Particle Studio (PS) [3] simulation results for the dipolar and the total transverse beam coupling impedance.

* Work supported by IDC-20101074, FPA2013-47883-C2-P and ANR-11-IDEX-0003-02

Two Wire Method

The dipolar component of the transverse impedance of the striplines has been measured by producing a dipolar field with two wires, of 0.5 mm diameter each, driven with opposite phases by using two hybrids. To have a measurable effect, the wire spacing should be significantly smaller than the aperture, due to the fact that the dipolar field created only interacts with the fringe fields and, therefore, the effects are small: a wire spacing of about a third of the aperture appears to be a good compromise [1]. In our case, for an aperture of 20 mm a wire spacing of 7 mm has been chosen. In order to match the two wire line impedance to the impedance of the Network Analyzer, the hybrids and the loads, a matching resistor at the ends of each wire has been used. To calculate the resistance value of each matching resistor, the following equation has been used:

$$R_S = Z_{line}/2 - Z_0 \tag{1}$$

where Z_{line} is the differential-mode line impedance and $Z_0 = 50\,\Omega$. The differential-mode line impedance for two wires with opposite polarity is given by:

$$Z_{line} = \frac{120}{\sqrt{\epsilon_r}}\text{acosh}\frac{\Delta}{d} \tag{2}$$

where ϵ_r is the relative permittivity of the medium between the wires ($\epsilon_r = 1$ here), d is the wire diameter and Δ is the wire spacing. In our case, using Eq. (2), the calculated value of Z_{line} is 399.7 Ω: low-inductance (carbon film) single series resistors of 160 Ω have been used for the matching network. The transmission parameter S_{21} has been measured with the Network Analyzer, and from this measurement the longitudinal impedance $Z_{||}$ can be estimated by using the formula [1]:

$$Z_{||} = -2Z_{line}\,ln(S_{21}) \tag{3}$$

Then the dipolar component of the transverse impedance has been found from the following equation:

$$Z_{\perp,dip} = \frac{cZ_{||}}{2\pi f\Delta^2} \tag{4}$$

where c is the speed of light, and f is the frequency at which the S_{21} parameter is measured. Results for the dipolar horizontal and vertical impedance are shown in Fig. 2, when terminating the electrodes with the "ideal" 50 Ω resistors from

DESIGN STUDY AND CONSTRUCTION OF A TRANSVERSE BEAM HALO COLLIMATION SYSTEM FOR ATF2

N. Fuster-Martínez, IFIC (CSIC-UV)*, Valencia, Spain
A. Faus-Golfe, IFIC (CSIC-UV) and LAL, Université Paris-Sud, Orsay, France
P. Bambade, S. Liu, S. Wallon, LAL, Université Paris-Sud, Orsay, France
F. Toral, I. Podadera, CIEMAT, Madrid, Spain
K. Kubo, N. Terunuma, T. Okugi, T. Tauchi, KEK and SOKENDAI, Japan

Abstract

The feasibility and efficiency of a transverse beam halo collimation system for reducing the background in the ATF2 beamline has been studied in simulations. In this paper the design and construction of a retractable transverse beam halo collimator device is presented. The wakefield induced-impact of a realistic mechanical prototype has been studied with CST PS, as well as the wakefield beam dynamics impact by using the tracking code PLACET.

INTRODUCTION

ATF2 is a Beam Delivery System (BDS) built after the ATF Damping Ring (DR) providing a scaled-down version of the Future Linear Collider (FLC) Final Focus System (FFS) [1]. The two main goals of ATF2 are to obtain a vertical beam spot size at the virtual IP of 37 nm and to stabilize the beam at the nanometer level. The control and reduction of the beam halo that could be intercepted in the beam pipe producing undesired background is a crucial aspect for FLC and ATF2. A beam halo collimation system in ATF2 will play an essential role in the reduction of the background noise that could limit the performance of key diagnostic devices around the final focal point (IP), especially the Shintake Monitor (IPBSM) used for measuring the nanometer level vertical beam sizes and the recently installed Diamond Sensor (DS) in the post-IP beamline to investigate the beam halo distribution [2, 3]. A first feasibility study was done and reported in [4]. From these studies a vertical collimator system has been considered as the first priority. In this paper we present a first 3D mechanical design as well as a transverse wakefield study for the realistic 3D prototype by using the 3D electromagnetic solver CST PS [5]. Also the wakefield impact on the orbit and beam size has been evaluated by using the tracking code PLACET [6].

DETAILED 3D MECHANICAL DESIGN

A detailed version of the 3D mechanical design based on the optimized geometrical parameters reported in [4] and previous experiences in [7–10] is shown in Fig.1. The collimator jaws will be made of Copper (Cu) and the rest of the components including the transition part will be made of Stainless Steel (SS) because of stiffness and assembly considerations.

* Work supported by IDC-20101074, FPA2013-47883-C2-1-P and ANR-11-IDEX-0003-02

The seal of the rectangular chamber will be made with indium wires and other seals will be Cu seals for DN40CF flanges. An important part of the collimation device will be the retractable movable system with a expected precision of $\pm 10\mu m$. Two step by step EMMS-ST-42-S-...-G2 motors will be used to move independently the two rectangular vertical tapered jaws. In Fig.1 (right) a more detailed picture of the movers and slides is shown. The collimator is under construction and it will be installed at ATF2 in the 2015 fall run.

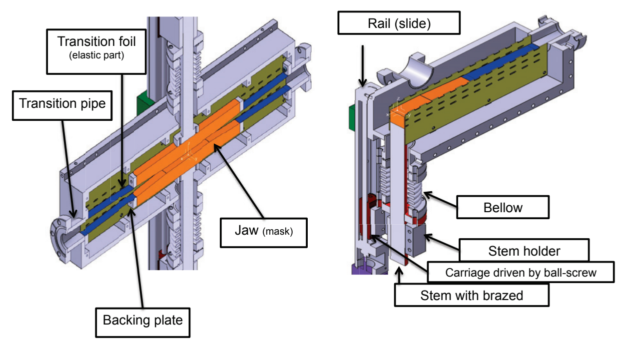

Figure 1: Detailed 3D mechanical design.

WAKEFIELD IMPACT STUDY: CST PS NUMERICAL SIMULATIONS

In this section we present a wakefield impact study of a realistic rectangular vertical tapered halo collimator structure based on the 3D mechanical design of Fig.1. The collimator system will add an impedance on the beamline that could perturb the beam stability, therefore it is important to minimize the wakefields and to demonstrate that the impact on the beam can be tolerated in terms of beam stability. The model simulated with CST PS is shown in Fig.2. The 3D model is divided in 3 millions of hexahedral mesh cells. The electromagnetic fields are exited by a gaussian bunch of 7 mm bunch length, 1 pC bunch charge and 1 mm offset in the vertical plane. The frequency up to which the fields will be taken into account for the wake potential calculation was set to 20 GHz. The main volume of the model is set to vacuum and it is surrounded by perfectly conducting material. The jaws are made of Cu and the material of the transition foil has been studied. Simulations have been made with SS and Aluminium (Al) transition foils. The resulting wakepotential can be seen in Fig.3. The impact of the material on this component of the collimator is small therefore SS has been

ESS PLC CONTROLS STRATEGY

D. Piso, S.L. Birch, A. Nordt, T. Gahl, P. Arnold, J. Weisend II, T. Korhonen
European Spallation Source, Lund, Sweden

Abstract

The European Spallation Source ESS AB is an accelerator-driven neutron spallation source. The Integrated Controls System (ICS) division is responsible for providing controls and monitoring for all parts of the machine (accelerator, target, neutron scattering systems and conventional facilities). Also, Accelerator Division, Target Division and other parts of the organisation will be deploying PLC Automation Systems. A large number of applications have been identified across all the facility where PLCs will be used: cryogenics, vacuum, water-cooling and fluid systems, power systems, and safety & protection systems. This work describes the different activities put in place and the strategy followed at ESS regarding PLC technologies. This strategy consists not only of the standardisation of a PLC vendor but also testing activities, generation of documentation and standardisation of other aspects (for instance, regarding installation). The documentation about PLC controls integration and standardisation and the approach to insert PLCs in the different controls workflows are described. Finally, the results of different tests (PLC timing correlation) are shown.

HARDWARE STRATEGY

The ICS division has deployed a hardware strategy based on the different types of applications expected in the ESS project. At the same time, a compromise is needed in order to keep the number of the different used technologies to a minimum, which ensures maintainability from a long term point of view. According, to this premises ICS has standardised three different types of technologies:

- **Fast, real-time signal processing**. In this category fall those cases that need state-of-the-art technology, a range of acquisition in MHz or GHz sampling rates, and FPGA-based processing in many occasions is included. For this type of applications ESS has decided to use the microTCA platform [1]. Currently, ICS is working in all the processes needed after the platform selection (firmware, software, operational procedures). This also, involves the selection of other technologies and standards like FMC (FPGA Mezzanine Card).

- **Middle-range I/O**. This segment is designated to fill the gap between the fast real-time I/O described above and the traditional industrial I/O solutions. In this segment, real-time requirements have still to be met but the requirements for data processing and transfer are less stringent. The ESS standard platform for this range of tasks is the EtherCAT [2] standard that uses regular Ethernet wiring but has a specialised protocol that enables tight time synchronization (kHz range I/O).

- **Industrial I/O**. Most of the systems that do not require tight synchronisation with the ESS accelerator cycles (14 Hz) are best served by programmable logic controllers (PLCs). PLCs will be considered when the built-in logic ensures safe operation of the device under control even if the connection to the upper layer (EPICS) is broken. Cooling systems, vacuum control, (slow) interlocks, etc., are typical examples of areas where PLC is an appropriate choice.

USE CASES

A large number of applications have been identified across all parts of the facility where PLCs will be used: cryogenics, vacuum, water-cooling, fluid and power systems, building management, safety and protection systems. They have common characteristics in terms of relatively long response for their control systems (tens to hundreds of miliseconds), standard industrial sensors and actuators, etc.

- **Cryogenic Systems**. ESS will own a number of cryogenic systems. The cooling power will be produced in 3 different cryoplants (Accelerator Cryoplant, Test Stand & Instruments Cryoplant and Target Moderator Cryoplant). A Cryogenic Distribution System will connect the cryoplants to the Accelerator, Target and Cryomodule Test Stand. The most important characteristics of these control systems (regarding PLCs) is that regulation-using PIDs will be needed. The I/O needed will be based on analog and digital acquisition. The protocols Profibus PA, Profibus DP and Profinet CBA, defined in the standard IEC 61784-1 will be extensively used, as the I/O needs to be highly distributed. Communication processors with serial interfaces may be also needed.

- **Vacuum Systems**. Vacuum Controls involve the handling of different types of signals, at different scanning rates and a great part of them at a suitable range for PLCs (<1Khz). Reading analog and digital signals from different gauges, controlling vacuum equipment with analog and digital signals (eg. mass flow controllers and gate valves) are the main use cases. In term of logic, PLCs will be mainly used for interlocks and maybe for implement states diagrams in order to control equipment.

- **Water-Cooling and Fluid Systems**. These are also typically industrial systems where the most frequent signals are analog I/O, digital I/O, PT100 temperature sensors and fieldbuses to distribute this periphery. From the logic point of view interlocking and regulation could be the major applications. Fluid Systems. Specialty

MAX IV 3 GeV STORAGE RING MAGNET BLOCK PRODUCTION SERIES MEASUREMENT RESULTS

M. Johansson*, L-J. Lindgren, M. Sjöström, P. F. Tavares, MAX IV Laboratory, Lund, Sweden

Abstract

The magnet design of the MAX IV 3 GeV storage ring replaces the conventional support girder + discrete magnets scheme of previous third-generation synchrotron radiation light sources with a compact (Ø25 mm aperture) integrated design having several consecutive magnet elements precision-machined out of a common solid iron block. The production series of 140 integrated magnet block units, which was totally outsourced to industry, was completed mid-2014. This article presents mechanical and magnetic field measurement results of the full production series.

INTRODUCTION

The MAX IV synchrotron radiation facility [1], consisting of two storage rings, 3 GeV and 1.5 GeV, and a full energy linac, is currently being installed/commissioned in Lund, Sweden. The 3 GeV storage ring [2] has a multibend achromat (MBA) lattice, consisting of 20 achromats, each consisting of 7 cells, with a circumference of 528 m. The integrated magnet design concept of the 3 GeV ring has each lattice cell realized as one "magnet block", consisting of several consecutive magnet elements in a common solid iron yoke (see Fig. 1), so that the whole lattice consists of 140 such magnet block units. A detailed presentation of this magnet design has been given previously in [3].

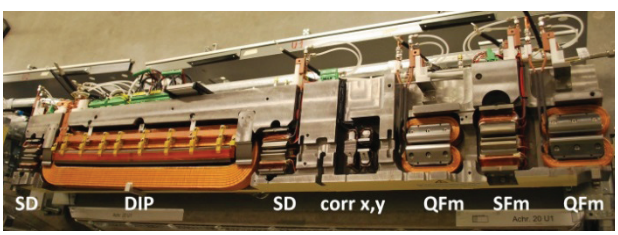

Figure 1: U1 magnet block bottom half.

There are 7 magnet block types per achromat (see Fig. 2). M1 and M2, 2.3 m long, are mirror identical. U1 and U2, 2.4 m long, are identical and U4/U5 are mirror identical to U1/U2. U3, 3.4 m long, has similar layout to the other U, but symmetric around its own midpoint.

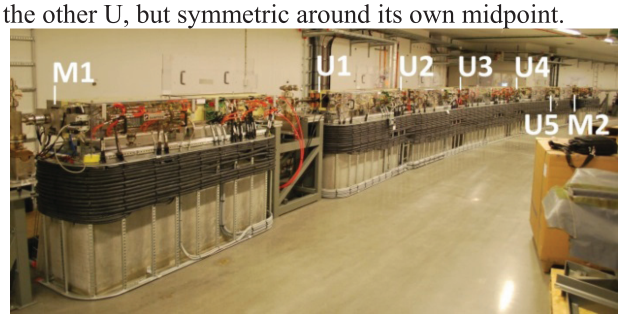

Figure 2: Achromat 04 in the 3 GeV ring, fully assembled.

*martin.johansson@maxlab.lu.se

Mechanical Design Concept

The main structural parts of the magnet blocks are the yoke bottom and yoke top blocks (Fig. 3), which are each machined from a single block of iron[1].

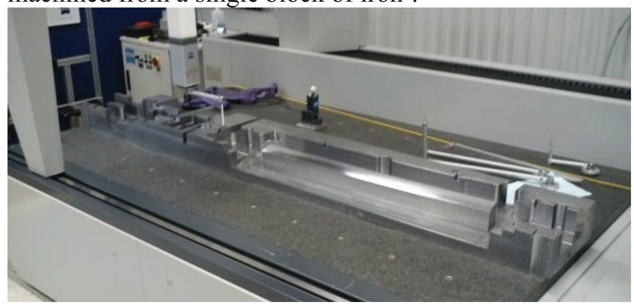

Figure 3: U4/U5 yoke bottom half undergoing 3D mechanical measurement.

The pole surface of the dipole is machined directly out of the block, whereas the quad and corr. pole tips are dismountable, to allow coil installation. Sextu- and octu-poles are designed as complete magnet halves, which are mounted in the yoke blocks (see Fig. 1). Mechanical tolerances for the different categories of function critical surfaces in the yoke bottom/top blocks are:

- Vertical mating planes for quad pole tips and sextupole/octupole yoke halves: distance to midplane ±0.02 mm.
- Sideways guiding slots for quad pole tips and sextupole/octupole yoke halves: distance to sideways ref. surfaces[2] ±0.02 mm.
- Midplane: flatness[3] tolerance 0.04 mm.
- Dipole: surface shape[4] tolerance 0.04 mm.

And tolerances for the other critical yoke parts are:

- Quad pole pieces: surface shape tolerance 0.02 mm
- Sextupole/octupole yoke halves with poles assembled: surface shape tolerance 0.04 mm.

Procurement

The production of the magnet blocks was outsourced as build to print-contracts, based on a technical spec. and full set of drawings [4] provided by MAX-lab, with suppliers being responsible for mechanical tolerances, and for performing field measurements according to MAX-lab instructions, and MAX-lab being responsible for the field measurement results. The contracts for the magnet blocks production were awarded in the fall of 2011, to two

[1] "ARMCO Pure Iron grade 4", C < 0.01%.

[2] Two outer corners on the yoke block together with the midplane define the mechanical reference frame in which all the tolerances are evaluated

[3] The mechanical tolerance called "flatness" is defined as peak-to-peak deviation between measured data points and a best fit-plane.

[4] The mechanical tolerance called "surface shape" is defined as the twice the amplitude of the largest deviation within the tolerance zone, ie 0.04 mm means ±0.02 mm.

PROGRESS AT THE FREIA LABORATORY

M. Olvegård, A. K. Bhattacharyya, D. Dancila, T. Ekelöf, J. Eriksson, K. Fransson, K. Gajewski, V. Goryashko, L. Hermansson, M. Holz, M. Jacewicz, M. Jobs, Å. Jönsson, H. Li, T. Lofnes, H. Nicander, R. Ruber, A. Rydberg, R. Santiago Kern, R. Wedberg, V. Ziemann, Uppsala University, Sweden, R. Yogi, ESS, Lund, Sweden

Abstract

The FREIA Facility for Research Instrumentation and Accelerator Development at Uppsala University, Sweden, has reached the stage where the testing of superconducting cavities for the European Spallation Source (ESS) is starting. The new helium liquefaction plant has been commissioned and now supplies a custom-made, versatile horizontal cryostat, HNOSS, with liquid helium at up to 140 l/h. The cryostat has been designed and built to house up to two accelerating cavities, or, later on, other superconducting equipment such as magnets or crab cavities. A prototype cavity for the spoke section of the ESS linac will arrive mid 2015 for high-power testing in the horizontal cryostat. Two tetrode-based commercial RF power stations will deliver 400 kW peak power each, at 352 MHz, to the cavity through an RF distribution line developed at FREIA. In addition, significant progress has been made with in-house development of solid state amplifier modules and power combiners for future use in particle accelerators. We report here on these and other ongoing activities at the FREIA laboratory.

INTRODUCTION

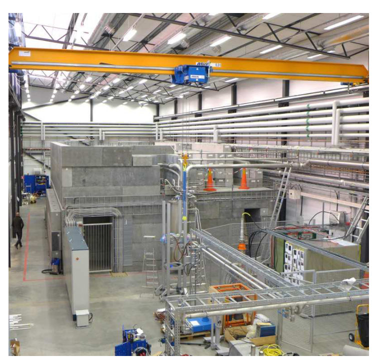
The European Spallation Source (ESS) [1] is under construction in Lund, Sweden. Once completed it will deliver spallation neutrons to a large number of experiments with users from various disciplines interested in the fundamental atomic and molecular properties of materials. As any major accelerator complex, ESS strives to keep the power consumption to a minimum, which motivated the use of a superconducting linac. This linac provides an intense 5 MW proton beam of 2 GeV energy, in 2.86 ms long pulses with 14 Hz repetition rate to the ESS target.

The first superconducting section of the linac uses double-spoke cavities designed and tested at low power at Institut de Physique Nucléaire d'Orsay (IPNO), France. FREIA is charged with designing and testing RF generation and distribution systems for ESS and to test the double-spoke cavities at nominal power. One or several prototype cavities, equipped with a input power coupler and a cold tuning system, are expected mid 2015. The high-power tests require feeding the cavity with 3.5 ms long 352 MHz RF pulses of 400 kW power. It also includes cooling the cavity to, and keeping it at, 2 K. To this end, FREIA has a high capacity helium liquefaction plant and a tailor-made horizontal cryostat, which can serve two superconducting cavities simultaneously.

In parallel with the ESS study, FREIA hosts research programs such as the development of solid-state amplifiers for accelerator applications, the design of a combined compact THz/X-ray source, and studies within the ESS neutrino super-beam project. This paper gives a status overview of the FREIA laboratory, reporting on progress in infrastructure subsystems and on its main activities.

THE FREIA LABORATORY

The FREIA laboratory was inaugurated in June 2013 and is now nearly full of state-of-the-art equipment for accelerator research and development. The view of the 1000 m^2 hall, displayed in Fig. 1(a), is dominated by three radiation bunkers built with an iron pre-loaded concrete material (magnetite) to shield people and environment from the potential X-rays emitted during operation with high-power RF. The main bunker contains the superconducting RF (SRF) equipment for the spoke cavity and cryomodule tests for ESS. A smaller bunker has been pre-assigned to tests of high-gradient, high-frequency copper accelerating structures, either for the Compact Linear Collider or for possible future free electron lasers, or medical accelerators. Another small bunker will house a neutron source for research and educational activities in applied nuclear physics.



(a) FREIA

(b) HNOSS

Figure 1: The FREIA laboratory (a) and the horizontal cryostat HNOSS installed in the main bunker (b).

Helium Liquefaction Plant

The heart of the laboratory is the helium liquefaction and recovery plant. The liquefier L140 was acquired from Linde Kryotechnik AG and commissioned in March 2014.

HALL PROBE MEASUREMENTS OF 80 UNIT CELL MAGNETS FOR THE MAX-IV STORAGE RING

A. Ahl, Scanditronix Magnet, Vislanda, Sweden

Abstract

80 unit cell magnet segments have been manufactured by Scanditronix Magnet for the 3 GeV storage ring at MAX-IV in Lund, Sweden. All of the magnets have been approved by Max-lab after a large field measuring campaign using both a high precision Hall probe bench, as well as a new rotating coil system. Each unit cell magnet consists of one dipole, two quadrupole, three sextupole and one vertical and one horizontal corrector magnets. The Hall probe bench was used to measure the dipole magnet (with combined dipole and quadrupole component) as well as the quadrupole magnets. This paper will focus on the Hall probe measurements performed on the dipole magnets from the perspective of a manufacturer. E.g. the repeatability of the measurements and the relation between field performance and mechanical tolerances will be analysed.

MAX-IV

MAX-IV aims to be the new centre for synchrotron light in Sweden, and will be the replacement of the smaller MAX-II and MAX-III storage rings. The accelerator complex will consist of a linac and two storage rings (see Fig. 1), with the larger one having a circumference of 528 m and electron energy of 3 GeV. The concept is similar to that of the MAX-III accelerator, focusing on a compact magnet design, with combined function magnets. Also with separate magnetic elements built into the same iron block. This keeps the overall dimensions of the magnets down, as well as simplifies the alignment of the magnets [1].

The entire 3 GeV storage ring contains 20 achromats, with each achromat consisting of two matching cells and five unit cells. The cells contain one dipole magnet each which gives the storage ring the advantages of a multi-bend achromat lattice, which lowers the electron beam emittance. It also has the benefits of increasing the energy acceptance, as well as improves the dynamic aperture [2].

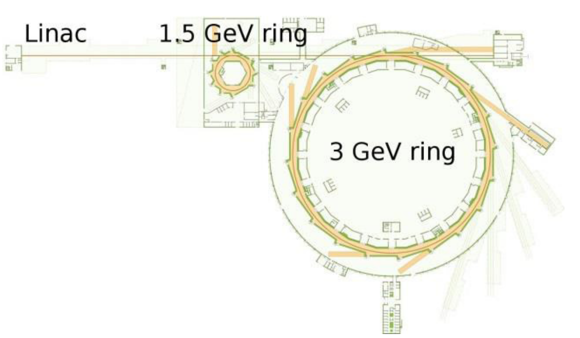

Figure 1: An overview of the MAX-IV accelerator complex. Courtesy of MAX IV Laboratory.

Scanditronix has produced four of the five unit cell families (U1, U2, U4 and U5) as seen in Fig. 2. The magnets contained in the U1 and U5 cells are identical, and U2 and U4 as well, the only difference is that the cells are mirrored versions of each other. However, all four families contain the same dipole magnet.

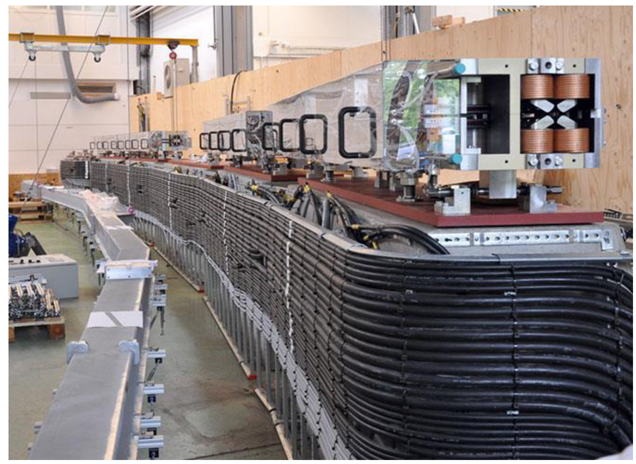

Figure 2: Image of one achromat (mock-up). Courtesy of MAX IV Laboratory.

Scanditronix Magnet selected two subcontractors for the machining of the iron blocks to keep the tight time schedule for the project. One company produced the U1 and U2 segments, and the other produced the U4 and U5 segments. It is seen from the results of the field measurements that there are no significant difference between the magnets machined at the two subcontractors.

HALL PROBE BENCH

Scanditronix Magnet acquired a new state-of-the-art Hall probe mapping bench (see Fig. 3) to meet the high precision in measurements that was required by Max-lab. This is located in a temperature controlled room where the magnets were stored until correct measuring temperature was achieved. The base of the measurement system is a 3D coordinate measuring machine (CMM) of portal type from Hexagon Metrology. This is built on a flat table of solid granite, to ensure a horizontal placement of the magnets, as well as a good resistance against vibrations.

The CMM has been equipped with a Hall probe and teslameter from Group3, with an absolute accuracy of ±0.01% of reading ±0.006% of range [3].

The CMM has a volumetric measuring range of 3000x1200x1000 mm, and an accuracy of about 5 µm per

UPGRADE OF THE TCDQ DILUTERS FOR THE LHC BEAM DUMP SYSTEM

M. G. Atanasov, W. Bartmann, J. Borburgh, C. Boucly, C. Bracco, L. Gentini, B. Moles, W. Weterings, CERN, Geneva, Switzerland

Abstract

The TCDQ diluters are installed as part of the LHC beam dump system to protect the Q4 quadrupole and other downstream elements during a beam dump that is not synchronised with the abort gap, or in case of erratic firing of the extraction kickers. These diluter elements installed during Run 1 were compatible with beam up to 60 % of the nominal intensity, which was insufficient for the second run of the LHC. This paper describes the requirements for the upgrade done during the First Long Shutdown (LS1), to make the TCDQ compatible with the full 7 TeV LHC beam at intensities that are required for the future runs of the machine. Subsequently the mechanical design changes, implementation and commissioning of the TCDQ are reported.

INTRODUCTION

The need to upgrade the single jaw moveable diluter elements Target Collimator Dump Quadrupole (TCDQ) was already apparent during the first run of the LHC. Whereas the initial design was sufficient for operating at the lower intensity adopted for the first physics run of the machine, simulations have shown that the system would not survive the impact of the LHC beam at ultimate intensity and beyond [1]. The proposed upgrade required the absorber material to be changed from 1.77 g/m^3 graphite to a sandwich of lower density carbon fibre-reinforced carbon (C/C) and graphite, and the total absorber length to be increased from 6 to 9 m [2]. The displacement system would also have to accommodate for a ±1 mrad radial displacement with respect to the longitudinal centre of the diluter [3] [4].

CONSTRUCTION OF THE ABSORBER

The upgrade of the diluter required the dismantling of the four tanks from the tunnel and the two spares for the replacement of the graphite absorber blocks with the C/C and graphite sandwich, and the refurbishment of the cooling circuit fittings. The old graphite blocks have been removed and stored in a radioactive storage bunker. The estimated dose rate during the dismantling was 1 µSv/h at 10 cm.

Absorber Blocks

The new absorber blocks measure 250 mm in length and 72 mm in height. The width is 40 mm for the C/C and 35 mm for the graphite. The C/C blocks of densities 1.4 and 1.75 g/m^3 are produced from carbon fibre preforms (or pre-pregs) using the Rapid Chemical Vapour Infiltration (R-CVI) technique. The first axis of maximum strength is the vertical *y* axis as seen by the beam. The fibre orientation in adjacent layers is 0º/90º/0º/90º. The graphite is of type R4550 with a density of 1.8 g/m^3. Figure 1 shows one of the C/C blocks during the quality assurance.

Figure 1: C/C absorber block.

In order to condition the new blocks for the Ultra-High Vacuum (UHV) of the LHC both material types were pre-cleaned with small amounts of alcohol and acetone. The final cleaning was done by CO_2 jet blasting. To reduce the outgassing rates, the blocks were subsequently heat-treated under vacuum in two two-hour stages at 600 ºC and 1000 ºC with several stabilization plateaux. Beam impedance considerations require the face of the C/C blocks adjacent to the beam to be copper coated by means of magnetron sputtering with a first layer of titanium providing better adherence for the 5 µm layer of copper. Furthermore as the figure shows the blocks at the extremities of each vacuum tank are tapered for a smooth transition between the racetrack endplate and the interior of the absorber structure.

Vacuum

After assembly the vacuum tanks were baked-out in an oven at 300 ºC for 24 hours with a temperature ramp of 13 ºC/h and a stabilization plateau at 150 ºC and subsequently aligned in a clean room. The tanks are equipped with heating jackets for bake-out in the LHC tunnel during commissioning of the vacuum sectors. The vacuum levels achieved during the validation in the assembly and test lab were in the order of $1{\cdot}10^{-10}$ mbar. The newly constructed spares are reaching the 10^{-11} mbar

UPGRADE OF THE CERN SPS EXTRACTION PROTECTION ELEMENTS TPS

J. Borburgh, B. Balhan, M. Barnes, C. Baud, M. Fraser, V. Kain, F. Maciariello, G. Steele, F. Velotti, CERN, Geneva, Switzerland

Abstract

In 2006 the protection devices upstream of the septa in both extraction channels of the CERN SPS to the LHC were installed. Since then, new beam parameters have been proposed for the SPS beam towards the LHC in the framework of the LIU project. The mechanical parameters and assumptions on which these protection devices presently have been based, need validation before the new upgraded versions can be designed and constructed. The paper describes the design assumptions for the present protection device and the testing program for the TPSG4 at HiRadMat to validate them. Finally the requirements and the options to upgrade both extraction protection elements in the SPS are described.

INTRODUCTION

Extraction protection elements (TPSGs) are installed upstream of the magnetic septa in the SPS extraction channels towards the LHC. In Long Straight Section 4 (LSS4), the TPSG4 is installed upstream of 6 thick (MSE) septa, while in LSS6 the TPSG6 is installed just upstream of 2 thin (MST) septa. The first TPSG4 was installed in 2003, while the TPSG6 was installed in 2007 [1]. They protect the magnetic septa against mis-steered beams. This case should remain rare and the current of the extraction bumpers is interlocked to reduce the risk of a full impact. The case of an asynchronous firing of the kicker would result in a sweep of the beam over the diluter and the septa.

In case of full impact the TPSGs will dilute the beam such that the energy deposition and the subsequent temperature rise in the downstream MST septa conductors will stay at tolerable levels. In particular, the energy deposition in the cooling water of the septum conductor is critical, as it provokes shock waves in the cooling water circuit, which may lead leaking water to the beam vacuum.

ACTUAL DESIGN

The present devices were designed for direct impact of the full, so called LHC ultimate, LHC beam. The aim on the device was to properly protect the downstream septa, while surviving itself the impact sufficiently to avoid an exchange. Following updated calculations [2] more robust designs were proposed and built, making use of then state of the art 2D Carbon Reinforced Carbon (CfC). The TPSG4 was modified and the highly stressed graphite was partly replaced by CfC to cope with the dynamic mechanical stresses. With respect to the earlier version the TPSG4 was lengthened up to 3100 mm to compensate for the lower density of the CfC with respect to graphite. The design assumed impact centred around on a septum conductor cooling tube as on the initial calculations [3,4]. For the final design of the TPSG6 the CfC was also used to replace part of the graphite. The final absorbing sandwich is indicated in Table 1.

The graphite and CfC parts of the diluters themselves would sustain a full impact, while the Von Mises stress levels would exceed the maximum values permitted for the metallic blocks at the exit of the diluters. Since this stress level would only be exceeded in a small volume, it was deemed acceptable.

Table 1: TPSG Diluting Structure

	TPSG4	TPSG6
Graphite (CZ5) [m]	0.5	
Carbon reinforced Carbon [m]	1.7	1.75
Graphite (CZ5) [m]	0.3	0.85
Titanium (TiAl6V4) [m]	0.3	0.3
Inconel (Inco 718) [m]	0.3	0.6
Total dilution length [m]	3.1	3.5

The protection requirements for each TPSG (Table 2) are based upon the assumptions that the coil can withstand the same dynamic pressure as the coils are statically tested during construction. The maximum permissible pressure rise is obtained by reducing the pressure of the cooling circuit in operation in the SPS tunnel (25 bar) from the static test pressure. The maximum permissible copper temperature rise is determined by the space available in the yoke for the increase in length of the coil from the normal operating temperature. Finally the maximum water temperature rise in the cooling channels was determined from the permissible pressure rise using the ELSE code [2, 4].

TESTS AT HIRADMAT

To validate the diluter design assumptions, tests were prepared which took place at HiRadMat in 2012. The tests' aim was two-fold: to validate the design assumptions to protect the septa and to validate the assumption exceeding the maximum Von Mises stresses locally in the metallic blocks of the diluter is acceptable. A spare MSE and TPSG4 were made available for this test.

MEASUREMENT TECHNIQUES AND APPLICATION OF COMBINED PARALLEL/ORTHOGONAL MAGNETIC BIAS ON A FERRITE TUNED RESONATOR IN LOW FREQUENCY RANGE (3-10 MHz)

G. Favia, CERN, Geneva, Switzerland; University of Rome "La Sapienza", Roma, Italy
F. Caspers, M. Morvillo, C. Rossi, C. Vollinger, CERN, Geneva, Switzerland

Abstract

We present several measurement methods for evaluation of magnetic properties of magnetically biased and non-biased ferrite samples in a coaxial test fixture. One important aspect is the crosscheck of results obtained by using different and independent measurement and evaluation methods. Since a rather high DC bias current has to be applied, a dedicated network was designed that allows the passage of up to 50 A DC without degradation of the RF performance. With a combination of calibration methods and a compensating topology with two identical sample holders, a good performance was achieved. In this context, magnetic material parameters for about 10 different types of ferrite were obtained. The orthogonal magnetic bias was added by placing the entire test fixture into a large toroidal coil. Thus, the bias field can be supplied independently from, and in addition to the classical parallel bias. An optimal combination between the two biasing fields was found, resulting in a reduction of magnetic losses up to 50 % on certain ferrites. We show that the mixed magnetization, normally used for garnets only, is beneficial also for other types of ferrites.

INTRODUCTION

Ferrite materials are used in the accelerator field as the core of the resonators for cavity frequency tuning purposes. The application of the ferrite however results in an increase of the losses and the inductance, since ferrite materials are characterized by their complex permeability μ_r that is expressed by: $\mu_r = \mu' - j\mu''$, where μ' contains information about the inductance and μ'' represents the magnetic losses. When exposed to a magnetic orthogonal or parallel bias field, one can observe a reduction of the ferrite permeability. Since the resonant frequency varies with the relative permeability as $1/\sqrt{\mu_r}$, it is therefore possible to tune a resonator by applying an external field. An accurate characterisation of the ferrites properties is essential since the choice of the ferrite has to take into account the range of the required frequency as well as the tolerated losses.
There exist many standard methods for μ-evaluation on ferrites, but we have to adapt one of them for the sample and core size in our applications. Indeed, we need to measure ferrite complex permeability and its dependence on external bias field for several reasons: datasheet information insufficient for our requirements, identification of unknown ferrite samples, study of the different behaviour of the samples caused by the magnetic remanence and characterization of special production ferrites.

OVERVIEW OF THE MEASUREMENT TECHNIQUES

The measurement test set consists of a coaxial line with one shorted end partially or completely filled with one or more toroidal shaped samples, placed at the shorted end. Ferrite samples of different shapes and materials have been characterized; that resulted in most of the cases in re-designing the sample holders to allow the implementation of the needed connections and a better fitting of the ferrite under test within the structure. Moreover, as will be described in the following, the measurements of the ferrite parameters were carried out with and without a magnetic bias field.

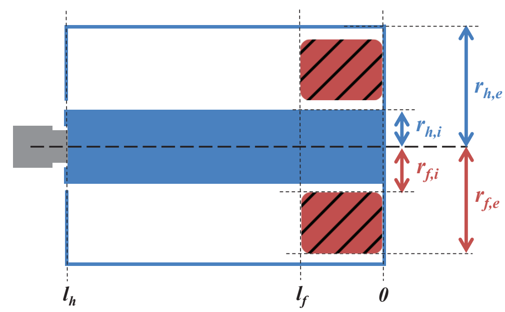

Figure 1: Schematic drawing of the experimental setup. The metallic holder (blue) houses a toroidal shaped ferrite (red) and features a connector (grey) used for S_{11} measurements.

Unbiased Measurements Technique

The permeability of the ferrite samples is evaluated from reflection coefficient measurements, performed with a Vector Network Analyzer (VNA). All measurements were performed using OSM (Open-Short-Matched) one-port calibration at the end of the test cable.
The S_{11} parameter calculated at the short end is obtained by normalizing the measured reflection coefficient of the sample holder filled by the ferrite sample $S_{11_{filled}}$ to the one of the empty sample holder $S_{11_{empty}}$:

$$S_{11} = \frac{S_{11_{filled}}}{S_{11_{empty}}}. \quad (1)$$

The input impedance of the ferrite under test, Z_f, is a complex number and is determined by:

$$Z_f = Z_0 \frac{1 + S_{11}}{1 - S_{11}} \quad (2)$$

with $Z_0 = 50\ \Omega$ being the characteristic impedance of the VNA. A first approach to evaluate the ferrite permeability

ENHANCED DIAGNOSTIC SYSTEMS FOR THE SUPERVISION OF THE SUPERCONDUCTING CIRCUITS OF THE LHC

R. Denz, Z. Charifoulline, K. Dahlerup-Petersen, A. Siemko, J. Steckert, CERN, Geneva, Switzerland

Abstract

Being an integral part of the protection system for the superconducting circuits of the LHC, the data acquisition systems used for the circuit supervision underwent a substantial upgrade during the first long shutdown of the LHC (LS1). The sampling rates and resolution of most of the acquired signals increased significantly. Newly added measurements channels like for the supervision of the quench heater circuits of the LHC main dipoles allow identifying specific fault states. All LHC main circuits are meanwhile equipped with earth voltage feelers allowing monitoring the electrical insulation strength, especially during the fast discharges. The protection system for the bus-bar splices is now capable to operate in different modes. By this measure, it is possible fulfilling the requirements for different specific tests like the warm bus-bar measurements and current stabilizer continuity measurements (CSCM) without field interventions.

INTRODUCTION

The protection system for the superconducting circuits of the LHC (QPS) covers 544 circuits with nominal current ratings from 100 A to 11870 A [1]. A total of 2516 data acquisition systems (DAQ) ensure the supervision of the protection system and diagnostics of the superconducting circuits. These systems communicate through field-bus links with the LHC accelerator control system.

Table 1: Circuits covered by the protection system

Circuit type	Quantity	DAQ systems
Main bends and quads	24	2124
Inner triplets	8	8
Insertion region magnets	94	68
Corrector magnet circuits	418	316
Total	**544**	**2516**

While status flags provide information on the state of the protection equipment and its readiness for operation, the majority of recorded analog signals serve for diagnostic purposes.

Based on the experience gained within the LHC operation so far and taking into account requests by equipment specialists, the data acquisition systems have been submitted to a major upgrade during LS1. The enhanced supervision capabilities, e.g. for the quench heater circuits, allow performing more detailed diagnostics of the superconducting circuits and facilitating the event analysis by automatic tools and equipment specialists. During the LHC hardware commissioning campaign in 2014/2015, magnet experts made already extensive use of the enhanced capabilities, e.g. for the analysis of 179 primary quench events recorded during main dipole powering tests [2].

QPS SUPERVISION UPGRADE

The various layers of the QPS supervision underwent a substantial revision, necessary to integrate new equipment, signals and commands. At this occasion, also the sampling rates and resolution of many analog signals have been revised and increased.

QPS Signals

The QPS DAQ transmits about 130000 signals, to the LHC accelerator control system with sampling rates of 0.1, 5 and 10 Samples/sec, when in normal operation mode. Depending on the signal type sampling rates during post mortem events, e.g. a magnet quench can be significantly higher.

Table 2: Signals produced by the QPS DAQ

Circuit type	Analog	Status flags	Total
Main bends and quads	26228	56388	82616
Inner triplets	200	248	448
Insertion region magnets	1408	4044	5452
Corrector magnet circuits	4088	17112	21200
Generic controller signals			22548
Total	**31924**	**77792**	**132264**

Field-bus Network

The QPS field-bus network, based on the WorldFIP™ standard, has been extended during LS1 by changing the network configuration and adding new segments and repeaters. This measure allowed reducing the number of individual clients per field-bus segment and almost doubling the transmission capacity of the physical layer of the QPS field-bus (see table 3). As a result, the time required for the transmission of the significantly larger post mortem data blocks is still within reasonable limits (~10 min). It is noteworthy that this time is independent of the number of simultaneously recorded events. The sampling rate for the majority of QPS analog signals

STATUS AND PLANNED EXPERIMENTS OF THE HIRADMAT PULSED BEAM MATERIAL TEST FACILITY AT CERN SPS*

Nikolaos Charitonidis, Ilias Efthymiopoulos, Adrian Fabich#, Malika Meddahi
CERN, Geneva, Switzerland
Eliana Gianfelice-Wendt, Fermilab, Batavia, Illinois, USA

Abstract

HiRadMat (High Irradiation to Materials) is a facility at CERN designed to provide high-intensity pulsed beams to an irradiation area where material samples as well as accelerator component assemblies (e.g. vacuum windows, shock tests on high power targets, collimators) can be tested. The beam parameters (SPS 440 GeV protons with a pulse energy of up to 3.4 MJ, or alternatively lead/argon ions at the proton equivalent energy) can be tuned to match the needs of each experiment. It is a test area designed to perform single pulse experiments to evaluate the effect of high-intensity pulsed beams on materials in a dedicated environment, excluding long-time irradiation studies. The facility is designed for a maximum number of 10^{16} protons per year, in order to limit the activation of the irradiated samples to acceptable levels for human intervention. This paper will demonstrate the possibilities for research using this facility and go through examples of upcoming experiments scheduled in the beam period 2015/2016.

INTRODUCTION

In the new era of high-brightness accelerators, the power of the circulating beam can be destructive during its interaction with the machine equipment (collimators, magnets, beam dumps). To avoid any possibly destructive incident that will compromise the operation of the accelerator, it is preferred that an experimental verification of the beam interaction with the equipment and materials is performed beforehand. Apart from the accelerator design itself, in the targetry applications, where a high-energy beam impinges on a target material for producing secondary particles, as is the case of Neutrino Beam facilities [1] or Muon Collider, where the flux of secondary particles requires a MW or even multi-MW power of the primary beam, the need of experimentally verifying the behaviour of the target material is imperative. HiRadMat (High Radiation to Materials) is a unique facility providing a pulsed, high-energy beam, available for tests in a controlled and safe way.

EXPERIMENTS IN HIRADMAT

The facility was commissioned in 2011. During 2012-2013, nine experiments were approved by the facility's scientific and technical boards and completed the data taking successfully [2]. Those experiments covered a broad spectrum of research topics, from a fully assembled LHC collimator and a SPS magnet septum, to high-power targetry investigating the effect of the proton beam on a tungsten powder target.

Depending on the scientific scope of each experiment online and/or offline (post -irradiation) analysis was used. Although rather challenging, online measurements are very interesting as they provide information on the dynamics of the beam impact. The main systems used for online measurements covered the following techniques: Doppler-laser-vibrometry measuring instantaneous deformations (up to 24 m/s at 2.5 MHz sampling), a fast camera (few kHz frame rate) for optical observations, accelerometers to measure the propagation of shock waves, temperature and acoustic measurements, and pressure gauges. The challenge in online instrumentation comes from the radiation field in the cavern that prohibits any installation of active electronics nearby unless specifically designed.

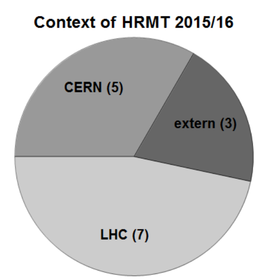

Figure 1: The context of the approved experiments for the beam period 2015-2016.

Following the start-up of the CERN accelerators after the LS1, for the period 2015-2016, fifteen experiments have already submitted their requests for beam time in the facility. The context of the experiments is shown in Fig. 1: seven experiments are directly related to accelerator operation for LHC (e.g. collimator materials), five have a general CERN oriented context (e.g. target development for the AD facility), and 3 experiments are proposed from international collaborations external to CERN (high-power targetry, optical microphones as beam loss monitor and testing the strength limits of beryllium windows for vacuum applications). For 2015, seven of these experiments are approved and scheduled. The current schedule of the experiments along with the cumulative proton budget can be seen in Fig 2.

ELECTROMAGNETIC CHARACTERIZATION OF NEG PROPERTIES ABOVE 200 GHz FOR THE CLIC DAMPING RINGS

E. Koukovini-Platia*, G. Iadarola, G. Rumolo, C. Zannini, CERN, Geneva, Switzerland

Abstract

Non-Evaporable Getter (NEG) will be used in the CLIC Electron Damping Rings (EDR) to suppress fast beam ion instabilities due to its effective pumping ability. The electromagnetic (EM) characterization of the NEG properties up to high frequencies is required for the correct impedance modeling of the Damping Ring (DR) components. The properties are determined using WR-3.4 and WR-1.5 rectangular waveguides, based on a combination of experimental measurements of the complex transmission coefficient S_{21} with a Vector Network Analyzer (VNA) and CST 3D EM simulations, for the frequency ranges of 220-330 GHz and 500-750 GHz. The results obtained from NEG-coated Aluminum (Al) waveguides are presented in this paper.

METHOD

The impedance modeling of the DR chambers must include the contribution from coating materials applied for ultra-low vacuum pressure. This advocates for the correct characterization of this impedance in a high frequency range. The short DRs bunch length of 1.8 mm rms, translates into a frequency spectrum up to hundreds of GHz, therefore the characterization of NEG is necessary up to those frequencies.

The proposed method requires the use of a rectangular waveguide connected to a VNA and the 3D CST [1] simulation of the exact geometry waveguide. The waveguide is a 2-port network that can be described by means of the S-parameters as a function of frequency. The transmission coefficient S_{21}, from the scattering matrix, is related to the waveguide's attenuation, which depends on the effective conductivity.

The exact geometry waveguide can be simulated with CST and S_{21} is calculated assuming a certain conductivity of the coating material. However, assuming that conductivity is the unknown, several simulations can be done sweeping this parameter. Intersecting the measured data with the CST simulation, the conductivity that matches the measured losses is extracted at a specific frequency. By repeating the intersection over the whole frequency range of interest, the conductivity can be extracted as a function of frequency.

The method has been successfully benchmarked with known materials like copper and stainless steel and was used to characterize NEG at frequencies between 10 and 11 GHz [2].

MEASUREMENTS AT 220-330 GHz

Four rectangular waveguides, of type WR3.4, were used for measurements between 220 and 330 GHz. The waveguides were purchased from Virginia Diodes (VDI) [3] and are produced in 2-split blocks made of Al with a thin gold plating (see Figure 1).

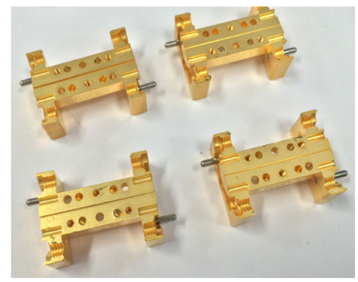

Figure 1: WR3.4 and WR1.5 waveguides from VDI made of Al with thin gold plating, with 25 mm length.

The waveguides were coated at CERN by magnetron sputtering, targeting at 3 μm NEG thickness. In Figure 2, the transmission S-parameters are plotted for the four waveguides (labeled as 1, 5-12, 5-15 and 5-16) as a function of frequency. In the same figure, the simulated S_{21} from CST is shown, assuming DC conductivity of NEG equal to 0.57×10^6 S/m and a uniform profile of 3 μm thickness.

The DC value was extracted from resistance measurements on NEG-coated glass samples with known coating thickness. From the measurements, the DC conductivity of NEG was scattered between 0.5×10^6 S/m and 0.7×10^6 S/m with an uncertainty of 15%. A factor of 1.5-2 difference with older measured values of the DC conductivity (1×10^6 S/m) is observed. This is attributed to the different coating setup used, and consequently due to the different cathode used for the NEG deposition.

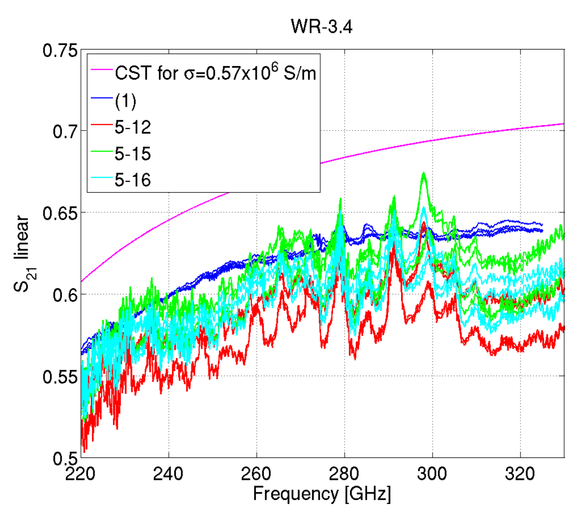

Figure 2: S_{21} comparison between CST (magenta) and measurements using the four WR3.4 waveguides.

MEASUREMENT OF NEG COATING PERFORMANCE VARIATION IN THE LHC AFTER THE FIRST LONG SHUTDOWN

V. Bencini, G. Bregliozzi, V. Baglin, C. Yin Vallgren, R. Kersevan, P. Chiggiato
CERN, Geneva, Switzerland

Abstract

During the Long Shutdown 1 (LS1) of the Large Hadron Collider, 90% of the Non-Evaporable Getter (NEG) coated beam pipes in the Long Straight Sections (LSS) were vented to undertake the planned upgrade and consolidation programmes. After each intervention, an additional bake-out and NEG activation were performed to reach the vacuum requirements. An analysis of the coating performance variation after the additional activation cycle has been carried out by using ultimate pressure and pressure build-up measurements. In addition, laboratory measurements have been carried out to mimic the LHC coated beam pipe behaviour. The experimental data have been compared with calculation obtained by Molflow+.

INTRODUCTION

In February 2013, after three years of productive data collection, the LHC operation stopped for a 2-year-long shutdown (LS1) aiming at consolidating and upgrading the collider for 13 TeV centre-of-mass energy collisions.

During this period, all LHC arcs were warmed up to room temperature (RT) to allow the consolidation of the magnet bus-bars located at each magnet interconnects and, in parallel, a re-commissioning of the room temperature LSS [1].

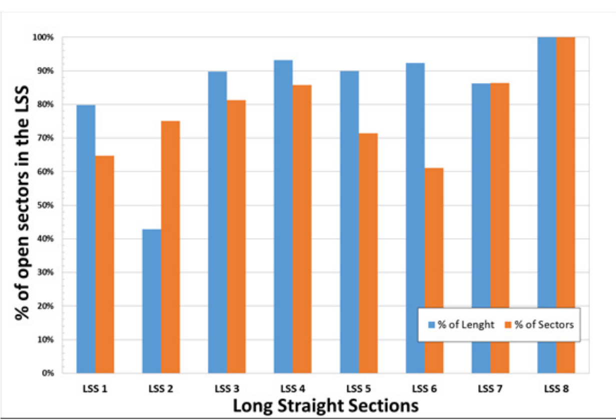

Figure 1: Percentage of open sectors during LS1.

The total length of the 8 LSS is 5.8 km which represents 14 % of the LHC ring length. By design, the LSS room temperature vacuum system is baked. About 85% of its surface is coated with 1-µm thick TiZrV film which provides most of the pumping speed once activated. During LS1, 148 room temperature vacuum sectors (about 5.1 Km) were opened and re-commissioned [1].

Figure 1 shows the percentage of the vacuum sectors that were opened during LS1 in the 8 different LSS; most of the sectors were vented. Afterwards, those sectors were baked and the NEG coating was activated.

Figure 2 shows the number of venting/activation cycles undergone by the vacuum sectors since their installation. About 80% of the NEG coated chambers had already been vented at least once before LS1. Possible detrimental effects on the vacuum performance of multiple venting/activation cycles were studied.

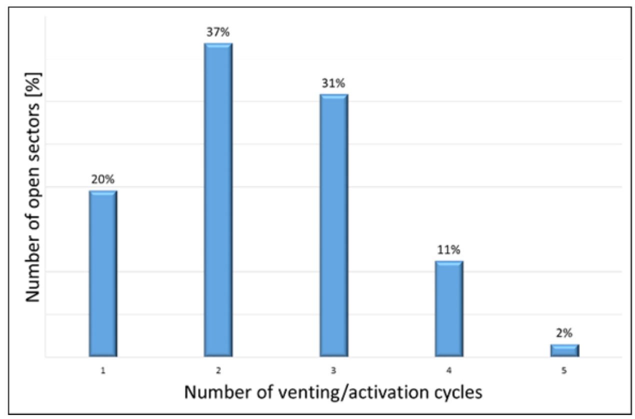

Figure 2: Distribution of baked sectors after LS1.

PRESSURE DISTRIBUTION ANALYSIS

As a first step, the study focused on the ultimate pressure values measured in the LSS. All data were collected one month after the end of the NEG activation. All NEG activations were always performed at 230°C and lasted 20 to 24h.

The distributions (see Fig. 3) of the measured values after each cycle were then plotted in order to identify possible trends. For each distribution, a curve fitting was added and the statistical central values were indicated by arrows. A clear decreasing trend of the pressures after each venting / activation cycle can be seen. The statistical central value decreases by a factor 0.7 after each venting/activation cycle as calculated by linear regression. This behaviour is the result of the combination of two different phenomena described in [2]: in one hand, the decrease of the outgassing rate of the Bayard-Alpert gauges and of the stainless steel module and, on the other hand, the decrease of the pumping speed, i.e. the sticking probability, of the NEG coating after each cycle. The latter was measured in a dedicated experimental set-up.

PRESENT QUALITY ASSURANCE FOR THE LHC BEAM VACUUM SYSTEM AND ITS FUTURE IMPROVEMENT

J. Sestak ,V. Baglin, G. Bregliozzi, P. Chiggiato
CERN, Geneva, Switzerland

Abstract

During the Long Shutdown 1 (LS1), the LHC beam vacuum system was upgraded to minimize dynamic vacuum effects like stimulated desorption and beam-induced electron multipacting. A quality assurance plan was mandatory due to the demanding vacuum performance and the limited access to the equipment during the following operation period. Laboratory assessment tests and underground interventions were performed following well-defined and approved procedures. All vacuum related activities were documented and written reports stored in dedicated databases. Quality controls were performed to find mechanical, cabling and equipment functionality non-conformities. Possible issues were identified, classified and tracked in a non-conformity database for future corrective actions. This contribution give an overview of the quality assurance policy followed during the LS1 and the non-conformities reported after quality control. Possible future improvements are also discussed.

INTRODUCTION

The LHC beam vacuum system [1] has several interfaces with other LHC systems. Its performance and reliability are one of the key-factors for successful operation of the accelerator. Because of the limited access for maintenance during operation, any unsuspected issue can bring significant time delay and additional cost. Due to these requirements, a quality management was implemented as an important part of LHC beam vacuum upgrade during the LS1 period.

LHC BEAM VACUUM SYSTEM AND LS1 UPRGADE

The LHC beam vacuum system consists of beam pipes at cryogenic temperature in the superconducting magnets, mainly in the arcs (ARC), and the long straight sections (LSS) operating to the greatest extent at room temperature. The ARC beam vacuum represents 86% of the total 27 km and is divided into 8 arcs operating on 1.9 K at an operational pressure lower than 10^{-6} Pa.

The LSS beam vacuum represents the remaining 14% of the storage ring circumference and accommodates the 4 main LHC experiments. The LSS include in total 174 vacuum sectors operating at room temperature together with 84 cryogenics sectors, stand-alone magnets (SAM) and inner triplets, operating at 4.5 K and 1.9K, respectively. Ultrahigh vacuum in the LSS is achieved using NEG coated chambers, NEG cartridges and ion sputtering pumps. Common pressure in the LSS after NEG activation is lower than10^{-9} Pa.

LS1 Beam Vacuum System Upgrade

During the LS1 upgrade (2013 – 2015) [2] both ARC and LSS were vented to air in order to integrate engineering changes. The LHC beam vacuum system was upgraded from the point of view of safety, performance, and reliability to meet RUN 2 requirements with 13 TeV collisions in the centre of mass.

For the ARC beam vacuum the following activities were held:

- Installation of Plug-In-Modules (PIM) half-shell protection.
- Installation of rupture disc at all quadrupole magnets.
- Installation of penning gauges to selected quadrupole magnets.
- Repair of non-conform PIM.

For the LSS the following activities were conducted:

- Repair of RF bridges in 96 warm modules.
- Exchange of solenoids by NEG coated RF bridges.
- Installation of additional 400 l/s NEG cartridges.
- Installation of NEG cartridges at SAM cryogenics sectors.
- Installation of modified ion-pumps with integrated NEG cartridges.
- Installation of vacuum and NEG pilot sectors.
- Upgrade of the experimental areas in order to improve the vacuum performance and reduce background.
- Re-commissioning due to activities on other systems (collimation, injection, instrumentation etc.).

LHC QUALITY ASSURANCE PLAN

The LHC Quality Assurance Plan (QAP) [3] was introduced during the LHC project phase in order to implement a Total Quality Management System, based on defect prevention and continuous process improvement. Using the quality assurance guidelines [4], QAP defines a whole product lifecycle including data management systems CERN EDMS (Data Management System) and CERN MTF (Manufacturing and Testing Folder).

LHC QAP for the Beam Vacuum System

During the LS1, all LHC arcs and the 148 room temperature vacuum sectors were vented and re-commissioned. In parallel with the underground activities,

CHARACTERIZATION OF THE RF FINGERS CONTACT FORCE FOR THE LHC WARM VACUUM BELLOW MODULES

C. Blanch Gutiérrez, V. Baglin, G. Bregliozzi, R. Kersevan, P. Chiggiato
CERN, Geneva, Switzerland

Abstract

Along the 27 Km of LHC beam pipe, various types of vacuum bellow modules are needed to compensate the mechanical misalignments of the vacuum chambers during installation and to absorb their thermal expansion during the bake-out. In order to reduce the beam impedance during operation with beams these modules are equipped with RF bridges to carry the image current. They are usually made out of a copper tube insert at one side and Cu-Be RF fingers at the other end of the module. A spring is used to keep the contact between the RF fingers and the tube insert. The geometry and the choice of this spring become critical to ensure a good electrical contact.

In this paper, a description of the test bench used to measure the contact force together with the procedure applied and the measurements performed are given. A summary of the maximum radial and axial offsets between the RF fingers and the insert tube while keeping a good electrical contact is presented.

INTRODUCTION

In the LHC vacuum system almost 200 different types of warm vacuum modules are installed, making a total number of more than 1800 units. With different length, diameter and/or inner aperture, each type of module, by means of the RF transition inside, must ensure a good electrical continuity between the adjacent chambers. This electrical continuity is provided by the RF fingers and the tube insert which make a proper path, without geometrical discontinuities, for the image current when the beam is circulating through, avoiding large local impedances and electrical breakdown [1].

The electrical contact between the RF fingers and the tube insert depends on the geometry of both parts as well as on a spring, which assures the force to keep the contact [2] [3].

In order to qualify this electrical contact a test bench was implemented to measure the contact force between the RF fingers and the tube insert. Two different non-standard RF inserts types, one circular and one hippodrome geometry have been firstly tested and a bunch of tests are foreseen to characterize the rest of RF inserts installed currently in the LHC vacuum system.

THE TEST BENCH DESCRIPTION

Mechanical Set Up

The test bench used (Fig. 1) is made with three manual translational stages which allow the movement in the three axes. In one side of the test bench the RF fingers are fixed while in the other side the tube insert is attached.

With this set up, three degrees of freedom are allowed between both components of the RF bridge, being possible to set offsets positions in the three axes within a ± 0.5 mm precision.

The transition tube is wrapped with Kapton tape in order to insulate its electrical contact with all the RF fingers except one of them in which the contact force will be measured.

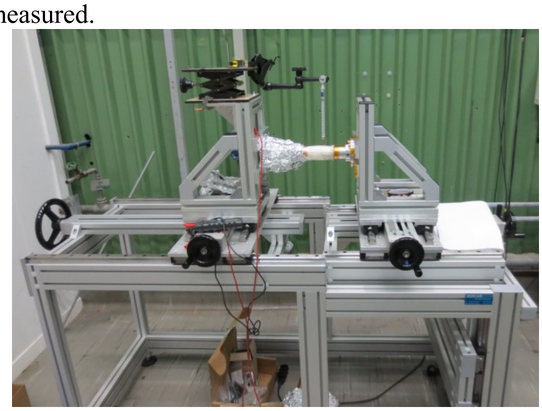

Figure 1: Test bench.

Above this finger a dynamometer attached to a mobile platform is placed. This dynamometer can measure in a range from 0 to 50g with a precision of 0.5g.

Electrical Set Up

The electrical set up consists in a Keithley multimeter connected in 4-wires measurement resistance mode (Fig. 2), to measure the contact resistance between the RF finger and the transition tube.

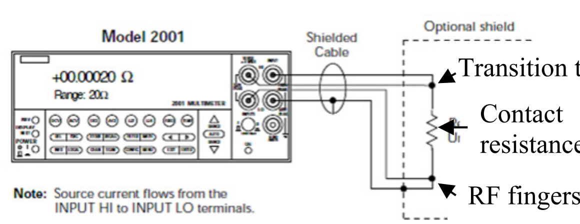

Figure 2: Electrical connection.

A different electrical set up was tested, applying 1 A constant current from the transition tube to the RF fingers, and measuring the voltage drop between them. Since $R=\Delta V/I$ and $I=1$ A, the voltage drop measured was equal to the resistance. However, since no difference or resolution improvement was observed with this second method, the first method was chosen for all the tests.

RECOMMISSIONING OF THE COLDEX EXPERIMENT AT CERN

R. Salemme, V. Baglin, F. Bellorini, G. Bregliozzi, K. Brodzinski, P. Chiggiato, P. Costa Pinto, P. Gomes, A. Gutierrez, V. Inglese, B. Jenninger, E. Michel, M. Pezzetti, B. Rio, A. Sapountzis, R. Kersevan, CERN, Geneva, Switzerland

Abstract

COLDEX (COLD bore EXperiment), installed in the Super Proton Synchrotron (SPS) at CERN, is a test vacuum sector used in 2001-2004 to validate the Large Hadron Collider (LHC) cryogenic vacuum system with LHC type proton beams. In the framework of the R&D for the High Luminosity upgrade of the LHC (HL-LHC), COLDEX has been re-commissioned in 2014. The objective is the validation of the performance of amorphous carbon (a-C) coating at cryogenic temperature with LHC type beams. The existing COLDEX Cu beam screen has been therefore dismounted and carbon coated, while a complete overhaul of the vacuum, cryogenic and control systems has been carried out. This contribution describes the phases of re-commissioning, reviews the current experimental set-up and gives an overview of the possible measurements with COLDEX, in view of its HL-LHC experimental program.

INTRODUCTION

COLDEX is an experimental test vacuum sector that mimics the cold bore and beam screen cryogenic vacuum system adopted in the LHC cryomagnets. Originally designed to measure synchrotron radiation induced gas desorption [1], COLDEX was installed in SPS in 2001 to evaluate the impact of electron-cloud effects onto cryogenic vacuum systems [2].

During LHC Run 1, significant heal load due to beam induced electron cloud was observed on the beam screen of the Inner quadrupole Triplets. Extrapolation of these observations to the High Luminosity upgrade of the LHC (HL-LHC) predicts an intolerable increase of the dissipated heat load to the cryogenic system due to electron cloud build-up [3]. In order to reduce it, a-C coating is a potential candidate to mitigate the electron cloud effects due to its low Secondary Emission Yield (SEY) achieved at room temperature [4]. For HL-LHC purpose, this proposed base-line must be validated at cryogenic temperature with LHC type beams. For these reasons, COLDEX was re-commissioned and upgraded with a-C coated beam screen in 2014. A review of its scientific objectives is available in [5].

VACUUM SYSTEM

The COLDEX cryostat has been recovered from 2004. It houses a ~2.2 m long OFE copper beam screen (BS) inserted in a 316LN stainless steel cold bore (CB). The inner diameter (ID) of the CB is 113 mm. The BS is a circular, ID 67 mm, extruded pipe (Figure 1). It is perforated by two rows of 7.5x2 mm elongated holes (slots) which gives a transparency of 1% to the CB. The slots are shielded on their back with baffles capable to intercept straight electron paths to the CB. The BS is equipped with two 0.1 mm thin copper coated cold-to-warm transitions (CWTs) at its extremities. RF continuity is assured with RF fingers. The final adaptations to the upstream and downstream ID 100 mm chambers are tapered with conical apertures of 45°. Total pressure is measured at these two warm locations, *i.e.* upstream and downstream the BS, via calibrated Bayard-Alpert (VGI) hot cathode and Penning (VGHB) cold cathode ionization gauges.

Figure 1: Picture of the a-C coated beam screen during re-installation on February 2014.

A room temperature chimney faces a circular, ID 35 mm, vacuum port derived at the centre of the BS. At its top, a BA gauge is installed. This gauge allows monitoring the gas pressure in the BS which may be affected by electron stimulated desorption during electron cloud bombardment.

Two calibrated quadrupole mass spectrometers (RGA) are mounted on the BS chimney top and on the downstream chamber to perform analyses of the residual gas species in the cryogenic and room temperature parts, respectively. In the downstream warm chamber, a gas injection system, consisting in a bakeable 3.1 litres gas reservoir equipped with capacitance pressure gauges and connected to the vacuum system via variable leak valve, is fitted. This system is used to perform studies of gas transmission along the BS and pre-condensation of gas species onto the cold surface of the BS.

In order to give direct indication of electrons activity, two electrodes are employed. The chimney circular, Ø18 mm, electrode faces the BS aperture to the chimney

AMORPHOUS CARBON COATINGS AT CRYOGENIC TEMPERATURES WITH LHC TYPE BEAMS: FIRST RESULTS WITH THE COLDEX EXPERIMENT

R. Salemme, V. Baglin, G. Bregliozzi, P. Chiggiato, R. Kersevan, CERN, Geneva, Switzerland

Abstract

Extrapolations of the Large Hadron Collider (LHC) Run 1 observations to the High Luminosity upgrade (HL-LHC) beam parameters predict intolerable increase of heat load on the beam screens of the Inner Triplets due to electron cloud. Amorphous carbon (a-C) coating of the beam screen surface is proposed to reduce electron cloud build-up, thereby minimising its dissipated power. In order to validate this baseline, COLDEX (COLD bore EXperiment) has been re-commissioned. Such experiment mimics the performance of the LHC cold bore and beam screen cryogenic vacuum system in the Super Proton Synchrotron (SPS). The main objectives of the study is the performance qualification of a-C coatings with LHC type beams while operating the beam screen in the 10 K to 60 K temperature range and the cold bore below 4.5 K. This paper reviews the status of COLDEX and the results obtained during its first experimental runs.

INTRODUCTION

During the Large Hadron Collider Run 1, considerable heat load (~200W) due to electron cloud was observed on the Inner Triplets (IT) beam screens during operation with 25 ns bunch spaced beams of nominal intensity. Extrapolations of these observations to the High Luminosity upgrade (HL-LHC) beam parameters predict an intolerable increase of heat load due to electron cloud build-up [1]. The increase of heat load is expected to be accompanied by increase of background to the LHC experiments. In order to mitigate the electron cloud build-up and, in turn, limit the heat load to an amount compatible with the IT cryogenics cooling capacity, the current baseline is to lower the IT beam screen surface Secondary Electron Yield (SEY) by amorphous carbon (a-C) thin film coating. Previous studies have shown that such a coating provides reliably low, as-received, SEY (typically <1.1 at room temperature) suitable in un-bakeable vacuum systems [2].

Successful mitigation of the electron cloud build-up with a-C coatings has been demonstrated in some SPS room temperature (RT) vacuum chambers with LHC type beams [2]. In order to further validate the HL-LHC baseline at cryogenic temperature, the COLDEX experiment has been re-commissioned in 2014. COLDEX is an experimental cryostat installed on a field-free by-pass of the SPS Long Straight Section (LSS) 4 which mimics the LHC cold bore and beam screen cryogenic vacuum system. A detailed description of the re-commissioning phases performed in 2014 and the current experimental setup is available in [3]. The main goal is the performance qualification of a-C coatings with LHC type beams while operating the beam screen in two temperature windows: the 5 to 20 K range, currently adopted for LHC and suitable for HL-LHC Inner Triplets, and the 40 to 60 K range under study for HL-LHC matching sections.

The experimental setup is conceived to study the beam induced multipacting in a LHC type cryogenic vacuum system as a function of the BS temperature (and, depending on it, of the presence of adsorbed gas species on its surface) and the circulating beam parameters (bunch intensity and spacing, total circulating intensity, at injection and flat-top energy). During a run, total pressure is measured along the vacuum system, *i.e.* in the RT upstream and downstream sections and in the cryogenic BS atmosphere. The dynamic pressure rise due to electron cloud is monitored with respect to the different circulating beams, and the conditioning obtained by beam dose is observed. The gas composition is followed-up constantly in both cryogenic and warm parts by residual gas analysers. In case of gas desorption, the primary and recycling desorption yields of the system can be estimated. The heat load dissipated by electron cloud onto the BS surface is measured as well as the electrons activity. Through benchmarking with available electron cloud build-up codes, the SEY of the surface can be deduced. The effects of adsorbed gas on the BS surface at cryogenic temperature is reproduced in dedicate runs by gas injections.

RESULTS DURING RUN 1

COLDEX first experimental run with a-C coating took place during the first SPS Scrubbing Run in November 2014. In a 7-day period, the accumulated beam dose exceeds 4 A·h. Two BS temperatures have been chosen: first 50 K, then 5 to 10 K. The CB was constantly kept at 4.5 K. At this temperature, the CB is capable of condensing all gas species (except He, which is only adsorbed up to 10^{14} He/cm^2), with a pumping speed fixed by the 1% transparency to the BS. One to four batches of 72 bunches, 25 ns bunch spaced, up to $1.3 \cdot 10^{11}$ proton per bunch (ppb), passed into COLDEX, mainly at 26 GeV/c, but also with energy ramp to 450 GeV/c. Hybrid (5+20 ns) bunch spaced doublet beams circulated as well, up to 4 batches and with a maximum intensity of $1.4 \cdot 10^{11}$ proton per doublet (ppd), equally split. Figure 1 shows the pressure evolution during the run along the COLDEX sector as well as the temperature range kept on the BS.

Significant pressure rises (up to ~$5 \cdot 10^{7}$ mbar, green and yellow curves) correlated to the beam circulation were observed upstream and downstream the COLDEX BS due to electron stimulated desorption. These parts are made of

PROPAGATION OF RADIOACTIVE CONTAMINANTS ALONG THE ISOLDE BEAMLINE

M. Maietta, G. Vandoni, M. Ady, A. Dorsival, R. Kersevan, CERN, Geneva, Switzerland
A. Gottberg, TRIUMF, Vancouver, Canada

Abstract

Several Radioactive Ion Beam (RIB) facilities are in construction worldwide or undergoing upgrade. To ensure safe management of radioactive contamination, RIB vacuum systems are completely hermetical, with collection and storage of the effluents before controlled release. The layout of new RIB vacuum systems would be designed more efficiently with a better knowledge of the contaminant's propagation along the machine. At CERN, an experimental analysis of the propagation of radioactive species along the beam-line of ISOLDE was carried out during the last beam-run. The Monte-Carlo code Molflow+ was then used to interpret the results. We observe that radioactive rare gases are the major source of contaminant propagation. Propagation times of the order of some seconds were calculated and benchmarked with measurements for ^{6}He performed on beta scintillators on-line. The blocking effect of magnet separators and beam optics elements was partially confirmed.

INTRODUCTION

Since the first production of a radioactive ion beam (RIB) at the Niels-Bohr Institute in 1951 and the first ISOLDE facility in 1967 at CERN, RIB facilities have flourished worldwide, fostering nuclear research with exotic nuclei production. Several new projects [1], including an intensity upgrade of ISOLDE are bound to see the light of day in the coming years.

ISOLDE [2] produces RIBs by irradiation of a thick target with the pulsed 1.4GeV, 2μA average current proton beam from the PS Booster accelerator. Exotic nuclei generated by the collision diffuse and effuse through a tiny transfer line to the ion source, where ~10% of them are selectively ionized. Isotope separation is then achieved in either of two on-line separators. The General Purpose Separator (GPS) consists of a 70° bending magnet and an electrostatic switchyard, allowing selection of three mass separated beams. The High Resolution Separator (HRS) consists of two (90° and 60°) bending magnets plus focussing-defocussing and correction electrostatic multi-poles. The HRS is followed by a Radio Frequency Quadrupole Cooler and Buncher. The two separator lines converge into a common beam distribution system at the main switchyard, conveying high purity isotope beams to several experimental stations.

Most of the nuclei produced in the target are not ionized [3]; the volatile species diffuse via the transfer line across the ion source and through the beam-line. These are believed to be the cause of the contamination of the vacuum of RIB machines. To avoid contaminants dispersion along the beam-line, vacuum is achieved by turbomolecular pumps, connected via a totally hermetical common backing manifold to a set of primary pumps [4]. These convey the effluent gases to a gas storage system, which confines radioactive gas for controlled decay before release to the atmosphere via the nuclear ventilation system. By this scheme, all vacuum effluents from target to experimental beam-lines flow together into a common storage, thus mixing highly contaminated with less contaminated gas.

In order to gain knowledge on the distribution of neutral contaminants along the beam-line, we have sampled contamination with filters installed along the vacuum system, which were then analysed by gamma spectroscopy. In parallel, we have carried out a Monte-Carlo simulation of the diffusion of rare gases from the target along the beam-line. This article presents the approach and preliminary results obtained on the GPS branch of Isolde.

SAMPLING OF RADIOACTIVE SPECIES

Hybrid filters were installed at the exhaust of each turbomolecular pump during the machine shutdown. They consist in two filtering disks, one of 150μm thickness in hydrophilic mixed cellulose ester with 3 μm pores, the other one in carbon impregnated cotton fibre, clamped together by two stainless steel nets and installed in the thickness of a ISO-KF standard o-ring supporting ring. The turbomolecular pumps being isolated both at the inlet and at the outlet by valves, installation did not require venting of the beam-line nor of the backing manifold. The filters were kept in place for 4 months, seeing 9 different targets and more than 30 beams. The 3 filters installed on the turbomolecular pumps of the GPS branch were then removed after a 40h beam stop and analysed within 7 days in gamma spectroscopy with a high-purity Germanium detector. Pump GPS21 is installed upstream of the separator magnet and switchyard, while GPS22 and GPS23 are both installed at the same longitudinal coordinate right downstream of it. Radioactive species appearing in the 3 filters and relative activity are presented in Figure 1.

All species, besides ^{194}Au, are long-lived isotopes, of half-lives of the order of days. The gold isotope ^{194}Au is progeny of the very long-lived ^{194}Hg, in secular equilibrium. With the exception of the antimony isotopes, all species are issued from rare gas parents (radon, xenon and krypton) or from mercury (^{185}Os). Indeed, the specific

THE VACUUM SYSTEM OF THE EXTRA-LOW ENERGY ANTIPROTON DECELERATOR ELENA AT CERN

R. Kersevan, CERN, Geneva, Switzerland

Abstract

The Extra Low Energy Antiproton ring (ELENA) is a CERN project aiming at constructing a 30 m circumference synchrotron which will take antiprotons extracted at 5.3 MeV from the Antiproton Decelerator (AD), and further decelerate them down to 100 keV [1].

The ring will be equipped with two electrostatic (ES) pulsed extraction deflectors which will allow to deliver the low-energy, cooled antiproton beams to a number of experimental beamlines [2]. The total length of these transfer lines, equipped with ES optical elements is of the order of 100 m. From the vacuum point of view, machine physics issues related to rest-gas scattering and intra-beam scattering mandate a very low average pressure limit, calculated to be 4.0E-12 mbar [3,4]. The very compact ring and the beam-instrumentation installed on it, with many components placed inside of the vacuum system, and lack of space to install lumped pumps, has pushed us to design a pumping system based primarily on non-evaporable getter (NEG) coatings, and few lumped integrated NEG-ion pumps.

The vacuum requirements for the transfer lines are a bit more relaxed, in the 1.0E-10 mbar range, but still require state-of-the-art solutions in order to reduce the potentially large outgassing of the many electrodes, insulators, metal connections used for the ES components installed inside the vacuum system. NEG-coating and integrated NEG-ion pumps will therefore be used here too.

The entire vacuum system of ELENA, with the exception of a short, initial part of the injection line coming from the AD machine, has been specified to be bakeable at 250 ºC.

MACHINE PHYSICS ISSUES AND VACUUM REQUIREMENTS

The low-energy of the antiproton beams, and the length of the deceleration and cooling cycles, mandate a very low average pressure along the ring, 4.0E-12 mbar [1,3-4]. This is not an unprecedented vacuum requirement at CERN, since the LEIR ring has, in the past, required the design of a vacuum system capable of reaching similar performances [5].

OVERVIEW OF THE MACHINE AND TRANSFER LINES

In the following, the naming conventions adopted for the ELENA project will be used, for brevity:

- LNI: injection line from AD;
- LNR: ELENA ring;
- LNExx: transfer lines (total of 9 sections/segments);
- LNS: H^+/H^- commissioning source

Figure 1 shows a bird's eye view of LNI, LNR, LNExx, and LNS. Figure 2 shows a busy intersection of vacuum lines, LNI, LNE, and LNS.

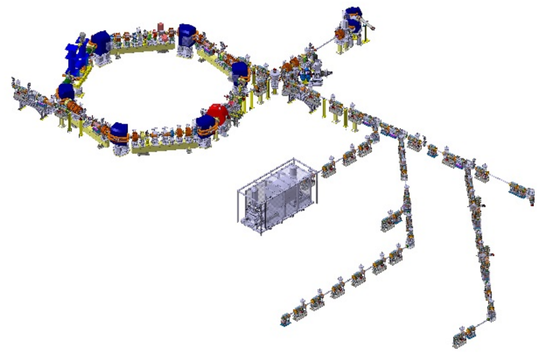

Figure 1: view of the whole ELENA complex, accelerators and beamlines.

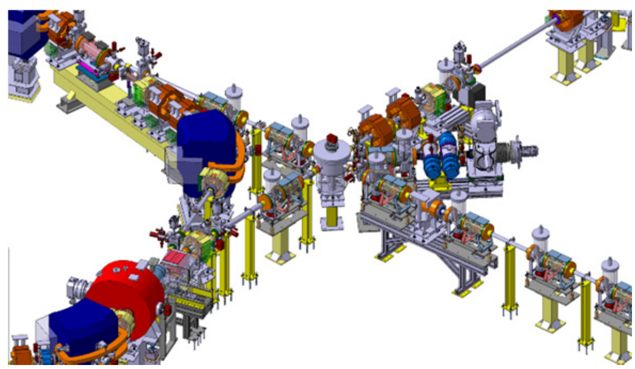

Figure 2: a busy crossing; the ion-switch (IS) chamber is in the middle, with its 5 connections to, clockwise from the 2-hour position: LNI from AD, LNS, LNE03, LNI going into LNR, and LNE00 coming out of the ring.

VACUUM CHAMBER MATERIALS AND FLANGES

Materials

The very low energy of the antiproton beam after the deceleration and cooling cycles mandate the choice of a very low magnetic permeability material. The choice has fallen on austenitic stainless steel, 316 LN grade, 3D-forged for all parts machined from blocks, and for flanges.

Flanges

The already mentioned lack of space longitudinally along the ring has pushed us to choose a conical ConFlat flange design, with collars instead of the usual holes. This is a solution which is already employed and validated at CERN on several machines since a long time, both for un-

PHOTODESORPTION AND ELECTRON YIELD MEASUREMENTS OF THIN FILM COATINGS FOR FUTURE ACCELERATORS

M. Ady, P. Chiggiato, R. Kersevan, CERN, Geneva, Switzerland
Y. Tanimoto, T. Honda, KEK, Tsukuba, Japan

Abstract

The performance of future accelerators could be limited by electron cloud phenomena and high photodesorption yields. For such a reason, the study of secondary electron and photodesorption yields of vacuum materials is essential. The eradication or mitigation of both secondary electron and molecule desorption could strongly reduce the beam scrubbing time and increase the availability of nominal beams for experiments.

Surface modifications with the desired characteristics can be achieved by thin-film coatings, in particular made of amorphous carbon and non-evaporable getters (NEG).

In the framework of a new collaboration, CERN's vacuum group has manufactured several vacuum chambers with a geometry similar to the beam pipe of future accelerators, and has applied different coatings on each of them. The samples were then irradiated at KEK's Photon Factory (PF) with synchrotron radiation of 4 keV critical energy during several days, allowing the measurement of the photodesorption yield as a function of the photon dose.

This paper presents the experiment and briefly summarizes the preliminary photodesorption and photoelectron yield data of different coatings. The results can be used for future machine design with similar conditions, such as the FCC-hh.

INTRODUCTION

When designing future accelerators, synchrotron radiation (SR) must be taken into account not only for its thermal effects, but also because the induced electron cloud and high photon stimulated desorption (PSD) reduce the beam's lifetime. One way to mitigate these phenomena is the application of different types of thin film coatings.

To measure their efficiency, a collaboration has been set up between CERN's vacuum group and KEK: the goal was to characterize the effectiveness of NEG and amorphous carbon coatings, and the effect of activation and vacuum firing. CERN has therefore manufactured six vacuum chambers, each conditioned and coated differently, then these chambers were installed in one of the PF's experimental hutches in Tsukuba, Japan and data was collected during a two-month test campaign.

SAMPLES

The 1200 mm long, 61 mm internal diameter vacuum chambers are manufactured of 316L type stainless steel, with three 35 mm ports opened by mechanical extrusion and subsequent welding. All ports use standard ConFlat flanges, one rotatable (machine side) and four fixed.

The three ports are connected to DN40 CF vacuum feedthroughs with a pin on the vacuum side - these pins hold bent stainless steel disc-shaped electrodes. A screw fixing system allows precise height and orientation adjustment to ensure that the discs follow the tube profile, while leaving a 1 mm gap allowing to use them as electrodes kept at high voltage.

The tube is closed from one side by a DN63 blank flange with a 4 mm injection tube drilled from its side: this allows gas injection during the experiment. The other side is open. All chamber components were cleaned following standard CERN chemical degreasing procedure, and fasteners and small parts, such as screws were cleaned with ultrasound in an ethanol solution. Following this basic treatment, each sample was conditioned and coated differently. Table 1 summarizes the treatment and coating types.

Table 1: Treatment Types and Experiment Durations for the Six Vacuum Chambers

Sample	Treatment and coating	Experiment duration (days)
1	Reference stainless steel sample basic treatment only	10
2	Stainless steel sample vacuum fired	7
3	TiZrV NEG coating not activated	6
4	TiZrV NEG coating, activated prior to the experiment	6
5	TiZrV NEG coating vacuum fired, activated	7
6	Amorphous carbon coating vacuum fired	11

Samples 2, 5 and 6 were vacuum fired at 950 °C for 2 hours to liberate the H_2 gas stored in the bulk. Once ready, all samples were transported to Japan filled with nitrogen for protection of the inner surface.

EXPERIMENTAL SETUP

We performed our experiment in PF's BL-21 hutch. The beam current, SR critical energy and the incidence angle are chosen to correspond with future machine designs, such as the FCC-hh (4028 eV critical energy, 490 mA beam, 30.7 W/m SR power [1]): the SR in our setup is originating from a 0.9634 T dipole magnet 13 m upstream, with critical

SYNCHROTRON RADIATION DISTRIBUTION AND RELATED OUTGASSING AND PRESSURE PROFILES FOR THE HL-LHC FINAL FOCUS MAGNETS*

R. Kersevan, CERN, Geneva, Switzerland

Abstract

The HL-LHC upgrade consists of many different subprojects. One of the most important ones is the installation of very large gradient inner triplet (IT) magnets, comprising 4 long superconducting (SC) quadrupoles, and a new superconducting D1 hosting a corrector package in the same cryostat. D2 is also a newly conceived SC magnet, and provision is made for 4x crab-cavities on each of the two separate beam lines, between D2 and Q4.

The HL-LHC final focus area, from Q4 to the interaction point, has been modelled based on the latest vacuum chamber geometry and orbits. The synchrotron radiation (SR) fans are computed using the Monte Carlo code SYNRAD+ [1]. The angular and energy dependence of the reflectivity of the copper surfaces is considered, as well as a representative surface roughness. Once the SR distributions are computed, they are converted into outgassing profiles by using conversion curves found in literature. The test-particle Monte Carlo code Molflow+ is then used [2] to compute the related gas density distribution. Warm areas are supposed to be NEG-coated, in order to reduce SR-induced desorption and the generation of secondary electrons. The calculation is repeated for 3 different conditioning times, corresponding to 1, 10, and 100 days at full nominal current of 1 A. It is shown that the resultant gas densities are always below the limit dictated by the ATLAS and CMS detectors' background and by the beam-gas scattering lifetime τ in the machine (τ >100 h). The SR ray-tracing calculations are carried out in the short-dipole approximation, i.e. no provision is made for edge radiation.

GEOMETRICAL ASSUMPTIONS

The latest geometry for the octagonal beam screen with tungsten-based shielding has been considered [3]. For the recombination chamber between D1 and TAN a "Y" chamber is assumed, with a common part for the two beams modelled as a 230 mm internal diameter (ID) round pipe splitting into two 80 mm ID separate chambers for the two beams. This "Y" chamber is supposed to be at room temperature, and NEG-coated, as presently done in the LHC. Since the exact geometry of the cold and warm beam-position monitors (BPMs) has not been finalized yet, they have been modelled as circular cylindrical objects connected to the neighbouring chambers via small-angle tapers. The cylindrical surface where the BPM electrodes are supposed to be located has a slightly bigger radius, so as to recess the electrodes and prevent them from being hit by direct SR coming from the triplet area magnets. A similar model has been assumed for the RF contact fingers of the sliding joints placed in the inter-connects between the different cryostats and/or room-temperature vacuum chambers.

SYNCHROTRON RADIATION RAY-TRACING

The orbits for round beams at collision on the right side of IR1/IR5 have been considered [4]. It is against these orbits that the ray-tracing code SYNRAD+ has been checked prior to generating the detailed 3D model of the internal part of the perforated beam-screen (BS) and vacuum chambers. To this aim, the corresponding twiss file has been used, setting the initial point of each trajectory segment and the corresponding angles in SYNRAD+ to the same values as in the orbit file. For clarity, the case of the vertical crossing in IR1 has been chosen. Figure 1 shows the 8 different orbit segments in Q1, Q2a, Q2b, Q3, D1 and D2 (where Q1 and Q3 are in effect 2 shorter quadrupoles sitting inside the same cryostat, while Q2a and Q2b have separated cryostats with additional corrector packages). Initially the complete SR fan is collected separately for the outgoing B1 beam and incoming B2 beam on two large planar rectangular facets which allow us to calculate the global SR photon flux, power, and spectra, see Fig. 1. It has been decided to set a low-energy photon cut-off value of 4 eV, since neither molecular desorption nor photo-electron production is expected to be generated by photons having energies lower than this value. The MC code automatically calculates the fraction f of photons generated within the 4-500 eV energy interval. The critical energy for the SC magnets D1 and D2 is equal to 29.4 eV and 23.6 eV respectively, while the critical energy of the 4 SC triplet magnets depends on the distance between the orbit and the magnetic centre of the particular magnet. The fraction f is, 0.116, 0.152, 0.229, 0.237, 0.187, 0.171, for Q1a, Q1b, Q2a, Q2b, Q3a, and Q3b, respectively. This shows that only a small fraction of the photon flux calculated analytically is actually a potential source of molecules or photo-electrons, and that using the analytic formula which gives the number of photons emitted per unit length of trajectory largely over-estimates the flux and the related photo-desorption and photo-electron production.

The beam size at each point of the orbit is calculated by taking into account the beam emittance, horizontal and vertical beta function, and dispersion as per standard formulae. Figure 1 shows in blue the cloud of source points of the SR rays traced. The local angle of emission is obtained by combining the natural SR divergence and

THE ASSEMBLY EXPERIENCE OF THE FIRST CRYO-MODULE FOR HIE-ISOLDE AT CERN

Y. Leclercq#, G. Barlow, J-A. Bousquet, A. Chrul, P. Demarest, J-B. Deschamps, J-C. Gayde, M. Gourragne, A. Harrison, G. Kautzmann, D. Mergelkuhl, V. Parma, J-A. Ferreira-Somoza, M. Struik, M. Therasse, L. Williams, CERN, Geneva, Switzerland,
J. Dequaire, Intitek, Lyon, France

Abstract

The HIE ISOLDE project aims at increasing the energy of the radioactive ion beams of the existing REX ISOLDE facility from the present 3 MeV/u up to 10 MeV/u for an A/q up to 4.5 [1]. The upgrade includes the installation of a superconducting linac in successive phases, and ultimately comprising two low-β and four high-β cryo-modules. The first phase involves the assembly installation and test of two high-β cryo-modules, each housing five high-β superconducting cavities and one superconducting solenoid, aligned within tight tolerances. Following design and procurement of cryo-module components for 2 units, the first unit is now being assembled at CERN, in a dedicated facility including class100 (ISO5) clean rooms equipped with specific tooling. The assembly is foreseen to be complete and the cryo-module delivered to the beam-line in May 2015. In this paper, we present the assembly of the first unit, including the methodology, special tools, assembly procedures and quality assurance aspects. We report on the experience from this first assembly, including tests results, and present prospects for the next-coming cryo-module assemblies.

INTRODUCTION

The decision to implement a major upgrade [2] of the energy and intensity of the existing ISOLDE and REX-ISOLDE radioactive ion beam facilities at CERN requires the replacement of most of the existing ISOLDE post-acceleration equipment by a superconducting linac based on quarter-wave RF cavities housed together with superconducting solenoids in a series of four high-β and two low-β cryo-modules. The design and component procurement phases of the project complete for 2 high-β cryo-modules, CERN is now engaged for the first time in the assembly of cryo-modules, featuring a common insulation and beam vacuum, requiring, to preserve RF cavity performance, the installation of a purpose built ISO5 quality clean room and associated infrastructure. The assembly of the first high-β cryo-module started in late August 2014 and now at end April 2015 is completed. Although in all respects it is clearly a prototype, this first unit is destined for installation onto the HIE-ISOLDE beam-line in May 2015 and will there be subjected to full functional testing.

THE CRYOMODULE ASSEMBLY

The complete high-β cryo-module assembly is shown in Fig.1. The components and sub-assemblies comprising the cryo-module their specific characteristics and expected performance are detailed in [3].

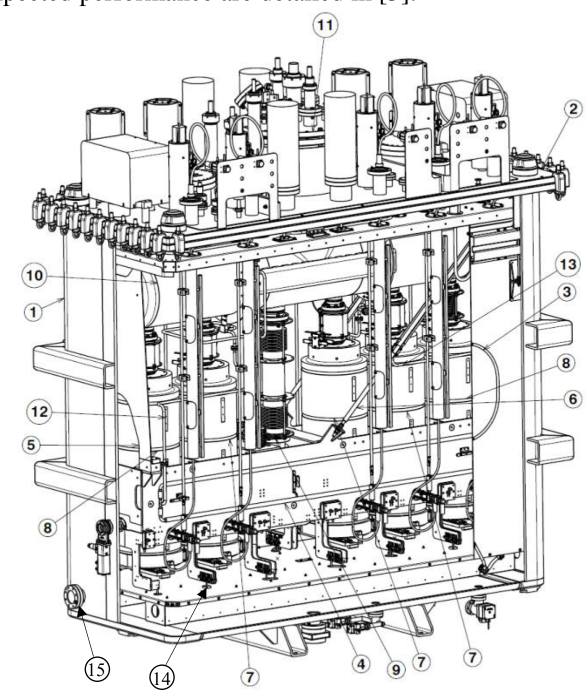

Figure 1: The complete HIE-ISOLDE high-β cryo-module; 1 Vacuum vessel lower box, 2 Vacuum vessel top plate assembly, 3 Thermal shield lower box, 4 Support frame, 5 Suspension end plate, 6 Tie-rod, 7 Inboard cavity, 8 Outboard cavity, 9 Down tube to solenoid, 10 Helium vessel, 11 Chimney assembly, 12 Support frame cooling supply, 13 Support frame cooling return, 14 Mathilde targets, 15 Mathilde viewport.

A vertical assembly, suspended from the mobile frame (see Figure 3) and essentially built from top downwards is implemented. The complete cryo-module assembly process has been separated into 20 sub-assembly stages, in a sequence imposed by the cryo-module design and by the tooling characteristics and featuring the installation of the RF cavities at the latest possible stage in order to minimize the risk of their contamination.

BEAM TESTS USING A WIDE BAND RF SYSTEM PROTOTYPE IN THE CERN PS BOOSTER

M.M. Paoluzzi, M.E. Angoletta, A.J. Findlay, M. Haase, M. Jaussi, A. Jones, J. Molendijk, J. Sanchez Quesada
CERN, Geneva, Switzerland

Abstract

In the framework of the LHC Injectors Upgrade project (LIU) and in view of a complete replacement of the existing CERN PS Booster (PSB) RF systems, a small scale, wide band prototype cavity was installed in 2012 in the machine. Following the encouraging tests done using this limited set up, an almost full scale, RF system prototype has been built and installed in the PSB during the Long Shutdown 1 (LS1). This modular, Finemet® loaded system covers the band 0.5 ÷ 4 MHz corresponding to the *h=1* and *h=2* frequency ranges. It uses solid-state power stages and includes fast RF feedback for beam loading compensation. New dedicated digital low level electronics have been implemented for all loops required for beam acceleration and interfaces with the general PSB control system. It allows using the new equipment at the fundamental and/or second harmonic of the beam revolution frequency as well as operating it in parallel with the existing RF systems. This paper describes the low level and power sections of the project and reports about the achieved results and experience built up so far.

INTRODUCTION AND SYSTEM DESCRIPTION

With the program under implementation in the frame of the LIU project [1, 2] and the coming into operation of the Linac4, the PSB extraction energy will rise to 2 GeV and the beam intensity to 2E13 ppb (nominal) or even 2.5E13 ppb (absolute maximum). This brings the beam peak current to ~32 A (half sine approximation) and the fundamental, second harmonic and DC components to 13 A, 8.5 A and 7.2 A respectively. Among other parameters, the ability of the machine to digest the highest intensities depends on the current and power available from the RF systems. To cope with this more demanding situation the performance of the PSB RF systems must be substantially improved. This can be achieved replacing the existing narrowband, tuned RF systems covering the *h=1* (C02 RF system) and *h=2* (C04 RF system) frequency ranges with cavities based on the wideband frequency characteristics of Finemet® magnetic alloy (MA) [3]. Full exploitation of the wideband characteristics suggests using a cellular configuration in which an accelerating gap is surrounded by a MA core on each side [4, 5], is driven by a solid-state amplifier and produces a fraction of the total accelerating voltage. 12 cells can be fitted in the space presently used by each C02 and C04 cavity for a total 8 kV per section. As three straight sections are presently occupied by these systems, the total maximum voltage can either be kept to 16 kV using two straight sections only or increased to 24 kV. The wide band response allowing multi harmonic operation, flexible adjustment of the *h=1* and *h=2* voltage components is possible and only limited by the total maximum voltage. However, installing wideband cavities in the PSB rings introduces longitudinal impedance covering many revolution frequency harmonics and special care must be taken for compensating the beam-loading. A fast RF feedback loop takes partial care of this and additional measures are implemented in the low level electronics.

Figure 1: 10-cell prototype MA cavity in PSB Ring 4.

To validate the choice of these deep and complex changes the prototype system installed in 2012 was upgraded during LS1 to 10 cells for a total of 7 kV. The experience gained with the 2012 amplifier prototypes allowed designing and producing a new generation of power stages. All weaknesses shown by the previous version were corrected. In particular mitigation of the of radiation effects on the solid-state devices is obtained by

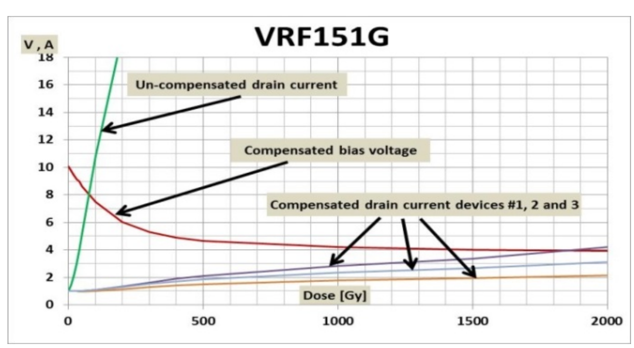

Figure 2: Mitigation of radiation effects on VRF151G RF Mosfet. The compensated device drain current variation vs. integrated dose is greatly reduced.

EXPERIMENTAL SETUPS TO DETERMINE THE DAMAGE LIMIT OF SUPERCONDUCTING MAGNETS FOR INSTANTANEOUS BEAM LOSSES

V. Raginel, B. Auchmann, R. Schmidt, D. Schoerling, A. Verweij, D. Wollmann
CERN-TE, 1211 Geneva 23, Switzerland

Abstract

The damage mechanisms of superconducting magnets due to the direct impact of high intensity particle beams are not well understood. Obvious candidates for upper bounds on the damage limit are overheating of insulation, and melting of the conductor. Lower bounds are obtained by the limits of elasticity in the conductor, taking into account dynamic effects (elastic stress waves). The plastic regime in between these two bounds will lead to differential thermal stress between the superconductor and stabilizer, which may lead to a permanent degradation of the magnet. An improved understanding of these mechanisms is required especially in view of the planned increase in brightness of the beams injected into the LHC [1] and of the future High Luminosity-LHC [2] and Future Circular Collider (FCC).

In this paper the plans for room temperature damage tests on critical parts of superconducting magnets and the strategy to test their damage levels at 4.3 K in the HiRadMat facility at CERN [3], using a 440 GeV proton beam generated by the Super Proton Synchrotron (SPS), is presented. Moreover the status of numerical simulations using FLUKA and multi-physics FEM code (ANSYS) to assess the different effect and the irradiation of the proposed experimental setup in preparation of the test is shown.

INTRODUCTION

Losses of the LHC beam can happen at very different time scales, the most critical are so-called ultrafast losses, less than 270 μs (~3 LHC turns). Protection against such losses depends on passive devices intercepting lost particles. The interaction between the LHC beam and these passive devices generates particle showers which can be intercepted by the downstream elements such as superconducting magnets causing quenches or in the worst case damage.

At several occasions the passive devices for injection protection demonstrated their efficiency: due to failures of the injection kickers the injected beam was partially intercepted by the injection absorbers thus preventing damage. However, one event is not understood, which lead to the damage of small corrector magnets. During LHC Run 1, three small corrector circuits in the LHC inner triplet left of IP2 (IT.L2) have been found open after a failure during injection. Several magnets including the main quadrupole magnet where these correctors are mounted on the front face quenched during this event [4].

In this paper the thermo-mechanical effects due to the interaction between high energetic particles and matter are described. Then potential damage of critical parts of a superconducting magnet and their consequences for the magnet are discussed. The roadmap to perform damage tests with and without proton beam is presented. A preliminary experimental setup for a test of superconducting coils and cable samples at 4.3 K at CERN HiRadMat facility with a 440 GeV proton beam is shown. Finally it is explained how the thermo-mechanical effect of beam impact on the proposed experimental setup will be assessed with numerical simulations.

THERMO-MECHANICAL EFFECTS

The absorption of intense high-energy proton pulses of several micro-seconds duration causes a considerable temperature increase of the same rise-time inside the intercepted material. During this short period, thermal expansion of the irradiated material is partly prevented by its mass inertia. This gives rise to dynamic stresses propagating through the material [5].

With increasing energy deposition in a material, dynamic stresses pass from the elastic, to the plastic and ultimately to the shock wave domain. No damage occurs if the material stays in the elastic domain but shock waves will lead to severe damage in the affected components.

For cryogenic copper, which is major part of superconducting cables, the limit of the elastic regime is reached with an energy deposition of < 50 J/cm3. For metal-based materials, like superconducting cables, it can be shown that shock waves do not appear before melting [6]. The energy deposition to melt copper is ~6 kJ/cm^3 [7]. It is not understood if energy deposition in the plastic regime between 50 J/cm^3 and 6 kJ/cm^3 will cause damage to NbTi filaments or a degradation of the polyimide tape insulation and therefore cause a permanent loss of performance of the magnet.

IDENTIFIED CRITICAL PARTS OF MAGNET

Superconducting cable, insulation, quench heater, copper wedges and end spacers were identified as the critical parts of the superconducting magnets of the LHC.

The LHC superconducting cables are classical Rutherford cables made out of NbTi/Cu wires (see Fig. 1). The breaking of some NbTi filaments due to high dynamic stresses could lead to a reduction of the critical current.

As shown in Fig. 2, cables are insulated with several layers of polyimide tapes. Damage on the insulation due to high temperature could cause a short circuit either to ground – fatal for the magnet – or inter-turn short – leading

Abstract

The copper-stabilizer continuity measurement (CSCM) was devised in order to attain complete electrical qualification of all busbar joints, lyres, and the magnet bypass connections in the 13 kA circuits of the LHC. A CSCM is carried out at ∼20 K, i.e., just above the critical temperature, with resistive magnets. The circuit is then subject to an incremental series of controlled powering cycles, ultimately mimicking the decay from nominal current in the event of a magnet quench. A type test to prove the validity of such a procedure was carried out with success in April 2013, leading to the scheduling of a CSCM on all main dipole circuits up to and including 11.1 kA, i.e., the current equivalent of 6.5 TeV operation. This paper details the procedure, with respect to the type test, as well as the results and analyses of the LHC-wide qualification campaign.

INTRODUCTION

Following the 2008 incident [1], thorough investigation found that this was as a result of discontinuities in the superconducting busbar-joints' copper stabilizer - depicted in Fig. 1. To prevent such an event happening again, the LHC was operated at 3.5-4 TeV for the duration of Run 1. To allow for operation of up to nominal energy, it was decided that, during Long Shutdown 1 (LS 1), every interconnect (over 10,000) was to be repaired and consolidated with each splice having an electrical shunt applied, Fig. 2 [2].

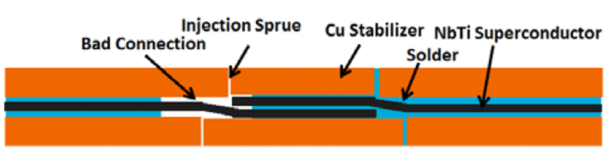

Figure 1: Depiction of a typical main dipole splice showing both good (right side) and bad (left side) continuity.

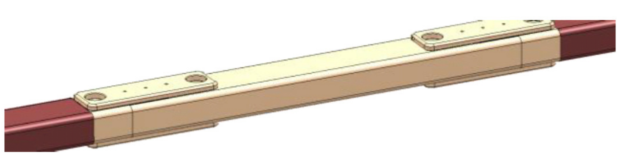

Figure 2: Illustration of the splice consolidation shunts, as applied, to reduce overall connection resistance and prevent adverse consequences from quenches in these locations [2].

LS 1 electrical quality control (ELQC) measurements at warm, ∼300 K, found that 5.9 % of all splices exceeded the acceptance criteria [3]. Furthermore, abnormally high resistances were found in the magnet bypasses, $> 200\ \mu\Omega$ (accepted maximum being $15.5\ \mu\Omega$) [4], as well as other types of soldered/welded connections [5]. Even though all discovered defects were consolidated, due to the foreseen quench training, with over 100 quenches predicted [6], an LHC-wide copper-stabilizer continuity measurement (CSCM) was carried out on all the main dipole circuits to guarantee that no defects were missed during LS 1 ELQC and that all aspects of all circuits are intact, in particular, the lyres, as they contain welded connections, but were not systematically checked during LS 1.

CSCM TEST PROCEDURE

The principle of a CSCM is to have the current bypass the magnets by operating at ∼20 K - just above the critical temperature, making the magnets resistive. Fig. 3 shows the expected current flowing through the magnet bypass along a main dipole circuit. To provide sufficient voltage to account for this, two 6.5 kA/200 V sub-converters had to be connected in series, normally connecting in parallel. The result, however, is that tests require a short period of over-current. The test also required protection system (PS) board modifications to monitor both the voltage across all busbar segments from the magnet voltage taps, "BS board A", and the voltage across the busbar segments as well as the adjacent diode leads connections, at the diode voltage taps, "BS board B". The difference of the two (B − A) gives the voltage across the bypass diode leads, which encompasses six contacts. The BS boards allowed for V, $\mathrm{d}V/\mathrm{d}t$ and $\mathrm{d}^2V/\mathrm{d}t^2$ thresholds to be set, ensuring detection and protection against any thermal runaways, by turning off the power converter (PC) (0.03 s decay constant due to the atypical inductance during a CSCM of only 3 mH, compared to 15.7 H during normal operation). Other, "DS", boards allowed for the monitoring of the voltage directly across the diodes.

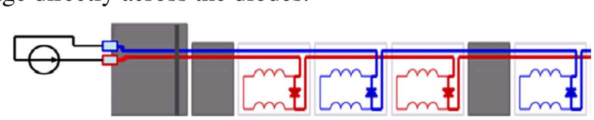

Figure 3: Depiction of the current flow during a typical CSCM test on a main dipole circuit. Note that all current flows through the bypass diodes instead of the magnets.

CSCM TYPE TEST IN LHC SECTOR 23

In April 2013, a CSCM type test was carried out [7]. Being prior to the splice consolidation campaign, thermal run-

DEVELOPMENT AND PRODUCTION OF NON EVAPORABLE GETTER COATINGS FOR THE VACUUM CHAMBERS OF THE 3 GeV STORAGE RING OF MAX IV

P. Costa Pinto*, B. Bartova, B. Holliger, S.D. Marques dos Santos, V. Nistor, A. Sapountzis, M. Taborelli, I. Wevers, CERN, Geneva, Switzerland
J. Ahlbäck, E. Al Dmour, M. Grabski, C. Pasquino, MAX IV Laboratory, Lund University, Sweden

Abstract

MAX IV is presently under construction at Lund, Sweden, and the first beam for the production of synchrotron radiation is expected to circulate in 2016. The whole set of 3 GeV ring beam pipes is coated with Ti-Zr-V Non Evaporable Getter (NEG) thin film in order to fulfil the average pressure requirement of 1×10^{-9} mbar, despite the compact magnet layout and the large aspect ratio of the vacuum chambers. In this work, we present the optimizations of the coating process performed at CERN to coat different geometries and mechanical assembling used for the MAX IV vacuum chambers; the morphology of the thin films is analysed by Scanning Electron Microscopy; the composition and thickness is measured by Energy Dispersive X-ray analysis; the activation of the NEG thin film is monitored by X-ray Photoemission Spectroscopy; the vacuum performance of the coated beam pipes is evaluated by the measurement of hydrogen sticking coefficient. The results of the coating production characterization for the 84 units coated at CERN are presented.

INTRODUCTION

The 3 GeV storage ring of the MAX IV photon facility has a circumference of 528 m and includes 20 achromats with 19 straight sections devoted to insertion devices. The ring is characterized by ultra-low emittance obtained by applying a multi-bend achromat (MBA) magnet concept. Compact magnet design, (bore of 25 mm), and limited space between consecutive magnets poses drastic limitations on the vacuum system. To integrate the vacuum system with the magnets, the majority of the vacuum chambers were designed as 22 mm inner diameter, 1 mm thick copper tube. In order to ensure ultra-high vacuum conditions in the ring, the conductance limited chambers are coated with Non-Evaporable Getter (NEG) by DC magnetron sputtering [1]. To adapt the existing technology to coat the specific beam pipes of the 3 GeV ring, CERN and MAX IV Laboratory have set a collaboration. Currently, the majority of the chambers are manufactured and are being coated at three different facilities, including CERN where chambers with uncommon geometries are treated.

COATING PRODUCTION

All chambers were fabricated by FMB-Berlin. VC01, VC02A and VC02B are made of OFS copper while the VC02L is in 316LN stainless steel. The surface treatment was done at the fabricant following CERN standards [2], with the only exception of the copper tubes used in the construction of the VC01 type. For this case, the tubes were previously etched at CERN in a solution of ammonium persulphate in order to remove the outmost 80 µm of the surface (damaged skin) and passivated with a sulpho-chromic acid bath.

The VC01 is composed of three bent sections for a total deviation of 1.5°, a total length of 2.55 m and a circular aperture of 22 mm (Figure 1 a). In the bent sections, alumina spacers were used to ensure the centring of the cathode, which is made of 3 intertwisted elemental wires, each one of 1 mm diameter, of Ti, Zr and V). Each coating run lasted four days and two chambers were coated per run.

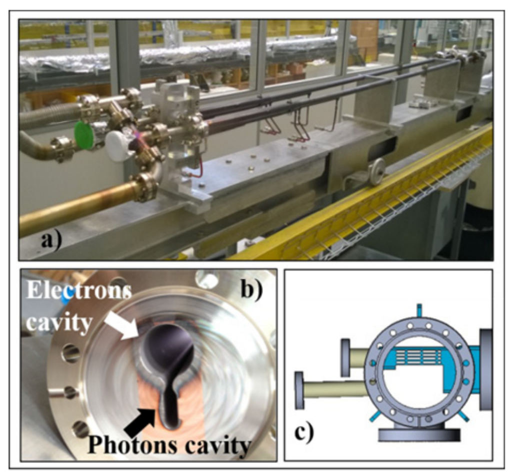

Figure 1: a) VC01 chambers on the coating support; b) photon and electron cavities for VC02B chamber (similar to VC02A); c) top view of the VC02L, with the inner grid.

The VC02A and VC02B are composed of two cavities, for the electron and extracted photon beams, respectively (Figure 1 b). They have a total length of 300 mm and 435 mm, respectively. The aperture of the electron cavity is the same for both, i.e. 22 mm, and the apertures of the photon cavities are tapered from 5 mm × 11 mm to 6 mm × 22 mm for VC02A and from 6 mm × 22 mm to 7 mm × 34 mm for VC02B. Electron cavities are coated using a cathode made of 1 mm elemental wires and presented no particular difficulty. Coating the photon cavities was the main challenge for this type of chambers. The cathodes were made from 3 intertwisted elemental wires with a

TITANIUM COATING OF CERAMICS FOR ACCELERATOR APPLICATIONS

Wilhelmus Vollenberg, Pedro Costa Pinto, Benjamin Holliger, Antonios Sapountzis, Mauro Taborelli, CERN, Geneva, Switzerland

Abstract

Titanium thin films can be deposited on ceramics, in particular alumina, without adherence problems. Even after air exposure their secondary electron yield is low compared to alumina and can be further reduced by conditioning or beam scrubbing. In addition, depending on the film thickness, titanium provides different surface resistances that fulfil requirements of ceramics in particle accelerators. Titanium thin films (MOhm range) are used to suppress electron multipacting and evacuate charges from ceramic surfaces. Thicker films (5-25 Ohm range) are applied to lower the surface resistance so that the beam impedance is reduced. In this contribution, we present the results of a development aimed at coating 2-meter long alumina vacuum chambers with a uniform surface resistivity by a dedicated DC magnetron sputtering configuration.

INTRODUCTION

Ceramic windows are frequently used for transmitting Radio-Frequency (RF) power, while maintaining the separation between vacuum and atmospheric pressure. However, the electrically insulating materials used for the ceramic windows have a high Secondary Electron Yield (SEY), far above the typical value for air exposed metal surfaces, and can lead to multipacting. Part of the power of the RF is dissipated in the multipacting electrons reducing efficiency. In addition the electrons impinging on the walls can generate local heating, which in turn can lead to cracking due to thermal stresses [1]. In general lowering the SEY can be achieved by appropriate thin film coatings [2, 3]. For instance Non-Evaporable Getters (NEG) are an ideal candidate in an Ultra High Vacuum (UHV) environment, provided a baked-out to at least at 180 ºC is possible (in addition, NEG thin films also pump most of the gas species present in UHV systems). On unbaked ceramics thin titanium films have proved their effectiveness also from the point of view of adhesion [4] and carbon coatings could be envisaged [3] as a solution in the future. In the case of RF windows the functional performance depends crucially on the correct electrical resistivity of the coating. Therefore in-situ resistance measurement during the thin film deposition process is systematically applied as a control method.

Ceramic vacuum chambers are also widely used for fast pulsed magnets, in order to avoid eddy current issues. Resistive titanium films are deposited inside these chambers to reduce the wall impedance perceived by the particle beam. In this case, as well, the surface resistance is measured during the coating process and after venting to air. Since the range of resistivity is tuned by the thickness in the following two examples we present the so called “ultrathin” and “thin” titanium films.

TITANIUM “ULTRATHIN” FILMS

RF ceramic Al_2O_3 windows are coated by DC sputtering in a dedicated coating set-up. Ceramics are degreased and vacuum fired (2 hours at 800 ºC under vacuum) prior to coating. A central titanium cathode is used in a cylindrical configuration to coat uniformly the inner surface of the ceramic window (Fig. 1). Prior to coating the system was pumped down to $3x10^{-7}$ mbar, without a bake-out. The coating takes 5 – 10 minutes at a plasma power of 50 W and Ar pressure of $4x10^{-2}$ mbar. The overall resistance (R_{total}) is measured in situ during the coating process between the top and bottom metallic collars of the ceramic assembly. Special attention should be given to enable an appropriate electrical contact between the collar and the titanium thin film during the process.

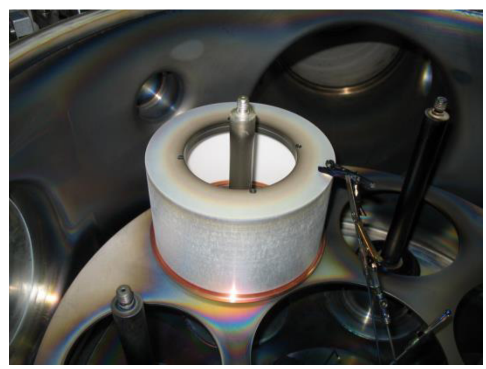

Figure 1: Cylindrical coating configuration for high resistivity coating of RF ceramic windows.

The square resistance (R□), which is a shape independent quantity characterising the coating, can be calculated from R_{total} and the given geometry of the ceramic assembly (by multiplying times the length and dividing by the width of the rectangular developed surface). RF windows are generally coated with R□ =10-20 MOhm, as measured in vacuum before venting. This is an empirically established value. By assuming the specific resistivity of bulk titanium this value would imply a thickness in the order of 10^{-4} nm, which is not physical. In reality the coating probably forms clusters leading to a percolation path for the transport. As a consequence of the air exposure after coating, the R□ increases to GOhm range values. Measurements on the resulting titanium coated Al_2O_3 samples show a SEY reduction from 7 (for uncoated alumina) to 2 [6]. These values refer to samples that were transported in air from the coating system to the SEY measurement system.

STATUS OF HIE-ISOLDE SC LINAC UPGRADE

A. Sublet#, L. Alberty, K. Artoos, S. Calatroni, O. Capatina, M. A. Fraser, N. Jecklin, Y. Kadi, P. Maesen, G. Rosaz, K.-M. Schirm, M. Taborelli, M. Therasse, W. Venturini Delsolaro, P. Zhang, CERN, Geneva, Switzerland

Abstract

The HIE-ISOLDE upgrade project at CERN [1] aims at increasing the energy of radioactive beams from 3MeV/u up to 10 MeV/u with mass-to-charge ratio in the range 2.5-4.5. The objective is obtained by replacing part of the existing normal conducting Linac with superconducting Nb/Cu cavities. The new accelerator requires the production of 32 superconducting cavities in three phases: 10 high-beta cavities for phase 1 (2016), 10 high-beta cavities for phase 2 (2017) and possibly 12 low-beta cavities for phase 3 (2020). Half of the phase 1 production is completed with 5 quarter-wave superconducting cavities ready to be installed in the first cryomodule. The status of the cavity production and the RF performance are presented. The optimal Linac working configuration to minimize cryogenic load and maximize accelerating gradient is discussed.

INTRODUCTION

The superconducting post accelerator for the HIE-ISOLDE project [1] entered gradually the construction phase in 2013 after an R/D stage which had taken off in 2009 with the formal approval by CERN. The schedule of the project foresees to deliver beams up to 4.2 MeV/u for the heaviest species in autumn 2015 with a single high-beta cryomodule of 5 cavities. A second cryomodule will then be installed during 2016 bringing the beam energy up to 5.5 MeV/u for all the radionuclides available at ISOLDE. This will complete phase 1, making Coulomb excitation studies possible up to mass-to-charge ratio (A/q) = 4.5.

The cryomodules house five superconducting high-beta Quarter Wave Resonators (QWR) based on Nb/Cu technology [2-4], and a superconducting solenoid for beam focusing.

The QWR are installed in a common vacuum cryostat, i.e. the beam vacuum and the thermal insulation vacuum are connected. They are designed to work at 4.5 K at the resonant frequency of 101.28 MHz, and with a maximum power dissipation of 10 W at 6 MV/m.

This article presents the performance of the cavities and their assembly in first cryomodule.

COATING, TUNING AND TESTING

Production Scheme and Coating

The first cryomodule cavities production started end of 2013 and finished end of 2014: 5 cavities and a spare unit have been coated. The prototype and series QWR nomenclature chosen is QPX.Y and QSX.Y respectively, with X the cavity serial number and Y the Nb coating process number [5]. The copper substrates were manufactured at CERN for the two first prototypes (QP2 and QP3), the substrates for the series were manufactured by industry (QS1, QS2, QS3 and QS4) [6].

The coating process is based on DC-bias diode sputtering, the hardware setup (UHV chamber, Nb cathode, DC power supplies, etc.) and the process have been kept identical (production steps, coating recipe, etc.) for all the cavities produced as described in details in [7], except for QP2 substrate, which has seen an additional annealing prior to coating. Over the one year production period, a total of 7 coatings have been made on these 6 substrates: one cavity has been coated twice due to bad initial RF performances (QP3.2), one has been rejected due to bad initial RF performances (QS2.1) and has been stripped and re-coated (QS2.2) in February 2015. It will be used in the second cryomodule. Typically a period of about two months is necessary [8] from the copper substrate reception at CERN in order to obtain a coated cavity and verify its RF performance.

Cavity Tuning

To match the Linac frequency of 101.28 MHz at 4.5 K under vacuum the QWR must be tuned. This process is done in two distinct steps [9, 10] that take into account and compensate:

1. the frequency shifts (about 400 kHz) induced by: the manufacturing deviations, the chemical polishing, the Nb coating, the thermal contraction at the operation temperature
2. the cumulated frequency uncertainties (~10 kHz).

The first step addresses the frequency shifts, it consists of a pre-tuning of the cavity after reception at room temperature and before coating by trimming it to a determined “tip-gap” length [9, 10]. This length is calculated depending on the foreseen duration and number of chemical polishing (SUBU) [11] to which the substrate will be submitted. The chemical polishing is used to eliminate surface defects (inclusions, spatter, etc.) from the as received substrate. The cavity frequency shift has a linear dependence to the SUBU duration and typically a 26.5 +/- 3 kHz frequency shift was observed after the initial 40 minutes SUBU. The SUBU process might reveal additional defects that must be either mechanically or chemically polished again, thus introducing a further frequency shift. The stripping of one cavity and the new coating process (including SUBU) will also induce a frequency shift.

The second step addresses the frequency uncertainties within an active tuning range of about 40 kHz at 4.5 K.

CHARACTERIZATION OF NB COATING IN HIE-ISOLDE QWR SUPERCONDUCTING ACCELERATING CAVITIES BY MEANS OF SEM-FIB AND TEM

B. Bártová#, S. Calatroni, A. Sublet, M. Taborelli, CERN, Geneva, Switzerland
A.B. Aebersold, D.T.L. Alexander, M. Cantoni, EPFL, Lausanne, Switzerland

Abstract

The Quarter Wave Resonators (QWR) high-β cavities (0.3 m diameter and 0.9 m height) are made from OFE 3D-forged copper and are coated by DC-bias diode sputtering with a thin superconducting layer of niobium. The Nb film thickness, morphology, purity and quality are critical parameters for RF performances of the cavity. They have been investigated in a detailed material study.

INTRODUCTION

In the frame of the High Intensity and Energy (HIE) ISOLDE project [1], the niobium coating of high beta superconducting quarter-wave resonators (QWRs) has entered series production. The first cryomodule is upon to be finalized [2], however development activities continue to improve the understanding and optimization of the sputtering setup and process. One major focus is the thin film characterization and its relation with the functionality of the layer. This paper presents the results of the microscopic approach to characterize the Nb layer of the cavity coating baseline process.

EXPERIMENT

A dummy copper cavity (Q4) [3] has been designed as a sample holder to characterize the niobium layer. Samples supports are 35 mm long, 10 mm wide and 1 mm thick copper plates. Samples are identified by their position in internal (i) or external (e) conductor and their distance from the bottom to the top of the cavity. Top band (TB) sample placed over the weld on the top of the cavity was observed as well.

The applied DC-bias sputtering baseline parameters are: 0.2 mbar Ar pressure, 8 kW powered Nb cathode, -80 V biased cavity, and a substrate temperature rising from 300°C up to 630°C (below the bake out temperature of 650°C) on the inner conductor during a coating step. The whole coating process lasts 4 days and is done in 14 steps of 25’ coating + 5h35’ cool down to 300°C each, leading to a net coating time of 6h.

The film morphology, its thickness and quality from the selected places along the cavity’s inner and outer conductors were studied by dual beam high-resolution field emission Scanning Electron Microscope (SEM) with Focused Ion Beam (FIB).

Transmission Electron Microscopy (TEM) observation were performed together with Energy Dispersive Spectroscopy (EDS) measurements and orientation and phase mapping with a spatial resolution of 2-3 nm. TEM lamella sample from top part of the cavity was prepared to study chemical composition, structure and grain orientation of coating grains.

X-ray florescence measurements (XRF) were performed to cross check the coating thickness.

CROSS-SECTION IMAGING

A standard sample preparation of the cross-section consists of 4 steps on a selected area of interest [4, 5]: (i) a deposition of protective layer (in our case carbon of 1.5 µm thickness) onto the sample surface in order to protect it from the ion beam damage during further milling, (ii) the removal of the material by sputtering using the staircase-like pattern with high Ga^+ beam current to form the large trench, (iii) reduction of the beam current and milling to reduce redeposition of sputtered material onto the sample surface, (iv) imaging of the final surface using either secondary or back-scattered electrons or secondary ions depending on the goal of the study. All SEM images presented in this paper were acquired using in-column secondary electron detector and low accelerating voltage in order to visualize grain structure at different places in the cavity and possible presence of porosity.

The niobium layer thickness, its structure and the presence of porosity

The coating thickness was measured by two techniques – XRF and from the cross-section images after the FIB preparation. It is evident from Table 1 that the inner conductor coatings i4 and i7 are much thicker comparing with the same positions on external conductor e2 and e7. The measurements by FIB shows higher values than by XRF.

Table 1: Comparison of Coating Thicknesses Characterized by FIB and XRF Techniques

Thickness [µm]	FIB	XRF
i4	7.25	6.68
i7	5.74	5.41
i9	2.66	2.21
e2	1.79	1.64
e7	2.27	2.07
e9	2.53	2.16
TBi	2.78	2.50

FERRITE-TUNER DEVELOPMENT FOR 80 MHz SINGLE-CELL RF-CAVITY USING ORTHOGONALLY BIASED GARNETS

C. Vollinger, F. Caspers, CERN, Geneva, Switzerland

Abstract

In the frame of the LHC Injector Upgrade program involving the existing 80 MHz cavities in the CERN PS accelerator, an orthogonally biased ferrite tuner is foreseen to complement the current motor-driven piston tuner. This ferrite tuner shall provide the possibility of a fast frequency shift of about 200 kHz on the fundamental mode, to allow a fast switching between proton and ion frequencies. In order to avoid water cooling and related issues, the challenge was to bring magnetic losses in the tuner to a minimum such that a forced air cooling scheme will be sufficient. The tuner was first designed with simulation tools, a prototype was built and low-power RF testing was performed on the tuner-cavity combination to evaluate tuning range, bandwidth, and stability. These tests were carried out on a single-cell copper RF cavity mock-up with a resonance frequency of 88 MHz, where the ferrite tuner is connected via a tuning loop and the perpendicular magnetic bias for the ferrite tuner is provided by a DC bias supply. Simulations and test data will be presented.

INTRODUCTION

For the acceleration of protons and ions, the CERN PS accelerator makes use of three single-cell RF-cavities with a resonance frequency of 80 MHz [1]. These existing cavities are currently equipped with piston tuners for frequency shifts to allow the acceleration of protons and ions. We developed a ferrite tuner with the intention to complement the motor-driven piston tuner and to provide a fast frequency shift of about 200 kHz on the fundamental mode. Consequently, we aimed for a design that provides a maximum frequency range that should be reached with a minimum change of biasing field while keeping the ferrite material sufficiently magnetized such that the material stays entirely in the low loss state during operation.

TUNER DESIGN

The tuner consists of a coaxial structure terminated with a shortened plug. The space between inner and outer conductor is partly filled with the low-loss tuneable ferrite garnet G-510 [2] and the tuner is inserted into a toroidal coil set-up that provides orthogonally magnetic biasing fields, i.e. the bias field is oriented perpendicular to the magnetic RF-field. The actual tuning is achieved by making use of the fact that the relative permeability of ferrites can be changed if a magnetic bias field (static or slowly varying) is applied to the material. In a first step, a design was carried out by means of simulations in HFSS. Figure 1 (left) shows a sketch of the ferrite-filled tuner with the biasing coils connected in series, and the HFSS model including the coupling loop that indicates the connecting plane to the cavity (right). It should be noted that the simulations have been carried out on the geometry of the 80 MHz cavity, for which also the final tuner design is intended.

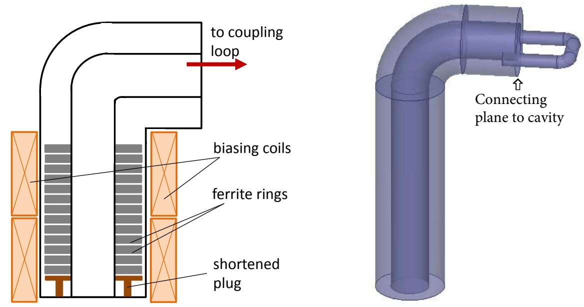

Figure 1: Left: Sketch of coaxial ferrite-filled tuner with bias coils; Right: HFSS model of tuner with coupling loop.

Due to availability, however, measurements were carried out on an 88 MHz mock-up cavity structure. Figure 2 shows a picture of the set-up with which a tuning range of ± 100 kHz around the resonant frequency f_{res} is pursued.

Figure 2: Picture of the mock-up 88 MHz cavity used for testing of the tuning-concept with the fast ferrite tuner.

The tuner design was constrained by a fixed ferrite ring size in order to make use of rings being available from a former application, and one of the existing access ports to the cavity had to be used due to local space restrictions. As a consequence, the tuner's coupling strength is limited due to its location, however, as we could show from our

PRELIMINARY DESIGN OF A PERPENDICULAR BIASED FERRITE LOADED ACCELERATING CAVITY

J. Eberhardt, CERN, Geneva, Switzerland; TU Darmstadt, Darmstadt, Germany
F. Caspers, C. Vollinger, CERN, Geneva, Switzerland

Abstract

A ferrite loaded accelerating cavity with a frequency sweep of 18 to 40 MHz is studied for a possible upgrade of the CERN accelerator complex. The resonance frequency of a ferrite loaded cavity shifts by applying an external magnetic bias field to the ferrite material by means of changing the relative permeability. We present the electromagnetic design of such a cavity with a special emphasis on the modeling of the nonlinear, anisotropic and dispersive characteristics of the ferrite's relative permeability above magnetic saturation. For experimental crosscheck, a ferrite loaded resonant test setup was built which provides results for the material performance in a magnetic bias field. A comparison of numerical simulations and experimental measurements is shown and calculations are benchmarked by measurement data. Based on this study a preliminary design of a ferrite loaded accelerating cavity is described.

INTRODUCTION

The characteristics of ferrite loaded accelerating cavities are dominated by the properties of the ferrite material. During the development process it is essential to know the electromagnetic properties of the filling material. A measurement setup is described to investigate a possible resonance frequency swift, to measure the quality factor and to characterize the relative permeability of the ferrite material exposed to a perpendicular magnetic bias field. Moreover we model the measurement setup in an electromagnetic field simulation program and compare the results with the measurements. Based on this, we investigate an electromagnetic design of an accelerating cavity with a frequency sweep of 18 to 40 MHz.

FERRITE LOADED TEST SETUP

For the accelerating cavity, toroidal cores of the ferrite G-510 of 350 mm OD and 200 mm ID consisting of five segments were the largest size currently available by Trans-Tech Inc. [1]. The five segments were glued on top of an 3.3 mm thick *Al 995* toroidal carrier disc with the two component epoxy glue *Stycast 2850 FT*. *Al 995* provides high thermal conductivity of 29.3 W/m.K, a small dielectric loss factor of $\tan\delta_e = 2.9 \cdot 10^{-4}$ at 10 MHz and tight fabrication tolerances. Up to now, the large rings were only investigated in two resonant test setups with different purposes [2]. First, it was shown that doubling the resonance frequency of a measurement cavity is possible by changing a perpendicular magnetic bias field. But the frequency range achieved was well above the desired 18 to 40 MHz and a radiating open gap degraded the measured Q. Second, it was pointed out with another ferrite loaded resonant cavity that high quality factors of up to 5000 can be obtained, but the ferrite shift was limited due to a ferrite filling factor of ca. 25%. A dedicated test setup was developed to investigate the ferrite rings with two different measurement methods. A resonant measurement method is used to investigate the resonance frequency sweep dependent on the magnetic bias field and to measure the corresponding quality factor within the frequency range of interest. With the second method, a 1-port reflection measurement, we measured the complex permeability spectra, similar to the measurement setup presented in [3].

Resonant Measurement

The measurement cavity consists of a main cell, a top cover and a piston all made out of aluminum, see Fig. 1. A capacitive load of up to 1900 pF can be achieved by placing a 0.1 mm Teflon foil between top cover and the piston which reduces the resonance frequency of the empty cavity to 44.7 MHz.

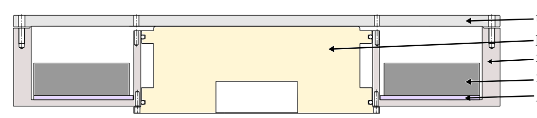

Figure 1: Resonant measurement setup.

The measurement setup is placed within the aperture of an H-dipole to apply a magnetic bias field which is perpendicular to the RF magnetic field. We could not detect resonances for magnetic bias fields below 35 mT, since in that range the losses of the ferrite material are rather high. With increasing magnetic bias field from 35 to 300 mT the resonance frequency shifts from 18.8 to 43.7 MHz due to the decreasing relative permeability of the ferrite, which is shown in Fig. 2.

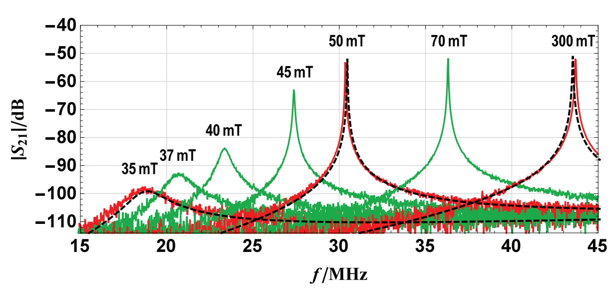

Figure 2: Measurement results (solid traces) of resonant ferrite filled setup in comparison with driven modal simulation results (dashed traces).

The unloaded quality factor can be measured via the 3 dB bandwidth of the transmission signal as a weakly coupling

DESIGN OF A VARIABLE X-BAND RF POWER SPLITTER

Hao Zha, Igor Syratchev, Dmitry Gudkov, Alexej Grudiev, CERN, Geneva, Switzerland

Abstract

The design of the variable high RF power X-Band splitter is presented. The RF power division ratio is adjusted by mechanically changing the position of a special RF short circuit piston. The piston is mounted on a step-motor providing the precise linear movement. Throughout the design, special measures were taken to reduce the maximum electric field on the copper surface, as well as to maximise the frequency bandwidth of the device.

INTRODUCTION

High RF power X-band test stands for testing the normal conducting CLIC accelerating structures are now in operation at CERN. In general, these tests require a precise adjustment of the driving RF power level [1]. The RF splitter with arbitrary division ratio will be used to meet this need without changing the RF power provided by RF source itself. The RF splitter is a three port device, where one output port is connected to the DUT (Device Under Test) itself and the other is connected to the matched RF load, which absorbs the excessive RF power. The division of RF power between the two is adjusted by mechanically changing the position of a special RF short circuit piston (see Fig. 5 in [2]). The piston is an RF contact free device and is mounted to a step-motor providing the precise movement. Thus a continuous adjustment of the RF power is achieved.

PRINCIPLE OF OPERATION

The schematic of the splitter RF circuit is shown in Fig. 1. For the known parameters s_{ij} in the scattering matrix (1), the output power in each port y_n can be calculated using equation (2). Parameter ρ in equations (1 and 2) is the reflection from the RF short circuit piston.

The output power in the ports y_1, y_2 and y_3 depends on the RF phase of the reflection ρ. By controlling the position of the RF short circuit piston, this phase can be changed, thus the output power at ports 2 and 3 can be adjusted. In order to minimize the overall reflection, the RF splitter should be matched, thus y_1 should be equal to zero. Consequently s_{11} and s_{14} should be equal to zero as well, but not s_{41}, otherwise y_2 and y_3 will be de-coupled. This condition ($s_{14} \neq s_{41}$) breaks the symmetry of the RF circuit and makes matching of the device impossible.

$$\begin{pmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{pmatrix} = \begin{pmatrix} s_{11} & s_{12} & s_{13} & s_{14} \\ s_{21} & s_{22} & s_{23} & s_{24} \\ s_{31} & s_{32} & s_{33} & s_{34} \\ s_{41} & s_{42} & s_{43} & s_{44} \end{pmatrix} \begin{pmatrix} 1 \\ 0 \\ 0 \\ \rho y_4 \end{pmatrix} \quad (1)$$

$$\begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix} = \begin{pmatrix} s_{11} \\ s_{21} \\ s_{31} \end{pmatrix} + \begin{pmatrix} s_{14} \\ s_{24} \\ s_{34} \end{pmatrix} \frac{\rho s_{41}}{1-\rho s_{44}} \quad (2)$$

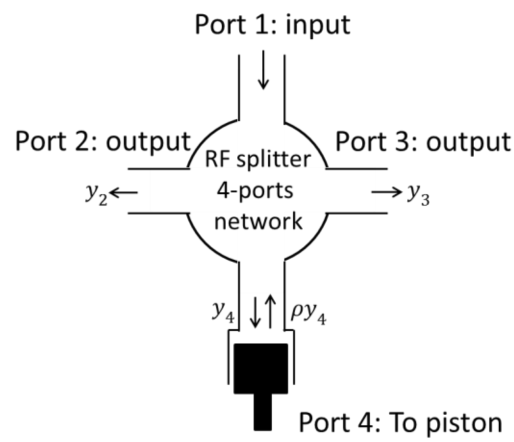

Figure 1: The 4 port network proposal for RF splitter.

The way to approach matching is to have a 5-port network where two ports are connected to the piston. It can be proven that a solution for the symmetric network exists in this case. A schematic of such a 5-port network is shown in Fig. 2. It uses 3 symmetric RF splitters to split the input port to 4 output branches. Each of the symmetric RF splitters is designed in a way that every port sees the combined impedance of the two others. The distance between the first and second symmetric RF splitter is a quarter-wavelength. According to transmission line theory, the total impedance seen by the input port is $\frac{1}{Z_2+Z_4} + \frac{1}{Z_3+Z_5}$, where Z_i is the impedance of each port by itself. As shown in Fig. 2, port 2 and 3 are output ports, thus $Z_2 = Z_3 = 1$. The RF short circuit pistons bring reactance, so that the values of Z_5 and Z_4 are purely imaginary. The input port will be matched if $Z_5 * Z_4 = 1$. That can be achieved by having 180 phase difference in reflection between the two short circuit pistons. The power division ratio is now determined only by the reflection phase of the pistons and can be varied from 0 to 1. This network design is very compact and has a broad frequency bandwidth. However, two synchronised short circuit pistons are needed, thus a certain complication of the mechanical design is unavoidable.

SOLID STATE AMPLIFIER DEVELOPMENT FOR THE SWISS LIGHT SOURCE*

M. Gaspar†, T. Garvey, Paul Scherrer Institut, Villigen, Switzerland

Abstract

The Paul Scherrer Institute (PSI) currently operates a klystron amplifier on the booster ring of the Swiss Light Source (SLS). In order to have an optional RF source for the booster cavity, we have been developing a compact 500 MHz 65kW solid state RF amplifier. An important goal in this development is the optimization of efficiency at any given operating point. In order to achieve this, each RF module has been equipped with its own DC power supply (PS Controller), providing sufficient intelligence to adjust the drain and bias voltages in a fully independent and automatic way. With this technique it is possible to maximize the overall efficiency at any given RF output power. Considerable effort has been made in order to obtain extensive measurements from each individual module with the aim of investigating the behaviour of such a large number of combined arrays. We will discuss the amplifier design and present the results of measurements.

THE CONSTRUCTED 65 kW POWER AMPLIFIER SYSTEM

INTRODUCTION

Since the introduction of solid-state amplifiers on the synchrotron light source SOLEIL there has been considerable interest in use of such devices at other light source laboratories [1]. A modest R&D effort was started at the Paul Scherrer Institute (PSI) in order to develop this technology at 500 MHz resulting in a 4.5 kW prototype [2,3]. More recently, supported by the Swiss Commission of Technology and Innovation, we have developed a 65 kW amplifier described in this paper. This technology has been transferred to AMPEGON AG, our industrial partner for this project, for industrialization and commercialisation.

DESIGN DESCRIPTION

A large variety of tests were performed to evaluate the 65 kW amplifier system described here. Long duration tests were done with the amplifier delivering output powers of, 60 kW, 64 kW, and 68 kW. The system performed in an extremely stable fashion under all conditions.

Figure 1 shows a block diagram of the system. In this configuration all the 108 output amplifier stages, those that contribute to the system output power, are placed in parallel and are all combined by a large high power combining structure [4].

Figure 2 shows the conceptual design of the proposed system. In the middle, one sees the high power combiner tree, a fundamental component of existing high power distributed amplifiers based on solid-state technology. The RF amplifier modules and the PS Controllers are mounted around the combiner tree on 2 meter tall aluminium bars which are water cooled.

Figure 3 shows the constructed high power solid-state amplifier system. The amplifier itself is placed to the right. It is composed of six 2 m long cooling bars. Each cooling bar supports 18 RF amplifier modules on one side and 18 PS Controllers on the other side.

The RF output of the amplifier system is connected to a 100 kW water cooled load through a 3 m long high power EIA $6\frac{1}{8}$ coaxial transmission line, seen at the top. The water cooled load is placed at the left of the amplifier, and behind the rack.

The 19" rack to the left houses part of the components required to connect the amplifier to the mains, other components for monitoring and communication purposes and the pre-amplifiers with their power supplies. The amplifier system is connected to the rack at the top through a cable support.

The complete amplifier system weighs approximately 900 kg.

MEASUREMENT RESULTS

Figure 4 shows a typical output power scan, P_{out} and Efficiency vs. P_{in}. A complete power scan such as shown in Fig. 4 may take a full day to be done because of the time required for the measurements of the calibrated water cooled load to stabilize.

Figure 5 shows a frequency scan, P_{out} and Efficiency vs. P_{in} realized with a fixed power supply value, V_{dd} = 48 V, and for two different output power levels, P_{out} = 20 kW, a low efficiency operation, and P_{out} = 50 kW, a high efficiency operation. Assuming a good trade-off between gain and efficiency, a bandwidth better than 20 MHz at P_{out} = 50 kW is available with an efficiency better than 45%. At lower output power, as P_{out} =20 kW, the efficiency reduction is not an issue any more, thus much wider bandwidths are available.

The graph of Fig. 6 shows the quite high quality of the output frequency spectrum. This illustrates the noise near the carrier. Measurements over a wider span show that the second harmonic is present at -45 dBc and the third harmonic is absent, probably due to the limitations of the transistor to generate it.

The amplifier system was operated at full reflection, with a short circuit applied at the output, for about 15 minutes at

POWER SAVING STATUS AT NSRRC

J.C. Chang, W.S. Chan, T.S Ueng, Z.D. Tsai, Y.C. Lin, C.Y. Liu, Y.C. Chung, Y.F. Chiu, C.W. Hsu, Y.C. Chang, and K.C. Kuo
National Synchrotron Radiation Research Center (NSRRC), Hsinchu 30076, Taiwan

Abstract

National Synchrotron Radiation Research Center (NSRRC), Taiwan has completed the construction of the civil and utility system engineering of the Taiwan Photon Source (TPS) in 2014. On the last day of 2014, the Taiwan Photon Source (TPS) has delivered its first synchrotron light with 1mA stored beam current. The machine is in commission currently. The power consumption of TPS was about 5MW then. The ultimate power consumption of the TPS is estimated about 12.5MW. To cope with increasing power requirement in the near future, we have been conducting several power saving schemes, which include adjustment of supply air temperature according to the atmosphere enthalpy, replacement of old air conditioning unit (AHU), power consumption control by the operation of chillers, power factor improvement, and reduction of power consumption during long shutdown.

INTRODUCTION

NSRRC has been conducted several major projects, such as installation of superconducting rf cavities and magnets, construction of extension buildings in the Taiwan Light Source (TLS) for years. Besides, the TPS project has been in commission process. Those projects have been greatly increased the electrical power consumption. Currently, the contract power capacities of the Taiwan Light Source (TLS) and the TPS with the Taiwan Power Company (TPC) are 5.5MW and 7.5MW, respectively.

As the price of petroleum increased, the power bill had also been raised three times since 2008. The power bill of per kW-hr was increased about 35%, 40%, and 10% in 2008, June 2012, and Oct. 2013, respectively. Fig. 1 shows monthly average power bill per kW-hr of TLS from 2011 to 2015.

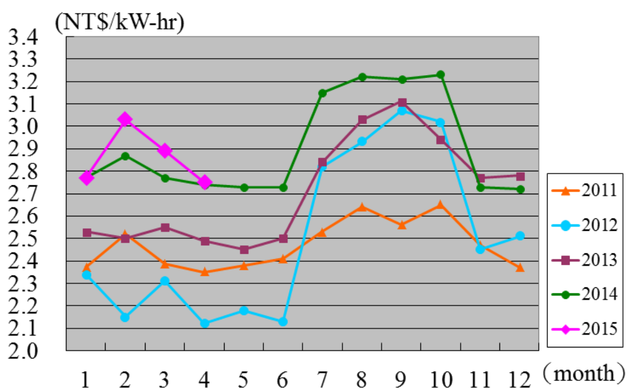

Figure 1: Monthly average power bill per kW-hr in NSRRC from 2011 to 2015.

To cope with fast growth of the power consumption and power bill, NSRRC has been conducting a series of power saving schemes since 2006 [1]. Those power saving schemes include optimization of chiller operation, power consumption control, improvement of temperature and humidity control, electrical power factor improvement, lighting system improvement, and application of heat pumps. We keep conducting those schemes and create some new ones, including modified run-around coil AHU, change of power bill calculation mode, and promotion of power saving. Some major schemes are described as follows.

CHILLED WATER PIPES CONNECTION BETWEEN TPS AND TLS

There are three utility buildings in NSRRC. The Utility Building I was constructed for the TLS 23 years ago. There are three chillers, each with 320 RT in capacity installed inside. Utility Building II was construction for the cryogenics and superconductivity systems 13 years ago. There are two 600 RT chillers and two 450 RT chillers installed inside. We had ever connected chilled water pipes between Utility Buildings I and II. It saved about 70 kW.

The civil construction Utility Building III for the TPS had been completed in Dec. 2012. Three chillers, each with 1,400 RT in capacity, had been installed inside. We had connected supplied and return chilled water pipes, each with 10 inch in diameter, between the second and the third Utility Buildings in 2013.

Figure 2 shows the chilled water piping system in the Utility Building II. The blue lines are the pipes connected between Utility Building I and II. The green lines are the pipes connected between Utility Building II and III.

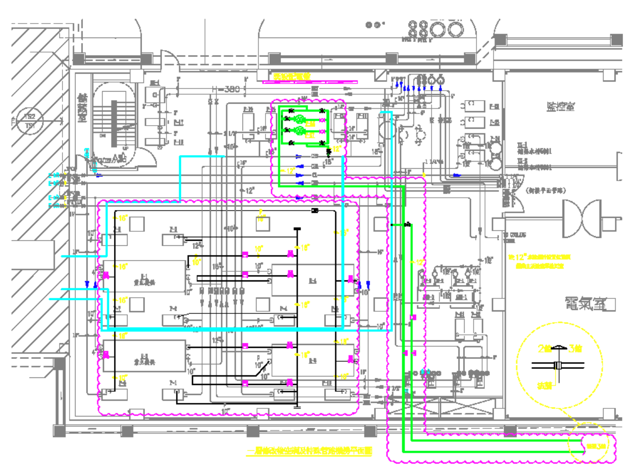

Figure 2: Chilled water piping in the Utility Building II.

Abstract

The construction of the utility system for the 3.0 GeV Taiwan Photon Source (TPS) was started in the end of 2009. The utility building for the TPS ring had been completed in the end of 2014. The final acceptance test and improvement had also been completed in the end of 2014. The TPS is in commission and TLS is still in operation. Within limited manpower and budget, it is challenge to operate both utility systems stable and reliable. We provide good quality of electrical power, cooling water and precision air temperature. Power saving is also an important issue. The utility system presented in this paper includes the electrical power, cooling water, air conditioning, compressed air, and firefighting systems.

INTRODUCTION

Utility system is the infrastructure of a facility. It is also one of critical subsystem of an accelerator. Therefore, a good utility system can provide not only stable and precision electrical power, cooling water and air temperature for the beam operation, but also a safety, comfortable and working environment for all personnel. Besides, power saving becomes another important issue for the environment. There are more requirements for the utility system than ever.

After 22-year operation of TLS, TPS has been constructed and in the phase of commissioning. Based on the operation experience of TLS utility system and utility system design of other advanced accelerators, the utility system of TPS had been designed and constructed [1].

Considering the efficiency of operating TLS and the TPS, the TPS is constructed adjacent to TLS on the NSRRC campus. Some areas of TPS and TLS are even overlapped. Figure 1 shows the bird view of TPS, TLS and three Utility Buildings. The existing Research building is enclosed by the TPS storage ring building.

There are three utility buildings providing utility system for TLS and TPS. Utility Building I was constructed with TLS storage ring building in 1992. Utility Building II was constructed for the Cryogenics and superconducting systems in 2002. Main utility equipment of the TLS is installed in Utility Buildings I and II. Utility building III, especially for the TPS, is designed near the existing two utility buildings, as shown in Fig. 1.

There are two utility trenches from the Utility Building I and the Utility Building II respectively connecting to the TLS ring for the piping system and electrical power transmission. Likewise, there is a trench connecting the Utility Building III and TPS.

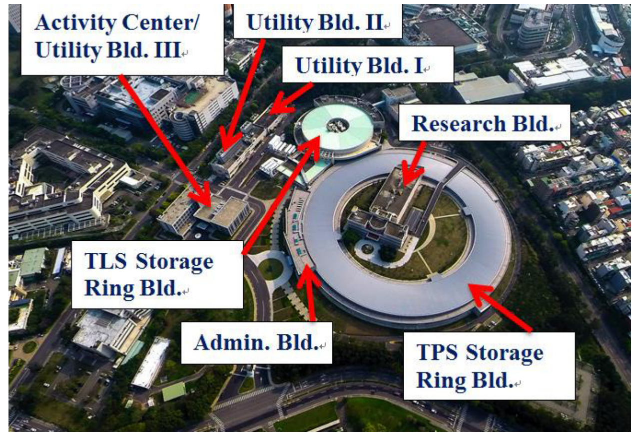

Figure 1: Bird view of TPS, TLS and three Utility Buildings.

MAN POWER OF UTILITY SYSTEM

When the TLS was constructed, there was an Engineering Division in charge of the civil and utility system construction and maintenance. Most members of the engineering division were engineers and technicians. As accelerator technique developed, the requirements of precision and stability of utility system were much higher than ever. The Engineering Division was reorganized under the Instrumentation Development Division as the Utility Group and recruited scientist members in 1996.

We had made many efforts on studying utility effects on beam quality and upgrading utility system since 1998. [2] Our monitoring and control system was first set up in 1999. The first SCADA (supervisory control and data acquisition) of electrical power system was built in 2003.

For the civil construction of TPS, there was a civil management group formed in 2006. As the civil construction was completed, the utility and civil management groups were merged as the utility and civil group in 2015. The man power of each subsystem is listed in Table 1.

Table 1: Man Power of Utility and Civil Group

Subsystem	Scientist	Engineer	Technician
Electrical Power		2	1
Water	1	1	1
Air Conditioning		2	1
Grounding/ EMI	1	1	
Civil		1	1
Others	1	1	
Total	3	8	4

EMI MEASUREMENT FOR TPS BOOSTER KICKER AND SEPTUM SYSTEMS*

Yung-Hui Liu#, Chin-Shen Chen, June-Rong Chen, Wen-Shuo Chan,
NSRRC, 101Hsin-Ann Road, Hsinchu Science Park, 30076, Taiwan

Abstract

The purpose of this paper is to estimate the conducted and radiated Electromagnetic Interference (EMI) for subsystems in the TPS booster ring. A LISN (Line Impedance Stabilizing Network) system with a wide frequency range was conducted to measure the EMI spectrum of pulsed magnet system. The radiated EMI was tested by magnetic field probe, which the measurement frequency range is 100 kHz ~ 3 GHz. A stray current was tested by wide frequency current transformer in order to measure the conducted current for kicker and septum systems. According to the experiment results, the stray current could flow through the other subsystems or booster chamber, and it might be affected the stability of booster operation. Therefore reducing and eliminating the interference of EM waves will be a very important issue. The EMI prevention scheme will be continued.

INTRODUCTION

According to the experience of synchrotron operation, Electromagnetic Compatibility (EMC) is one affected factor for beam stability [1]. Electromagnetic Interference (EMI) also be an issue of TLS because of the limited space and top-up mode operation [2]. For TPS project, top-up mode injection will also be the basic operation mode in the future. Therefore, injection magnets will produce conducted and radiated EMI similar to TLS existing condition [3]. In order to eliminating and reducing interference between injection sections, a good EMI design should be implement in the beginning. Firstly, a good impedance match between pulsed power supply and magnet (load) should be notice carefully. Reducing EMI level by using appropriate EMI filters from power source could also reduce conducted EMI [4]. Secondly, the grounding scheme will design based on the TLS experience. Every kicker will have exclusive grounding bus directly connect to grounding networks. The spray current will also collect by several routs in order to increasing efficiency. Finally, the EMI enclosure is proved effective and will implement to kicker magnet and its pulser. All three steps are the total solutions to reduce conducted and radiated EMI of TPS pulsed magnets.

TPS PULSED MAGNETS LOCATIONS

The pulsed magnets in TPS are divided into 3 parts, shown as Fig. 1. The first part is booster injection section; there are one booster injection septum and one kicker included. The booster injection magnets guide the electron beam from LINAC to booster ring. After increasing the electron beam energy from 150 MeV to 3.0 GeV, the electron beam extract to the second part - booster extraction section. There are 2 booster extraction kickers and two septa in booster extraction section. Passing by the BTS (booster to storage ring) section, the electron beam is inject to the storage ring by 4 kickers and two septa (2 AC septum).

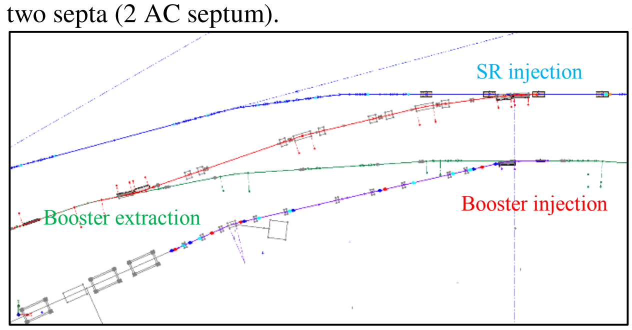

Figure 1: TPS pulsed magnets position.

GROUNDING SCHEME

According to TLS experience, the grounding scheme of TPS injection section as shown in Fig. 2. Every pulsed magnet will have exclusive grounding bus directly connect to TPS grounding networks. Because of the pulser and pulsed magnet are placed in different location, the grounding routes are connected separately for conduct stray current independently. Thus, paths of spray currents have no interchange between other subsystems.

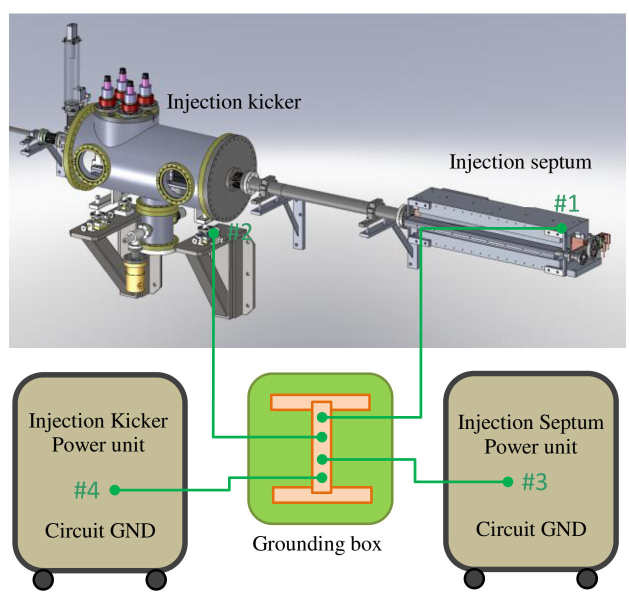

Figure 2: TPS injection pulsed magnets grounding scheme.

STUDY ON THE LN2 CONSUMPTION OF THE BEAMLINE LN2 TRANSFER SYSTEM FOR TPS PROJECT

H. C. Li, F. Z. Hsiao, H. H. Tsai, T. F. Lin, W. S. Chiou, S. H. Chang, W. R. Liao and W. S. Chan,
National Synchrotron Radiation Research Center, Hsinchu, 30076, Taiwan

Abstract

One system to transfer liquid nitrogen (LN_2) will be installed at TPS in 2015 for beamline. This system includes two transfer lines (length 600 m), eight keep-full devices and 26 branch lines with 26 control valves for 24 straight sections of beam lines. The required consumption of LN_2 for each beam line is 30 L/h. An archive system was developed to monitor and to calculate the consumption of LN_2 for each beam line. This consumption was calculated based on the pressure difference and the flow coefficient (K_v) of the control valve. This paper presents the configuration of the LN_2 supply system at NSRRC and a test bench of the calculation of LN_2 consumption. A simple test result is presented and discussed.

INTRODUCTION

A helium-cryogenic system with refrigeration (450 W) began its operation from 2003. The liquid-nitrogen (LN_2) supply system entered service at the same time. Figure 1 is the current status of the LN_2 supply system at NSRRC. The LN_2 supply system was finished for Taiwan Light Source (TLS) in 2009. The LN_2 transfer system for the Taiwan Photo Source (TPS) project began its installation and commissioning in 2013.

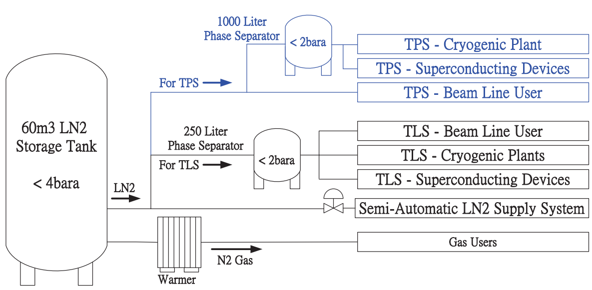

Figure 1: Configuration of the LN_2 supply system at NSRRC.

LN_2 Supply System at NSRRC

One LN_2 storage tank (60 m^3) replaced the original one (20 m^3) in 2009. In total, the LN_2 flows through a vacuum-shielded LN_2 transfer line (length > 300 m) and one phase separator (250 L) to users at TLS [1]. The TLS users comprised of two liquid-helium (LHe) refrigerators (450 W) [2], one superconducting RF cavity, five superconducting magnets, two beam-line laboratories, and one semi-automatic LN_2 supply system. A line (length > 300 m) for gaseous nitrogen (GN_2) used to purge or to clean the machine or experimental samples also existed inside the LN_2 system.

We installed a vacuum-shielded LN_2 transfer line (150 m), one phase separator (1000 L) and one helium refrigeration system (700 W) [3] in 2013. We finished the commissioning of a multi-channel line (LHe/GHe/LN_2 /GN_2) for four TPS superconducting RF cavities in 2015 April. The total length is more than 130 m. We began to install two vacuum-shielded LN_2 transfer lines (length 600 m) with 26 control valves used in TPS beam-line laboratories in 2015 April. Figure 3 shows the configuration of the LN_2 transfer system of NSRRC.

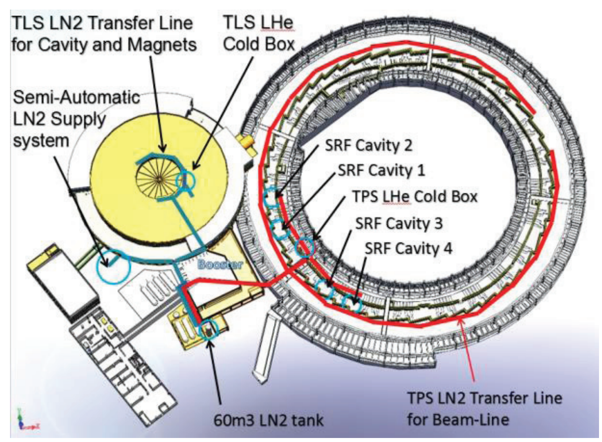

Figure 2: Configuration of LN_2 transfer line of NSRRC.

LN2 Consumption

Increasing numbers of users introduce a rapidly increasing consumption of LN2. Figure 3 shows the LN_2 consumption at NSRRC from 2005 to 2014. The average consumption is about 955 m^3 per year from 2005 to 2009, but the average consumption increased to 1777 m^3 per year from 2010 to 2014. The major increase was due to the TPS project. Many machines and systems were tested and commissioned during these five years. Figures 4 and 5 show the LN_2 ratio of users. It was easy to estimate the budget of TLS LN_2 consumption because of the stabilized operation in year 2009, but more than 51 % of the total amount LN_2 consumption was used to support the relevant testing of TPS in year 2013. It is difficult to estimate the LN_2 consumption under such conditions. To understand the LN_2 consumption of each user is an important issue for the stability of the LN_2 supply due to the budget control. A typical theory of valve sizing can help us to calculate the real-time consumption of LN_2

ELECTRICAL POWER SCADA SYSTEM OF TAIWAN PHOTON SOURCE

Tzong-Shyan Ueng, Yung-Feng Chiu, Yu-Chih Lin, Kung-Cheng Kuo, Jui-Chi Chang, Wen Shuo Chan, NSRRC, Hsinchu, Taiwan

Abstract

The architecture of power SCADA system of TPS and its monitored real time data are described in this report. The on-line monitored and measured items include voltage/current, real power/reactive power, power factor, harmonic distortion, etc. These data are presented. The electric energy, the power quality and the harmonic distortion obtained with the SCADA system are used to study the status of the power system, and also provide information for the future improvement.

INTRODUCTION

The Taiwan Photon Source (TPS) is a newly constructed accelerator facility in National Synchrotron Radiation Research Center (NSRRC). It is adjacent to Taiwan Light Source (TLS). This new storage ring has 518 m in circumference and can deliver electron beam of 3.0 GeV and 500 mA, which is much more elaborate than the present TLS facility. During the last 20 years, the researchers have used TLS to produce many excellent scientific research results. Adding TPS to the present facility will provide the researchers with needed facility and resources to stay ahead in the scientific and technological competition. In order to keep this new synchrotron facility running smoothly for producing excellent experimental results, an electrical system with a good power quality is crucial.

ELECTRICAL POWER SYSTEM AND ITS LOADS

The electric power used in TPS is provided by Taiwan Power Company (Taipower) through two main distribution feeders, feeder A and B, to the main substations for TPS in NSRRC. These two feeders have rated voltage of 22.8 kV each. The power demand from Taipower is 12.5 kW. Two local generators can deliver 2000 kW for emergency need. There are 17 local substations for the power loads in TPS. All the loads are sorted and distributed evenly on the two feeders, Fig. 1. The loads of the accelerator facility are mostly for the subsystems of accelerator and the experimental stations, while the loads of the utility system are chillers, pumps, air handling units, smoke exhaust fans, hot water furnaces and those utilities for public use.

MONITORING AND DATA ACQUISITION SYSTEM

The real time monitoring and data acquisition system used for the TPS power system adopted the graphical programming approach but with one-line diagram in mind. This system has functions of I/O communication, storing trend data, real time alarm and remote GUI operation. In Fig. 2 the GUI of SCADA system shows the control panel of the main feeder A which displays the real time values of real power, maximum demand power and reactive power in main feeder A. It also displays voltage, current and power consumed at each substation. More information of the power system can be seen by further clicking the icon on the screen. The communication architecture adopts the Modbus RTU communication protocol, Fig. 3. The protection relays, digital multi-meters, thermal relays, automatic power factor regulators (APFR), DC chargers, generators and air circuit breakers (ACB) are connected to the I/O servers, then, the I/O servers convert the communication protocol to Modbus TCP protocol and communicate to the main server using optical fiber through Ethernet switch. The optical fiber is connected as a ring type which can transfer data in both directions to the two main servers. These two servers can access data from the I/O servers and monitor the status of devices simultaneously. Each server can also be used as backup of the other server in case one server is failed.

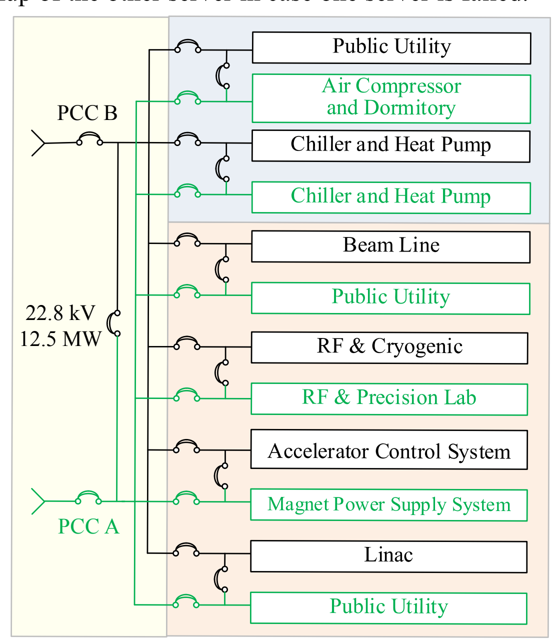

Figure 1: Block diagram shows the loads used at TPS.

MEASUREMENT AND ANALYSIS OF POWER QUALITY

The real time information of feeder B measured by the power SCADA system are shown in Fig. 4. The feeder B provides the power for most of the accelerator subsystems. It shows the voltage/current of each phase, real/reactive

COMMISSIONING OF THE DE-IONIZED WATER SYSTEM FOR TAIWAN PHOTON SOURCE

W.S. Chan*, J.C. Chang, Y.C. Chang, C.S. Chen, Y.C. Chung, C.W. Hsu, C.Y. Liu, and Z.D. Tsai
National Synchrotron Radiation Research Center (NSRRC), Hsinchu 30076, Taiwan

Abstract

The de-ionized water (DIW) system plays a critical role in removing waste heat from an accelerator machine. Through years of design and constructs, the DIW system for Taiwan Photon Source (TPS) was complete at the end of 2013, but it is important to confirm that the quantity and quality of DIW comply with the requirements of the accelerator machine. Testing, adjustment and balancing methods have been applied to verify that the DIW system for TPS can provide flow rates greater than 1659, 380, 1284 and 1238 GPM in the individual Cu, Al, RF and booster subsystems. The proposed system can supply DIW of quality such that the resistivity is greater than 10 MΩ-cm at 25±0.1 °C; the concentration of dissolved oxygen (DO) is less than 10 ppb.

INTRODUCTION

The main utility equipment of TPS includes a deionized water (DIW) system installed in Utility Building III to avoid vibration and power noise induced by these cooling-water facilities, including cooling towers, chillers, heat pumps and water pumps [1]. A utility trench from Utility Building III connects to TPS for the piping system and electric power transmission [2]. Figure 1 has a schematic drawing of TPS and Utility Building III.

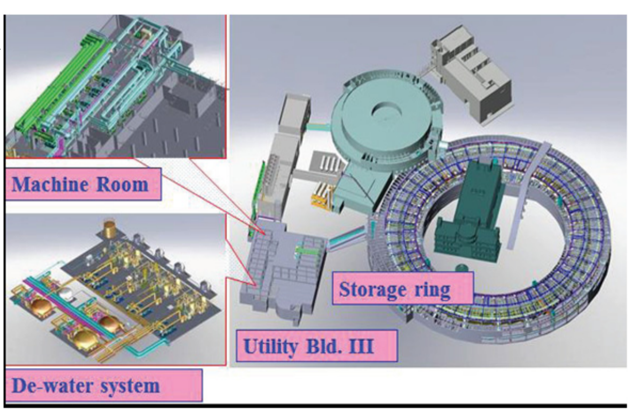

Figure 1: TPS storage ring and Utility Building III.

The DIW system for TPS has four subsystems -- Cu DIW for magnets and power devices, Al DIW for vacuum chambers, RF DIW for the RF facility, and booster DIW for booster devices and beamline optical instruments. The demanded flow rate that depends on the heat load for each portion of the TPS synchrotron accelerator is listed in Table 1.

Table 1: Flow Rate Requirements of DIW Subsystems

Point of use	flow rate /GPM			
	Cu	Al	RF	booster
magnet	594	-	-	136
power devices	501	-	-	-
vacuum	260	312	-	-
front end	296	68	-	-
RF facility	-	-	1284	-
cryogenics	-	-	-	17
Linac	-	-	-	435
mechanical	8	-	-	-
beamline	-	-	-	650
total	1659	380	1284	1238

All DIW flow circulates in a closed loop and removes heat within a stable range of temperature and pressure. Each return DIW flows through two plate heat exchangers for heating and cooling, then flows via a mixing buffer tank for highly precise temperature control. Respective DIW subsystems possess two pumps with variable-frequency drives (VFD) that achieve flow regulation, energy conservation and uninterrupted commission.

Water treatment is an important aspect of a DIW system. Impurities in DIW typically include particles, electrolytes, micro-organisms, organic substances and gases that must be removed with a physical or chemical mechanism. The activated carbon filter (ACF), reverse-osmosis equipment (RO), resin-mixed bed (MB), micro-filter (MF), ultraviolet sterilizer (UV) and dissolved oxygen membrane deaerator (MD) have been installed to sustain the water quality [3]. Of the primary loop flow, 5 % DIW flows through this recycle loop as shown in Fig. 2; the entire DIW system must meet specifications listed in Table 2.

In the TPS storage-ring building, an individual DIW subsystem has been divided into 48 manifolds for the 24 sections of the accelerator machine, as shown in Fig. 3. Every manifold has filters, flow-balance valves and sensors for temperature, pressure and flow, which provide an optimal flow balance and real-time DIW status. Every inlet and outlet piping connected with the accelerator machine has a flexible hose to prevent the propagation of vibration.

DEVELOPMENT OF AN IGBT PULSER FOR TPS LTB KICKER

C.L. Chen#, C.S. Fann, H.P. Chang, K.L. Tsai, Y.S. Cheng, S.Y. Hsu, K.T. Hsu, K.K. Lin
National Synchrotron Radiation Research Center, Hsinchu, Taiwan

Abstract

The Linac to Booster (LTB) injection kicker for Taiwan Photon Source (TPS) was first commissioned using Pulse Forming Network (PFN) pulser equipped with a thyratron switch. Although its bench-testing results fulfilled all specifications, the performance was degraded due to a couple of unavoidable integration difficulties. After evaluating several improving options in hand, an alternative pulser using IGBT switch is proposed for off-the-bench beneficial purpose. The results of the upgraded pulser satisfy the overall specifications with comfortable margins. Some major performance parameters, such as flattop and tail ringing, are emphasized concerning their influence on beam injection. This report describes the field-testing result of this new IGBT pulser.

INTRODUCTION

TPS LTB kicker pulser was installed for system test in 2014 using PFN- thyratron switch. This PFN pulser was designed and constructed in house, and it fulfils all the performance specifications, such as flattop width, pulse-to-pulse stability, and current pulse fall time with respect to the designed inductive load. The overall bench tested performance of the kicker pulser is listed in table 1. However, due to hardware design constrains, the load inductance (4.4 µH) exceeded the existing circuitry tuning limits of compromising margin, so the overall performance of PFN pulser was degraded, as illustrated in figure 1.

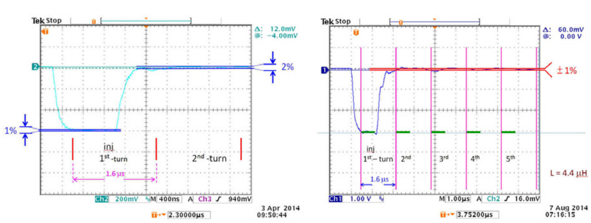

Figure 1: current pulse at (L) bench test; and (R) field test.

The contents in Table 1 indicate that the flattop, its ripple, and fall time, are consequently influenced. Several improving attempts have been studied in order to eliminate the postpulse oscillation, which has tail ripples and could induce extra kick, while the injected beam is circulating around in the booster ring. The urgent improvement attempt by modifying the electrical circuit and reducing the field inductance was made in time for booster injection system test in 2014 [1]. Yet, for the modified PFN circuitry, the available flattop region is reduced to 200 ns due to the unavoidable prolonged fall time. This reduction in the flattop duration does not only limits the bunch train tuning capability in the MB (multi-bunch) operation, but also restricts the bunch pattern manipulation flexibility in the MB+SB (single bunch) hybrid mode operation [2].

The initiation of this IGBT study is to improve TPS injection pulser by using an alternative approach. After evaluating several improvement options in hand, a pulser using IGBT switch is introduced. Comparing its performance with the modified PFN pulser [3] using same inductive load, the IGBT pulser provides a couple of advantages in this particular application, as follow:

1. Fall time can be reduced;
2. Flattop duration can be increased;
3. Small postpulse oscillation can be achieved;
4. Installation space is greatly reduced in the accelerator tunnel.

Some disadvantages are to be considered before implementing the IGBT pulser. There are: i) limitation of reducing fall time due to the existing inductive load; ii) noise interference with the low triggering threshold of IGBT switch. After examining the corresponding bench tested countermeasures, the results indicate that the performance of this IGBT pulser satisfies the specifications with comfortable margins. This report describes the field-testing result of this IGBT pulser in details.

Table 1: LTB Kicker Pulser Tested at Bench and Field

Booster Injection Kicker			
Parameter	**specifications**	**bench-test**	**field-test**
Pulse Shape	flat-top	flat-top	flat-top
Type	PFN	PFN	PFN
Pulse Length (µs)	1	1	0.7
Nominal Current (A)	280	280	280
Inductance (µH)	1.6	1.6	4.4
Fall Time (µs; 5-95%)	0.4	0.4	0.9
Pulse-to-pulse Stability (%)	0.1	0.1	0.1
Flatness (%)	± 1	± 1	± 2
Postpulse ripple (%)	± 1	± 1	± 1.5
Repetition Rate (Hz)	3	3	3

IGBT PULSER LAYOUT

The upgraded injection pulser consists of two parts: an IGBT switching unit and a DC charging power supply (DC-PS). Choosing the IGBT switch is primarily based on its capability of high delivery power and rapid switch-off ability [4]. A functional block diagram of using IGBT switch for the LTB kicker PS is shown in figure 2. A DC-PS charges the capacitor bank to a designated value. Then IGBT trigger is switched on by a control unit according to

DESIGN STORAGE RING AND BOOSTER RING POWER SUPPLY CABLING IN TAIWAN PHOTON SOURCE

Yong-Seng Wong, Kuo-Bin Liu, Chen-Yao Liu, Yuan-Chen Chien, Bao-Sheng Wang
National Synchrotron Radiation Research Center
Hsinchu 30076, Taiwan

Abstract

For this paper is studies the storage ring and booster ring power supply cabling design, Papers can be divided into cabling design, control and instrument area construction (CIA), and testing; design including estimated cable length and arrangement, the CIA construction part site of the cable erection and overcome barriers of space; detection section is high resistance meter and insulation testing [1]. Circumference of booster ring is 496.8 meter and storage ring is 518.4 meter, TPS (Taiwan Photon Source) beam current is 500mA at 3GeV. Booster Ring dipole into BD and BH series 54 magnets, cable size is 250 mm^2 and total length of 5000m [2]. Booster Ring and storage ring quadrupole 150 magnets and cable size 250 mm^2, total length of 17000m. Storing Ring dipole 48 magnets cable size 325 mm^2, total length of 6000m. On the positive and negative voltage cables will produce magnetic interference effects generated through cabling overlapped technology eliminates magnetic interference [3]. Finally, using a high-impedance machine to detect cabling insulation effect. TPS power supply to the energy transfer is to ensure safe and correct magnet.

INTRODUCTION

"Taiwan Photon Source interdisciplinary laboratory facilities construction plan" to be executed in National Synchrotron Radiation Research Center. Subsystems must begin to build the system in the unfinished building structure; the degree of complexity is really unimaginable. Needed a software system can provide substantial help in a limited space, so that all of the equipment, planning to do effectively. National Synchrotron Radiation Research Center has embarked on a way to build 3D graphics module, virtual all parts through one to one 3D module, ensure that the planning can be more complete. Spatial planning magnet arrangement and cabling is a major work of this plan in the power supply group. The construction site using a 3D simulation module, early start magnet arrangement design and planning in civil engineering structures has not been completed, such as: cable length, procurement budget ..... Cabling works of various space-related configuration parameters refer to the values obtained in the 3D virtual environment module, essentially greatly enhance the efficiency of the design. 3D software will make the arrangement of the power supply to the magnet parts and models, including: Magnet coding, magnet placement, interference region. Model contains booster ring area, storage ring area, linac to Booster ring (LTB) and booster to storage ring (BTS) area; clearly show the main structure through 3D simulation software.

CONTROL AND INSTRUSMENT AREA

CIA is located in the inner circle adjacent to TPS tunnel. DC power supplies of magnets and ID controller are placed on the 1st floor. Figure 1 has shown cable tray design in CIA to tunnel magnets side. Colour tray is design by power supply group. It can separate to left and right hand side, power supply machine placed in CIA 1F and cable will through trench into the tunnel area of storing ring tray connect to magnets. Figure 2 has shown power rack and magnet placed on CIA cable tray, CIA place on 6 power rack that are 4 QF-SF rack and 2 corrector rack. Each side QF-SF rack will supplies energy to each 5 quadrupole magnets and 4 sextupole magnets.

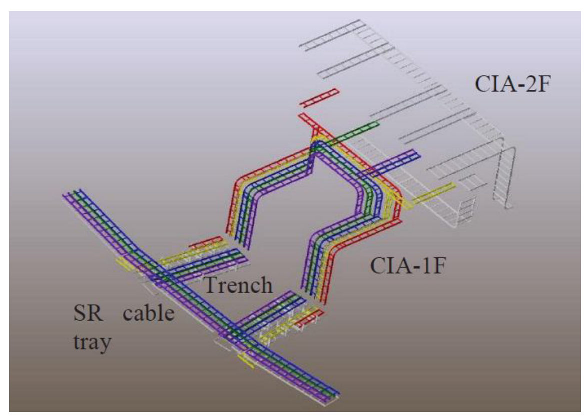

Figure 1: CIA power supply cable tray.

UPGRADING THE PERFORMANCE OF THE POWER SUPPLY FOR THE TPS BOOSTER DIPOLE MAGNETS*

Chen-Yao Liu#, Yuan-Chen Chien, Bao-Sheng Wang, Yong-Seng Wong, Kuo-Bin Liu, NSRRC, Hisnchu 30076, Taiwan

Abstract

The performance of the power supply for the dipole magnet is important for the TPS booster ring. The output current of the power supply follows the beam current from 150 MeV ramping to 3 GeV. The frequency of the power supply is 3 Hz. The power supply must thus push enormous energy into the dipole magnets at $\pm$1000 V and $\pm$1200 A, and can handle this job. Because the TPS booster dipole supply is bipolar and the voltage is large, the lodged capacitors have large effects that produce common-mode high-frequency current noise, which drives the power supply beyond specification. The TPS booster ring hence fails to meet the dc and ramping specification.

We designed a common-mode filter to solve the high-frequency current noise by absorbing the current noise from the path of the lodged capacitors to the ground pad. The TPS booster dipole supply thus works within the specification when the power supply is in the dc or ramping mode. The beam current from the 150-MeV dc mode for the injection mode can ramp the beam current to 3 GeV. This paper reports the excellent results.

INTRODUCTION

The booster ring of Taiwan Photon Source (TPS) uses 48 dipole magnets in series connection to build the topology. A bipolar switching-mode power supply pushes the booster dipole magnets from 47 A to 980 A, which maps 150 MeV to 3 GeV.

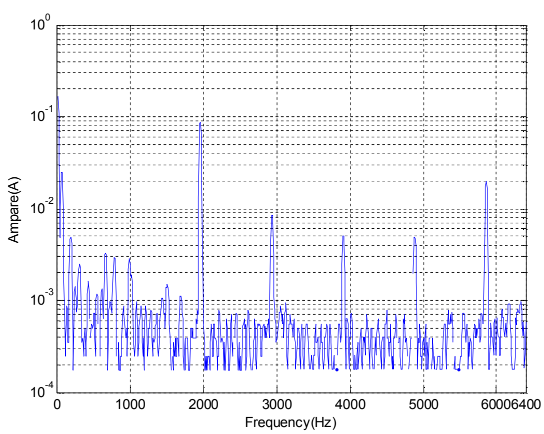

Figure 1: Current ripple in the dc mode (frequency from 0 to 6.4 kHz).

The current waveform follows the control system; the waveform is like a sine wave. Measured with instrument Agilent 35670A, the current ripple in the dc mode for the current set at 47 A for 150 MeV can be scanned from 0 to 51.2 kHz. When we read the current ripple in the frequency domain as shown in Fig. 1 and Fig. 2, we found that the current ripple is too large and beyond specification.

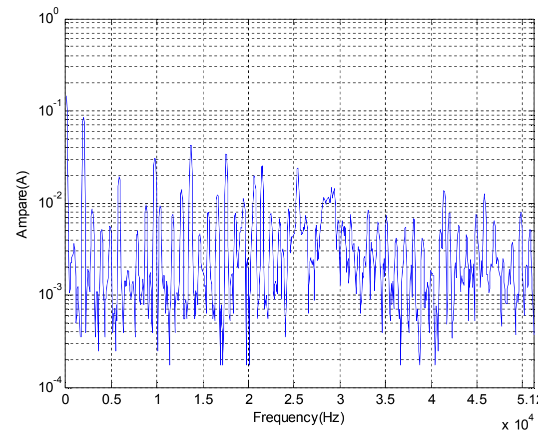

Figure 2: Current ripple in dc mode (frequency from 0 to 51.2 kHz).

As the dipole magnets act like a low-pass filter, the output current of the dipole power supply should possess a low-frequency current waveform, but the TPS booster ring has lodged capacitors that generate a high-frequency current ripple. The effect is especially large when the lodged capacitors for working voltage $\pm$1000 V are in the PWM mode. The ground current becomes large when the dipole power supply is in the ramping mode [1-2].

We added a common filter to the booster dipole power supply that can absorb the current noise in the path from the lodged capacitors to the ground pad. The filter is named a Y circuit. The TPS booster dipole supply can thus work within specification when the power supply is in both the dc and ramping modes. The beam current can proceed from the 150-MeV dc mode for the injection mode to ramp the beam current to 3 GeV, so the TPS booster ring can succeed in its task.

TOPOLOGY OF THE POWER SUPPLY

The topology of the booster dipole supply is an H bridge with a power bus at 1000 V. The power device is IGBT module. It can generate 1200 A to the dipole magnets. The power supply generates a unipolar current and a bipolar voltage to the magnets. The switching frequency is 2 kHz in the PWM mode. Figure 3 shows the topology of the H-Bridge.

INRUSH CURRENT SUPPRESSION SCHEME OF HOT SWAP POWER MODULES

Yi-Ta Li, Kuo-Bin Liu, Chen-Yao Liu NSRRC, Hsinchu, Taiwan

Abstract

The corrected magnet power supplies apply modular designed for Taiwan Photon Source synchrotron project (TPS). If the module is damaged in the chassis, it must to be replaced without interrupting the power. However, the modular is a shared DC bus. If there is no good design and planning, it will cause the protection circuit into action.

In this article the theoretical derivation and implementation are used to prove the feasibility and necessity of the soft-start circuit. In the actual signal measurements it could be clearly seen the inrush currents is refrained and improved. Finally, the soft-start circuit is implemented applications in correction magnet power supply modular of Taiwan Photon Source synchrotron project (TPS).

INTRODUCTION

TPS corrected magnet power supplies apply modular designed, the architecture shown in Figure 1. A chassis can be installed eight corrected magnet power supplies module. These three busses in main power and operating voltage and control signals were shared by eight corrected magnet power supply modules. Shared these busses can effectively reduce the volume of the machine itself, and complexity of the hardware circuit, that also equivalent to achieved higher economic returns [1-2].

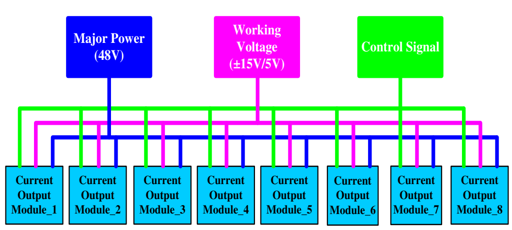

Figure 1: The architecture of TPS corrected magnet power supplies modular.

The modular power supply systems in practical applications, usually uninterrupted power supply of equipment systems. When the modules in the chassis were damaged, must replace the modules of the systems in uninterrupted power supplies.

The prototype of TPS corrected magnet power supply systems as an example. The waveform of the modules was plugged into the main systems, shown in Figure 2. The main power supply voltage 48V had plunged, which plunged about 9.2V (19%), the lowest voltage was 38.8V. When the main power supplies voltage was below 45V, corrected magnet power supply modules itself sent the mains input voltage failure signal and stopped working, it can be seen from the chart the voltage below the 45V duration approximately 2mS. The all of Corrected magnet power supply modules inside the chassis were stopped working, which was with the original modular designed concept different. It's worth noting that when the corrected magnet power supply modules plugged into main power bus, which main power supply output current swelled to 230A, shown in Figure 2. This current phenomenon was called Inrush current, Inrush current can cause to fuse was burned and damaged to other electronic components with the system can't operated normally.

In order to maintain the normal operation of the power supplies, so added the soft start design to the power supplies. The soft-start design can be ranged into active and passive two types, the active design must need a controller and a current sensor to control switches, so in this paper used passive design.

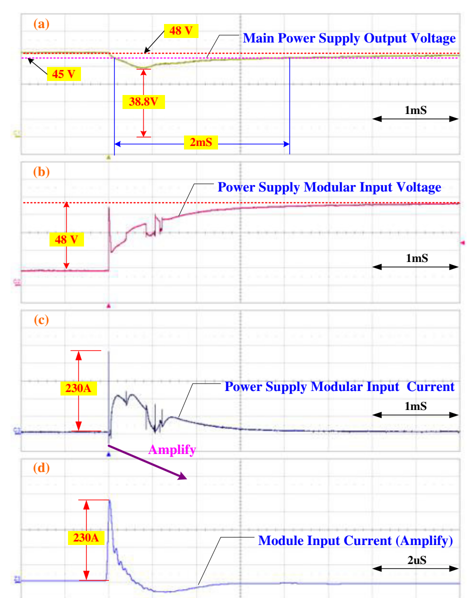

Figure 2: Corrected magnet power supplies modular plugged into the main system's waveform.

PRINCIPLE OF PASSIVE INRUSH CURRENT LIMTERING

Understand the impact caused by the inrush current, then in this section was proposed ways to improve the inrush current. Due to the charging of capacitors, so that were produced the inrush current when the corrected magnet power supply modules plugged into the chassis. Using the resister and capacitor (RC) charge circuit for the architecture is shown in Figure 3, the capacitor charging current formula such as the equation (1).

STATUS OF AC POWER SUPPLIES FOR TPS BOOSTER RING

Yuan-Chen Chien, Bao-sheng Wang, Yong Seng Wong, Chen-Yao Liu, Kuo-Bin Liu, Chunyi Wu, Pei-Chen Chiu, Kuo-Tung Hsu, NSRRC, Hsinchu, Taiwan

Abstract

TPS is a third generation 3 GeV synchrotron light source under commission in Taiwan. The TPS Booster ring is concentric ring design sharing the same tunnel with storage ring. The booster ring power supplies are responsible of accelerating the 150 MeV Linac output energy to 3 GeV before the beam is preserved in the storage ring. The booster ring power supplies are required to operate at 3Hz sinusoidal waveform with 1000 A peak current for the dipole magnet. All power supplies' specifications and output performance are demonstrated here in this paper.

INTRODUCTION

Taiwan Photon Source (TPS) is a concentric ring with booster and storage ring allocated in the same tunnel. A combined function FODO lattice is chosen to be an optimal solution for the TPS booster ring lattice structure in terms of cost and performance. There are total six super-periods, in which each consists of 8 cells of combined–function FODO lattice. Figure 1 shows a portion of the super-period FODO lattice in the TPS ring [1].

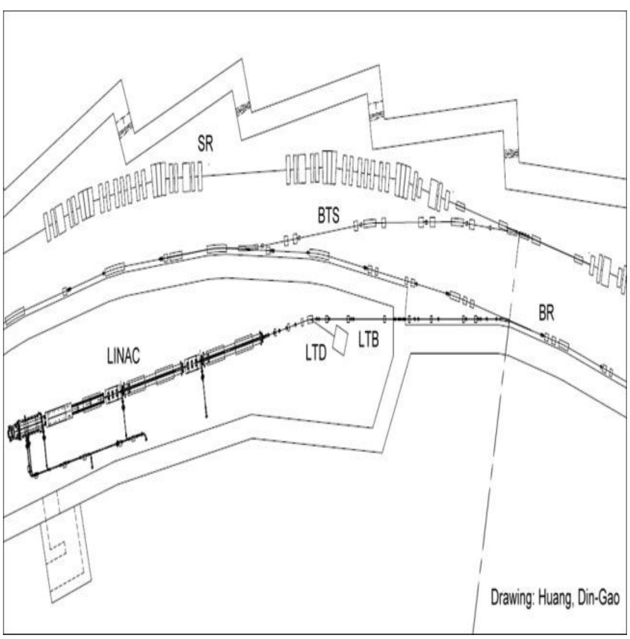

Figure 1: TPS concentric ring.

Based on this design, the TPS booster ring, with a circumference of 496.8m, includes 54 bending magnets, 72 quadruple magnets, 24 sextuple magnets and 96 corrector magnets. The detailed parameters of the booster magnets are listed in Table 1.

Table 1: Booster Magnet Specifications

Magnet	Qty	Load	Cable	Total
BD	48	1.973mH 9mΩ	29.18mΩ	94.854mH 467.2mΩ
BH	12	0.999mH 5mΩ		
Q1	12	4.683mH 49mΩ	67.86mΩ	56.196mH 655.8mΩ
Q2	12	2.298mH 33mΩ	67.86mΩ	27.567mH 463.8mΩ
QM	12	0.625mH 19mΩ	67.86mΩ	7.5mH 295.8mΩ
QF	48	4.683mH 49mΩ	67.86mΩ	224.78mH 2419.8mΩ

BOOSTER POWER SUPPLY

Dipole Power Supply

The two families of dipole bending magnets BD and BH are connected all together in series and driven by a single Dipole AC Power Supply (DPS). While, Q1, Q2, QM and QF of the quadruple magnets are powered independently by four quadruple power supplies (QPS1, QPS1, QPSM, QPSF). All magnets in the same family are also connected in series. The internal topology of the Dipole Power Supply is depicted in Figure 2.

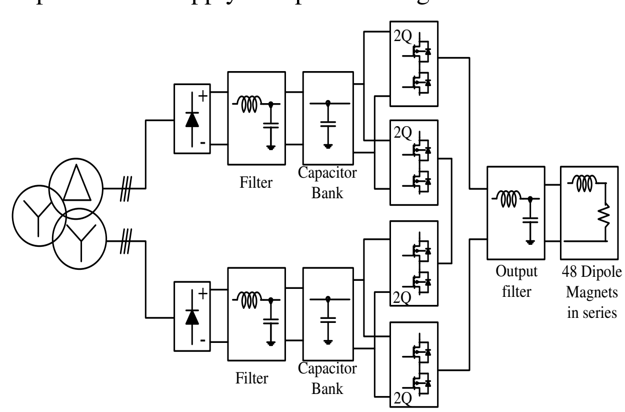

Figure 2: DPS functional diagram.

The DPS is composed of two identical DC voltage bank and 4-Quadrants IGBT switching module connected in series to boost up the output voltage as demanded. The 4-Quadrants IGBT switching module is made up of connecting two 2-Quadrants IGBT modules in parallel and the IGBT is switched with 4 kHz frequency.

The output filter is specially designed and fine-tuned to the magnet load with adequate cut-off frequency to minimize the output current ripple and earth leakage current due to the parasitic capacitance to earth ground from the magnet body.

ALGORITHM AND CIRCUIT TO IMPROVE ZERO-CROSSING STABILITY OF BIPOLAR TPS TRIM COIL POWER SUPPLY

Bao-Sheng Wang, Yuan-Chen Chien, Yong-Seng Wong, Chen-Yao Liu, Kuo-Bin Liu, Chun-Yi Wu, Pei-Chen Chiu, Kuo-Tung Hsu, NSRRC, Hsinchu, Taiwan

Abstract

In TPS (Taiwan Photon Source) project, 58 home-built small form factor bipolar power supplies are used to fine-tune the trim coil of booster ring bending dipole magnets. With the preliminary analog PI control loop design version, current output will tend to behave with poor linearity around zero current. By employing DSP chip, a full digital PI control loop design together with optimal MOSFT switching algorithm and 13bits PWM output capability is capable of improving the output current performance around zero current. Before the final realization, MATLAB SIMULINK is utilized to find out the optimal MOSFT switching algorithm, and then physical circuit is implemented and tested. The result and design will be demonstrated in this paper to show significant improvement around zero current.

INTRODUCTION

In TPS the sextuple and trim coil magnets converters of booster ring under operation are made by NSRRC and ITRI, the output current behaves nonlinearly at zero crossing with the analogy regulation control loop. In this paper, the original analog regulation loop is replaced by the fully digital regulation control one.

NI sb-RIO board is selected to implement digital PID controller and PWM command generation. NI sb-RIO board has FPGA built inside. All the digital control circuit are designed and written in VHDL code, thus design can be downloaded on the fly to the board for rapid verification.

The development of this NI sb-RIO board-based digital regulation control circuit of TPS's storage sextuple and corrector magnet power converters is based on the framework of NSRRC-ITRI CPS converter with a shunt as a current sensing component that could reduce the cost and less compromised performance to fulfill the fully digital regulation control implementation.

During the preliminary design phase, Matlab simulink is used to simulate the characteristic of the full bridge construction, the function of compensator and the PWM regulation algorism, and the accuracy of the control policy is confirmed.

With the NSRRC-ITRI CPS converter with the full bridge architecture as the test platform, the original analog regulation control loop circuit is replaced by the home-made digital regulation control circuit, including NI sb-RIO Board, Analog to Digital converter, Digital to Analog converter, gate drives of MOSFETs.

With digital regulation control is implemented, the long and short term output current stability and low current tracking error is largely improved.

THE STRUCTURE OF CORRECTOR MAGNET POWER CONVERTER

The full digital corrector magnet power converter could be roughly divided into six functional blocks: 1) Power regulation and L-C filter, 2) high resolution AD7767 24-bits analogy to digital converter, 3) four channel DA8734 16-bits digital to analogy converter, 4) high performance NI sb-RIO 9606 board controller, 5) DIO control trigger port and 6) USB, RS232, RS485, Ethernet and control page transmission interface. The functional blocks are shown in Fig. 1.

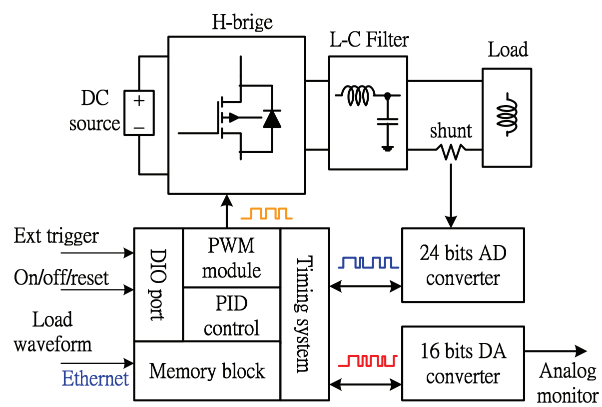

Figure 1: The structure of corrector magnet power converter.

PWM REGULATION METHOD

The PWM computation algorithm is done in the FPGA on the NI sb-RIO 9606 board. The compensated current command output from the PID block is exported to this PWM generation block, where the MOSFET switching signals S1, S2, S3 and S4 are generated by comparing the current command to two saw-tooth waveforms with 180 degree phase difference as illustrated in Fig. 2. It is shown in Fig. 2, the left waveforms are the MOSFET switching waveforms while the current setting is positive, while the waveforms when current is set to negative is depicted in the right [1].

The MOSFET Switch Modes with various load current flow are plotted in Fig. 3. There are 6 modes of load current flow. Mode Ⅰ～Ⅲ are positive current flows through the load, while in ModeⅣ~Ⅵ are modes when negative current occurs.

COMMISSIONING OF THE TPS COOLING SYSTEM: TESTING, ADJUSTING, BALANCING AND NUMERICAL SIMULATION

Z. D. Tsai,[#] W. S. Chan, C. S. Chen, C. Y. Liu, Y. C. Chung, C. W. Hsu, Y. C. Chang
National Synchrotron Radiation Research Center (NSRRC), Hsinchu 30076, Taiwan

Abstract

The civil construction and utility systems of the 3-GeV Taiwan Photon Source (TPS) at NSRRC are ready for machine commissioning in 2014. To achieve a highly precise control of temperature, the thermal load must be carefully controlled and balanced. On analysis of the characteristics between the water pipes and the balance valves, a specified control philosophy can effectively adjust the pressure load on the branch pipes to balance the water flow. With regard to the air flow, we use a damper, baffle plant or variable air-volume (VAV) box to balance the air flow of each diffuser. Here we discuss the mechanism through a numerical simulation of the hydrodynamics and verify the practical influences of the testing, adjusting and balancing (TAB) for de-ionized water and the heating, ventilation and air-conditioning (HVAC) system.

INTRODUCTION

The TPS infrastructure including civil and utility systems has been under construction since 2009 December and was completed in 2014 December [1]. The TPS facility is currently in the stage of commissioning. As the utility system is a most critical subsystem affecting the beam quality and reliability, much effort has been devoted to these designs [2]. Here we address mainly the testing, adjusting and balancing (TAB) design of the cooling system of the finalized utility system.

In the accelerator field in general, thermal waste can be treated through circulating deionized water (DIW) and air conditioning (AC). The main system for cooling water of TPS includes the cooling tower, chilled water, hot water, de-ionized water and HVAC system. Each manifold located near control-instrument areas (CIA) provides four loops for varied demand of facilities, including stable temperature, pressure and flow. The air-handling units (AHU) located at the inner and outer rings provide highly stable cooling air for the storage-ring tunnel, CIA, experimental hall and Linac area. Programmable automation controllers (PAC) and direct digital controllers (DDC) have been implemented in this hybrid utility system for highly precise control and status monitoring. To provide a stable cooling source, we must fine-tune the system to meet our requirements. The TAB process for de-ionized water and HVAC system is a critical procedure in the commissioning stage of the utility system. This paper reports that mechanism through numerical simulation of hydrodynamics and verifies the practical influences of the TAB process.

E-mail: zdtsai@nsrrc.org.tw

NUMERICAL SIMULATION OF HYDRODYNAMICS

We use a software package (fluent) to simulate the air flow in the air ducts with and without taper, as shown in Figures 1a and 1b. The boundary conditions are listed in Table 1. According to Bernoulli's principle, the system must maintain a constant total pressure. When the air flow encounters a divided flow, the dynamic pressure decreases and the static pressure increases, so that the end of the air duct has a larger static pressure, as shown in Figure 2. To overcome this problem with a consistent outlet airflow pressure, we must make tapers for the air duct or use a damper, baffle plant or VAV box to balance the air flow of each diffuser, as shown in Figure 1b. Figure 3 shows that each diffuser can downgrade the static pressure to match our requirement. If we use a damper or VAV box, we can efficiently control the air flow to balance the consistent outlet air pressure.

Aspects of the water system are shown in Figure 4; the water system flows through three loops for subsystem cooling and forms a closed-loop system. The pipe friction decreases the static pressure related to the distance; the divided flow can increase the static pressure as in the red line shown in Figure 5. In the return loop of the water, the pipe friction continually decreases the static pressure related to distance, and the merged flow also decreases the static pressure as in the white line shown in Figure 5. The pressure difference between the red and white lines is thus the actual pressure for each loop. The actual pressure is least in the latest part of the pipe loop, which even leads to no water flow at the end of the pipe. The TAB is so critical for a water system that we use a balance valve to fine-tune the water flow to meet each loop requirement.

Table 1: Boundary Conditions of Cases 1 and 2 of Air Duct

	case 1	case 2
length of air duct /m	20	20
diffuser area/m^2	0.14	0.14
cross-sectional area 1/m^2	1	1
cross-sectional area 2/m^2	1	0.757
cross-sectional area 3/m^2	1	0.49
cross-sectional area 4/m^2	1	0.303
inlet pressure of air duct /Pa	100	100

National Tsing-Hua University, Taiwan

Abstract

After the construction of Taiwan Photon Source (TPS) was finished, the variation of the survey fiducials was stable. However, the following precise alignment work is concerned by the change of temperature critically. In this paper, the whole process of alignment work in the TPS storage ring with the relation of survey network and thermal issues of the environment will be described. We analysed these survey data so that the correction of survey network could be estimated by the change of temperature, thus all the elements for example, booster, pedestals, and girders could be positioned within the shortest time.

INTRODUCTION

Taiwan Photon Source is a new 3-GeV synchrotron ring under construction at the NSRRC in Taiwan. For stability reasons, the entire building has been constructed half underground. Since the construction is underground, it would take more time during the process of constructing the building's foundation and the transport of heavy machinery. In order to implement the operating test of the booster immediately after the building of TPS was constructed, we need to advance the schedule of the installation work. We carried out the installation work when the building was under construction. However, there are a lot of components (beam potion monitor in the vacuum system, pedestals of storage and booster ring, and the magnets) that needed to be installed, which could not be completed in a short time.

Since the work was carried out for a long time, the building was shape shifting due to the variation of thermal issues and the proceeding of the building's construction. To provide the precise fiducial points for positioning, those components will be critical. To achieve the purpose, the survey network of TPS was constructed since July 2012 until now. According to the historical survey data and the current temperature, we can conjecture the variable of shape shift of the building approximately during positioning.

Up to present, the major part of positioning work has been completed, and the booster system of TPS is under operating test. The fiducial points of TPS are still being surveyed periodically for constructing the coordinates of the survey network. In this paper, we also describe the process of survey and installation work and the results of the positioning work.

THE TPS NETWORK DESIGN

The network is the important foundation work to complete the alignment assignment of the TPS project. For stability reason, the TPS building is constructed half underground and has an outer wall blocking the measuring instrument from measuring one site to another directly. Thus, there are 8 fiducial points of global position system (GPS) set up around the building to confirm the location and the shape of TPS construction, as shown in Figure 1. By using these fiducial points of GPS, the primary fiducial points of survey network could be constructed.

Figure 1: The photo of TPS building.

Considering the variation of outdoor temperature, the GPS fiducial points are made by granite to reduce the effect of thermal variation. After the one year of construction, the GPS fiducial points seem to stabilize within time, as shown in Figure 2.

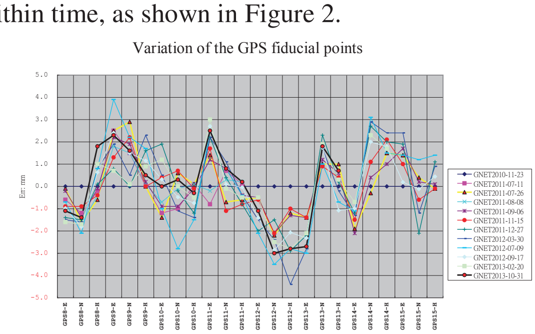

Figure 2: The variation of GPS fiducial points.

Since these fiducial points are stabilized, we can now then construct the primary survey network based on these fiducial points. The primary survey network is constructed by using theodolite and GPS due to environment issues during construction. By reasons of survey data of the altitude direction obtained from the GPS system is not sufficiently accurate. The 8 GPS

DESIGN AND CONSTRUCTION OF THE RF ELECTRONIC SYSTEM AT TAIWAN PHOTON SOURCE

F.-T. Chung#, M.-S. Yeh,T.-C. Yu ,Ch. Wang, L.-H. Chang, C.-H. Lo, M.-H. Tsai, M.-H. Chang, T.-C. Yu, L.-J. Chen, Z.-K. Liu, M.-C. Lin, P.-Y. Chen, C.-L. Tsai, National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract

The RF electronic system at NSRRC was made fully in house by the RF group from design through construction to completion. The first RF electronic system includes an analogue LLRF system, a step motor, and an ARC module of a Petra cavity. It was successfully integrated with a 100-kW RF transmitter, high-power RF transfer system, and a cooling system and applied to the booster of TPS. Two duplicated RF electronic system were then applied to the storage ring but integrated with the 300-KW transmitters. With these RF systems, the TPS storage ring achieved beam current 100 mA on 2015 March 26.

INTRODUCTION

This article explains the architecture of the RF electronic system for Taiwan Photon Source (TPS). Modularization of the RF electronic subsystems can duplicate the subsequent second and third storage-ring RF electronic systems efficiently to operate individual RF plant in the first stage of TPS commissioning. The main objective of this article is the construction of the electronic system for booster RF plant, which has also a preliminary role for all RF plants.

The principle of this design is to realize both local and remote monitoring and control of the RF cavity. The booster RF system can provide maximum accelerating voltage 1200 kV to boost the electron beam with maximum RF power 100 kW for nominal operation of the TPS booster ring. The planning and allocation of electric power, cooling water, cooling air, cable tray and signal cabling would be shown as a preliminary preparation for construction of the booster RF plant. The complete construction of the booster and storage ring RF plants were designed to support the first-stage commissioning of the synchrotron accelerator with target beam current 100 mA; the parameters of TPS [1] are listed in Table I.

ELECTRIC UTILITY

To construct operating environment of the RF plants, firstly the AC power was allocated as follows:

(1) 3P4W (general AC power) 380V/220V 250/650A

(2) 3P4W (general AC power) 208V/120V 32/40A

(3) 3P4W (emergency AC power) 208V/120V 50/63A.

The components of the RF system are distributed around the building according to their function. To manage efficiently the electric power to each rack and module for all these components in a balanced and safe condition, the original power racks must their capacity with anti-EMI pipes to the load as shown in Figure 1.

Table 1: Parameters of the TPS Booster Ring

Parameter	Value
injection energy	150 Mev
extraction energy	3 GeV
circumference	496.8 m
harmonic number (h)	828
momentum compaction factor (alpha)	0.002474
repetition rate	3 Hz
RF frequency	499.65 MHz
energy spread (Linac to booster)	0.095 %

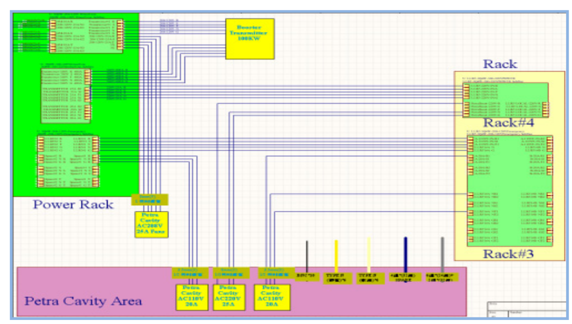

Figure 1: Allocation of AC power for the TPS booster RF system.

AC Power for Transmitter

The RF transmitter requires general AC power of capacity 380 V/400 A through a cable (200 mm^2, 400 A, Hypalon) and AC power (208 V/120 V) for the control panel through cable (22 mm^2, 50 A). As the transmitter rack has its own circuit breaker, the power line can be simply plugged in.

AC Power for Signal Controller

The controller rack area collects the entire control system; emergency power with an uninterruptible power supply is hence required. Racks 3 and 4 integrate a 3P4W AC power distributor to each rack. As the circulator part requires low AC power, this power is supplied by Rack 8.

AC Power for Cavity Control System

The cavity of the booster ring requires emergency electric power at 110 V/20 A for the controller rack, general electric power at 220 V/25 A for the controller rack and general electric power at 110 V/20 A for the main breaker. 220 VAC is supplied to ion pumps.

OUTGASSING ANALYSIS DURING TRANSPORT FOR 14-m-LONG ARC-CELL VACUUM CHAMBERS OF THE TAIWAN PHOTON SOURCE

L. H. Wu#, T. Y. Lee, C. H. Chang, S. W. Chang, Y. C. Yang, Z. W. Chen, Y. P. Chang, C. S. Huang, Y. T. Huang, C. C. Chang, S. N. Hsu, C. K. Chan, C. M. Cheng, B. Y. Chen, H. P. Hsueh, G. Y. Hsiung, and J. R Chen, National Synchrotron Radiation Research Center, Hsinchu, Taiwan

Abstract

An outgassing analysis during transportation for the large, 14-m-long, ultra-high-vacuum aluminum arc-cell chambers of the Taiwan Photon Source (TPS) was performed using residual gas analysis (RGA). Each cell was baked to 150 °C in the laboratory to achieve ultra-high vacuum. Under pumping by primarily ion pumps (IP) and non-evaporable getter (NEG) pumps, the cells obtained pressures of 6.4×10^{-9} Pa on average, and the main residual gas was H_2. Here, vacuum pressure measurements and residual gas analyses were performed in situ while a cell chamber was being transported. It was found that the vibration of the arc-cell vacuum chamber caused the pressure to rise abruptly; in this case, the main outgassing gas was CH_4. Once the arc cell had been fully installed, the vacuum pressure gradually decreased to the original vacuum pressure because of the pumping effect of the ion gauges.

INTRODUCTION

Construction of the Taiwan Photon Source (TPS) began in 2010, and it is expected to begin operations in 2015. The TPS uses a medium-energy electron storage ring operating at 3 GeV. The vacuum chambers of the TPS storage ring are constructed of an aluminum (Al) alloy because of its high thermal conductivity, absence of magnetism, low residual radioactivity, and ease of machining [1]. The TPS contains 24 aluminum arc-cell vacuum chambers in the electron storage ring. Each arc-cell chamber is 14 m in length, including two straight chambers (S3 and S4) and two bending chambers (B1 and B2), as shown in Fig. 1. The straight chambers were constructed from extruded aluminum alloy and subjected to chemical cleaning in a sequential process [2]. The bending-chamber components were manufactured using computer numerical control (CNC) alcohol machining and cleaned with ozonated water [3-4]. Then, each chamber was assembled and jointed using tungsten inert gas (TIG) welding. A residual gas analyzer was installed in the arc-cell vacuum chamber to observe the outgassing of residual gases. According to previous research, [5] ozonated water effectively removes residual carbon from the surfaces of aluminum alloys, and the thermal outgassing rate of such alloys has been found to decrease to 6.7×10^{-12} Pa·m·s^{-1} after baking. Each cell was assembled in the laboratory to create the closed vacuum vessel with two sector gate valves and then pumped by turbo pumps and dry pumps, followed by a 24-hour bakeout. After bakeout and 24 hours of pumping, pressures of less than 1.0×10^{-8} Pa were achieved at room temperature for all cells. Once the vacuum pressure of the 14-m-long aluminum vacuum chamber had achieved UHV levels, the four ion pumps were turned off to investigate the outgassing and to analyze the residual gas using the pressure build-up method. The TPS cell vacuum system is described in detail below.

For one cell aluminum vacuum chamber, which is 14 m in length, the components of the vacuum assembly include two sector gate valves (SGVs) (comb-type RF shield; VAT), two pumping gate valves, bellows, beam position monitors (BPMs), extractor ionization gauges (IGs) (IE514, with an IM 540 gauge controller; Oerlikon), non-evaporable getters (NEGs) (MK5-type SAES getters), ion pumps (IPs) (Starcell 200 L·s^{-1} for nitrogen; Agilent), crotch absorbers, photon stoppers, front-end valves, angle valves, a residual gas analyzer (RGA) (Transpector 2, H100M, used with the control software Tware 32; Inficon), turbomolecular pumps (TMPs) (V81M; Agilent, STP 451; Edwards), and dry pumps (Drytel 1025; Adixen). The vacuum components were assembled in a clean room (class 10,000) under controlled dust-level and humidity conditions to minimize the outgassing rate from the chamber's inner surfaces.

The RGA spectrum was continuously recorded during pumping. In all experiments in this study, the following species were recorded: m/z = 2, 4, 12, 13, 14, 15, 16, 18, 28, 32, 40, and 44, associated with H_2^+, He^+, C^+, CH^+, CH_2^+, CH_3^+, CH_4^+/O^+, H_2O^+, N_2^+/CO^+, O_2^+, Ar^+, and $CO2^+$, respectively. The current I that is reported here represents a RGA spectrum rather than a partial pressure. Although the partial pressure could not be calculated exactly, the predominant component of the residual gas could be inferred by referring to the manufacturer's instructions for the RGA.

This paper focuses on the types of gases produced with increasing vacuum pressure during the cell transportation. While the cell was transported, the ion pumps were turned off and the ion gauges and RGA spectrums were both recorded. It is observed what kinds of gases were responsible for the variation of vacuum pressure. After the arc cell had been fully installed, the variation of the vacuum pressure was continuously observed and the pumping mechanism was discussed.

Abstract

Taiwan Photon source (TPS) is in its first stage commissioning in 2014-2015. The vacuum systems of TPS were installed for commissioning since August 2014. After four months performance testing and subsystem integration, the commissioning of booster ring began on 12 December and then the first 3 GeV beam was stored on 31 December. 100mA beam current, 35Ah accumulated beam dose was archived in March 2015 before machine shut down.

The average pressure in storage ring is 2.8×10^{-8} Pa before commissioning, rising to 1.33×10^{-7} Pa with 100mA beam current. In 35Ah accumulated beam dose, the target of beam cleaning effect has reached to 8.92×10^{-10} Pa/mA. The vacuum performance, experience and events during commissioning will be presented in this paper.

INTRODUCTION

TPS is a low-emittance 3-GeV synchrotron ring with the concentric storage and booster rings in the same tunnel. The storage ring, with 518.4m circumference, is divided into 48 sections by RF gate valves, including 24 arc cells and 24 straight sections [1]. The 14m arc cells, which were prebaked to ultra-high vacuum in NSRRC's facility during 2012 November to 2013 August, and installed into TPS tunnel under vacuum in 2013 October to 2014 March. The straight sections, six of length 12 m and 18 of length 7 m are assembled continually, including one injection section, one diagnostic section, two PETRA cavities and other dummy sections until 2014 August. During the installation of straight sections of storage ring, booster ring, the transfer line from the LINAC to the booster ring (LTB, LINAC to booster ring) and the transfer line from the booster ring to the storage ring (BTS, booster to storage ring) were also assembled at the same time.

Aluminium alloy was chosen as the material of vacuum chamber because of its lower thermal outgassing rate and good experience in Taiwan Light Source at NSRRC in the past 20 years. For the arc sections, the triangularly shaped vacuum chambers were designed and Cu crotch absorbers located downstream intercepts more than 70 % of the synchrotron radiation from the bending magnet. Pumping unit combined sputtering ion pump (SIP) with non-evaporable getter pump (NEG) was design and located at the antechamber so as to decrease the pumping ports and produce a smooth vacuum surface with small impedance. Besides, near the crotch absorbers and photon stoppers, NEG pumps were also installed to enhance pumping speed. In addition, exhaust pumping systems with turbo-molecular pumps were used to remove large amount of the photon stimulated desorption during machine commissioning. The geometric layout of bending chamber in arc section is shown in Figure1.

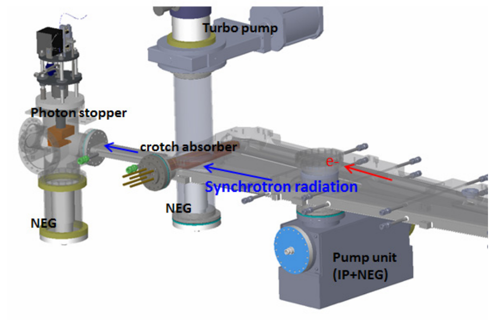

Figure 1: The geometric layout of bending chamber in arc section.

Extractor ion gauge (EIG) was used as pressure reading and safety interlock system in TPS storage ring while cold cathode gauges (CCG) were used in booster ring. Total 144 gauges installed averagely into 48 vacuum sections were planned; it means all 3 gauges were installed between two section gate valves (SGV). 1×10^{-4} Pa pressure trip was set as high limit for vacuum interlock. If any two gauges reach high limit or malfunction, the logic trigger signal would then be sent out to close the SGVs at this section. In order to extend the operation lifetime, self-protection mode of EIGs was set. In such mode, EIGs will be switched off automatically when the vacuum pressure raises higher than 1×10^{-3} Pa [2].

Due to impedance issue and reducing the interference from scatter electron, EIG was installed into pumping unit shown as EIG3 in Figure 2. In straight section, another one was installed near the orbit of electron beam, especially in out-of-vacuum insertion device which has no space to install. The reading of EIGs in different location was summarized in table1. In static pressure, the readings were similar; a 1.5x difference was found in dynamic condition with 100mA beam current.

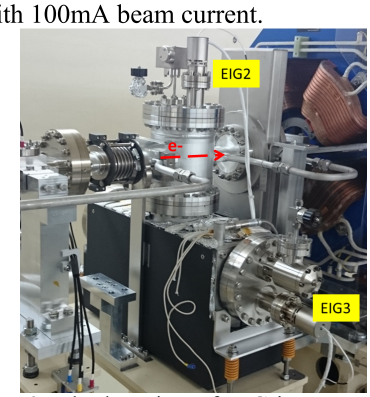

Figure 2: The location of EIG in storage ring.

DEMAGNETIZE BOOSTER CHAMBER IN TPS

I. C. Sheng#, C. K. Kuan, C.T.Chen, Y. C. Yang, National Synchrotron Radiation Research Center (NSRRC), HsinChu, Taiwan

Abstract

Taiwan Photon Source (TPS) project starts its booster commissioning starts from August 2014. Few issues have been discovered and fixed. Since the booster aperture is relatively small and number of magnets is barely sufficient. Therefore extreme precise control of booster chamber alignment and the corresponding chamber permeability is as well important.

In this paper, we present how the booster chamber is uninstalled, demagnetized and reinstalled within three weeks. This procedure is proven to result in the lowest booster chamber permeability in the world and a good high vacuum booster ring is built in 3 weeks.

INTRODUCTIONS

National Synchrotron Radiation Research Center (NSRRC) in Taiwan has just completed the construction of third generation synchrotron accelerator named Taiwan Photon Source (TPS) in second quarter of 2014, this 3GeV, 500mA designed energy machine will provide 48 beam lines in the future. The machine finished the Linac was commissioned in August 12, 2014 and the booster ring started its beam-based hardware testing right after that date.

However during the booster commissioning the operation group encountered several problems such as booster dipole magnet power overheated, even the power supply group quickly resolved the problem but the operation staff still had problem to store the beam in the 500m circumference concentric booster chamber. This 35mm x 20mm stainless steel 304 elliptical chamber was drawn from circular stainless steel tube and is 0.7mm thick, as shown in Figure 1.

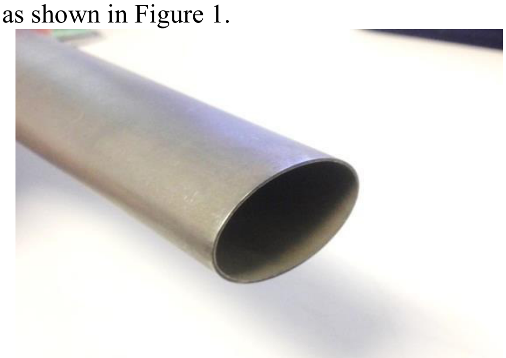

Figure 1: TPS booster chambers.

Beam dynamics staff had problem to fully control the electron beam even with correctors. Simulation shows that difference of closed orbit distortion (COD) can be up to $\pm 20\mathrm{mm}$ without corrections. While everyone was wondering what might be the causes. In November 12, 2014, one of engineering staff found that elliptical chambers attracted his small piece of NdFeB magnet. We further discovered that the chamber does meet our low permeability requirement (typically magnetic relative permeability for stainless steel $\mu_r = 1.01$ and some of them was found to be $\mu_r = 1.8$!). This explains why operation staff failed to store the electron beam in the booster no matter how hard they have tried to tweak the magnetic fields.

Since the target schedule is planning to have beam stored in the storage ring by the end of 2014, we have to demagnetize the booster chamber as soon as possible. As a matter of fact, vacuum group has to remove total 500m long booster chambers, demagnetize, reinstall and pumping down in three weeks.

Table 1: Heat Treatment Material Processing to Demagnetize Metals

Process	Pros	Cons
Continuous heat treat furnace	▪ Large size	▪Non-uniform heating, large deformation. ▪Not clean.
Demagnetizer	▪ Convenient to use. ▪ Cost effective	▪Temporarily demagnetize but not permanent.
Vacuum furnace	▪ Compliance with UHV	▪Limited heat treatment sizes.

The demagnetization process is to heat up stainless steel to Austenite (γ) phase at elevated temperature. This heat treatment process is to re-transform Martensitic structure back to Austenitic one. The carbon composition of SST304 we procured is 0.06, and the suggested demagnetized temperature is $1050\ ^{o}C$ [1], then cool down to room temperature. As shown in Table 1, there are several processes to demagnetize the stainless steel. It is clear that vacuum furnace is the only way to go, except we have many long tubes which are over 2-4meters long. And most of domestic heat treat companies have only less than 1.2m maximum size furnace.

Another challenging of this demagnetization task is how to efficiently sort out all the elliptical chambers, and restore them back within the time frame.

DEMAGNITIZATION

Table 2 indicates the original quantity of the booster chamber with their corresponding flange-to-flange length range.

A. Alacakir, TAEK-SANAEM, Ankara, Turkey
G. Unel, UCI, Irvine, California, USA

Abstract

SANAEM Project Prometheus (SPP) has been building a proton beamline at MeV range. Its proton source, two solenoids, and a low energy diagnostic box have been already manufactured and installed. These are going to be followed by a 4-vane RFQ to be powered by two stage PSU. The first stage is a custom-built solid state amplifier providing 6 kW at 352.2 MHz operating frequency. The second stage, employing TH 595 tetrodes from Thales, will amplify this input to 160 kW in a short pulsed mode. The power transfer to the RFQ will be achieved by the means of a number of WR2300 full and half height waveguides, 3 1/8" rigid coaxial cables, joined by appropriate adapters and converters and by a custom design circulator. This paper summarizes the experience acquired during the design and the production of these components.

INTRODUCTION

SANAEM, Saraykoy Nuclear Research and Training Center of Turkish Atomic Energy Authority in Ankara, has begun to build a Proton Linac, under the name of SPP, with a modest target: aiming to get at least 1 mA of current at the energy of 1.3 MeV [1]. This low-energy proton linac is also going to serve as a domestic know-how build-up instrument by which young scientists and engineers, as well as the local industry, will get acquainted with accelerator technology. The RF power section of this linac consists of three main parts: the Power Supply Unit (PSU), a circulator, and the power transmission line including appropriate waveguide adapters and converters. The RF transmission system is to feed the 4-vane RFQ with the design parameters presented in elsewhere [1], [2]. The power requirement for the SPP RFQ is calculated by taking into account the ohmic losses on the RFQ walls (60 kW obtained after computer simulations) together with the transmission and coupling losses (30 kW a worst case scenario estimation). Folding in a safety factor of 1.3, one finds 120 kW as the required RF power under the assumption of continuous operation. SSP will initially operate with a duty factor less than 3% to reduce the requirements on the RF PSU. The entire RF power supply and transmission system is shown in Fig. 1.

* salim.ogur@boun.edu.tr

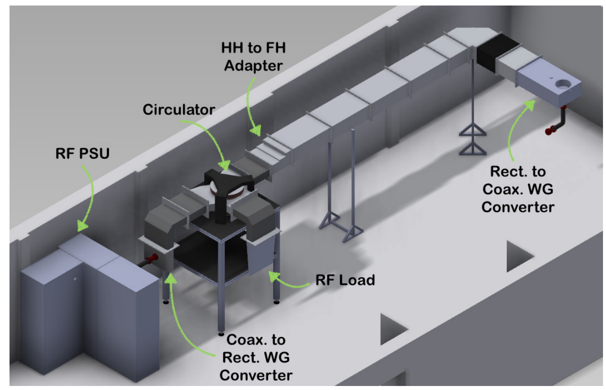

Figure 1: The overview of the SPP RF transmission line.

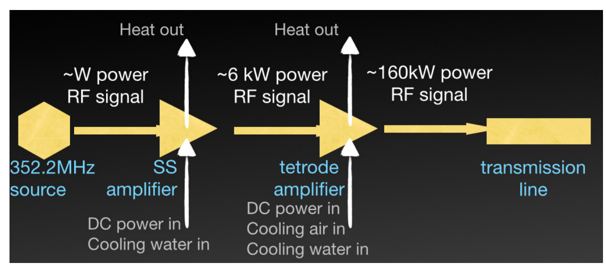

Figure 2: SPP PSU design.

POWER TRANSMISSION LINE

Power Supply Unit

The operating frequency of the SPP RFQ is 352.2 MHz. This operating frequency is chosen to be compatible with similar machines in Europe and to take advantage of already available RF amplifier market. The accelerator is intended to operate at a maximum duty factor of about 3%. To fulfill these requirements, two stage amplification has been selected, as summarized in Fig. 2. The power supply is designed by the SPP-team, and manufactured by a local company [3].

The construction of the first stage of the PSU started around the BLF-578XR high power transistor [4]. The water cooled solid state amplifier circuit designed around this transistor provides about 1.7 kW of RF power for a pulse length shorter than 500 milliseconds, with an amplification of about 18.3 dB. A photo of the SS amplifier unit test bench can be seen in Fig. 3. The combiner system, consisting of 8 such boards, achieves a total power of 6 kW in continuous mode and over 10 kW in pulsed mode. For this particular

Abstract

In developing superconducting coatings for SRF cavities, the coated samples are tested using various techniques such as resistance measurements, AC, and DC magnetometry which provide information about the superconducting properties of the films such as RRR, H_{c1}, H_{c2} and vortex dynamics. However, these results do not allow the prediction of the superconducting properties at RF frequencies. A dedicated RF cavity was designed to evaluate surface resistive losses on a flat sample. The cavity contains two parts: a half-elliptical cell made of bulk niobium (Nb) and a flat Nb disc. The two parts can be thermally and electrically isolated via a vacuum gap, whereas the electromagnetic fields are constrained through the use of RF chokes. Both parts are conduction cooled hence the system is cryogen free. The flat disk can be replaced with a sample, such as a Cu disc coated with a Nb film. The RF test provides the cavity Q-factor and thermometric measurements of the losses on the sample. The design advantages are that the sample disc can be easily installed and replaced; installing a new sample requires no brazing/welding/vacuum or RF seal, so the sample preparation is simple and inexpensive.

INTRODUCTION

Superconducting coatings (SC) for radio-frequency (RF) cavities in particle accelerators have been used since the 1980s [1]. They provide many advantages such as combining the good thermal conductivity of copper and the superconducting properties provided by a thin niobium film. However, the RF performance of these SC cavities (such as Q_0 and E_{max}) has always been lower than those made of bulk niobium. Several research laboratories around the world have put in an effort to improve the quality of SC cavities [2-4]. This required understanding the correlation between (a) deposition parameters and conditions, (b) surface analysis, (c) superconducting properties and (d) performance in an RF field. To enable the UK capability in SC cavity production and to improve the quality of SC cavities the ASTeC team has employed a number of systems to evaluate the properties of the coated layer. Deposited samples are studied with surface analysis systems to study the film compositions and morphology, chemical bonding, grain size, crystal structure and phase. They then undergo the superconducting properties characterisation: measurements of quantities such as RRR, T_c, H_{c1} and H_{c2} (residual resistivity ratio, critical temperature, and critical H-fields 1 and 2) with DC and AC magnetic susceptibility methods [5–7]. However, these measurements do not allow the prediction of the behaviour of such a film in RF conditions. Depositing the coating on a different cavity for each type of film would be too expensive and time consuming; therefore a test cavity for quick evaluation of planar samples is required. This paper is devoted to the RF, cryogenic and mechanical design along with the implementation of such a cavity.

EXPERIMENT SETUP

As the cavity is not completely coated in the thin film, it is necessary to separate the losses on the bulk Nb walls from that on the sample. A convenient way of doing so is using a calorimetric method using a DC heater placed underneath the sample plate: the temperature of the sample is measured with no RF, then the RF is switched on while the DC heater is turned down to keep the sample at the same temperature, hence the losses on the sample are equal to the reduction in heater power. However for this measurement to be accurate it is necessary to thermally isolate the sample from the cavity.

Here we propose to have a vacuum gap between the two structures with RF chokes to prevent RF leakage. Both parts are conduction cooled to avoid having the cavity immersed in a LHe bath. The experiment is then placed in a large vacuum chamber, eliminating the need for any vacuum seals between the two parts. As such the cavity and the sample require no physical connection between them. The chokes increase the cavities transverse size hence a cavity frequency of 7.8 GHz is proposed in order to fit in the conduction cooling cryostat. The cavity will be used to measure BCS resistance as a function of cavity field. Due to the fact that R_{BCS} at 1.8 K will be 165 nΩ it will not be possible to measure the residual resistance.

RF CAVITY DESIGN

The project required the design of an RF structure capable of subjecting the sample surfaces to surface currents. In order to keep the sample as simple as possible, it was decided to design a cavity able to test a

SURFACE RESISTANCE RF MEASUREMENTS OF MATERIALS USED FOR ACCELERATOR VACUUM CHAMBERS

Philippe Goudket[1,3], Lewis Gurran[1,2], Graeme Burt[2], Mark Roper[1,3], Stuart Wilde[1,4], Oleg B. Malyshev[1,3], Reza Valizadeh[1,3]
[1]ASTeC, STFC, Daresbury Laboratory, Daresbury, Warrington, Cheshire, UK

[3]Cockcroft Institute, Warrington, Cheshire, UK
[4]Loughborough University, Loughborough, UK

Abstract

The RF surface resistance of accelerator vacuum chamber walls can have a significant impact on the beam quality. There is a need to know how the use of a new material, surface coating or surface treatment can affect the RF surface resistance. ASTeC and Lancaster University have designed and built two test cavities where one face can be replaced with a sample in the form of a flat plate. The measurements are performed with a network analyser at the resonant frequency of approximately 7.8 GHz.

INTRODUCTION

If one considers the formulation of the unloaded quality factor Q_0 of an RF cavity [1] one can write

$$Q_0 = \frac{2\pi f_0 \mu_0 \iiint_V |\boldsymbol{H}|^2.dV}{\iint_S R_S |\boldsymbol{H}|^2.dS} \quad (1)$$

where H is the magnetic field, R_S is the surface resistance of the cavity walls and f_0 is the resonant angular frequency of the cavity. To accommodate the possibility of a cavity being comprised of two parts (a cavity and a sample) which could be made of different metals or otherwise have different R_S values, one can most conveniently rewrite this as

$$Q_0 = \frac{G}{R_S^{sample} p_S + R_S^{cavity} p_C} \quad (2)$$

where G is the geometry constant of the cavity [1], defined as

$$G = \frac{2\pi f_0 \mu_0 \iiint_V |\boldsymbol{H}|^2.dV}{\iint_S |\boldsymbol{H}|^2.dS} \quad (3)$$

R_S^{sample} and R_S^{cavity} are the surface resistance of the sample and the cavity respectively, and p_S and p_c the sample and cavity ratios – the proportion of the total field dissipated over their respective surfaces, i.e.

$$p_S = \frac{\iint_{sample} |\boldsymbol{H}|^2.dS}{\iint_S |\boldsymbol{H}|^2.dS} \quad (4)$$

$$p_C = \frac{\iint_{cavity} |\boldsymbol{H}|^2.dS}{\iint_S |\boldsymbol{H}|^2.dS} = 1 - p_S \quad (5)$$

For any similarly-shaped cavity G and p_S are in principle constant, irrespective of the materials used.

This implies that, knowing R_S^{cavity}, G and p_S for a given cavity we can calculate R_S for any sample by placing it on top of the cavity and finding the unloaded Q-factor of the resulting RF resonance.

$$R_S^{sample} = \frac{G/Q_0 - R_S^{cavity}(1-p_S)}{p_S} \quad (6)$$

METHOD

Calculation of Q_0

Two double-choked pillbox-type cavities were used to take our measurements, one of which can be seen in Fig. 1. The choked cavity allows the testing of flat samples without the need for flanges and RF seals. Both cavities were manufactured to identical dimensions by Niowave Inc. [2], one being made from aluminium and one from niobium.

Figure 1: A two-choked 8 GHz Al test cavity.

In each case the samples, in the form of flat plates or discs of sufficient width to completely cover the outer choke, were placed on top of the cavity with spacers providing a gap of ~2 mm between the cavity and the sample. An axially-mounted coaxial antenna was attached to a calibrated network analyser to induce RF resonance, and the coefficient of signal reflection (S_{11}) measured against frequency. Initial setup required that the spacing between the sample and the cavity was adjusted to

COMMISSIONING OF THE TRANSVERSE DEFLECTING CAVITY ON VELA AT DARESBURY LABORATORY

A.E. Wheelhouse#, R.K. Buckley, S.R. Buckley, L. Cowie[1], P. Goudket, L. Ma, J. McKenzie, A.J. Moss, STFC ASTeC, Daresbury, Warrington, Daresbury Laboratory, Sci-Tech Daresbury, Warrington, WA4 4AD, UK
G.C. Burt, M. Jenkins, Lancaster University, Cockcroft Institute, Lancaster, LA1 4YW, UK

Abstract

A 9-cell S-band transverse deflecting copper cavity (TDC) has been designed and built to provide a 5 MV transverse kick in order to perform longitudinal profile measurements of the electron bunch on the Versatile Electron Linear Accelerator (VELA) at Daresbury Laboratory. The cavity has been manufactured by industry and has been field flatness measured using a bead-pull system. The cavity has then been installed on to the VELA facility and commissioned for operation with the electron beam. This paper discusses the cold testing and the RF conditioning of the cavity.

INTRODUCTION

The Versatile Electron Linear Accelerator (VELA) [1] at Daresbury Laboratory is a facility which has been built for the investigation and development of novel and compact accelerator technology specifically aimed at medical, health, security, energy and industrial processing. For this purpose the facility consists of two separate user areas for scientific research.by industrial users. In addition VELA is to be used to study fundamental requirements for the next generation FEL as part of the development of the Compact Linear Accelerator for Research and Applications (CLARA) facility being built at Daresbury Laboratory [2].The VELA facility is designed to provide a 4 - 6 MeV electron beam with bunch charges between 10 - 250 pC, a short bunch length 0.1 – 3 ps) and low transverse emittance. The facility consists of an S-band photo-injector gun with a copper cathode which is driven by a Coherent Inc. UV laser providing a pseudo-Gaussian profile of 1 mm FWHM at the cathode. The beam is then transported to either of the user areas via a diagnostic line consisting of a transverse deflecting cavity (TDC), a wall current monitor, YAG screens, Faraday cup and slit/strip line beam position monitors (BPMs).

To accurately measure the longitudinal profile of the electron bunch an S-band 9-cell copper transverse deflecting cavity has been designed [3], built, characterised, installed (Fig.1) and commissioned. The cavity was manufactured by Research Instruments GmbH, Germany and was designed to provide a transverse kick of around 5 MV to the electron bunch which converts the longitudinal position into a transverse offset seen on a YAG screen enabling the bunch profile to be analysed [4]. The specifications of the TDC are shown in Table 1.

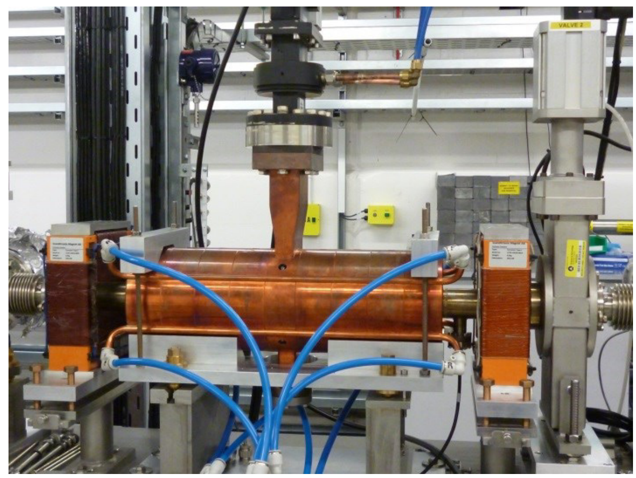

Figure 1: VELA Transverse Deflecting Cavity.

Table 1: VELA TDC Parameters

Parameter	Value	Units
Frequency	2998.5	MHz
Bunch energy	4-6	MeV
Time resolution	10	fs
Phase stability required	0.1	°
Operating mode	TM110-like	
Nearest mode separation	>5	MHz
Available RF power	5	MW
Pulse length	Up to 3	µs
Average RF power loss	<150	W
Input coupling	WR284	

CAVITY RF COLD TESTS

On delivery the frequency and field flatness of the cavity were measured. S-parameter measurements from the input coupler to the probe showed a room temperature operating mode frequency of 2999.1 MHz. This dictated an operating temperature of 55°C to achieve the required 2998.5 MHz. The water temperature will be reduced during RF operation to maintain the cavity frequency and to compensate for RF heating. An S21plot and the S11 Smith chart with the cavity at 55°C and under vacuum are shown in Figure 1. The bandwidth of the operating mode is 383 kHz and Q_0 is measured to be 13700.

The cavity has a vertical probe that couples to the operating mode, and a horizontal SOM coupler that couples to the orthogonal polarisation of the operating mode. The power in the cavity when in use is of the order

Abstract

CERN's Compact linear collider (CLIC) will require crab cavities to align the bunches to provide effective head-on collisions. An X-band quasi-TM_{11} deflecting cavity has been designed and manufactured for testing at CERN's Xbox-2 high power standalone test stand.

The cavity is currently under test and has reached an input power level in excess of 40MW, with a measured breakdown rate of better than 10^{-5} breakdowns per pulse. This paper also describes surface field quantities which are important in assessing the expected BDR when designing high gradient structures.

INTRODUCTION

At the CLIC interaction region electron and positron bunches collide with a 20 mrad crossing angle and have an elongated shape (45 µm long and 45 nm wide). These two factors cause a 90% reduction in luminosity compared to a head on collision. Crab cavities on each linac are required to rotate each of the bunches before the interaction point. The luminosity can be restored to within 98% of which is attainable for a head on collision [1].

For cavities placed just before the final quadrupole doublets, the required voltage kick is 2.55MV per cavity. In order to reduce wakefields, a structure with a low cell count is preferred. Therefore, to obtain the required kick a high gradient design is needed. An 11.9942 GHz design was chosen in order to utilise the expertise and RF infrastructure already available within the CLIC project.

RF DESIGN

The cavity was designed at Lancaster University/Cockcroft Institute, UK. It is a travelling wave structure employing a quasi-TM11 dipole mode with $2\pi/3$ phase advance per cell. There are ten regular cells and two coupling cells. The cavity's specifications were finalised by considering the limits upon beam loading sensitivity, wakefields and peak power available from the high power RF network.

The iris radius is 5mm and was chosen to keep short range wakefields within acceptable limits. For long range wakefields, the same order mode (SOM) is actively damped by using a racetrack cell shape. The frequency of the SOM is shifted such that every other bunch damps the unwanted mode. The shifted frequency must be a factor of 3n/2 of the bunch reputation rate (2 GHz). A SOM frequency of 13GHz was chosen to this effect. In the final design, the lower order monopole mode and higher order modes also require damping. Studies have been conducted to design cavities with choke mode or waveguide damping. Waveguide damping was found to be superior [2] and two prototype cavities were commissioned to be built and tested at CERN; an un-damped prototype and a damped prototype (albeit without silicon carbide absorbers). The un-damped prototype has been built and is currently under high power test at CERN.

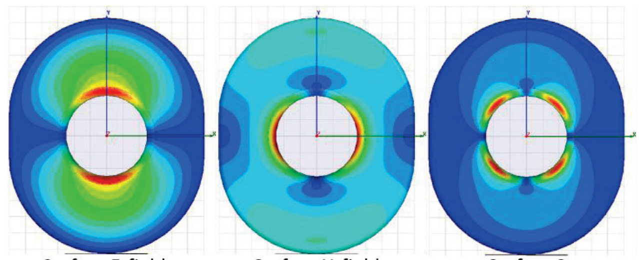

Figure 1 shows the cell geometry and the E-field, H-field and the modified pointing vector 'Sc' [3] of the un-damped crab cavity as simulated in HFSS.

As shown in Figure 1, the surface quantities affect breakdowns have peaks at different locations around the iris. For monopole mode structures all of the quantities shown in Figure 1 are distributed evenly around the iris. Therefore, this cavity provides an opportunity to test which surface quantities (electric field, magnetic field or power flow) contribute most strongly towards causing breakdowns. This can be achieved through a post-mortem inspection using optical and/or electron microscopy. A so called 'dark current spectrometer' can be used to look at the geometric source of emitted electrons during a BD in real-time. Both of these methods will be used with the latter being described in the following paper [4].

Table 1 shows the characteristics of the CLIC T24 un-damped accelerating structure, the LCLS deflector [5] and the CLIC crab cavity

Property	**CLIC T24 (unloaded)**	**LCLS deflector**	**CLIC Crab (un-damped)**
Input Power	37.2 MW	20 MW	13.35 MW
Transverse Kick	-	24 MV	2.55 MV
Peak surf. E-field	219 MV/m	115 MV/m	88.8 MV/m
Peak surf. H-field	410 kA/m	405 kA/m	292 kA/m
Peak Sc	3.4 MW/mm^2	-	1.83 MW/mm^2

Abstract

Bulk niobium cavities are widely employed in particle accelerators to create high accelerating gradient despite their high material and operation cost.

In order to reduce this cost, thin layer of niobium are deposited on a copper cavity, which has lower material cost with higher availability and more importantly higher thermal conductivity.

The coating of superconducting cavities currently is synthesized by physical vapour deposition (PVD) method which suffers from lack of conformity. By using chemical vapour deposition (CVD) and plasma enhanced chemical vapour deposition (PECVD) it is possible to deposit thin Nb layers uniformly with density very close to bulk material. This project explores the use of PECVD / CVD techniques to deposit metallic niobium on copper using NbCl5 as precursor and hydrogen as a coreagent. The samples obtained were then characterized via SEM, TEM, SAD, XRD, XPS, and EDX as well as assessing their superconductivity characteristics (RRR and Tc) All the samples deposited are superconductive and polycrystalline; the sample obtained with CVD measured RRR=31 and Tc=7.9 K, while the sample obtained with PECVD exhibited RRR=9 and Tc= 9.4 K. In both cases the films grew in a (100) preferred orientation.

INTRODUCTION

Superconductive niobium cavities are widely used in particle accelerators to provide the gradient required to accelerate the desired particles via RF energy. Technology has caught up with the physical limits of bulk niobium, exploiting the material to its maximum potential [1]. Since the SRF requires less than 1 micron of material, it could be possible to obtain the same properties of niobium bulk with niobium thin films [2]. Thin films are a considerably cheaper option than bulk materials for the following reasons, firstly less material is being used and secondly, since SRF cavities operate at temperatures below 10K, the films can be deposited on high thermal conductivity materials such as copper making it easier to cool and maintain the low temperatures than with bulk superconductors [3]. Theoretical studies [4] have also suggested that the use of Superconductor / Insulator / Superconductor thin films (ISI) can lead to an increase in the accelerating gradient, surpassing the limits of bulk niobium. CVD [5] is a chemically driven technique that allows the coating of large areas with great control over the produced film. This technique is therefore being explored to verify the feasibility of depositing metallic superconductive niobium with a homogeneous and uniform structure.

The purpose of the present study is to deposit thin films of Nb using CVD and plasma enhanced CVD (PECVD) techniques. The use of plasma enables reduction of the deposition temperature and allows coating of shapes with a high degree of complexity, such as cavities [6].

After microstructural evaluation, the films have then been assessed for their superconducting properties showing their suitability for use in SRF cavities.

EXPERIMENTAL SETUP

A steel spherical chamber is kept at a base pressure of 10-6 mbar and constantly heated to 120 °C as shown in figure 1. The carrier gas (argon) and the reducing gas (hydrogen) are purified through a heated filters system to ensure that the presence of residual contaminants in the deposition chamber is kept as low as possible.

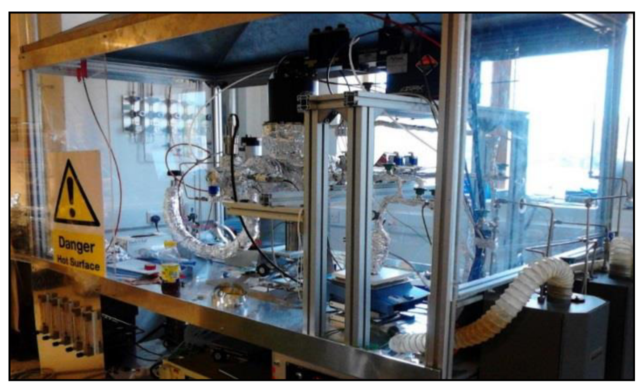

Figure 1: Deposition facility.

The chemical precursor ($NbCl_5$) is placed under controlled atmosphere in a two-legged steel bubbler. The bubbler is then connected to the deposition rig and maintained at the chamber base pressure. Oxygen free copper substrates are cleaned via in-house process (acetone – IPA- distilled water) to further reduce the quantity of contaminants. A substrate is introduced in the chamber and kept at the chamber base pressure for 24 hours prior deposition. The NbCl5 precursor is heated up until a vapor pressure suitable for the deposition is

PHYSICAL VAPOUR DEPOSITION OF THIN FILMS FOR USE IN SUPERCONDUCTING RF CAVITIES

Abstract

The production of superconducting coatings for radio frequency cavities is a rapidly developing field that should ultimately lead to acceleration gradients greater than those obtained by bulk Nb RF cavities. Optimizing superconducting properties of Nb thin-films is therefore essential. Nb films were deposited by magnetron sputtering in pulsed DC mode onto Si (100) and MgO (100) substrates and also by high impulse magnetron sputtering (HiPIMS) onto Si (100), MgO (100) and polycrystalline Cu. The films were characterised using scanning electron microscopy, x-ray diffraction and DC SQUID magnetometry.

INTRODUCTION

Superconducting radio frequency (SRF) cavity technology in particle accelerators is now reaching the limit of performance achievable with bulk Nb cavities [1]. Since superconducting properties for SRF are confined to a penetration depth of less than one micron [2] then Nb thin-films offer an alternative to bulk Nb with the advantage of Cu substrates which have a factor of three higher thermal conductivity than Nb [3]. A Nb thin-film which is oriented parallel to a magnetic field can have a higher first critical magnetic field than bulk Nb if the film is thinner than the London penetration depth. There is also the possibility of multilayer films that provide greater magnetic shielding [4]. With better thermal stability and higher critical fields it is possible to have higher accelerating gradients within SRF cavities allowing for better performance, reduced cost and reduced volumes of Nb [5]. Physical vapour deposition by magnetron sputtering has been used as a preferred process due to its high deposition rate and ease of scalability in order to produce superconducting thin films within SRF cavities [6,7]. The purpose of the present study is to compare films deposited by both pulsed DC and HiPIMS and to compare films deposited onto Si (100), MgO (100) and polycrystalline Cu substrates. Nb thin films were deposited using the Advanced Energy Pinnacle + in pulsed DC mode. Films were then deposited by HiPIMS using an Ionautics HiPSTER 1000 power supply. HiPIMS has a characteristic peak current which is two orders of magnitude higher than pulsed DC at the expense of a reduction in deposition rate. The variable parameters are deposition current, voltage, pulsed duty cycle, pulsed frequency, substrate temperature, and substrate bias. After morphological evaluation the films have then been assessed for their superconducting properties showing their suitability for use in SRF cavities.

EXPERIMENTAL

Thin film samples were deposited simultaneously onto Si (100), MgO (100) and polycrystalline Cu substrates using Kr sputtering gas. Each substrate was prepared by cleaning in ultrasonic baths of acetone, methanol, IPA, then deionised water [8]. In the case of HiPIMS deposition, the substrate was then plasma cleaned using oxygen plasma, then ion bombarded for 30 minutes before deposition. The pulsed DC power was set to 400 W at 350 kHz with a 50% duty cycle. The HiPIMS power supply was varied between 100 and 400 W. Pulse lengths were operated between 100 and 300 µs at frequencies between 100 and 300 Hz. A typical current – voltage – time profile for the HiPIMS power supply is shown in Fig 1.

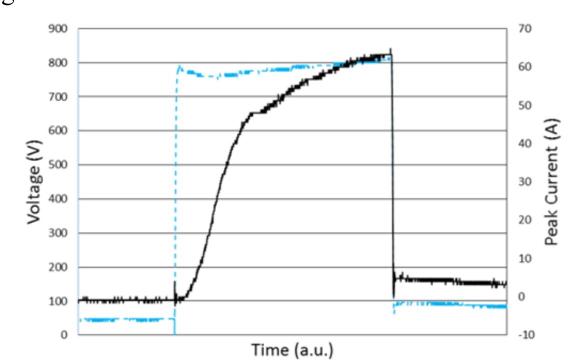

Figure 1: The current – voltage – time profile of a HiPIMS pulse. Peak current is shown in black and voltage in blue.

The current voltage characteristics of both power supplies are shown together in Fig 2. A DC bias voltage can be applied to the substrate and was varied between 0 and -100 V. RF biasing was used at 19 W. The base pressure of the unbaked UHV chamber reached ~10^{-8} mbar and the Kr pressure was set to 3 mbar.

Morphological analysis was performed by SEM and XRD. SEM analysis was used to determine the film structure and grain size at the surface. XRD analysis results show average grain size and lattice orientations within the film. RRR measurements have been performed using a purpose built cryostat housing a four point probe.

5MW POWER UPGRADE STUDIES OF THE ISIS TS1 TARGET

Cristian Bungau, Adriana Bungau, Robert Cywinski, Thomas Robert Edgecock,
University of Huddersfield, Huddersfield, UK
Christopher Neal Booth, Lei Zang, Sheffield University, Sheffield, UK

Abstract

The increasing demand for neutron production at the ISIS neutron spallation source has motivated a study of an upgrade of the production target TS1. This study focuses on a 5 MW power upgrade and complete redesign of the ISIS TS1 spallation target, reflector and neutron moderators. The optimisation of the target-moderator arrangement was done in order to obtain the maximum neutron output per unit input power. In addition, at each step of this optimisation study, the heat load and thermal stresses were calculated to ensure the target can sustain the increase in the beam power.

INTRODUCTION

ISIS [1] is currently the world's most productive spallation neutron source hosting two target stations TS1 and TS2. The TS1 target station operates at proton beam powers of up to 200 kW. The goal of this study is to find the maximum beam power the TS1 target can sustain without changing the existing design concept of using fixed solid W plates. There are many factors that could limit the performance of a high power target therefore the design of such a target presents a major technical challenge in terms of the engineering constraints of heat removal and structural radiation damage while optimising the neutron yield. The ISIS accelerator has been upgraded to achieve the increased beam intensity necessary to provide a 10 pulses per second (pps) proton beam to TS2 at the same time as maintaining present intensity to TS1 where the repetition rate is reduced from 50 pps to 40 pps. The ISIS TS1 target is driven by an 800 MeV, 200 μA proton beam equivalent to almost 0.2 MW beam power.

THE TS1 TARGET

A schematic diagram of the ISIS target is shown in Fig. 1. It consists of a stack of 12 solid tungsten plates (105 $\times$ 80 mm) of different thicknesses (from 15 to 50 mm) enclosed in a stainless steel pressure vessel which contains heavy water for cooling the plates. Each tungsten plate is cladded in a 2 mm thick tantalum layer in order to avoid water corrosion of bare tungsten. The Ta/W interface must remain in close contact as developing gaps would restrict the coolant flow and create resistance to the heat evacuation generated by the target. The gaps between the plates is 2 mm and is used for cooling the plates with heavy water. The flow of heavy water is redistributed using stainless steel manifolds.

Four moderators are used to slow down fast neutrons escaping from the target to the lower speeds required for neutron scattering experiments. Two use water at room temperature, one uses liquid methane at 100 K and the fourth consists of liquid hydrogen at 20 K. The different temperatures result in different energy neutron beams. The moderators are small, about 0.5 l, and are surrounded by a water-cooled beryllium reflector which scatters neutrons back into the moderators and doubles the useful flux of neutrons. Surrounding radially the reflector are the neutron channels which conduct the neutrons to the instruments for neutron scattering applications.

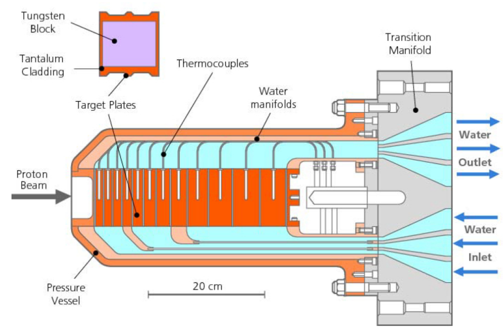

Figure 1: Layout of the ISIS-TS1 spallation target.

The ISIS TS1 target geometry was implemented into the Geant4 Monte Carlo code [2], and Fig. 2 shows the modelling of the target and the surrounding components. In this figure, the four neutron moderators that are used to thermalise the neutrons are shown in different colours: the two water moderators (blue), the liquid methane moderator (green) and the liquid hydrogen (yellow). The two water moderators are at ambient room temperature 300 K, the liquid methane moderator operates at 100 K and the liquid hydrogen moderator at 20 K. The liquid methane moderator has curved surfaces unlike the others. The target and the moderators are embedded in a beryllium reflector shown here in grey. Also the neutron beamlines are shown (lower right) which lead the neutrons to the experimental stations.

GEANT4 Versus MCNPX Simulations

The neutron yields energy spectra measured at various instruments pointing to the neutron moderators are shown in Fig. 3. Because the neutron moderators operate at different temperatures the neutron spectra show a strong dependence on the moderator temperature, resulting in an increase in the number of thermal neutrons for lower operating temperatures. This validation study shows an excellent agreement between the GEANT4 and MCNPX predictions for

Abstract

The Laser Applications at Accelerators Network (LA³NET) is receiving funding of up to 4.6 M€ from the European Union within the 7th Framework Program to carry out R&D into laser-based particle sources, laser acceleration schemes and laser-based beam diagnostics. This international network joins universities, research centers and private companies and has been training 19 early stage researchers at network nodes across Europe since 2011. This contribution presents research outcomes from LA³NET's main work packages, covering electron beam generation, acceleration and diagnostics. Results from surface studies of photocathodes for photo injector applications in the framework of the CLIC project are presented along with information about expected accelerating gradients in dielectric laser-driven accelerators as identified for non-relativistic and relativistic electron beams using the CST and VSIM simulation codes. Initial results from energy measurements using Compton backscattering at the ANKA Synchrotron at KIT are also presented. In addition, a summary of recent and upcoming international events organized by the consortium is also given.

INTRODUCTION

The LA³NET Fellows are hosted by 11 partner institutions all over Europe and although their work focuses on research, they are provided not only with scientific supervision and opportunities of secondments to other institutions involved in the project, but also complementary training through network-wide events [1]. This includes international schools and topical workshops, as well as a final project conference and numerous outreach events. Through the involvement of almost 30 associated and adjunct partners the project gains an interdisciplinary dimension including strong links to industry. The network carries out many dissemination and outreach activities aimed at interesting a wide audience in science and to raise public awareness of the application of lasers and accelerators in many different fields that have influence on everyone's life, such as medicine, electronics, energy and the environment. LA³NET trains accelerator experts for academia and industry, joins the accelerator and laser communities and to raises public awareness of the importance of this research for society. In the following section examples of recent research results from across the consortium are given.

* This project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement no 289191.

RESEARCH

The Fellows carry ou research within one out of 5 thematic work packages within LA³NET. These are particle sources, acceleration, beam diagnostics, system integration and detector technology.

Surface Characterization of Photo Cathodes for Photoinjector Applications

Within the CLIC (Compact Linear Collider) project, feasibility studies of a photoinjector option for the drive beam are on-going, covering both, the laser and the photocathode side. The main challenge is to achieve high bunch charges, long trains and high bunch repetition rates together with sufficiently long cathode lifetimes. Cs_2Te cathodes, sensitive to ultra-violet (UV) laser beam that were produced at CERN showed good quantum efficiency and reasonable lifetime [2]. However, the available laser pulse energy in the UV for 140 µs long pulse trains is currently limited due to a degradation of the beam quality during the 4th harmonics conversion process. Using green laser beam in combination with Cs_3Sb cathodes would overcome this limitation. Cs_3Sb and Cs_2Te photocathodes were produced at CERN by co-deposition process and tested in the PHIN RF photoinjector, see [3]. LA³NET Fellow I. Martini who is based at CERN led a detailed analysis of cathode surface composition through X-ray Photoelectron Spectroscopy (XPS) and correlated the findings to the cathode performance [4]. The Quantum Efficiency (QE) map shows an overall efficiency reduction in used cathodes as compared to newly produced ones, see Fig. 1 as an example. This can be explained by changes in the composition of the photoemissive layer.

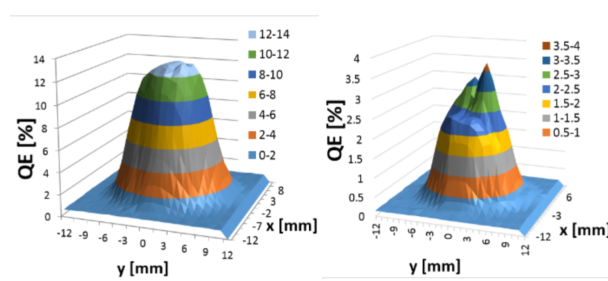

Figure 1: QE maps of Cathode #198 (Cs_2Te) as newly produced (left) and used in the RF photoinjector (right).

The XPS studies showed that both cathodes were oxidized during operation. Moreover, the detailed

MAGNET DESIGNS FOR THE MULTI-BEND ACHROMAT LATTICE AT THE ADVANCED PHOTON SOURCE*

M. Jaski, J. Liu, Argonne National Laboratory, Argonne, IL 60439, USA
A. Jain, C. Spataro, Brookhaven National Laboratory, Upton, NY 11973, USA
D. J. Harding, V. S. Kashikhin, M. L. Lopes, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

The Advanced Photon Source (APS) is currently investigating replacing the existing two-bend 7 GeV lattice with a 6 GeV seven-bend achromat magnet lattice in order to achieve a low electron beam emittance [1]. This new lattice requires 1320 magnets, of which there are nine types. These include high strength quadrupoles (gradient up to ~97 T/m), sextupoles with second derivative of field up to ~7000 T/m^2, longitudinal gradient dipoles with field ratio of up to 5, and transverse gradient dipoles with gradients of ~50 T/m and central field of ~0.6 T. These field requirements and the limited space available pose several design challenges. This paper presents a summary of magnet designs for the various magnet types developed through a collaboration of APS with FNAL and BNL.

INTRODUCTION

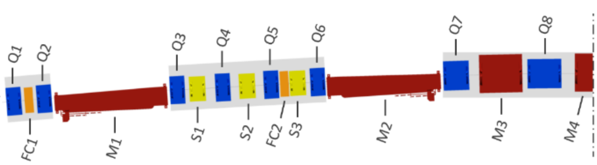

Figure 1: Half sector with magnet identifications.

The storage ring consists of forty sectors. There are 7 dipoles, 16 quadrupoles, 6 sextupoles, and 4 fast steering correctors, totalling 33 magnets in each sector. A representation of a half sector is shown in Fig. 1 along with magnet identifications. Table 1 lists the magnets and their respective lengths and maximum strengths. All magnets are solid core magnets with the exception of the corrector magnet, which requires a laminated core. The minimum pole tip radius for all magnets is 13 mm. For quadrupole, sextupole, and corrector magnets the minimum vertical gap between the poles is 10 mm and minimum vertical gap between the coils is 16 mm to allow for extraction of the photon beam. The fractional field deviation for each unwanted harmonic is limited to a maximum of 10^{-4} at a 10 mm reference radius. Any discrepancies in magnet harmonics are evaluated on a case-by-case basis.

VANADIUM PERMENDUR

Analysis shows that making quadrupole pole tips out of vanadium permendur (VP) can increase the field by 9% compared to steel core tips at the same magnetic efficiency. Figure 2 shows a plot of simulated integrated quadrupole field vs. insertion length for mushroom VP, mushroom steel, and straight steel tips. This plot was used in the lattice design to estimate obtainable quadrupole strengths for a given insertion length. Similar plots were developed for sextupole, Q7, and Q8 magnets. VP is expensive (~200x more than steel) so minimizing or eliminating the use of VP is desirable. During design, steel pole tips are the material of choice, unless the field could not be achieved for a given length.

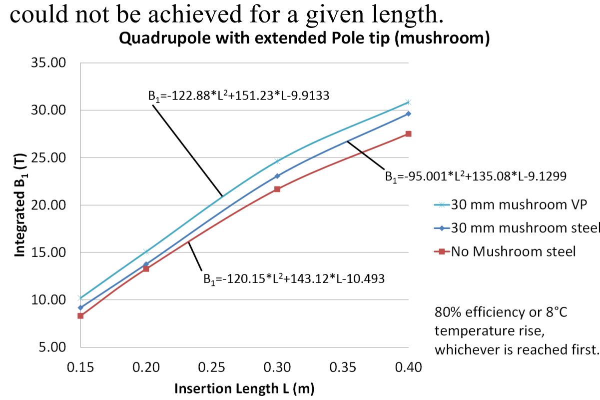

Figure 2: Quadrupole integrated field vs insertion length for VP and steel mushroom poles.

QUADRUPOLE MAGNETS

All quadrupole magnets are made of solid steel, two-piece (top and bottom) yokes with removable poles and pole tips. The Q1 through Q6 have long mushroom style pole tips. Figure 3a shows a magnet model of a Q1 magnet. The long mushroom style pole tips allow higher integrated field gradients at high saturation compared to straight pole tips at the same saturation. The Q1 quadrupole magnet operates at a high field gradient and requires VP pole tips. Prototypes of quadrupole magnets are under construction at APS and are expected to be ready for measurement in September 2015.

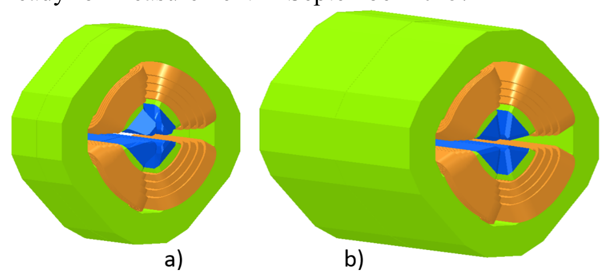

Figure 3: a) Q1 quadrupole magnet model. b) Q8 quadrupole magnet model.

MATHEMATICAL MODELING AND ANALYSIS OF A WIDE BANDWIDTH BIPOLAR POWER SUPPLY FOR THE FAST CORRECTORS IN THE APS UPGRADE CONTROLLER*

Byeong M. Song and Ju Wang
ANL, Argonne, IL 60439, USA

Abstract

This paper presents the mathematical modeling and analysis of a wide bandwidth bipolar power supply for the fast correctors in the APS Upgrade controller. A wide bandwidth current regulator with a combined PI and phase-lead compensator has been newly proposed, analyzed, and simulated through both a mathematical model and a physical electronic circuit model using MATLAB and PLECS. The proposed regulator achieves a bandwidth with a -1.23dB attenuation and a 32.40° phase-delay at 10 kHz for 0.3% AC component. The mathematical modeling and design, simulation results of a fast corrector power supply control system are presented in this paper.*

INTRODUCTION

Argonne National Laboratory's Advanced Photon Source (APS) Upgrade requires a bipolar power supply with a 10 kHz and -3dB small signal bandwidth for the fast correction magnets. In addition, low output current offset and DC drift to achieve a few hundred parts per million (ppm) output current stability are required. These requirements present a technical challenge to the design because the magnet load may have a significant inductance, making it difficult to achieve a high bandwidth for the current, and the input DC bus voltage may be limited. Until now, there have been no known commercial-off-the-shelf (COTS) power supplies that meet the 10kHz bandwidth requirement.

In order to meet the requirements, different circuit topologies and regulators are being investigated. One of the candidates is a standard full-bridge power circuit topology with a high switching frequency to provide a ±15A DC output current with an AC component less than 1% of the full DC scale with the required bandwidth.

In this paper, a 200kHz interleaved pulse-width-modulation (PWM) power supply circuit with a proportional-and-integral (PI) and phase-lead current regulator is proposed for the fast corrector power supply. The proposed current regulator is mathematically analyzed and optimized, so that it achieves the performance requirement of the power supply by minimizing the attenuation and phase-shift of the compensated closed-loop control system. The performance evaluation of the current regulator has been conducted through Matlab and PLECS simulations.

A WIDE BANDWIDTH BIPOLAR POWER SUPPLY

Main Circuit and Its PWM Operation

Figure 1(a) shows a bi-directional power circuit for fast corrector power supplies. The circuit consists of a 200kHz interleaved full-bridge MOSFET power circuit and a 50kHz low pass filter. The power circuit has four switches in two legs, S_1 and S_3, and S_2 and S_4.

Figure 1(b) shows the key PWM switching of the power circuit. Two references with the same amplitude but opposite sign, $+V_{ref}$ and $-V_{ref}$, are compared with a 100kHz triangular waveform, V_c, to generate two sets of PWM signals. The output voltage, V_o, is proportional to the duty cycle, $D*(1-D)$, and input voltage, V_{in}. With this switching pattern, the output current, i_o, has a ripple frequency that is twice the PWM frequency. Thus, this low current ripple can reduce the size of magnetic components and capacitors of the low pass filter in the power circuit.

SUPERCONDUCTING HARMONIC CAVITY FOR THE ADVANCED PHOTON SOURCE UPGRADE*

M.P. Kelly[1,#], A. Barcikowski[1], J. Carwardine[1], Z.A. Conway[1], D. Horan[1], M. Kedzie[1], S.H. Kim[1], P.N. Ostroumov[1], J.Rathke[2], T. Schultheiss[2], G. J. Waldschmidt[1]
[1)]Argonne National Laboratory, Argonne, IL 60439, U.S.A.
[2)]Advanced Energy Systems, Inc., Medford, NY 111763, U.S.A.

Abstract

A new bunch lengthening cryomodule using a single-cell 'higher-harmonic' superconducting cavity (HHC) based on the TESLA shape and operating at the 4th harmonic (1408 MHz) of the main RF is under development at Argonne. The system will be used to improve the Touschek lifetime and increase the single-bunch current limit in the upgraded multibend achromat lattice of the Advanced Photon Source electron storage ring. The 4 K cryomodule will fit within one half of a straight section, ~2.5 meters, of the ring. The system will use a pair of moveable 20 kW (each) CW RF power couplers to adjust the loaded Q and extract power from the beam. This will provide the flexibility to adjust the impedance presented to the beam and run at various beam currents. Higher-order modes (HOMs) induced by the circulating electron beam will be extracted along the beam axis and damped using a pair of room temperature beam line absorbers. Engineering designs and the prototyping status for the cavity, power couplers and HOM absorbers are discussed.

INTRODUCTION

The Advanced Photon Source Upgrade (APS-U) project [1] will have a relatively short Touschek lifetime [2] and a bunch lengthening cavity is required to mitigate the effect. Harmonic cavities provide lengthening by modifying the longitudinal potential to produce reduced slope near the bunch center [3] and are demonstrated and in use elsewhere [4,5].

Superconducting RF (SRF) cavities have major advantages over normal conducting cavities in many high-current, high-power CW applications, including for the 6 GeV, 200 mA electron storage ring in the APS-U:

- One beam-driven single-cell harmonic cavity easily provides all of the required voltage
- The large beam aperture and single-cell minimize the total beam-induced HOM power and the complexity of HOM power extraction
- The high quality factor, $Q_0>10^8$, combined with a variable coupler, permit adjustment of the loaded quality factor, Q_L, for near-optimal lengthening for various beam currents

# mkelly@anl.gov

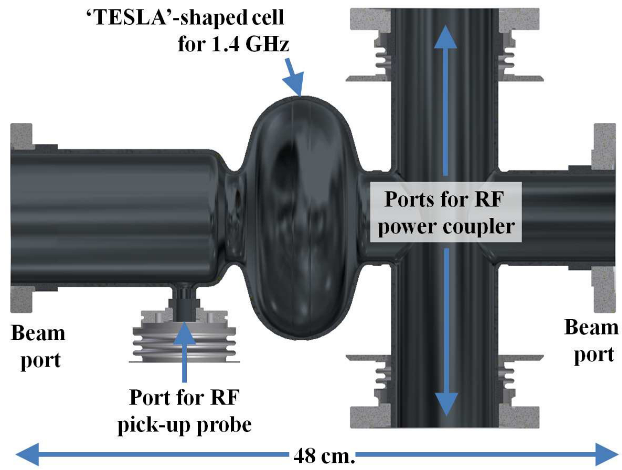

Figure 1: A higher-harmonic cavity for bunch lengthening in the Advanced Photon Source Upgrade.

A study of possible 3rd, 4th, and 5th harmonic SRF cavities has been performed based on analytical calculations. These assume 'optimal' bunch lengthening [6]. Differences are modest with the most lengthening, by ~20%, with the 3rd harmonic. However, the extracted power (through RF couplers) is double that for the 4th harmonic due to higher voltage and smaller detuning angle for the optimum condition. Multi-particle, collective effects and transients were not included. Tracking simulations [2] using ELEGANT, include these, and do not support a clear advantage with the 3rd harmonic. Finally, the 4th harmonic cavity choice (Figure 1) was influenced by practical considerations.

The 1.4 GHz frequency is sufficiently close to the 1.3 GHz linear collider frequency that existing infrastructure and techniques can be used to reduce development time. Performance needs are modest and are listed Table 1.

Table 1: Harmonic Cavity Main Parameters

Parameter	Value
Frequency, MHz	1408
Operating temperature, K	4.5
Beam induced voltage, MV	0.84
Cavity Q_0 at 4.5 K	2×10^8
R_{SH}/Q, Ω	109
G, Ω	270

PRESERVATION OF QUALITY FACTOR OF HALF WAVE RESONATOR DURING QUENCHING IN THE PRESENCE OF SOLENOID FIELD*

S.H. Kim#, Z.A. Conway, M.P. Kelly, P.N. Ostroumov, S.M. Gerbick, T.C. Reid, M.J. Kedzie, S.W.T. MacDonald, D.M. Caldwell,
ANL, Argonne, IL 60439, USA

Abstract

The Proton Improvement Plan II at FNAL relies upon a 162.5 MHz superconducting half-wave resonator cryomodule to accelerate H- beams from 2.1 to 10 MeV. This cryomodule contains 8 resonators with 8 superconducting solenoid magnets interspersed between them. X-Y steering coils are integrated with a package of the superconducting solenoid magnets. The center of the solenoids is located within ~50 cm of the high surface magnetic field of the half-wave resonators and in this study we assess whether or not magnetic flux generated by this magnet is trapped into the half-wave resonators niobium surface and increases the RF losses to liquid helium. To test this we assembled a solenoid with a 162.5 MHz half-wave resonator spaced as they will be in the cryomodule. We measured the quality factor of the cavity before and after the cavity quenched as a function of field level in the coils. No measurable change in the quality factor was observed. In this paper, we will present details of the measurements and discuss the magnetic field map.

INTRODUCTION

Argonne has developed a 6 T superconducting solenoid (0.75 T·m field integral) with integral x-y dipole steering coils each producing a maximum 0.25 T steering field (30 T·mm field integral) [1,2]. This magnet will be used in the 162.5 MHz superconducting half-wave resonator (HWR) cryomodule which contains 8 resonators and 8 magnets and will be employed to accelerate H- beams from 2.1 to 10 MeV in the proposed Proton Improvement Plan II (PIP-II) at FNAL [3,4].

This solenoid integrates with bucking coils to minimize stray field such that the magnetic field on the cavity surface is much smaller than the (first) critical field for niobium. The intent is to avoid trapped magnetic flux and the associated increase of the surface resistance [1]. This minimization of the stray field reduces the possibility of flux trapped when cavity experiences thermal breakdown (quenching) [5,6]. Experimental studies show that magnetic flux can be trapped around the quench location where a normal region is present in the niobium for ~100 ms [6].

We assembled this solenoid with the 162.5 MHz HWR, which is the second cavity fabricated for PIP-II HWR cryomodule and the first one was reported on in ref. [7], and measured change of trapped magnetic flux after the cavity quenched in the presence of the solenoid/steering coil fields. We note that probability of cavity quenching during normal operation would be very low in the PIP-II HWR cryomodule because this cavity quenches at the accelerating gradient of E_{ACC}~18 MV/m while the operational accelerating field will be E_{ACC}=8 MV/m.

In the following sections, we will discuss the stray field generated by the solenoid and steering coils and then discuss measurement hardware and results.

STRAY FIELD

The stray field of the solenoid is minimized by integral bucking coils as shown in Fig. 1. These are wound in series with the main solenoid coil. Another pair of the dipole coils is located in the plane perpendicular to the cross-section shown in Fig. 1.

The simulated stray field generated by the solenoid, a combination of the main and bucking coil, is as shown in Fig. 2. We note that the unperturbed field is simply overlaid on the cavity and no Meissner effect is included. The stray field on the cavity surface is of the order 10 Gauss around the nosecone, placed in the high RF electric field region, and it is exponentially decayed along the surface toward the end torus of HWR so the stray field on a cavity surface in the high RF magnetic field region is much smaller than the lower critical field of the niobium [8]. The measured stray fields are in rough agreement with the design, differing by a factor of 3 [2].

The stray field generated by the steering coils at maximum deflection is estimated to be ~200 Gauss on the cavity niobium surface, relatively higher than for the main solenoid because these do not include bucking coils or shielding.

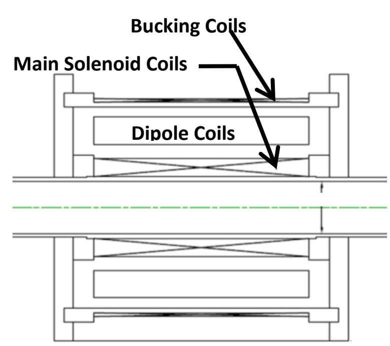

Figure 1: Structure of the coils in the superconducting solenoid magnet integrated with dipole steering coils. The bucking coil is wired in series with the main solenoid coils.

ELECTROPOLISHING FOR LOW-BETA AND QUASI-WAVEGUIDE SRF CAVITIES*

T. Reid[#], P.N. Ostroumov, M. P. Kelly, Z.A. Conway, S. M. Gerbick, M. Kedzie
Argonne National Laboratory, Argonne, IL 60439, U.S.A.

Abstract

Argonne National Laboratory (ANL) has extended high quality electropolishing techniques based on those developed for the International Linear Collider to several more complex superconducting RF cavities. These include the co-axial TEM-mode quarter-wave and half-wave cavities as well as a 2.815 GHz quasi-waveguide structure for beam bunch rotation. This system is an improved version of the one developed for 1.3 GHz 9-cell cavities and includes easy provision for direct water cooling using the helium jacket. The performance of these SRF cavities both in terms of RF fields and losses equals or exceeds that of most 9-cell elliptical cavities built and tested today.

INTRODUCTION

The Superconducting Surface Processing Facility (SCSPF) at ANL is a 200 m^2 laboratory which houses a pair of class 100 clean rooms for HPR and clean assembly, a class 1000 anteroom, and two separate chemistry rooms. The facility was originally designed to support processing of 1.3 GHz 9-cell cavities for the ILC, but has since expanded its capabilities to chemically process accelerating structures of various geometries.

In this paper we present the electropolishing and subsequent cold test results of three distinct cavity geometries. The first of which are β= 0.077, 72.75 MHz quarter-wave resonators (QWR) developed for the ANL ATLAS efficiency and intensity upgrade completed in 2014. The second are β= 0.11, 162.5 MHz half-wave resonators (HWR) currently being developed and fabricated for the PXIE injector experiment at Fermilab. Finally we will briefly review the tooling used to electropolish a 2.815 GHz deflecting cavity for novel beam manipulations.

LOW-BETA CAVITIES

Quarter-wave Cavities for ATLAS

A cryomodule containing seven 72 MHz quarter-wave resonators (QWRs) was recently installed into the ATLAS heavy-ion accelerator as part of the ATLAS Intensity Upgrade (AIU) project [1]. The prototype 72 MHz QWR was the cavity used to commission the newly built low-β EP tool at Argonne in 2011 [2], and developed the procedures generically employed for all of our cavities. The remaining six production cavities followed in 2012 [3]. The low-β EP tool was based on Argonne's experience with the horizontal electropolishing of 1.3 GHz 9-cell cavities for the global ILC effort [4]. One of the unique features of the ANL low-β tool is its versatility which enables the chemical polishing of many different cavity geometries. A QWR is shown in Figure 1. QWRs were the first cavities processed with this tool and the processing sequence used is described below.

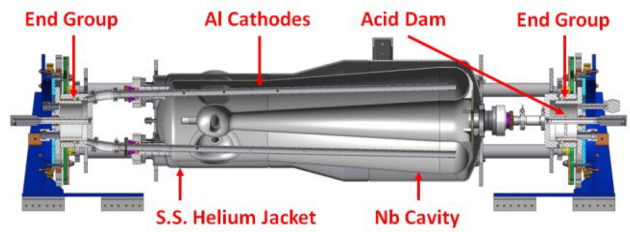

Figure 1: Section view of the low-β EP tool with 72 MHz quarter-wave cavities.

Prior to installation into the low-β EP tool, the finished cavities are ultrasonically cleaned for 60 minutes at 120°F in a 2% liquinox, 98% DI water solution. After the QWR is installed in the ANL low-β EP tool it receives a 20 µm buffered chemical polish (1:1:2; 48% HF: 70% HNO_3: 85% H_3PO_4) to remove the oxide layer formed during the final electrostatic discharge machining (EDM) of the cavity. This BCP step is necessary because the EDM oxide layer is not removed during EP. The BCP process has several similarities to the EP. The first is the helium jacket of the QWR is used for direct water cooling to keep the temperature of the niobium cavity below 17°C, minimizing the risk of contaminating the bulk niobium with hydrogen. Second, the BCP is done in the horizontal position and the cavity is rotated at 0.5 rpm. Since the cavity is not completely filled with the BCP electrolyte, the hydrogen gas which evolves during the procedure bubbles up through the bath and not along the cavity surface. This eliminates the surface pitting and groove formation inherent to the process when the hydrogen gas bubbles travel along the niobium surface.

After the BCP, a bulk 150 µm EP (1:9; 48% HF: 96% H_2SO_4) is performed using four 3003 series aluminium cathodes to achieve uniform polishing of the RF surface. With the low-β EP tool, cathodes are used to flow acid both into and out of the cavity, as well as flow N_2 gas into the cavity RF volume to purge the H_2 gas produced as part of the EP reaction. To accomplish this, a dam sets the acid level at ~60% of the cavity diameter, allowing there to be two cathodes submerged in the acid bath and two cathodes above the acid bath during the majority of the EP process. The two submerged cathodes are used to

Abstract

The multi-bend achromat (MBA) storage ring of the APS Upgrade (APS-U) requires more than 2200 power supplies with either unipolar or bipolar DC output currents. The power supply performance requirements are much more stringent than what can be achieved with commonly available and off-the-shelf commercial power supplies. The power supply output currents must be calibrated to the given specifications and confirmed with independent and accurate measurement. The bipolar power supplies for the fast correction magnets are required to have a wide bandwidth of 10 kHz. There are also new requirements for the power supply controls and communications that are much more demanding than those in the existing APS power supply systems. This paper reports on the conceptual designs of the power supply systems and the R&D programs that have been developed to find solutions to the technical challenges.

INTRODUCTION

The APS Upgrade with an MBA storage ring [1] requires power supplies with a stability better than 10 parts per million (ppm) of the full scale for the dipole, quadrupole, and sextupole magnets. This stability requirement is an order of magnitude more stringent than the original requirement of the existing power supplies, and a factor of two or more than what has been achieved today. The proposed real-time feedback (RTFB) beam orbit correction system has a designed bandwidth of 1 kHz, which requires the power supplies for the fast correctors to have a -3dB and small signal bandwidth at 10 kHz or higher in order to minimize the power supply's impact on the RTFB system. In addition to more demanding power supply performance requirements, there are other requirements to better facilitate the machine operations and the power supply fault identification. Those requirements include independent magnet current measurement, fast control and communication interfaces, and intensive data acquisition to monitor power supply operation status and conditions.

To meet these requirements, the conceptual designs and R&D programs are underway to investigate and evaluate commercial power supply options and to develop technical solutions.

UNIPOLAR DC POWER SUPPLY SYSTEM

The MBA storage ring needs 1000 unipolar power supplies with the output current up to 230 A, which is designated as DCU-230 in the conceptual design. The DCU-230 system is based on a 10 ppm stability-class commercial DC-to-DC power supply with modifications to satisfy the APS needs. The modifications are mostly in the input and output stages of the power supplies in order to utilize the existing APS DC distribution system.

Figure 1 shows a conceptual design of the unipolar power supply system. The system includes a commercial power supply, an external DCCT (DC current transducer) with a high precision measurement circuit for independent performance verification and calibration, and a power supply controller to provide the control and communication interfaces.

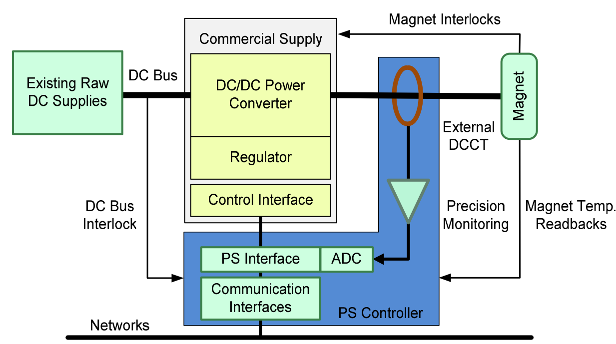

Figure 1: Unipolar power supply system.

Two different commercial power supply approaches have been evaluated through the R&D program. The first approach uses a 200A Danfysik 9100 power supply, which is a current-regulated power supply with a stability specification of 10 ppm. The second approach uses an external current regulator by BiRa Systems and SLAC to regulate a 250A TDK-Lambda Genesys power supply operating in the voltage mode. The evaluation results show that both approaches can meet the stability requirement. During a 7-day and 100A test, both approaches achieved a stability better than 0.5 ppm RMS and better than 5 ppm peak-to-peak. The two approaches were also tested for 24-hour runs with the output currents at 50 A, 100 A, and 200 A, respectively. The largest current deviation during the 24-hour runs is 0.7 ppm RMS and 4 ppm peak-to-peak.

In addition to DCU-230, there is also a requirement of two AC-to-DC power supplies for the L-bend, M1 and M2, dipole magnets. The maximum output currents are 880 A and 500 A, respectively, with the output voltage up to 450 volts. These sorts of power supplies – with a few ppm current stability – are available commercially.

MULTIPLE SCATTERING EFFECTS OF A THIN BERYLLIUM WINDOW ON A SHORT, 2 nC, 60 MeV BUNCHED ELECTRON BEAM

E.E. Wisniewski, M. Conde, W. Gai, J.G. Power, ANL/HEP, Argonne, IL USA
G. Ha, POSTECH, Pohang, Kyungbuk, S. Korea and ANL/HEP, Argonne, IL USA

Abstract

The Argonne Wakefield Accelerator (AWA) 75 MeV drive beamline at Argonne National Laboratory has as its electron source a Cesium telluride photocathode gun with a vacuum requirement on the order of 10^{-10} torr. In conflict with this, the experimental program at AWA sometimes requires beamline installation of experimental structures which due to materials and/or construction cannot meet the stringent vacuum requirement. One solution is to sequester these types of structures inside a separate vacuum chamber and inject the beam through a thin Beryllium window. The downside is that multiple scattering effects degrade the beam quality to some degree which is not well-known. This study was done in an effort to better understand and predict the multiple scattering effects of the Be thin window, particularly on the beam transverse size. The results of measurements are compared with GEANT4 simulations via G4beamline and analytical calculations via GPT.

MOTIVATION FOR USE OF BE WINDOWS AT AWA

The Argonne Wakefield Accelerator beamlines have a demanding vacuum environment, necessary to preserve the Cs_2Te photocathode in the drive gun. Cs_2Te photocathodes require vacuum pressures on the order of 10^{-10} torr, the upper range of Ultra-high vacuum (UHV). The strict vacuum requirements have a large impact on experimental design, severely limiting material choices to those that are UHV compatible. In addition, for all practical purposes, the UHV requirement completely prevents access to experimental structures after installation. Thus, the experiment must work "as installed". If it does not, at best, the consequences can include lengthy downtime while the device under test (DUT) area is vented and the experimental device is uninstalled, modified, cleaned, and re-installed. After this occurs, the experimental section of the beamline must then be pumped and baked to attain UHV vacuum pressure before the operations and the experiment may resume. This typically takes more than one week.

One way of easing the vacuum requirement and also allowing quick and easy access to make changes to the experimental setup is to place a vacuum chamber sequestered behind a Be window at the end of the beamline. The required vacuum pressure in this "dirty" vacuum chamber can be relaxed to 10^{-8} torr, which can be attained in a matter of hours with much fewer restrictions. The downside is the degradation of beam quality due to multiple scattering at the Be window. It is hoped to develop some guidance to be used in planning such installations in the future by trying to measure the effect on the beam and compare it to numerical and analytical predictions.

AWA has had some experience with this limiting effect of the increase in beam transverse size and emittance due to a Be window. Two recent experiments (RF choke cavity and a photonic-bandgap structure) come to mind. Both had an aperture I.D.=6 mm and required the beam to be moved within the aperture from an on-axis position to off-axis without significant beam loss inside the structure. In other words, a tightly focused beam was required with a fairly constant transverse size much less than the aperture I.D. Performing these experiments with a beam through a Be window was indeed a challenge.

SIMPLE FORMULA FOR MULTIPLE SCATTERING ANGLE

An electron beam traveling through matter primarily interacts with the nuclei via the Coulomb force. Electrons experience many mostly small deflections as they scatter multiple times within the media. The distribution of scattering events is described by Moliere's theory. The details of the theory are beyond the scope of this paper.

The Review of Particle Physics [1] presents a simplified equation based on a Gaussian approximation to Moliere's theory for the multiple scattering angle. For $\theta_0 = \theta_{rms\ plane} = \frac{1}{\sqrt{2}}\theta_{rms\ space}$. The width is:

$$\theta_0 = \frac{13.6\text{MeV}}{\beta pc} z \sqrt{\frac{x}{X_0}} \times (1 + 0.038) \ln\left(\frac{x}{X_0}\right)) \qquad (1)$$

for a relativistic electron beam of momentum p, velocity βc, charge number z, and scattering due to a foil of thickness x, made of material with radiation length X_0. Eq. 1 is accurate to 11% or better for the range $10^{-3} < x/X_0 < 100$ [1].

For the AWA drive beam during these tests, $p = 60$ MeV/c. And for the thin Be window: x = foil thickness (0.007" = 178 μm = 0.0178 cm) and X_0= 35.28 cm (beryllium) we finally have $\theta_0 = 0.0036 = 3.6$ mrad. This approximation was the basis of one of the simulations, the results of which are presented later in this paper. Note: This foil thickness results in a value of $x/X_0 = 0.0005$, just outside the quoted range of 11% accuracy, and that value will move further from that range as the foil is made thinner.

TESTING A Be WINDOW AT AWA

A vacuum chamber separate from the beamline vacuum was installed at the end of the drive beamline. The Be window (Materion) is circular with a 2" diameter aperture. The

J/›“RPHOTOCATHODE PERFORMANCE IN THE AWA HIGH-CHARGE HIGH-GRADIENT DRIVE GUN

E.E. Wisniewski, M. Conde, D.S. Doran, W. Gai,
W. Liu, J.G. Power, and C. Whiteford, ANL/HEP, Argonne, IL USA
S.P. Antipov, C. Jing, ANL/HEP Argonne, IL, USA & Euclid TechLabs, LLC, Solon, OH, USA

Abstract

The unique high-charge L-band, 1.3 GHz, 1.5 cell gun for the new 75 MeV drive beam is in operation at the Argonne Wakefield Accelerator (AWA) facility (see M.E. Conde, this proceedings.) The high-field (> 80 MV/m) photoinjector has a large area, high QE Cesium telluride photocathode (diameter > 30 mm). The photocathode, a crucial component of the upgraded facility, is fabricated on-site. The photoinjector generates high-charge, short pulse, single bunches (Q > 100 nC) and long bunch-trains (Q > 600 nC) for wakefield experiments. The performance of the photocathode for the AWA drive gun is detailed. Quantum efficiency (QE) measurements indicate long, stable photocathode lifetime under demanding conditions.

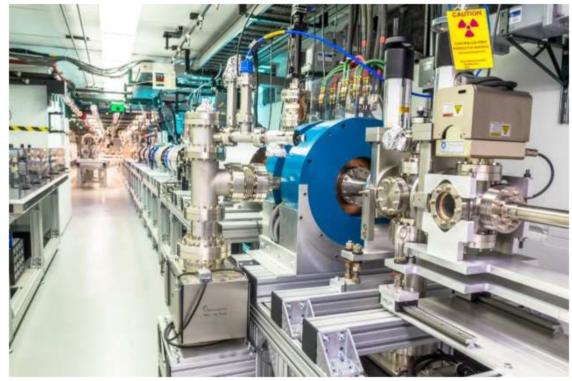

Figure 1: AWA upgrade: The new drive beam photocathode gun, looking in the direction of the beam. In the foreground is the cathode load-lock system.

THE ARGONNE WAKEFIELD ACCELERATOR (AWA) DRIVE PHOTOCATHODE GUN

The AWA L-band drive gun for the new 75 MeV drive linac has been commissioned and is operating. The 1.3 GHz photo-injector operates at high gradient (85 MV/m). The 31 mm dia. Cesium telluride photocathode, specifically designed for the production of high charge, is fabricated on-site. The photoinjector generates high-charge, short pulse, single bunches (Q > 100 nC) and long bunch-trains (Q > 600 nC) for wakefield experiments. A load-lock system was designed and built in-house for the required vacuum transport and installation of the cathode. The photocathode requirements at AWA were determined by the drive beam parameters. The AWA drive beam parameters are summarized in Table 1 [1].

Table 1: AWA Drive Beam Cathode Operating Parameters

Cathode peak RF field	>85 MV/m
RF pulse length	≈7.6 μs
Average dark current	<5 nC/RF pulse
QE%	>1%
QE lifetime	>1 month
Laser pulse width	1.5 – 8 ps FWHM
Single-bunch charge	100pC to >100nC
Multi-bunch mode:	• up to 50 nC/bunch • 2 to 32 bunches • bunch spacing = 770 ps • Max charge = 0.6 μC

PHOTOCATHODE FABRICATION

The method of fabrication used at AWA was based on and developed from methods published by researchers at LANL and INF and described in detail elsewhere [2, 3]. Using those sources for guidance, the AWA Cs_2Te photocathode is fabricated in a UHV chamber with a base pressure of 1.5×10^{-10} Torr.

The natural decline in QE of the photocathode while under UHV conditions can be reversed (up to a point) with a process referred to in the literature as rejuvenation. Previous studies on photocathode rejuvenation have shown a QE recovery up to about 60% of the original value [2, 4]. Two different rejuvenation methods have been reported. Reference [2] reported rejuvenation by heating the photocathode at 120-200°C for a period of several hours to a few days, while Ref. [4] reported that QE rejuvenation required simultaneous heating and illuminating with UV light.

Photocathodes have been rejuvenated at AWA many times, in most cases after the QE has dropped to about 5%. Rejuvenation was achieved by heating the photocathode in the deposition chamber at T=120°C for 1-3 days. The results have shown a minimum increase in QE of 60% above the QE measured just before heating. It was noted that the rejuvenated photocathodes also had a slower QE decay rate in the deposition chamber. This observation lead to applying the heating step immediately after fabrication in an attempt to retard QE decay. It was found that photocathodes formed with this post-deposition heating (annealing) step consistently showed improved QE lifetime. Figure 2 shows a comparison plot of QE lifetime for several photocathodes fabricated with and without the anneal. This plot indicates that QE decays

Abstract

The APS multi-bend achromat (MBA) upgrade storage ring will support two bunch fill patterns: 48 singlets and a 324 singlets. A “swap out” injection scheme is adopted. In order to minimize beam loss and residual oscillation of the injected beam and to minimize perturbation of the stored beam during a swap-on injection, the rise, fall, and flat-top parts of the kicker pulse must be held within a 22.8-ns interval. Traditional ferrite-core-type kickers can’t meet the timing requirements; therefore, we decided to use stripline-type kickers. We have completed a preliminary design of a prototype kicker geometry. Procurement of the pulser supply and other components of an evaluation system is under way. We report the specification and design of the fast kicker and current status.

2-D KICKER MODEL

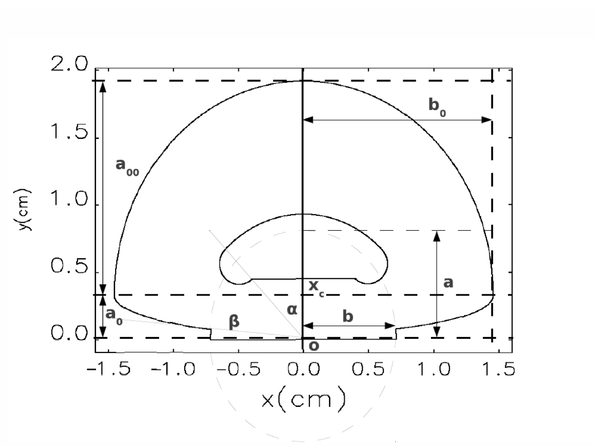

Figure 1: Geometry of the stripline kicker 2-D model.

The basic shape of the kicker stripline is shown in Figure 1. Specifications of the MBA injection/extraction kickers are listed in Table 1. Two-blade stripline type kickers with a line impedance of 50 Ω are selected, mainly due to fast rise and fall time, high voltage requirement and commercial availability of vacuum feedthroughs, connectors and cables. Similar devices have successfully been developed at KEK [1] and DAΦNE [2]. Impedance-matching plays an essential role in achieving maximum kicker strength, reducing local high-voltage concentration that can lead to breakdown, and minimizing beam impedances. Our optimization strategy is to match the differential impedance as close as possible to 50 Ω while allowing some mismatch in the common-mode impedance. A “vaned” outer body geometry is adopted to ease common-mode impedance-matching, while “D” shaped blades are used to improve field-uniformity in the good field region. The kicker has tapered end sections for matching impedance to the feedthroughs. Optimization is performed by running a multi-objective sddsoptimize [3] process with a 2-D simulation program [4]. Figure 1 shows the parametrization of geometry. The outer shell consists of two connected half-ellipses defined by the half axes (a0; b0) & (a00; b0), the center xc and the vanes on the horizontal axis. The inner blade is defined by an ellipse with axes (a, b), and by the thickness of the blade. Table 2 lists optimized parameters, and Figure 2 shows the 2-D E-field distribution. Results of the optimized parameters are shown in Table 2.

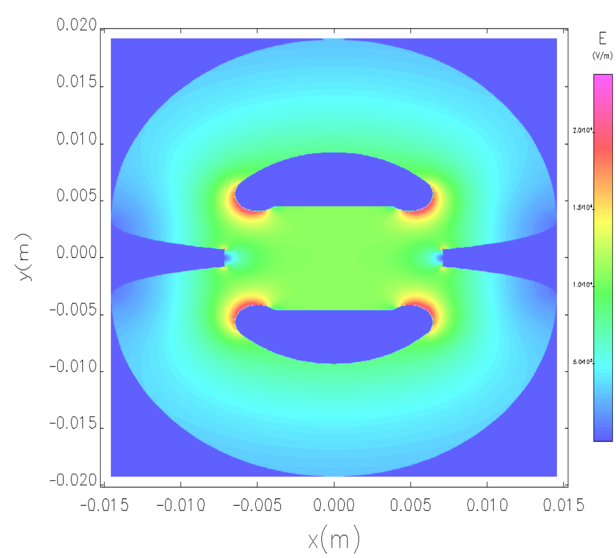

Figure 2: Field distribution of 2-D optimized model.

3-D MODELING

A 3-D simulation was performed with CST studio [5] in order to further verify 2-D result and to optimize the tapered part of the stripline kicker. The tapered parts are shown in Figure 3. Both the dimension of the body cavity and the width of the blades reduce gradually. The interface between the blade and the inner conductor of the feedthrough is under development. Optimization is performed on the blade width and the shape of the interface to minimize reflections. Figure 4 shows the TDR

Abstract

Beryllium is extensively used in various accelerator beam lines and target facilities as material for beam windows, and to a lesser extent, as secondary particle production targets. With increasing beam intensities of future accelerator facilities, it is critical to understand the response of beryllium under extreme conditions to avoid compromising particle production efficiency by limiting beam parameters. As a result, the planned experiment at CERN's HiRadMat facility will take advantage of the test facility's tunable high intensity proton beam to probe and investigate the damage mechanisms of several grades of beryllium. The test matrix will consist of multiple arrays of thin discs of varying thicknesses as well as cylinders, each exposed to increasing beam intensities. Online instrumentations will acquire real time temperature, strain, and vibration data of the cylinders, while Post-Irradiation-Examination (PIE) of the discs will exploit advanced microstructural characterization and imaging techniques to analyze grain structures, crack morphology and surface evolution. Details on the experimental design, online measurements and planned PIE efforts are described in this paper.

INTRODUCTION

Beryllium is currently widely used as the material of choice for beam windows, as well as secondary particle production targets, in many accelerator beam lines and target facilities. With the increasing beam intensities of future accelerators [1,2], it is essential to evaluate the performance of beryllium under even more extreme conditions to successfully design and reliably operate windows and targets, without compromising particle production efficiency by limiting beam parameters.

An upcoming experiment at CERN's HiRadMat facility [3] will test beryllium specimens exposed to intense proton beams. The test facility is able to deliver high intensity proton beams, up to 4.9×10^{13} protons per 7.2 μs pulse (288 bunches), with a Gaussian beam sigma ranging from 0.1 mm to 2 mm [4]. The main objectives of the experiment are to explore the onset of failure modes of beryllium under controlled conditions at highly localized strain rates and temperatures, identify any thermal shock limits, and validate highly non-linear numerical models with experimental measurements.

EXPERIMENTAL SET-UP

The test rig is based on a double containment design to ensure containment of the beryllium specimens and any potential radioactive contamination created from beam interaction. The specimens will be arranged in four horizontal arrays aligned vertically in a single column. Figure 1 shows the test chamber positioned on the HiRadMat mobile table.

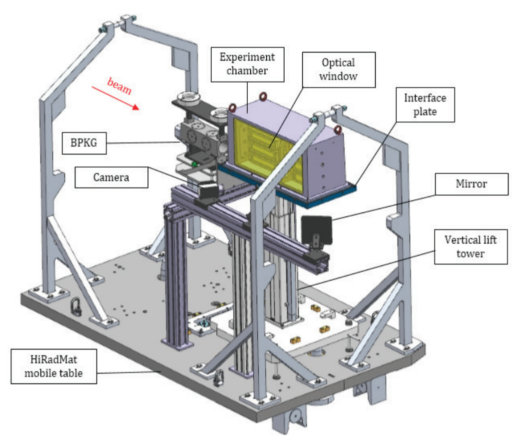

Figure 1: Test chamber positioned on mobile table.

The experiment chamber is an outer containment box, which encloses the specimen inner containment boxes. Small apertures on the outer box allow the beam to enter and exit, using a shutter system to provide post-experiment containment. Additionally, the internal volume of the outer chamber is continuously evacuated by a pump which draws the air out of the box via a HEPA filter (not shown in Figure 1). The continuous pumping and lower pressure within the outer chamber ensures no airborne particulate escapes the containment box. The HEPA filter will be analyzed upon completion of the experiment to check for any containment breach of the array boxes.

Specimen Housing

As shown in Figure 2, each specimen type within an array is enclosed in a separate containment box, sealed with glassy carbon beam windows [5]. Gafchromic foils are po-

RF MODELLING OF A HELICAL KICKER FOR FAST CHOPPING*

M. Awida#, G. Sawert, A. Chen, T. Khabiboulline, and V. Yakovlev
Fermilab, Batavia, IL 60510, USA

Abstract

High intensity proton particle accelerators that support several simultaneous physics experiments require sharing the beam. A bunch by bunch beam chopper system located after the Radio Frequency Quadrupole (RFQ) is required in this case to structure the beam in the proper bunch format required by the several experiments. The unused beam will need to be kicked out of the beam path and is disposed in a beam dumb. In this paper, we report on the RF modelling results of a proposed helical kicker. Two beam kickers constitute the proposed chopper. The beam sequence is formed by kicking in or out the beam bunches from the streamline. The chopper was developed for Project X Injection Experiment (PXIE).

INTRODUCTION

PIP-II is a proposed high intensity superconducting accelerator to be built in Fermilab to replace the current 40 year old Linac injector of the accelerator complex. The new SRF Linac will secure the required Megawatt beam power required by the laboratory's future experiments, in particular by the Long Baseline Neutrino Experiment (LBNE) [1-2].

PXIE, Project-X injection experiment is planned to test the integrated systems of PIP-II (formerly called Project-X). Among those systems is the chopping mechanism in the Medium Energy Beam Transport (MEBT).

Having the beam shared between several experiments with different bunch sequences (as might happen in the future) puts a stringent specification on the overall bunch sequence supplied by the accelerator. In order to achieve the required bunch sequence, it is planned to have a bunch-by-bunch chopper located in the 2.1 MeV Medium Energy Beam Transport (MEBT) [3].

Figure 1 illustrates the function of the chopper in the MEBT section of PXIE. The beam originates from a 5 mA DC H- source and is then bunched and accelerated by a CW normal-conducting RFQ to energy of 2.1 MeV. A chopper system with a pre-programmed timeline is used then to format the bunch pattern and structure the beam.

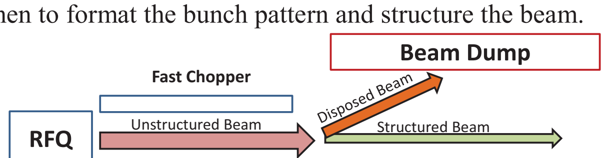

Figure 1: Simplified block-diagram of the Medium Energy Transport (MEBT) of PXIE indicating the function of the chopper.

*Operated by Fermi Research Alliance, LLC, under Contract DE-AC02-07CH11359 with the U.S. DOE
#mhassan@fnal.gov

Since the Linac pulsed beam current is limited to 2 mA and the beam current of the ion source can be as high as 5 mA, undesired beam bunches has to be removed by the chopper in normal operating conditions. The unused beam will get disposed in a beam dump.

GEOMETRY OF THE KICKER

The proposed kicker structure is a pair of traveling wave helices positioned on opposite sides of the beam [4]. The helices are wound with 13 gauge flat wire and are supported above a copper ground tube with four narrow ceramic spacer strips positioned every 90 degrees, as shown in in Fig. 2. Applied kicking voltages propagate along the helix at a speed matching the beam velocity having a beta = 0.0667. Flat, field-shaping electrodes are welded to every turn of wire on the side facing the beam. The resulting helix structure has a 200 Ω characteristic impedance.

Full 3D helical kicker models were built to carry out transient time electromagnetic simulation using CST microwave studio [5]. 200 Ohm excitation ports were used in the transient simulations.

DEVELOPMENT OF 650 MHz β=0.9 5-CELL ELLIPTICAL CAVITIES FOR PIP-II*

M. Awida#, M. Foley, C. Grimm, I. Gonin, T. Khabiboulline, A. Lunin, and V. Yakovlev
Fermilab, Batavia, IL 60510, USA

Abstract

5-cell 650 MHz elliptical cavities are being developed for the Proton Improvement Plan II (PIP-II) of Fermilab. The cavities are designed to accelerate protons of relative group velocity β=0.9 at the high energy part of the linear particle accelerator. In this paper, we report on the status of these cavities and summarize the results of the quality control measurements performed on four initial prototypes.

INTRODUCTION

Fermilab is proceeding with the Proton Improvement Plan PIP-II, which will revamp Fermilab's accelerator complex to meet future needs of Megawatt high intensity proton beam. PIP-II relies on replacing the current 40 years old 400 MeV normal conducting injector linear accelerator with an 800 MeV superconducting one with higher average beam current [1-2].

Two types of elliptical superconducting cavities are employed in the proposed superconductor Linac to accelerate the beam at relatively higher energies; specifically at a relative group velocity of 0.6 and 0.9 [2]. Both types of cavities consist of 5-cell and are operating at 650 MHz. Four prototypes of the 650 MHz β=0.9 5-cell cavity were fabricated by Advanced Energy Systems (AES) and were received at Fermilab. Prototype cavities passed the typical quality control process at Fermilab from visual inspection, and Coordinate Measurements (CMM). Meanwhile, RF measurements have been also performed on the prototype cavities.

In this paper, we report on the latest RF measurements results carried out to assess the spectrum, field flatness, and existence of trapped modes in the prototype cavities. In addition we present some of the latest simulations and analyses carried out to improve the performance of the 650 MHz β=0.9 5-cell cavity.

MICROPHONICS AND LFD DETUNING

We have studied both the frequency sensitivity to pressure fluctuation df/dP, and Lorentz Force Detuning LFD in the 650 MHz β=0.9 5-cell cavity dressed with helium vessel (HV) using Comsol Multipysics [3]. Upon coupling the electromagnetic problem to the solid mechanics one, we were able to calculate the frequency sensitivity coefficients. The resonance frequency of the π-mode is calculated before and after applying the pressure load. Deformation is calculated using the solid mechanics module then the mesh is deformed with the resultant displacement values to acquire the frequency change.

*Operated by Fermi Research Alliance, LLC, under Contract DE-AC02-07CH11359 with the U.S. DOE
#mhassan@fnal.gov

The mechanical design of the cavity's helium vessel underwent several iterations [4]-[6] in order to minimize the df/dP coefficient. The first generation of the HV design adopted a blade tuner with a 441 mm diameter bellows [4]. Later on a modified design was presented in [5]-[6] with an end tuner that can afford smaller diameter bellows.

Figure 1 depicts that cavity geometry with the blade and end tuner locations indicated. Also the stiffening ring size is an important factor that changes the stiffness of the cavity and thus affects the frequency sensitivity coefficients. Fig. 2(a) demonstrates how the df/dP coefficient and the stiffness changes versus the radius of the stiffening rings. It is clear that by increasing the stiffening ring radius, the cavities becomes stiffer reducing the frequency sensitivity coefficient df/dP.

ANALYSIS OF A QUASI-WAVEGUIDE MULTICELL RESONATOR FOR SPX *

M. Awida#, I. Gonin, A. Lunin, T. Khabiboulline, and V. Yakovlev, Fermilab, Batavia, IL 60510
A. Zholents, ANL, Lemont, IL 60439, USA

Abstract

A compact deflecting cavity is needed for the Short Pulse X-rays (SPX) at the Advanced Photon Source (APS) of Argonne national laboratory. The deflecting cavity has to be quite efficient, providing a 2 MV kick voltage and satisfying stringent requirements on aperture size and total cavity length. Meanwhile, the cavity should allow operation up to 100 mT peak surface magnetic field before quenching. In this paper, we report on the latest analysis carried out on the cavity structure to investigate frequency sensitivity to pressure fluctuations, frequency sensitivity to tuning forces, mechanical resonances, and wakefield losses.

INTRODUCTION

A compact deflecting cavity was under development in a collaboration effort between Fermi and Argonne national laboratories to produce an efficient deflecting structure to be used in the Short Pulse X-rays (SPX) at the Advanced Proton Source (APS) of Argonne national laboratory. Using a deflecting cavity for SPX was initially suggested by Zholents, et al. in [1].

The cavity was designed to meet stringent requirements on both electromagnetic and mechanical performances. Table 1 lists the design parameters of the APS deflecting cavity, which operates at 2.815 GHz with an optimal group velocity of 1. The cavity should produce a nominal kick voltage of 2 MV, while keeping the peak surface electric field below 55 MV/m to avoid surface emission and the peak surface magnetic field below 80 mT to avoid thermal quench. Based on beam dynamics, the aperture of the cavity was required to be 12 mm x 30 mm.

Cavity design underwent several iterations to meet the specified design goals and in addition lower the higher order modes losses and simplify the fabrication process. Final electromagnetic design was reported in [2] with detailed higher order mode analysis. The cavity design named Quasi-waveguide Multicell Resonator (QMiR) is shown in Fig. 1. The proposed design meets the requirements and sustains a peak surface electric field of 54 MV/m and a peak surface magnetic field of 75 mT at the nominal operating kick of 2 MV. The designed cavity has a G-factor of 130 Ω.

Argonne successfully constructed a cavity prototype for the QMiR structure and initial testing results were reported in [3].

In this paper, we present the analysis carried out on the QMiR structure to examine the frequency sensitivity to pressure fluctuations and tuning forces. In addition modal and wakefield analyses are also reported.

QMIR DEFLECTING CAVITY

Figure 1 shows the geometry of the QMiR cavity. The cavity consist of 3-cells. Each cell shape was optimized to lower the surface fields as explained in [2]. The cavity operates at 2.815 GHz in the transverse electric TE dipole mode, which is needed to produce the required transverse kick. The power coupler is located on the side of the cavity and its position was optimized to lower the external quality factor of higher order modes (HOM).

The cavity prototype was machined from a solid brick of Niobium. Fig. 1(b) shows a section of the cavity with the Niobium walls highlighted. Series of blind holes is to be used for cooling the high magnetic field areas at the cell centers.

TRANSVERSE FIELD PERTURBATION FOR PIP-II SRF CAVITIES*

P. Berrutti#, T. N. Khabiboulline, V. Lebedev, V. P. Yakovlev, Fermilab, Batavia, IL, 60510 USA

Abstract

Proton Improvement Plan II (PIP-II) consists in a plan for upgrading the Fermilab proton accelerator complex to a beam power capability of at least 1 MW delivered to the neutrino production target. A room temperature section accelerates H- ions to 2.1 MeV and creates the desired bunch structure for injection into the superconducting (SC) linac. Five cavity types, operating at three different frequencies 162.5, 325 and 650 MHz, provide acceleration to 800 MeV. This paper presents the studies on transverse field perturbation on particle dynamic for all the superconducting cavities in the linac. The effects studied include quadrupole defocusing for coaxial resonators, and dipole kick due to couplers for elliptical cavities. A multipole expansion has been performed for each of the cavity designs including effects up to octupole.

INTRODUCTION

PIP-II stands for Proton Improvement Plan-II [1] which is Fermilab plan for future improvements to the accelerator complex. The upgrade is aimed at providing LBNE (Long Base Neutrino Experiment) operations with a beam power of at least 1 MW on target. The central element of the PIP-II is a new 800 MeV superconducting linac, injecting into the existing Booster. The PIP-II 800 MeV linac is a derivative of the Project X Stage 1 design. The room temperature (RT) section includes a Low Energy Beam Transport (LEBT), RFQ and Medium Energy Beam Transport (MEBT), accelerating H- ions to 2.1 MeV and it creates the desired bunch structure for injection into the superconducting (SC) linac. This article focuses on the SC linac and its five cavity types, half wave resonator (HWR), single spoke resonator (SSR1 and SSR2), low beta (LB) and high beta (HB) elliptical cavities. The technology map of the PIP-II linac, Fig. 1, shows the transition energies between accelerating structures, and the transition in frequency, HWR operates at 162.5 MHz (same as RT section), SSR1 and SSR2 at 325 MHz, LB and HB elliptical cavities at 650 MHz.

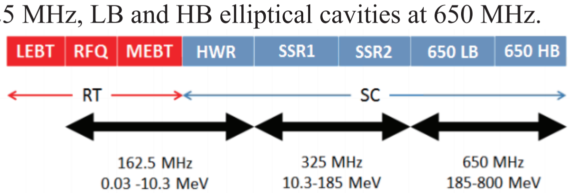

Figure 1: PIP-II linac technology map.

The three families of coaxial resonators show quadrupole perturbation to the transverse fields [2], this is due to the inner electrode which breaks the azimuthal symmetry of the cavity. Elliptical cavities do not have inner posts, but the transverse symmetry is broken by the coupler port on top of the beam tube, leading to a dipole perturbation to the transverse fields. All the results presented are based on EM fields simulated with Comsol multi-physics, the simulation technique requires local mesh refinement around the beam axis to improve transverse field quality. In this article transverse field perturbation is calculated and analyzed for all the cavities in the SC linac of PIP-II, multipole expansion has been performed to show if any higher order effect on the beam dynamic can be present, e.g. sextupole and octupole.

TRANSVERSE KICK

The transverse momentum gain is calculated by direct integration of the electric and magnetic fields transverse to the beam direction. Considering the z axis as the longitudinal (beam) direction, electric and magnetic fields will have x and y components. Assuming the particle velocity constant along z axis, β is constant, one can write:

$$\Delta p_x(r,\alpha)c = \int_{z_i}^{z_f}\left(\frac{E_{x(r,\alpha)}}{\beta} - \boldsymbol{Z}_0 iH_y(r,\alpha)\right)e^{i\frac{kz}{\beta}}dz \qquad (1)$$

$$\Delta p_y(r,\alpha)c = \int_{z_i}^{z_f}\left(\frac{E_y(r,\alpha)}{\beta} + \boldsymbol{Z}_0 iH_x(r,\alpha)\right)e^{i\frac{kz}{\beta}}dz \qquad (2)$$

$\Delta p_x(r,\alpha)c$ and $\Delta p_y(r,\alpha)c$ are functions of the radius and the angle α on the x-y plane, α is taken with respect to the x axis: α=0 corresponds to x axis and α=π/2 refers to y axis. For low-beta structures, the radial component variation will be maximum between the kick on x and on y axis; to have an estimation of the asymmetry one can define a parameter called Q:

$$Q = \frac{\Delta p_x(r,0)c - \Delta p_y(r,\pi/2)c}{(\Delta p_x(r,0)c + \Delta p_y(r,\pi/2)c)/2}. \qquad (3)$$

Asymmetry parameter Q gives partial information on the transverse kick, evaluating $\Delta p_R c$ on the whole x-y plane, it is possible to calculate the multipole expansion of the transverse momentum gain:

$$\Delta p_R c(r,\alpha) = A_0(r) + \sum_{n=1}^{\infty} A_n(r)\cos(n\alpha) + B_n(r)\sin(n\alpha) \qquad (4)$$

where $A_n(r) \propto nr^{n-1}$ and $B_n(r) \propto nr^{n-1}$ are the Fourier series coefficient of $\Delta p_R c$ while $A_0(r) \propto r$ and it is the mean value. One coefficient set out of two has non zero values and the other vanishes. Normal or skew components are due to the symmetry of the problem and to the choice frame of reference to define x-y plane. The transverse kick has been expanded up to octupole, corresponding to $n = 4$.

DESIGN OF A MARX-TOPOLOGY MODULATOR FOR FNAL LINAC*

T.A. Butler#, F.G. Garcia, M.R. Kufer, H. Pfeffer, D. Wolff, FNAL, Batavia, IL 60510, USA

Abstract

The Fermilab Proton Improvement Plan (PIP) was formed in late 2011 to address important and necessary upgrades to the Proton Source machines (Injector line, Linac and Booster). The goal is to increase the proton flux by doubling the Booster beam cycle rate while maintaining the same intensity per cycle, the same uptime, and the same residual activation in the enclosure. For the Linac, the main focus within PIP is to address reliability. One of the main tasks is to replace the present hard-tube modulator used on the 200 MHz RF system. Plans to replace this high power system with a Marx-topology modulator, capable of providing the required waveform shaping to stabilize the accelerating gradient and compensate for beam loading, will be presented, along with development data from the prototype unit.

INTRODUCTION

The Fermi National Accelerator Laboratory (FNAL) Linear accelerator accelerates H^- beam pulses from 750 keV up to 400 MeV. The lower energy Linac section, built in 1969, uses 201.25 MHz Alvarez style drift tube cavities powered by a 5 MW triode power tube (therein referred as 7835) accelerating beam up to 116 MeV, while the higher energy section uses 805 MHz side coupled cavities powered by a klystron to boost the beam energy to 400 MeV. The 7835 is plate modulated using a hard-tube topology modulator where a high voltage capacitor bank provides energy that is switched via three parallel grid-controlled electron tubes to regulate the anode on the triode. These series-pass tubes were discontinued in the early 2000s, so in order to sustain operations, these tubes required the development and management of a dedicated maintenance schedule in order to rebuild depleted tubes. This approach has been extending the life of the present modulator, but is not sustainable for long term operations.

Within the Proton Improvement Plan (PIP) [1], the chosen path to mitigate this reliability issue was to replace the hard-tube modulator with a modern solid state modulator which improves reliability, lowers operational costs while maintaining the same waveform accuracy required to accelerate the beam. The main challenge in designing a replacement for the present hard-tube modulator is achieving the waveform shaping that is required to regulate the accelerating cavity fields. Unlike other Linac RF systems, which typically use direct feedback (driving the RF input to the power amplifier to regulate gradient), the 7835 triode amplifier uses the plate voltage to regulate the cavity field, requiring a modulator capable of creating an adaptable waveform to compensate for beam loading and overshoot for filling the cavity.

*Operated by Fermi Research Alliance, LLC under Contract No. De-AC02-07CH11359 with the United States Department of Energy.
tbutler@fnal.gov

PRESENT MODULATOR TOPOLOGY AND SPECIFICATIONS

The present tube based modulator acts essentially as a large operational amplifier with finite gain. When operated in an analog feedback loop, it has the ability to regulate its output to any desired shape, which is presently chosen as a trapezoidal ramped waveform. Furthermore, this system compensates in real time for pulse-to-pulse gain changes, which are present in many amplifier stages. By choosing the feedback signal as the peak detected accelerating cavity gradient, the feedback system is able to regulate the cavity fields with ~0.2%. In Table 1, a subset of the most critical parameters for the modulator are listed.

Table 1: Linac Modulator Specifications

Parameter	Value	Units
Maximum Voltage	35	kV
Maximum Current	375	A
Voltage Regulation	±25	V
Minimum Slew Rate	15	kV/µs
Maximum Rise/Fall Step	1.5	kV
Maximum Beam Step	8	kV
Maximum Beam Tilt	±5	kV
Maximum Pulse Width	460	µs
Variable Rise/Fall Time	50-150	µs
Pulse Repetition Rate	15	Hz

NEW MODULATOR DESIGN

A careful study of the numerous alternative options were conducted and down-selected to the two best designs. Among the alternative options were 1) replace the modulator with another hard-tube modulator; 2) replace with industry developed solid state modulator and 3) adapt the Marx-topology modulator developed by SLAC for the International Linear Collider (ILC) project [2]. Despite having strong features most of the options would involve significant development costs in order to meet the desired operational requirements. In particular, the later was extensively studied, but it had slightly higher cost and more engineering time required to convert the design to operate in real time feedback, which is critical for meeting the desired operational requirements [3]. Therefore, the best option chosen for Linac was to design a new system, based on Marx-topology modulator which was designed to meet the critical specifications with the ability to run in real time feedback without compromising any other requirements.

Abstract

In this study we prove that the mechanism at the basis of quality factor degradation due to quench involves the entrapment of ambient magnetic field. The cavity quench in the absence of magnetic field does not introduce any extra losses, and a clear trend between the external field and the extra losses introduced by the quench was observed.

It is demonstrated that the quality factor can be totally recovered by quenching in zero applied magnetic field. A dependence of the amount of quality factor degradation on the orientation of the magnetic field with respect to the cavity was also found.

INTRODUCTION

Superconducting accelerator cavities are devices used in accelerator physics to accelerate charged particles [1, 2]. Such accelerating structures are limited in field (E_{acc}) by the quench of the superconductive state, which leads to the break-down of the resonating electromagnetic field. During such phenomenon a normal conducting region is created on the cavity wall, whose dimension is related to the stored energy of the cavity at the moment of quench. When this normal conductive hole opens, some magnetic flux may be trapped [3], adding extra losses to the resonator and lowering its quality factor (Q_0).

Several different hypotheses where formulated in the past regarding the origin of trapped magnetic field during the quench, such as: thermocurrents driven by the local thermogradient in the quench zone [3], RF field trapped in the penetration depth, or ambient magnetic field. In this study the results obtained at Fermilab, indicate that trapping of ambient magnetic field is the principal cause of the quench-related Q_0 degradation, ruling out the other two proposed mechanisms.

EXPERIMENTAL SET-UP

In this study we used a bulk niobium 1.3 GHz TESLA type cavity nitrogen-doped with the recipe adopted for LCLS-II: 2 min at 800°C in 20 mTorr of N_2 plus a diffusion step of 6 min at 800°C followed by 5 μm EP removal. All the vertical tests were performed at the Fermilab vertical test facility.

The schematic of the setup is shown in Fig. 1. In order to resemble as much as possible the cryomodule situation, the cavity was hanged in the cryostat horizontally, so the cooling started at the very bottom equator point to the very top - also equator - point of the cavity. The cavity was equipped with two Helmholtz coils, capable of creating the magnetic field parallel and orthogonal with respect to the cavity axis, and the magnetic field was measured by means of four single-axis Bartington Mag-01H cryogenic flux-gates magnetometers. Two flux-gates were aligned axially to the cavity, one on top and the other at the middle position, while the other two were set vertically, one on top and one at the bottom.

The helium bath temperature was always maintained around 1.5 K, so the temperature dependent part of the surface resistance can be neglected. The quench study was performed by recording the degradation of Q_0 at the fixed accelerating field after RF quenching the cavity ($E_{quench} \simeq 29 MV/m$) in the presence of external magnetic field. After every quench we also tried to recover the Q_0 by quenching in zero magnetic field.

RESULTS AND DISCUSSION

We performed two series of quenching with either non-zero axial or non-zero orthogonal components of the ambient field H only. The change in the residual resistance

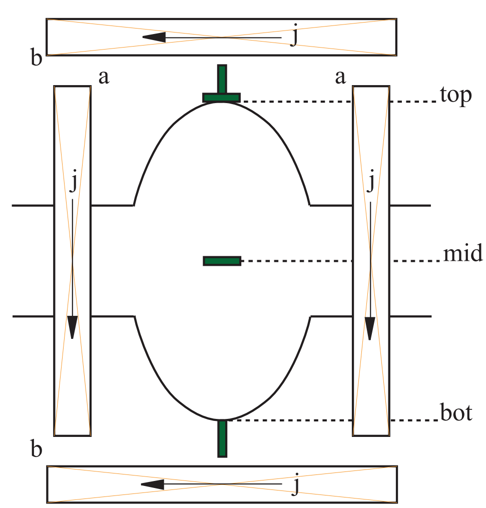

Figure 1: Experimental set-up. The flux-gates are represented by green rectangles, while the letters *a* and *b* indicate the two Helmholtz coils: axial and orthogonal respectively.

MODIFICATIONS OF SUPERCONDUCTING PROPERTIES OF NIOBIUM CAUSED BY NITROGEN DOPING RECIPES FOR HIGH Q CAVITIES*

A. Vostrikov#, Y.-K. Kim, University of Chicago, Chicago, IL 60637, USA
A. Romanenko, A. Grassellino, FNAL, Batavia, IL 60510, USA

Abstract

A study is presented on the superconducting properties of niobium used for the fabrication of the SRF cavities after treating by recently discovered nitrogen doping methods. Cylindrical niobium samples have been subjected to the standard surface treatments applied to the cavities (electropolishing, 120C bake) and compared with samples treated by additional nitrogen doping recipes routinely used to reach ultra-high quality factor values ($>3\cdot10^{10}$ at 2K, 16MV/m). The DC magnetization curves and the complex magnetic AC susceptibility have been measured.

Evidence for the lowered field of first flux penetration after nitrogen doping is found suggesting a correlation with the lowered quench fields. Superconducting critical temperatures T_c = 9.25 K are found to be in agreement with previous measurements, and no strong effect on the critical surface field (B_{c3}) from nitrogen doping was found.

INTRODUCTION

Superconducting radio frequency (SRF) cavities are the key technology for future particle accelerators for high-energy physics, nuclear physics, light sources, and accelerator-driven subcritical reactors. Several decades of SRF research and development at laboratories and universities worldwide have led to the successful realization of niobium cavities that reliably achieve very high gradients and quality factors.

Recent breakthrough discovery at Fermilab demonstrated positive impact on cavity's quality factor from the doping of certain amount of nitrogen into niobium cavity walls. However, this treatment reduces somewhat the maximum gradient achievable in the cavity, i.e. reduction of quench field takes place. It was demonstrated that SRF cavities, which surfaces prepared with electrolytic polishing (EP) method and low temperature (120ºC) bake-out for 48 hours, can have quench fields over 40 MV/m, while cavities which undergone nitrogen doping are limited by a quench field of 25-30 MV/m. [1]

Magnetic measurements on niobium samples are a useful tool to investigate the effect of nitrogen doping on niobium critical fields. The experimental studies on the magnetization and susceptibility of niobium samples presented in the paper have been carried out with the aim to gain an understanding of superconducting properties change by nitrogen doping.

*Work supported by DOE HEP.
#vostrikov@uchicago.edu

EXPERIMENTAL PROCEDURE

The samples for the magnetization and susceptibility measurements are cylinders with diameter of 2.85 mm and a height of 7.0 mm, which are cut from RRR~300 fine grain niobium sheets used for SRF cavity production. Bulk EP of ~120 um removal was done on all samples. After that, one of the samples was baked for 48 hours at 120ºC in the vacuum. Such surface preparation in SRF cavities typically leads to maximum accelerating fields of 40 MV/m and above. Two other samples are prepared using different nitrogen doping recipes, which found to deliver SRF cavities with optimal quality factor ($>2.7\cdot10^{10}$ and above at 16 MV/m and 2 K). The procedure of surface treatment (after initial bulk EP) is the following:

- high temperature bake at 800ºC for 3 hours in vacuum;
- bake at 800ºC for time t_1 with nitrogen gas in the chamber (diffusion of nitrogen into niobium happens);
- after diffusion bake at 800ºC for time t_2 in vacuum (diffused nitrogen redistributes inside the niobium walls to produce desired nitrogen concentration profile);
- 5 µm surface layer removal by EP (nitrides formed at the surface removed, desired surface concentration of nitrogen is achieved).

Time parameters t_1 and t_2 are subject to optimization. Optimal in terms of quality factor recipes have the following parameters: t_1 = 2 min, t_2 = 6 min and t_1 = 20 min, t_2 = 30 min. Cavities prepared with the first recipe have quench fields of up to ~30 MV/m. Cavities prepared with the second recipe have quench fields of up to~25 MV/m. One more presented sample had no extra treatment after bulk EP.

Sample DC magnetization is measured with a commercial magnetometer (Quantum Design PPMS) at 2 K in external DC magnetic field between zero and 1 T. The same system is also used for AC susceptibility measurements. A frequency of 10 Hz and AC field amplitude of 0.2 mT allow good noise suppression and an acceptable measurement time. In all measurements external magnetic fields are aligned parallel to the symmetry axis of the cylindrical samples.

The demagnetization factor was calculated according to the theoretical expression [2]

$$N_Z = 1 - \frac{1}{1 + \frac{d}{h}\left(\frac{4}{3\pi} + \frac{2}{3\pi}\tanh\left(1.27\frac{h}{d}\ln\left(1 + \frac{d}{h}\right)\right)\right)},$$

LBNF 1.2 MW TARGET: CONCEPTUAL DESIGN & FABRICATION*

C. Crowley#, K. Ammigan, K. Anderson, B. Hartsell, P. Hurh, J. Hylen, R. Zwaska
FNAL, Batavia, IL 60510, USA

Abstract

Fermilab's Long-Baseline Neutrino Facility (LBNF) will utilize a modified design based on the NuMI low energy target that is reconfigured to accommodate beam operation at 1.2 MW. Achieving this power with a graphite target material and ancillary systems originally rated for 400 kW requires several design changes and R&D efforts related to material bonding and electrical isolation. Target cooling, structural design, and fabrication techniques must address higher stresses and heat loads that will be present during 1.2 MW operation, as the assembly will be subject to cyclic loads and thermal expansion. Mitigations must be balanced against compromises in neutrino yield. Beam monitoring and subsystem instrumentation will be updated and added to ensure confidence in target positioning and monitoring. Remote connection to the target hall support structure must provide for the eventual upgrade to a 2.4 MW target design, without producing excessive radioactive waste or unreasonable exposure to technicians during reconfiguration. Current designs and assembly layouts will be presented, in addition to current findings on processes and possibilities for prototype and final assembly fabrication.

CONCEPTUAL DESIGN

The 1.2 MW fin width has increased from 6.4 mm to 10 mm, with a roughly 5.5 mm expansion in height to accommodate accident conditions and prevent errant beam with a 1.7mm spot size from striking a cooling line. To mitigate the increased heat generation, cooling loop count was doubled. The outer containment tube also increased in size, gaining a 20% larger O.D., (see Fig. 1).

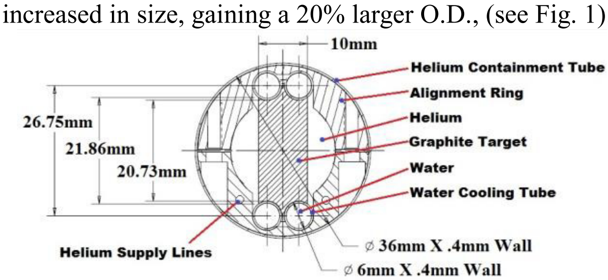

Figure 1: Target core cross section.

Since the design is rooted in a target used on a similar experiment, and with identical focusing horns, some design boundaries apply:

1. Target must be capable of being inserted into horn 1 inner conductor for a low-energy neutrino spectrum.
2. Mass should be kept to a minimum to reduce effects of beam energy deposition on horn conductors.

Target Braze Assembly

The braze assembly consists of twin continuous cooling loops, and forty-seven 20 mm long graphite fins, the first three of which are flared. TiCuNi braze foil at the interface, measuring .05 mm (.002") thick, bonds the assembly by use of specialized fixturing in a vacuum brazing furnace.

Containment Tube

Requirements of the containment tube are that it provide alignment stability, as well as enable the target to withstand a +/-1 atm pressure differential. The target must be pumped down to vacuum for initial installation, then backfilled with helium. This helium flow is piped to the D.S. window for cooling and back out from the target can.

Transition to Down Stream Window

The down stream (D.S.) window will be fabricated from .5 mm (.020") thick beryllium foil, then diffusion bonded to a 3000 series aluminum frame. Transitioning from 3000 series aluminium to grade 2 (CP) titanium requires the use of an explosion bonded or roll bonded Ti-Al bimetal ring. This ring can be fused to the mating halves by means of E-beam welding or micro-TIG welding to achieve a leak tight interface.

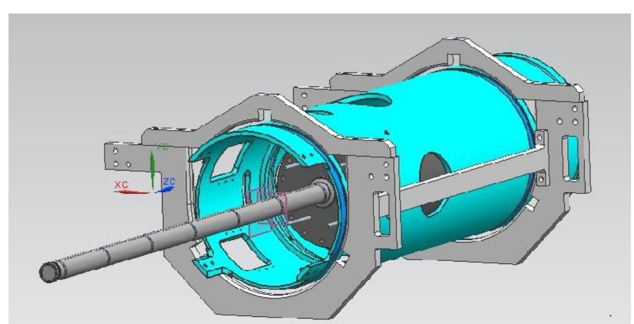

Figure 2: Target core assembly in alignment tube & support frame.

GENERAL LAYOUT & MATERIALS

A notable difference from the NuMI 400 kW design is the absence of a Budal monitor. It was made redundant by vertical & horizontal beam position thermometers located on the U.S. end of the target can. Also present in the 1.2 MW design are additional cooling passages: An outer can water jacket, and a U.S. window and beam position thermometer cooling loop, (see Figs. 2, 3 & Table 1).

LBNF HADRON ABSORBER: MECHANICAL DESIGN AND ANALYSIS FOR 2.4 MW OPERATION*

B. Hartsell†, K. Anderson, J. Hylen, V. Sidorov, S. Tariq, FNAL, Batavia, IL 60510, USA

Abstract

Fermilab's Long-Baseline Neutrino Facility (LBNF) requires an absorber, essentially a large beam dump consisting of actively cooled aluminum and steel blocks, at the end of the decay pipe to stop leftover beam particles and provide radiation protection to people and groundwater. At LBNF's final beam power of 2.4 MW and assuming the worst case condition of a 204 m long helium filled decay pipe, the absorber is required to handle a heat load of about 750 kW. This results in significant thermal management challenges which have been mitigated by the addition of an aluminum 'spoiler' and 'sculpting' the central portion of the aluminum core blocks. These thermal effects induce structural stresses which can lead to fatigue and creep considerations. Various accident conditions are considered and safety systems are planned to monitor operation and any accident pulses. Results from these thermal and structural analyses will be presented as well as the mechanical design of the absorber. The design allows each of the core blocks to be remotely removed and replaced if necessary. A shielded remote handling structure is incorporated to hold the hadron monitor when it is removed from the beam.

DESIGN OVERVIEW

The absorber consists of two major sections, as shown in the left image of Figure 1. The core, a section consisting of replaceable water-cooled blocks, is shown inside the green box. It is enlarged in the right image of Figure 1. The core consists of an aluminum spoiler block to initiate the particle shower, five aluminum mask blocks with air space in the center to allow the shower to spread, nine sculpted aluminum blocks of reduced central density to further distribute the heat load, four solid aluminum blocks, and four solid A36 steel blocks. All aluminum in the core is 6061-T6. The beam power deposited into the core during 2.4 MW operation is approximately 520 kW, which is the majority of the incoming beam power into the absorber. Outside of the core is forced-air cooled steel and concrete shielding.

ANALYSIS

Using MARS15 [1] energy deposition results as a basis for heat load on the absorber and its core blocks, many iterative simulations between MARS and ANSYS have been carried out to determine the final configuration of the absorber. The main driver of this optimization is reduction of temperature and stress to acceptable levels for the materials during both normal operation and accident scenarios. Creep and fatigue effects have been considered when applicable.

Aluminum core blocks are all water cooled via four 1 inch diameter gun-drilled channels in the aluminum with 20 gallons per minute (gpm) volumetric flow rate through each channel. The water will be cooled to 10°C to help reduce steady state temperatures. Steel blocks are cooled via two 1 inch diameter stainless steel lines along the perimeter of the block with 20 gpm flow rate each.

Steady State Operation

Steady state temperatures and stresses were evaluated at the locations shown in Table 1 for both 120 GeV and 60 GeV operation. 120 GeV operation is by far the worst case due to the lower amount of beam scattering and higher overall beam power compared to 60 GeV operation. Further analysis shown will focus only on 120 GeV operation.

Table 1: Maximum Temperature and Von-Mises Stress for Steady State Operation

Location	Temperature (°C)	Von-Mises Stress (MPa)
Spoiler	60	34
Mask Block 1	25	-
Sculpt Al 3, Ctr	88	103
Sculpt Al 3, WL	25	74
Solid Al 2	84	48
Steel 1	225	199

Creep must be considered since the aluminum is being held at an elevated temperature under stress – 103 MPa at 88°C in the worst case. Creep data for 6061-T6 aluminum bus conductors [2] shows an average stress required to produce 1% creep at 100°C for 10 years to be 172 MPa. Other data [3] indicates the stress values are well below the 250 MPa needed to produce even 0.1% creep at 100°C, although this data only extends to 1000 hours.

A possible concern is losing the T6 temper of the aluminum due to elevated temperature for an extended period of time. After 100,000 hours (11.2 years) at 100°C, there is no change to tensile strength, yield strength, elastic modulus, or elongation [3].

Another consideration is the effect of a failed water line. In the case of the 3rd sculpted aluminum block, the downstream end of the block has a larger energy deposition than the upstream side. For this analysis, convection in the downstream inner water line is removed and the analysis is re-run. Maximum temperature and Von-Mises stress reach 109°C and 174 MPa respectively. At this temperature and stress level, the block would be at least temporarily operable while

DESIGN OF A COMPACT FATIGUE TESTER FOR TESTING IRRADIATED MATERIALS*

B. Hartsell†, M. Campbell, P. Hurh, FNAL, Batavia, IL 60510, USA
T. Ishida, T. Nakadaira, KEK, 1-1 Oho, Tsukuba 305-0801, Japan
M. Fitton, RAL, Didcot, UK

Abstract

A compact fatigue testing machine that can be easily inserted into a hot cell for characterization of irradiated materials is beneficial to help determine relative fatigue performance differences between new and irradiated material. Hot cell use has been carefully considered by limiting the size and weight of the machine, simplifying sample loading and test setup for operation via master-slave manipulator, and utilizing an efficient design to minimize maintenance. Funded from a US-Japan collaborative effort, the machine has been specifically designed to help characterize titanium material specimens. These specimens are flat cantilevered beams for initial studies, possibly utilizing samples irradiated at other sources of beam. The option to test spherically shaped samples cut from the T2K vacuum window is also available. The machine is able to test a sample to 10^7 cycles in under a week, with options to count cycles and sense material failure. The design of this machine will be presented along with current status.

JUSTIFICATION

Currently there is a lack of data concerning fatigue life for irradiated Titanium 6Al-4V, both standard (grade 5) and extra low interstitial (ELI, grade 23). This is of particular concern since a vacuum window with 6Al-4V titanium components directly interacting with the beam is currently installed in the T2K beam line, shown in Figure 1. When the current vacuum window is decommissioned and a new window is installed, it is possible that samples could be cut from the irradiated material. In addition, pre-machined flat samples are planned to be irradiated at other sources of particle beam. These samples can then be used in various tests to characterize irradiated 6Al-4V Ti. In order to estimate effects of irradiation on fatigue, a fatigue testing machine must be constructed that can fit within an existing hot cell design to provide radiation shielding. The results from these fatigue tests can then be compared to control samples run on the same machine prior to irradiation. Samples are expected to be run out to at least 10 million (10^7) cycles to approximate the number of beam pulses on a production window.

SYSTEM DESIGN

The fatigue testing machine used to test the samples must fit inside a hot cell due to sample radioactivity, with a maximum pass-through cross section of a square measuring 9 inches per side. The master-slave manipulators also impose restrictions on material handling, weight capacity, and machine operation. The machine must be able to withstand multiple fatigue runs of 10 million cycles or more with minimal maintenance.

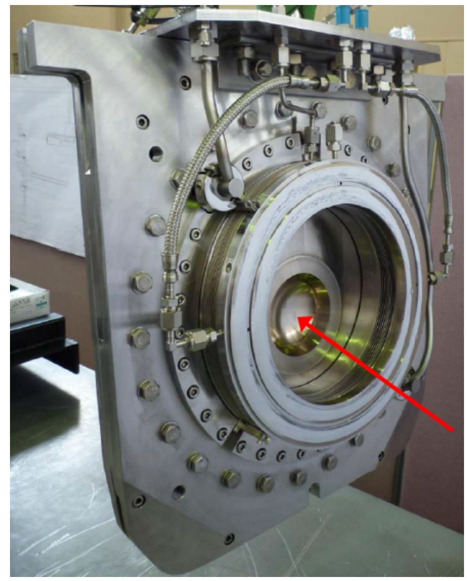

Figure 1: T2K vacuum window assembly, with a red arrow highlighting the approximately 15 cm diameter Ti window.

Sample Design

Two different fatigue samples were designed to accommodate two different test setups. First, a flat fatigue sample was designed in order to simplify the commissioning process of the fatigue testing machine as well as provide the ability to test samples irradiated at other particle beam facilities. Second, a sample with a spherical profile was designed to approximate samples cut from the T2K vacuum window.

Flat fatigue samples are designed as cantilever beams similar to the ASTM D671 standard. While the standard is meant for evaluating flexural fatigue of plastics, the geometry works well for all materials. Flat sample geometry can be seen in Figure 2. It features a wide area for clamping of the material, a transition to a narrower section through a curved profile, and a narrow gauge length. This geometry ensures that the maximum stress occurs away from the clamp and in the region transitioning to the thin gauge length. The effective testing length of the sample, which is the distance from the edge of the clamp to the point where the sample is

KICKER PULSERS FOR RECYCLER NOVA UPGRADES

Chris C. Jensen, FNAL, Batavia IL, USA

Abstract

An upgrade of the Recycler injection kicker system required a faster rise time pulser. This system required a field rise and fall time of < 57 ns and a field flattop of 1.6 µs. This paper describes the variety of improvements made over the years that have resulted in this latest thyratron pulser. The effects of the trigger, the reservoir and the load impedance on delay and rise time will be discussed.

OVERVIEW

These pulsed power supplies have a fairly high peak power (25 kV, 1 kA), modest repetition rate (15 Hz), very fast rise times (15 ns), very flat pulse tops (+/- 1% for 1.6 us), operate around the clock for many years with limited downtime (1 extended maintenance per year), and the magnets are in a significant radiation field (100 kRad / year). The rise time and flattop requirements are driven by the need for more beam power and maintaining low losses in the accelerator [1].

The topology chosen to meet all of these requirements is a floating switch in a remote service building and a resistive termination mounted at the traveling wave magnet. The high radiation field and limited downtime require the pulser to be located outside the beam line enclosure. The tight flat top requirement requires a low loss pulse forming line. Additionally, the load must be located on the magnet to remove reflections between the load, cable and magnet that reduce flattop stability. To meet the high peak power and fast rise time requirements a thyratron switch was chosen. Low timing jitter and drift are required to maintain stable accelerator operation.

The magnet [2] and load [3] for this system have been previously described. The charging system for a different pulser was briefly described in [4] and [5] and further details are presented herein. The thyatron trigger system described previously [6] has been updated, but the filament and reservoir systems have never been described. Finally, measurements of current rise time for the complete system, without magnet, are presented.

CABLE AND CHARGING SYSTEM

A pulse forming line (PFL) is used instead of a lumped pulse forming network to generate a very square pulse. Low dispersion is required to maintain the fast rise time for the cable run from the pulser to the magnet, about 45 m in this case, and to preserve the prompt fall time at the end of the pulse. The cable used has the same dimensions as RG220/U but with two additional features. First, two foil layers are bonded to the polyethylene core under the bare copper braid to reduce dispersion at higher frequencies. Second, the center conductor has stricter tolerance on dimensional stability and surface roughness to maintain tighter impedance control and increase voltage rating. High voltage pulse testing (60 kV) and impedance testing (±0.4 Ohm) are done on all cables to verify performance.

A two-step command resonant charging system is used. A capacitor, which stores slightly more energy than the PFL, is connected through a thyristor switch to a step up transformer, then through a diode to the PFL. The leakage inductance of the transformer and the capacitance determine the charging time. The capacitor charging supply fully charges the capacitor once a kicker fire is requested, typically to ~ 4 kV in ~ 30 ms. This reduces voltage stress on the capacitor and improves lifetime. The PFL is then charged, typically to ~ 55 kV in ~ 250 µs. This decreases the time there is voltage on the thyratron so that the reservoir can be substantially increased while maintaining a low self triggering rate. That is a critical adjustment for achieving fast rise time as is shown later. The step up transformer is also used because of the limited voltage range of commercial charging supplies.

The resonant charging time is significantly shorter than other applications and there have been no issues. The reduced time was due to accelerator transfer timing requirements and the jitter between different clock systems. A side benefit is the reduced size of the transformer. Balancing resistors of 6 Meg Ohm are used to insure equal voltage division across the thyratron gap during the rapid charging. The negative bias on the G2 voltage trigger must be low impedance to prevent thyratron self triggering.

THYRATRON SUBSYSTEMS

Filament and Reservoir

Stray capacitance from cathode to ground is one fundamental limit to the rise time. One contribution to this capacitance is the transformers used to couple filament, reservoir and trigger power to the cathode. At Fermilab, we have used high frequency (20 kHz) AC to couple power to a floating cathode since the early 1990s.

This is done with two series transformers with a common, grounded intermediate winding. Power is applied to the primary of the first transformer with low isolation voltage. The intermediate winding is formed with a single turn of the improved RG220 cable going through the center of both transformers and the thyratron enclosure serving as the return. The ground conductors are removed from the cable and the center conductor is at ground potential. The second transformer provides the high isolation voltage with the cathode enclosure forming an electrostatic shield at high voltage. The capacitance of

FERMILAB LINAC LASER NOTCHER*

D.E Johnson#, T.R. Johnson, K. Duel, M. Gardner, V. Scarpine, R.J. Tesarek,
Fermilab, Batavia, IL, USA

Abstract

Synchrotrons or storage rings require a small section of their circumference devoid of any beam (i.e. a "notch") to allow for the rise time of an extraction kicker device. In multi-turn injection schemes, this notch in the beam may be generated either in the linac pulse prior to injection or in the accelerator itself after injection. In the case of the Fermilab Booster, the notch is created in the ring near injection energy by the use of fast kickers which deposit the beam in a shielded collimation region within the accelerator tunnel. With increasing beam powers, it is desirable to create this notch at the lowest possible energy to minimize activation. Fermilab has undertaken an R&D project to build a laser system to create the notch within a linac beam pulse at 750 keV, where activation issues are negligible. We will describe the concept for the laser notcher and discuss our current status and future plans for installation of the device.

MOTIVATION

The current Fermilab Booster utilizes multi-turn injection and adiabatic capture to populate all RF buckets in the ring. To minimize losses from the rise time of the 8 GeV extraction kicker, a portion of the beam (about 60 ns. out of 2.2 μs.) in the ring is removed by fast kickers at low energy into an absorber. This empty section of the circumference is called a "Notch". On Booster cycles that are ultimately injected into the MI for the Neutrino program this process takes place at approx.700 MeV. At the completion of the Proton Improvement Plan (PIP) these losses are expected to contribute approximately 300 W of the total administrative limit of 525W. Moving this process out of the Booster tunnel to the 750 keV Medium Energy Beam Transport (MEBT) of the linac is expected to reduce the loss to 17 W, assuming a 90% efficiency in the Linac Notch creation and 10% clean-up in the Booster ring.

LINAC & BOOSTER BEAM

At the completion of PIP, the Fermilab Booster will be operating at 15 Hz. The length of the linac pulse injected into Booster is N*τ where N is the number of injected turns and τ is the Booster revolution period at injection. Creating a notch in the linac pulse requires removing a number sections of the linac beam at the Booster revolution period, where the number of sections to be removed is N-1. The spacing between these removed sections should guarantee that when the H- is injected into the Booster, the empty sections fall on top of one another in the ring producing a single notch in the Booster. This process is shown in Fig. 1. The top pane shows the 15Hz linac pulses to be injected into Booster. The bottom pane shows a single linac pulse with 60 ns notches created within the pulse separated by ~2.2 μs, the Booster revolution period. Not shown is the 200 MHz bunch structure in the linac pulse.

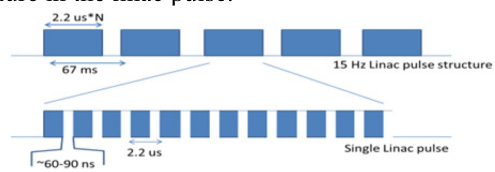

Figure 1: Linac pulse showing the notch structure for a single linac pulse.

LASER NOTCHER CONCEPT

The technique employed to produce the notch is to remove the outer electron of the H- ion using photoionization for the appropriate beam sections. There have been discussions on using lasers to create a notch in the linac beam for some time. [1-3] This technique was demonstrated in 2000. [1] The photoionization cross section has a broad peak centered at 1.51 eV (λ=821 nm) photon energy in the center-of-mass frame of the electron with a cross section of 4.2x10^{-17} cm^2. [4] The choice of the lab frame photon energy is dependent of the H- energy and the interaction angle through the standard Lorentz transformation. The laser technology for both solid state (Nd:YAG) and Yd doped fiber with a laser wavelength of 1064 nm has matured significantly over the last decade such that it is the natural choice for the laser system. The cross section for these photons with CM energy 1.165 eV is 3.66x10^{-17} cm^2, only 13% off the peak. When the probability of interaction between the photons and electrons is high and the mechanism does not depend on the electron intensity, the fraction of electrons that are detached from the moving H- ions is given by

$$F_{neut} = {}^{N}/_{N_0} = \left(1 - e^{-f_{CM}\sigma(E)\tau}\right),$$

where f_{CM} is the flux of photons at the interaction point in the rest frame of the H- [photons/cm^2/sec], σ(E) is the photoionization cross section for photon energy E, and τ is the interaction time of the photons and electrons. The center of mass flux can be expressed in lab frame parameters as

$$f_{CM} = \gamma\left(\frac{E_{laser}\lambda_{LAB}}{hc\tau_{laser}}\right)\left(\frac{1}{A_{laser}}\right)(1 - \beta\cos\theta),$$

where $\boldsymbol{E}_{\mathbf{laser}}$ is the laser pulse energy, $\boldsymbol{\lambda}_{\mathbf{LAB}}$ is the lab frame wavelength of the laser, τ_{laser} is the laser pulse length, $\boldsymbol{A}_{\mathbf{laser}}$ is the laser cross sectional area, γ and β are the usual relativistic parameters, and θ is the interaction angel between the photons and H-. Figure 2 shows the "single pass" neutralization fraction as a function of laser pulse energy to neutralize a single 60 ns section of the 750 keV H- linac pulse, assuming a 90° interaction angle.

MEASUREMENTS OF STRONTIUM FERRITE HYBRID PERMANENT MAGNET QUADRUPOLES AFTER REMOVAL FOR THE FERMILAB NOVA UPGRADE IN 2012

O. Kiemschies*, FNAL, Batavia, IL 60510 USA

Abstract

During the 2012 NOvA upgrade forty strontium ferrite hybrid permanent magnet quadrupoles from the injection, extraction and electron cooling regions of the Recycler accelerator, which had been measured in 2000 and subsequently installed in the tunnel, were replaced. The basic design of the quadrupoles [1] and expected decay rate [2] are described in design documents. Nine of these magnets, of varying strength were measured in 2014. Measurements were made with a rotating coil in a fashion similar to their initial pre-installation measurements in 2000. The 2014 measurements are compared to the 2000 measurements and the expected decay.

.

PERMANENT MAGNETS IN THE RECYCLER

The Fermilab Recycler contains approximately 500 permanent magnets [2] of several different types. These magnets use grade 8 Strontium Ferrite bricks to produce the magnetic field and machined steel poles to create the field shape [2]. Segments of a 4x6x1 bricks (cut to 2"x1" bricks of varying length) were used. To compensate for the change in magnetization as a function of temperature, 2"x1" thin pieces of 30% Ni 70% Fe alloy were interspersed among the ferrite segments [3].

During the initial years of the Recycler, measurements were made of several different magnets to understand the evolution of magnet strengths over time [2].

NOVA UPGRADE

For the 2012 NOvA upgrade, approximately forty 20" permanent quadrupole magnets (Figure 1) in the transfer lines and in the decommissioned electron cooling region of the Recycler needed to be modified or replaced because of new field strength requirements. The decision was made to replace them with new magnets [4]. This meant 40 magnets were uninstalled, allowing for the measurement of these magnets and the comparison of current measurement data with measurement data recorded prior to installation. Due to radiation these magnets remained an unused section of tunnel until 2014, at which time activation for nine magnets was low enough allowing for easier handling.

ASSEMBLY AND INSTALLATION

Assembly

Assembly data was captured in "travelers" recorded during fabrication, and any modifications. Measurement data was captured in the Fermilab Magnet Test Facility system. The dates of measurements are correct, however dates of ferrite magnetization are approximate. The traveler records when the bricks were acquired from a pool of recently magnetized bricks. The time gap between magnetization and assembly is small (weeks to months range) compared to the time between these measurements. Initial strength specifications required the magnets to be within 5 units of grel [5].

Installation

Eight magnets listed were installed in the Recycler Ring and were in the proximity of Recycler Ring vacuum chamber "bake-outs". This typically involved baking sections of beam tubes in the range of 100^{o} C to 130^{o} C. Exact temperatures on the magnets were not measured. This is significant due to the potential effect of elevated temperature on the long-term decay of magnet strength [2]. RQMF009, however, was located in a transfer line so was not subjected to potential elevated temperatures.

ADDITIONAL STORED MAGNET MEASURED

PQP003

In addition to the removed quads, three additional magnets which had not been in the tunnel were measured. PQP003 was an early 20" permanent quadrupole prototype. Prior to 2009 there is uncertainty regarding modifications to this magnet. There are records of modifications as late as 1997. Because of the uncertainty, Measurements prior to 2009 were excluded. However, data from 1997 to 2009 would agree with the general trends in grel change since 2009. Since it is a form of 20" quad, PQP003 was included in Table 1.

RGF005

RGF005 is the first production gradient magnet which met Recycler specifications. It was kept as a standard magnet and was measured periodically since 1997 [2]. Continual measurements exist for this magnet. It was stored a temperature controlled building when not being measured.

Abstract

RF Breakdown in strong magnetic fields has a negative impact on a cavity performance. The MuCool Test Area at Fermilab has unique capabilities that that allow us to study the effects of static magnetic field on RF cavity operation. We have tested an 805 MHz pillbox-like cavity in external magnetic fields up to 5 T. Results confirm our basic model of breakdown in strong magnetic fields. We have measured maximum achievable surface gradient dependence on external static magnetic field. Damage inspection of cavity walls revealed a unique observed breakdown pattern. We present the analysis of breakdown damage distribution and propose the hypothesis to explain certain features of this distribution.

INTRODUCTION

Muon ionization cooling channel designs require RF cavities to be operated in strong magnetic fields up to several Tesla [1,2]. RF cavity performance is limited by breakdown: current discharge across a cavity accompanied by an abrupt drop in stored energy, light and x-ray emission, and a transient increase in vacuum pressure. It has been previously experimentally demonstrated that in strong magnetic fields the breakdown rate increases [3].

A model has been proposed which explains the effects of strong magnetic fields on breakdown-related cavity damage [4]. In the presence of a strong, solenoidal magnetic field, field-emitted electrons are focused into "beamlets" with current densities of 10^3 - 10^5A/m^2 at impact site. Space charge effects prevent further increase in beamlet current density above 0.5 T. These beamlets persist over multiple RF cycles and, through their impact on cavity surfaces, cause pulsed heating, cyclic material fatigue, and eventual breakdown. This type of damage may lead to increased breakdown probability. Materials with higher radiation length might be less prone to cyclic fatigue under such circumstances.

Cavity Design and Instrumentation

The cavity used in this study was designed to operate wither under vacuum or filled with high-pressure gas, in order to study the role of gas pressure in the suppression of breakdown [5]. Due to this flexibility, the cavity was described as "a cavity for all seasons". The walls of so-called All Seasons Cavity (ASC) are fastened with bolts and aluminum seals, allowing for relatively easy assembly and disassembly. The experimental goals of ASC program included determination of maximum achievable gradient for external magnetic fields between zero and five Tesla for cavity pressures between 10^{-8} Torr and 100 atmospheres, optimization conditioning scheme for stable cavity performance at high gradients, assessment of different cavity wall materials such as copper, aluminum, beryllium [6,7]. This paper presents results from vacuum operation of the ASC.

Figure 1 shows the cross section of the cavity with simulated electrical field distribution. The cavity was designed with two thick copper plated (25 μm) detachable end plates. Flat thin Al gaskets were used to make RF and vacuum seal. Coaxial capacitive coupling was used for power transmission into the cavity. The list of RF properties of ASC is presented in Table 1.

ESTIMATION OF CRYOGENIC HEAT LOADS IN CRYOMODULE DUE TO THERMAL RADIATION *

A. Saini†, V. Lebedev, N.Solyak, V. Yakovlev, Fermilab, IL 60510, USA

Abstract

Cryogenic system is one of major cost drivers in high intensity superconducting (SC) continuous wave (CW) accelerators. Thermal radiations coming through the warm-ends of cryomodule and room temperature parts of the power coupler result in additional cryogenic heat loads. Excessive heat load in 2K environment may degrade overall performance of the cavity. In this paper we present studies performed to estimate additional heat load at 2K due to thermal radiation in 650 MHz cavity cryomodule in high energy section of PIP-II SC linac.

INTRODUCTION

The Proton Improvement Plan -II (PIP-II) is proposed to develop a high intensity proton beam facility at Fermilab. It is primarily based on construction of 800 MeV CW SC linac that would initially operate in the pulse mode. A schematic of linac baseline configuration is shown in Fig. 1. It consists of room temperature front-end and SC linac. Each superconducting section in Fig. 1 is represented by optimal beta of respective cavities except for LB and HB sections where geometrical beta of corresponding cavities are shown. A detail description of baseline configuration of PIP-II SC linac is presented elsewhere [1].

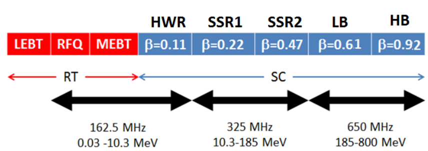

Figure 1: Technology map of PIP-II linac

All cryomodules in SC linac are connected by room temperature sections. This arrangement provides an option of possible beam collimation after each cryomodule which could help to minimize uncontrolled beam losses in cryogenic environment. Furthermore, it also provides space for additional beam diagnostics (transverse and longitudinal profile monitors, beam loss monitors, etc.).

GENERAL

The major infrastructure investment and the operational cost of a superconducting linear accelerator are outlined by its cryogenic requirements. As can be noticed from Table 1, the cryogenic efficiency is significantly lower at 2 K and it is required about 800 W of wall-plug power to remove every Watt of power dissipated in this environment. Consequently, cryogenic load at 2K derives size and therefore the cost of cryogenic-plant. While the dynamic cryogenic load at 2K

Table 1: Typical Cooling Efficiency at Different Cryogenic Temperatures

Temperature	2K	4K	70
Wall-plug power per Watt of power dissipation	800 W	250 W	25 W
Cryo- efficiency	0.125%	0.4%	4 %

is primarily determined by the RF power dissipation in an accelerating cavity, heat transfer due to conduction and radiation through various channels (Helium vessel supports, transfer lines, cables etc.) largely outlines the static heat load of cryomodule. Contribution of heat transfer through the convection is relatively negligible in cryomodule because of its vacuum vessel that maintain high vacuum for thermal insulation. A multilayer insulation using low emissivity material and intermediate temperature screenings (thermal shields) limit the radiation load in cryomodule. However, lateral radiation coming through the warm-ends of cryomodule and penetration of a room temperature surface into the cryogenic environment still result in an accountable radiation load. Heat transfer through the conduction can usually be estimated precisely, but estimation of the radiation heat load in a cryomodule is non-trivial and strongly affected by the geometry and the physical properties of a surface.

Insertions of warm section between cryomodules in PIP-II SC linac result in an increase of static cryogenic load due to lateral thermal radiation entering from both warm-ends of cryomodule. Room temperature parts of the power coupler also add radiation heat load. Radiation heat load in a cryomodule increases in proportion to cross-section area of beam pipe. Thus, radiation heat load for high beta (HB) 650 MHz cryomodules having beam pipe aperture of 118*mm* is higher than any other cryomodules in the SC linac. In this paper we present contribution of radiation to the cryogenic load at 2K in HB 650 MHz cryomodule and discuss its impact on overall performance of 5-cell elliptical shape HB 650 MHz cavity. This estimation allows us to take a decision on the requirement for 80 K thermal shield between HB cryomodules.

THERMAL RADIATION FROM CRYOMODULE WARM-ENDS

As shown in Fig. 2, niobium-beam pipe is not the part of helium jacket and it is cooled down by process of the conduction-cooling. Thus, heat removal in the niobium-beam pipe is not as efficient as in the cavity. Excessive heat deposition may rise temperature in the beam pipe that causes increase in the BCS surface resistance [2]. Consequently, RF

C. Speirs, C. Whyte, USTRAT/SUPA, Glasgow, UK

Abstract

A first electropolished 201-MHz RF cavity for the international Muon Ionization Cooling Experiment (MICE) has been assembled inside a special vacuum vessel and installed at the Fermilab's MuCool Test Area (MTA). The cavity and the MTA hall have been equipped with numerous instrumentation to characterize cavity operation. The cavity has been commissioned to run at 14 MV/m gradient with no external magnetic field; it is also being commissioned in presence of fringe field of a multi-Tesla superconducting solenoid magnet, the condition in which cavity modules will be operated in the MICE cooling channel. The assembly, installation and operation of the Single-Cavity Module gave valuable experience for operation of full-sized modules at MICE.

INTRODUCTION

The International Muon Ionization Cooling Experiment (MICE) is under construction at Rutherford Appleton Laboratory (RAL, UK). It is designed to demonstrate feasibility of an ionization cooling channel for use in such high-intensity muon sources like a Neutrino Factory or a Muon Collider [1].

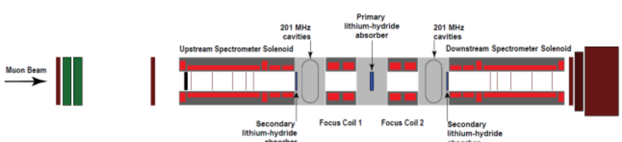

Figure 1: Final configuration of MICE cooling channel, showing two RF cavity modules.

Final MICE channel configuration [2] contains two RF Assembly (RFA) modules very similar to the module being tested at the MuCool Test Area (MTA). Each cavity will be driven by a 2-MW amplifier system to operate at a gradient of at 10.3 MV/m. The cavities also need to operate in fringe fields of multi-tesla solenoidal magnets.

MTA has a 5-T superconducting solenoid that provides operational conditions very similar to MICE channel. MTA Hall is also equipped with numerous detectors to monitor cavity environment and radiation levels, since radiation from RF cavities would affect various components of MICE channel [3] (e.g., radiation damage to detectors, thermal load on liquid hydrogen vessel, etc.). The cavity has also been equipped with instrumentation to characterize its behaviour during operation.

CAVITY INSTALLATION

RF Cavity body was manufactured in industry using techniques developed at LBNL, it was electropolished at LBNL and sent to Fermilab for installation and testing in a special vacuum vessel designed by LBNL, which is very similar to the final design to be used in MICE [4].

The cavity was initially installed and equipped with all the instrumentation in Lab 6 area, which has a class 100 (ISO 5) clean environment. All instrumentation, including the tuning system has been fully tested.

The tuner system consists of 6 stainless steel tuner forks driven by pneumatic actuators. Pneumatic system has a release valve at pressure of 120 PSI, and setup was tested up to 100 PSI at Lab 6, providing "pull" and "squeeze" with ~ 4 KHz/PSI tuning sensitivity [5].

The cavity was then moved to the MTA hall. It was removed from its vacuum vessel to reduce the dimensions during transport. The assembly installation in the vacuum vessel was finished in the MTA clean room [6].

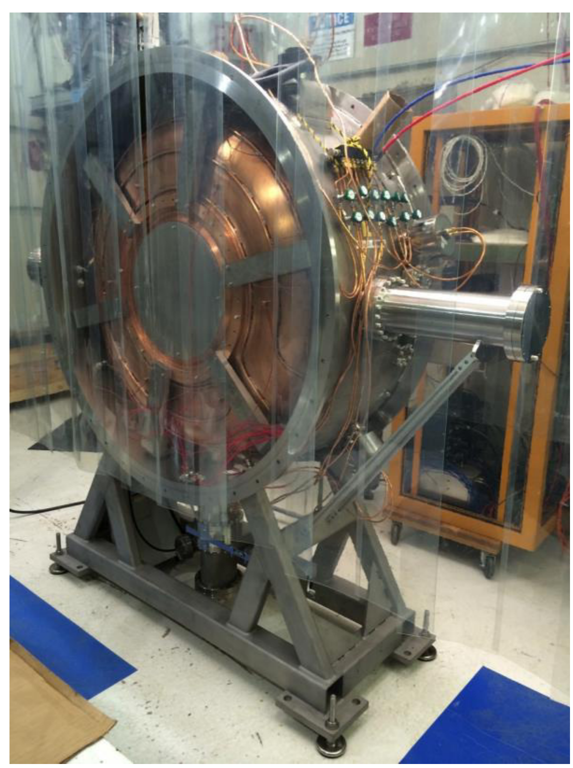

Figure 2: MICE Cavity in the MTA clean room, shortly after it was moved from Lab 6.

A CONCEPT FOR A HIGH-FIELD HELICAL SOLENOID

S. T. Krave#, N. Andreev, R. C. Bossert, M. L. Lopes, J. C. Tompkins, R. H. Wands, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA
G. Flanagan, Muons Inc., Batavia, IL, 60510, USA
K. Melconian, Texas A&M University, College Station, TX 77845 USA

Abstract

Helical cooling channels have been proposed for highly efficient 6D muon cooling to produce the required helical solenoidal, dipole, and gradient field components. The channel is divided into sections, each subsequent section with higher field. Simulations have shown that for the high-field sections the use of Nb3Sn superconductor is needed. A continuous winding method and novel stainless steel collaring system has been developed for use in the high field section of a helical cooling channel. Each collar layer is identical, for ease of fabrication, and assembled by both flipping and rotating the subsequent layers. Mechanical and magnetic simulations were performed using a combination of ANSYS and OPERA. The winding and collaring method has been demonstrated on a three coil prototype using a Nb_3Sn Rutherford cable. Details of the mechanical design and winding method are presented.

INTRODUCTION

Helical cooling channels (HCC) based on a magnet system with a pressurized gas absorber in the aperture have been proposed as a highly efficient way to achieve 6D muon beam cooling [1-2]. The magnet system superimposes solenoid (*Bs*), helical dipole (*Bt*), and helical gradient (*G*) fields. The cooling channel was divided into several sections to provide the total phase space reduction of muon beams on the level of 10^5-10^6, and to reduce the equilibrium emittance each consequent section has a smaller aperture and stronger magnetic fields. The field components (*Bt* and *G*) are a function of many geometric parameters as it was presented in [3-6].

The Helical Solenoids (HS) are formed by transverse displacements of short solenoid rings following a helix. Due to this unusual geometry, large transverse forces are generated. In order to intercept the forces a support structure must be designed accordingly. HS prototypes based on NbTi super-conductor were developed and are presented in [7-8]. HS models based on YBCO tape are presented in [9]. These materials do not need a reaction cycle, therefore the winding and impregnation are straight forward.

Nb_3Sn is required for the medium field sections of the HCC. That material requires a reaction cycle to the temperature of 650°C, which restricts the material choices for the support dramatically. In particular the outer support should allow for expansion during the reaction at the same time it should pre-stress the coil during the cool-down. A collar approach allows different materials to be used in each stage of the coil manufacturing and coil operation.

*Work supported in part by Fermi Research Alliance under DOE Contract DE-AC02-07CH11359.
#skrave@fnal.gov

MECHANICAL DESIGN

Nb_3Sn presents a more difficult path to finished product than either NbTi or HTS Tapes as it requires a reaction cycle to ~650°C before use. This is typically implemented in a wind and react configuration in which magnet coils are wound onto a temporary fixture and undergo a reaction cycle in an inert atmosphere. After the reaction cycle, the superconductor becomes extremely brittle and strain intolerant. Coils are typically transferred into an impregnation fixture then impregnated with epoxy, setting the final size of the coil. After impregnation, it is traditionally possible to assemble coils into the final magnet configuration.

As the concept for the helical solenoid as presented is for a long array of multilayer coils, the magnet assembly would ideally be splice-less, leading to a stepped structure that becomes impractical to remove the winding mandrel after winding. For this reason, the inner mandrel of the coil is integrated into the structure and must be able to withstand the reaction cycle with no ill-effects. As the superconductor is not tolerant of strain, the differential thermal expansion of the superconductor during reaction should be well matched to the inner support. For this reason, 316L Stainless Steel has been chosen as the material of the winding mandrel which is also the reaction fixture.

The Collaring Concept

A similar difficulty appears during coil winding in that while hoops may be installed after each layer of coil winding, they must be sufficient to support the hoop and shear forces generated during operation. Using a series of bolt on half structures was rejected due to the complex nature of the helical shape of the coil and the level of forces involved.

A novel mechanical structure has been developed to provide coil alignment and support along both the base helix of the solenoid system and the center axis of the helix. A collared lamination system with locking load keys has been explored to enable the fabrication of a continuously wound helical magnet while maintaining the ability to expand the helical solenoid indefinitely. The collared structure also allows for a temporary support structure to be used during reaction. The basis of the

Abstract

Nitrogen doping results in ultra-high quality factors in SRF niobium cavities but currently achievable gradients in doped cavities are, on average, somewhat lower than in EP/120 °C baked cavities. The origin of this difference is explored in the reported work by detailed temperature mapping studies on several single cell nitrogen doped cavities.

INTRODUCTION

Superconducting accelerating cavities have recently received a large improvement in terms of quality factor, thanks to the discovery of nitrogen doping treatment. Before this beneficial treatment was discovered, the performance of niobium cavities were limited, in terms of Q-factor, to $2 \cdot 10^{10}$ at 16 MV/m (at 2 K, for 1.3 GHz cavities). Nitrogen doped (N doped) cavities can instead reach quality factors of $4 \cdot 10^{10}$ at 16 MV/m [1]. On the other hand, the performance achieved in terms of accelerating field is nowadays lower for N doped cavities, that is in the range of $20 - 30$ MV/m, compared with EP/120 °C baked cavities which reach even 40 MV/m.

In this paper the quench mechanism is analyzed using temperature maps [2] captured before and during the quench of nitrogen doped cavities, allowing the localization of the quench spot. The study is done taking into account cavities with different doping treatment, in order to see if any differences appear between them, or if something systematically occurs before or during their quenches.

EXPERIMENTAL SET-UP

For the doping treatment, niobium cavities are typically treated with 800 °C degassing in HV for 2-3 hours, followed by injection of niotrogen (N_2) at high temperature. The N_2 flow is set to a specific partial pressure for a certain amount of time. During this step nitrogen reacts with the niobium at the surface and diffuses inside. After that, it is possible to perform a second, optional, step in which the cavity is maintained at high temperature, without nitrogen, in order to promote the diffusion of the nitrogen atoms inside the bulk, smoothing the concentration profile. Then, the heating is shut off and the cavity is let cooling till room temperature.

In Table 1 the nitrogen doping treatment of the analyzed cavities is listed. Only the cavity TE1AES011 is doped including the second step which promote the nitrogen diffusion. Depending on the doping treatment the cavity can be under-doped, for example increasing the time of the second step, or over-doped, for example increasing the time of the first step [3].

Table 1: Doping Treatment of the Analyzed Cavities

Cavity	Doping Treatment
TE1AES003	28 mTorr of N_2 for 10 min at 1000 °C
TE1NR005	25 mTorr of N_2 for 10 min at 800 °C
TE1AES011	25 mTorr of N_2 for 2 min at 800 °C plus 6 min without N_2 at 800 °C
TE1ACC002	25 mTorr of N_2 for 20 min at 800 °C

After the doping treatment the cavities are electropolished with a total removal of about $5\mu m$ for all the cavity analyzed except for TE1AES003 in which the removal is about $60\mu m$.

The temperature map system was used to capture the cavity temperature before and during the quench, in order to understand the mechanism responsible to the quench. The T-map system used in this experiment is shown in Fig. 1. It consists on 36 board placed around the cavity every 10°, and 16 thermometers are placed on each board, for a total of 576 thermal sensors all around the cavity.

RESULTS AND DISCUSSION

The Q-factor versus accelerating field of the nitrogen doped cavities for the T-map runs analyzed in this paper is shown in Fig. 2. The RF test of one EP and one EP/120 °C cavities are also shown as reference. It is important to notice that some of the N doped cavities do not show very high Q performance during these T-map runs because these tests were done with some imposed magnetic field and under not full flux expulsion cooling regimes. In particular the TE1ACC002 cavity had showed significant flux trapped under 10 mGauss field applied via Helmholtz coils.

Comparing TE1AES011 with the EP cavity, they reached almost the same accelerating field, but it is possible to notice that TE1AES011 is not affect by high-field Q-slope

DESIGN AND TEST OF COMPACT TUNER FOR NARROW BANDWIDTH SRF CAVITIES

Y. Pischalnikov, E. Borissov, I. Gonin, J. Holzbauer, T. Khabiboulline, W. Schappert, S.Smith, J.C. Yun.
FNAL, Batavia, IL 60510, USA

Abstract

The design of the compact tuner for 1.3 GHz 9-cell elliptical cavity will be presented. This compact tuner is designed for future accelerators that will operate in CW and pulsed RF-power modes. The major design features include highly reliable active components (electromechanical actuators and piezo-actuators) and the ability to replace tuner active components through designated ports in the cryomodule vacuum vessel. Results of tuner testing with cold cavity will also be presented.

TUNER DESIGN

Schematics of the tuner design are shown in Figure 1. The coarse tuner is a double lever tuner (with a 20:1 ratio) similar to the design of the SACLAY I tuner. The tuner works by compressing the cavity. The piezo-stack is installed close to the cavity end flange. This means that the piezo stroke is translated directly to the cavity, not through flex and/or bearing connections. This configuration will deliver better piezo-tuner resolution and decrease group delay of the fast tuner. Safety rods have been designed between the cavity end flange and main lever of the tuner. These safety rods protect the cavity from non-elastic deformation during cavity/helium vessel system leak check.

A split ring is attached to the conical flange welded to the cavity beam-pipe (Purple in Figures 2&3). All forces/stroke from the tuner to the cavity are translated through this split ring. The tuner is anchored to the helium vessel with two strong horizontal arms (Yellow in Figure 2). These arms have adjustment capabilities to accommodate differences (+3mm/-7mm) in the length of the 9-cell cavities after final tuning. The electromechanical actuator connects to the left arm and the lever system is attached through the bearings to the right arm. To decrease the cost of the tuner assembly, it was designed in several parts that are connected by welding or using screws. Set-screws and special washers were included to prevent loosening of the assembly screws during warmup and cool-down cycles.

A special adjustment screw (Figure 1) to hold the left side of the lever system to the left arm was introduced into the design. This addition allows the release of forces between the cavity and tuner system when either the electromechanical actuator or piezo-stack needs to be replaced through the designated port in the cryomodule.

Balls connections were chosen for the connections between the top & bottom encapsulated piezo-stack and the main lever. This prevents the build-up of shearing forces on the piezo-stack during tuner operation which are detrimental to piezo lifetime. Two adjustment screws (one in each main arm) help to uniformly preload piezo-stacks during assembly.

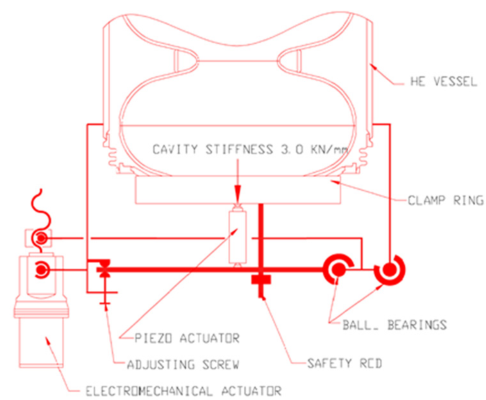

Figure 1: Schematic of the Tuner.

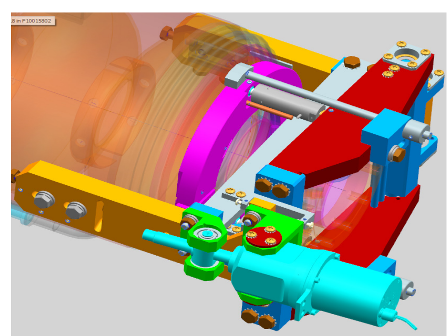

Figure 2: 3-D model of the Tuner, assembled on the cavity/helium vessel system.

ACTIVE COMPONENTS OF THE TUNER

The electromechanical actuator is the active element of the slow/coarse tuner. The electromechanical actuator translates rotation of the stepper motor to linear motion of the tuner arms. The tuner is equipped with a Phytron actuator (LVA 52-LCLS II-UHVC-X1) [1] designed for the FNAL linear SRF project. The Phytron actuator is built from:

- Stepper motor XXX
- Planetary gear (1:50 ratio)
- M12X1 spindle made from titanium
- Traveling nut made from stainless steel and radiation hard plastic material

PROGRESS AT FNAL IN THE FIELD OF THE ACTIVE RESONANCE CONTROL FOR NARROW BANDWIDTH SRF CAVITIES*

W. Schappert#, J. Holzbauer, Yu. Pischalnikov, FNAL, Batavia, IL 60510, USA

Abstract

Recent efforts at FNAL to actively compensate microphonics in narrow bandwidth cavities are discussed. Feed-forward compensation of Lorentz force detuning in combination with feedback of the forward/probe phase difference to a piezo actuator successfully stabilized the resonance of a 325 MHz spoke resonator to within 11 mHz of the frequency of the open-loop CW RF drive over a two hour interval.

INTRODUCTION

Many of the next generation of particle accelerators (ERLs, XFELs) are designed for relatively low beam loading. The cavities are designed to operate with narrow cavity bandwidths to minimize capital and operational costs of the RF plant. With such narrow bandwidths, cavity detuning from microphonics becomes a significant factor, and in some cases can drive the cost of the machine [1]. Piezo actuators have been successfully used to actively stabilize cavity resonant frequencies. This paper will present the results of ongoing detuning compensation efforts at FNAL using prototype 325 MHz SRF single spoke resonators designed for the PIP-II project at Fermilab [2].

PREVIOUS EFFORTS

Active compensation of both Lorentz force detuning and microphonics had been previously studied using an earlier SSR1 prototype with two different power couplers. An adaptive feedforward algorithm developed for pulsed 1.3 GHz 9-cell elliptical cavities [3] was able to reduce detuning in the spoke resonator from several kHz to 50 Hz or better during pulsed operation with a 150 Hz bandwidth power coupler (see Fig. 1). Feedback to the piezo actuator during CW operation at 4.3 K with a 0.5 Hz bandwidth coupler was able to limit detuning due to helium pressure variations to 0.4 Hz RMS. [4].

SECOND PROTOTYPE SSR1 SPOKE RESONATOR

A second SSR1 prototype was installed in the Spoke Test Cryostat (STC) in late 2014. The cavity was equipped with a matched coupler (0.6 Hz bandwidth) to allow quality factor measurements. The cavity was also equipped with two piezoelectric actuators that could provide dynamic tuning. The piezos were held in place by a dummy slow tuner that did not allow static tuning of the cavity. This cavity had been the focus on an active design effort to reduce and minimize pressure sensitivity [2]. During these tests the cavity was powered with CW at an operating temperature of 4.5 K. Despite the much lower measured value of df/dP (5 Hz/torr), the cavity would still not remain on resonance for any extended period without active stabilization.

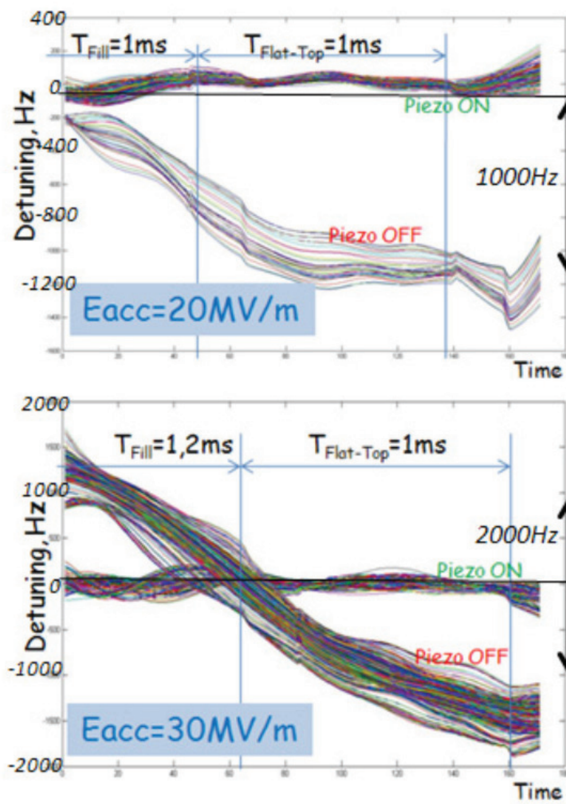

Figure 1: Pulsed compensation of Lorentz force detuning in an SSR1 cavity by adaptive algorithm.

FEED FORWARD COMPENSATION OF PONDEROMOTIVE EFFECTS

Radiation pressure from the EM fields in a powered resonator induces a mechanical deformation which in turn leads to shifts the cavity resonance frequency. The frequency shift is proportional to the square of the gradient as shown in Fig. 2.

A PERPENDICULAR BIASED 2ND HARMONIC CAVITY FOR THE FERMILAB BOOSTER*

C.Y. Tan†, J. Dey, R.L. Madrak, W. Pellico, G. Romanov, D. Sun, I. Terechkine,
Fermilab, Batavia, IL 60510, USA

Abstract

A perpendicular biased 2nd harmonic cavity is currently being designed for the Fermilab Booster. Its purpose cavity is to flatten the bucket at injection and thus change the longitudinal beam distribution so that space charge effects are decreased. It can also with transition crossing. The reason for the choice of perpendicular biasing over parallel biasing is that the Q of the cavity is much higher and thus allows the accelerating voltage to be a factor of two higher than a similar parallel biased cavity. This cavity will also provide a higher accelerating voltage per meter than the present folded transmission line cavity. However, this type of cavity presents technical challenges that need to be addressed. The two major issues are cooling of the garnet material from the effects of the RF and the cavity itself from eddy current heating because of the 15 Hz bias field ramp. This paper will address the technical challenge of preventing the garnet from overheating.

INTRODUCTION

It is well known that the addition of a 2nd harmonic cavity (in this paper, 2nd harmonic means the frequency is twice that of the fundamental) can be used to improve capture of the beam at injection. It is also possible to use this type of cavity at transition as well, to aid in crossing transition. For example, see ref. [1]. Simulations have shown that, in order, to increase capture, the voltage of the 2nd harmonic must be greater than 10% of the total accelerating voltage of the fundamental. This value sets the minimum voltage for the 2nd harmonic design, which for Booster means that it is about 100 kV.

In order to achieve this voltage in the limited space in the Fermilab Booster tunnel, it was decided to pursue a cavity design that is perpendicularly biased rather than parallel biased. [2] The reason is that the high Q of the garnet material used for a perpendicular biased cavity allows this voltage to be achieved with a single gap rather than with a double gap that is required for a parallel biased cavity. A double gap cavity essentially means a doubling of the length w.r.t. a perpendicular biased cavity (PPBC).

However, this choice is not without risk. PPBC's have been proposed and built before, for example, for the SSC low energy booster [3] and the kaon factory at TRIUMF [4]. Although the TRIUMF prototype did achieve its required specifications [5], it eventually developed a vacuum problem. And the SSC cavity never achieved its design power because localized heating in the garnet caused it to fail. [6] The repair and postmortems of these failures are also challenging because safety requirements have to be met. For example, the handling of beryllium oxide (BeO) cooling disks that are sandwiched between the garnet disks.

Besides localized heating of the garnet from the RF, there are other challenges, like the eddy current heating from the magnetic bias field ramp that will not be discussed here.

NEW DESIGN

The new design is shown in Fig. 1. The goal is to exploit the SSC and TRIUMF experiences to create a cavity that can work reliably without overheating. Although this new cavity looks similar to the SSC and TRIUMF designs, it is actually quite different: (a) Removal of BeO cooling disks — cooling is achieved by water paths that are outside the cavity. This design allows cooling of the inside circumference and outside circumference of the garnets. (b) The garnet is no longer symmetric about the RF neck region.

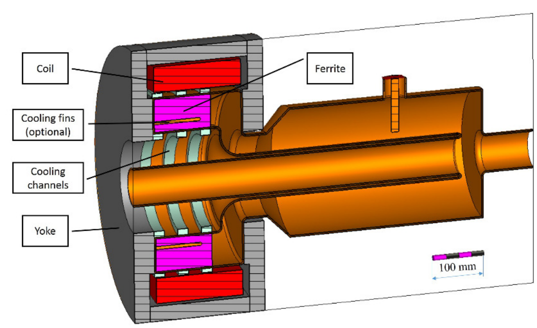

Figure 1: The cavity model.

Localized Heating

Localized hotspots are the major problem with all PPBC's designed and built so far. In order to mitigate this problem, it is essential that MWS be able to correctly calculate the heat density and the hot spots in the garnet material. Unfortunately, the magnetic and electric characteristics of the garnet material, AL800, that is used in the present design from published sources are insufficient for this application and thus, the AL800 properties have to be measured at Fermilab.

AL800 PROPERTIES

The biggest challenge in designing a workable cavity of this type is due to unavoidable nonuniformities in the garnet internal magnetic field. As the real and the imaginary parts of the biased garnet permeability are strong non-linear

QUENCH PERFORMANCE OF THE FIRST TWIN-APERTURE 11 T DIPOLE FOR LHC UPGRADES*

A.V. Zlobin#, N. Andreev, G. Apollinari, E. Barzi, G. Chlachidze, A. Nobrega, I. Novitski, S. Stoynev, D. Turrioni, FNAL, Batavia, IL 60510, USA
B. Auchmann, S. Izquierdo Bermudez, M. Karppinen, L. Rossi, F. Savary, D. Smekens, CERN, CH-1211 Geneva 23, Switzerland

Abstract

FNAL and CERN are developing a twin-aperture 11 T Nb_3Sn dipole suitable for installation in the LHC. A single-aperture 2-m long dipole demonstrator and two 1-m long dipole models have been fabricated and tested at FNAL in 2012-2014. The two 1 m long collared coils were then assembled into the first twin-aperture Nb_3Sn demonstrator dipole and tested. Test results of this twin-aperture Nb_3Sn dipole model are reported and discussed.

INTRODUCTION

The planned upgrades of the Large Hadron Collider (LHC) call for additional collimators in the dispersion suppressor (DS) areas around points 2, 3, 7, and CMS and ATLAS detectors [1]. The work on the development of the 11 T Nb_3Sn dipole for the LHC collimation system upgrade, started in 2011 [2], continues at FNAL [3] and at CERN [4]. Seven 1 m long coils were fabricated at FNAL since 2012. Four coils were assembled in two collared coil blocks and tested in a single-aperture configuration [5]-[7]. Both collared coils were trained above the LHC nominal operation current of 11.85 kA to a field in the magnet aperture of ~11.6 T at 1.9 K, or 97% of the dipole design field of 12 T. During the tests important information on the magnet quench performance and field quality, including geometrical harmonics, coil magnetization, iron saturation and dynamic effects in 11 T dipole models, was obtained [5]. These collared coils have been assembled in a first twin-aperture dipole model MBHDP01 and tested in February-March 2015. This paper summarizes the twin-aperture magnet design and construction, and reports test results of this Nb_3Sn dipole model focusing on magnet quench performance including training, ramp rate sensitivity and temperature dependence of the magnet quench current. The twin-aperture dipole quench performance is compared with the data for the single-aperture models MBHSP02 and MBHSP03.

MAGNET DESIGN AND CONSTRUCTION

The design concepts of the 11 T Nb_3Sn dipole in single-aperture and twin-aperture configurations, developed at FNAL and at CERN, are described in [2]-[8]. The calculated 2D design parameters for single- and twin-aperture dipoles (FNAL design) at I_{nom} of 11.85 kA, T_{op} of 1.9 K, nominal strand J_c(12T,4.2K) of 2750 A/mm^2 and cable I_c degradation of 10% are reported in Table 1.

Table 1: 11 T Dipole Design Parameters

Parameter	Single-aperture	Twin-aperture
Yoke outer diameter, mm	400	550
Nominal bore field at I_{nom}, T	10.88	11.23
Short sample field B_{SSL} at T_{op}, T	13.4	13.9
Margin B_{nom}/B_{SSL} at T_{op}, %	81	83
Stored energy at I_{nom}, kJ/m	424	969
F_x/quadrant at I_{nom}, MN/m	2.89	3.16
F_y/quadrant at I_{nom}, MN/m	-1.58	-1.59

In a twin-aperture configuration, two collared coils are placed inside a vertically split iron yoke with an iron spacer in between, and are surrounded by a thick welded stainless steel skin. Two thick stainless steel end plates, welded to the skin, restrict the axial motion of both collared coils.

MBHDP01 uses two collared coils: one, tested in MBHSP02, consists of coils 05 and 07 and the other one, tested in MBHSP03, consists of coils 09 and 10. Based on the test results in a single-aperture configuration, the collared coil with coils 09 and 10, was re-collared with a slightly larger radial shim of 0.075 mm installed in between coil and collar to increase the coil pre-stress. The midplane collar-yoke shims, the same for both collared coils, were reduced to the minimum size necessary to compensate for the difference in collar and yoke thermal contraction. These midplane shims, the same as in MBHSP03, provide some small collared coil bending at room temperature to keep contact between the collar and the yoke after cooling down. All the coils are electrically conneted in series as shown in Fig. 1 (left). The assembled twin-aperture dipole model MBHDP01 before end plate welding and coil splicing is shown in Fig.1 (right).

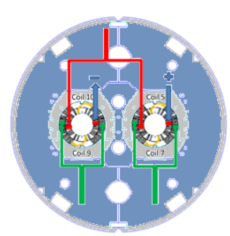

Figure 1: The coil electrical connection (left) and the assembled MBHDP01 cold mass before end plate welding and coil splicing (right).

DESIGN CONCEPT AND PARAMETERS OF A 15 T Nb_3Sn DIPOLE DEMONSTRATOR FOR A 100 TeV HADRON COLLIDER*

A.V. Zlobin#, N. Andreev, E. Barzi, V.V. Kashikhin, I. Novitski, FNAL, Batavia, IL 60510, USA

Abstract

FNAL has started the development of a 15 T Nb_3Sn dipole demonstrator for a 100 TeV scale hadron collider. This paper describes the design concept and parameters of the 15 T Nb_3Sn dipole demonstrator. The dipole magnetic, mechanical and quench protection concept and parameters are presented and discussed.

INTRODUCTION

Hadron Colliders (HC) are the most powerful discovery tools in modern high energy physics. Interest to a HC with energy above the LHC reach gained further momentum in the strategic plans recently developed in the U.S., Europe and China [1-3]. To build a ~100 TeV HC in a ~100 km tunnel, ~15 T dipoles operating at 1.9 or 4.5 K with 15-20% margin are needed. A nominal operation field up to 15-16 T can be provided by the Nb_3Sn technology. A practical demonstration of this field level in accelerator-quality magnets and a substantial reduction of magnet costs are key conditions for the realization of such a machine.

The main challenges for 15 T Nb_3Sn magnets include significantly stronger Lorentz forces and larger stored energy. The stronger forces generate higher stresses in the coil and mechanical structure and, thus, may need stress control to maintain them below 150 MPa, which is acceptable for brittle Nb_3Sn. The larger stored energy leads to further complications in the magnet quench protection.

FNAL has started the development of a 15 T Nb_3Sn dipole demonstrator for a 100 TeV scale HC based on the optimized "cos-theta" coil design. As a first step, the existing 11 T dipole, developed for LHC upgrades [4], will be modified by adding two layers to achieve the field of 15 T in a 60 mm aperture. Then, to increase the field margin the innermost 2-layer coil will be replaced with an optimized coil using the conductor grading approach. This paper describes the design concept and parameters of the 15 T Nb_3Sn dipole demonstrator.

MAGNET DESIGN STUDIES

The coil width w, needed to generate the bore field $B0_{max}$, could be estimated from the following equation for the cos-theta dipole coil with an azimuthal angle of 60 degrees

$$B0_{max} = \frac{\sqrt{3}\,\mu_0}{\pi} \cdot \lambda J_c(B_{max\_coil}) \cdot w$$

where λ is the fraction of superconductor in a coil (λ=0.25) and $J_c(B_{max\_coil})$ is the superconductor critical current density at B_{max_coil} in the coil (usually B_{max_coil} is ~ $1.05 \cdot B0_{max}$). Thus, to achieve $B0_{max}$=15 T using Nb_3Sn strands with a realistic $J_c(15\ T)$ of 1500 A/mm^2, the coil width w has to be ~60 mm. When using the same 15 mm wide cables as in the FNAL 11 T dipole [4], this requires a 4-layer coil design.

The chosen coil aperture of 60 mm, convenient for re-using the 11 T dipole coils, provides also enough room for a beam screen to intercept the large synchrotron radiation expected in a 100 TeV scale HC. To reduce the demonstrator cost, a collarless design with 2 mm thick spacer between the coil and the yoke was adopted. The standard thickness of the insulation between the coil layers as well as the coil ground insulation thickness are 0.5 mm. The mid-plane insulation is 0.2 mm.

Several four-layer coils were designed using two cables with a width of 15 mm and different thickness. The cable parameters are listed in Table 1. The cables use 1.0 and 0.7 mm Nb_3Sn strands with a critical current density $J_c(15T;4.2K)$ of 1500 A/mm^2 and a nominal Cu/SC ratio of 1.13. Nb_3Sn cables with these or similar parameters have already been developed at FNAL and used in HFDA and 11 T dipole models [5], [6].

Table 1: Reacted Cable Parameters

Parameter	Cable 1	Cable 2
Number of strands	28	40
Mid-thickness, mm	1.870	1.319
Width, mm	15.10	15.10
Keystone angle, degree	0.805	0.805

The coil cross-sections were optimized using the ROXIE code [7]. The goal was to achieve a maximum dipole field of 15 T or higher at 4.3 K and geometrical field harmonics below the 10^{-4} level at R_{ref}=17 mm, reduce the coil volume and inductance, and control the coil azimuthal stress. Five 4-layer coil designs with graded coils were analyzed. The main parameters of these coils are summarized in Table 2. The coil cross-sections with relative field errors in the aperture (dark blue area) and numbers of turns per coil layer N_L are shown in Fig. 1.

Table 2: Coil Parameters

Parameter	Coil design				
	4L-1	4L-2	4L-3	4L-4	4L-5
N_{L1}	15	17	18	18	18
N_{L2}	25	25	25	25	26
N_{L3}	47	40	39	36	33
N_{L4}	54	43	38	35	32
N_{tot} coil	141	125	120	114	109
S_{coil}, cm^2	31.4	28.4	27.5	26.3	25.4
$B0_{max}$(4.3K), T	16.3	16.1	16.0	15.8	15.7
I_{max}(4.3K), kA	9.89	10.34	10.52	10.84	11.10
L, mH/m	39.9	33.8	31.5	28.7	26.5
$W(B_{max})$, MJ/m	1.95	1.81	1.74	1.69	1.63

PULSED POWER SYSTEMS FOR ESS KLYSTRONS

I. Roth, M. P.J. Gaudreau, M. Kempkes, Diversified Technologies, Inc., Bedford, MA 01730 USA
J.L. Lancelot, P. Dupire, J.D. Holzmann, SigmaPhi Electronics, 67500 Haguenau, France

Abstract

Diversified Technologies, Inc. (DTI) is building three long pulse solid-state klystron transmitters to meet spallation source requirements. Two of the three will be installed at CEA Saclay and the National Institute of Nuclear and Particle Physics (IN2P3) in 2015, to be used as test stands for the European Spallation Source (ESS), The third system will be installed at Oak Ridge National Laboratory (ORNL) for the Spallation Neutron Source (SNS).

INTRODUCTION

Diversified Technologies, Inc. (DTI), in partnership with SigmaPhi Electronics, has designed an advanced, high voltage solid-state modulator for the European Spallation Source (ESS) klystron tubes (Figure 1). The ESS modulator uses a series-switch design driving a pulse transformer, with an advanced, patent pending regulator design to maintain a highly regulated cathode voltage as well as a constant load to the external power grid. The success of the design in meeting the ESS pulse requirements (Table 1) is shown in Figure 2.

The ESS modulator is a proven design, delivering significant advantages in klystron performance through:

- Highly reliable operation, demonstrated in hundreds of systems worldwide, and predicted to significantly exceed ESS requirements
- Flicker- and droop-free operation over a range of operating parameters
- All active electronics in air for easy maintenance

Table 1: ESS Modulator Requirements

Specification	
Voltage	-115 kV
Current	50 A
Pulse Width	3.5 ms
Frequency	14 Hz (max)
Average Power	290 kW
Droop	< 1%
Pulse Repeatability	< 0.1%

Figure 1: System designed for Oak Ridge National Laboratory Spallation Neutron Source. Design is optimized for long pulse operation with highest possible reliability and availabilityrequired for particle accelerator user facilities and test stands. High voltage cables connect to dummy load or klystrons not shown in figure.

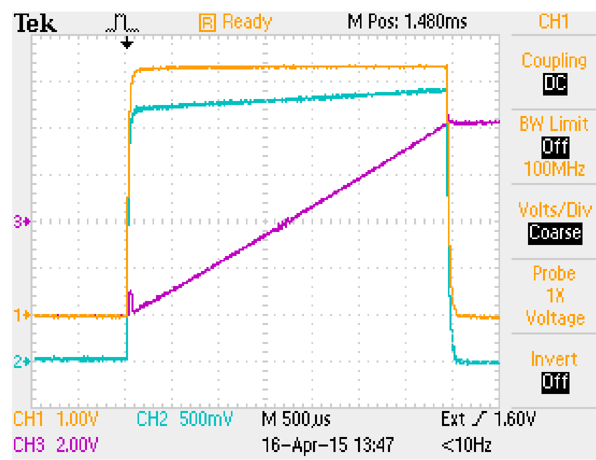

Figure 2: 106 kV, 58 A test pulse showing output voltage (yellow, 20 kV/div), current (blue, 10 A/div) and regulator voltage (purple, 200 V/div). Current increases slightly with time due to heating of the resistive load.

DESIGN

The heart of the ESS modulator is a high voltage solid-state switch. The switch is made of seven series-connected IGBT modules, and operates at 6.7 kV. The IGBTs in the switch give N+2 redundancy: two of the devices can fail without affecting the ability of the switch

SHORT PULSE MARX MODULATOR*

R. Phillips, M. P.J. Gaudreau, M. Kempkes, R. Simpson,
Diversified Technologies, Inc., Bedford, MA 01730, USA
J. Casey, Rockfield Research, Inc., Las Vegas, NV, 89135, USA

Abstract

Under a U.S. Department of Energy grant, Diversified Technologies, Inc. (DTI) has developed a short pulse, solid-state Marx modulator. The modulator is designed for high efficiency in the 100 kV to 500 kV range, for currents up to 250 A, pulse lengths of 0.2 to 5.0 µs, and risetimes <300 ns. Key objectives of the development effort are modularity and scalability, combined with low cost and ease of manufacture. For short-pulse modulators, this Marx topology provides a means to achieve fast risetimes and flattop control that are not available with hard switch or transformer-coupled topologies.

INTRODUCTION

Under a DOE SBIR grant and based on research begun under the Next Generation Linear Collider (NLC) program, Diversified Technologies, Inc. (DTI) has developed a short pulse, solid-state Marx modulator relevant to the Compact Linear Collider (CLIC) and numerous X-Band accelerator designs (Fig. 1). The modulator is designed for high efficiency in the 100 kV to 500 kV range, for currents up to 250 A, pulse lengths of 0.2 to 5.0 µs, and risetimes <300 ns (Table 1). This fully optimized, transformer-less modulator design is capable of meeting the demanding requirements of very high voltage pulses at short pulsewidths.

Table 1: Yale Marx Design Parameters

Item	Specification
Pulse Voltage	500 kV
Pulse Current	250 A
Pulse Width	1.8 us
Repetition Rate	20 Hz
Module Voltage	12.5 kV
Module Capacitance	0.6 µF
# Modules for Base Pulse	40
Total # Modules in System	48 – 50
Expected Risetime	300 ns
Heater Voltage	24 VDC
Heater Current	21 A
Insulation	Oil

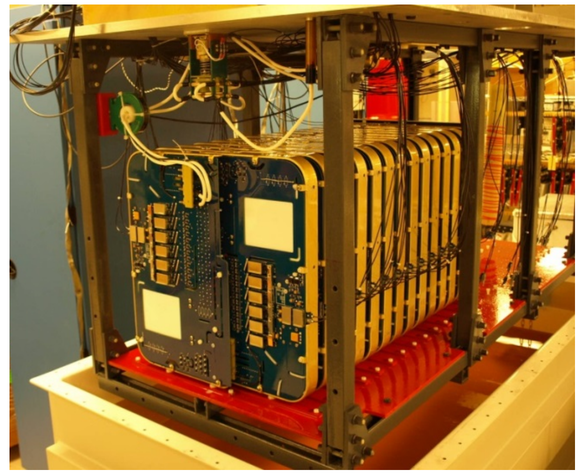

Figure 1: The Yale Marx 500 kV modulator charges many stages in parallel at low voltage, then discharges in series at high voltage. Each 12.5 kV, 250 A “flat pack” module is identical, providing for low fabrication and assembly cost.

A Marx generator is a system with energy storage capacitors which are charged in parallel at low voltage and discharged in series to provide high voltage output. This is a legacy idea, practiced for decades using resistor charging networks and spark-gaps for discharge. Constrained by the limits of closing switches, such systems required pulse forming networks and crowbars, with their attendant limitations.

The Marx topology allows a new degree of freedom unavailable to other architectures – DTI can intentionally underdamp the series snubbing within the pulse circuit. This cannot be done conventionally – the reactive overshoot endangers the load. In a Marx, we can compensate for the overshoot by initially firing only a subset of the switches – thus “sling-shotting” the leading edge faster than otherwise possible. We can tune the number and timing of subsequent module firings to counter the reactive ringing, and hold a flattop pulse to the desired voltage and accuracy.

Similarly, additional modules may be added to fire sequentially later in the pulse to compensate for capacitor droop. This is a critical enabling technology motivating Marx use for long-pulse accelerators (such as ILC), and yields valuable optimization even for very short-pulse systems. The reduction of capacitor size afforded by this flexibility further reduces parasitic capacitance, and thus reduces equipment size and cost while increasing power efficiency.

PHASE TRANSIENTS IN THE HIGHER HARMONIC RF SYSTEM FOR THE ALS-U PROPOSAL*

J. M. Byrd, S. De Santis, T. Luo, C. Steier, LBNL, Berkeley, CA, USA

Abstract

The proposed upgrade of the ALS to a diffraction limited light source (ALS-U) requires lengthening the bunch by a factor up to four in order to limit the emittance growth due to intra-beam scattering, increase the Touschek lifetime to a value consistent with a on-axis swap-out period of about 30 seconds, improve beam stability, and lower the peak current with consequent reduction of high-frequency wakefields and beampipe heating.

To obtain the necessary bunch lengthening factor, a higher harmonic RF system will be used to flatten the total accelerating voltage seen by the circulating bunches. A fourfold increase of the bunch length requires operating the harmonic RF system near the optimum flat condition, which corresponds to cancellation of first and second derivatives of the main RF voltage waveform at the time of the bunch passage (i.e. at the synchronous phase). Such a situation presents particular challenges since a significantly stretched bunch covers a large interval of RF phases and it deviates considerably from the usual gaussian longitudinal density distribution. Furthermore, in the case of a passive harmonic system, gaps in the fill pattern may cause part of the bunch train to miss the lengthening target. At this time, two options, 500 and 100 MHz, are being evaluated for the main RF frequency and we have calculated the main parameters for a harmonic system in each case. The 500 MHz option requires gaps at least 10 ns long in the fill pattern for the rise time of the on-axis injection kickers, while with a 100 MHz main RF frequency it is possible to use a perfectly uniform beam. Since the first one is the favoured option for several reasons, ensuring that gaps are not a limiting factor in lengthening the bunch is necessary before committing to this solution. In this paper we present our studies, using both computer simulations and experiments on the ALS, that show that a 500 MHz main RF system, together with a 1.5 GHz harmonic system is a viable solution for the ALS-U requirements.

INTRODUCTION

The ALS-U proposal envisions the upgrade of the present ALS synchrotron light source into a new ultra-low emittance machine for the production of diffraction-limited soft X-rays. The details of the proposal are reported in [1]. At our 2 GeV beam energy, intra-beam scattering becomes a serious limitation in achieving the desired ultra-low beam transverse emittance, of the order of 50 picometers, without decreasing the stored current. Therefore harmonic RF cavities are included in the machine design, to lengthen the bunch. In addition to reducing intra-beam scattering, longer bunches have a longer Touschek lifetime, which allows to increase the interval between bunch train swap-outs. The spread in synchrotron frequency caused by the flattened accelerating voltage waveform introduces Landau damping, thus improving beam stability. Finally, the lower peak current reduces beam heating of vacuum chamber elements and the high-frequency components of the beam power spectrum are also eliminated. At present, we are investigating two different options for the main RF frequency, as detailed in [2]. Depending on the frequency chosen the harmonic system would operate at 1.5 GHz (third harmonic of 500 MHz), or at 500 MHz (fifth harmonic of 100 MHz). Fill patterns are also different between the two options: in order to allow 10 ns long gaps for the operation of the injection/extraction kickers, the 500 MHz main RF machine would store 11 trains of 26 bunches each, while in the 100 MHz main RF case all the 66 RF buckets would be filled. The RF main parameters are summarized in Table 1.

Table 1: Main RF Parameters

Parameter	Value	
Beam Energy (E_b)		2 GeV
Circumference (L_R)		196.44 m
Beam Current (I_b)		500 mA
Main RF Frequency (f_{RF})	500 MHz	100 MHz
Number of Bunches (N_b)	275	66
Energy Loss/Turn (U_0)		165 keV (260 keV with ID's)
Energy Spread ($\Delta\varepsilon$)		$8{\cdot}10^{-4}$
Mom. Compaction (α)		$2.69{\cdot}10^{-4}$
Nat. Sync. Tune (Q_s)		0.002
Main RF Voltage (V_{RF})	760 kV	420 kV
Nat. Bunch Length (σ_b)	11 ps	35 ps
Higher Harm. Freq. (f_H)	1.5 GHz (3rd harm.)	500 MHz (5th harm.)
Req. Lengthening Factor		3-4

ABSTRACT

PXIE is a prototype front end system [1] for the proposed PIP-II accelerator upgrade at Fermilab. An integral component of the front end is a 162.5 MHz, normal conducting, continuous wave (CW), radio-frequency quadrupole (RFQ) cavity that was designed and is being fabricated by LBNL. This RFQ will accelerate a continuous stream of up to 10mA of H- ions from 30 keV to 2.1 MeV. The four-vane, 4.45 meter long RFQ consists of four modules, each constructed from 2 pairs of identical modulated vanes. Vane modulations are machined using a custom carbide cutter designed at LBNL. Other machined features include ports for slug tuners, pi-mode rods, sensing loops, vacuum pumps and RF couplers. Vanes at the entrance and exit possess cutbacks for RF matching to the end plates. The vanes and pi-mode rods are bonded via hydrogen brazing with Cusil wire alloy. The brazing process mechanically bonds the RFQ vanes together and vacuum seals the module along its length. Vane fabrication is successfully completed, and the braze process has proved successful. Delivery of the full RFQ beam-line is expected in the middle of 2015.

VANE FABRICATION

For details on the PXIE RFQ design, please refer to [2]. Fabrication began with end machining of all vanes, followed by rough machining on all sides. Each vane was then sent out for gun-drilling ~ 1.0 meter long cooling channels. After gun drilling was complete, copper plugs were electron-beam welded to seal the cooling channels at the drilled end. The vanes then returned to LBNL where flow and leak tests were performed to verify the integrity of the e-beam weld, as well as check for any flow blockages in the cooling channels. After this, machining of tuner, pi-mode rod, sensing loop, and vacuum ports began. In addition to port features, several tapped hole patterns were machined in the backside for vane handling and mounting, which proved critical for handling and restraining the vanes later in the fabrication process. Once finished, each vane underwent CMM inspection of the backside to verify tolerances for flatness and port locations, as seen in Figure 1.

#arlambert@lbl.gov

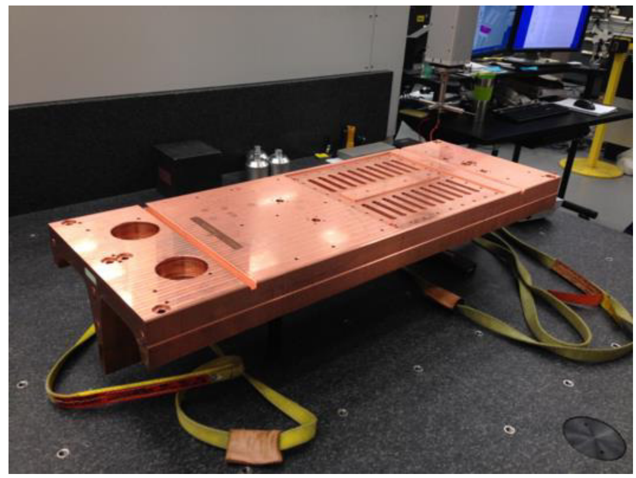

Figure 1: Backside port CMM check.

The vanes were then mounted to 3 in. thick stainless steel plates that restrained the copper during inner cavity rough machining, as well as subsequent final cavity machining. CMM inspection was then performed after rough machining of the cavity, followed by machining of the cavity walls to their final dimension. Vanes for modules 1 and 4 then had their cutbacks machined, as well the radial matcher for module 1 vanes. The cutback machining is initially checked with aluminum blanks to verify the machine program, as seen in Figure 2.

Figure 2: Aluminum test pieces to verify cutback machining program, if acceptable the program is saved on machine to be duplicated on the production part.

The vanes are again submitted to CMM inspection; after which the modulation machining begins. Each modulation program is initially verified using test pieces

PROGRESS ON THE MICE 201 MHz CAVITIES AT LBNL*

T. Luo†, A. DeMello, A. Lambert, D. Li, S. Prestemon, S. Virostek
LBNL, Berkeley, CA 94720, USA

Abstract

The international Muon Ionization Cooling Experiment aims to demonstrate the transverse cooling of a muon beam by ionization in energy absorbers. The final MICE cooling channel configuration has two RF modules, each housing a 201 MHz RF cavity used to compensate the longitudinal energy loss in the absorbers. The LBNL team has designed and fabricated all of the MICE RF cavities. The cavities will be post-processed and RF measured before being installed in the RF modules. We present the recent progress on this work, including the low level RF measurement on cavity body and Be windows, the electro-polishing (EP) on the cavity surface, the numerical simulation on cavity Be window detuning, and the ongoing mechanical designing work of cavity components.

INTRODUCTION

The international Muon Ionization Cooling Experiment (MICE) [1] aims to demonstrate the transverse cooling of a muon beam by ionization in energy absorbers. The final MICE cooling channel configuration has two RF modules, each housing a 201 MHz RF cavity to compensate the longitudinal energy loss in absorbers [2]. Recently a lot of work has been done at LBNL on the cavity production, including the characteristic frequencies measurement of cavity bodies and beryllium windows, electro-polishing of cavity inner surface, simulation of frequency detuning due to Be windows, modification of cavity coupler design, actuator design and prototype test, etc. In this paper, we will report these progresses.

CAVITY BODY AND BE WINDOW FREQUENCY MEASUREMENT

The MICE cavity is composed of a copper cavity body and two Be windows. Due to the production process, each cavity body and window has slightly different characteristic frequency. Under the first order approximation, the cavity frequency can be decomposed into the linear combination of cavity body frequency f_b and each window frequency f_{w1} and f_{w2}:

$$f_c = f_b \pm f_{w1} \pm f_{w2},$$

where the "+" corresponds to the curved-out window and "-" the curved-in. Once we know all the f_b and f_w, we can predict the cavity frequency with any combination of cavity body and Be windows without assembling one. The accuracy of this prediction is proved to be within 5kHz by Omega3P [3] simulation.

To measure the characteristic frequencies, we assemble a cavity, flip the direction of the Be windows one at a time and measure the cavity frequency for each assembly. With the linear approximation:

$$\begin{aligned} f_{c1} &= f_b - f_{w1} - f_{w2}, \\ f_{c2} &= f_b - f_{w1} + f_{w2}, \\ f_{c3} &= f_0 + f_{w1} - f_{w2} \end{aligned}$$

, and with the measured f_{c1}, f_{c2} and f_{c3}, we can calculate f_b, f_{w1} and f_{w2}. The measurement set up and the S11 measurement on a Network Analyzer are shown in Figure 1. The frequency results are shown in Table 1. After the electropolishing, we will select the two cavities bodies with the best surface condition, then pick up a pair of Be windows for each body to achieve the desired cavity frequency.

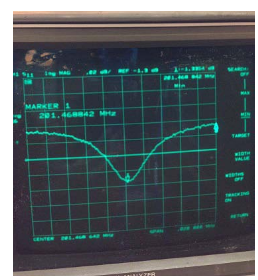

Figure 1: Cavity frequency measurement Left: Set up; Right: S11 measurement on Network Analyzer.

Table 1: Characteristic Frequency of Cavity Body and Be Window

THERMAL AND LORENTZ FORCE ANALYSIS OF BERYLLIUM WINDOWS FOR A RECTILINEAR MUON COOLING CHANNEL*

T. Luo†, D. Li, S. Virostek, LBNL, Berkeley, CA 94720, USA
R. Palmer, D. Stratakis, BNL, Upton, NY 11973, USA
D. Bowring, FNAL, Batavia, IL 60510, USA

Abstract

Reduction of the 6-dimensional phase-space of a muon beam by several orders of magnitude is a key requirement for a Muon Collider. Recently, a 12-stage rectilinear ionization cooling channel has been proposed to achieve that goal. The channel consists of a series of low frequency (325 MHz-650 MHz) normal conducting pillbox cavities, which are enclosed with thin beryllium windows (foils) to increase shunt impedance and give a higher field on-axis for a given amount of power. These windows are subject to ohmic heating from RF currents and Lorentz force from the EM field in the cavity, both of which will produce out of the plane displacements that can detune the cavity frequency. In this study, using the TEM3P code, we report on a detailed thermal and mechanical analysis for the actual Be windows used on a 325 MHz cavity in a vacuum ionization cooling rectilinear channel for a Muon Collider.

INTRODUCTION

Recently, interest has increased in the possibility of using muon in high-energy physics as the colliding particles in μ^+-μ^- colliders [1]. The liability of muons is that they are created in a diffuse phase-space. As a result, the volume of the 6-Dimensional (6D) phase-space must be rapidly reduced via ionization cooling [2] by several orders of magnitude in order to be able to further accelerate it.

To reduce the transverse emittance, the beam is strongly focused with high magnetic fields and subsequently sent through an absorber material to reduce the overall momentum. The beam regains longitudinal momentum in RF cavities, resulting in an overall loss in transverse emittance. Longitudinal emittance reduction is achieved by shaping the absorbers into wedges and providing a bending magnetic field, generating a dispersion such that particles with higher energy are sent through more material. Recently, a 12-stage tapered rectilinear scheme for cooling a muon beam sufficiently for use in a Muon Collider has been designed and simulated [3].

Thin Be windows may be utilized in the cooling channel to increase shunt impedance of the closed-cell rf cavities. In this study, using the TEM3P code, we report on a detailed thermal and mechanical analysis for the actual Be windows used on the first stage (stage A1), which is the most challenging due to its large beam aperture (30 cm).

† tluo@lbl.gov

RF CAVITY WITH BERYLLIUM WINDOW

The cavities in the rectilinear Muon Cooling channel are of pillbox type. The Be windows enclose the cavity on both sides to increase the cavity shunt impedance significantly.

The Be window needs to be thin enought to be almost transparent to the muon beam. However, the thinner the window, the poorer its thermal conduction. Besides, there is no extra cooling on the window with all the heat transfered out by thermal conduction. A "step" window design is proposed as a compromise between emittance dilution and the thermal heating. The window parameters of the first four stages are shown in Table 1.

Table 1: Window Parameters for the Frst 4 Stages of the Cooling Channel

Stg	f (MHz)	rWin (cm)	rStep (mm)	t0 (mm)	t1 (mm)
A1	325	30.0	16.0	0.300	1.40
A2	325	25.0	15.0	0.200	0.80
A3	650	19.0	10.0	0.200	0.60
A4	650	13.2	11.4	0.125	0.38

In this paper, we will focus on the cavity for A1 stage, which has the largest aperture, thus most challenging for the thermal heating. A schematic drawing of A1 stage lattice cell and its RF cavity model are shown in Figure 1.

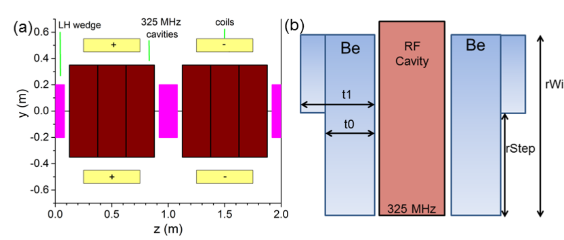

Figure 1: (a) Schematic drawing of Stage A1, and (b) RF cavity model.

Like MICE cavity, the Be windows are designed into a curved profile to control the direction of thermal expansion and reduce the thermal stress. Based on the parameters in Table 1 and the window curvature from MICE cavity, we build a 3D cavity model, as shown in Figure 2, for further study.

AN RFQ DIRECT INJECTION SCHEME FOR THE ISODAR HIGH INTENSITY H_2^+ CYCLOTRON*

D. Winklehner, MIT, Cambridge, MA, USA
R. Hamm, R&M Technical Enterprises, Pleasanton, CA, USA
J. Alonso, J. Conrad, MIT, Cambridge, MA, USA

Abstract

IsoDAR is a novel experiment designed to measure neutrino oscillations through $\bar{\nu}_e$ disappearance, thus providing a definitive search for sterile neutrinos. In order to generate the necessary anti-neutrino flux, a high intensity primary proton beam is needed. In IsoDAR, H_2^+ is accelerated and is stripped into protons just before the target, to overcome space charge issues at injection. As part of the design, we have refined an old proposal to use an RFQ to axially inject bunched H_2^+ ions into the driver cyclotron. This method has several advantages over a classical low energy beam transport (LEBT) design: (1) The bunching efficiency is higher than for the previously considered two-gap buncher and thus the overall injection efficiency is higher. This relaxes the constraints on the H_2^+ current required from the ion source. (2) The overall length of the LEBT can be reduced. (3) The RFQ can also accelerate the ions. This enables the ion source platform high voltage to be reduced from 70 kV to 30 kV, making underground installation easier. We are presenting the preliminary RFQ design parameters and first beam dynamics simulations from the ion source to the spiral inflector entrance.

INTRODUCTION

In the IsoDAR (Isotope Decay-At-Rest) experiment [1], H_2^+ ions will be delivered by a high performance ion source, accelerated to 60 MeV/amu in a compact cyclotron, and then stripped to protons and dumped on a beryllium target surrounded by a lithium sleeve. Neutrons generated by the protons hitting ^{9}Be will be captured on ^{7}Li, and the resulting ^{8}Li will then beta decay-at-rest, producing a very pure $\bar{\nu}_e$ beam. This accelerator and target system will be placed close (16 m from the center) to an existing neutrino detector (e.g. KamLAND) to measure $\bar{\nu}_e$ disappearance from neutrino oscillations via inverse beta decay. This process is depicted in Figure 1. The short baseline will allow tracing out more than a full period of the oscillation wave inside the detector, thus presenting a definitive search for proposed sterile neutrinos that may participate in the oscillation but not in the weak interaction. In order to get definitive results over the course of a few years, a high neutrino flux is necessary; hence a very high primary proton beam is desired.

In the summer months of 2013 and 2014, tests of high intensity H_2^+ production, transport, and injection into a cyclotron were conducted at Best Cyclotron Systems, Inc.

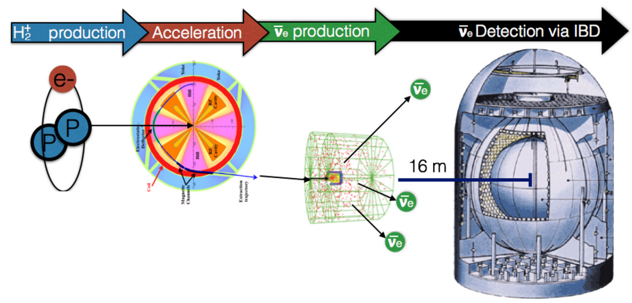

Figure 1: Cartoon of the IsoDAR experiment. Detector image courtesy of the KamLAND collaboration.

(BCS) in Vancouver, Canada. The ion source, borrowed from INFN Catania in Italy, was the "versatile ion source" (VIS), an off-resonance 2.45 GHz ECR ion source. From the VIS, it was possible to extract 12 mA of H_2^+. The main objective was to test the extent to which space charge will be a limiting factor in the low energy beam transport and the injection into the cyclotron through a spiral inflector. It was possible to show that the transmission through the spiral inflector at beam currents on the order of 10 mA was $\approx$ 95%. The typical acceptance of an unbunched beam into the cyclotron RF bucket is on the order of 5%, and with a 2-gap multiharmonic buncher, this acceptance can be increased to 10-20%. Considering the present performance of the VIS and suggested improvements to the source, the nominal 5 mA of H_2^+ extracted from the cyclotron is achievable, but pushing the limits. We are exploring two avenues to improve the situation: (1) We are constructing a new ion source (multicusp) dedicated to the production of H_2^+, and (2) we are investigating the use of an RFQ to replace the LEBT. The RFQ is a linear accelerator that can focus, bunch, and accelerate a continuous beam of charged particles at low energies with high bunching and transmission efficiencies. RFQs are very attractive for low energy ion accelerators, e.g. for applications with high current beams or in combination with sources such as an ECR, because the source can be close to ground potential and is easy to operate and to service. Because the basic RFQ concept can be implemented over a wide range of frequencies, voltages, and physical dimensions, it is an ideal structure to use for bunching an intense ion beam for injection into a cyclotron and has already been used in several cyclotron systems for radial injection of input beams [2]. It can also be used for axial injection at much lower energies as first proposed in 1981 [3]. However, to date, direct axial injection into a compact cyclotron using an RFQ has not yet been realized. For high acceptance into

Abstract

The Helical Cooling Channel scheme envisioned for a Muon Collider or Neutrino Factory requires high pressure gas filled radio frequency cavities to operate in superconducting magnets. One method to shrink the radii of the cavities is to load them with a dielectric material. The dielectric constant, loss tangent, and dielectric strength are important in determining the most suitable material. Low powered RF measurements of the dielectric constant and loss tangent were taken for multiple purities of alumina and magnesium calcium titanate, as well as cordierite, forsterite, and aluminum nitride. Measurements of alumina were consistent with previously reported results. The results were used to design an insert for a high powered RF test that will include sending beam through the cavity.

INTRODUCTION

One muon cooling channel scheme, the Helical Cooling Channel (HCC), utilizes high pressure gas filled radio frequency (HPRF) normal conducting cavities placed within superconducting solenoids [1]. Current magnet technology dictates the radial size of these cavities be smaller than that of a pillbox cavity filled with hydrogen gas in the TM_{010} mode at 325 or 650 MHz [2]. Loading the cavities with a dielectric material is one solution with which to shrink the radii of the cavities. An experiment to determine the dielectric strength of 99.8% pure alumina has already been performed [3]. This paper will present an expansion of those results, including the dielectric constant and loss tangent of different purites of alumina, as well as magnesium calcium titanate (MCT), cordierite, forsterite, and aluminum nitride (AlN).

MATERIAL SELECTION

For a simple pillbox filled with a dielectic, the resonant frequency is

$$f_{nml} = \frac{c}{2\pi\sqrt{\mu_r\,\epsilon_r}}\sqrt{\left(\frac{p_{nm}}{R}\right)^2 + \left(\frac{l\pi}{L}\right)^2} \qquad (1)$$

where c is the speed of light, μ_r and ϵ_r are the relative permeability and permittivity, respectively, and R and L are the radius and length of the cavity, respectively. Therefore in order to maintain a constant resonant frequency, one may add a dielectric in order to decrease the radius of the cavity. The loss tangent, $\tan\delta$, of a dielectric is related to the permittivity by

$$\epsilon = \epsilon_0\,\epsilon_r(1 - j\,\tan\delta) \qquad (2)$$

where ϵ_0 is the permittivity of free space.

The choice of material is important in designing a cooling channel in that an appropriate amount of material, based on its permittivity, must be inserted in order to bring the radius of the cavity down while minimizing the energy dissipation in the dielectric material.

Samples of alumina of various purities were obtained from Morgan Advanced Ceramics [4], CoorsTek [5], and Accuratus [6]. Samples of cordierite, forsterite, and magnesium calcium titanate were obtained from Euclid Techlabs [7]. A sample of aluminum nitride was obtained from Sienna Technologies, Inc. [8]. Table 1 lists the quoted properties of each sample by the manufacturer. The dielectric constant and loss tangent of each were measured in order to design a realistic cooling channel dielectric insert.

Table 1: Dielectric Constant and Loss Tangent Values (including the Frequencies) Reported by Each Manufacturer. 1 = Morgan, 2 = Accuratus, 3 = CoorsTek, 4 = Euclid, 5 = Sienna

STRIPLINE KICKER FOR INTEGRABLE OPTICS TEST ACCELERATOR

Sergey A. Antipov, University of Chicago, Chicago, Illinois, USA
Alexander Didenko, Valeri Lebedev, Alexander Valishev, Fermilab, Batavia, Illinois, USA

Abstract

We present a design of a stripline kicker for Integrable Optics Test Accelerator (IOTA). For its experimental program IOTA needs two full-aperture kickers, capable to create an arbitrary controllable kick in 2D. For that reason their strengths are variable in a wide range of amplitudes up to 16 mrad, and the pulse length 100 ns is less than a revolution period for electrons. In addition, the kicker should have a physical aperture of 40 mm for a proposed operation with proton beam, and an outer size of 70 mm to fit inside existing quadrupole magnets to save space in the ring. Computer simulations using CST Microwave Studio® show high field uniformity and wave impedance close to 50 Ω.

KICKER DESCRIPTION

Integrable Optics Test Accelerator is a relatively small research storage ring with the circumference of 40 m. It will operate with short bunches of 150 MeV electrons injected from the ASTA linac [1], and later with 2.5 MeV protons from HINS RFQ [2]. The ring has a flexible linear optics to allow for a variety of physics experiments [3], including nonlinear integrable optics, the concept of which is described in [4]

The nonlinear dynamics research program at IOTA involves construction of Poincare maps of phase space, and that requires two kickers: a horizontal and a vertical to be able to place the beam at an arbitrary initial amplitudes in the transverse phase space. The kickers have to be tunable in a wide range from small to full-aperture, with the physical aperture of the machine being quite large: beam pipe inner radius is 24 mm or 40 sigma of horizontal size of electron beam at the place with maximum beta-function [3]. In addition, the vertical kicker will also serve as an injection kicker.

To support the required short length of kicker pulse a stripline kicker was preferred. It is also relatively simple in design and fabrication. The kickers are going to be fed by recommissioned power supplies from Fermilab's Tevatron injection kickers, which are capable of producing variable voltage pulses up to 25 kV. The power supplies have rise/fall time of about 20 ns, and are capable of producing a 100 ns-long pulse, which is slightly shorter than a revolution period of the ring – 130 ns. That allows us to make sure that the beam is affected on one turn only, and that is critical for the accuracy of experiments. The kickers are loaded with 50 Ω external resistive load.

Position of kickers in the ring is depicted in Fig. 1. Both kickers are located in the injection straight, downstream to injection Lambertson magnet. To minimize the required space one of the kickers is placed inside a quadrupole doublet. Their aperture of 72 mm determines a limit on the outer dimensions of the kicker's pipe. Table 1 lists basic parameters of the ring and its kickers.

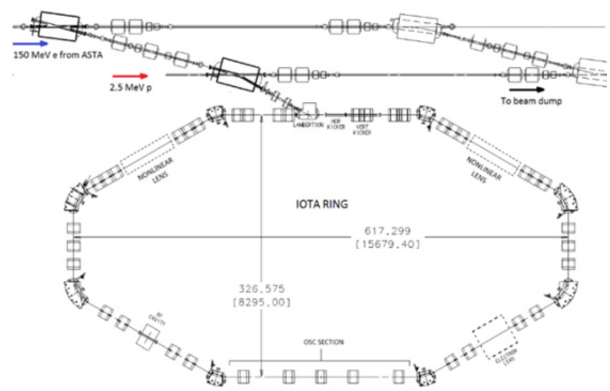

Figure 1: IOTA Ring, configuration for nonlinear optics.

Table 1: Parameters of IOTA Ring and its Kickers for Electron Operation. Proton Parameters are in Parentheses

Beam energy	150 MeV (2.5 MeV)
Revolution period	130 ns (1.8 μs)
RMS beam size at kicker	~ 0.2 mm (~ 3 mm)
Max plate voltage	±25 kV
Pulse duration, rep. rate	100 ns, < 1 Hz
Max. kick angle: hor., vert.	16, 8 mrad

DESIGN

The design of the kickers was inspired by a work carried out at the Budker Institute (BINP), Russia [5]. The geometry was adjusted to fit inside the existing quadrupole magnets. Since IOTA ring hosts several different experiments, requiring their own set of optics, it was crucial to minimize limitation of physical aperture, while meeting the requirements on the strength, field quality, wave impedance, and spatial constraints. The physical aperture was tentatively set to be at least 40 mm for future experiments with a proton beam. The kicker cross-section is depicted in Fig. 2.

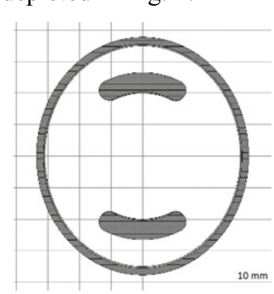

Figure 2: Kicker cross-section (vertical kicker).

GRID WINDOW TESTS ON AN 805-MHz PILLBOX CAVITY*

Y. Torun†, Illinois Institute of Technology, Chicago, IL 60616, USA
A. Moretti, Fermilab, Batavia, IL 60510, USA

Abstract

Muon ionization cooling channel designs use pillbox shaped RF cavities for improved power efficiency and fine control over phasing of individual cavities. For minimum scattering of the muon beam, the ends should be made out of a small thickness of high radiation length material. Good electrical and thermal conductivity are required to reduce power dissipation and remove the heat efficiently. Thin curved beryllium windows with TiN coating have been used successfully in the past. We have built an alternative window set consisting of grids of tubes and tested these on a pillbox cavity previously used with both thin Be and thick Cu windows. The cavity was operated with a pair of grids as well as a single grid against a flat endplate.

CAVITY WINDOWS FOR MUON COOLING

Muon ionization cooling requires sections of RF acceleration at fairly low muon energy ($\beta \simeq 0.85$) interspersed with energy absorbers at low-$\beta_\perp$ locations in a strong focusing magnetic lattice. Since there is already material in the beam path and muons do not interact strongly, additional material at high-$\beta_\perp$ locations where the RF cavities are can be acceptable as long as the contribution to beam scattering is small compared to the absorbers. Thus, the pillbox cavity geometry can be used for muon beams if electrical termination of cavity irises is done with high radiation length material. This typically yields a factor of two or higher gain in the ratio of accelerating to peak surface field compared to the standard elliptical cavity geometry with open irises. The requirements for the windows are:

- thickness that is a small fraction of radiation length for minimal beam scattering
- high electrical conductivity for reduced RF power dissipation
- high thermal conductivity to carry away the heat
- mechanical strength to withstand pulsed heating from the RF field
- mechanical strength to limit Lorentz force detuning
- low secondary electron yield to avoid multipacting
- low dark current
- ultra high vacuum compatibility

Thin curved beryllium windows with TiN coating have been used in 805- and 201-MHz prototype cavities with excellent results [1]. However, beryllium is expensive and requires special precautions due to personnel safety issues. Thermal stress at the center of the window as well as Lorentz force detuning can force a gradient limit that is lower than that due to surface breakdown considerations alone [2]. Table 1 shows a summary of window configurations used in the past on cavities built for muon cooling R&D.

Table 1: Window Configurations Tested for Muon Cooling

Window type	Application: 805-MHz pillbox	Application: 201-MHz MICE prototype
Flat thick Cu endplates	OK	OK
Flat thin pre-stressed Be	Unstable at high power	–
Curved thin Be foils	OK	OK

GRID WINDOWS

A solid conductor is not needed to achieve a pillbox-like field pattern at RF frequencies. An alternative window layout has been studied [3] and consists of a grid of tubes. This configuration has the following useful features:

- Mechanical strength
  - less prone to electromagnetic impulse detuning for the same thickness
  - can be made thinner than solid windows for the same strength
- Cooling: hollow tubes can accommodate active cooling
- Holes: beam aperture can be left open in the middle
- Cost: cheaper than curved Be foils
- Safety: no Be

There are potential disadvantages as well:

- Electric field enhancement
  - smaller radius of curvature than solid curved window means higher surface field on the grids which may lead to higher field emission and breakdown probability
- Irregular material distribution in beam path
  - the effect on the beam needs to be evaluated for a cooling channel application

TEST SETUP

In order to carry out a first test of the concept on an actual pillbox type cavity, we have built a pair of 16-cm-diameter windows consisting of 1-cm-diameter solid tubes spaced 3.2-cm apart. These prototype windows were made out of aluminum, their surfaces were electropolished after fabrication and one of the windows was TiN coated on one side. They were designed to fit on an existing pillbox type cavity used in the past with Be windows.

Abstract

A special vacuum vessel prototype was built [1] to house the first electropolished 201-MHz RF cavity for the International Muon Ionization Cooling Experiment (MICE) [2]. The resulting prototype RF module has been assembled, instrumented, installed and commissioned at Fermilab's MuCool Test Area (MTA) [3] and the effort has provided valuable experience for design and assembly of modules that will be used in the cooling channel for the experiment.

MECHANICAL ASSEMBLY AND INSTALLATION

Cavity Insertion

There is little clearance between the dressed cavity assembly (with the tuner forks installed) and the vacuum vessel. The cavity was inserted into the vacuum vessel using a material lift with a custom fabricated attachment to match the stiffener ring. The setup is shown in Fig. 1. During adjustment of the suspension struts that form the six-axis platform to center the cavity in the vessel, several of the rod ends seized. This was most likely due to the lubricant film on the threaded rods being removed during cleaning or stripped during adjustment under load. The strut bodies and threaded rods were both made of stainless steel which increases the likelihood of galling. New strut bodies were machined out of aluminum bronze to avoid this problem. Magnetic permeability of the new parts were measured to confirm that they would be acceptable for use in a strong magnetic field. In addition, a test fixture was designed and built in order to gain some familiarity with the adjustment procedure without a heavy load. This fixture consisted of a hoop with identical attachment points as the cavity so it could be used with the same struts and fasteners. After successful testing of the system with the fixture, the cavity was reinstalled in the vessel using the new struts and adjustments could be made easily by turning the strut bodies by hand while the full weight of the cavity assembly was suspended.

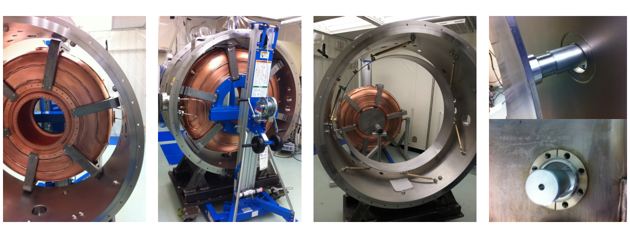

Figure 1: Left to right: cavity insertion, lift, test fixture with the new struts, and an alignment rod on the test fixture seen from inside (top) and outside (bottom) the vessel.

Tuner System

Initial tests of the pneumatic actuators were made on a separate fixture [4]. Alignment rods screwed into the tuner forks were used to center the tuner actuator shafts with respect to the corresponding vessel ports while adjusting the cavity position. Each actuator consists of a concentric inner and outer shaft pair with threaded sections at their tips. The shafts have identical thread spacing and are screwed into corresponding holes in the fork body. Initial installation of the actuators on the vessel revealed another issue; most actuator vacuum flanges would not mate up with the vessel port flanges before the inner actuator shafts bottomed out on the forks. This was resolved by removing a short section (about one thread) from the end of each inner shaft. After the cavity was aligned inside the vessel, detailed measurements of the mechanical (pressure to displacement) and RF control (pressure to frequency) transfer functions were carried out [5, 6] (Fig. 2). While the vessel was under vacuum in the MTA experimental hall, one of the actuators developed a vacuum leak during testing. No spare unit was available at the time, so the faulty actuator was removed and the corresponding port blocked off. This unit was repaired and reinstalled during reconfiguration of the module. Testing under vacuum revealed a vacuum leak in another unit which was replaced with a spare. The actuator design was modified to eliminate the weak joint responsible for the leak.

NOVEL HIGH POWER SOURCES FOR THE PHYSICS OF IONOSPHERIC MODIFICATION*

B.L. Beaudoin, T.M. Antonsen Jr., I. Haber, T.W. Koeth, A.H. Narayan, G. Nusinovich, K. Ruisard,
Institute for Research in Electronics & Applied Physics,
University of Maryland, College Park, MD 20742-3511, USA

Abstract

The ionosphere plays a controlling role in the performance of critical civilian and DoD systems including the ELF-ULF communications, radars, navigation (including GPS) and geo-location systems. Ionospheric Modification (IM) is a complementary approach to passively studying the ionosphere that has intensified over the last 30 years with the construction of the High-Frequency Active Auroral Research Program (HAARP). The objective of IM is to control and exploit triggered ionospheric and magnetospheric processes to improve the performance of trans-ionospheric Command, Control, Communications and Intelligence (C3I) systems and to develop new applications that take advantage of the ionosphere as an active plasma medium. A key instrument in IM is the Ionospheric Heater (IH), a powerful High Frequency transmitter that modifies the properties of the ionospheric plasma by modulating the electron temperature at preselected altitudes.

A major reason for the development of a Mobile IH source (MIHs) is that it would allow investigators to conduct the needed research at different latitudes without building permanent installations. As part of a multi-university research initiative (MURI), UMD will develop a powerful RF source utilizing Inductive Output Tube (IOT) technology running in class-D amplifier mode. This technology was chosen because it has the potential to operate at high efficiencies. Some of the technical challenges presented in this paper will include: a gun design that minimizes intercepted current, a compact tunable hybrid cavity operating in the 1-10 MHz range, and an efficient modulator system capable of modulating a high power electron beam.

MAGNETRON INJECTION GUN (MIG) IOT DESIGN

A major concern with the gridded class-D operation of an IOT device is the heating of the grid due to intercepted electrons. A design using a MIG-type cathode that produces a hollow beam avoids this complication, as a small mod-anode local to the thin annular cathode can be used to bias the beam on and off without intercepting any electrons. We already possess a MIG-type cathode with a negative injection angle for this purpose. The proposed source with a Pierce-type geometry has been characterized with the Michelle code [1] with 2D axisymmetric geometry as shown in Fig. 1a. Steady state electrostatic PIC simulations show that for 60 kV on the anode and 200 V on the mod-anode, we can expect approximately 2 A of beam current from a 4.7 cm^2 emitter. The magnetic field design was identified by using Maxwell 2D (axisymmetric geometry) code to simulate solenoid coils/pole piece geometries. Iterations over several geometries maximized the dot product of the field lines with the unmagnetized beam trajectory (to minimize conversion of longitudinal to transverse momentum). The most recent iteration is shown below in Fig. 1b. The field lines follow the unmagnetized beam trajectory closely, except near the cathode surface. An additional set of coils or iron field shapers behind the cathode may be used to adjust the field lines in this region. As seen in simulation (Fig. 1b), with a 1.4 kGauss field (shown in Fig. 1c), the beam ripple due to transverse energy gain is minimal. This field simulation assumes ideal iron.

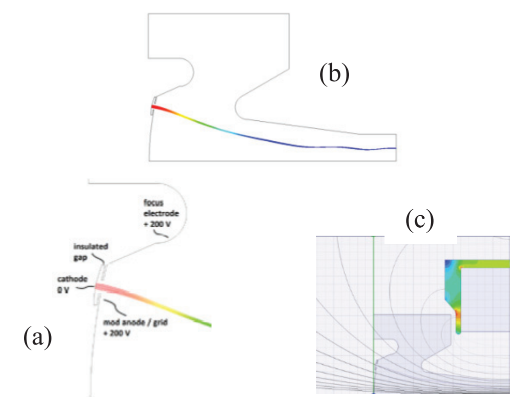

Figure 1: (a) Geometry of cathode, focusing electrode and mod-anode of a MIG-type gun and the particle trajectories. (b) Beam trajectory with field from a solenoid (c), with a peak on-axis field of 1.4 kGauss.

Steady state Michelle simulations were used to estimate the capacitance seen by the grid driver due to the focus electrode-mod anode spacing in the vicinity of the cathode. Calculations were done with and without beam in a 2D axisymmetric Michelle simulation, and the no-beam case was verified against a Maxwell 3D model of the gun assembly. Michelle and Maxwell measurements agreed to within 2 %, with the most likely discrepancy being a difference in mesh density. Additional comparisons of Michelle simulations with and without beam, predicts a 1 % increase in capacitance due to beam loading. We predict that the capacitance due to the inner surface of the mod-anode is 15.6 pF, requiring the grid driver to pull 2 A for a 5 ns rise time on a 600 V swing.

ADAPTABLE MACHINE PROTECTION ARCHITECTURE FOR CW, HIGH INTENSITY ACCELERATORS

Saeed Assadi, Texas A&M University, College Station, TX 77843, USA

Abstract

An adaptable architecture of a machine protection system (MPS) suitable for continuous wave (CW), high intensity accelerators like those proposed for Accelerator Driven Systems (ADS) for subcritical reactor strategies and heavy ion accelerators for the production of rare isotopes is presented. A system of databases, networks and nodes that can systematically and flexibly be reconfigured to rebalance the required metadata is used. Additional features include reconfigurable machine setup templates that can rigorously be tested with mirror redundant online backups, the utilization of external reconfigurable geometric algorithms for the data channels and the network distribution, and the inclusion of initial system requirements as well as envisioned upgrades.

BACKGROUND

High power, high intensity proton drivers (Fig. 1) for nuclear fuel transmutation are required to have *High Availability* (Table 1) or better performance - otherwise the electric utilities do not consider these drivers as a viable solution. The implementation progress has been steady- however it has stalled at low 90%. The driving forces behind fourth generation superconducting accelerator machine protection system [MPS] is avoid incremental gain but structural.

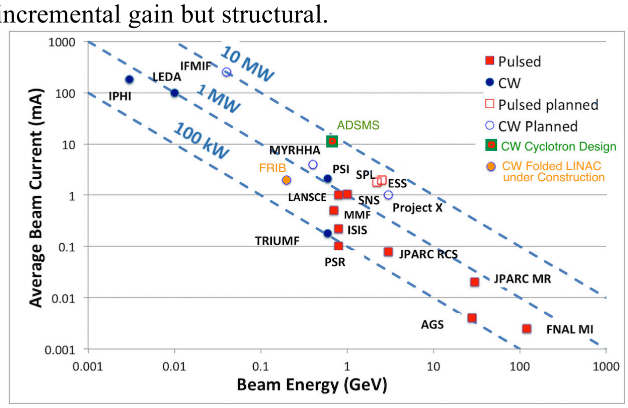

Figure 1: High Power Accelerator History

Table 1: Beam Availability Score

System Type	Availability	Unavailability
Fair	90%	37 days/year
Well-managed	99.9%	526 (min/year)
Fault-tolerant	99.99%	53 (min/year)
High-availability	99.999%	5 (min/year)

The generations are based on beam interaction with accelerator surrounding, beam power, technology and management mandate as systems have come to existence from the Tevatron and PSI to SNS and LHC. Although the MPS of each of these accelerators has significantly improved from its predecessor, the up time is in ~92% after four decades of operations, and cannot be sustained due to the complexity of tens of thousands of variables without a complete overhaul. Databases have become overwhelmed, and at times have become mere warehouses of information, that often provides valuable information, after accidents to discover a catastrophe in developing from days. In this paper I address one systematic approach that all MPS designers have considered but its implementation has fallen short due to cost, available technology and or integration framework factors. Data management is one aspect of high availability accelerator operation, automation, instrumentation and control, which are integral parts of forming the framework of MPS as machine performance manager.

METHODOLOGY

To achieve much better than 99% availability, one cannot simply attempt to squeeze efficiency without major architectural re-evaluation, and the bottom up systematics of running accelerators is even more model-driven with beam-hardware dynamic feedback. Moreover, the MPS has to provide reliable, redundant valid information from the start of the commissioning, rather than relying on limited physics studies to debug massive MPS on reliability, as it's failure will be the demise of an

DIAGNOSTICS FOR HIGH POWER CW ACCELERATORS*

Saeed Assadi#, Texas A&M University, College Station, TX, USA

Abstract

High power, continuous wave (CW) accelerators are proposed for applications such as Accelerator Driven Systems (ADS) for subcritical reactor strategies and heavy ion accelerators for the production of rare isotopes. Because of the high beam powers and high energy loss with beam interception of material, the beam diagnostic designs are necessarily shifting to non-intercepting, real-time feedback devices that can be fully integrated with the accelerator machine protection system (MPS) and operation control system including online models. Appropriate for these applications, three types of beam diagnostics (lanthanum bromide scintillation coincidence detectors, GaN neutron and gamma detectors, and beam position monitors) are presented.

BACKGOUND

Next generation of high power accelerators are more than ever in need of seamless integrated beam instrumentation, online models, controls system and agile beam characterization of particle losses and feedback systems. Role of beam diagnostics have shifted from a collection of exotic instruments with multiple platforms run individually by engineers and scientists adapted to an accelerator to base lattice from inception optimized specifically for operation. This methodology, not only requires inline beam instruments to be 3D multi-particle integrated modelled with lattice optimized as the accelerator being optimized in lattice but it has to foresee in advance the expected commissioning, operation and upgrade scenarios. To keep up with all expected modes of operations, we have limited choices to preserve design integrity, reliability, safety, and performance. (A) Design and test in collaboration of experts as soon as the project is formalized in an integrated form the fundamental beam instruments such as beam position electrodes and their expected signal delivery. (B) Tools for software development such as complete test stations. In this paper, I report on two such accelerator systems. (1) At Texas A&M University, a complete conceptual Accelerator Driven Subcritical Molten Reactor System is designed. The 100-800 MeV Cyclotron with strong focusing channels of twenty-three helical orbits (Figure 1) is embedded in more than 100 tons of iron preventing any externally accessible beam instrumentation such as loss monitors. It requires active beam orbit feedback system for 10 MW of CW proton beam with the possibility of aborting and landing segmentation loaded beam in numerous aborts located at the missing cavity extraction channel. There is about 0.75 Cm spacing at the inner radii for 100 MeV 400 W faraday cup abort dumps. This highly challenging cyclotron is compact, flexible and can be reconfigured to run if one of the ten superconducting cavities fails [1]. Second is the most versatile version of a CW Rare Isotope LINACs that have an added complexity of lattice change over to accelerate different radioactive species of same atomic mass to charge ratio as often as once every 4-6 weeks. These LINACS such as the one being considered by Jlab for MEIC or Facility for Rare Isotope Beam designed by R. York in 2009 [2] require full integration of beam diagnostics and operation changeover databases and online applications.

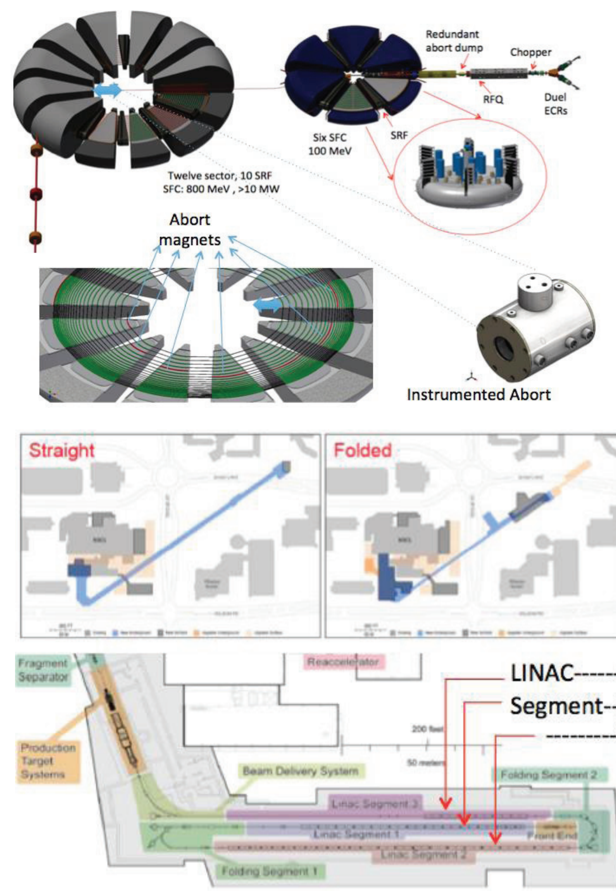

Figure 1: Top shows SFC at Texas, bottom is FRIB design status at MSU in 2010.

Both ADSMS and FRIB require specialized directional beam loss monitors such with energy discrimination, which will be discussed.

ALTERNATE METHODS FOR FIELD CORRECTIONS IN HELICAL SOLENOIDS*

M. L. Lopes#, S. T. Krave, J. C. Tompkins, K. Yonehara, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA
G. Flanagan, S. A. Kahn, Muons Inc., Batavia, IL, 60510, USA
K. Melconian, Texas A&M University, College Station, TX 77845 USA

Abstract

Helical cooling channels have been proposed for highly efficient 6D muon cooling. Helical solenoids produce solenoidal, helical dipole, and helical gradient field components. Previous studies explored the geometric tunability limits on these main field components. In this paper we present two alternative correction schemes, tilting the solenoids and the addition of helical lines, to reduce the required strength of the anti-solenoid and add an additional tuning knob.

INTRODUCTION

Helical cooling channels (HCC) based on a magnet system with a pressurized gas absorber in the aperture have been proposed as a highly efficient way to achieve 6D muon beam cooling [1-2]. The cooling channel was divided into four sections to provide the total phase space reduction of muon beams on the level of 10^5-10^6, and to reduce the equilibrium emittance each consequent section has a smaller aperture and stronger magnetic fields.

The strength of the solenoid (*Bs*), helical dipole (*Bt*), and helical gradient (*G*) fields are strongly dependent on the coil and helix geometry [3-6]. The ratio *Bt*/*G* is fixed by the geometry but the absolute value can be adjusted independently from *Bs* by the means of an external anti-solenoid. However, this can be quite challenging due to the required magnetic field strength of this solenoid [4]. An additional knob capable of adjusting the ratio *Bt*/*G* independently of the coil geometry is highly desirable.

TILTED COILS

The coils for the helical cooling channel produce a dipole and gradient which rotates with the period of the helix. Two tilting schemes, shown in figure1, and their effect on the two transverse field components, were studied. In the "pitch" tilting arrangement, the coils were rotated about an axis at each coil which was tangent to the helix. The "yaw" tilting is about the axis of the angle to the rotated coil position, or an axis that is perpendicular to the pitch tilting.

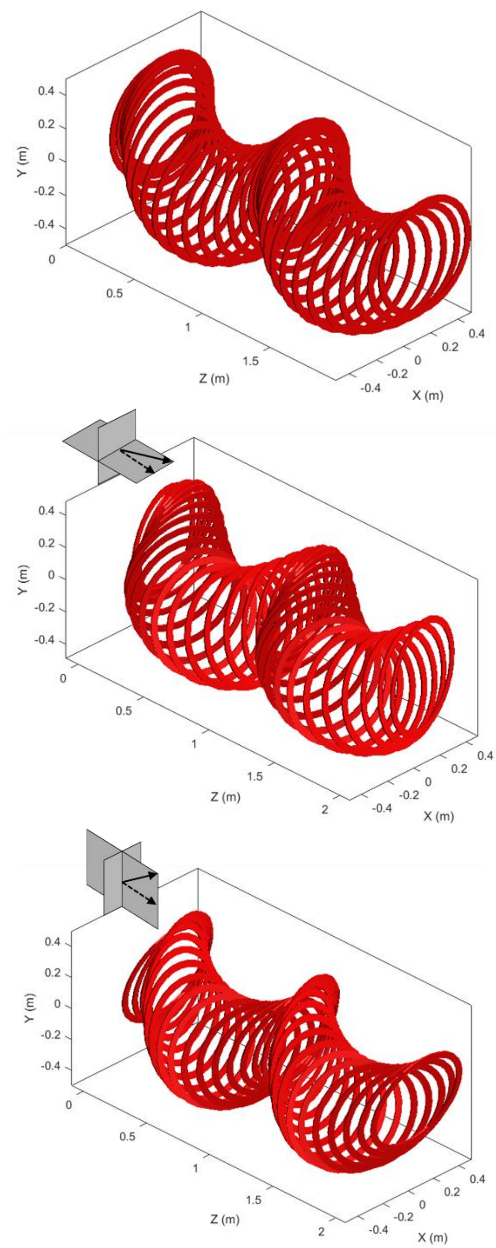

Figure 1: Helical coil arrangement of the non-tilted coil (top), Yaw tilt (middle), and Pitch tilt (bottom). The spacing between the coils and tilt were exaggerated for clarity.

VIRTUAL WELDING AS A TOOL FOR SUPERCONDUCTING CAVITY COARSE TUNING *

A. Facco[1,2], C. Compton[1], J. Popielarski[1], G. J. Velianoff[1]
[1] Facility for Rare Isotope Beams, Michigan State University, East Lansing, MI 48824, USA
[2] Istituto Nazionale di Fisica Nucleare - Laboratori Nazionali di Legnaro, Padova, Italy

Abstract

Reaching the final frequency in the construction of Superconducting Half-Wave Resonators (HWR), either coaxial or spoke, is often a painful and time consuming process which requires several intermediate frequency tests and parts machining between subsequent welding steps. In spite of that, the final frequency error after final welding is often far from the target due to difficult to predict material contraction and cavity deformation induced by electron beam welding (EBW). Final coarse tuning is required by plastic deformation or differential etching. In coaxial HWR, both can decrease the cavity frequency but are not easily suitable to increase it. A novel method developed at MSU is "virtual" welding, i.e. deformation of the cavity shape by applying systematically EBW on the cavity outer surface to induce controlled Nb material contraction in strategic positions. This technique allows to increase the cavity frequency with excellent precision and predictability, thus simplifying and making less expensive and more reliable HWR coarse tuning. Method and experimental results will be described and discussed.

INTRODUCTION

Superconducting Half-Wave Resonators (HWR), in their coaxial and spoke versions, after being confined for decades in the R&D environment, have been recently used in a real accelerator [1] and are becoming fundamental components of large proton and ion linear accelerators under construction or planned [2]. These low- and medium-β resonators are closed cavities with relatively small apertures and their frequency is mostly determined by the length of their inner conductor. A common problem is the difficulty of building them with the right frequency, because it is not always easy to predict contraction of the Niobium material and thus the final cavity size after welding together its different parts. Coarse tuning of HWR cavities requires intermediate frequency measurements and length adjustments throughout the welding procedure. A large fine tuning range of the mechanical tuner is usually required to compensate for possible errors.

A typical problem is the difficulty of correcting the center frequency after the cavity is completely welded and closed. Two main methods are used, both well suitable for lowering the frequency:

1) Plastic deformation. It is often used in the beam port region for coarse tuning, but its application in HWRs is not always easy due to their structural stiffness and, for large frequency corrections, it can be dangerous for cavity mechanical integrity. Corrections are not very precise, nor smooth: initial elastic response is followed by a sudden adjustment to a new frequency, and the risk of going beyond the desired point is not negligible. Moreover, while it is easy to plastically push the beams ports in and lower the frequency, in HWRs it is rather difficult to pull them out safely to obtain the opposite effect.

2) Differential etching. Material from the rf surface inside the resonator is removed selectively by Chemical Polishing (CP). This is routinely applied since several years in QWRs [3][4], where it is possible to remove material either in the high B or in the high E region, causing frequency decrease or increase, respectively. It is easy to realize that in HWRs differential etching can be used without difficulty only to remove material from the end (shorting) plates, making the resonator longer and its frequency lower, while it seems almost impossible to increase the frequency by removing material only from the high E region near the beam port axis. So, at present, frequency corrections in closed HWRs are safely feasible only in the down direction, making final coarse tuning somehow difficult and time consuming.

TUNING BY VIRTUAL WELDING

In the original FRIB HWR construction plan, the beam ports were the last parts welded and their position was adjusted to reach the final goal frequency. We soon realized, however, that the mechanical contraction caused by such difficult full penetration weld from outside was moving the beam ports far from the initially planned position, and that a large and rather unpredictable frequency error was finally left. This method was then abandoned: the beam ports are now safely welded to the outer conductor from inside, at an early stage. Coarse tuning is made by adjusting the inner and outer conductor length before welding them to the shorting plates. Due to material contraction, however, this procedure is still leaving a large uncertainty on final frequency of several hundreds of kHz. It became clear that a good coarse tuning sequence required also a viable method to increase the final frequency.

PROGRESS ON THE CRYOGENIC AND CURRENT TESTS OF THE MSU CYCLOTRON GAS-STOPPER SUPERCONDUCTING MAGNET*

M. A. Green, S. S. Chouhan, G. Bollen, J. DeKamp, C. Magsig, and A. F. Zeller, FRIB, and D. Morrissey, J. Ottarson and S. Schwarz, NSCL, MSU, East Lansing, MI 48824, USA

Abstract

The Michigan State University (MSU) cyclotron gas stopper magnet is a warm iron superconducting cyclotron dipole. The desired field shape is obtained by the pole iron profile. Each coil of the two halves is in a separate cryostat and connected in series through a warm electrical connection. The entire system is mounted on a high voltage platform, and is cooled using six two-stage 4.2 K pulse tube coolers. This paper presents the progress on the magnet fabrication, cooling, and current testing.

INTRODUCTION

The fragmentation of fast heavy-ion particles enables fast chemistry-independent production, separation and delivery of exotic isotope beams. The resulting beams have high energies (<100 MeV/A) and large emittances. The range of experiments can be extended by slowing the fast ions, extracting them, and then re-accelerating them. The ReA3 [1] re-accelerator under construction at MSU will reaccelerate thermalized ions (~10 keV) to provide low emittance exotic ion beams over a range of energies.

A solution to thermalize and extract light to medium mass beams is to apply a strong gradient dipole magnetic field in a large magnetic gap that forces the ions into a spiral path while slowing them down in He gas at 80 K. Low energy ions near the extraction port are transported in a central extraction orifice by an RF carpet [2], [3]. The ions are transformed into low-energy beams using a differentially pumped ion guide. The low-energy low-emittance beams are transported directly to experiments or to other accelerators for reacceleration. The super-ferric cyclotron gas-stopper magnet at MSU will enable the capture of short-lived rare isotopes.

THE GAS-STOPPER MAGNET

The cyclotron gas-stopper magnet has evolved since it was first proposed in 2007 [4]. The gradient dipole field is produced in a gap of 180 mm between sector cyclotron poles. The peak field in the gap is ~2.6 T. A pair of superconducting solenoid coils produce the field. The warm iron poles and flux return can be separated so that the deceleration system can be maintained. Each pole has its own coil and liquid helium cryostat. The two 300 K magnet poles are connected through the iron return path. The coils are not connected at 4 K. Forces to the yoke are transmitted by the cold mass supports. The common axis of the magnet coils is horizontal.

The work reported in this paper was supported in part by an NSF grant PHY-09-58726 and PHY-11-02511.

The space between the poles is evacuated to provide an insulating vacuum for the 80 K magnet beam chamber. Figure 1 shows the assembled magnet with the iron poles closed. Figure 2 shows the magnet poles open. The magnet cryostat on the right has the cylindrical part of the beam chamber vacuum vessel attached. There is a double o-ring seal between the cylindrical portion of the vacuum vessel and the magnet cryostat installed in the left pole piece. One can see the shaped face of the shaped sector cyclotron pole on the pole to the right of Fig. 2.

Figure 1: The assembled magnet is shown fully closed.

Figure 2: The magnet is shown with poles separated. The beam chamber insulating vacuum chamber is visible along with one of the shaped cyclotron poles.

MULTIPACTOR BREAKDOWN MODELLING USING AN AVERAGED VERSION OF FURMAN'S SEY MODEL*

S. Rice, J. Verboncoeur#, Michigan State University, East Lansing, MI USA

Abstract

Furman's seconday electron yield model is commonly used for the simulation of multipactor in accelerating cavities and other resonant structures. While accurate, the stochastic model requires many Monte Carlo simulations in order to characterize susceptibility to multipactor. This paper generalizes our previous research in characterizing a reduced-order Furman model, in which we replace the stochastic Furman model with a deterministic model based upon the Furman model's underlying statistics. Favorable comparisons between the full Furman model and the reduced-order Furman model are shown for multipactor simulations in a coaxial cavity, and the results are expected to generalize to other geometries.

INTRODUCTION

Multipactor [1, 2] is a resonant phenomenon in which an electromagnetic field causes free electrons to impact a surface, resulting in the surface emitting secondary electrons which can sustain the cyclic process. The formation of multipactor is strongly dependent upon the secondary electron yield (SEY) of a surface, and the emission velocities of the emitted electrons. A popular SEY model proposed by Furman and Pivi [3] is frequently used to simulate multipactor. This model is based around a stochastic scattering process, which necessitates computationally costly Monte-Carlo simulations in order to simulate the formation of multipactor in a given system.

In our previous work [4], we presented an approximation to Furman's model, in which for a given particle impact velocity, a single weighted particle is emitted deterministically, thus avoiding Monte Carlo simulations to model multipactor current; this particle was chosen to be simply the median of the underlying stochastic parameters in the SEY model. In this present work, we examine other cumulative probability statistics other than the 50th percentile (median) statistic. The results were obtained through simulations in a coaxial geometry, but are expected to be generalizable to other geometries.

SIMULATION DESCRIPTIONS

Consider a coaxial cavity shorted at both ends as shown in Fig. 1, which is excited by a TEM mode specified by $V_o \cdot \cos(\omega t+\theta) \cdot \sin(\pi z/L)$, where V_o is the peak instantaneous voltage, θ is the phase, ω is the cavity-dependent resonant angular frequency, z is the position along the axial direction as measured from the cavity end, L = 1.86 m is the cavity length, a = 1 cm is the cavity inner radius, b = 5.65 cm is the cavity outer radius. These dimensions were chosen to yield maximum multipactor response for $V_o \approx 1000$ V at the fundamental TEM mode resonant frequency of 80.5 MHz.

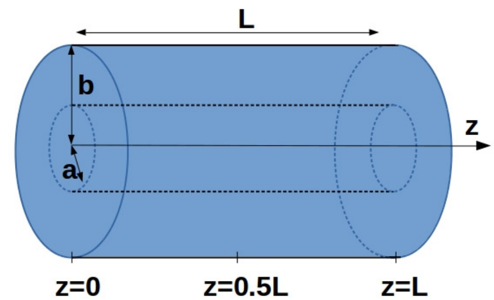

Figure 1: Coaxial Geometry

For each voltage V_o and phase θ to be simulated, particle-tracking (single particle) simulations were performed for 10 cycles, where a cycle is defined to end whenever either a boundary strike or a complete RF period elapses, whichever occurs first. For each simulation, an electron starts from rest from the outer wall at the z=0.5L position, and the following loop is carried out for each cycle:

(1) Electron is accelerated by the cavity fields until it strikes a boundary.
(2) Record SEY for the impact.
(3) Generate a secondary electron from emission energy and angle distributions.
(4) Repeat from step #2.

For Furman's full model, the number of secondary electrons can randomly range from 0 to a maximum integer value. If no electrons are emitted, then the SEY is set to 0, and the simulation terminates. If more than one electron is emitted, then one of these electrons are randomly chosen to continue propagating the multipactor simulation. For more sophisticated multipactor simulations, we would need to track each emitted electron, but by running a large number of Monte Carlo trials (1000 for this investigation), we are still able to sample the entire multipactor initiation space while tracking only one particle for each simulation.

The net SEY is defined to be the product of all the single-impact SEY values, with the adjustment that if less than two boundary impacts occurred over the 10 simulation cycles, then the net SEY is automatically set to 0. This net SEY gives a proxy measure of whether or not multipactor can initiate, since net SEY less than unity

CO-LINEAR X-BAND ENERGY BOOSTER (XCEB) CAVITY AND RF SYSTEM DETAILS

T. Sipahi, S. V. Milton, S. G. Biedron, Colorado State University (CSU), Electrical & Computer Engineering Dept., Fort Collins, CO, 80523, USA

Abstract

Due to their higher intrinsic shunt impedance X-band accelerating structures offer significant gradients with relatively modest input powers. At the Colorado State University Accelerator Laboratory (CSUAL) we would like to adapt this technology to our 1.3-GHz, L-band accelerator system in order to increase our overall beam energy in a manner that does not require investment in an expensive, custom, high-power X-band klystron system. Here we provide the design details of the X-band structures that will allow us to achieve our goal of reaching the maximum practical net potential across the X-band accelerating structure while driven solely by the beam from the L-band system.

GENERAL CONCEPT

The Colorado State University Accelerator and FEL Laboratory has an L-band system capable of generating 6 MeV electron bunches [1]. We would like to further increase the electron beam energy without additional significant investment. Our idea is to utilize the electron beam from our linac as a drive source for an otherwise unpowered (passive) X-band linac structure, thus allowing us to increase the beam energy by using the L-band power together with the inherent high shunt impedance of the X-band structure.

For our proposed Co-linear X-band Energy Booster system we start with the power extraction mechanism using the beam from the L-band linac passing through the power extraction cavity (PEC). This power is then delivered to the X-band main accelerating cavity (MAC) structures. One can then periodically pass a bunch through the whole system and achieve significantly higher beam energies. This is done by simple switching of the photocathode drive laser pulses and shifting the phase onto the cathode such that it puts the bunch into the accelerating phase of all accelerator structures. Finally, we describe a possible use of this high-energy electron beam using our existing undulator at CSU.

While we have presented this concept before in other conference papers [2,3,4], we would like to reiterate the idea as well as add some additional information that has been accomplished since our last publication on the topic.

X-BAND POWER EXTRACTION CAVITY DESIGN

Here we choose to use a $2\pi/3$ mode TW X-band structure with parameters given in Table 1 and as computed by the design code SUPERFISH [5] (Figure 1). As we found in our earlier paper even for moderate shunt impedance the structure is relatively short as we are limited by the maximum amount of energy we can remove from the drive beam [6]. Based on our previous study the length of this cavity should be 15.4 cm in order to decelerate the beam from 6 MeV down to 1 MeV. Under such conditions the net X-band rf power that can be generated is 1.42 MW.

Figure 1: Electric and magnetic field patterns for $a/\lambda = 0.2$ in (a) Neumann boundary condition at end walls for $2\pi/3$mode (b) Dirichlet boundary condition at end walls for $2\pi/3$ mode

Table 1: Parameters for X-band PEC Structure

a/λ	0.2
Phase Advance per cell (ψ)	$2\pi/3$ Radian
Iris radius (a)	0.00512466 m
Cavity Radius (R)	0.0110955 m
Disk Thickness (h= $2r_1$)	0.002 m
Quality factor	6656 .15
Length	0.154 m
Frequency	11.7 GHz
Shunt impedance	57.15 MΩ

X-BAND MAIN ACCELERATING CAVITY DESIGN

The optimization for the X-band MAC design follows a different path. In this design we wish to maximize the energy gain in an optimum length and get the highest integrated potential through one or more cavities; therefore, we chose to design a new geometry, and change the phase advance from $2\pi/3$ to a higher mode, $5\pi/6$. This slows the group velocity and allows us to increase the length of the structure and provide more opportunity to increase the integrated potential [7,8,9].

Table 2 gives the resulting geometry parameters for a $5\pi/6$ phase advance MAC structure. This cavity will see a single, relatively low charge electron bunch, so the aperture requirements are not as severe as with the PEC. Further, we wish to maximize the overall integrated voltage seen by the beam during its passage. This clearly argues for high shunt impedance and as long a structure as reasonable.

THERMAL-MECHANICAL ANALYSIS OF THE FRIB NUCLEAR FRAGMENT SEPARATOR DIPOLE MAGNET*

S.A. Kahn#, A. Dudas, G. Flanagan, Muons, Inc., Batavia, IL, 60510, USA
R.C. Gupta, BNL, Upton, NY 11973, USA

Abstract

Dipole magnets in the Facility for Rare Isotope Beams (FRIB) fragment separator are critical elements used to select the desired isotopes. These magnets are subjected to high radiation and heat loads. High temperature superconductors (HTS), which have been shown to be radiation resistant and can operate at 40 K where heat removal is substantially more efficient than at 4.5 K where conventional superconductors such as NbTi and Nb_3Sn operate, are proposed for the magnet coils. The magnet coils carry large currents and will be subject to large Lorentz forces that must be constrained to avoid deformations of the coils. It is desirable to minimize the use of organic materials in the fabrication of this magnet because of the radiation environment. This paper will describe an approach to support the coils to minimize coil deformation and cryogenic heat loss.

INTRODUCTION

The FRIB facility at MSU will provide intense isotope beams for physics research [1]. Large quantities of various isotopes are produced when a 400 kW linac beam hits the target. A variety of secondary nuclides with various ionic charge states is produced. Following the target are the fragmentation separator magnets which consists of three quadrupole magnets to provide focusing and two dipole magnets to select the desired nuclei. The beam enters the first dipole magnet with a spread of rigidities. The undesired nuclides are removed with a beam dump between the two dipole magnets.

To collect a sufficient sample of the rare isotopes the magnets in the fragment separator will have large apertures and strong. The radiation level in the fragment separator magnets is quite high and these magnets need to be radiation resistant. The radiation dose seen by the first quadrupole after the target is estimated to be 2.5×10^{15} neutrons/cm^2 per year [2] which corresponds to 10 kW/m of deposited power. The deposited power will drop by a factor of 10 when it reaches the bending dipole. The radiation environment influences the choice of materials used. Although NbTi and Nb_3Sn are robust conductors in radiation, they must operate at 4.5 K which is not practical, since the anticipated heat load would be difficult and costly to remove efficiently at that temperature. HTS conductors are reasonably resistant to radiation and can carry a significant current at 40 K where the heat capacity of the refrigerant is much larger and the Carnot efficiency is greater making heat removal and refrigeration easier. Also we would like to minimize the use of organic materials, both for conductor insulation and for coil support as these materials can degrade in the radiation environment.

Brookhaven National Laboratory has been involved in an R&D program to develop the quadrupole magnets for fragment separator at FRIB [3-6] using HTS conductor. The design of the fragment separator dipole magnets has relied on the technology learned from the quadrupole project. Previous articles [7-9] describing design aspects of this dipole magnet have been published.

MAGNET DESIGN

A superferric design has been chosen for this magnet where HTS coils are used to magnetize the iron which provides the desired field. The coils surround the iron poles and each coil is enclosed in its individual cryostat. Because of the large bend angle and the desire to avoid winding a coil with negative curvature the coil is wound with a "D" shape [10] with the inner section straight and the outer section curved. The coil and cryostat package is recessed behind the iron pole to protect them from direct exposure from the beam. Most of the radiation and the associated heat deposition will be deposited into the iron pole and flux return which are at room temperature and water cooled. The main source of radiation into the coils comes from neutrons that can penetrate deeply into material. It is estimated that ~700 W will be deposited into the coil cryostats [9]. The design parameters of the fragment separator magnet are shown in Table 1.

QUADRUPOLE MAGNET FOR A RAPID CYCLING SYNCHROTRON*

H. Witte†, J. S. Berg, Brookhaven National Laboratory, Upton, NY, USA

Abstract

Rapid Cycling Synchrotrons (RCS) feature interleaved warm and cold dipole magnets; the field of the warm magnets is used to modulate the average bending field depending on the particle energy. It has been shown that RCS can be an attractive option for fast acceleration of particles, for example muons which decay quickly.

In previous studies it was demonstrated that in principle warm dipole magnets can be designed which can provide the required ramp rates, which are equivalent to frequencies of about 1 kHz. To reduce the losses it is beneficial to employ two separate materials for the yoke; it was also shown that by employing an optimized excitation coil geometry the eddy current losses are acceptable.

In this paper we show that the same principles can be applied to quadrupole magnets targeting 30 T/m with a repetition rate of 1kHz and good field quality.

INTRODUCTION

A number of accelerators have been proposed recently to facilitate rapid acceleration. One application which requires extremely fast acceleration is a potential future Muon Collider; the rapid acceleration here is necessary due to the short lifetime of the particles.

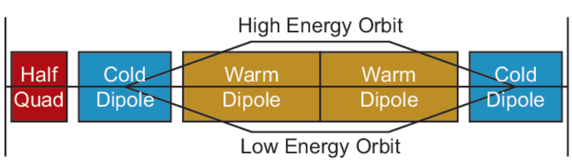

Figure 1: Rapid Cycling Synchrotron - Lattice.

Hybrid synchrotrons have been shown to be an attractive alternative to accelerate muons [1]. A hybrid synchrotron features interleaved warm and cold dipole magnets as shown in Fig. 1; the warm dipole magnets are expected to be ramped at rates equivalent to 400–1000 Hz with a repetition rate of 15 Hz in order to achieve the correct integrated bending strength for the particles.

In previous papers we have outlined solutions for those dipole magnets [2–4]; in this paper we show that the same design ideas are applicable to quadrupole magnets.

MAGNET REQUIREMENTS AND CONCEPT

The lattice requires 35 T/m quadrupole magnets, but 30 T/m are acceptable even though this increases the total installed length of the quads from 520 m to 606 m. The good field region is ±30 mm horizontally and ±12.5 mm vertically. The RCS for the muon collider requires a gradient quality of $1 \cdot 10^{-3}$ or better.

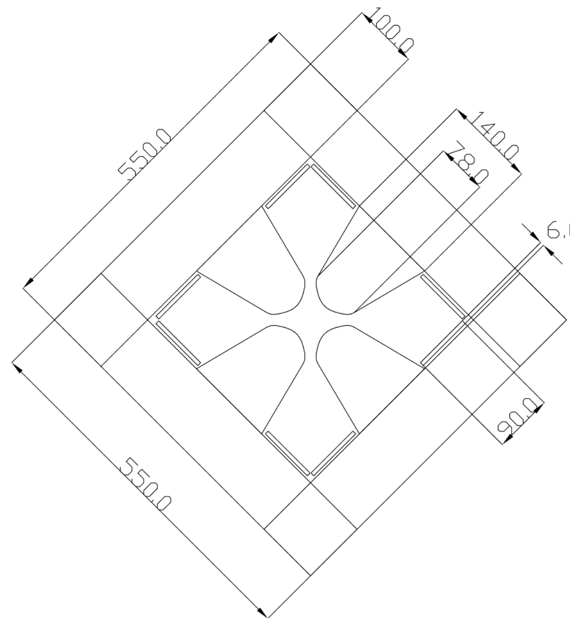

Figure 2: Magnet Geometry (all dimensions in mm).

Due to the high frequency it is of vital importance to minimize the losses in the quadrupole. In general there are two contributions:core losses in the yoke and eddy current losses in the excitation coil.

We employ two different materials for the yoke of the magnet in order to lower the overall losses. One material (3% SiFe) is used for the pole due to its higher saturation value [5]. The rest of yoke is made of 6.5% SiFe, which has very low losses at high frequencies [6]. The yoke of the magnet is assumed to be made of laminations with 100 μm (6.5% SiFe) and 127 μ (3% SiFe) thickness. In addition, the poles of the quadrupole are tapered to minimize the amount of iron at higher saturation.

To minimize the eddy current losses in the excitation coils thin current sheets are employed. Each sheet is 2 mm thick; three of these sheets (with Kapton insulation in between) are bundled together to form a bus-bar with total dimensions of 90×6 mm^2.

Figure 2 shows the geometry of the magnet; the pole shape is hyperbolic with an inscribed radius a of 30 mm ($y = a^2/2/x$).

SIMULATION RESULTS

For computer simulations we employ the commercial software package COMSOL Multiphysics[1]. 2D magnetostatic

T-MAPS TAKEN DURING COOL-DOWN OF AN SRF CAVITY: A TOOL TO UNDERSTAND FLUX TRAPPING

R. Eichhorn#, M. Ge, F. Furuta,
Cornell University, Ithaca, NY, 14853, USA

Abstract

During the past years a new effect has puzzled the community working in the field of superconducting RF cavities. I was found that the RF losses of the cavities are impacted by the cool-down procedures. On the flux trapping properties of superconducting cavities have been under investigation. We have measured temperature distributions of a multi-cell cavity using a T-map set-up to understand the transition to superconductivity in detail. We will report how the spatial disorder is affected by the cool-down speed and relate our findings to data on flux pinning.

INTRODUCTION

Continuous wave mode operation of future accelerators haven driven the research on achieving high quality factor SRF cavities to keep operation cost low. As the surface resistance of superconducting cavities approaches the theoretical limits parasitic effects limiting the performance came into focus of research. One interesting finding was that the quality factor of a cavity is impacted by the cool-down speed under which the cavity transits into the superconducting state.

This effect was first reported in 2011 by HZB [1]. With respect to magnetic flux pinning, they observed on samples that a slow cool-down can enable better external flux expulsion. Similar results were gained at Cornell, seeing that an initial cool-down to 4 K, followed by a thermo-cycle warming to 20 K and a slow re-cool through the critical temperature increased the quality factor significantly[2].

In contrast to this, FNAL [3] saw an increase of the quality factor of nitrogen doped cavities after a fast cool-down and claimed that – in contrast to [1]- flux expulsion is more efficient during a fast cool-down. In [4], it was proclaimed that the cool-down is more uniform during a fast cycle, which seems counter-intuitive.

As Cornell's multi-cell temperature-mapping system has unique capabilities [5], we started investigating cool-down dynamics of multi-cell cavities to get an understanding how the transition region between the normal and the superconducting state moves along the cavity.

THE EXPERIMENTAL SET-UP

The Cornell multi-cell Temperature-map system [6] has nearly two thousand thermometers, able to cover 7 cells with 11 sensors along the perimeter times 24 azimuthal angles. The temperature sensors are 100 Ω carbon Allen-Bradley resistor (5%, 1/8 W). To ensure good thermal contact, each sensor is pushed tightly against the cavity surface by a spring. APIEZON® type N grease, which has good thermal conductivity at low temperature, is applied to fill the gap between the sensors and the surface. Our data was taken on a TESLA-shape 9-cell cavity with the T-map place to cover the centre cells, shown in Figure 1.

In this paper, we only consider the T-map covered cells and define the cell numbers 1 to 7 from top to bottom. A read-out of all sensors takes about one minute when using 2^{14} samples per sensor which gives an accuracy in the temperature reading of 1.5 mK at 2 K. Usually, this system is operated at a constant bath temperature to identify heating spots and/ or quench locations of cavities. Under these conditions, calibration of the resistors is done against the Cernox sensors.

To take data during a cool-down, the system had to be modified: the sampling rate had to be reduced (to get shorter sampling times) and a careful recalibration had to be done.

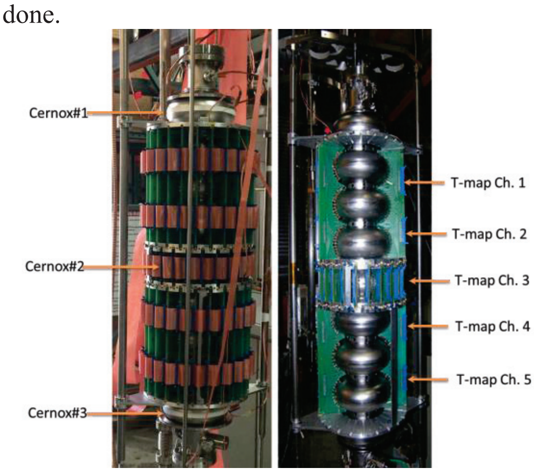

Figure 1: (Left):The multi-cell temperature-mapping system mounted on a TESLA-shape 9-cell SRF cavity. (Right): Several T-map boards have been removed to expose the cavity.

CALIBRATION

Cornell's T-map data acquisition system usually measures the resistance of each sensor which is converted into a temperature using calibration data. During calibration, the ambient temperature surrounding the T-map resistors, measured with calibrated cernox sensors mounted on the equator of top, middle, and bottom cell, is varied and the resistance curve of each T-map sensor is taken and calibrated against the nearest cernox sensor. For Our measurement, the calibration was performed during a slow warm-up, going from 4.2 K to 50 K in about 3 hours. The maximum temperature gradient along the cavity was 0.2 K.

THERMAL AND MECHANICAL ANALYSIS OF A WAVEGUIDE TO COAX SYMMETRIC COUPLER FOR SUPERCONDUCTING CAVITIES

R. Eichhorn *, J. Robbins and V. Veshcherevich
CLASSE Cornell University, Ithaca, NY 14853, USA

Abstract

As kicks from fundamental power couplers become a concern for low emittance future accelerators, a design of a symmetric coupler for superconducting accelerating cavities has been started. In this coupler, a rectangular waveguide transforms into a coaxial line inside the beam pipe to feed the cavity. So far the RF design revealed an extremely low transversal kick but concerns about cooling and the thermal stability of the coaxial transition line remained. This contribution addresses this. We calculated the heat, heat transfer and thermal stability of this coupler and evaluated the risk of quenching due to particle losses on the coupler.

INTRODUCTION

The low energy section of a superconducting linac can significantly contribute to the emittance increase of the accelerated beam. One component of that can be asymmetric fields coming from the fundamental power coupler. Usually, power couplers are antenna type couplers attached to a side port of the beam pipe near the cavity, usually placed on one side, generating a strong dipole kick. With a symmetric arrangement like in the Cornell injector one can avoid emittance increase due to the dipole kicks. However, quadrupole kicks remain, which guided us in designing a waveguide-to-coaxial type coupler resulting in super-symmetric fields [1]. In this paper, we will complement our earlier findings with investigations on the thermal stability of the coupler under different conditions and report on mechanical properties.

THERMAL ANALYSIS

Niobium Parameters

The thermal conductivity values that we used in our simulations were taken from a combination of theoretical models and experimental data. The theoretical model that we used was the thermal conductivity equation given by [2].

$$K_s(T) = \frac{K_{es}}{K_{en}}\left(\frac{\rho_{295K}}{L \cdot RRR \cdot T} + aT^2\right)^{-1} + \left(\frac{1}{D\, e^{\frac{\alpha T_c}{T}}\, T^2} + \frac{1}{B\, l T^3}\right)^{-1} \quad (1)$$

$K_{es}/K_{en}(T)$ is the ratio of superconducting to normal-conducting electron contributions to thermal conductivity. Constant parameters are given in Table 1. This model is valid for $T < 5.8$ K. For temperatures above 5.8 K, an experimental data set was used [3].

The specific heat of the niobium cylinder was assumed to follow the Debye model $C_v = \gamma T + AT^3$. Using experimental data from [4], values for the parameters were calculated as $\gamma = 0.0946 \frac{J}{kg\,K^2}$ and $A = 1.28 \times 10^{-3} \frac{J}{kg\,K^4}$ (for $T > T_c$) and $\gamma = 0$ and $A = 5.01 \times 10^{-3} \frac{J}{kg\,K^4}$ for $T < T_c$.

Analysis

Thermal calculations were performed using the transient thermal analysis system in ANSYS®. The front face of the cylinder was fixed at 2 K, assumed being perfectly cooled by the helium. To model the power deposition from the electron beam halo hitting the niobium surface, a heat flux of 0.5 W was applied to the rear face of the cylinder, which would be the worst case scenario.

Due to the RF field, there is additional heating along the cylinder surfaces which follows the equation

$$\frac{dP}{dA} = \frac{1}{2} R_s |\mathbf{H}|^2 \quad (2)$$

ASYMMETRIC THERMO-CURRENTS DIMINISHING SRF CAVITY PERFORMANCE

R. Eichhorn#, J, May-Mann
Cornell Laboratory for Accelerator-Based Sciences and Education, Ithaca, NY 14853-5001, USA

Abstract

Over the past years it became evident that the quality factor of a superconducting cavity is not only determined by its surface preparation procedure, but is also influenced by the way the cavity is cooled down. In this paper we will present results from numerical field calculations of magnetic fields produced by thermo-currents, driven by temperature gradients and material transitions. We will show how they can impact the quality factor of a cavity by producing a magnetic field at the RF surface of the cavity.

INTRODUCTION

The need to reduce the cost of the cryogenic infrastructure for future CW accelerators has driven the research on achieving high quality factor superconducting cavities. As a result, state of the art treated cavities display surface resistance approaches the theoretical limits. This allowed a deeper insight into the physics of parasitic effects, as they now become a prominent factor in limiting the performance of SRF cavities. One interesting finding, reproduced in different labs was that the quality factor of a cavity is impacted by the details of the cool-down procedure [1-3].

As of now, there seem to be two contributions resulting in the cool-down dependency of the cavity performance. One is flux pinning, the other is thermo-current.

Flux pinning describes the effect that a residual magnetic field is not fully expelled as the cavity becomes superconducting, resulting in an only partial Meissner effect. The trapped flux then concentrates in vortices which stay normal conducting and as a result, increases the losses of the cavity, denoted by a drop in the quality factor.

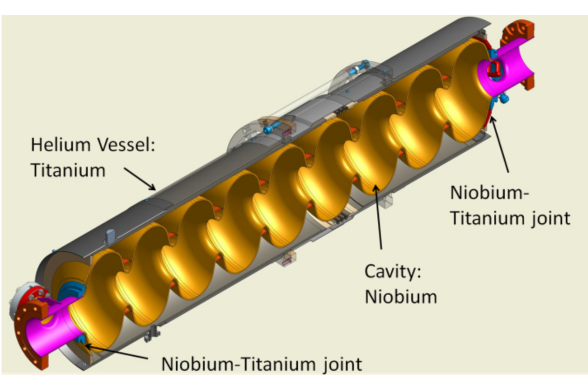

Figure 1: A superconducting cavity, welded into its helium vessel (dressed cavity).

#r.eichhorn@cornell.edu

Thermo-currents on the other hand have no direct effect. They are a result of the Seebeck effect that exist if material joints are held at different temperatures. As shown in fig.1, a superconducting cavity, welded into its helium vessel, is essentially a Seebeck current loop. As of their nature, thermo-currents generate a magnetic field-which then may be pinned during cool-down. In the past, an analytical analysis argued that the axial symmetry of SRF cavities leads to no (or when considering the potential asymmetry from vessel or cavity port: negligible small) thermo-electric induced magnetic fields in the relevant RF penetration layer at the inner cavity surface [4]. The author concluded that thermo-electric currents are not a concern for the performance of SRF cavities. However, our findings indicated early-on [5] that thermo-electric currents may have a more severe impact on the SRF performance as so far predicted [6].

SEEBECK EFFECT

Thermo-currents are the result of the Seebeck-effect, which is well known in physics for more than a century: Discovered in 1826, Seebeck found that a current will flow in a closed circuit made of two dissimilar metals when the two junctions are maintained at different temperatures. The voltage is dependent on the material, leading to the definition of the Seebeck coefficient *S*:

$$\Delta U = S \cdot \Delta T\,. \tag{1}$$

Seebeck coefficients of metals can have either sign as they are defined relative to platinum. In a single metal arrangement, this voltage exists across the metal but does not result in a current flowing other than simply building up the charges, initially. If there is a material transition, where two different metals are joined, not only does a potential difference exist, there might also be a persistent current, driven by the temperature difference, if the loop is closed. As superconducting cavities are made out of niobium while the helium vessel enclosing them is typically titanium this effect is relevant for accelerator physics: During the cool-down of a dressed cavity (a cavity welded into its helium vessel) it is easy to imagine that both ends of the cavity (where the Nb-Ti transition is located) have different temperatures. Seebeck coefficients are temperature dependent, as given in tab. 1 for niobium and titanium. With the more general definition of the Seebeck coefficient, the thermo-voltage becomes

$$U_{th} = \int_{T_1}^{T_2} \left(S_{Nb}(T) - S_{Ti}(T) \right) dT \tag{2}$$

Abstract

Cornell University has finished building a 10 m long superconducting accelerator module as a prototype of the main linac of a proposed ERL facility. This module houses 6 superconducting cavities- operated at 1.8 K in continuous wave (CW) mode - with individual HOM absorbers and one magnet/ BPM section. In pushing the limits, a high quality factor of the cavities ($2 \bullet 10^{10}$) and high beam currents (100 mA accelerated plus 100 mA decelerated) were targeted. We will review the design shortly and present the results of the components tested before the assembly. This includes data of the quality-factors of all 6 cavities that we produced and treated in-house, the HOM absorber performance measured with beam on a test set-up lessons learned during assembly.

INTRODUCTION

Energy-Recovery Linacs (ERLs) can provide beams with high currents, small emittances, and low energy spread. The current can be as large as typically in rings, 100mA in the case of Cornell's x-ray ERL, while the emittances and the energy spread can stay as small as only possible in linacs. While the current limit for conventional linacs is determined by the available acceleration power, ERLs recapture the energy of the spent beam and the current then becomes limited by other effects like higher order mode (HOM) heating and beam-break up (BBU). Cornell University has started an extensive R&D program to address these questions and proposed an ERL as a driver for hard x-ray sources [1].

One part of that R&D program was building a linac cryo-module, based on 1.3 GHz cavities, optimized for a high BBU-limit and good HOM damping, with extraordinary high quality factors to reduce operating cost. This module, show in Fig.1, has been completed recently which allows us to highlight our findings within this paper.

CRYOMODULE CONCEPT

The Main Linac Cryomodule (MLC) prototype houses six superconducting 7-cell cavities and has an overall length of 10 m. The design has been guided by the ILC Cryomodule while necessary modifications have been made to allow CW operation. In addition, we decided to align all components inside the module by reference surfaces on the helium gas return pipe (HGRP). As a consequence, the cold-mass as a whole will shrink during cool-down, requiring the power couplers to flex.

#r.eichhorn@cornell.edu

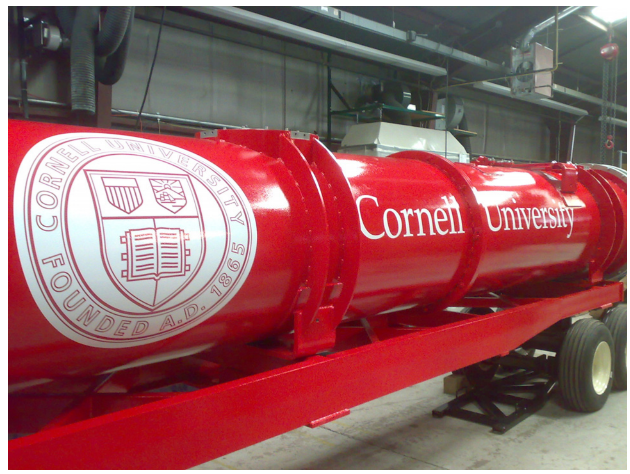

Figure 1: Cornell's Main linac cryo-module.

Due to the high beam current combined with the short bunch operation a careful control and efficient damping of the HOMs is essential, leading to the installation of dampers next to each cavity. There are more comprehensive details on the design in [2-5].

CAVITY PRODUCTION AND RESULTS

For the cavities, a 7-cells, 1.3 GHz design was made while an envisaged Q of $2x10^{10}$ was targeted at a gradient of 16 MV/m. All 6 cavities for the MLC module have been produced in-house starting from flat metal niobium sheets. To investigate microphonics, we decided to build 3 unstiffened cavities as well as 3 cavities with stiffening rings. All cavities were tested vertically, the summary of these test are given in Fig. 2. All six cavities exceeded the design quality factor, averaging to $2.9*10^{10}$ at 1.8K. At 2 K, the average Q was $1.8*10^{10}$, at 1.6 K we found $4.3*10^{10}$[6]. It should be noted that the Q we measured on the prototype cavity at 1.8 K was $2.5 *10^{10}$ in the vertical test, but $6*10^{10}$ in the horizontal test where magnetic shielding is more efficient [7].

The reproducibility of the Q versus E curves for all cavities is remarkable, also the fact that none of the cavities needed additional processing- giving a 100 % yield.

TIME RESOLVED CRYOGENIC COOLING ANALYSIS OF THE CORNELL INJECTOR CRYOMODULE

R. Eichhorn#, S. Markham, E. Smith, P. Quigley
Cornell Laboratory for Accelerator-Based Sciences and Education, Cornell University
Ithaca, NY 14853-5001, USA

Abstract

Managing parallel cryogenic flows has become a key challenge in designing efficient and smart cryo-modules for particle accelerators. In analyzing the heating dynamics of the Cornell high current injector module a power-full computational tool has been set-up allowing time resolved analysis and optimization. We will describe the computational methods and data sets we have used, report the results and compare them to measured data from the module being in good agreement. Mitigation strategies developed on basis of this model have helped pushing the operational limitations..

INTRODUCTION

In preparation for full ERL at Cornell [1], an injector cryomodule was designed and built to demonstrate high current generation and achieving low emittances. The construction of the Cornell injector was completed in the summer of 2007 when initial beam commissioning experiments revealed an issue with charging up of one set of ferrites in the higher-order mode (HOM) absorbers. After a rebuilt taking out the troublesome material, commissioning resumed leading to a world record performance in achieving 75 mA beam current [2]. However, the goal set for the ERL was 100 mA and in pushing for that we realized that heating of the 80 K thermal intercept of the power couplers is the limitation. As beam power ramps up, RF power transmitted by the coupler increases. Even though the couplers are designed for 60 kW we observe a significant heating which at the level of around 40-50 kW leads to temperatures around 140 K at an intercept which should be hold cold at 80 K.

Even though the heating itself is not an issue, the increase in vacuum pressure in the coupler leads to breakdowns- eventually limiting us in increasing the beam current. A careful analysis of the insufficient cooling of the 80 K intercept of the coupler revealed an adequate sizing of the heat exchanger but a deficient mass flow through the cooling channel, which happened to be a parallel flow to the cooling of the higher order mode absorbers. This cryogenic flow diagram is symbolized in fig.1.

Having parallel cooling flows is one of the key concepts to be used in designing highly cryogenically efficient accelerator modules, and we have investigated the stability of parallel flows under variations of operating parameters in the past [3]. In this paper, we describe the iterative numerical method we used to investigate and understand the transient heating issue and find a solutions which finally helped us to resolve the problem: We found that by adding a high impedance inlet pipe to each of the HOMs, we can reduce the flow rate of the whole system by 50%, while both improving the stability of the flow and reducing the operating equilibrium temperature of the couplers.

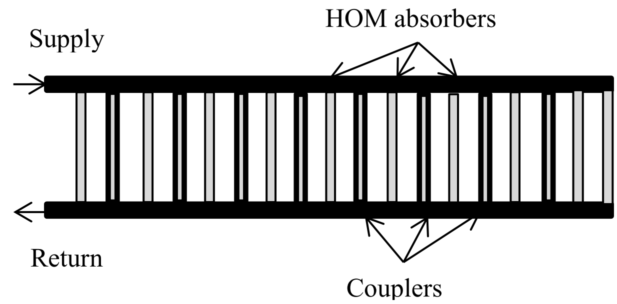

Figure 1: The 80 K cryogenic cooling piping: The thermal intercept of the ten coupler and the 12 channels to cool the higher order mode absorbers a fed in parallel.

METHOD

ICM Setup and Model Specifications

The focus of this paper is to outline the setup and results to a computational simulation intended to understand time dependent heating an their impact in diverting mas flows in parallel cooling channels. This paper focuses specifically on the HOM and coupler 80 K parallel flow channels of the injector cryo module (ICM) but our method is more general and can be applied to other scenarios, too.

In the ICM, the cooling helium is supplied at 80K. The fluid undergoes heat transfer as well as pressure drop as it flows across the couplers or the HOMs from the supply to the return pipe. Each of the HOM absorbers are represented in fig. 1 by thinly outlined channels, while the couplers are represented with thicker outlines. Because each coupler and HOM is geometrically identical, and as there is negligible head loss in the supply and return manifolds we can model this cryogenic system as a two pipe parallel system, shown in fig 2.

Accommodating this simplification, the total mass flow has to be calculated as $\dot{m_{tot}} = 10\, \dot{m_{coupler}} + 12\, \dot{m_{HOM}}$. To conduct the calculation, the following geometrical data describing the cooling piping was used: In the ICM,

[2]FNAL, Batavia, IL 60510, USA

Abstract

The Linac Coherent Light Source-II (LCLS-II) is a new x-ray source that is planned to be constructed in the existing SLAC tunnel. To meet the quality factor specifications (2.7×10^{10} at 2.0 K and 16 MV/m), nitrogen-doping has been proposed as a preparation method for the SRF cavities. In order to demonstrate the feasibility of these goals, four 9-cell cavity tests have been completed in the Cornell Horizontal Test Cryomodule (HTC), which serves as a test bench for the full LCLS-II cryomodule. Here we report on the most recent two cavity tests in the HTC: one cavity nitrogen-doped at Cornell and tested with high Q input coupler and then again tested with high power LCLS-II input coupler. Transition to test in horizontal cryomodule resulted in no degradation in Q_0 from vertical test. Additionally, increased dissipated power due to the high power input coupler was small and in good agreement with simulations. These results represent a crucial step on the way to demonstrating technical readiness for LCLS-II.

INTRODUCTION

The Linac Coherent Light Source-II (LCLS-II) Project will construct a 4 GeV CW superconducting linac in the first kilometer of the existing SLAC tunnel [1]. In order to maximize cryogenic efficiency of the linac and ensure economic feasibility, the superconducting RF (SRF) cavities must reach an intrinsic quality factor (Q_0) of 2.7×10^{10} at 2.0 K and 16 MV/m. To meet this high Q_0, nitrogen-doping [2] of the SRF cavities has been proposed. Cornell has recently recommissioned the Horizontal Test Cryomodule (HTC) [3] to hold a 9-cell ILC shaped cavity. As part of the LCLS-II R& D program, four 9-cell tests have been completed so far in the HTC. The first two (using ILC helium tanks) were discussed thoroughly in [4]. This paper will focus on the most recent cavity and compare its performance vertically and un-dressed, vertically and dressed (in LCLS-II helium tank), horizontally with high Q input coupler, and horizontally with high power input coupler.

EXPERIMENTAL METHOD

The Cornell HTC is a full cryomodule that can hold one 9-cell ILC shaped cavity, see Fig. 1. It was designed as

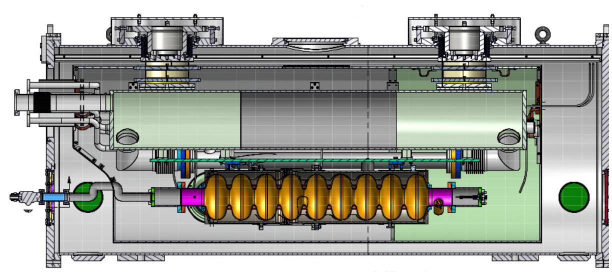

Figure 1: A schematic of a 9-cell cavity in the HTC.

a prototype to test SRF cavities under realistic cryomodule conditions. The cryomodule design is very similar to the LCLS-II cryomodule that will be used in the full machine. Ambient magnetic fields in the HTC are less than 5 mG. A 9-cell cavity (TB9AES018) was prepared with nitrogen-doping at Cornell. This consisted of a bulk vertical electropolish (VEP) of 120 μm, heat treatment in vacuum at 800°C for three hours, heat treatment in 60 mTorr of nitrogen gas for 20 minutes at 800°C, an annealing stage in vacuum at 800°C for 30 minutes, and finally an additional 24 μm VEP. It was then welded into a prototype LCLS-II helium tank at FNAL. The dressed cavity was assembled into the HTC with a high Q input coupler ($Q_{ext}\approx 3\times 10^{10}$). The cavity was also surrounded by a solenoid in order to induce a uniform external magnetic field parallel to the cavity axis for the purposes of studying cavity Q_0 sensitivity to ambient magnetic fields. A total of 13 cool downs were completed with various cool down rates, spatial temperature gradients, and applied external magnetic fields. After the first cool down, Q_0 vs E_{acc} was measured at different temperatures between 1.6 and 2.0 K in order to extract R_{BCS} vs. field (details of the method used to extract material properties are discussed in [5]). For each subsequent cool down, Q_0 vs E_{acc} was measured at 2.0 and 1.6 K. From this data, we were able to extract residual resistance and evaluate its dependence on cool down gradient and applied magnetic field. This test of TB9AES018 with high Q input coupler will be referred to as HTC9-3.

Following the HTC9-3 test, the cavity was removed from the HTC and an LCLS-II high power input coupler was installed [6] before re-assembly in the HTC. This test will be referred to as HTC9-4. This coupler has an adjustable

UPDATE ON NITROGEN-DOPING: QUENCH STUDIES AND SAMPLE ANALYSIS*

D. Gonnella†, F. Furata, M. Ge, J. Kaufman, M. Liepe, J. Maniscalco
CLASSE, Cornell University, Ithaca, NY 14853, USA

Abstract

Recently, nitrogen-doping of niobium has emerged as a promising preparation method for SRF cavities to reach higher intrinsic quality factors than can be reached with typical cavity preparation. Nitrogen-doped cavities prepared at Cornell have shown quality factors higher than 4×10^{10} at 2.0 K and 16 MV/m. While Q results have been very exciting, a reduced quench field currently limits nitrogen-doped cavities with quench typically occurring between 15 and 25 MV/m. Here we report on recent results from Cornell on single-cell and 9-cell cavities, focusing on new preparations and maximum and critical fields. First we discuss results from over-doping niobium with nitrgoen, baking nitrogen-doped cavities at 120°C, and doping with Argon. For a subset of these cavities we show results from quench studies that have been completed using temperature mapping. Finally, we present the first measurements of the higher critical field, H_{c2}, for nitrogen-doped niobium samples.

INTRODUCTION

Nitrogen-doping has been shown to increase the intrinsic quality factor, Q_0, of niobium SRF cavities to levels previously unreachable. Doping consists of giving cavities a heat treatment at high temperatures in a gaseous atmosphere [1]. An ongoing effort has been undertaken at Cornell, Jefferson Lab, and Fermilab to understand the benefits of nitrogen-doping and to create an optimal recipe for cavity preparation. Unfortunately, many cavities prepared with nitrogen-doping have shown a lower quench field than cavities prepared by other means. Cornell has recently been focusing on studying the cause of this lower quench field by systematically preparing cavities by different methods. Furthermore, we have employed the use of both single and 9-cell temperature mapping systems for quench detection along with OSTs. We have also measured the higher critical field, H_{c2} of nitrogen-doped niobium samples using Physical Property Measurement System (PPMS). Additionally, we have continued studying different preparation techniques such as doping with argon instead of nitrogen and subjecting a nitrogen-doped cavity to a 48 hours 120°C bake. These latest measurements push us closer to understanding the mechanisms behind higher Q_0's, lower quench fields, and other unique properties of nitrogen-doped cavities.

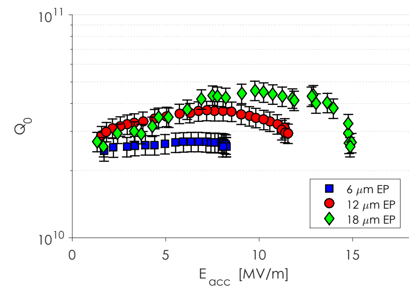

Figure 1: 2.0 K Q_0 vs E_{acc} performance for the over-doped cavity. Quench field increases with more material removal.

SINGLE-CELL STUDIES

Over-Doping

A single-cell 1.3 GHz ILC shaped cavity was given an "overdoping" of nitrogen. This consisted of a bulk electropolish (EP), followed by a heat treatment in vacuum at 900° for 3 hours, followed by 900°C heat treatment in 60 mTorr of nitrogen gas for 20 minutes, followed by an additional 900°C heat treatment in vacuum for 30 minutes. Finally, the cavity was given a series of 3 additional EPs in steps of 6 μm with tests in between. Typically, cavities have been treated at 800°C [1, 2]. By increasing the temperature by 100°C, we saw an increase in nitrogen uptake of ∼ 1.75× that for previous cavities. The 2.0 K Q_0 vs E_{acc} results are shown in Fig. 1. We can see that initially (after 6 μm EP), the cavity quenched at 8.3 MV/m with a maximum Q_0 of 2.7×10^{10}. After an additional 6 μm EP (total of 12 μm) the quench field increases to 11.5 MV/m with a maximum Q_0 of 3.7×10^{10}. Finally, after another additional 6 μm (total of 18 μm), the quench field increases to 15 MV/m with a maximum Q_0 of 4.6×10^{10}.

The increase in Q_0 with additional material removal is fairly well understood. Nitrogen-doping has been shown to optimize the BCS material properties and thus minimize the BCS resistance of SRF cavities [3]. By removing more material, we are reaching a more optimial place on the BCS curve. Nitrogen-doping has also been shown to form a lossy nitride layer on the surface. It is possible that this layer (which is now significantly thicker due to the higher temperature doping) causes the quench field to be even lower in this cavity than in previous cavities. This is consistent with the quench field increasing as more material is removed. A discussion of the quench location will be presented in a later section.

RECENT STUDIES ON THE CURRENT LIMITATIONS OF STATE-OF-THE-ART Nb_3Sn CAVITIES*

Abstract

Recent advances in the study of Nb_3Sn at Cornell University have yielded single-cell cavities that show excellent performance without the limiting Q-slope seen in previous work. This performance has been shown to be repeatable across multiple cavities. However, they are still limited by a quench field of approximately 16 MV/m, as well as residual resistance. In this work we present results quantifying the impact of ambient magnetic fields on Nb_3Sn cavities, as well as discuss the impact of cavity cooldown procedures on cavity performance. Finally, we will briefly discuss XRD results that shed light on the composition of the Nb_3Sn layer and how this relates to the current limits of these cavities.

INTRODUCTION

Studies on the fabrication and use of Nb_3Sn in superconducting radio-frequency (SRF) cavities at Cornell University have recently made considerable progress in developing Nb_3Sn as an alternative to niobium [1–4]. In this work we present results from the most recent work on Nb_3Sn at Cornell, with particular emphasis on measurements to determine the impact of ambient magnetic fields on the residual resistance of Nb_3Sn cavities. We also present data from two different cavity tests that demonstrate the impact that the procedure used to cool the cavity below its superconducting transition temperature has upon the cavity's performance. These measurements are critical in predicting how a Nb_3Sn cavity will behave when placed inside a cryomodule assembly, and what, if any, modifications will need to be made to accommodate it. Finally, we will briefly describe other recent measurements that have been made to determine both the fundamental properties and material parameters of Nb_3Sn fabricated at Cornell University using the vapour deposition method.

EXPERIMENTAL PROCEDURE

Cooldown Procedure

It is critical that niobium cavities coated with Nb_3Sn be cooled slowly through the transition temperature T_c of 18 K down to below 6 K to minimise the effects of magnetic fields generated by electric currents induced from thermal gradients. The method used to cool the cavities below their transition temperature is more completely described in Ref. [1], although a condensed version will be surmised here: the cavity is mounted upon an insert that is placed into a magnetically shielded cryostat, whereupon liquid helium is passed at a low flow rate through an injection port that is lined with heating elements, warming the incoming helium and thus allowing fine control of the temperature inside the cryostat. As the power of the heating elements is slowly reduced, the rate of the temperature decrease inside the cryostat is carefully controlled to ensure a minimal impact from thermal currents. This control system allows a rate control of between 2-30 min/K, with spatial gradients across the cavity of < 50-1000 mK (the latter being dependent upon the rate with time).

Flux Trapping Measurements

The method used to quantify the impact of external DC magnetic fields has been used in previous studies to investigate both standard niobium cavities as well as niobium cavities that have been doped with nitrogen [5]. Two solenoid coils are placed above and below the cavity in a Helmholtz configuration, to generate a magnetic field parallel to the cavity axis. Two flux gate magnetometers are placed on the cavity, one placed on the upper iris in parallel with the cavity z-axis (considering a cylindrical coordinate system in which the z-axis is placed along the path of the beam through the cavity), and one placed next to the previous pointing in the $\hat{\phi}$ direction. These are used to measure the field that is applied by use of the solenoids. As the cavity passes into the superconducting state and a fraction of the magnetic flux is expelled from the bulk of the cavity, these measurements are used to determine the amount of magnetic flux that has been trapped. A subsequent measurement of the cavity quality factor Q as a function of both temperature T and accelerating gradient E_{acc} is then used to quantify the impact of the externally applied magnetic field on residual surface resistance and its field dependence.

XRD and Phase Determination

XRD measurements were carried out at the APS at Argonne National Lab on Nb_3Sn samples fabricated at Cornell. The XRD provides a diffraction pattern from a region of spatial extent of approximately 1 mm wide and deep. The diffraction spectrum is used to determine the lattice parameter of the Nb_3Sn crystals, which is in turn used to infer

H_{c2} MEASUREMENTS OF Nb_3Sn AND NITROGEN-DOPED NIOBIUM USING PHYSICAL PROPERTY MEASUREMENT SYSTEM*†

J. T. Maniscalco‡, D. Gonnella, D. L. Hall, M. Liepe, and S. Posen
CLASSE, Cornell University, Ithaca, NY, 14853, USA

Abstract

The measurement of the upper critical field of a type-II superconductor, H_{c2}, is an important step in determining its superconducting properties, and therefore its suitability as a material in SRF cavities. However, measuring H_{c2} directly can be challenging, as performing electrical measurements causes changes in the very properties one seeks to measure. We present a method for extracting H_{c2} from resistivity measurements made near the transition temperature for varied applied fields and excitation currents. We also present first results of these measurements made on Nb_3Sn and nitrogen-doped niobium.

INTRODUCTION

In the field of superconducting radio frequency (SRF) accelerators, niobium has had a long and successful career as the fabrication material of choice. However, as accelerator demands increase, the field is behooved to find new materials with improved qualities. One promising type of new material is surface-treated niobium, *i.e.* bulk niobium with a thin layer of a different material on the RF-active surface. In this paper we investigate the properties of two such materials, namely Nb_3Sn and nitrogen-doped niobium; we develop a method for finding the upper critical field of a material, from which one can calculate many other figures of merit, including the coherence length ξ and the mean free path ℓ.

The upper critical field H_{c2} of a type-II superconductor is the minimum magnetic field at which the material cannot superconduct, regardless of temperature. This field is very difficult to observe directly, as it requires holding the temperature of the sample at absolute zero while measurements are made. Instead, it must be extrapolated from measurements of the superconducting transition at higher temperatures.

The Physical Property Measurement System (PPMS, Quantum Design) and machines like it allow the researcher to perform low-temperature electrical and magnetic measurements with direct control over the temperature and applied magnetic field at the sample. Using such a machine, we can set a magnetic field and measure the resistivity of a sample of the material of interest, for a chosen magnetic field and temperature, with a lower bound of 1.9 K for the temperature and an upper bound of 9 T for the field.

* Funding provided by NSF grants PHY-1305500 and PHY-1416318.
† This work made use of the Cornell Center for Materials Research Shared Facilities which are supported through the NSF MRSEC program (DMR-1120296).
‡ jtm288@cornell.edu

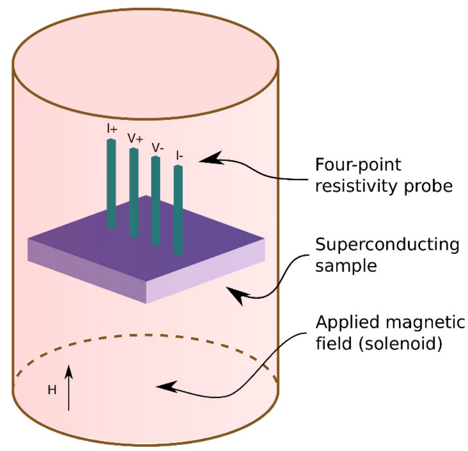

Figure 1: Schematic of testing environment inside PPMS. Spring-loaded press contacts act as a four-point resistivity probe on the surface of the superconducting material. The apparatus sits inside a solenoid, which applies an external magnetic field.

METHOD

At a given applied magnetic field strength, a superconductor will transition to its normal-conducting state at some temperature T. We can invert this function to get $H_{c2}(T)$, the magnetic field where, for a given temperature, the material makes its phase transition. Given a set of measurements of transitions with values of T and $H_{c2}(T)$, we can extrapolate the upper critical field $H_{c2} = H_{c2}(0)$ and the critical temperature T_c using Eq. 1 [1][1]:

$$H_{c2}(0) = H_{c2}(T)\left[1 - \left(\frac{T}{T_c(0)}\right)^2\right]^{-1} \tag{1}$$

In order to perform these measurements, we use the PPMS to perform four-point resistivity measurements on the sample at fixed magnetic fields and varying temperature. For these measurements, four needles are pressed against the surface of the sample and a 17 Hz AC signal is applied between the first and fourth pins for a short time. While the current is being applied, the voltage across the two center pins is measured, and the PPMS calculates and records the resistivity. Figure 1 shows the typical experimental setup. In the superconducting

RF PERFORMANCE STUDIES OF THIN-FILM SUPERCONDUCTORS USING A SAMPLE HOST CAVITY *

J. T. Maniscalco†, D. L. Hall, M. Liepe
CLASSE, Cornell University, Ithaca, NY, 14853, USA

Content from this work may be used under the terms of the CC BY 3.0 licence (© 2015). Any distribution of this work must maintain attribution to the author(s), title of the work, publisher, and DOI.

Abstract

Thin-film superconductors have the potential for reducing cost and for improved SRF performance over traditional bulk niobium superconducting cavities. Materials such as Nb3Sn, multilayer NbN/MgO, and thin-film Nb are currently under investigation for cost reduction or possible improvements in RF losses and accelerating gradients. Due to the complex geometries of traditional RF cavities, it is preferable to use a sample host cavity to study flat samples of the novel materials. The Cornell sample host cavity has been commissioned and has now reached peak magnetic surface fields of 100 mT. We present updates on the recent performance of the cavity.

INTRODUCTION

In the field of superconducting radio frequency (SRF) accelerators, many materials are currently being studied as alternatives to bulk niobium for RF operation. Particularly, thin film materials such as Nb_3Sn, nitrogen-doped niobium, and thin-film niobium show promise as future materials.

In order to study the material properties of candidate SRF materials, Cornell has developed a series of versatile sample host cavities [1–4]. The third and most recent of these cavities operates at a frequency of 4 GHz. Recent tests of the cavity have reached peak fields of 100 mT on the surface of the sample plate.

The sample host cavity operates in a TE mode, with a coupler extended upwards through the single beam tube. The clamp at the top of the cavity holds a removable sample plate in place. The plate, a flat five-inch disk, is mounted with an indium seal and can be manufactured, treated, and examined separately from the rest of the cavity. Figure 1 shows the assembled cavity.

RECENT RESULTS

The sample host cavity has now reached peak fields of over 100 mT on the sample plate. This is a significant step towards the empirically inferred limit of 120 mT, based on thermal runaway in previous TE cavities [4].

Recent tests of the sample host cavity have shown a Q-slope, as shown in Fig. 2. This is problematic, since the utility of the sample host cavity relies on achieving high Q at all fields: reaching high Q increases the sensitivity of the measurements of sample performance by reducing the background signal from the rest of the cavity.

* This work supported by NSF Career grant PHY-0841213 awarded to Matthias Liepe.
† jtm288@cornell.edu

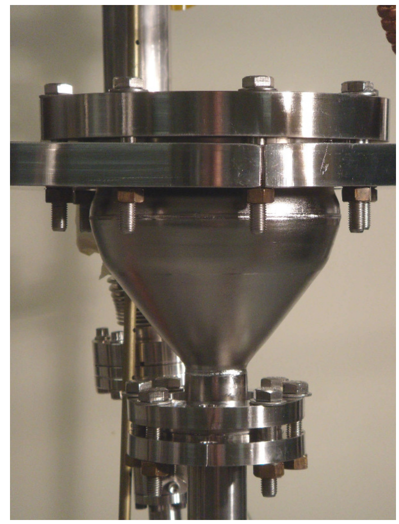

Figure 1: Third-generation Cornell TE sample host cavity.

It was speculated that the observed Q-slope effect was caused by indium losses, which can occur if the indium sealant approaches the RF surface at the cavity-sample plate interface. In order to investigate this possibility, we examined the relation between the quality factor Q and the temperature T for this high-field test, shown in Fig. 3. If the indium used as a sealant between the sample plate and cavity was interfering enough to bring rise to RF losses, we would expect that Q would decrease significantly above the superconducting critical temperature of indium, 3.4 K. However, the data do not suggest any such change in Q, implying that the observed Q-slope was not caused by indium losses. More work is needed to investigate this Q-slope.

A more recent test featuring a niobium-tipped coupler (discussed below), also seen in Fig. 2, aligns with the Q-slope of the high-field test, though the test did not reach fields high enough to make a direct comparison.

NIOBIUM COUPLER TIP

Previous tests of the sample host cavity suggested that the copper coupler assembly was introducing losses and affecting the intrinsic quality factor of the cavity [4,5]. In light of this, and in an effort to increase the Q of the system, the tip of the coupler for the sample host cavity was replaced with a duplicate made with niobium. In theory, a superconducting coupler tip would lower coupler losses significantly due to the strongly decreased resistance.

As Fig. 4 shows, to first order this coupler tip replacement does not appear to decrease the impact of the coupler on the

ON QUENCH PROPAGATION, QUENCH DETECTION AND SECOND SOUND IN SRF CAVITIES

R. Eichhorn# and S. Markham
Cornell Laboratory for Accelerator-Based Sciences and Education, Cornell University
Ithaca, NY 14853-5001, USA

Abstract

The detection of a second sound wave, excited by a quench, has become a valuable tool in diagnosing hot spots and performance limitations of superconducting cavities. Several years ago, Cornell developed an oscillating super-leak transducer (OST) for these waves that nowadays are used world-wide. In a usual set-up, several OSTs surround the cavity, and the quench location is determined by triangulation of the different OST signals. Convenient as the method is there is a small remaining mystery: taking the well-known velocity of the second sound wave, the quench seems to come from a place slightly above the cavity's outer surface. We will present a model based on numerical quench propagation simulations and analytic geometrical calculations that help explain the discrepancy.

INTRODUCTION

Superconducting Radio Frequency (SRF) cavities are fabricated carefully to make a smooth, uniform surface. This ensures that electric current flows uniformly on the surface of the cavity, so that minimal heating of the cavity surface occurs. Despite precautions taken, it is still common for cavities to bear small (sub-millimeter) surface defects that impede cavity performance. These defects cause localized excess heating. If severe enough, this can heat the surrounding superconducting material (in most cases niobium) to above its critical temperature. When this happens, the niobium becomes normal conducting and begins to heat even more rapidly. This causes a runaway effect wherein all the cavity's stored energy is quickly converted into heat, called a quench. Because defects cause quenching, which severely detriments a cavity's performance, it is important to be able to locate the defect so that it can be removed.

One method of locating a defect involves using oscillating superleak transducers (OSTs,[1]) to detect second sound waves emitted from the cavity. Second sound is a phenomenon observed in superfluid helium[2] wherein heat propagates as a wave with properties comparable to that of a classical sonic wave. The speed of the second sound depends somewhat on the parameters of the fluid, but is almost a constant of 20 m/s, within the temperature range of 1.6 to 2 K.

Once the second sound wave has been produced, the signal propagates through the helium until it reaches an OST. A typical arrangement is given in Fig. 1. By calculating the difference in time between when the quench occurred, which one can measure as the time at which the cavity begins to lose its stored energy, one can use trilateration to deduce the location of the defect [1]. Problematically, when this procedure is performed, there is a discrepancy between the predicted location of the defect and the defect's actual location. In fact, the defect is often detected to be off the surface of the cavity entirely. Also, others [3] have noted that the quench expands faster enough that it may not behave as a point-like emitter of a second sound wave.

Previously, we investigated the possibility of a delay between the loss of stored energy in the cavity and the triggering of a second sound wave [4]. As we did so we could explain a discrepancy in the order of 2-3 mm.

In this paper we will investigate how heat propagation in the niobium can contribute to the quench signal propagation and its effect on quench location.

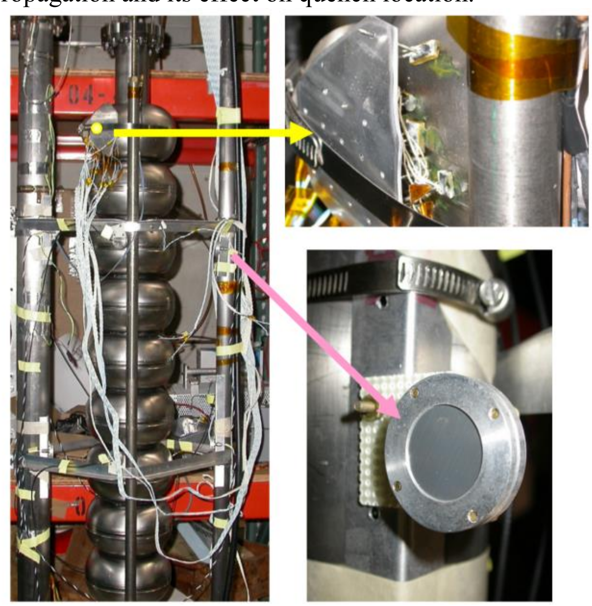

Figure 1: Basic layout of OST quench detection setup. OSTs are set up in an array around the exterior of the cavities, and submerged in He-II (Image from [1]).

GEOMETRICAL SETUP

Calculating Propagation Time

Figure 2 illustrates the basic geometry of the problem. For simplicity, the niobium is assumed to exist simply on a plane. The niobium is in thermal contact with a bath of helium-II. The OST is placed at a distance R from defect and an angle θ from the normal.

Naively, one would assume a signal propagates to the

HIGH Q_0 AT MEDIUM FIELDS IN Nb_3Sn SRF CAVITIES AT 4.2 K*

S. Posen†, Daniel Leslie Hall, and M. Liepe
Cornell Laboratory for Accelerator-Based Sciences and Education, Ithaca, NY, 14853, USA
T. Proslier
Argonne National Laboratory, Argonne, Illinois 60439, USA

Abstract

Nb_3Sn has proven itself to be a very promising alternative SRF material. With twice the critical temperature of niobium cavities, 1.3 GHz Nb_3Sn cavities can achieve quality factors on the order of 10^{10} even at 4.2 K, significantly reducing cryogenic infrastructure and operational costs. In addition, its large predicted superheating field may allow for maximum accelerating gradients up to twice that of niobium for high energy applications. In this work, we report on new cavity results from the Cornell Nb_3Sn SRF program demonstrating a significant improvement in the maximum field achieved with high Q_0 in a Nb_3Sn cavity. At 4.2 K, accelerating gradients above 16 MV/m were obtained with Q_0 of 8×10^9, showing the potential of this material for future applications. In addition to this result, current limitations are discussed.

INTRODUCTION

For decades, niobium has been the material of choice for superconducting RF cavities in particle accelerators. It has excellent superconducting properties and is relatively easy to work with to fabricate cavities. However, because it has a critical temperature T_c of ~9.2 K, it is usually necessary to cool niobium cavities with subatmospheric helium at ~2 K in order to achieve high quality factor Q_0. Furthermore, while accelerating gradients E_{acc} in niobium cavities have been steadily increasing over years of development, cavities are now regularly being produced with fields close to the ultimate limit set by the superheating field B_{sh} of niobium.

Nb_3Sn is an alternative SRF material currently under development that already is showing great promise. It has a T_c of 18 K, approximately twice that of niobium, allowing for high Q_0 operation even at 4.2 K, opening up the possibility of operation with atmospheric helium, reducing the infrastructure costs for cryogenic plants, and increasing their efficiency. Nb_3Sn is also is predicted [1] to have a B_{sh} of 400 mT, approximately twice that of niobium, which could halve the number of cavities required to reach a given energy.

Many laboratories contributed to pioneering research in the 1970s-1990s into Nb_3Sn SRF cavities [2–8]. Building on their work based on the vapor diffusion process [9], a Nb_3Sn SRF program was started at Cornell University in 2009. After a successful program to demonstrate high quality coatings on small samples [10], the cavity program began.

RF TESTING

A coating chamber built for an ulta-high vacuum furnace (see details in [11]) was used to coat two single cell 1.3 GHz niobium cavities with Nb_3Sn. Cavity 1 received BCP chemical removal before coating, and Cavity 2 received EP. The performance of the cavities was evaluated in vertical RF test. After evaluation, the coating layer of Cavity 1 was removed with BCP, then it was coated and tested again. This was repeated a total of four times. Details of the coating are presented elsewhere [12]. The performance curves of these coatings are presented in Fig. 1.

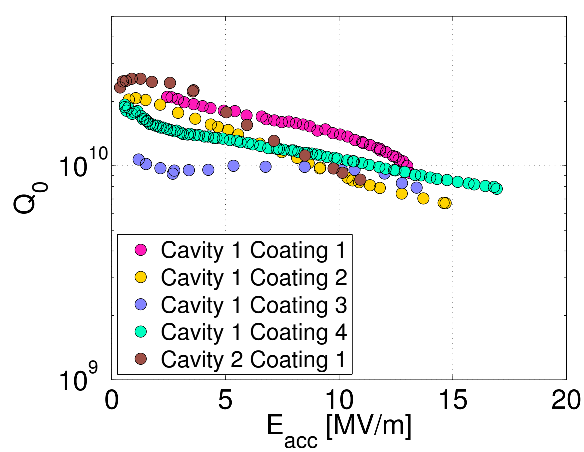

Figure 1: Q_0 vs E_{acc} at 4.2 K for single cell 1.3 GHz cavities over a series of five Nb_3Sn coatings.

In each test, Q_0 at 4.2 K on the order of 10^{10} is measured up to E_{acc} above 10 MV/m. Maximum fields are limited by quench without x-rays. An average quench field of 14 MV/m was measured, with an average Q_0 at quench of 8×10^9. The maximum field achieved was 17 MV/m. Moderate Q-slope was observed in each case, but it is far less strong than that observed by previous researchers studying Nb_3Sn accelerator cavities [13].

Material parameters were extracted during RF testing from fits to Q_0 versus temperature T data and resonant frequency f versus T data, as described in [14]. The results are shown in Table 1, along with the maximum fields in each test.

Q_0 on the order of 10^{10} at 4.2 K is a significant development in the effort to reduce power consumption in cryogenic

HIGH GRADIENT TESTING OF THE FIVE-CELL SUPERCONDUCTING RF MODULE WITH A PBG COUPLER CELL*

S. Arsenyev†, Massachusetts Institute of Technology, Cambridge, MA 02139, USA
W.B. Haynes, D. Shchegolkov, E. Simakov, T. Tajima, Los Alamos National Laboratory, PO Box 1663, Los Alamos, NM 87545, USA
C.H. Boulware, T.L. Grimm, A.R. Rogacki, Niowave, Inc., 1012 North Walnut Street, Lansing, MI 48906, USA

Abstract

We report results of high-gradient testing of the first 5-cell superconducting radio frequency (SRF) module with a photonic band gap cell (PBG).

Higher order mode (HOM) damping is vital for preserving the quality of high-current electron beams in novel SRF accelerators. Because HOMs are not confined by the PBG array, they can be effectively damped in order to raise the current threshold for beam instabilities. The PBG design increases the real-estate gradient of the linac because both HOM damping and the fundamental power coupling can be done through the PBG cell instead of via the beam pipe at the ends of the cavity. A superconducting multi-cell cavity with a PBG damping cell is therefore an attractive option for high-current linacs.

The first-ever SRF multi-cell cavity incorporating a PBG cell was designed a LANL and built at Niowave Inc. The cavity was tuned to a desired gradient profile and underwent surface treatment at Niowave. A vertical test (VTS) was then performed at LANL, demonstrating an abnormally low cavity quality factor in the accelerating mode of 1.6×10^6. Future tests are proposed to determine the source of the losses and resolve the problem.

INTRODUCTION

Superconducting radio frequency (SRF) cavities are the natural choice for future generations of high energy linacs, especially for high-duty-factor machines where the heat produced in the accelerating structure cannot be effectively extracted [1]. Going to higher frequencies in SRF cavities is desirable in some applications for various reasons. First, it allows us to lower cost and increase achievable luminosity of an electron beam. Second, it is necessary for harmonic cavities operating at multiples of accelerator frequency. However, higher-order-mode (HOM) wakefields excited by a beam scale as the frequency cubed and can easily destroy the beam in a high-frequency machine. One high-current linac of relatively high frequency is the proposed SRF harmonic linac for eRHIC [2], which would be used to undo nonlinear distortion of the beam's longitudinal phase space induced by the main linac waveform.

Photonic band gap (PBG) cavities are of interest to the particle accelerator community because they have reduced

Figure 1: 2.1 GHz 5-cell module with a PBG center cell, made from bulk niobium.

higher-order modes that can degrade beam quality [3,4]. Unlike a room temperature PBG cell, the superconducting cell must be closed in the transverse plane and utilizes waveguide couplers to extract the HOMs (Fig. 1). Waveguide couplers are commonly used as an HOM suppression mechanism but are usually attached to the beam pipe (see, for example, [5]). In contrast, low field at the periphery of the PBG cell allows us to attach the waveguide couplers directly to the outside wall of the cell. This is beneficial to HOM damping and increases real estate gradient by saving space on the beampipes [6].

One of the three waveguides is also utilized as a fundamental power coupler (FPC). This particular 5-cell module was originally designed for the LANL Navy FEL beamline with high beam current (100 mA), and therefore requires a strongly coupled FPC, which is achieved by removing one of the PBG rods. Accelerating properties of the module are similar to that of a design with 5 elliptical "low loss" cells [7].

Previous superconducting tests of single PBG cells have achieved high gradients and high quality factors [8]. However, building a 5-cell module involved new challenges such

FIVE-CELL SUPERCONDUCTING RF MODULE WITH A PBG COUPLER CELL: DESIGN AND COLD TESTING OF THE COPPER PROTOTYPE*

S. Arsenyev†, Massachusetts Institute of Technology, Cambridge, MA 02139, USA
D. Shchegolkov, E. Simakov,
Los Alamos National Laboratory, PO Box 1663, Los Alamos, NM 87545, USA
C.H. Boulware, T.L. Grimm, A.R. Rogacki, Niowave, Inc.,

Abstract

We report the design and experimental data for a copper prototype of a superconducting radio-frequency (SRF) accelerator module. The five-cell module has an incorporated photonic band gap (PBG) cell with couplers. The purpose of the PBG cell is to achieve better higher order mode (HOM) damping which is vital for preserving the quality of high-current electron beams. Better HOM damping raises the current threshold for beam instabilities in novel SRF accelerators. The PBG design also increases the real-estate gradient of the linac because both HOM damping and the fundamental power coupling can be done through the PBG cell instead of on the beam pipe via complicated end assemblies.

First, we will discuss the design and accelerating properties of the structure. The five-cell module was optimized to provide good HOM damping while maintaining the same accelerating properties as conventional elliptical-cell modules. We will then discuss the process of tuning the structure to obtain the desired accelerating gradient profile. Finally, we will list measured quality factors for the accelerating mode and the most dangerous HOMs.

INTRODUCTION

Superconducting radio frequency (SRF) cavities are the natural choice for future generations of high energy linacs, especially for high-duty-factor machines where the heat produced in the accelerating structure cannot be effectively extracted [1]. Going to higher frequencies in SRF cavities is desirable in some applications for various reasons. First, it allows us to lower cost and increase achievable luminosity of an electron beam. Second, it is necessary for harmonic cavities operating at multiples of accelerator frequency. However, higher-order-mode (HOM) wakefields excited by a beam scale as the frequency cubed and can easily destroy the beam in a high-frequency machine. One high-current linac of relatively high frequency is the proposed SRF harmonic linac for eRHIC [2], which would be used to undo nonlinear distortion of the beam's longitudinal phase space induced by the main linac waveform.

Photonic band-gap (PBG) cavities are of interest to the particle accelerator community because they have reduced higher-order modes that can degrade beam quality [3, 4]. Unlike a room temperature PBG cell, the superconducting cell is closed in the transverse plane and utilizes waveguide couplers to extract the HOMs. Waveguide couplers are commonly used as an HOM suppression mechanism but are usually attached to the beam pipe (see, for example, [5]). In contrast, low field at the periphery of the PBG cell lets the waveguide couplers be connected directly to the outside wall of the cell. This is beneficial to HOM damping and increases real estate gradient by saving space on the beampipes [6].

Figure 1: Copper prototype of the 5-cell accelerating module.

A niobium cavity was fabricated to test the maximum achievable accelerating gradient at superconducting temperature [7]. It was decided, however, that a much cheaper copper prototype (Fig. 1) would be fabricated prior to the niobium cavity for two reasons. This prototype serves to demonstrate the novel tuning required for the multi-cell structure with the PBG coupling cell, applied later to the niobium cavity. Also, HOM damping can be analyzed in the copper cavity by measuring external quality factors Q_e for the most dangerous HOMs. At room temperature, the Q_e can be calculated more accurately in the copper prototype because the conductivity of copper is about 10 times higher than that of niobium at room temperature. Mode overlapping, which is an issue for measurements in the niobium cavity at room temperature, is less of a problem. Unloaded Q factors for the copper prototype are in the order of 1.5×10^4 which is

COOLING SYSTEMS FOR THE NEW 201.25 MHz FINAL POWER AMPLIFIERS AT LOS ALAMOS NEUTRON SCIENCE CENTER (LANSCE)*

W.C. Barkley#, C.E. Buechler, J.T.M. Lyles, A.C. Naranjo, LANL, Los Alamos, NM 87544, USA
D. Baca, R.E. Bratton, Compa Industries, Los Alamos, NM 87544, USA

Abstract

Two new 201.25 MHz RF Final Power Amplifiers (FPAs) have been designed, assembled, installed and successfully tested at the Los Alamos Neutron Science Center (LANSCE), in Module 2 of the Drift Tube Linac (DTL). These production units were fabricated at Continental Electronics Corporation. In this paper, we summarize the FPA air and water cooling requirements and cooling systems [1].

Description of Systems

Figure 1 shows a CAD model of the FPA installation.

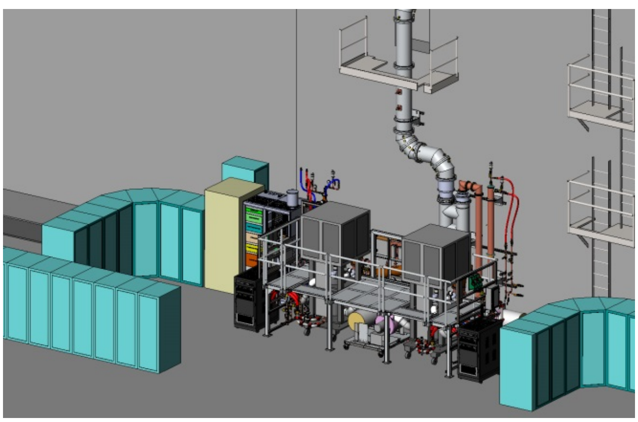

Figure 1: Model of FPA Installation.

Three separate water systems were required to fully cool each FPA and its auxiliary components. Two existing systems were modified and a new system was installed to meet the cooling requirements. A deionized water system (A01), cools the two power-combined FPAs and Intermediate Power Amplifier (IPA) directly. A chilled water system (A05), cools the RF reference source for the LANSCE accelerator and ignitrons in each of the four capacitor rooms. A treated water system (A06), cools the solid state driver amplifier (Rack 5), FPA and IPA water loads.

Flow requirements for the three water systems were developed for combined amplifier power, 3.4 MW at 13% duty factor or 442 kW each [2]. In addition, air cooling was implemented where water cooling was not practical.

The A01 System

The A01 system is an existing deionized water system that served the obsolete power amplifier that was previously located at Module 2 of the DTL. Centrifugal pumps, located in an adjacent mechanical room, deliver 88 psi, 1,250 gpm for the four DTL modules. One pump operates while the other serves as a backup. Adaptation of this water system consists of demolishing the existing plumbing at the module and installing the new plumbing as depicted in Fig. 2. Deionized water is required to eliminate the potential electrical path to ground in an ionized system. The A01 system is adapted to cool both FPAs and the IPA which is not shown in Fig. 2.

AN OVERVIEW OF THE MaRIE X-FEL AND ELECTRON RADIOGRAPHY LINAC RF SYSTEMS

J. Bradley III, D. Rees, A. Scheinker, R. Sheffield - Los Alamos National Laboratory, USA

Abstract

The purpose of the Matter-Radiation Interactions in Extremes (MaRIE) facility at Los Alamos National Laboratory is to investigate the performance limits of materials in extreme environments. The MaRIE facility will utilize a 12 GeV linac to drive an X-ray Free-Electron Laser (FEL). Most of the same linac will also be used to perform electron radiography. The main linac is driven by two shorter linacs; one short linac optimized for X-FEL pulses and one for electron radiography. The RF systems have historically been the one of the largest single component costs of a linac. We will describe the details of the different types of RF systems required by each part of the linacs. Starting with the High Power RF system, we will present our methodology for the choice of RF system peak power and pulselength with respect to klystrons parameters, modulator parameters, performance requirements and relative costs. We will also present an overview of the Low Level RF systems that are proposed for MaRIE and briefly describe their use with some proposed control schemes [1].

THE MaRIE FACILITY

The MaRIE facility will include a 12 GeV linac to provide a suite of measurement devices to investigate the performance limits of materials in extreme environments. One of MaRIE's most powerful tools will be the ability to multiplex an X-ray FEL, electron, and proton radiography onto a target material to study dynamic events as they develop.

The existing LANSCE proton linac will be used to provide proton radiography (pRad) [2]. The MaRIE electron linacs will be built in a new tunnel north of the existing LANSCE proton linac tunnel as shown in Figure 1.

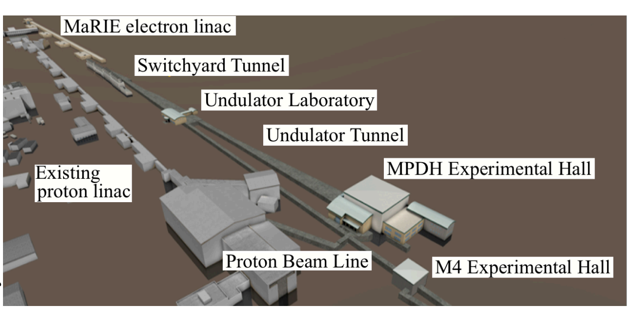

Figure 1: The MaRIE Facility layout.

MaRIE BEAM REQUIREMENTS

The MaRIE electron beams consist of micropulses for an X-ray FEL (XFEL) undulator and micropulses for electron radiography (eRad). A feature of the MaRIE facility is the ability to provide unevenly spaced XFEL and eRad micropulses distributed over a macropulse of up to 100 µs. The macropulse repetition rate is 60 Hz.

Each XFEL micropulse includes up to 0.2 nC of charge. Each 100µs long macropulse can include up to 30 XFEL micropulses. Each eRad micropulse includes up to 2 nC of charge. Each 100µs long macropulse can include up to 10 eRad micropulses.

The spacing between micropulses is determined by the experimental needs. The minimum separation between micropulses is determined by the time for cavity wakefields to decay. The minimum spacing after each eRad micropulse is 25 ns, while the minimum spacing after each XFEL micropulse is 2.5 ns.

COMBINATION LINAC DESIGN

Linac Layout

The XFEL and eRad micropulses are produced by and accelerated on separate injectors and initial linac sections. Both sections include an injector and L1 linac section, but the XFEL side also includes two bunch compressors and a short L2 linac section. The outputs of these parallel beamlines feed the L3 main linac as shown in Figure 2. A switchyard at the end of the L3 linac splits the XFEL and eRad beams off to go through undulators or directly to the target.

RF Cavity Details

The MaRIE linacs will use proven RF cavity designs. Four hundred sixty cavities will be of the 1.3 GHz TESLA type used in the FLASH [3], LCLS-II [4] and European XFEL [5] projects. The L3 linac includes 360 of these cavities. The L2 linac includes 78 of these cavities and the L1 linacs each include 11 of these cavities. Like the International Linear Collider (ILC), the 460 TESLA cavities are run at an average cavity field of 31.5MV/m [6].

The 22 third harmonic linearizer cavities will be of the 3.9 GHz type used in the FLASH linearizer [3]. Each L1 linac includes 7 of these cavities and the L2 linac includes 8 of these cavities. The average cavity gradient is 20 MV/m.

For beam diagnostics, the facility will use three transverse deflection cavities (TCAV) at 1.3 GHz and one normal conducting, traveling wave TCAV at 11.4 GHz.

INSTALLATION AND OPERATION OF REPLACEMENT 201 MHz HIGH POWER RF SYSTEM AT LANSCE

J. T. M. Lyles[#], W. Barkley, J. Davis, D. Rees, G. Sandoval,
AOT Division, Los Alamos National Laboratory, Los Alamos, NM
R. Bratton, R. Summers, Compa Industries, Los Alamos, NM

Abstract

The LANSCE RM project has restored the linac to high power capability after the power tube manufacturer could no longer provide triodes that consistently met our high average power requirement. Diacrodes® now supply RF power to two of the four DTL tanks. These tetrodes reuse the existing infrastructure including water-cooling systems, coaxial transmission lines, high voltage power supplies and capacitor banks. The power amplifier system uses a combined pair of LANL-designed cavity amplifiers using the TH628L Diacrode® to produce up to 3.5 MW peak and 420 kW of mean power. Design and prototype testing was completed in 2012, with commercialization following in 2013. The first installation was completed in 2014 and a second installed system is ready to test. The remaining replacement will follow in 2016. Meanwhile, there is a hybrid of old/new amplifiers until the changeover is complete. Operating results of the replacement system are summarized, along with observations from the rapid-paced installation project.

RF SYSTEM IMPROVEMENTS

The LANSCE drift tube linac (DTL) uses four Alvarez cavities powered at 201.25 MHz, to accelerate both protons (H^+) and negative hydrogen ions (H^-) from 0.75 to 100 MeV before injection into a coupled-cavity linac (CCL). Pulsed RF power must be capable of 12% duty factor (DF) and as high as 3.5 MW of peak RF power, with corresponding average power capability of 420 kW per cavity. This is in contrast to the high-peak/low-average power machines at 200 MHz proton injector linacs at Fermilab, CERN, RAL and BNL. Over the past 25 years, manufacture of reliable RF amplifier triodes operating at this high average power has been unpredictable. Both premature loss of cathode emission and ceramic cracking have occurred in some tubes when operated at LANL.

In 2006, the operating point of the power amplifiers (PA) had to be reduced in order to hold operating costs on budget (for all-too-frequent tube replacements) and prevent excess downtime. This led to the decision to operate LANSCE at half of its design original duty factor. A primary goal of the LANSCE Risk Mitigation project has been to double the linac duty factor by replacing the original 201.25 MHz amplifiers with modern power amplifier circuits with new generation tetrodes. Another goal has been to modernize the low level RF controls. Finally, end-of-life klystrons for the CCL are being replaced with forty-five new CPI VA862A1 1.3 MW klystrons [1].

Gridded Tube Cavity Amplifier

A previous report [2] explained the reasoning behind the choice of the TH628L Diacrode® from Thales Electron Tubes as the active device for this application. Combining the outputs of two PAs (Fig. 1) provides suitable headroom in peak and average power, allowing the tubes to operate well within their rating. Increased amplifier reliability and tube lifetime results from this pairing.

The caveat for gridded tubes is that a matching cavity amplifier circuit must be developed around a chosen device. The solution was to develop a commercially buildable PA design by our team, with technical assistance from the Thales tube product engineering team. The common-grid PA configuration uses a full wavelength double-ended coaxial line output circuit, in order to double the RF power available over a traditional single-ended tetrode. Progress on the mechanical and electrical design of the PA, supporting electronics and intermediate power amplifier (IPA) are discussed elsewhere [3][4][5]. Months of testing in 2012-13 ran up to 2.5 MW peak power at 12% duty factor and up to 3 MW into water loads to demonstrate design capability and to test the cathode emission capabilities of the tube. Each PA operates at < 1.85 MW at the DTL.

A tender for manufacturing the LANL-designed PA was issued in 2012 and the work was subsequently awarded to Continental Electronics Corporation [6]. Five PAs were delivered in 2013-2014 and tested at LANL. Two additional units are being manufactured for delivery in late 2015. Six TH628L Diacrodes® from Thales Electron Tubes have been received and tested. Two more are coming in late 2015. Three intermediate power amplifiers (IPA) have been produced by Betatron Electronics, Inc. with a fourth to be delivered in May. This amplifier assembly uses a Thales TH781 tetrode and matching TH18781 cavity amplifier. One IPA drives two final PAs (FPA) at each DTL RF station. All amplifiers conveniently reuse the same cooling water plant, the HV power supplies, capacitor banks and the 35.5 cm diameter coaxial transmission lines of the old RF powerplant.

Coaxial Transmission Lines

The 7.9 cm (3 1/8 inch) diameter coaxial transmission line from the 175 kW IPA is split by a λ/4 hybrid into two

DESIGN OF A RADIAL KLYSTRON*

Massimo Dal Forno**, Sami G. Tantawi, Ronald D. Ruth, Aaron Jensen,
SLAC National Accelerator Laboratory, CA 94025, USA

Abstract

The radial klystron is a multidimensional rf source where the beam is generated by a cylindrical gun and it propagates in the radial dimension. The advantage of this design is that the space charge effects are balanced in the azimuthal dimension and a lower magnetic fields is required to focus the electron beam. The bunching is made with concentric coaxial resonators, connected by drift tube. The electron beam interaction with the cavity fields has been analyzed by means of particle tracking software in order to evaluate the beam bunching and the beam dynamics. This paper shows the klystron design, optimizing the shape and the position of each cavity, in order to maximize the efficiency of the device.

INTRODUCTION

The traditional klystron is a linear-beam rf source, where a focused electron beam interacts with resonant cavities. The beam must be focused by a solenoid, to compensate the space charge forces. Gain and efficiencies are limited by the space-charge. It is possible to reduce the space charge effects by allowing the electrons to propagate in the natural expansion according to the space charge forces. This can happen if the beam is generated from a central source (cathode) and it expands in the three-dimensional space (Fig. 1). In this ideal case, the transversal space-charge forces are

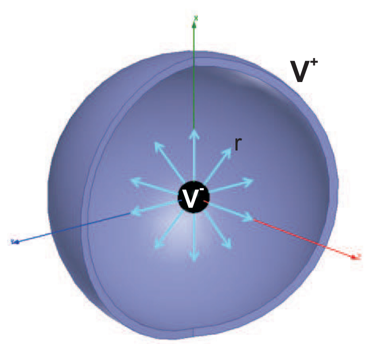

Figure 1: Three-dimensional natural expansion of electrons.

fully balanced (where the transverse dimension is the orthogonal to the propagation of each electron). No magnet is required to compensate space charge effects. This approach uses the multidimensional beam motion to avoid or reduce the space-charge effects.

This paper analyzes a radial klystron [1], which is a cylindrical device. It is the simplest case of multidimensional rf source. The electrons are generated by a cylindrical gun and propagate in the radial direction (Fig. 2(a)). The cavities are coaxial resonators endowed by drift tubes (Fig. 2(b)). The space charge effects are reduced since the

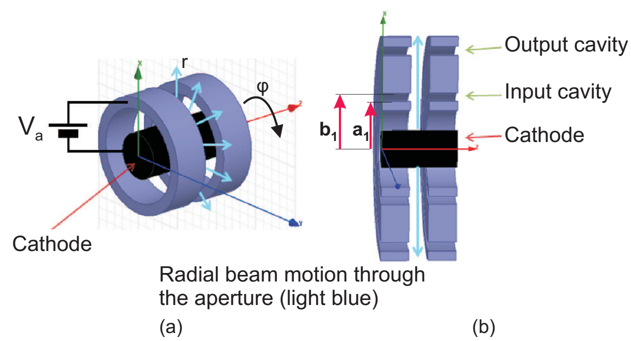

Figure 2: Cylindrical gun with expansion of electrons (a), Radial klystron with two coaxial resonators (b).

electron beam is balanced along the azimuthal direction (Indicated in Fig. 2(a)). Remnant space charge effects will decay when the beam is expanding. A lower magnetic field will be required to keep the beam focused.

This paper presents the ballistic design of a radial klystron. A coaxial mode stability test in presence of electrons have been analyzed. The electron beam interaction with the cavities has been analyzed with an in-house developed particle tracking software. The maximum efficiency of the output cavity has been evaluated with a Dirac delta beam test. Afterwards the whole klystron has been designed.

MODES STABILITY ANALYSIS

This section reports the single cavity stability results. A single cavity crossed by a DC beam can behave as an oscillator. This happens when the noise starts bunching the electron beam. The latter releases energy to the cavity, contributing to further bunching. If the feedback is positive, the released energy overcomes the losses and the cavity self-oscillates. To guarantee the stability a method has been proposed in [2, 3] to evaluate the stability function. When the cavity is stable, the stability function is negative.

A coaxial resonator has been considered. It approximates the input cavity of Fig. 2(b). The fundamental mode is the TEM_1 and its resonant frequency in vacuum is given by: $f_{TEM1} = c/(2L)$. High order resonant modes exist,

FPC AND HI-PASS FILTER HOM COUPLER DESIGN FOR THE RF DIPOLE CRAB CAVITY FOR THE LHC HILUMI UPGRADE*

Zenghai Li[1], SLAC, Menlo Park, CA 94025, USA
J. R. Delayen, S. U. De Silva, HyeKyoung Park, and R. G. Olave, ODU, Norfolk, VA 23529, USA

Abstract

A 400-MHz compact RF dipole (RFD) crab cavity design was jointly developed by Old Dominion University and SLAC under the support of US LARP program for the LHC HiLumi upgrade. The RFD cavity design is consisted of a rounded-square tank and two ridged deflecting poles, operating with a TE11-like dipole mode, which is the lowest mode of the cavity. A prototype RFD cavity is being manufactured and will be tested on the SPS beam line at CERN. The coaxial fundamental Power Coupler (FPC) of the prototype cavity was re-optimized to minimizing the power heating on the coupler internal antenna. A hi-pass filter HOM damping coupler was developed to achieve the required wakefield damping while maintaining a compact size to fit into the beam line space. In this paper, we will discuss the details of the RF optimization and tolerance analyses of the FPC and HOM couplers.

INTRODUCTION

A crabbing scheme [1] has been adopted as the baseline tool for the LHC HiLumi upgrade. The nominal scheme for the HL-LHC is the local crabbing with the 400 MHz superconducting deflecting cavities. Due to the small beam line separation close to the IP, the transverse size of the crab cavity is limited to 145-mm. To meet such a space constraint, an RF dipole (RFD) cavity [2-6] is being developed by a SLAC and ODU joint effort. The RFD design in concern is shown in Fig. 1. It consists of a rounded-square tank and two ridged deflecting poles. The operating mode is a TE11-like dipole mode, which is the fundamental mode. The frequency of the TE11-like mode is in principle not constrained by the cavity dimension in the deflecting plane, so the cavity dimension can be very compact. The rounded-square shape chosen for the present design is to accommodate for both the horizontal and vertical crabbing schemes. The present design also incorporates a curved pole profile as shown in Fig. 1 to improve the field uniformity within the beam aperture. Table 1 lists the major dimensions and RF parameters of the cavity. The lowest HOM frequency is more than 230 MHz above the operating mode. This large mode separation provides flexibilities of implementing different damping schemes for the HOMs using either waveguide [5] or high-pass filter HOM couplers. In this paper, we present a newly developed high-pass filter HOM coupler and the optimized FPC coupler design for the RFD cavity. This cavity design is being manufactured and will be tested on the SPS at CERN [7,8].

HOM COUPLERS

The HOM mode spectrum calculated using Omega3P [9,10] up to 2 GHz is shown in Fig. 2. The first HOM is a horizontal dipole mode at 634 MHz. The first important accelerating mode is at 761 MHz and the first vertical dipole mode is at 783 MHz.

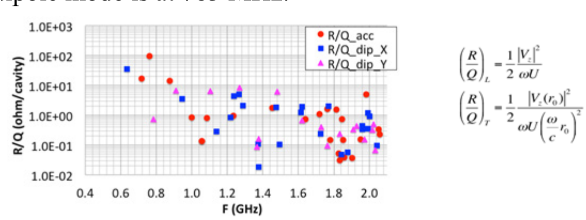

Figure 2: HOM mode spectrum.

The HOM and FPC coupler design were to meet the following design requirements: 1) be clear of the second beam line which is 194 mm away; 2) all coupler ports are oriented in the up-vertical direction to simplify the cryostat design; 3) the HOM couplers need be able to handle high HOM power that could potentially be generated by the beam. For example, the maximum beam (σ_z=76 mm) induced power by the first major accelerating mode at 761 MHz (R/Q~200) is $48I_b^2Q_{ext}$. A half-ampere beam would produce a power of 3.6 kW for a Q_{ext} of 300

NOVEL APPROACH TO VARIABLE VOLTAGE SUBSTATION PROTECTION

C. Jach, M. Mehtabuddin, S. Olek, SLAC, Menlo Park, CA 94025, USA

Abstract

Conventional electrical system protection of variable voltage substations (medium voltage rated) of using fuses and phase overcurrent and/or phase time overcurrent protection is not adequate. This was evident from the recent variable voltage substation (VVS) electrical fire at SLAC. Using information obtained from the fire investigation, ETAP simulations, and event reports of the faults which led to the fire, SLAC put into action a fast, feasible, and economical relay protection plan into adequately protecting VVS until long term plan of replacements is implemented. The plan utilizes the existing microprocessor protection relays on the upstream breakers and included the following adjustments: Adjusting the long-time overcurrent according to the de-rated cable ampacities, dual-fed arc flash fault protection, adding negative sequence settings and relay control logic to allow for two sets of settings for inrush mode and normal mode.

INTRODUCTION

The challenges we met were repetitive low fault currents in short durations not being protected by the fuses. At the same time, according to the protection coordination study results, the transformers' damage curves are positioned very close to the transformers' full load amps (FLA). It would not be possible to find a fuse fitting such configuration without creation of a significant risk of unintended tripping, as the transformers operated very close to the FLA. The ideal solution would be replacement of fuses by breakers controlled by protection relays equipped with differential protection elements and temperature monitoring. Use of the protection relays would also give us an opportunity to fine-tune the overcurrent time-current curve to fit it precisely between the full load amps point and the damage curve. This however would not be feasible in the short term due to restriction to capital resources and schedule impact to sciences.

An alternative solution presented in this document has been worked out and implemented instead. Thanks to the implemented protection system modification the transformers' protection at the low fault current range has been significantly improved in a very short period of time and at very low cost.

THE VARIABLE VOLTAGE SUBSTATIONS (VVS)

There are a total of 16 VVS in the SLAC linear accelerator. They are powered from breakers at the Master Substation with 3-500 MCM EPR insulated copper feeder cables. Each of the individual feeders can supply up to several (from 1 to 4) VVS substations, thus several 12.47/0.6 kV transformers may be powered by a single 12.47 kV breaker. The load break disconnect switches are deemed not operable due to their age and condition. The energizing of VVS is instead done at upstream breakers at Master Substation through the use of SEL 751A relays.

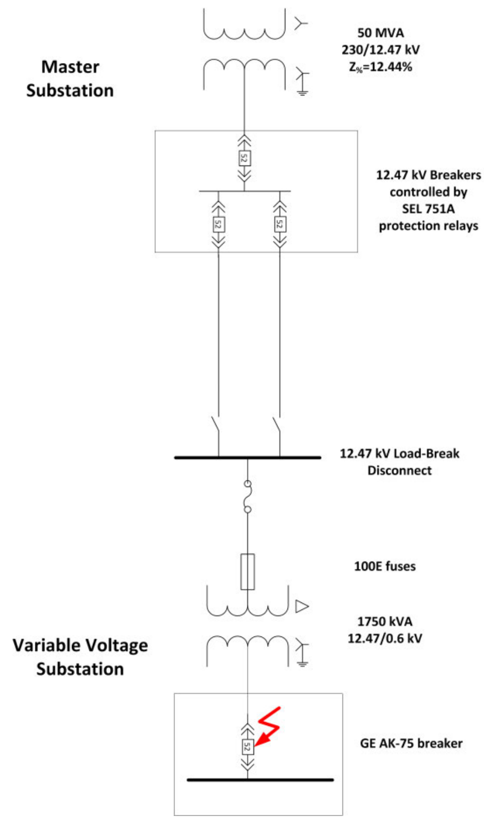

Figure 1: Simplified single line diagram of the VVS substation powering system.

VVS SUBSTATIONS PROTECTION SYSTEM AT THE TIME OF THE FIRE

The VVS substation protection system coordination plot is presented at Fig. 2. The 12.47/0.6 kV transformer damage curve has been shifted to reflect the overcurrent protection ability to see the fault current on the primary side of the transformer for secondary side faults. The plot shows that VVS 12.47 kV fuses do not ensure proper protection of the VVS 12.47/0.6 kV transformer for the range of currents below 220 A, which corresponds to time over 50 seconds on the 100E fuse time-current curve. The SEL 751A protection relay overcurrent settings were following.

- Function 50: I = 4.8 kA, time delay: 0.02 s.
- Function 51: extremely inverse U4 time-current curve, I = 451 A, time dial: 5.3 s

DITHER COILS FOR THE SUPERKEKB FAST COLLISION FEEDBACK SYSTEM*

U. Wienands†, S.D. Anderson, S. Gierman, M. Kosovsky, C.M. Spencer, M.K. Sullivan, SLAC, Menlo Park, CA 94025, USA
Y. Funakoshi, M. Masuzawa, T. Oki, KEK, Ibaraki, JP

Abstract

The collision feedback system for the SuperKEKB electron-positron collider at KEK will employ a dither feedback with a roughly 100 Hz excitation frequency to generate a signal proportional to the offset of the two beams. The excitation will be provided by a local bump across the interaction point (IP) that is generated by a set of eight air-core solid-wire magnet coil assemblies, each of which provides a horizontal and/or vertical deflection of the beam, to be installed around the vacuum system of the SuperKEKB Low Energy Ring. The design of the coils was challenging as large antechambers had to be accommodated and a 0.1% relative field uniformity across a good-field region of Âś1 cm was aimed for, while keeping reasonable dimensions of the coils. This led to non-symmetric, non-flat designs of the coils. The paper describes the magnetic design and the method used to calculate the magnetic field of the coils, the mechanical design and the field measurement results. Tracking in the lattice model has indicated acceptable performance.

INTRODUCTION

The SuperKEKB asymmetric e^+e^- collider [1] will employ a fast dither feedback scheme similar to the one developed for PEP-II [2, 3] to maintain collision between the two beams. [4] "Dither coils" are air-core magnet coils used to wiggle one of the two beams across the collision point by a small distance at a frequency near 100 Hz. Any offset between the two beams reveals itself in a modulation of the luminosity signal with the dither frequency. The coils are mounted around the vacuum chamber near the interaction point. Each coil assembly is to provide both horizontal and vertical deflection. In SuperKEKB, there are 8 coil assemblies to be able to independently vary the beam coordinates at the interaction point (IP) independently in position and angle in both directions while keeping the orbit change localized and correct for any coupling. The parameters of the coils are given in Table 1.

The coils will be mounted onto the vacuum chamber. The vertically deflecting coils have to go around the antechamber of the vacuum system. If flat rectangular coils were to be used, this would lead to very large coils with a large gap in between; inefficient magnetically and requiring a large support structure, and causing significant stray field. In order to keep the coils compact, a wrap-around design was adopted that brings the conductor relatively close to the vacuum chamber. Figure 1 shows the two different chamber cross sections that were accommodated and the schematic shape of the coils. Three different coil shapes had to be wound: a common shape for the horizontal deflectors and a narrow and a wide shape for the vertical deflectors depending on the chamber they are to be placed around.

Table 1: Design Parameters of the Coils

Parameter	Unit	Value
Overall Length	cm	25
Aperture radius	cm	5.24
Wire diameter	mm	1.291 (#16 AWG)
# of turns per coil		39
Coil cross section (h×v)	mm^2	19×3.8

Good-field region	cm	1
Field uniformity (rel.)	1	$\pm 1 \times 10^{-3}$

*: Measured parameter

COIL MODELLING AND DESIGN

The magnetic design of the coils was done in *Maple*®. [5] We use equations (4), (5) and (6) given by Misakian [6] for the field of a flat, rectangular coil with vanishing wire size. The complex shape of each coil is modeled as a sum of flat rectangular subcoils in the proper orientation with respect to each other. This required us to be able, programmatically, to rotate and translate the subcoils in space thus building a whole coil assembly from the individual pieces. Maple's "Record" data structure allows one to do this by defining a general prototype (which knows about its orientation in space) and creating and translating/rotating/reflecting each instance until the assembly model is complete. Each horizontal-field coil is modeled as three subcoils; the field at each point in space is then the sum of the contributions from each individual subcoil per coil and the two coils making

TTF3 POWER COUPLER THERMAL ANALYSIS FOR LCLS-II CW OPERATION*

L. Xiao, C. Adolphsen, Z. Li, C. Nantista and T. Raubenheimer, SLAC, Menlo Park, CA, USA,
N. Solyak and I. Gonin, FNAL, Batavia, IL, USA

Abstract

The TESLA 9-cell SRF cavity design has been adopted for use in the LCLS-II SRF Linac. Its TTF3 coaxial fundamental power coupler (FPC), optimized for pulsed operation in European XFEL and ILC, requires modest changes to make it suitable for LCLS-II continuous-wave (CW) operation. For LCLS-II it must handle up to 7 kW of power, fully reflected, with the maximum temperature around 450 K, the coupler bake temperature. In order to improve TTF3 FPC cooling, an increased copper plating thickness will be used on the inner conductor of the 'warm' section of the coupler. Also the antenna will be shortened to achieve higher cavity Qext values. Fully 3D FPC thermal analysis has been performed using the SLAC-developed parallel finite element code suite ACE3P, which includes electromagnetic codes and an integrated electromagnetic, thermal and mechanical multi-physics code. In this paper, we present TTF3 FPC thermal analysis simulation results obtained using ACE3P as well as a comparison with measurement results.

INTRODUCTION

The TTF3 FPC, depicted in Fig. 1, brings 1.3 GHz RF power from an external waveguide feed to an SRF cavity inside a cryomodule via a coaxial structure incorporating two cylindrical vacuum windows and bellows for Qext tuning. The design was developed for pulsed operation, as in XFEL and ILC.

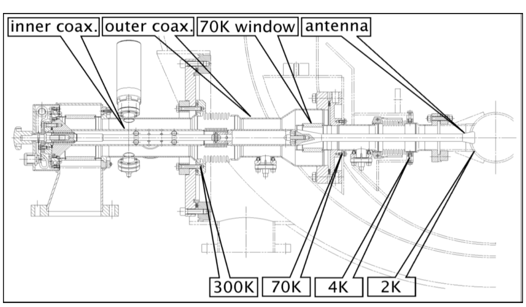

Figure 1: TTF3 FPC design. The FPC is made of copper plated stainless steel except for the cold-part center conductor antenna, which is made of solid copper (courtesy of DESY).

Past studies suggest its suitability up to at most 5 kW in standing-wave CW operation [1], less than the 7 kW required (worst case) for LCLS-II. The plating on the stainless steel inner conductor of the warm section will be increased from 30 μm to 150 μm to significantly lower its peak temperature to a level comparable to that during its bake-out (450 K). In addition, the antenna tip will be trimmed by 8.5 mm to increase the mid-range Qext value. For the low-current LCLS-II beams, Qext will be set to 4×10^7, about 10 times higher than for ILC.

Fully 3D LCLS-II FPC thermal analysis was performed using the SLAC developed ACE3P, a comprehensive set of conformal, higher-order, parallel finite-element electromagnetic codes with multi-physics capabilities in integrated electromagnetic, thermal and mechanical simulation [2]. TEM3P is ACE3P's multi-physics module. Its thermal capabilities include non-linear thermal conductivity in near superconducting condition, non-linear heat flux and convective boundary conditions for fluid-solid interface, shell elements for surface coating and volume RF heating for ceramic window loss.

2D SIMULATION BENCHMARKING

TTF3 FPC thermal simulations have been carried out using commercial software, such as ANSYS and COMSOL [3][4]. Because of single processor memory limitation, the FPC thermal simulations have been limited to its 2D model. In order to benchmark with COMSOL, a one-sixteenth slice of the FPC 2D structure, as shown in Fig. 2, was simulated using TEM3P. The second order tetrahedral meshes having 100k and 660k mesh elements for RF and thermal modelling, respectively are shown in Fig. 3.

NITROGEN DOPING STUDY IN INGOT NIOBIUM CAVITIES*

Pashupati Dhakal#, Gianluigi Ciovati, Peter Kneisel, and Ganapati Rao Myneni
Jefferson Lab, Newport News, VA 23606, USA
Junki Makita, Old Dominion University, Norfolk, VA 23529, USA

Abstract

Thermal diffusion of nitrogen in niobium superconducting radio frequency cavities at temperature ~800 °C has resulted in the increase in quality factor with a low-field Q-rise extending to B_p > 90 mT. However, the maximum accelerating gradient of these doped cavities often deteriorates below the values achieved by standard treatments prior to doping. Here, we present the results of the measurements on ingot niobium cavities doped with nitrogen at 800 °C. The rf measurements were carried out after the successive electropolishing to remove small amount of material from the inner surface layer. The result showed higher breakdown field with lower quality factor as material removal increases.

INTRODUCTION

In the past few years much progress has been made in the development of the high quality factor superconducting radio frequency (SRF) cavities via the material diffusion in the thin layer of inner surface of the cavities. The motivation behind this process development is to reduce the cryogenic operating cost of current and future accelerators with reliable operation. The possibilities of higher quality factor in SRF cavities were first realized by the titanium doping [1, 2, 3] during annealing (~1400 °C) without any post-annealing chemistry and later by nitrogen doping at 800 °C [4], followed by electropolishing (EP). The diffusion process not only showed the increase in quality factor at low field levels, but also an increase in quality factor with increasing accelerating gradient, contrary to the previously observed Q-slope; except some anodized cavities showed the extended Q-rise in the past [5,6]. Possible explanation for the high quality factors are trapping of hydrogen due to the diffused materials [7,8] at interstitial sites, prohibiting the formation of lossy hydrides; the Q-rise phenomenon is a result of the broadening of the peaks at the gap edges in the electronic density of states by the rf current within the rf penetration depth [9,10].

A project-driven collaboration between Jefferson Lab, Fermi Lab and Cornell University began to investigate the robustness of the nitrogen doping process to meet the specifications for cavities for the LCLS-II, requiring a Q_0 value of at least 2.7×10^{10} at 2.0 K and a gradient of E_{acc}=16.0 MV/m in 9-cell, 1.3 GHz cavities [11]. The work of this collaboration was focused on developing the process on fine-grain (ASTM > 5), high purity (RRR>300) Nb cavities. In this contribution, we present the results of the rf measurements on high-purity single cell ingot niobium SRF cavities doped with nitrogen at 800 °C followed by the successive EP steps in small increments to understand the effects of nitrogen diffusion on ingot niobium and its correlation to the cavity performances.

CAVITY PREPERATION AND TEST RESULTS

Ingot Nb is an alternative material for the fabrication of SRF cavities having grain size of few cm^2. Cavities made from ingot have potential for material cost reduction and tend to have higher quality factor [12] even after the standard treatments [13]. Two single-cell 1.3 GHz cavities (labeled TD #3 and #4) with B_p/E_{acc} = 4.12 mT/(MV/m) made from ingot niobium with RRR~300 supplied by Tokyo-Denkai are used in this present study. The cavities have been processed thru several steps of typical cavity processing technique including the high temperature heat treatment (800-1250 °C) and buffer chemical processing. The baseline rf measurements were done after ~40 μm surface removal by buffer chemical polishing (BCP). The breakdown field at 2.0K was measured >150 mT during the baseline rf measurements. After the baseline rf measurements, cavities were heat treated at 800 °C for 3 hours followed by 20 minutes of exposure to nitrogen at pressure of ~25 mTorr at this temperature. The nitrogen is then evacuated and the cavities were further annealed at 800 °C for 30 min. The duration of the nitrogen exposure and subsequent annealing time were explored on several single and multi-cell fine grain cavities [14]. The cavities' inner surface was electropolished to remove the inner surface layer, followed by high pressure rinse with ultra-pure water. The rf test consisted of the measurements of $Q_0(T)$ at different constant B_p from 4.3−1.6 K and $Q_0(B_p)$ at different temperature between 2.1−1.6K. In some measurements the temperature maps of the outer cavity surface were also taken during the rf tests [15].

Cavity TD#3 was measured after the successive (10, 20, 30 and 35 μm) EP of the inner surface. In all cases the temperature dependence of surface resistance is measured at B_p~10 mT of peak rf field and material parameters such as the energy gap, electronic mean free path and residual resistance were extracted using the measured surface resistance to the calculation of surface resistance using the BCS theory [16] as shown in Table 1. No significant change in material parameters are observed regardless of

RESULTS FROM THE FIRST SINGLE-CELL Nb_3Sn CAVITY COATINGS AT JLAB*

G. Eremeev†
Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, U.S.A.

Abstract

Nb_3Sn is a promising superconducting material for SRF applications and has the potential to exceed the limitations of niobium. We have used the recently commissioned Nb_3Sn coating system to investigate Nb_3Sn coatings on several single-cell cavities. We attempted to use the same coating procedure on several different single-cells with different 'genetics' and pre-coating surface preparation. We report on our findings with four 1.5 GHz CEBAF-shape single cell and one 1.3 GHz ILC single cavities that were coated, inspected, and tested.

CAVITY MATERIAL AND COATING PROCEDURE

Five cavities were used in these experiments. The cavity details are summarized in Table 1. Each cavity was measured at 2.0 K after the latest chemical treatment and the standard RF test preparation. After baseline tests, cavities were disassembled and prepared for Nb_3Sn coating. Following our experience with the first coated cavity C3C4, we adopted the following procedure:

- High pressure water rinsing, the cavity is left drying over the weekend
- Cleanroom assembly for Nb_3Sn coating
- Loading into the insert of Nb_3Sn coating system
- Nb_3Sn coating: 6 °C/min, 500 °C x 1 hr soak, 12 °C/min, 1200 °C x 3 hr soak. 3 gr of Sn and 3 gr of $SnCl_2$ used for each coating
- Visual inspection and KEK camera inspection
- Lapping of cavity flanges
- Low pressure water rinse
- Ultrasonic cleaning with 2% Liquinox detergent
- Assembly of the pick-up flange
- High pressure water rinsing
- Final assembly
- Slow pump down
- Leak check to $2{\cdot}10^{-10}$ ATM-CC/sec or better
- Cooldown to 4.3 K. ΔT across the cavity is maintained at less than 0.1K from 17.0 to 18.3 K.
- RF test at 4.3 K
- Warm up to above 18.3 K and cooldown to 2.0 K. ΔT across the cavity is maintained less than 0.1K from 17.0 to 18.3 K.
- RF test at 2.0 K

Because of the roughing pump failure, the coating of C1C2 had to be stopped, when the chamber was at about 1000 °C. The cavity then sat in the insert, until the heating profile was re-run a few days later.

OPTICAL INSPECTION

After the coating each cavity was moved to the optical inspection bench for optical inspection with KEK-style optical inspection bench [1, 2]. The focus of the inspection was largely the equatorial region, but pictures of beam tubes were also collected in several cases. The optical inspections of C3C4 and C1C2 revealed uniform complete coverage of the surface. In one place at the equator area of C3C4 we found several $\approx 100\ \mu$m-size features, Fig. 1. We did not find any outstanding features during the inspection of C1C2.

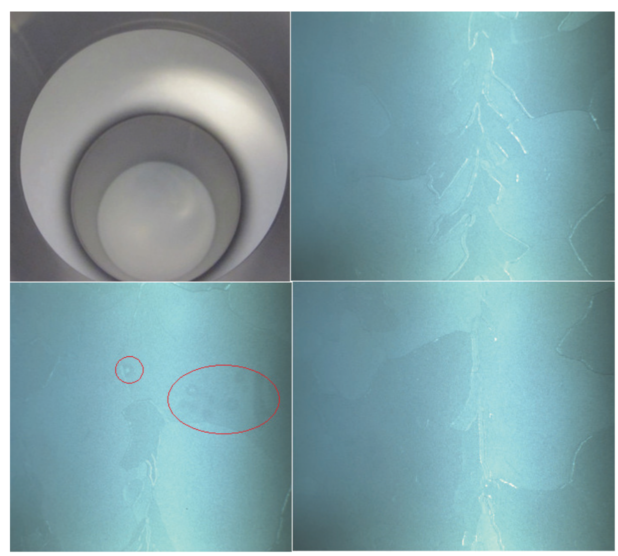

Figure 1: Optical inspection pictures of C3C4. Top left picture shows the coated surface of the cavity looking from one of the beam tubes. Top right and bottom right pictures show characteristic equatorial weld regions of the coated cavity. Bottom left picture shows the equatorial region with several observed features (marked with red circles).

COMMISSIONING OF Nb_3Sn CAVITY VAPOR DIFFUSION DEPOSITION SYSTEM AT JLAB*

G. Eremeev†, W. Clemens, K. Macha, H. Park, R. Williams
Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, U.S.A.

Abstract

Nb_3Sn as a BCS superconductor with a superconducting critical temperature higher than that of niobium offers potential benefit for SRF cavities via a lower-than-niobium surface resistance at the same temperature and frequency. A Nb_3Sn vapor diffusion deposition system designed for coating of 1.5 and 1.3 GHz single-cell cavities was built and commissioned at JLab. As the part of the commissioning, RF performance at 2.0 K of a single-cell 1.5 GHz CEBAF-shaped cavity was measured before and after coating in the system. Before Nb_3Sn coating the cavity had a Q_0 of about 10^{10} and was limited by the high field Q-slope at $E_{acc} \cong 27$ MV/m. Coated cavity exhibited the superconducting transition at about 17.9 K. The low-field quality factor was about $5{\cdot}10^9$ at 4.3 K and $7{\cdot}10^9$ at 2.0 K decreasing with field to about $1{\cdot}10^9$ at $E_{acc} \cong 8$ MV/m at both temperatures. The highest field was limited by the available RF power.

INTRODUCTION

Niobium is the the material of choice for the present SRF accelerators. Advances in the material fabrication and treatment has brought SRF niobium technology close to the superconducting limit of niobium material. Recent advances with mean free path variation has improved surface resistance by a factor 2-3[1, 2]. However, the present state-of-the-art for niobium is believed to be close to the fundamental limit of the material. Among other materials that have been considered for SRF applications, the most promising results in SRF cavities have been shown with Nb_3Sn[3, 4]. The Nb_3Sn transition temperature of about 18 K offers the opportunity of RF dissipation lower than that of niobium at the same temperature, while its superheating field expected at about 400 mT promises a higher breakdown field. In pursuit of Nb_3Sn coating on Nb cavities, we have built and commissioned a coating system that features a coating chamber of about 11" in diameter and 22" long.

CAVITY DEPOSITION SYSTEM

The deposition chamber comprises two main parts: the furnace that provides a clean heating environment to the coating chamber and the coating chamber that hosts the process vapors. The furnace was procured from T-M Vacuum Products Inc. The furnace was requested to be able to reach 1250 °C with the vacuum in 10^{-7} Torr range empty and the vacuum must be established by dry pumps. The furnace must be able to fit a 33" long by 11.5" diameter coating chamber with 24" long uniform (±5 °C) hot zone. A 14" mating conflat on the top must be provided for mating the insert to the furnace.

The coating chamber was built at JLab. The coating chamber was built as a cylinder 32" long x 11.5" diameter out of niobium, Fig. 1. Initially, the chamber was built to be inserted into JLab existing horizontal furnace 'Big Blue'. A

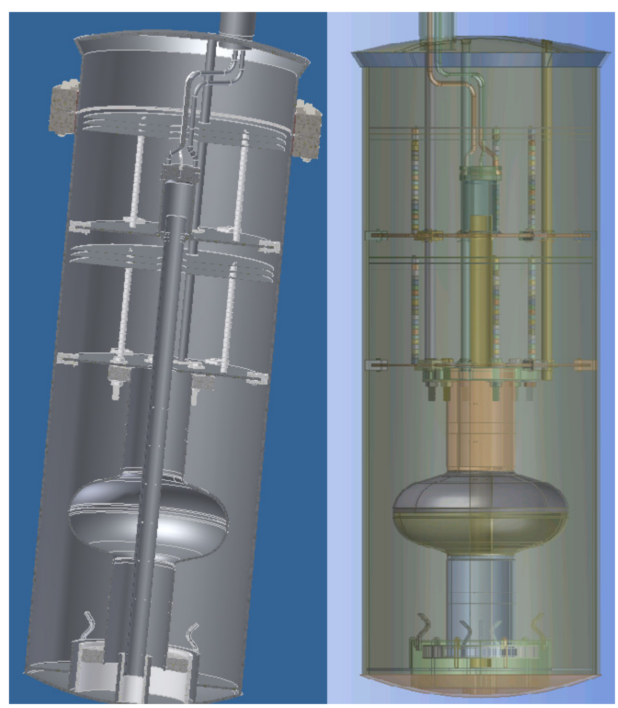

Figure 1: The Nb_3Sn insert drawing with a 1.3 GHz single cell cavity after(to the left) and before(to the right) conversion to vertical position. Note that Nb cylinder was split at the top with wire EDM to allow for 14" conflat stainless steel flange.

3" viewing port opening on the furnace door was adopted to allow niobium tube to extend from furnace space to the

FIRST ATTEMPT OF AT-CAVITY CRYOGENIC X-RAY DETECTION IN A CEBAF CRYOMODULE FOR FIELD EMISSION MONITORING*

R.L. Geng#, E. Daly, M. Drury, A. Palczewski, JLAB, Newport News, VA 23606, USA

Abstract

We report on the first result of at-cavity X-ray detection in a CEBAF cryomodule for field emission monitoring. In the 8-cavity cryomodule F100, two silicon diodes were installed near the end flange of each cavity. Each cavity was individually tested during the cryomodule test in JLab's cryomodule test facility. The behaviors of these at-cavity cryogenic X-ray detectors were compared with those of the standard "in air" Geiger-Muller (G-M) tubes. Our initial experiments establish correlation between X-ray response of near diodes and the field emission source cavity in the 8-cavity string. For two out of these eight cavities, we also carried out at-cavity X-ray detection experiments during their vertical testing. The aim is to track field emission behavior uniquely from vertical cavity testing to horizontal cavity testing in the cryomodule. These preliminary results confirmed our expectation and warrant further effort toward the establishment of permanent at-cavity cryogenic X-ray detection for SRF development and operation.

INTRODUCTION

Field emission is a known mechanism in loading a superconducting radio frequency (SRF) cavity [1-3]. The consequence of field emission can vary, depending on the nature and location of field emitters. In the least harmful scenario, field emitted electrons form a small current and gain little energy from the stored energy in the cavity, therefore there is hardly detectable impact to the quality factor of the cavity, although there might be clearly detectable X-rays by high-sensitivity radiation detectors placed in the vicinity of the cavity. Most of the time however, field emitted electrons form a large enough current and/or gain a high enough energy, resulting in significant impact to the quality factor. Due to the exponential field dependence of the current density, raising the gradient further in this scenario becomes quickly prohibitive as the RF power dissipation is dominated by the process of "accelerating" the unwanted stray electrons. Energetic electrons striking the cavity wall also raise the local cavity wall temperature and eventually may trigger the cavity to quench, setting a hard limit to the attainable gradient. SRF cavities are oftentimes assembled into a long "string" which is in turn embedded in a cryomodule for installation in accelerators. In case of such a long string, electrons field emitted from one cavity can traverse the full length of the cavity and continue to travel into the next cavity, resulting in high energy stray electrons. When these electrons ultimately get lost from striking cavity walls or beam line components, energetic gamma rays are resulted, which in turn generate neutrons via photo-nuclear reactions [4].

While the body of knowledge about the field emitters inside SRF cavities is well established and avoidance of field emission has been quite successful for individual cavity qualification by applying the state-of-the-art cavity surface processing and handling techniques, there remain some open questions regarding field emission from a successfully qualified cavity to a performing cavity in a cryomodule installed in an accelerator. Notable ones are:

- Why do some cavities degrade in performance due to field emission from single-cavity vertical qualification test to integrated cavity string horizontal test in a cryomodule? Where are the active field emitters located? What is the origin of active field emitters?
- Is it possible to gauge the severity of field emission in a "common language" that is unique to the cavity and independent of the testing facilities?
- Why do new field emitters turn on during beam operation of cavities in CEBAF [5]?

In order to address these questions, a concept of permanent at-cavity cryogenic X-ray detection (ACCXD) is introduced. Following the successful validation of X-ray detectors attached to cavities immersed in liquid helium for vertical testing at JLab's VTA facility, we carried out initial experiments of at-cavity X-ray detection during single-cavity qualification tests. We tested the concept in a 8-cavity cryomodule for CEBAF. First results of these efforts are reported in this contribution.

DETECTOR VALIDATION FROM VERTICAL CAVITY TESTING

Silicon diodes have long been used in the field for cryogenic X-ray instrumentation for field emission studies [6,7]. The Hamamatsu S12230-1 PIN diode has been chosen based on evaluation among several candidates [8]. The same diode has been recently used at JLab for field emitter localization by combining the measured X-ray distribution with the computed electron trajectories [9].

The standard X-ray monitoring for cavity field emission in JLab's VTA facility is realized by placing an ion chamber (Canberra AM-IP 100) in the air at a location outside the cavity vertical testing dewar but within the dewar radiation shield. The distance between the ion chamber and the top flange of a 9-cell ILC cavity is approximately 3 meters. We carried out vertical tests of several different cavities with simultaneous X-ray monitoring by at-cavity cryogenic diodes and in-air ion

NEW RESULTS OF DEVELOPMENT ON HIGH EFFICIENCY HIGH GRADIENT SUPERCONDUCTING RF CAVITIES*

R.L. Geng[#], JLAB, Newport News, VA 23606, U.S.A.
J.K. Hao, K.X. Liu, Peking University, Beijing 100871, China
H.Y. Zhao, OTIC, Ningxia 753000, China
C. Adolphsen, Z. Li, SLAC, Menlo Park, CA 94025, USA

Abstract

We report on the latest results of development on high efficiency high gradient superconducting radio frequency (SRF) cavities. Several 1-cell cavities made of large-grain niobium (Nb) were built, processed and tested. Two of these cavities are of the Low Surface Field (LSF) shape. Series of tests were carried out following controlled thermal cycling. Experiments toward zero-field cooling were carried out. The best experimentally achieved results are E_{acc} = 41 MV/m at $Q_0 = 6.5\times10^{10}$ at 1.4 K by a 1-cell 1.3 GHz large-grain Nb TTF shape cavity and E_{acc} = 49 MV/m at $Q_0 = 1.5\times10^{10}$ at 1.8 K by a 1-cell 1.5 GHz large-grain Nb CEBAF upgrade low-loss shape cavity.

INTRODUCTION

Following the six-year (2006-2012) high-gradient SRF cavity R&D for ILC [1] and over a year of interruption due to SRF infrastructure upgrade at Jefferson Lab, we resumed the high gradient SRF R&D with an emphasis not only on gradient but also on efficiency. Initial results reported earlier in 2013 [2] were mixed due to the presence of strong field emission, consequential of irregularities in the SRF facilities before the full recovery in February 2014. After a 2-year hiatus, the high gradient SRF R&D at JLab was finally re-started for 1-cell testing. The new results since IPAC13 will be presented in this contribution.

Five L-band single-cell cavities, including two 1.3 GHz Low-Surface-Field (LSF) shape cavities, are fabricated using large-grain Nb. The choice of large-grain Nb is encouraged by the experimental demonstration of higher Q_0 at medium- and high- gradient regimes [3-5]. This gain in large-grain Nb cavity Q_0 is due to a lower residual surface resistance (roughly by a factor of 2) as compared to its fine-grain niobium counterpart [6]. The reason behind this difference may originate from different flux trapping behaviors [7]. Prior experimental results have established an average of residual resistance of 3-4 nΩ in 1.3-1.5 GHz large-grain Nb cavities.

Various surface processing and treatment techniques are adopted for comparison. The effect of cryogenic thermal cycling on the quality factor is studied. Higher values of Q_0 are realized at high as well as medium gradients. Several cavities achieved a $Q_0 \sim 3\times10^{10}$ at 15 MV/m, 2×10^{10} at 35 MV/m at 2K. A 1.5 GHz CEBAF upgrade low-loss shape cavity achieved a best result of E_{acc} = 49 MV/m at $Q_0 = 1.5\times10^{10}$ at 1.8 K. A 1-cell 1.3 GHz large-grain Nb TTF shape cavity achieved a best result of E_{acc} = 41 MV/m at $Q_0 = 6.5\times10^{10}$ at 1.4 K

BNL 56 MHz HOM DAMPER PROTOTYPE FABRICATION AT JLAB

N. Huque, E. F. Daly, W. Clemens, JLab, Newport News, VA 23606, USA
G. McIntyre, Q. Wu, S. Seberg, S. Bellavia, BNL, Upton, NY 11973, USA

Abstract

A prototype Higher-Order Mode (HOM) Damper was fabricated at JLab for the Relativistic Heavy-Ion Collider's (RHIC) 56 MHz cavity at Brookhaven National Laboratory (BNL). Primarily constructed from high RRR Niobium and Sapphire, the coaxial damper presented significant challenges in electron-beam welding (EBW), brazing and machining via acid etching. The results of the prototype operation brought about changes in the damper design, due to overheating braze alloys and possible multi-pacting. Five production HOM dampers are currently being fabricated at JLab. This paper outlines the challenges faced in the fabrication process, and the solutions put in place.

INTRODUCTION

Work on the prototype 56 MHz HOM Damper was started at JLab in July, 2013[1]. The agreement between BNL and JLab called for the following to be completed at JLab:

- Determine an assembly and fabrication sequence and plan
- Fabricate required components
- Conduct required welding, chemistry, brazing and inspection
- Tune fabricated damper
- Perform pressure and leak checks as required

The prototype was delivered to BNL in December, 2013.

DESIGN

A cut-away view of the prototype damper is shown in Fig. 1. The two main subsections of the damper are the Main Inductor and Filter Assembly.

Main Inductor

The Main Inductor connects to the Loop at the cavity end of the damper, and supports the Filter Assembly at the other end. The Inductor acts as the primary cooling mechanism for the damper. Essentially, it is a Niobium tube, through which a copper rod runs. The rod is connected via an interference fit at the Loop (the area of highest heat generation) and is immersed in flowing liquid helium at the Cooling Turret.

Filter Assembly

The Filter Assembly is a capacitor consisting of three Niobium and three Sapphire rings. The Niobium rings are connected to the outer shell of the damper via three inductor rods, and to the N-Type connected via another inductor rod. In the prototype, the rings were joined together by means of Stycast™. The final tuning of the damper was achieved by moving the entire Filter Assembly in an axial direction along the Main Inductor. The response frequency was measured by a network analyser coupling to the Loop. Figure 2 shows the tuning response. Once in the proper position, it was fixed in place using more Stycast™.

INVESTIGATION OF DIFFERENTIAL SURFACE REMOVAL DUE TO ELECTROPOLISHING AT JLAB*

F. Marhauser[#], J. Follkie, C.E. Reece, Jefferson Laboratory, Newport News, VA, USA

Abstract

The surface removal of JLab's present electropolishing process has been analyzed utilizing experimental data of six nine-cell 1.3 GHz superconducting radio frequency cavities that have been chemically post-processed in the frame of the LCLS-II high-Q development plan.

INRODUCTION

Surface chemistry carried out for superconducting radio frequency (SRF) cavities such as buffered chemical polishing (BCP) and electropolishing (EP) aims to uniformly remove the interior surface of a cavity along the entire structure and within each cell from equator to iris. A uniform removal is not readily achievable for either BCP or EP - though conceptually different - due to the complex chemical processes and varying process parameters (e.g. fluid flow, temperatures). The process-specific differential surface removal for instance impacts the cavity cell target frequency defined at the manufacturing stage. Quantifying the non-uniform removal helps to concurrently obtain the desired frequency and field flatness of an SRF cavity with minimum tuning effort and within tight tolerances [1]. An assessment of JLab's BCP system has been done in the past. The differential surface removal as experienced in the EP system has been quantified more recently as described in the following. It is based on experimental data in conjunction with numerical simulations. This includes the impact of EP on a cavity's fundamental mode field flatness.

MEASURMENTS

Removal from Integrated Current

Six LCLS-II (TESLA-type) R&D cavities (AES031-036) have been processed in the frame of the high-Q development plan [2]. The cavities have received a main (bulk) EP in preparation of the Nitrogen-doping, which is carried out as part of the 800°C vacuum furnace bake-out. A final (light) EP is applied after the doping process. The rather slow EP generally polishes the interior with a mixture of hydrofluoric acid and concentrated sulfuric acid. The EP at JLab is carried out horizontally (see Fig. 1). To stabilize process temperatures along the cavity, the external surface is constantly water-cooled via spray nozzles from below the cavity, while the cavity rotates (1 rpm). Cavity wall temperatures can typically be controlled within 20-25°C. To estimate the removal during the EP process, the accumulated charge is determined by recording the current over time flowing from the inserted cathode to the anode (cavity) taking into account the surface area of the cavity. With five electrons per niobium atom removed from anode and cathode reactions, the bulk removal rate is 2.247e-5 cm^3 Nb/Cb. The nominal voltage between cathode and anode is 13.5 ± 0.2 V. The EP process is stopped once the prospected removal is achieved. The assessed wall removal based on this method is summarized in Table 1. The main rather slow EP was carried out in two steps for operational convenience since the duration consumes more than a normal workday. The total removal by EP was around 140 µm at this point of time and well controlled among cavities.

Figure 1: Left: LCLS-II R&D cavity prepared for EP at JLab. Right: Arrangement of water-spray nozzles for external cooling of cavity walls.

Table 1: Wall Removal Evaluated from the Integrated Current for the Main (1st And 2nd Pass) and Final EP

Cavity ID	Main EP 1st pass (µm)	Main EP 2nd pass (µm)	Final EP (µm)	Total (µm)
AES-031	106.9	21.4	16.1	144.4
AES-032	96.2	26.7	16.1	139.0
AES-033	96.2	26.7	16.0	139.0
AES-034	96.2	26.7	16.1	139.0
AES-035	90.9	32.1	16.1	139.0
AES-036	96.2	26.7	16.1	139.0

Ultra-sonic Thickness Measurements

Though the assessment based on the integrated current is sufficiently accurate to control the EP process, it does not provide information with regard to the differential removal between irises and equators. Therefore, wall thickness measurements utilizing an ultra-sonic (US) gauge have been performed before and after the main EP. The measurements include one location close to the equator and one close the stiffening ring for each half cell. Locations below stiffening rings and close to irises are not accessible. Yet, measurements have been done directly on the beam tubes adjacent to end cells. Figure 2 plots the removal averaged for four repetitive measurements per location along each cavity to consider systematic errors. A quite uniform removal among equators has been

QUENCH STUDIES OF SIX HIGH TEMPERATURE NITROGEN DOPED 9 CELL CAVITIES FOR USE IN THE LCLS-II BASELINE PROTOTYPE CRYO-MODULE AT JEFFERSON LABORATORY

A. D. Palczewski*, G. Eremeev, R.L. Geng, and C. E. Reece
Jefferson Lab (SRF R&D), Newport News, VA, USA

Abstract

Jefferson Lab (JLab) processed six nine-cell cavities as part of a small-scale production for LCLS-II cavity processing development utilizing the promising nitrogen-doping process. [1] Various nitrogen-doping recipes have been scrutinized to optimize process parameters with the aim to guarantee an unloaded quality factor (Q_0) of 2.7e10 at an accelerating field (Eacc) of 16 MV/m at 2.0 K in the cryomodule. During the R&D phase the characteristic Q0 vs. Eacc performance curve of the cavities has been measured in JLab's vertical test area at 2 K. The findings showed the characteristic rise of the Q0 with Eacc as expected from nitrogen-doping. Initially, five cavities achieved an average Q0 of 3.3e10 at the limiting Eacc averaging to 16.8 MV/m, while one cavity experienced an early quench accompanied by an unusual Q_0 vs. Eacc curve. The project accounts for a cavity performance loss from the vertical dewar test (with or without the helium vessel) to the horizontal performance in a cryomodule, such that these results leave no save margin to the cryomodule specification. Consequently, a refinement of the nitrogen-doping has been initiated to guarantee an average quench field above 20 MV/m without impeding the Q_0. This paper covers the refinement work performed for each cavity, which depends on the initial results, as well as a quench analysis carried out before and after the rework during the vertical RF tests as far as applicable.

INTRODUCTION

JLab is collaborating with FNAL and Cornell to expedite the development and exploitation of methods to produce dramatically lower-loss SRF cavities using the nitrogen-doping (N-doping) technique discovered by FNAL. [1] The LCLS-II project is eager to take advantage of these developments to minimize cryogenic capital and operating costs. JLab's contribution to this effort centered on systematic processing and tests of a set of single-cell 1.3 GHz cavities, followed by a "'production-style"' run treating six existing TESLA-style nine-cell cavities (AES031-036) to assess the performance in dependence on various nitrogen-doping recipes. Based on the single cell tests, a recipe for the nine-cell cavities has been determined which meets the desired project specifications. The initial nine-cell surface processing consisted of a UHV furnace heat treatment at 800 deg. C for 3 hours followed by controlled nitrogen injection for 20 minute at an average N2-pressure of 26 mTorr with an additional 30 minute annealing time under vacuum before letting the furnace cool down unconstrained with active pumping. After the N-doping each cavity received a 16 μm interior surface removal by Electropolishing (EP) to remove the topical highly nitrogen-enriched surface layer. [3] The nomenclature used in the following refers to the nitrogen injection time (N), annealing time (A) and EP surface removal, e.g. here **N20A30_EP16**. Three of the first nine-cell tests were published already. [4]

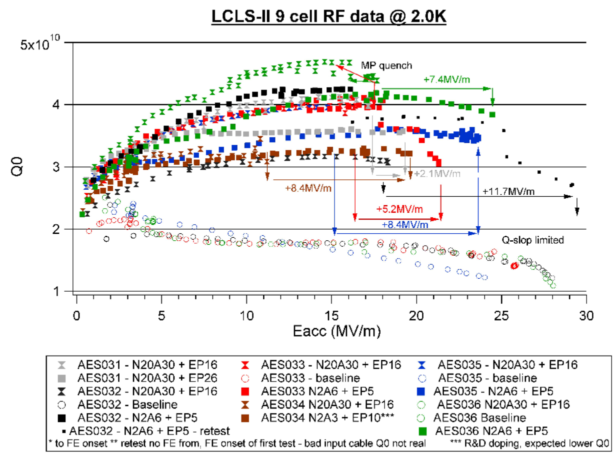

Figure 1: All RF test results for the 6 - 9 cell cavities.

At this time is became clear that although a sufficiently high Q_0 could be guaranteed at 16 MV/m, but the average quench field (Q_o >16=MV/m) was too close to the LCLS-II operating specification. In addition one has to consider that all N-doped cavities quenched at a much lower field than routinely achievable with conventional post-processing methods. [5] Consequently, an alternate recipe is scrutinized to obtain an average quench field beyond 20 MV/m without reducing the high Q0 already achieved. An N-doping refinement program resulted in a N2A6 EP5 recipe, which in fact resulted into quench fields 20 MV/m. [6] As a consequence, four of the six cavities at JLab were 'reset' by removing 50 μm from the

AN ANALYSIS OF THE TEMPERATURE AND FIELD DEPENDENCE OF THE RF SURFACE RESISTANCE OF NITROGEN-DOPED NIOBIUM SRF CAVITIES WITH RESPECT TO EXISTING THEORETICAL MODELS*

C. E. Reece#, A. D. Palczewski, JLab, Newport News, VA 23606, USA
B. P. Xiao, BNL, Upton, NY 11973, USA

Abstract

Recent progress with the reduction of rf surface resistance (R_s) of niobium SRF cavities via the use of high temperature surface doping by nitrogen has opened a new regime for energy efficient accelerator applications. For particular doping conditions one observes dramatic decreases in R_s with increasing surface magnetic fields. The observed variations as a function of temperature may be analyzed in the context of recent theoretical treatments in hopes of gaining insight into the underlying beneficial mechanism of the nitrogen treatment. Systematic data sets of Q_0 vs. E_{acc} vs. temperature acquired during the high Q_0 R&D work of the past year will be compared with theoretical model predictions.

INTRODUCTION

For many years the SRF community has informally assumed that the best performance to be obtained from SRF cavities was an rf surface with linear dissipation properties over the full dynamic range up until magnetic flux penetration phenomenon begins to create fundamental field limitations. The "best possible" performance was described by BCS losses produced by quasi-particle scattering according to the Mattis-Bardeen theory[1] for the surface resistance of a superconductor, and most conveniently calculated using the SRIMP code constructed by Halbritter[2] in the 1970's.

This changed in 2012-2014 when reports of experimental observation of unprecedentedly low $R_s(B)$ appeared with distinctly *decreasing* dependence on surface magnetic field appeared[3-5], as did first theoretical predictions of such a phenomenon[6, 7]. A fresh attempt at developing a theoretical expectation for $R_s(B,T)$ was a simplified theory that sought to extend Mattis-Bardeen theory to higher fields[6]. This analysis addressed rf current induced pair breaking, but principally noted the effects of anisotropies in the distribution function of quasiparticles due to significant current flow, in the limit of thermal equilibrium. This latter constraint implies that the quasiparticle inelastic scattering time is short compared with the rf cycle. The anisotropic Fermi surface effectively induces a broadening of the peaks in the quasiparticle density of states without significant modification of the gap. This simplified theory, while limited in scope, perhaps provides some conceptual guidance for understanding the rather surprising decrease in $R_s(B)$, which had previously been analyzed only for very thin superconducting films[8].

A more rigorous and general theoretical treatment has recently been proposed by Gurevich[9]. This treatment allows for non-equilibrium distribution functions and overheated quasiparticles.

It is interesting to examine the correspondence of these theoretical treatments with the field and temperature performance of some cavities that have received "nitrogen doping" to see if one may thereby gain insight into both mechanism and optimization strategies for best cavity performance.

DOPING NB

Evidence to date indicates that the beneficially "alloyed" N in Nb by thermal diffusion takes up residence interstitially with a concentration in the surface of ~0.1%[10, 11]. Analyses indicate that such N would first populate vacancies, then octahedral symmetry sites[12]. An expected effect of the interstitial nitrogen is lowering of the electron mean free path, l. It has been well recognized that a minimum in R_s with l ~ 35 nm is both experimentally observed and predicted by Mattis-Bardeen theory. Temperature dependent properties of the high-Q N-doped cavities have been consistent with l = 7–12 nm[13], significantly lower than would be the predicted optimum.

It has also been suggested that a beneficial role of the interstitial N is its ability to stabilize interstitial H, so that NbH nano-precipitates do not form. Previous work established that each N atom in an octahedral site will stabilized one H in a tetrahedral site[12, 14-16]. Creating conditions at elevated temperatures which give energetic preference to populating vacancies with N rather than O or multiple H, and adequate additional N distributed in octahedral sites to bind the available H during cavity cooldown (H diffusion length estimated at ~30 µm[17]) thus inhibiting the formation of Nb hydrides. Similar trapping of H by substitutional Ti diffused to fill vacancies is attributed to the comparable high-Q cavities realized by that technique[5, 18].

It is interesting to note that a very similar phenomenon was reported by Ballantini *et al.* in 1999[19], with dry oxidation of a niobium cavity after high temperature heat treatment. One may speculate that perhaps that also populated the near surface in a way which effectively inhibited the formation of particular hydride forms within the rf surface. The decrease of $R_s(B)$ to ~70 mT was

RF SYSTEM REQUIREMENTS FOR A MEDIUM-ENERGY ELECTRON-ION COLLIDER (MEIC) AT JLAB *

R. A. Rimmer#, J. Guo, J. Henry, Y. Huang, H. Wang, S. Wang, JLab, Newport News, VA 23606 USA

Abstract

JLab is studying options for a medium energy electron-ion collider that could fit on the JLab site and use CEBAF as a full-energy electron injector. A new ion source, linac and booster would be required, together with collider storage rings for the ions and electrons. In order to achieve the maximum luminosity these will be high current storage rings with many bunches. We present the high level RF system requirements for the storage rings, ion booster ring and high-energy ion beam cooling system, and describe the technology options under consideration to meet them. We also present options for staging that might reduce the initial capital cost while providing a smooth upgrade path to a higher final energy. The technologies under consideration may also be useful for other proposed storage ring colliders or ultimate light sources.

INTRODUCTION

The Medium-energy Electron Ion Collider (MEIC) proposed by JLab requires a very high luminosity to meet the physics goals [1,2]. The collider will be a "ring-ring" configuration [3,4], figure 1, with polarized electrons coming from CEBAF [5], and polarized ions from a new ion complex. The general design philosophy is closer to that used for the B-factories [6,7] than for traditional hadron colliders, namely employing a large number of bunches with short bunch length, reasonable charge per bunch, and acceptable beam-beam tune shift. Due to the large crossing angle envisaged in the detectors a crab crossing scheme is proposed. These parameter choices define the RF system requirements that, though demanding, can be fulfilled by existing state of the art systems or reasonable extrapolations thereof. Recent re-baselining of the project has resulted in the adoption of the former PEP-II high-energy ring (HER) as the basis for the MEIC electron collider storage ring. This necessitates a change in the baseline RF frequency so the other storage ring RF systems must now also be harmonics of the PEP-II frequency (476 ± 0.5 MHz). Tables 1 and 2 list the high-level parameters of the new RF systems for MEIC.

MAJOR SYSTEMS

Electron Ring

The electron ring will be based on the PEP-II HER, reusing major components such as the magnets, vacuum chambers and RF systems, and operate up to 10 GeV [8].

#rarimmer@jlab.org

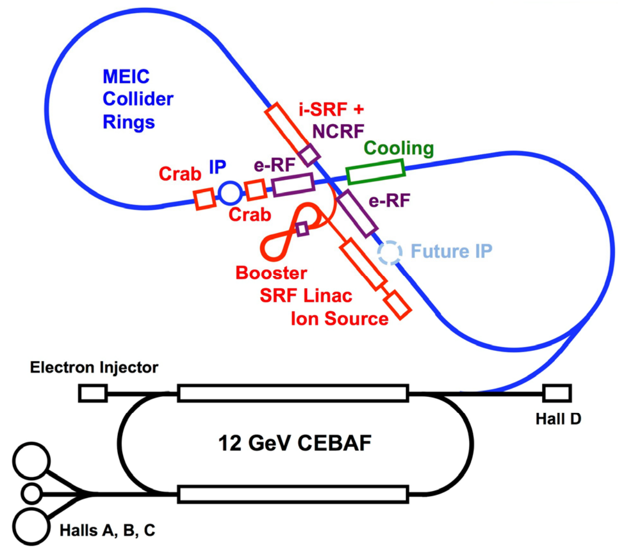

Figure 1: Schematic layout of figure-8 MEIC.

The circumference of the new baseline design figure-8 ring is similar to the PEP-II ring but since there is more total curvature the bending in each dipole is slightly higher than for PEP-II. At high energy the synchrotron radiation power density on the vacuum chamber wall in the arcs limits the current. The assumed vacuum chamber limit is 10 kW/m, and the maximum total synchrotron radiation power is chosen to not exceed 10 MW. 34 single-cell HOM-damped cavities and 13 1.2 MW klystrons are available from PEP-II, figure 2. At least 26 cavities and 10 klystrons will be needed for MEIC, though more may be installed to give operational margin.

Table 1: High Level MEIC RF Parameters

System	Frequency MHz	Total Voltage	Total Power
Booster	0.817-1.274	32 kV	98.5 kW
Ion capture	1.248-1.255	111 kV	357.4 kW
Ion-ring	952.6	18.94 MV	1.65 MW
e-ring	476.3	20.56 MV	12.8 MW
Crabbing	952.6	32.48 MV	~200 kW
Cooler ERL	952.6	56 MV	120 kW
Cooler inj.	952.6	10 MV	2.00 MW

VACUUM CHARACTERIZATION AND IMPROVEMENT FOR THE JEFFERSON LAB POLARIZED ELECTRON SOURCE*

M.L.Stutzman#, P.A.Adderley, M.Poelker, Jefferson Lab, Newport News, VA 23606, USA
Md.A.Mamun, Old Dominion University, Norfolk, VA 23529 USA

Abstract

Operating the JLab polarized electron source with high reliability and long lifetime requires vacuum near the XHV level, defined as pressure below 7.5×10^{-13} Torr. This paper describes ongoing vacuum research at Jefferson Lab including characterization of outgassing rates for surface coatings and heat treatments, ultimate pressure measurements, investigation of pumping including an XHV cryopump, and characterization of ionization gauges designed for this pressure regime.

MOTIVATION

The Jefferson Lab polarized electron source delivers an electron beam with polarization near 90% from a 130 kV DC high voltage electron gun. Lifetime is limited by the residual gasses in the system. These gasses are ionized by the electron beam and accelerated into the strained-superlattice photocathode, causing both ion implantation and affecting surface chemistry [1]. To enhance photocathode lifetime, and with the goal of developing higher current guns for future applications, a series of vacuum research measurements is underway. The pressure in a system is determined by the amount of gas entering the system and the effective removal of gas with pumps. As such, lower pressure can be obtained by reducing the gas load, which is dominated by hydrogen outgassing in UHV systems like photoguns, and/or increasing the pump speed. We describe our efforts to reduce outgassing and enhance pumping below. Furthermore, we discuss the challenges associated accurate pressure monitoring near the XHV regime.

OUTGASSING RATE STUDIES

Once a stainless steel vacuum chamber is baked to remove water vapor, the dominant gas in the chamber is hydrogen that originates from outgassing from the chamber walls. Measurements of the outgassing rate of small steel test chambers were made to determine the efficacy of reducing outgassing via medium temperature bakeouts, and by applying coatings to the chamber walls [2]. Two coatings were studied: titanium nitride (TiN) and amorphous silica (a-Si). Outgassing rates were measured for each system using a spinning rotor gauge and a gas accumulation method [3]. The lowest outgassing rates (at the room temperature of 25°C) are shown in Figure 1. Each value represents a significant outgassing rate reduction compared to the $1\text{x}10^{-12}$ $\text{TorrLs}^{-1}\text{cm}^{-2}$ outgassing rate typical of stainless steel that has undergone conventional 250°C bakeout.

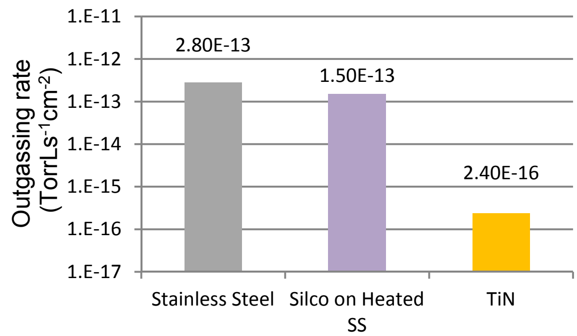

Figure 1: Best outgassing rate achieved for each chamber at room temperature of 25°C: the bare steel (304L stainless steel), the a-Si coating on 400°C heat treated steel, and the TiN coating.

BASE PRESSURE MEASUREMENTS

These outgassing rate values were inserted into the simple equation, $P = \frac{qA}{S}$, to predict the expected ultimate pressure P (Torr) that could be achieved for a given pump speed S (L/s), where q is the outgassing rate in $\text{TorrLs}^{-1}\text{cm}^{-2}$, and A is the internal area of the chamber in cm^2. Pumping for each chamber was provided by an ion pump [4] and non-evaporable getter modules [5], for a total pump speed of 1680 L/s. Following installation of pumps and bakeout, the pressure was measured using gauges with commercially rated for the XHV pressure range.

Table 1

Chamber	Expected Pressure (Torr)	Measured Pressure (Torr)
Stainless Steel	$8.6\times10^{-13} \pm 3\times10^{-13}$	$9.4\times10^{-13} \pm 4\times10^{-13}$
TiN Coating	$7.3\times10^{-16} \pm 3\times10^{-13}$	$1.0\times10^{-12} \pm 5\times10^{-13}$
a-Si coating	$4.6\times10^{-13} \pm 2\times10^{-13}$	$1.7\times10^{-12} \pm 8\times10^{-13}$

From Table 1, measured and predicted pressures are in reasonable agreement for the bare stainless steel and a-Si chambers. However, the measured pressure for the TiN system is greater than predicted pressure by three orders of magnitude. This can be understood by a careful examination of both the TiN coating chemical

SIMULATION STUDY USING AN INJECTION PHASE-LOCKED MAGNETRON AS AN ALTERNATIVE SOURCE FOR SRF ACCELERATORS

H. Wang, T. Plawski, R.A. Rimmer
Thomas Jefferson Lab, Newport News, VA 23606, USA

Abstract

As a drop-in replacement for the CEBAF CW klystron system, a 1497 MHz, CW type high efficiency magnetron using injection phase lock and amplitude variation is attractive. Amplitude control using magnetic field trimming and anode voltage modulation has been studied using analytical models and MATLAB/Simulink simulations. Since the 1497 MHz magnetron has not been built yet, previously measured characteristics of a 2.45GHz cooker magnetron are used as reference. The results of linear responses to the amplitude and phase control of a superconducting RF (SRF) cavity, and the expected overall benefit for the current CEBAF and future MEIC RF systems are presented in this paper.

MAGNETRONS VERSUS KLYSTRONS

Magnetrons used in industrial and medical accelerators normally have 85-95% electronic efficiency, much higher than typical klystrons within the same perveances [1]. As a comparison shown in Fig. 1, this advantage is independent of the wavelengths (which are given in Fig. 1 in cm marked up next to their data points). The pictures show the two types of klystrons used at CEBAF, one 2.45GHz cooker magnetron (used in our experiment in ref. [2]) and one family of L3 magnetrons (potential candidate for MEIC SRF system) for the reference data points. The fundamental difference between the two types of devices is the electron bunch formation: linear motion in the klystron; circular motion in the magnetron. Space charge effects in the motion dominate the efficiency. The spoke-on-hub bunches in a magnetron interact with the anode RF cavity in multi-gaps over multiple-passes. Space charge de-bunching effect on the spokes is reduced. The beam bunching and power extraction in a klystron is a linear interaction with cavity gaps and only one pass. Also the spent energy from decelerated electrons in a magnetron is returned to the cathode which further helps the emission. But in a klystron, it is dumped into a collector which reduces efficiency further.

The traditional klystron works as a high gain linear amplifier driven by a low level signal. Its output phase and amplitude can be controlled at both low and high levels. It can be also operated in either CW or pulsed mode with a modulator. The capital cost is in the range $5-25/output Watt depending on the power and production quantity. The magnetron is a saturated oscillator which does not need a drive for oscillation at high power output, but can be seeded by a back injection signal through its output waveguide, in which case its output phase will follow the injection phase. It can be also both operated in CW or pulsed modes as long as the pulse width is longer than the magnetron starting time. If it is designed properly, it can be operated in both high gain and high efficiency as well as low production cost, e.g. less than $1/output Watt for a typical oven magnetron.

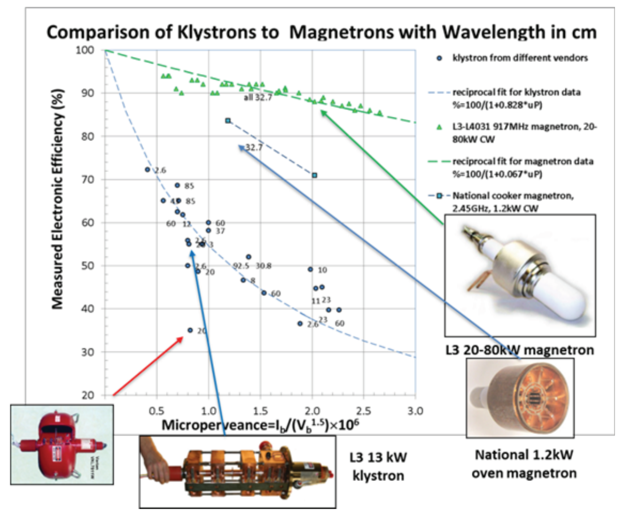

Figure 1: Comparison of electronic efficiencies between klystrons and magnetrons

BENEFITS TO CEBAF AND MEIC

The ultimate goal of using magnetrons instead of klystrons for the current CEBAF and future MEIC machines is the both capital and operation cost reduction in the electric power. Using the numbers from the RF power requirement for the current designed MEIC complex [3], a total DC power saving of 7.2-9.7MW has been estimated. This results $3.9-5.2M annual power cost saving if 41 weeks operation is assumed. Savings for CEBAF operation and other MEIC systems are shown in Table 1.

First demonstration and performance of an injection locked CW magnetron to phase control a SRF cavity was done at JLab in conjunction with Lancaster University, UK, in 2010 [1] with accuracy of 0.95° rms, -23.5dB injection input and 540W output.

However, using magnetrons to drive MEIC or other SRF accelerators like CEBAF still needs more R&D work particularly to demonstrate the amplitude control of a magnetron while preserving the high efficiency. If the magnetron can be operated as a voltage controlled oscillator while maintaining the injection phase lock, then this cost benefit will be significant to the accelerator community.

CAVITY DESIGN, FABRICATION AND TEST PERFORMANCE OF 750MHz, 4-ROD SEPARATORS FOR CEBAF 4-HALL BEAM DELIVERY SYSTEM

H. Wang, G. Cheng, L. Turlington, M. Wissmann
Thomas Jefferson Lab, Newport News, VA 23606, USA

Abstract

A short version of the original CEBAF normal conducting 4-rod separator cavity has been developed into a 750 MHz one [1] since the concept of simultaneous 4-hall operation for CEBAF is introduced [2]. This work has been advanced further based on the EM design optimization, bench measurement and by conducting RF-thermal coupled simulation using CST and ANSYS to confirm the cavity tuning and thermal performance. The cavity fabrication used matured technology like copper plating and machining. The cavity flanges, couplers, tuners and cooling channels adopted consistent /compatible hardware with the existing 500 MHz cavities. The electromagnetic and thermal design simulations have greatly reduced the prototyping and bench tuning time of the first prototype. Four production cavities have reached a typical 1.94 MV kick voltage or 3.0 kW wall loss on each cavity after a minor multipactoring or no processing, 7.5 % overhead power than the design specification.

INTRODUCTION

Delivering CEBAF electron beam simultaneously to four experimental halls A-B-C-D scheme has been proposed by Kazimi in 2013 [2]. In this scheme, all halls have to run 250MHz repetition rate and one of A-B-C halls has to share the 5^{th} beam pass with Hall D as shown in Fig. 1. To achieve this goal and not dismount existing 500MHz beam separation systems for Halls A-B-C, a 750 MHz RF separator system to kick beam bunches horizontally as the way shown in Fig. 2 is needed. Other hardware development and initial 750 MHz 4-rod type separator cavity were recognized [2].

Primary electromagnetic design optimization was done immediately after this proposal based on the existing 500 MHz, 4-rod type, normal conducting, deflecting cavities used at the CEBAF for 3-hall beam delivery system [1].

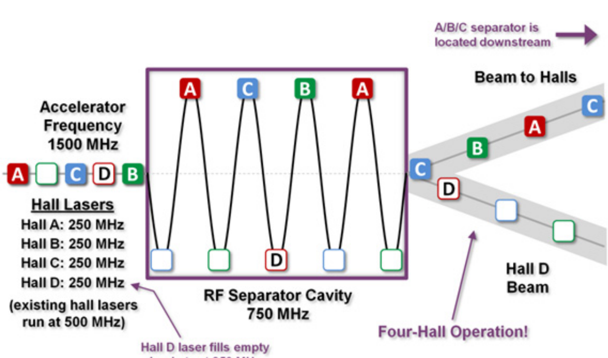

Figure 1: 4-hall beam operation with 750 MHz separator system proposed in ref. [2].

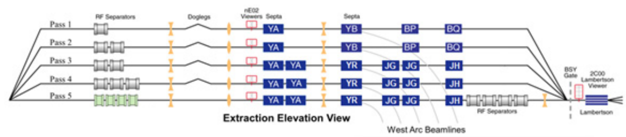

Figure 2: Four 750MHz separator cavities (in green colour) are installed on the 5^{th} pass of CEBAF beam extraction system for horizontal deflection.

CAVITY DESIGN AND SPECIFICATION

Primary design optimization shows that the TEM 4-rod type deflecting cavity has a relative high shunt impedance R_t compared to elliptical and TE type cavities as long as the beam aperture to wavelength ratio is small. So we used the same aperture diameter (15 mm) as the 500 MHz cavities for the new 750 MHz design. By varying the rod diameters from 2 cm, 2.5 cm, 3 cm to 4 cm, we found the 2 cm's design gives the highest R_t versus the thicker rod diameters. Using the same cavity structure, tuner, body, mid and end flanges hardware as the original 500 MHz's cavity, only shortening the rods and body lengths were needed for the new design. So we were able to quickly prototype and produce these new cavities.

The cavity design parameters and specification are listed in the Table 1. To get a 170μrad kick angle for the 11 GeV beam, the total peak transverse kick voltage is 1.87 MV. If 4 cavities are to be used, each cavity has to run at 2.79 kW in peak power.

Table 1: Cavity Design Parameters

Frequency (π mode, MHz)	748.5
0-mode frequency separation (MHz)	+5.944
Cell-to-cell coupling (%)	1.21
Beam aperture (mm)	15

INJECTOR CAVITIES FABRICATION, VERTICAL TEST PERFORMANCE AND PRIMARY CRYOMODULE DESIGN

H. Wang#, G. Cheng, B. Clemens, K. Davis, K. Macha, R. Overton, D. Spell
Thomas Jefferson Lab, Newport News, VA 23606, USA

Abstract

After the electromagnetic design [1] and the mechanical design [2] of a beta=0.6, 2-cell elliptical SRF cavity, the cavity has been fabricated. Then both 2-cell and 7-cell cavities have been bench tuned to the target values of frequency, coupling external Q and field flatness. After buffer chemistry polishing (BCP) and high pressure rinses (HPR), Vertical 2K cavity test results have been satisfied the specifications and ready for the string assembly. We will report the cavity performance including Lorentz Force Detuning (LFD) and Higher Order Modes (HOM) damping data. Its integration with cavity tuners to the cryomodule design will be reported.

SPECIFICATION AND STRING LAYOUT

The new SRF cryomodule construction for the CEBFA injector has been restarted and built until the string assembly. This cryomodule used to be two 5-cell cavities built within a quarter CEBAF cryomodule. Now it is going to be placed after the chopper, buncher and capture sections and before R100 (C100 prototype) cryomodule. In order to overcome the difficulties during the beam tuning up operation for the CEBAF injection particularly for the new 12 GeV machine, this new cryomodule contains a low beta cavity which can handle the low injection energy beam (~200 keV) well both in bunching and acceleration processes without blowing emittance up. After electrons reaching nearly relativistic ($\beta \approx 0.99$), acceleration can be taken by the R100, $\beta=1$ cryomodule up to 130MeV. Table 1 lists the cryomodule design specification derived from the beam dynamic analysis and beam user requirement. This derivation has been documented in a project note [3]. The minimization of transverse RF kick induced by the FPCs without a skew quadruple effect (x-y coupling) on the beam trajectory is critical for the cavity design. This achievement has been described in publication [1] and its references.

After the electromagnetic design [1] and the mechanical design [2] of the 2-cell cavity, the cavity has been fabricated in 2013. After delay holds due to funding, the project was restarted in April 2014. First step is to qualify both cavities in vertical tests. The second step is to advance the cryomodule design for primary components including cavity tuners, magnetic shields, and beam pipe components by taking the advantage of C100 type design for the 12GeV Upgrade. The third step will be hardware preparation for the clean room string assembly like the design layout in Figure 1.

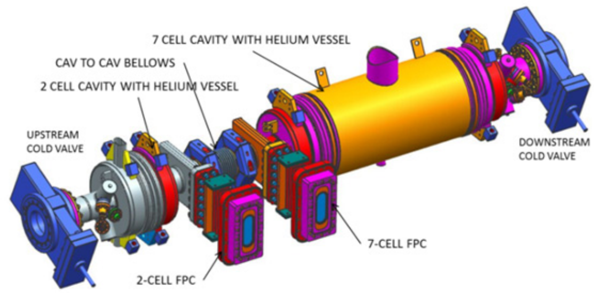

Figure 1: String assembly design of injector cryomodule electrons beam runs from 2-cell to 7cell cavity.

Table 1: Injector Cryomodule Design Specification

Cavity type	2-cell	7-cell
End beam energy (MeV)	0.533	5
Peak on axis E field (MV/m) nominal / (range)	4.6 (2-8)	13.2 (8-26)
E_{acc} including TTF (MV/m) nominal / (range)	2.6 (1.1-4.5)	7.1 (4.3-14.1)
Beam voltage V_a (MV) nominal / (range)	0.33 (0.13-0.54)	4.9 (3-10)
Beam current I (mA) nominal/max	0.38/1.0	
Geometry β_g	0.6	0.97
Q_0 at nominal gradient	>4E9	>8E9
Off-crest phase setup Φ_b (deg)	-17	-15
FPC Qext for max. beam current	6E6	9E6
FPC Qext for nominal beam current by using stub tuner	1.3E7	2.0E7
Klystron power for max E_{acc} 1mA beam current (kW)	0.547	14.6
HOMs dipole Imp.[1] $R_\perp$, Ω/m	<2.4E10	<2.4E10
FPC RF kick dP_y/P_z (mrad)	<1	<2
Tuning Sensitivity, (MHz/mm) ANSYS	2.63 cold	0.592 cold 0.431 warm m.
Helium Pressure Sensitivity (Ref. only, Hz/Torr)	382	320

CAVITIES' FABRICATION

The specification for two cavities for the vertical cold test acceptance criteria has been developed in Table 2.

MECHANICAL PROPERTIES OF NIOBIUM CAVITIES*

G. Ciovati#, P. Dhakal, J. Matalevich, G. R. Myneni, JLab, Newport News, VA 23606, USA

Abstract

The mechanical stability of bulk Nb cavity is an important aspect to be considered in relation to cavity material, geometry and treatments. Mechanical properties of Nb are typically obtained from uniaxial tensile tests of small samples. In this contribution we report the results of measurements of the resonant frequency and local strain along the contour of single-cell cavities made of ingot and fine-grain Nb of different purity subjected to increasing uniform differential pressure, up to 6 atm. Measurements have been done on cavities subjected to different heat treatments. Good agreement between finite element analysis simulations and experimental data in the elastic regime was obtained with a single set of values of Young's modulus and Poisson's ratio. The experimental results indicate that the yield strength of medium-purity ingot Nb cavities is higher than that of fine-grain, high-purity Nb.

INTRODUCTION

An important aspect of cavity design is a structural analysis under different load conditions to verify that the maximum stress is well below the yield strength of the material. Typically, the highest load applied to the cavities occurs at the beginning of a cavity cool-down from 300 K to liquid He temperature inside a cryomodule, when loading due to a mechanical tuner attached to the cavity and pressurized helium gas flowing around the cavity occurs [1]. In recent years, it was also realized that cavities can be considered part of a "pressure vessel", as they are part of the boundary of a liquid helium reservoir, and therefore the structural and material analysis should comply with "pressure vessel code" specifications, which are different in different regions of the world [2-4].

The structural analysis of cavities is typically done using commercial finite-element analysis (FEA) computer software, with user-defined stress versus strain curves for the niobium material. Such stress versus strain curves are derived from "conservative" reviews of literature data from uniaxial tensile tests of flat samples which had been subjected to different treatments. The literature data show a progressive reduction of both yield and tensile strength of fine-grain (ASTM ≥ 5) Nb after heat-treatment at increasingly higher temperature, above ~600 °C [5-7]. Large variations in the values of yield and tensile strength have been reported even for samples subjected to the same treatment, depending on batches of material and/or material supplier [8-11]. The situation is even more complicated when considering ingot Nb material, for which tensile test samples only have a very small number of grains, if any, which results in a large variability in tensile test results, depending on the crystal orientation of the samples [7, 12-14]. Furthermore, the Nb material is subjected to a plastic deformation during the deep-drawing into half-cells and, as a result of the subsequent annealing of the entire Nb cavity, the behaviour of the material under mechanical loading can, in general, be different than for the case of flat tensile test samples which have no initial plastic deformation [15].

In the following section we present some results on the measurements of the local strain and resonant frequency of single-cell elliptical Nb cavities of the same shape subjected to an increasing uniform external pressure at room temperature. The experimental data have been used to guide the FEA of the cavity.

EXPERIMENTAL RESULTS

The single-cell cavities used for this study have the same shape as that of the original cavities for the CEBAF accelerator [16]. A schematic drawing of the cavity is shown in Fig. 1 along with a schematic of the location of the strain gages. The strain gages attached near the iris are "tee rosettes", allowing to measure strain in the longitudinal (gages No. 1 and 3) and azimuthal directions (gages No. 2 and 4). The strain gages attached on the side wall (gage No. 5) and close to the equator (gage No. 6) measured strain in the longitudinal direction. Further details about the strain gages and the experimental setup can be found in Ref. [17] and in a forthcoming publication.

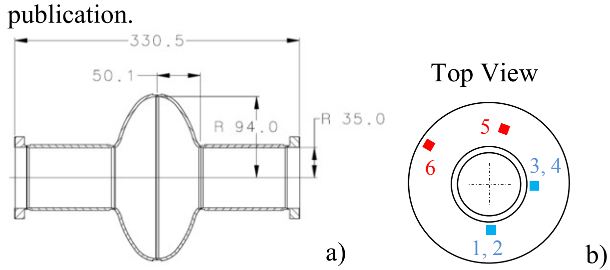

Figure 1: Schematic drawing of the single-cell cavity (a) and approximate location of the strain gages (b). Dimensions are in mm.

Cavities were placed inside a pressure tank. The inside volume of the cavity was filled with air at 1 atm. Uniform pressure is applied to the outside surface of the cavity by pumping DI water into the pressure tank. Strain, Δε, and frequency shift, Δf, as a function of applied pressure, P, were measured on four single-cell cavities made of Nb material with different properties, listed in Table 1. The fine-grain material was from ATI Wah Chang, the ingot

EFFECTS OF PLASMA PROCESSING ON SECONDARY ELECTRON YIELD OF NIOBIUM SAMPLES

M. Basovic, S. Popovic, M. Tomovic, L. Vuskovic, Center for Accelerator Science, Old Dominion University, Norfolk, VA 23529, USA
A. Samolov, F. Cuckov, Department of Engineering, University of Massachusetts, Boston, MA 02125, USA

Abstract

Impurities deposited on the surface of niobium (Nb) during both the forming and welding of accelerator cavities add to the imperfections of the sheet metal, which then affects the overall performance of the cavities. This leads to a drop in the Q factor and limits the maximum acceleration gradient achievable per unit length of the cavities. The performance can be improved either by adjusting the fabrication and preparation parameters, or by mitigating the effects of fabrication and preparation techniques used. We have developed the experimental setup to determine the Secondary Electron Yield (SEY) from the surface of Nb samples. Our aim is to show the effect of plasma processing on the SEY of Nb. The setup measures the secondary electron energy distribution at various incident angles as measured between the electron beam and the surface of the sample. The goal is to determine SEY on non-treated and plasma treated surface of electron beam welded samples. Here we describe the experimental setup, plasma treatment device, and fabrication and processing of the Nb samples.

INTRODUCTION

Apart from the accelerated beam particles, cavities under operating conditions contain a small amount of free charged particles. The number of particles inside the cavity is increased due to the Secondary Electron Emission (SEE). Free particles are accelerated by receiving energy from the electromagnetic field confined inside the cavities. Under specific conditions those particles can impact the surface of cavities and create additional free electrons. An increase in the quantity of the free electrons in a confined space of a cavity can cause a detrimental effect on the accelerated particles and thus limit the effectiveness of cavities. Multiplication of electrons is called multipacting (MP) and leads to the high power losses and heating of the cavity walls [1]. Energy consumed by the increasing number of electrons prevents the increase of the accelerating field by increasing the power input.

Substantial research effort on the topic of SEE to date has determined that SEY is highly dependent on the surface treatment. It has been shown that exposure of the material surface to increased temperatures progressively reduces the SEY [2, 3]. Various surface coatings have also shown the ability to reduce the SEY on various substrate materials [4, 5, 6, 7]. The scrubbing effect of the continuous exposure of the surface to electron beam has been noticed on the copper samples [8]. The effect of air exposed metal surfaces on SEY is shown in [9]. Exposure of the Nb to glow discharges of various gasses changed the SEY curve compared to the untreated surface [2].

SEE depends on the energy dissipated by the primary electrons near the surface. Our analysis of energy spectra of secondary electrons indicates that the fraction of the dissipated energy of primary electrons reaches the maximum at the primary energies that produce the maximum yield. It can be illustrated by a case of typical SEE energy distribution and SEY from a clean Nb coupon.

Total energy returned to the field has been carried equally by true, back-diffused, and elastically reflected secondary electrons, although their number distribution is more shifted toward low energy. Overall relative energy feedback carried by the secondary electrons is

$$\Gamma = \frac{1}{E_p}\int_0^{E_p} f_P\left(E_p, E\right) dE \cong 0.3 \quad for \quad E_p = 200\,eV. \qquad (1)$$

That is, only 30% of the primary energy has been returned to the field and 70% is dissipated in the Nb coupon. We have analyzed this energy balance for a number of metal targets, whereby we have been restricted only to experimental data on the secondary electron energy distribution. For example, the available data for copper show that maximum dissipation into the target coincides with the maximum yield (see Fig. 1).

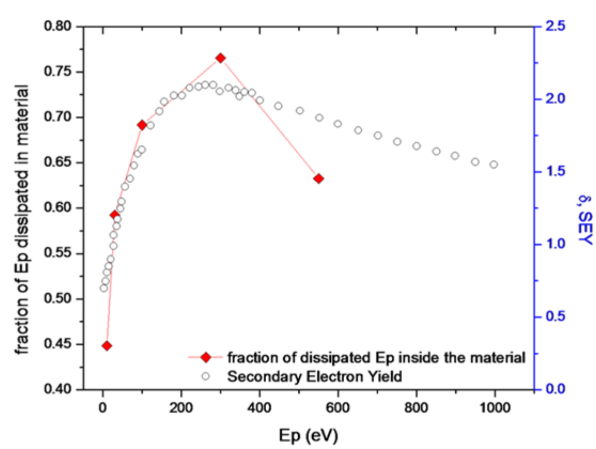

Figure 1: Energy dependence of the fraction of dissipated primary electron energy compared to the SEY curve for conditioned copper.

EFFECTS OF CRAB CAVITIES' MULTIPOLE CONTENT IN AN ELECTRON-ION COLLIDER*

Abstract

The impact on the beam dynamics of the Medium Energy Electron-Ion Colider (MEIC) due to the multipole content of the 750 MHz crab cavity was studied using thin multipole elements for 6D phase space particle tracking in ELEGANT. Target values of the sextupole component for the cavity's field expansion were used to perform preliminary studies on the proton beam stability when compared to the case of pure dipole content of the rf kicks. Finally, important effects on the beam sizes due to non-linear components of the crab cavities' fields were identified and some criteria for their future study were proposed.

INTRODUCTION

Strong interest has been generated among the nuclear physics comunity for building an Electron-Ion Collider with a broad range of center of mass energy ($\sqrt{s} = 20 - 70$ GeV) and high luminosities ($\sim 10^{34}\mathrm{cm}^{-2}\mathrm{s}^{-1}$) per interaction point (IP) [1]. In order to have a full acceptance detector, a relatively large crossing angle (50 mrad) of the colliding beams has to be introduced. Then, the only way to reach the high luminosity required is to implement crab crossing correctors. A crab cavity suitable for this application is an rf deflector that operates at the transverse voltages needed to restore this angle for both protons up to 150 GeV and electrons up to 20 GeV. The design proposed as crab cavity candidate for the MEIC at Jefferson Lab is an rf dipole geometry that operates on a fundamental TE-like mode. The exercises performed in the present paper use the former MEIC baseline frequency of 750 MHz to analyze the effect of the sextupole component of the rf kick given by such a cavity on the proton bunches at 60 GeV as a case study, even when the baseline frequency of collision may be changed, the methods developed here can easily be implemented for different beam energies and frequencies without major difficulties.

ANALYTICAL CONSIDERATIONS

If we treat the horizontal crabbing of the bunch as a chirp in x, then we can express the change in emittance due to this chirp [2] as:

$$\frac{\Delta\epsilon_x}{\epsilon_x} = \frac{\sqrt{\sigma_{x'}^2 + \sigma_{\Delta x'}^2}}{\sigma_{x'}^2} - 1. \qquad (1)$$

Using a definition of the thin-lense rf multipole transverse kick, such as:

$$\begin{aligned} \Delta x' &= \frac{\Delta p_x}{p_z} \\ &\approx \mathcal{V}_0 \left(b_1 + b_3\left(x^2 - y^2\right) + ...\right)\cos(\phi). \qquad (2) \end{aligned}$$

Where $\mathcal{V}_0 \equiv \frac{eV_x}{p_z mc^2 k}$, with V_x as the total crabbing voltage, p_z the particle momentum, $k = \frac{\omega_{rf}}{\beta c}$, b_1 and b_3 are the dipole and sextupole coefficients respectively, and $\phi = 270^o$ as the rf phase with respect to the bunch centroid.

Then we can write:

$$\sigma_{\Delta x'} \approx \frac{\mathcal{V}_0 b_3}{2}\sqrt{\sigma_{x^2}^2 + \sigma_{y^2}^2}, \qquad (3)$$

thus, using Eqns. 1 and 3 we express in this notation the change on emittance per turn as:

$$\frac{\Delta\epsilon_x}{\epsilon_x} = \frac{\sqrt{\sigma_{x'}^2 + \frac{\mathcal{V}_0^2 b_3^2}{4}\left(\sigma_{x^2}^2 + \sigma_{y^2}^2\right)}}{\sigma_{x'}} - 1. \qquad (4)$$

Which shows that the change in the emittance will depend on the transverse second momenta of the bunches and the sextupole component. This shows how geometrically the sextupole content on the crabbing kicks may have repercussions on the beam luminosity or even the beam lifetime. For this reason we will compare the cases with a pure dipole kick to some cases where there is a sextupole component to the rf kick to look for possible resonances or relative stability conditions for the crab cavities' operation.

TRACKING METHODS

In this section we will first describe the simplifications made to the lattice to focus our numerical studies on the section of the interaction region (IR), proposing a linear map for the proton storage ring that properly accounts for the transverse and longitudinal dynamics of the machine, leaving the IR description as a separate block. Secondly, we will discuss the tracking elements and basic calculations performed in different sections of the IR.

Modeling the Lattice

As mentioned above, we used linear maps for the 6D dynamics of the entire proton storage ring, excluding the interaction region as seen in the schematic on Fig. 1, while the interaction region and its transverse Twiss functions are described in Fig. 2

BEAM DYNAMICS STUDIES OF 499 MHz SUPERCONDUCTING RF-DIPOLE DEFLECTING CAVITY SYSTEM*

S. U. De Silva#, K. Deitrick, H. Park, J. R. Delayen
Old Dominion University, VA 23529, USA

Abstract

A 499 MHz deflecting cavity has been designed as a three-way beam spreader to separate an electron beam into 3 beams. The rf tests carried out on the superconducting rf-dipole cavity have demonstrated that a transverse voltage of 4.2 MV can be achieved with a single cavity. This paper discusses the beam dynamics on a deflecting structure operating in continuous-wave mode with a relativistic beam. The study includes the analysis on emittance growth, energy spread, and change in bunch size including effects due to field non-uniformities.

INTRODUCTION

A deflecting cavity system separates a single beam into multiple beams by applying a transverse momentum to the center of each bunch that displaces the bunch off axis at an angle. The Panofsky-Wenzel Theorem [1] describes the concept of producing a transverse momentum using the electromagnetic fields in an rf structure. A single beam can be separated into multiple beams depending on the rf phase at which the transverse kick is applied.

Jefferson Lab currently uses a three-way beam spreader system that separates the oncoming electron beam with a repetition rate of 1497 MHz in to 3 beams, that are delivered to the 3 experimental halls (Hall A, B and C) [2]. The rf separators system operating at 499 MHz will apply the transverse kick as shown in Fig. 1, that enables the delivery of the highest energy beam simultaneously to hall the 3 experimental halls.

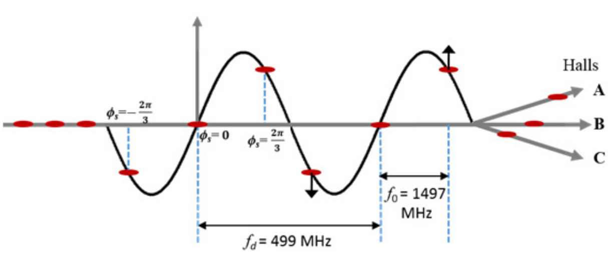

Figure 1: Bunch separation in the Jefferson Lab three-way beam spreader.

The rf separation for the 6 GeV CEBAF machined was achieved with the set of normal conducting cavities. The 4-rod cavity operating in TEM mode are also being used in the 12 GeV machine [2]. The optics in the beam switch yard region had been reworked that relaxed the transverse kick requirement for the 12 GeV upgrade [3]. The rf separators are required to deliver a transverse kick of 3.3 MV in order to deliver the required separation of 297 μrad in vertical direction. The required separation gives a ±17 mm separation at the extraction magnets [4].

RF-DIPOLE CAVITY

A superconducting rf deflecting cavity was initially proposed for the Jefferson Lab 12 GeV upgrade. The optimized 499 MHz rf-dipole cavity design shown in Fig. 2 was successfully fabricated and rf tested [5, 6, 7]. The rf properties of the cavity are listed in Table 1.

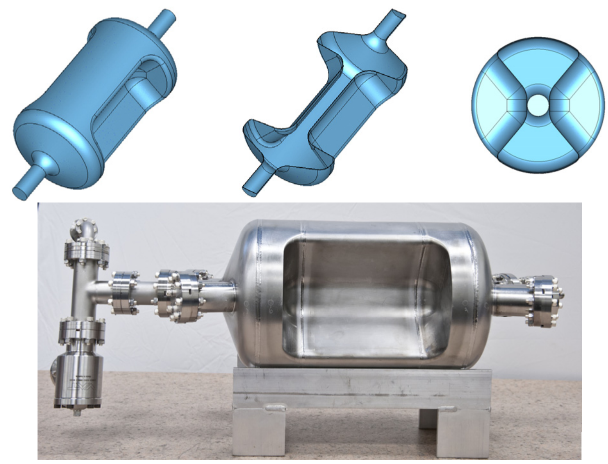

Figure 2: 499 MHz rf-dipole cavity design (top-left) with cross sections along z axis (top-center) and y axis (top-right), and the fabricated cavity (bottom).

Table 1: RF Properties of the 499 MHz rf-Dipole Cavity

Parameter	Value	Units
$\lambda/2$ of π mode	300.4	mm
Cavity length	440.0	mm
Cavity diameter	242.2	mm
Aperture diameter (d)	40.0	mm
Deflecting voltage (V_T*)	0.3	MV
Peak electric field (E_P*)	2.86	MV/m
Peak magnetic field (B_P*)	4.38	mT
B_P* / E_P*	1.53	mT/(MV/m)
Energy content (U*)	0.029	J
Geometrical factor	105.9	Ω
$[R/Q]_T$	982.5	Ω
$R_T R_S$	1.0×10^5	Ω^2
Operating Parameters		
Deflecting voltage (V_T)	3.3	MV
Peak electric field (E_P)	32	MV/m
Peak magnetic field (B_P)	49	mT
Power dissipation (P_{diss})	1.31	W

At E_T* = 1 MV/m

DESIGN AND PROTOTYPING OF A 400 MHz RF-DIPOLE CRABBING CAVITY FOR THE LHC HIGH-LUMINOSITY UPGRADE*

S. U. De Silva#, H. Park, J. R. Delayen, Old Dominion University, Norfolk, VA, USA
Z. Li, SLAC National Accelerator Laboratory, Menlo Park, CA, USA
T. H. Nicol, Fermi National Accelerator Laboratory, Batavia, IL, USA

Abstract

LHC High Luminosity Upgrade is in need of two crabbing systems that deflects the beam in both horizontal and vertical planes. The 400 MHz rf-dipole crabbing cavity system is capable of crabbing the proton beam in both planes. At present we are focusing our efforts on a complete crabbing system in the horizontal plane. Prior to LHC installation the crabbing system will be installed for beam test at SPS. The crabbing system consists of two rf-dipole cavities in the cryomodule. This paper discusses the electromagnetic design and mechanical properties of the rf-dipole crabbing system for SPS beam test.

INTRODUCTION

The LHC High Luminosity Upgrade will be using crabbing cavities to increase the luminosity for the operation with 14 TeV proton beam collision. These crabbing systems will also reduce the pile up at the interaction point. Two crabbing systems will be installed at the ATLAS and CMS experiments where the former will be crabbing in vertical plane and the latter in the horizontal plane. The two parallel beam lines set a very tight dimensional constraint in designing a crabbing cavity operating at 400 MHz [1].

A compact 400 MHz crabbing cavity has been designed jointly by ODU and SLAC to meet the system requirements for LHC. A proof-of-principle cavity has been fabricated and tested [2, 3]. Currently the cavity design is being integrated into a cryomodule design intended for SPS test.

RF-DIPOLE CRABBING CAVITY

The 400 MHz proof-of-principle (P-o-P) rf-dipole cavity shown in Fig. 1-(left) is a cylindrical shaped cavity with trapezoidal shaped loading elements that operates in a TE-11 like mode. The prototype cavity sown in Fig. 1-(right) has a fundamental operating mode identical to the cylindrical shaped cavity. The cavity is designed with a square shaped outer body to reduce the transverse cavity size and have improved rf properties shown in Table 1.

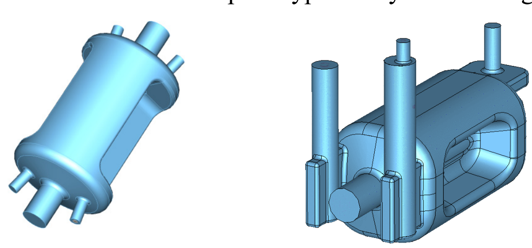

Figure 1: 400 MHz proof-of-principle (left) and prototype (right) rf-dipole cavities.

Table 1: RF Properties of Cylindrical Shaped P-o-P and Square Shaped Prototype rf-Dipole Cavities

Parameter	P-o-P Cavity	Prototype Cavity	Units
Cavity length	542	775	mm
Cavity diameter	340	281	mm
Aperture diameter	84	84	mm
Deflecting voltage (V_T*)	0.375	0.375	MV
Peak electric field (E_P*)	4.02	3.7	MV/m
Peak magnetic field (B_P*)	7.06	6.3	mT
B_P* / E_P*	1.76	1.71	mT/(MV/m)
Energy content (U*)	0.195	0.13	J
Geometrical factor	106	107	Ω
$[R/Q]_T$	287	430	Ω
$R_T R_S$	4.0×10^4	4.6×10^4	Ω^2

At E_T* = 1 MV/m

The P-o-P cavity was fabricated and rf tested at both 4.2 K and 2.0 K. The measured intrinsic quality factor (Q_0) as a function of V_T, E_T, E_P, B_P is shown in Fig. 2. The cavity achieved a V_T of 7 MV that exceeded the required V_T of 3.4 MV. The performance achieved by the P-o-P cavity shows that the rf-dipole cavity can be operated at 5.0 MV that would reduce the number of cavities required to achieve the total V_T of 13.4 MV. The Q_0 achieved during the first set of tests were low due to the surface losses at the SS blank flanges on the beam ports. The cavity was retested with Nb coated SS blank flanges and the cavity achieved a Q_0 of 1.25×10^{10} with reduced residual surface resistance (R_{res}) of 10 nΩ.

Table 2: Operating Parameters at 3.4 MV and 5.0 MV

Parameter	(A)	(B)	Units
Deflecting voltage (V_T)	3.4	5.0	MV
Peak electric field (E_P)	34	50	MV/m
Peak magnetic field (B_P)	57	84	mT
Power dissipation (P_{diss})	2.8	6.2	W

IMPERFECTION AND TOLERANCE ANALYSIS OF HOM COUPLERS FOR ODU/SLAC 400 MHz CRABBING CAVITY*

S. U. De Silva#, R. G. Olave, H. Park, J. R. Delayen, Old Dominion University, Norfolk, VA, USA
Z. Li, SLAC, Menlo Park, CA, USA

Abstract

In preparation for the LHC High Luminosity upgrade, a 400 MHz crab cavity has been developed jointly at ODU/SLAC, including two higher order mode couplers designed to damp the wakefields in order to comply with the impedance budget specified for the LHC system. During fabrication, assembly, and processing of the couplers, a number of imperfections may arise that could modify the higher order mode spectrum and the associated impedance for each mode. We present here a detailed study of the imperfections of the horizontal- and vertical- HOM couplers, and the associated allowed tolerances for manufacture, assembly and processing.

INTRODUCTION

A crabbing cavity system for the LHC High Luminosity Upgrade has been designed including the ancillary components such as the fundamental power coupler (FPC), higher order mode (HOM) couplers [1]. The corresponding high current operation demands extraction of 1 kW of HOM power and also impose a strict impedance budget. The full impedance study for the 7 TeV per beam LHC operation is ongoing.

The rf-dipole crabbing cavity is designed with a horizontal (H-HOM) and a vertical (V-HOM) HOM coupler set to meet the design specifications and dimensional requirements for LHC operation [2, 3]. The cavity design with the FPC and HOM couplers are shown in Fig. 1.

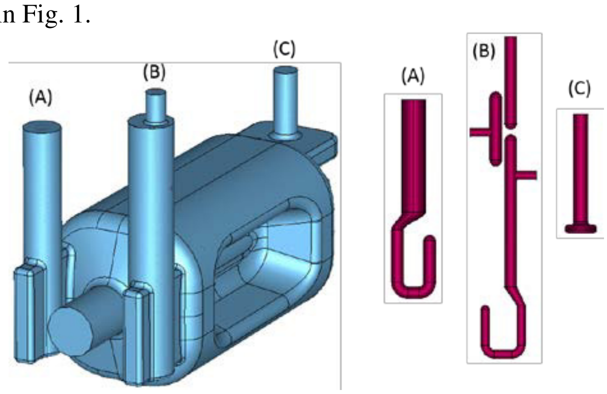

Figure 1: Complete rf-dipole cavity with (A) FPC, (B) HHOM filter, and (C) VHOM probe.

The rf-dipole geometry does not have any lower order modes or similar order modes. The H-HOM coupler is a high pass filter that cuts off the fundamental operating mode, and damps the horizontal dipole modes and accelerating modes. The high pass filter has excellent broad band transmission above 630 MHz up to 2 GHz [3]. The V-HOM coupler damps the vertical dipole modes and some of the accelerating modes. One attractive feature of the HOM couplers of the rf-dipole cavity is that all the couplers are at the end plates in the low field region. This reduces the rf heating at the HOM couplers.

HOM TOLERANCES

The fabrication procedure for the high pass filter is outlined in Ref. [4]. The H-HOM filter consists of three parts as shown in Fig. 1 with a hook, probe and T. The gap between T with the probe and hook is 2.8 mm, which needs to be controlled for precision during fabrication to minimize fundamental mode leakage through the filter.

The manufacturing, assembly, and processing may introduce deviations from the ideal filter shape. This may further have an impact to the effectiveness in HOM damping. Figure 2 shows the important tolerance parameters that have been investigated for the H-HOM high pass filter. HOM tolerances include translational in both vertical (gap probe, gap top, y tip) and transverse (gap bar P, gap bar H, gap T) directions and rotations around x and z axes.

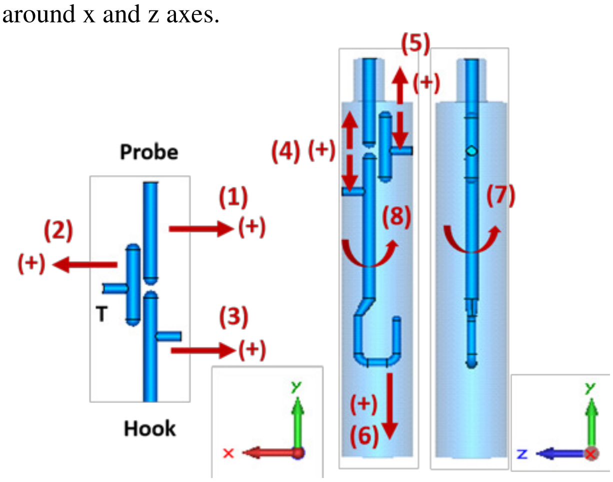

Figure 2: H-HOM tolerances: (1) gap bar P (2) gap bar T (3) gap bar H (4) gap probe (5) gap top (6) y tip (7) rotation about x axis (7) rotation about z axis.

Any variations on gap bar thickness in the T, probe and hook may be caused during fabrication of parts and chemical processing, which are the most crucial parameters for performance. The vertical and rotational deviations may be introduced during assembly of the components and electron beam welding (EBW) process. Extra measures are taken in using a collapsible fixture to hold parts during EBW. The welded parts will be measured to ensure the tolerances are met.

TEMPERATURE MAPPING OF NITROGEN-DOPED NIOBIUM SUPERCONDUCTING RADIOFREQUENCY CAVITIES*

Junki Makita†, Old Dominion University, Norfolk, VA 23529, USA
Gianluigi Ciovati, Pashupati Dhakal, Jefferson Lab, Newport News, VA 23606, USA

Abstract

It was recently shown that diffusing nitrogen on the inner surface of superconducting radiofrequency (SRF) cavities at high temperature can improve the quality factor of the niobium cavity. However, a reduction of the quench field is also typically found. To better understand the location of rf losses and quench, we used a thermometry system to map the temperature of the outer surface of ingot Nb cavities after nitrogen doping and electropolishing. Surface temperature of the cavities was recorded while increasing the rf power and also during quenching. The results of the thermal mapping showed no precursor heating on the cavities and quenching to be ignited near the equator where the surface magnetic field is maximum. Hot-spots at the equator area during multipacting were also detected by thermal mapping.

INTRODUCTION

Over the last few years, much progress has been made on building superconducting rf resonator with high quality factor (Q_0). Achieving higher values of Q_0 could mean substantial reduction in the operational cost of an accelerator. Recent discovery to anneal Nb cavities in the presence of nitrogen or titanium have shown suppression of surface resistance up to ~ 50% − 70% with increase of the low rf field [1, 2]. Analysis of the experimental field and temperature dependence of the surface resistance and a theory explaining the unconventional reduction of surface resistance by the rf field have been recently published [3–5]. Although the cavities doped with nitrogen or titanium have been tested to reach higher Q_0, they are limited by the quench field almost 40% lower than that of conventional undoped cavities [2].

In an attempt to understand the quench mechanism of the doped cavities, we have used an array of thermometers to map the temperatures of the outer surface of the 1.3GHz nitrogen doped single cell cavities. The thermometers are carbon resistors, whose resistance increases nearly exponentially with decreasing temperature. Fast response of the resistors and use of large number of thermometers that span the entire cavity outer surface provide powerful tool for diagnosing the quench and hot spot locations while in its operation below 4.2K. We present here the result of the temperature mappings of the nitrogen doped cavities.

† jmaki002@odu.edu

EXPERIMENTAL METHOD

The thermometry system consists of 36 arrays of circuit boards each containing 16 thermometers fixed around the outer cavity surface and is based on the design developed at Cornell [6]. The boards run azimuthally around the cavity, with 10° separations, and each resistor on the board is labeled from 1 to 16, with the resistor 1 at the top iris of the cavity, 8 at the equator, and 16 at the beampipe. Temperature mapping was recorded on two single-cell ingot niobium cavities labeled TD#3 and TD#4 with resonant frequency of 1.3 GHz. After the cavities were heat treated at 800°C for 3 hours, nitrogen was injected at 25 mTorr partial pressure for 20 minutes and annealed for 30 minutes. The cavities then went through electropolishing and high-pressure rinse with ultra-pure water. On TD#3, a total of ~ 35 μm was removed from the inner surface by electropolishing, while on TD#4, only ~ 10 μm was removed. The first round of temperature mapping of the outer surface cavity was collected while ramping up the rf power up to a quench field in small increments at 2.0K and 1.6K. The temperature mapping was also recorded as rf power was ramped down from the break-down field. The cavity was then thermally cycled to above 100K, and tests were repeated.

EXPERIMENTAL RESULTS

Results of the Q_0 vs B_p measurements are summarized in Fig. 1. In both cavities, quality factors showed some improvements after the thermal cycle to above 100K. For TD#4, the cool down rate through T_c=9.25K of the cryogenic dewar was approximately 106mK/sec for the first test and 487mK/sec during the thermal cycle. For TD#3, the dewar measured the slow cooling rate of 11mK/sec for the first test and 119mK/sec during the second measurement. The vertical cryogenic dewar is cooled from the bottom, and at T_c, temperature gradients across the cavities were greater when the dewar was cooled at slower rate. During the slower cooldown, the temperature difference measured between the middle of the dewar and the bottom was ~ 180 K while the difference was ~ 60 K − 90 K during the faster cooldown when the bottom of the dewar reached T_c. Although this result seems to be consistent with the recent work published on dependence of the residual surface resistance on the cooling dynamics, further investigation is required to fully understand the mechanism of the effect [7].

TD#3 cavity which has gone through extra amount of electropolishing compared to TD#4 showed higher breakdown field, but lower quality factor. At 1.6K, TD#3 reached the breakdown field of ~ 130 ± 6 mT while TD#4 cavity quenched at ~ 88 ± 4 mT. On the other hand, the quality

Abstract

The LHC is planning to employ crab cavities for the high luminosity upgrade. Old Dominion University and SLAC National Laboratory are developing a crab cavity completed with the HOM damping couplers [1]. The HOM couplers are coaxial type and perform over broadband up to 2 GHz. The amount of extracted power requires active cooling using liquid helium. The electromagnetic study has provided expected power dissipation on the coupler. Correlations between the fabrication tolerance and its damping performance have been studied and the results are providing guidelines on how to manufacture the HOM couplers. This paper summarizes the engineering studies; mechanical strength as a part of pressure system, thermal stability, and fabrication method to ensure the required tolerance.

HOM COUPLER DESIGN

The cavity is designed [2] to have the waveguide leading to the HOM coupler, of which cut off frequency is 945.8 MHz. Fig.1 is showing the overall cavity and the H-HOM coupler details inside.

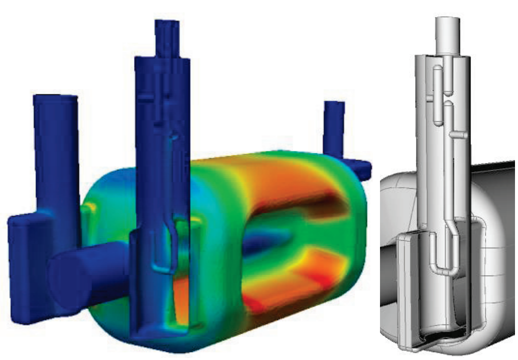

Figure 1: Cavity showing surface magnetic field distribution and H-HOM coupler internal structure.

There are two HOM couplers, one damping the horizontal HOM modes and the other damping the vertical HOM modes. The vertical HOM coupler is a simple coaxial probe type in the waveguide and the horizontal HOM (H-HOM) coupler is a high pass filter type comprised a hook and probes. This paper focuses on the horizontal HOM coupler.

THERMAL STUDY

The H-HOM coupler is designed with the niobium hook and probe. The dynamic and static heat loads must be dissipated by the liquid helium to ensure the niobium parts remain superconducting. To avoid a quench very conservative assumptions were used.

Thermal Properties of Material

The main property needed for the thermal study is the thermal conductivity of each material. Since the thermal conductivity is a temperature dependent property, a nonlinear thermal study was performed. The property curve of niobium is shown in Fig. 2 for example. Same type of nonlinear thermal conductivity was used for ceramic, stainless steel, and copper.

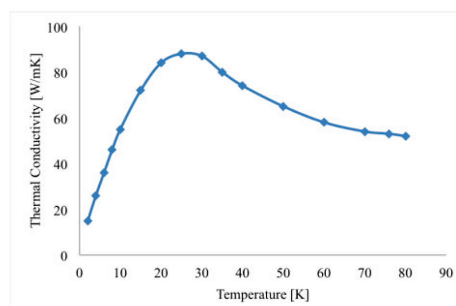

Figure 2: Temperature dependent thermal conductivity of niobium.

Dynamic Heat Load

The surface field is calculated from the finite element RF simulation, ACE3P developed at SLAC [2,3]. The heat load is Joule heating by this field and the surface resistance and it was numerically integrated as follows.

$$P = \frac{1}{2} R_s \int \left|\vec{H}\right|^2 da$$

where P is the power in Watt, Rs surface resistance in Ohm, H time averaged surface magnetic field in T. The power loss is scaled based on 1 kW of power extraction each mode. The surface resistance is assumed 10 nOhm, which is higher than typical niobium test results. For copper probe, the surface resistance was scaled to each frequency accounting for the anomalous limit of a normal conductor at the room temperature. Therefore, the

EXPERIMENT AND RESULTS ON PLASMA ETCHING OF SRF CAVITIES

J. Upadhyay, Do Im, J. Peshl, S. Popović, and L. Vušković
Department of Physics, Center for Accelerator Science, Old Dominion University, Norfolk, VA 23529, USA
A.-M. Valente-Feliciano and L. Phillips

Abstract

The inner surfaces of SRF cavities are currently chemically treated (etched or electro polished) to achieve the state of the art RF performance. We designed an apparatus and developed a method for plasma etching of the inner surface for SRF cavities. The process parameters (pressure, power, gas concentration, diameter and shape of the inner electrode, temperature and positive dc bias at inner electrode) are optimized for cylindrical geometry. To study the etching of the inner surface of the varied diameter cylindrical structure, a stainless steel pill box cavity has been made. The niobium samples placed inside this cavity has been studied for etch affects purposes. The inner electrode has been moved and plasma response to the movement of the powered electrode has been seen. Plasma characterization is done with the help of optical emission spectroscopy.

INTRODUCTION

Currently used technologies for superconductive radio-frequency (SRF) cavities processing are buffered chemical polishing or electro polishing. These technologies are based on the use of hydrogen fluoride (HF) in liquid acid baths [1], which poses major environmental and personal safety concern. Plasma etching would be a much more controllable, less expensive and more environment-friendly processing technology. It would also provide the unique opportunity to tailor the niobium surfaces for better superconducting rf properties.

We have been developing the plasma etching technology for SRF cavity in multiple stages. In the first stage, we demonstrated plasma etching of a flat coupon of niobium (Nb) in a microwave plasma of 2.45 GHz frequency inside a quartz tube with a gas mixture of 97% argon and 3% chlorine [2]. The effects of plasma etching on niobium surface on flat coupon samples were studied [3]. In the second stage, to demonstrate plasma etching on the inner surface of three dimensional structures, we designed a cylindrical cavity with diameter equal to the beam tube of single cell SRF cavity of 1497 MHz and length 15 cm. Ring shaped Nb samples were placed on the inner surface of this cylindrical cavity for etch rate measurements. Coaxial-type plasma was generated with the help of different diameter inner electrode and rf (13.56 MHz) power with a gas mixture of 85% argon and 15% chlorine. To overcome the asymmetry in ion energy bombarding the outer electrode wall and the inner electrode wall of this coaxial plasma, an external dc power supply is added. The etching of the samples placed on the outer wall was not possible without the help of the positive bias provided by an external dc power supply.

The dependence of the pressure, rf power, diameter of the inner electrode and chlorine concentration on the etch rate was measured [4]. The etch rate mechanism of Nb in the rf plasma of Ar/Cl_2 was determined by varying temperature, positive dc bias and gas conditions [5]. The variation of etch rate non-uniformity on two ring samples placed along gas flow direction on the process parameters were studied [5]. In this stage, the idea to change the inner electrode geometry for less asymmetric plasma production was implemented and a corrugated structured electrode was developed. The second stage addressed the problem of etching a cylindrical structure but an SRF cavity is a variable diameter cylindrical structure. In a third stage, we designed a steel pill box cavity with similar dimension as a single cell SRF cavity of 1497 MHz. The pill box cavity is filled with ring type and disk type Nb samples on the inner surface. The purpose of this stage is to study the etch rate behaviour of Nb on all the available surfaces of varied diameter cylindrical structure. In the fourth and final stage, single cell SRF cavities would be plasma etched and rf tested at cold temperatures.

MOVING INNER ELECTRODE IN CYLINDRICAL CAVITY EXPERIMENT

It was found that the ring sample placed further from the gas entry point has substantially lower etching than the sample placed closer to the gas entry point. The depletion of active radicals (positive ions, excited neutrals, negative ions) along the gas flow direction due to consumption by Nb during the etching process is a critical challenge to uniform etching of a long cylindrical tube. Segment-wise plasma production can be a viable alternative to overcome this problem. The movement of the inner electrode in a coaxial plasma, where the inner electrode is rf powered and positively dc biased is applied to produce the plasma in the segmented fashion. To achieve this, inner electrode is attached to thin flexible cylindrical bellows. The compression in the bellows allows the movement of the inner electrode in the vacuum while the plasma is on. The gas flow is in the opposite direction of the rf power flow direction.

A TABLE-TOP ALPHA-MAGNET*

A. V. Smirnov#, R. Agustsson, T. Campese, Y. Chen, J. Hartzell, F. O'Shea, and E. Spranza,

RadiaBeam Technologies LLC, Santa Monica, CA 90404, USA

Abstract

A compact electromagnetic alpha-magnet design, engineering, and operation are presented. The magnet was designed and engineered at RadiaBeam for a low-energy, laser-free, coherent Cherenkov THz-sub-THz source developed in collaboration with Argonne National Laboratory and integrated into the Injector Test Stand (ITS) of the Advanced Photon Source (APS). The magnet having 15 cm depth, 14" height, and up to 4 T/m gradient features a rectangular yoke, two on-axis coils, and substantially truncated, substantially non-hyperbolic poles. The profiled vacuum chamber for the magnet includes a motorized scraper and means of optical control.

INTRODUCTION

A growing number of low-energy electron beam applications impose serious limitations on the sizes of the beamline components that may include alpha-magnets. Among these applications are, e.g., compact ultra-short pulse X-ray radiation sources. In particular, an alpha-magnet can perform phase space rotation to enable a sub-ps microbunching of a few MeV electron beam injected from an RF electron gun (or small electron linac, "microlinac") having "natural" energy chirp. In that case a sub-ps laser photoinjector can be avoided allowing orders of magnitude higher average beam current. A substantial portion of the long RF bunch from the injector cannot contribute effectively into the microbunching in that case. That portion is usually filtered out (typically at low momentums) with a beam scraper placed inside the alpha-magnet chamber. RadiaBeam Technologies has developed such a compact alpha-magnet for 0.5 THz radiation source recently commissioned [1]. The experiment was jointly developed by RadiaBeam Technologies, LLC, and Accelerator Systems Division of Advanced Photon Source (APS) at Argonne National Laboratory (ANL) and performed in the Injector Test Stand (ITS) of the APS.

MAGNETIC DESIGN

Since the magnet to be deployable on the optical table of the existing ITS beamline, the main specification requirements to the magnet design are rather stringent: 360 mm magnet height (determined by beamline height ~180 mm), 4 T/m maximum gradient, ~15 cm maximum trajectory depth, and ~1% field quality.

*Work supported by the U.S. Department of Energy (award No. DE-SC-FOA-0000760)
#asmirnov@radiabeam.com

A novel design was introduced to satisfy the challenging requirements. It features co-axis coils and a rectangular frame yoke. Such an approach implies a pole profile that essentially deviates from the conventional hyperbolic shape, because the magnetic flux distribution within the core of the pole in such a C-shaped, dipole-like configuration acquires naturally some intrinsic gradient and also higher order multipole components. Corresponding distortions must be compensated all the way along the trajectory depth with a non-canonical pole shape.

A special algorithm has been developed to provide the compensation. It is integrated with the model and makes correction of the pole shape on each iteration step. It uses prediction-correction technique to minimize field deviation from the linear curve of an ideal magnet. The correction function balanced with "weights" is based on a magnetic circuit approach in which the gap is considered as an array of magnetic resistors. As an initial example the approach was applied to design a larger magnet with 34 cm trajectory depth, and 1.25" minimum gap. The iterative optimization enabled ~0.3% field inaccuracy. The second model of the magnet was designed using this approach specifically for the RadiaBeam-APS experiment. The Radia [2] code used for the simulations demonstrated exceptional efficiency and required only several iterations to converge (or achieve satisfactory field quality). The model is shown in Fig. 1.

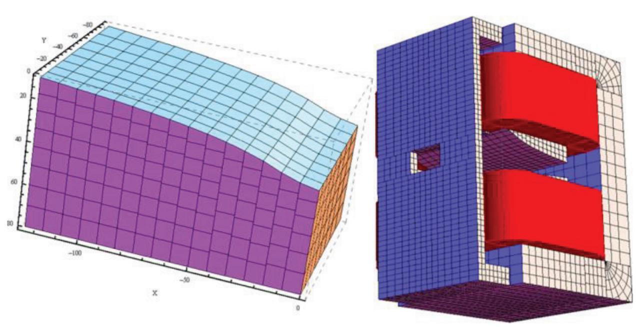

Figure 1: Radia model for the pole (left) and for the entire magnet (right).

The magnetization in the yoke is shown in Fig. 2. One can see that in spite of compactness the saturation effects in the yoke do not present the major limiting factor for the magnet performance. That enables gradients higher than 4 T/m for short periods of time.

In Fig. 3 and Fig. 4 the simulated magnetic field is plotted along the axis of symmetry and in the transverse direction respectively. The iterative simulation procedure

HIGH-POWER MAGNETRON TRANSMITTER FOR THE ELECTRON COLLIDER RING OF THE MEIC FACILITY*

Grigory Kazakevich#, Euclid TechLabs LLC, Cleveland, OH, USA
Brian Chase, Vyacheslav Yakovlev, Fermilab, Batavia, IL, USA
Yaroslav Derbenev, JLab, Newport News, VA, USA

Abstract

Operation of the 3-12 GeV electron collider 8-shape ring of the MEIC facility causes a Synchrotron Radiation (SR) of electrons in arcs with energy loss of ~20 kW/m at beam current of ~3 A. The total SR loss up to 2 MW per a turn is presumed to compensate by Superconducting RF (SRF) accelerating cavities. To minimize the beam emittance, each individual SRF cavity is proposed to feed by an individual and independent CW RF source allowing a wide-band control in phase and power. Most efficient and less expensive in capital and maintenance costs the high-power transmitters based on magnetrons, injection-locked by phase-modulated signals, controlled in wide-band are proposed as the RF sources. The magnetron RF CW sources utilizing 2-cascade magnetrons allowing a wide-band phase and power control by the injection-locking phase-modulated signals were experimentally modelled by 2.45 GHz, CW, 1 kW magnetrons. Results of additional modelling and adequacy of the transmitters for the SRF cavities are discussed in the presented article.

INTRODUCTION

Compensation of the SR losses in arcs of the electron collider of the MEIC project requires high-power CW RF sources for acceleration of the electrons in SRF cavities keeping the accelerating voltage phase and amplitude deviations in each cavity significantly less than 1 degree and 1% of nominal, respectively. The strict requirements follow from necessity in a precise orientation and positioning of the highly compressed electron bunches relatively the proton/ion bunches. Therefore minimization of emittances of the electron bunches is one of general requirements at compencation of the SR losses. The low-noise RF sources with a precisely-stable carrier frequency allowing a wide-band dynamic phase and power control by a feedback within closed loops, eliminating the parasitic amplitude and phase modulation inherent in the SRF cavities, are necessary to compensate the SR losses.

The traditional CW RF amplifiers (klystrons, IOTs, solid-state amplifiers) are applicable for this task, but they associate with high capital and maintenance costs, [1, 2]. Utilization of high-power klystrons feeding groups of the SRF cavities decreases the costs in some degree, but does not allow minimizing the beam emittances because of non-optimized phase and amplitude of RF field in individual cavities. Capability of transmitters based on 2-cascade magnetrons, frequency-locked by phase-modulated signals for a dynamic phase and power control of RF field in SRF cavity was shown in [3]. A dynamic control of a CW magnetron, frequency-locked by wide-band phase-modulated signal, stabilizing RF field in the SRF cavity, in phase and power up to 0.26 deg. rms and 0.3% rms, respectively, was first demonstrated in [4].

The results reinforce our proposal on the use of the magnetron transmitters for feeding of the SRF cavities compensating SR losses in the electron ring of MEIC. The transmitter models capabilities and tests are considered in the presented work.

MAGNETRONS WITH A WIDE-BAND PHASE CONTROL

Operation of the phase-controlled frequency-locked magnetron one can represent considering the transient processes in the magnetron caused by frequency/phase pulling and pushing. Since the magnetron is assumed to be frequency-locked, the magnitude of the locking signal has to be significantly more than the signal reflected from the SRF cavity into magnetron. The standard ferrite circulators have inverse losses ≥20 dB, so the locking signal power of >-15 dB for the magnetron may be enough to obtain precisely-stable carrier frequency in the SRF cavity at variable beam loading.

As it is shown in [3], the equation, describing phase pulling/ pushing in the frequency-locked magnetron at a steady-state is transformed into the following expression:

$$\tilde{V}_M = \cos\psi \cdot \exp(i\psi)\cdot\left(\frac{2Q_{LM}}{Q_{EM}}\tilde{V}_{FM} - \frac{Q_{LM}\cdot R_{ShM}}{2\cdot Q_{0M}}\tilde{I}_M\right). \quad (1)$$

Here: Q_{0M}, Q_{LM} and Q_{EM} are unloaded, loaded and external Q-factors of the magnetron cavity, respectively, $\tilde{V}_M$, $\tilde{V}_{FM}$ and $\tilde{I}_M$ are phasors of the voltage in magnetron cavity, of the injection-locking signal, and of the magnetron current, respectively, β is the magnetron cavity coupling coefficient, R_{ShM} is the magnetron shunt impedance, and ψ is angle between sum of phasors $-(2Q_{LM}/Q_{EM})\cdot\tilde{V}_{FM}$, $(Q_{LM}\cdot R_{ShM}/2\cdot Q_{0M})\cdot\tilde{I}_M$ and $\tilde{V}_M$, Fig. 1, [5].

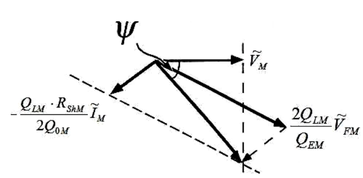

Figure 1: Phasor diagram of the injection-locked magnetron.

STATUS OF SUPERCONDUCTING TRAVELLING WAVE CAVITY FOR HIGH GRADIENT LINAC*

Roman Kostin#, Pavel Avrakhov, Alexei Kanareykin, Euclid Techlabs, LLC, Solon, Ohio, USA

Fermilab, Batavia, IL 60510, USA

Abstract

The use of a travelling wave (TW) accelerating structure with a small phase advance per cell instead of standing wave may provide a significant increase of accelerating gradient in a superconducting linear accelerator. The TW section achieves an accelerating gradient 1.2-1.4 times larger than TESLA-shaped standing wave cavities for the same surface electric and magnetic fields [1]. The final stage of a 3-cell superconducting travelling wave cavity development is presented. This cavity will be tested in travelling wave regime at cryogenic temperature.

INTRODUCTION

Accelerating gradient in RF cavities is one of the most important parameter of particle accelerator. It determines particle energy and accelerator length which is crucial for multi-kilometres accelerators such as International Linear Collider (ILC) [2]. The cost of this project highly depends on it. In order to reduce the cost with determined particle energy one should have a greater accelerating gradient. TESLA style superconducting standing wave (SW) cavity (180 degree phase advance per cell) is considered to be used as a current ILC design. Accelerating gradient shows the efficiency of acceleration and includes the multiplication of electric field gradient in a cavity and transit time factor which is around 0.7 for 180 degree phase advance. Standing wave cavities length is restricted to 1 meter in order have field flatness degradation less than 5% because of strong dependence on the cavity length. Thus, there is a gap between cavities (220 mm) which reduces accelerating rate by 22%. Superconducting traveling wave accelerating structure was proposed before in our previous publications [3, 4]. It requires feedback waveguide (WG) from one end of accelerating structure to another in order to make a closed loop for power distribution. Although, this cavity has more complicated design (additional waveguide) and tuning procedure (two tuners are required to tune operational frequency and compensate reflections along the loop) it has two urgent advantages. Firstly, field flatness has lower dependence on cavity length. If surface treatment and manufacturing process allow to build 10 meter long (cryomodule length) traveling wave cavity it will have better field flatness than 1 meter long standing wave cavity. This fact increases accelerating gradient by 22%. Secondly, traveling wave does not need to have 180 degree phase advance as it is required for standing waves cavities in order to have each cell filled with EM energy. Accelerating wave travels along the cavity together with accelerated particle. The geometry of TW cavity was optimized in order to obtain a higher accelerating gradient. 105 degree phase advance was found to have 24% higher accelerating gradient than in TESLA style SW cavity. The detailed information can be found in the following article [3, 4].

A 3-cell cavity was chosen to demonstrate traveling wave regime. It was optimized and is manufacturing in AES, Ink. This cavity will be processed and tested at Fermilab in the end of summer 2015. 3-cell tuning studies were presented in publications [5, 6]. They are the following for -30 dB reflections: WG deformation range is 90 um; WG deformation step is 20 nm; longitudinal position range ±4 mm, and longitudinal position step 0.5 um. WG deformation range was extended to 1 mm after some investigations with tuner design and tuning procedure. WG wall deformations were calculated by Ansys and 15 kN force was found to be required for 1 mm wall deformation at 2 K.

3-CELL TRAVELING WAVE CAVITY TUNER DESIGN

As was discussed in [6] 3-cell traveling wave cavity tuner must have the possibility to move the point of force application to the WG. This is the main feature which distinguishes it from conventional SW cavity tuners and the first attempt to make a design became SW tuners review. Cryogenic stepper motor actuator for vacuum application with a reinforced axial load was found in one of Fermilab tuner design. It consists of 200/1 stepper motor, 50/1 gearbox and a shaft with 1 mm thread. That means that 1 step of this actuator produce a 100 nm longitudinal displacement. This motor can withstand 1.3 kN of axial load (Fermilab experience shows 4 kN of axial force before nut failure), i.e. if 12/1 lever is involved 15 kN force and 8 nm step can be achieved by this motor. These numbers satisfy almost all of the requirements. The rest of them is the possibility of moving along the WG. That was solved by additional unit, called traverse, which is mounted to the active lever through linear guides and movable by the second actuator. The 3-cell tuner is depicted in Figure 1 with hidden front rib.

DEMONSTRATION OF COAXIAL COUPLING SCHEME AT 26 MV/m FOR 1.3 GHz TESLA-TYPE SRF CAVITIES*

Yi Xie†, A. Kanareykin, Euclid TechLabs, Solon, Ohio
T. Khabiboulline, A. Lunin, V. Poloubotko, A. Rowe,
N. Solyak, V. Yakovlev, Fermilab, Batavia, Illinois
J. Rathke, AES, Medford, New York

Abstract

Superconducting ILC-type cavities have an rf input coupler that is welded on. A detachable input coupler will reduce conditioning time (can be conditioned separately), reduce cost and improve reliability. The problem with placing an extra flange in the superconducting cavity is about creating a possible quench spot at the seal place. Euclid Techlabs LLC has developed a coaxial coupler which has an on the surface with zero magnetic field (hence zero surface current). By placing a flange in that area we are able to avoid disturbing surface currents that typically lead to a quench. The coupler is optimized to preserve the axial symmetry of the cavity and rf field. The surface treatments and rf test of the prototype coupler with a 1.3 GHz ILC-type single-cell cavity at Fermilab will be reported and discussed.

INTRODUCTION

The standard 1.3 GHz TESLA type SRF cavity has a fundamental power coupler and two asymmetric HOM couplers both upstream and downstream. The couplers break the cavity axial symmetry that in turn causes a rf field distortion and transverse wake field which may cause beam emittance dilution [1]. In order to preserve the axial symmetry of the acceleration channel, different schemes of coaxial coupler were proposed and developed [2], [3].

We suggested another design for the coupling unit, as shown in Figure 1. This coupler has the following features:

- The coupler unit preserves the axial symmetry of the acceleration channel. There are no RF kicks or wakes that lead to emittance dilution;
- It is a quarter-wave resonant coupler for the operating mode;
- The coupler is detachable, because in the operating mode the currents are small in the coupler corners, and non-welded superconducting joints may be used. Thus, the coupler unit can be a separate device that can be treated independently of the structure;
- It may be manufactured of low RRR niobium (reduced cost) compared with the main cavity;
- It is compact.

* This Work is supported by the US DOE SBIR Program DE-SC0002479.
† yixie@fnal.gov, now at Fermilab.

The magnetic field distribution for the operating mode is shown in Figure 2. One can see that the field in the corners is much smaller than in the main cavity. For the maximal acceleration gradient of 35 MeV/m the surface magnetic field is 147 mT. In this case in the corner it is about 0.15 mT, lower enough to definitely permit superconducting joints.

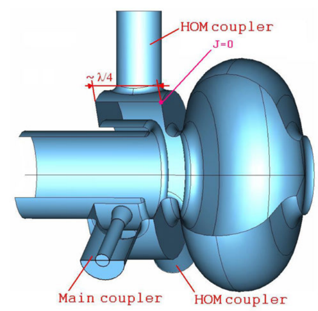

Figure 1: Schematic of Euclid proposed quarter-wave coaxial coupler.

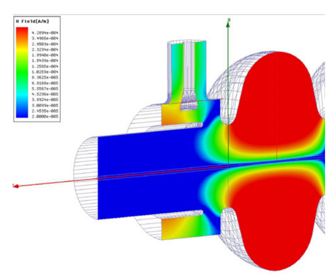

Figure 2: The magnetic field pattern in the coupler for the operating mode.

ELECTROMAGNETIC DESIGN

The first step in the coaxial coupler development was an adjustment of the shape to get the zero of the magnetic field at an accessible point for split flanges. The coaxial coupler which behaves like the coaxial resonator has an rf magnetic field and surface current minimum at the point $\lambda_{rf}/4$ from the corner (λ_{rf} is the wavelength in vacuum). This position can't be changed by appropriate choice of radii of the coaxial unit. Figure 3 shows the position of the magnetic field zero in the final design of the coaxial coupler. It satisfies the detachable design requirements.

The coupling to the fundamental mode has been modeled by the HFSS eigenmode solver for the shape depicted above.

Abstract

The Coherent electron Cooling Proof-of-Principle (CeC PoP) experiment at BNL includes a short electron linac. During Phase I, a 112 MHz superconducting RF photo-emission gun and two 500 MHz normal conducting bunching cavities were installed and are under commissioning. The paper describes the Phase I linac layout and presents commissioning results for the cavities and associated RF, cryogenic and other sub-systems.

INTRODUCTION

The CeC PoP experiment is under construction at BNL to demonstrate feasibility of this cooling scheme for future colliders [1, 2]. The experiment is aimed to cool only one bunch in RHIC. A 22-MeV high-bunch-charge beam will be delivered by a short linac [3, 4]. Phase I of the project includes installation and commissioning of a 112 MHz Quarter Wave Resonator (QWR) photoemission electron gun and two normal conducting bunching cavities as well as generating first beam. The Phase I linac layout is shown in Figure 1. The SRF gun cryomodule and bunching cavities were installed in the Interaction Region 2 (IR2) of RHIC tunnel during summer shutdown of 2014. The installed hardware is illustrated in Figure 2. In this paper we describe the first commissioning results for the 112 MHz SRF gun and two bunching cavities.

INSTALLATION AND COMMISSIONING OF THE 112 MHz QWR SRF GUN

The 112 MHz SRF QWR quarter-wave resonator was developed by BNL in collaboration with Niowave, Inc. [5-7]. It is designed to generate electron bunches with a charge range from 1 to 5 nC and repetition rate of 78 kHz, matching the RHIC revolution frequency. Multi-alkali photocathodes will be illuminated with a green (532 nm) light from a laser. More details of the gun design can be found in the cited references.

The gun operates at 4.3 K with liquid helium supplied from a so-called quiet helium source [8], which isolates the 112 MHz cryomodule from noise coming from the RHIC magnet supply line and the local helium compressor that processes the boil-off. The gun cryomodule together with associated sub-systems (cryogenics, RF, cooling water, vacuum, fundamental power coupler/tuner motion, cathodes insertion) was installed in RHIC during summer of 2014. Its commissioning began in the fall.

We started conditioning without a photocathode puck. Initially, numerous multipacting zones were encountered at very low cavity voltages. They have been cleaned out after several days of conditioning and never presented a problem afterwards.

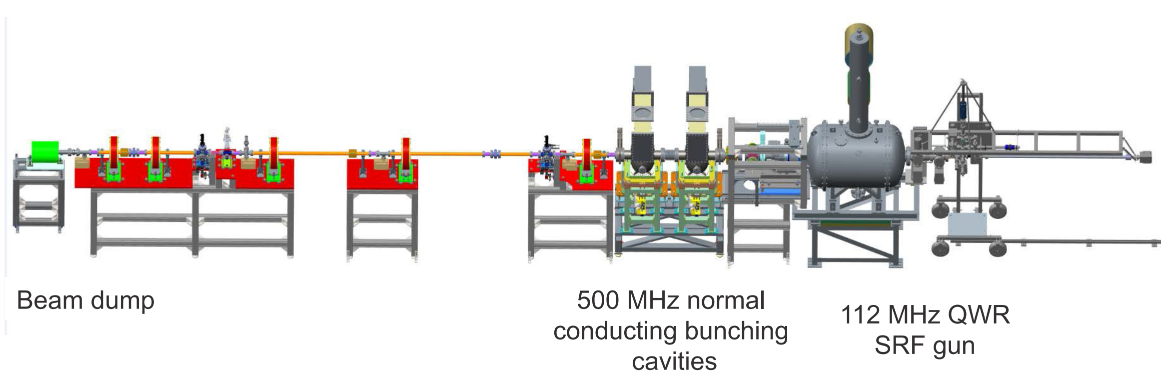

Figure 1: Layout of the Phase I of the CeC PoP linac installation.

Abstract

The Low Energy RHIC electron Cooling (LEReC) is under development at BNL to improve RHIC luminosity at low energies. It will consist of a short electron linac and two cooling sections, one for blue and one for yellow rings. For the first stage of the project, LEReC-I, we will install a 704 MHz superconducting RF cavity and three normal conducting cavities operating at 9 MHz, 704 MHz and 2.1 GHz. The SRF cavity will boost the electron beam energy up to 2 MeV. The warm cavities will be used to correct the energy spread introduced in the SRF cavity. The paper describes layouts of the SRF and RF systems, their parameters and status.

INTRODUCTION

One of the highest priorities for the RHIC experimental program is to map the QCD phase diagram at center-of-mass collison energies below 20 GeV (γ = 10.7). However, at present the RHIC luminosity at these energies does not provide sufficient statistics. It was proposed to apply bunched beam electron cooling to significantly increase the luminosity. The Low Energy RHIC electron Cooling is under design at BNL [1].

There are two options under consideration for the LEReC electron linac: one based on a DC photoemission gun and another based on an SRF photoemission gun. During the first phase of the project, LEReC-I, electrons will be accelerated only to kinetic energies from 1.6 to 2 MeV. As the DC gun option was chosen as the baseline, in this paper we present only SRF and RF system parameters relevant to this option of LEReC-I.

The linac will be located in the RHIC tunnel near the Interaction Point 2 (IP2) where it will benefit from sharing cryogenic system and some RF infrastructure with the coherent electron cooling proof-of-principle experiment [2]. The linac will include a Cornell-type DC photoemission electron gun [3] operating at 400 kV. The gun will be followed by a 704-MHz SRF booster cavity, and three normal conducting cavities operating at frequencies 9 MHz, 704 MHz and 2.1 GHz. The latter two cavities will serve for beam energy spread correction. The Phase I linac layout is shown in Figure 1 and RF system parameters are listed in Table 1.

The 9-MHz cavity is an existing spare cavity available from RHIC together with an RF amplifier. This cavity will be used in LEReC to compensate bunch-to-bunch energy variation inside the 30-car long bunch trains. This variation is due to beam loading effect in other cavities. Other RF systems are described below.

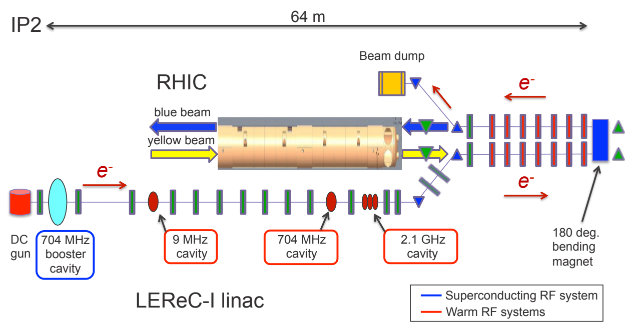

Figure 1: LEReC-I layout.

Table 1: Parameters of the LEReC-I RF Systems

Parameter	SRF booster	9 MHz	704 MHz	2.1 GHz
Cavity voltage	1.2 to 1.6 MV	3 kV	78 kV	7.5 kV
R/Q	96 Ω	190 Ω	247 Ω	487 Ω
Q_{ext}	5×10^5	35	2.6×10^4	1.09×10^4
Installed RF power	65 kW	1 kW	50 kW	10 kW

SRF BOOSTER

After generating a 400-keV beam in the DC gun, we need to boost its kinetic energy to 1.6 to 2 MeV. This will be achieved using a 704-MHz cryomodule converted from an SRF gun configuration to a booster cavity. At present, the cryomodule is installed in the R&D ERL at BNL and is under commissioning [4]. The SRF gun cavity has demonstrated very good performance, reaching its design voltage of 2 MV.

As soon as the R&D ERL beam experiments will be complete in 2016, the cryomodule will be removed and reconfigured to serve as a booster cavity for LEReC as illustrated in Figure 2. A photocathode stalk assembly will be removed and a specially designed beam pipe will be inserted in its place. In addition, the RF power coupling scheme will be modified to account much smaller beam loading in LEReC compared to R&D ERL. The booster will be powered from a 65-kW IOT-based high power RF amplifier.

Abstract

A 5-cell SRF cavity operating at 704 MHz will be used for the Coherent Electron Cooling Proof of Principle (CeC PoP) system under development for the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory. The CeC PoP experiment will demonstrate the new technique of cooling proton and ion beams that may increase the beam luminosity in certain cases, by as much as tenfold. The 704 MHz cavity will accelerate 2 MeV electrons from a 112 MHz SRF gun up to 22 MeV. This paper provides an overview of the design, the project status and schedule of the 704 MHz 5-cell SRF for CeC PoP experiment.

INTRODUCTION

The 5-cell 704 MHz SRF linac is being designed and fabricated in collaboration between BNL and Niowave. It will be the main 20 MeV electron accelerator for CeC PoP experiment under construction in RHIC at BNL [1]. The delivery of the 704 MHz SRF linac to BNL is scheduled for the end of June 2015. The 704 MHz SRF linac will be installed and ready for commissioning at the beginning of 2016 RHIC Run. An update on the layout of the fundamental power coupler , the tuner test results, the final buffer chemical polishing (BCP) and high pressure rinse (HPR) results, and the fabrication progress of several components including the completion of the helium vessel, magnetic shields, heat shield, cryogenic components and the ASME Code stamped cryostat are presented in this paper.

704 MHz COMPONENTS DESIGN

Fundamental Power Coupler

The 704 MHz SRF cryomodule [2] is powered by a coaxial coupler capable to deliver up to 20 kW CW RF power to the SRF cavity. The final model of the fundamental power coupler is shown in Fig. 1.

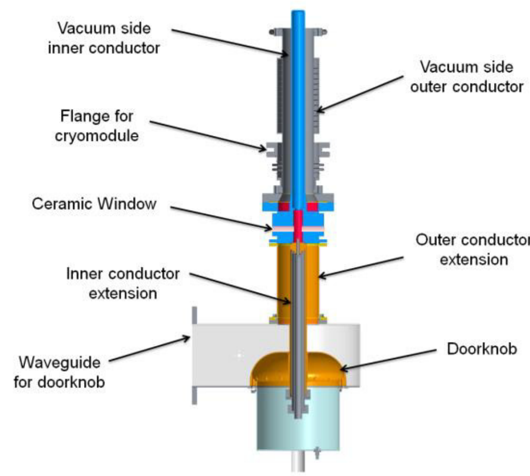

Figure 1: Fundamental power coupler design layout.

The FPC utilizes a coaxial RF window/antenna assembly from Toshiba Electron Tubes & Devices Co. [3], similar to the one currently in service on the 5-cell SRF cavity at the BNL's R&D ERL facility. On the vacuum side of the assembly, the outer conductor is a copper plated stainless steel tube with cooling channel used as a heat intercept and the inner conductor (antenna) is made of OFHC copper. The coaxial alumina window assembly has two instrumentation ports on the vacuum side: one for vacuum gauges the other one for an arc detector. The vacuum side outer conductor of the coaxial line will be cooled by 5 K helium gas, the vacuum side of the inner conductor will be cooled by air and the RF window will be cooled by water.

On the air side, the water–cooled inner extension is made of OFHC copper and the outer extension is made from copper-plated stainless steel. The FPC is coupled to a rectangular WR1150 waveguide via a waveguide doorknob transition supplied by Advanced Energy Systems, Inc. (AES) [4]. Custom conflat RF gaskets are used on all the outer conductor joints to provide good RF contact and at the same time a UHV joint.

TUNER MECHANISM

Mechanical Tuning System Design

The BNL3 cavity mechanical frequency tuning system was designed based on a tuner that has been successfully

COMMISSIONING AND EARLY OPERATION EXPERIENCE OF THE NSLS-II STORAGE RING RF SYSTEM*

Feng Gao[#], James Rose, John Cupolo, Tom Dilgen, Ben Rose, Bill Gash, Vishy Ravindranath[§], Murali Yeddulla[¶], Joe Papu, Pete Davila, Brian Holub, Jueri Tagger, Bob Sikora, Gloria Ramirez and John Kulpin, Brookhaven National Laboratory, Upton, New York 11973, USA

Abstract

The National Synchrotron Light Source II (NSLS-II) is a 3 GeV electron X-ray user facility commissioned in 2014. The storage ring RF system, essential for replenishing energy loss per turn of the electrons, consists of digital low level RF controllers, 310 kW CW klystron transmitters, CESR-B type superconducting cavities, as well as a supporting cryogenic system. Here we will report on RF commissioning and early operation experience of the system for beam current up to 200mA.

INTRODUCTION

The NSLS-II storage ring was designed to maintain a 3GeV, 500mA circulating electron beam with very small horizontal (down to 0.5 nm-rad) and vertical (8 pm-rad) emittance [1]. There are fifteen 9.3 m straights and fifteen 6.6 m straight in the ring, where two of the 9.3 m straights were allocated for RF cavities. The fully built-out RF system is expected to have two CESR-B type 500 MHz superconducting cavities and one passive 1500 MHz superconducting Landau cavity on each RF straight.

To operate these superconducting cavities, an 840 watt liquid helium (LHe) refrigeration system has been commissioned [2]. Currently NSLS-II has two 500 MHz CESR-B type cavities on site, one of which is in the ring for daily operation, while the other is in the blockhouse (a test setup) for conditioning and studies. A prototype passive 1500 MHz Landau cavity is on site, whose construction is pending a cold test with LHe. Two 310 kW klystron transmitters, driven by FPGA based cavity field controllers (CFC) [3], have been commissioned to power the two 500MHz cavities. We will first briefly describe the status, then discuss a few interesting cases we have experienced, and finally the future plan and summary.

CURRENT STATUS

Figure 1 shows a simplified diagram of the storage ring RF system. The 500 MHz cavitiy design was optimized with flexibility for various scenarios with one to four operating cavities, and both first built cavities have measured Qext of 79,000. To reduce power reflection under operation with low beam current (< 200 mA), a 3-stub tuner has been added to raise the Qext of the cavity to 200,000. A cavity frequency tuner PLC was implemented to adjust tuner position based on the phase difference between the cavity field and the forward field.

§ Vishy is currently with SLAC.
¶ Murali is currently with Varian Medical Systems.

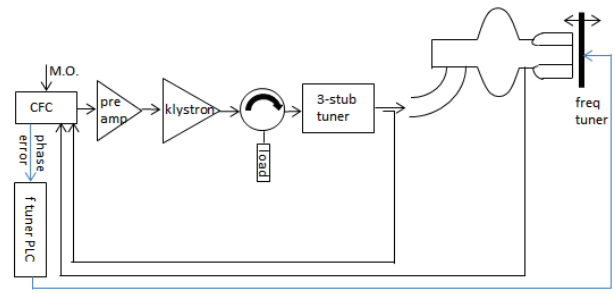

Figure 1: Simplified diagram of the NSLS-II storage ring RF system.

This PLC also monitors vacuum and water temperatures.

Table 1 shows typical operation parameters as of early April, 2015. The first cavity had been partially conditioned to 1.4 MV in the blockhouse before being moved to the ring. It then experienced frequent vacuum trips forcing the voltage to be lowered to 1.2 MV for reliability to accommodate optimization of other systems. In January 2015 the cavity was pulse conditioned to 1.87 MV with increasing duty cycles to CW, then the voltage was lowered to 1.778 MV for early operation.

Table 1: A Typical Set of Early Operation Parameters

M.O. frequency (MHz)	499.6815
r/Q (Ω)	89
Q0	2.7e+8

Abstract

Proposed proton-proton colliders with a center-of-mass energy up to 100 TeV in a tunnel of desired size require the dipole magnets to be of very high field—20 teslas in some proposals. This field is beyond the limit of present conventional Low Temperature Superconductors (LTS) and requires using High Temperature Superconductors (HTS). The preliminary magnetic design presented in this paper is an HTS/LTS hybrid design with high strength HTS tape used in higher field regions and less expensive LTS in lower field regions, with a goal of optimizing the performance while reducing the cost. A major concern in the magnets built with the HTS tape is the large field errors associated with the conductor magnetization. The strategy presented here aims to reduce those errors considerably. This paper also presents a proof-of-principle design and program to experimentally evaluate that concept.

INTRODUCTION

As a part of a recently funded Phase II Small Business Technology Transfer (STTR) award [1] by the U.S. Department of Energy (DOE), Particle Beam Lasers, Inc. (PBL), Brookhaven National Laboratory (BNL) and Energy to Power Solutions (E2P) are developing designs and technologies for accelerator magnets of very high field (20 T or more). Phase I of this STTR demonstrated this technology in a preliminary way [2]. To reduce cost, HTS/LTS hybrid designs are being examined. HTS is used in higher field regions, and conventional LTS in lower field regions. The designs are based on second generation (2G) ReBCO HTS tape with Hastelloy substrate, chosen primarily for its high strength and its ability to deal with large stresses. ReBCO is available in long lengths from several vendors around the world. The hybrid design presented here is based on a technique that is expected to keep the persistent current-induced harmonics to a manageable level despite the tape geometry of the conductor. These designs and technologies could be used in the proposed Future Circular Collider (FCC) at CERN [3] and/or the proposed Super proton-proton Collider (SppC) in China [4].

MAGNETIC DESIGN

A preliminary magnetic design of a 21 T, 50 mm aperture HTS/LTS hybrid design is presented in Fig. 1, showing one quadrant of a magnet. The field contours and types of conductor used are shown in Fig. 2. Key design parameters are listed in Table 1. The block design allows easy conductor block segmentation and furthermore better magnetic and mechanical optimization. A segmented mechanical structure intercepts accumulated forces, similar to that used in an earlier design [5]. The space between the blocks will be adjusted to allow for an adequate space for structure. Ends will be lifted up to clear the bore or have an overpass/underpass configuration [6]. LTS coils will be simple and flat. Only the ends of a few HTS coils will need to be lifted to clear the bore in a common coil configuration [7].

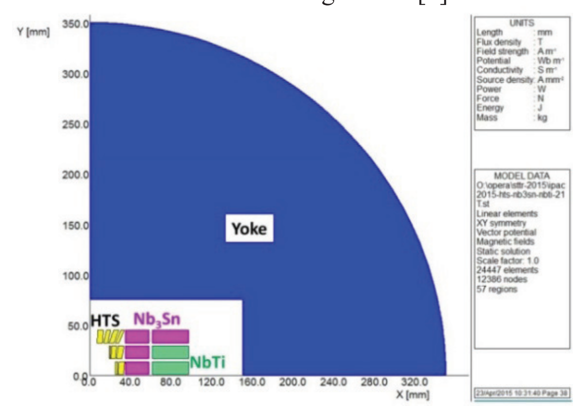

Figure 1: Quadrant of the magnetic model consisting of HTS, Nb_3Sn and NbTi (LTS) coil blocks and iron yoke.

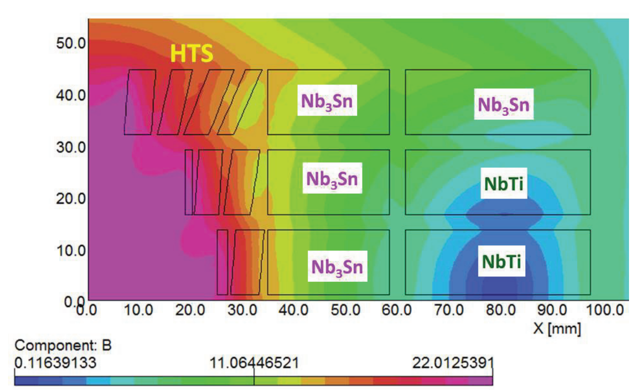

Figure 2: Field contours at central field of 21 T. Blocks with x<35mm use HTS (ReBCO tape); those with x>35mm use Nb3Sn or NbTi (LTS).

DESIGN AND TEST OF THE RHIC CMD10 ABORT KICKER*

H. Hahn,# M. Blaskiewicz, A. Drees, W. Fischer, Jian-Lin Mi, Wuzheng Meng, Ch. Montag, Chien Pai, J. Sandberg, N. Tsoupas, J. E. Tuozzolo, Wu Zhang
BNL, Upton, NY 11973

Abstract

In recent RHIC operational runs, planned and unplanned pre-fire triggered beam aborts have been observed that resulted in quenches of SC main ring magnets, indicating a weakened magnet kick strength due to beam induced ferrite heating. An improvement program was initiated to reduce the longitudinal coupling impedance with changes to the ferrite material and the eddy-current strip geometry. Results of the impedance measurements and of magnet heating tests with CMD10 ferrite up to 190 °C are reported. All 10 abort kickers in the tunnel have been modified and were provided with a cooling system for the RUN 15.

INTRODUCTION

The original RHIC design provided a beam abort system for machine protection comprising five kicker magnets with the associated pulsers and pulse forming networks in each ring [1, 2]. The 5 kickers are serially located in the beam vacuum and must deflect the bunches by ≥ 3.55 cm to reach the dump absorber, corresponding to a beam kick of 1.5 mrad or 0.252 Tm/kicker [3]. The beam is deflected horizontally, and in essence the magnet defines a 7σ dynamic aperture. Each kicker is driven by a pulsed power supply during a 12 μs long pulse to eject 111 bunches. The kick starts with 1 μs rise time in the gap, formed by 9 missing bunches out of 120. The pulser is capable of 29 kV and at operation with 27 kV delivers 18 kA while modulating down to 11 kA. The required 1 μs rise time without thyratron pre-fire depends on the reservoir heater setting [4, 5].

The abort system performance as designed for the disposal of ~200 kJ was adequate until Run 13, when planned and thyratron pre-fired beam aborts resulted in quenching of SC main ring magnets [6, 7]. Retuning of the coiled-wire inductors in the pulse forming network provided temporary correction and allowed completion of the run. Various explanations were considered but the lowering of the pulser current bottom dip shown in Fig. 1 identified beam induced heating of the magnet inductance as the culprit. Planned p intensity increases in Run 15 from 1×10^{11} to beyond 2.5×10^{11} ppb [8] triggered the kicker redesign efforts.

hahnh@bnl.gov

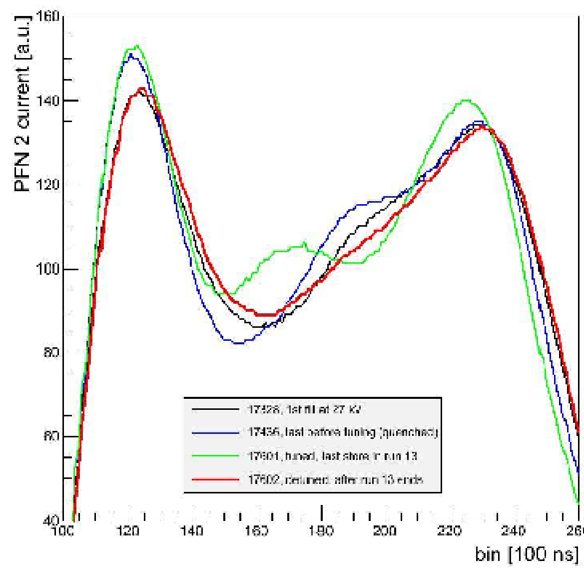

Figure 1: Pulser current at 27 kV in different operational stages: cold start, after quench, detuned in RUN13 and detuned cooled [6].

MAGNET INDUCTANCE

The magnet current sweep range results from an impedance mismatch between pulser and abort magnet impedance, ωL. The abort kicker inductance L has been largely determined by the dynamic beam aperture and by the power supply to be reasonably sized regarding voltage and peak current. The abort kickers are $\ell = 1.22$ m long and are constructed as window frame magnets with an aperture of $a = 5.08 \times b = 7.62$ cm in ferrite blocks, $w = 2.67$ cm wide. The inductance seen by the pulser can be estimated from $L \approx \mu_0 \frac{a\ell}{b} / \left(1 + a/\mu_F w\right)$ plus the feed-through inductance, that is the coaxial tube shown as Fig. 3 in Ref. [2]. The inductance is conveniently measured with a network analyzer via the bus bar input impedance as $L = Z_{BB}/\omega$ and is shown in Fig. 2 for the original magnet.

The kicker heating is dominated by the μ'' component of the ferrite and the search for better material beyond CMD5005 was done at many laboratories [9, 10], although limited here to the Ni-Zn ferrite CMD10 [11].

COMMISSIONING AND EARLY OPERATION FOR THE NSLS-II BOOSTER RF SYSTEM*

C. Marques†, J. Cupolo, P. Davila, F. Gao, A.Goel‡, B. Holub, J. Kulpin, K. McDonald, J. Oliva, J. Papu, G. Ramirez, J. Rose, R. Sikora, C. Sorrentino, N. Towne, NSLS-II, BNL, Upton, NY 11973, USA

Abstract

The National Synchrotron Light Source II (NSLS-II) at Brookhaven National Laboratory (BNL) is a third generation 3GeV, 500mA synchrotron light source [1]. We discuss the booster synchrotron RF system responsible for providing power to accelerate an electron beam from 200MeV to 3GeV. The RF system design and construction are complete and is currently in the operational phase of the NSLS-II project. Preliminary operational data is also discussed.

INTRODUCTION

The booster synchrotron NSLS-II RF system is designed to efficiently accelerate a range of bunches from 0.5nC in single bunch mode up to 15nC in multi-bunch mode injected from the linac at 200MeV to the final acceptance energy of the storage ring of 3GeV once every second. The performance goals for the booster are derived from the beam acceptance requirements for the storage ring including an RF acceptance of 0.85% [1].

The booster RF system can be divided into five subsystems namely a 500MHz 7-Cell PETRA-like cavity, a 500MHz transmitter using a 90kW Inductive Output Tube (IOT), a 38kV/4A Pulse Step Modulated High Voltage Power Supply (HVPS), a Cavity Field Controller (CFC) and a high power circulator. Some relevant machine parameters are listed in Table 1 while the layout for the booster RF system is shown in Figure 1.

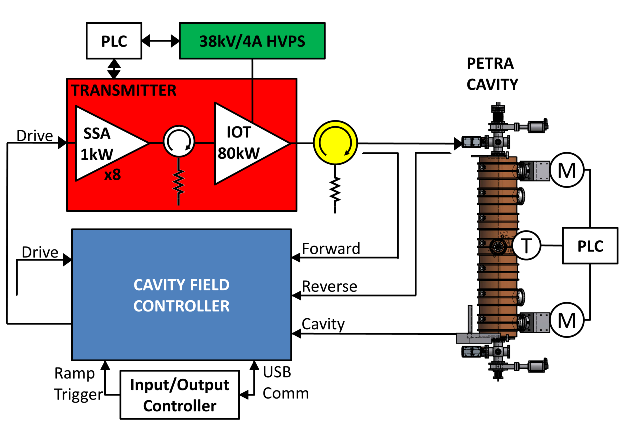

Figure 1: Simplified block diagram of the booster RF system.

SUB-SYSTEMS

Digital CFC

The Field Programmable Gate Array (FPGA) based CFC was developed as a common hardware platform for all NSLS-II RF systems and offers excellent versatility. A more detailed description of the CFC and the clock generating subsystem responsible for the FPGA clock, up/down conversions and timing can be found elsewhere [2, 3]. The booster CFC outputs a ramped RF waveform established by the host Input/Output Controller once a timing signal is initiated. The CFC uses a feedback control loop to stabilize the cavity field and phase throughout the ramp cycle.

Booster Transmitter

The 500MHz 90kW IOT is used to power the PETRA-like cavity. The cavity produces a ramped accelerating voltage from 200kV to 1200kV required for the acceleration from 200MeV to 3GeV. The measured output power of the IOT at extraction for a 3GeV acceleration was 47kW and is determined by the copper losses, beam loading and any external load. At peak operating levels the efficiency was measured to be 50%. The spectrum from the booster transmitter can be seen in Figure 2. The IOT is assembled on a cart which includes a focusing coil and input/output circuits. This modular approach allows switching out a tube assembly in about two hours. The transmitter is controlled via a Programmable Logic Controller (PLC) which communicates with the NSLS-II Experimental Physics and Industrial

A NUMBER OF UPGRADES ON RHIC POWER SUPPLY SYSTEM*

C. Mi#, D. Bruno, A. Di Lieto, J. Drozd, G. Heppner, T. Nolan, F. Orsatti, T. Samms, J. Sandberg, C. Schulthesis, R. Zapasek
Collider-Accelerator Dept., Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

This year marks the 15th run for the Relativistic Heavy Ion Collider (RHIC). Operation of a reliable superconducting magnet power supply system is a key factor of an accelerator's performance. Over the past 15 of years, the RHIC power supply group has made many improvements to increase the machine availability and reduce failures. During these past 15 years of operating RHIC a lot of problems have been solved or addressed. In this paper some of the essential upgrades/improvements are discussed.

INTRODUCTION

There are 6 above ground service buildings and 18 underground tunnel alcoves in the RHIC complex [1]. All power supplies and support instruments are in these locations around the RHIC ring. During the operations, the goal for all of the power supplies is to operate 24/7 without failure over the entire run. To achieve this high reliability a continuous improvement of the power supplies was required to reduce the failures over the years.

MACHINE PERFORMANCE OVER THE PAST SIX RUNS

Run 15 will be 22 weeks long. At the midway point of Run 15, the Mean-Time-Between-Failure (MTBF) rate is approximately 60 hours. This is the highest MTBF the power supply system has achieved. The MTBF has been improving steadily since Run 12. (See Table 1 for comparison)

Table 1: MTBF and Failures Over the Past Six Runs

Run	9	10	11	12	13	14
MTBF (hours)	15.1	35.4	17.7	39.0	40.4	41.1
# of Failures	215	117	205	89	61	82

UPGRADES AND IMPROVEMENTS

The upgrades and improvements were made in many different areas. They include adding new Print Circuit Boards (PCBs) into existing system, replacing power components, rework, adding redundant signal cables in the existing system, developing a drop in replacement power supply system for one type of power supply, swapping out old, obsolete PCBs and components to lengthen the power supply lifetime. All of the upgrades improved the power supplies reliability.

Replacement of Bipolar 300A and Bipolar 150A Power Supply

RHIC was commissioned in 1999. All of the original power supplies are still installed in the ring. Some of them are very reliable but some types have had more failures than other types. Some power supply types are easier to service than others due to the way they were packaged. Because of the serviceability issues, failures and aging a new replacement power supply is being installed.

Figure 1: 3 Kepco 10-100GL Units In Parallel.

There are a total 96 bipolar 150A model power supplies and 14 bipolar 300A model power supplies that are used in the RHIC superconducting power supply system. They are distributed in 6 service buildings. The topology of these power supplies is 3 phase AC input, full-bridge switch-mode pre-regulator with a linear output stage. The 150A model is the base unit and the 300A model is basically two 150A units paralleled to make a 300A unit. Due to the space constraints in the buildings, the packaging of these power supplies is extremely tight. The tight packaging of these power supplies means it is difficult to service them when a problem occurs.

A NEW BIPOLAR QTRIM POWER SUPPLY SYSTEM*

C. Mi#, D. Bruno, A. Di Lieto, J. Drozd, G. Heppner, T. Nolan, F. Orsatti, T. Samms, J. Sandberg, C. Schultheiss, R. Zapasek
Collider-Accelerator Dept., Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

This year marks the 15th run of RHIC (Relativistic Heavy Ion Collider) operations. The reliability of superconducting magnet power supplies is one of the essential factors in the entire accelerator complex. Besides maintaining existing power supplies and their associated equipment, newly designed systems are also required based on the physicist's latest requirements. [1] A bipolar power supply was required for this year's main quadrupole trim power supply. This paper will explain the design, prototype, testing, installation and operation of this recently installed power supply system.

INTRODUCTION

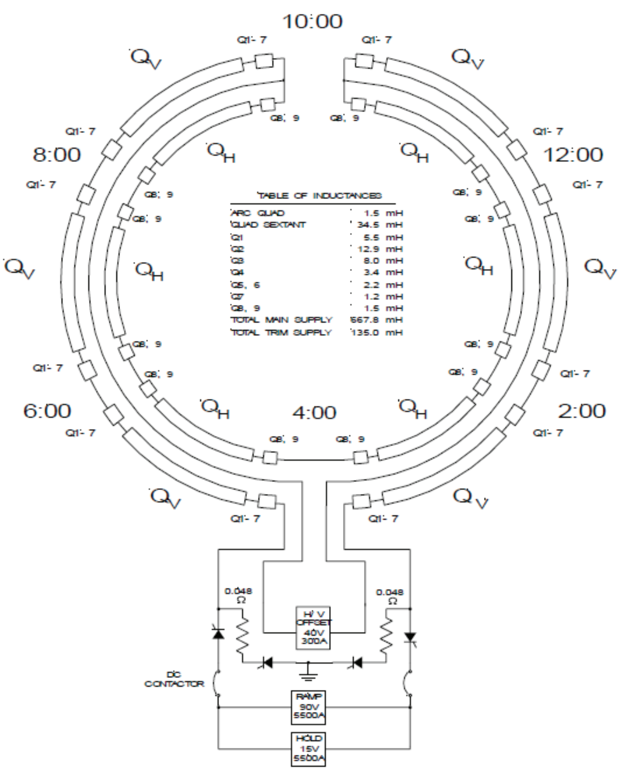

Figure 1: RHIC main quadrupole bus.

The existing quadrupole trim power supply (qtrim) was a unipolar power supply [2]. The power supply is connected in the middle of main quadruple magnet bus (Figure 1). The original qtrim power supply was a unipolar SCR type power supply. The accelerator physicist's required this new power supply to ramp up and down with bipolar capability. In order to keep the option of changing back to unipolar power supply setup in the future, it was decided to install a new power supply setup in an adjacent location.

*Work supported by Brookhaven Science Associates, LLC under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.
#cmi@bnl.gov

DESIGN CONFIGURATION

System Consideration

We did not use the original AC power feed so we could easily revert back to the original unipolar power supply configuration if it was necessary. We have 2 qtrim power supplies installed and operating, one for blue ring and one for yellow ring. Both of them are 40V 300A unipolar SCR type power supplies. The new system is output +/-300A maximum current at 40V. However we don't need 40V based on our operational experience. A DC power supply that has 22V maximum output voltage was chosen. See maximum voltage required for ramp up in Table 1. As of the time of this writing the p.s. has been running at only a maximum of +10A during the second half of run 15 it will be operated at +130A. The voltage on the p.s. has been checked during a shutoff but this was only at 10A. [3]

Table 1: b-qtrim-ps Maximum Voltage Requirement During Ramp Up

Ramp Name	Operating Current (A)	V_{max} (V) @$I_{operating}$, calculated	V_{max} (V) @300A, calculated
Au14-v0	138.3	7.33	10.52
pp13-v2	183.6	8.56	10.86
pp13-v4	201	8.8	10.75
Au104	171	7.95	10.5

System Integration

The system is integrated in Figure 2 with all major components. Two DC power supplies [4] are connected in parallel for a maximum of +/-22V and +/-300A. Two h-bridge bipolar amplifiers are connected in parallel to make up the bipolar output stage, and each H-bridge amplifier is rated for +/-160A @ +/-25V [5].

AC Compartment

The main purpose of AC compartment is to pass the 3 phase 208V_{ac} into the rack and distribute the AC into 4 different AC outputs: 2 outputs for DC power supplies, 2 outputs for the H-bridge Amplifier and 1 output for the control chassis 110V_{ac} power. Also, the AC compartment interfaces with the control chassis to receive contactor ON command and it sends the contactor ON status back to control chassis. See figure 3 for rear panel view.

Abstract

The National Synchrotron Light Source II is a 3 GeV X-ray user facility commissioned in 2014. A new helium refrigerator system has been installed and commissioned to support the superconducting RF cavities in the storage ring. Special care was taken to provide very stable helium and LN2 pressures and flow rates to minimize microphonics and thermal effects at the cavities. Details of the system design along with commissioning and early operations data will be presented.

INTRODUCTION

The NSLS-II RF cryogenic system, shown in Fig. 1, consists of a dedicated 4.5 K helium plant, LN2 system and RF system. The cryogenic system was designed for the complete build-out of the RF system, however only half of the RF is installed in the project scope. The cold box, compressors and dewar are all standard units, however boxes for helium and LN2 distribution are designed specifically with the application of superconducting RF in mind and have special features. Likewise the controls are split into two parts: one for the cryoplant operation, the second for the valve boxes that control the flow to and from the SRF cavities.

RF 4.5K COOLING REQUIREMENTS

The liquid helium cooling requirements for the NSLS-II RF cryogenic system was calculated for the full build out of two RF straights, each with two 500 MHz cavities and one 1500 MHz third harmonic cavity. The RF straights some 40 meters from the cold box and dewar, requiring some 45m each of vacuum jacketed transfer lines. In addition an RF test cave is located 20 m away. Each location requires valve boxes with 4 valves per cavity: LHe supply, cold GHe return, warm GHe return and LN2 supply. In addition the valve box for the RF test cave has valves for the transfer lines to the valve boxes (A and B) feeding the RF straights. Heat leaks were assigned to the rigid transfer lines (0.2 W/m), flexible VJ lines (1.6W/m), valve box and dewar losses. Dynamic heat loads from RF losses in the RF cavities were calculated as a function of cavity voltage. Since these losses are proportional to the square of the cavity voltage, and the required voltage of 3.3 MV per two cavities (1.5 MV each) and 4.8 MV per four cavities (1.2 MV each) the dynamic losses do not rise dramatically with the addition of the second RF straight. The 4.5K cooling requirements are summarized in Table 1.

Table 1: RF Cryogenic Requirements

Cryo=Plant Heat Load	Initial Project	Final Build
Total 500 MHz RF voltage (MV)	3.3	4.8
Number of 500-MHz cavities	2	4
R/Q (44.5 * # cavities)	89	178
Number of harmonic-cavities	1	2
R/Q (45 * # cavities)	90	180
Dynamic RF losses	(W)	(W)
500-MHz cavity Nb Q=7.5E8	69	71
500-MHz cavity Cu (W)	5	5
1500 MHz Nb (W) Q=3E8 (V= 1/3 V@500MHz)	20	31
1500 MHz Cu (W)	13	15
Dynamic Load Total	107	123
Static Heat Load	202	393
RF-ON, Total Load, W	309	516
150% Total Load	463	774

The total cryogenic load of 774 Watts is met by the largest of the Linde L280 series refrigerator/liquefier. Final specification was for a guaranteed 741 watts at 4.5 K as measured in the manifold box which is the central distribution point of the system.

CRYOGENIC PLANT

The cryogenic plant consists of the screw compressors, cold box with three (3) gas bearing turbo-expanders, 3500 L Dewar, gas management system, pure He gas storage tanks and helium purity analyser. The cold box includes integrated dual full flow 80 K adsorbers for manual regeneration, integrated single full flow 20 K adsorber for the removal of Neon and hydrogen, option of LN2 pre-cooling. The operation of the plant can be summarized as providing a full dewar of liquid Helium. The remainder of the cryogenic plant consists of the multichannel vacuum jacketed transfer lines, "manifold" valve box and two distribution valve boxes. The operation of the cavity side of the cryogenic system can be summarized as keeping the superconducting cavities helium vessel full of liquid with minimum of pressure and level variations which

HIGHER ORDER MODE FILTER DESIGN FOR DOUBLE QUARTER WAVE CRAB CAVITY FOR THE LHC HIGH LUMINOSITY UPGRADE*

Abstract

A Double Quarter Wave Crab Cavity (DQWCC) was designed for the Large Hadron Collider (LHC) luminosity upgrade. A compact Higher Order Mode (HOM) filter with wide stop band at the deflecting mode is developed for this cavity. Multi-physics finite element simulation results are presented. The integration of this design to the cavity cryomodule is described.

INTRODUCTION

The LHC High Luminosity upgrade (HL-LHC) envisages the implementation of the crab-crossing technique [1-4] to correct the geometric effects of the wider crossing angles at which bunches collide, and hence maximize the LHC's luminosity. To fit the geometric limit of the LHC beam pipes, a compact HOM filter is designed for DQWCC to reflect the deflecting mode at 400 MHz back to the cavity, and to offer a pass band to the HOMs up to 2 GHz. Modes with frequencies above 2 GHz are expected to be Landau damped due to natural frequency spread, chromaticity, Landau octupoles and synchrotron oscillations [5].

CRAB CAVITY

The DQWCC, with its cross section shown in Fig. 1(a) [2, 6], can be considered as two quarter-wave resonators sharing a load capacitor, thus dubbed a double quarter wave cavity. For the 400 MHz fundamental mode, there is a transverse electric field between the two capacitive plates, offering the crabbing voltage when the beam passes at an appropriate phase. The frequency of the lowest HOM is 170 MHz higher than the fundamental mode frequency. Due to the installation of the thermal and magnetic shielding, shown in Fig. 1(c), the total height of the cavity plus HOM filter is confined within 350 mm from the beam axis.

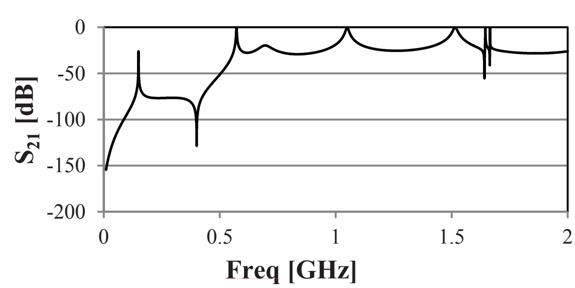

Figure 2: S_{21} of the HOM filter, with TE_{11} mode on the hook side and TEM mode on the port side.

RF DESIGN OF THE FILTER

The HOM filter, shown in Fig. 1(b), consists of a band stop LC structure right above the hook to minimize the RF loss on the Cu gasket that will be used to connect the cavity and the filter, shown in Fig. 1(a), and an L shape structure on the top to form a pass band starting from 570 MHz, the frequency of the first HOM. There are three

Abstract

A Proof-of-Principle (PoP) Double Quarter Wave Crab Cavity (DQWCC) was designed and fabricated for the Large Hadron Collider (LHC) luminosity upgrade. A vertical cryogenic test has been done at Brookhaven National Lab (BNL). The cavity achieved 4.5 MV deflecting voltage with a quality factor above 3×10^9. We report the test results of this design.

INTRODUCTION

The energy-frontier machine LHC at CERN is designed for high-energy particle physics, with energies up to 7 TeV per nucleon. Instead of upgrading the energies, the High Luminosity upgrade of the LHC (HL-LHC) will use the crab-crossing technique [1-4] to modify the angle at which bunches collide, and hence maximize the LHC's luminosity.

There are three phases for the LHC crab cavity project. The first one aims to validate the cryogenic performance of proof-of-principle (PoP) cavities. They must demonstrate a deflecting voltage of 3.34 MV per cavity. The second phase and the third phase will focus on fully dressed cavities in the Super Proton Synchrotron (SPS) and in the LHC. Eventually four cavities per beam will be needed at each side of the IP, i.e., 32 cavities in total plus spare ones.

The Quarter wave resonators (QWRs) first was proposed as a deflecting/crabbing cavity by Ben-Zvi [5, 6]. This design eventually evolved into a symmetric double quarter wave structure [1]. There is no lower order mode (LOM) or same order mode (SOM) exists in DQWCC, and its crabbing mode is the lowest resonant frequency, f_0. The first higher order mode (HOM) is well separated from the fundamental frequency f_0 by about $f_0/2$ due to the large capacitance. We describe the design, fabrication, and our results from testing the PoP DQWCC, built as part of the HL-LHC upgrade in this paper.

CAVITY DESIGN

The DQWCC shown in Fig. 1 can be considered as two quarter-wave resonators sharing a load capacitor. At the fundamental mode, there is a transverse electric field between capacitor's two plates, offering the crabbing voltage when the beam passes at an appropriate phase. Besides the two beam pipe ports, six extra ports are located on the top and bottom, with two on the top and four on the bottom, as shown in Fig. 1. These ports are designated for a fundamental power coupler (FPC), an RF pickup (PU) probe, and higher order mode couplers.

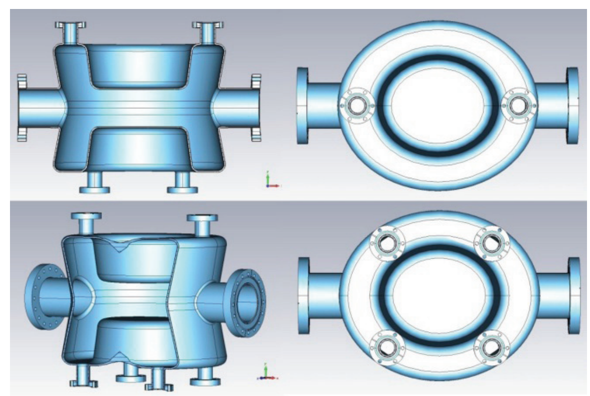

Figure 1: Geometry of the DQWCC. Top-left: Front sectional view; Top-right: Top view; Bottom-left: Front left sectional perspective view; Bottom-right: Bottom view.

Table 1 lists the key RF parameters of the DQWCC using CST Microwave Studio® with more than half a million tetrahedral meshes.

Table 1: Key RF Parameters of the Double Quarter Wave Crab Cavity

Fundamental mode frequency f_0 [MHz]	400
Nearest HOM frequency f_1 [MHz]	579
Deflection voltage V_t [MV]	3.34
R_t/Q (fundamental mode) [Ω]	406
Geometry factor [Ω]	85
Peak surface electric field E_{peak} [MV/m]	35.9
Peak surface magnetic field B_{peak} [mT]	83.9
Residual accelerating voltage V_{acc} [kV]	1.6
Stored energy [J]	10.9

Abstract

To improve RHIC luminosity for heavy ion beam energies below 10 GeV/nucleon, the Low Energy RHIC electron Cooler (LEReC) is currently under development at BNL. Two normal conducting cavities, a single cell 704 MHz cavity and a 3 cell 2.1 GHz third harmonic cavity, will be used in LEReC for energy spread correction. In this paper we report the design of these two cavities.

INTRODUCTION

To map the QCD phase diagram, especially to search the QCD critical point using the Relativistic Heavy Ion Collider (RHIC), significant luminosity improvement at energies below $\gamma = 10.7$ is required, which can be achieved with the help of an electron cooling upgrade called Low Energy RHIC electron Cooler (LEReC) [1].

An electron accelerator for LEReC (linac) consists of the photoemission gun (both the SRF and DC gun options are being developed) and the 5-cell 704 MHz SRF cavity. The SRF gun and 5-cell cavity are presently under commissioning in the R&D ERL [2]. In LEReC Phase I (electron kinetic energies up to 2 MeV) a one cell 704 MHz normal conducting cavity and a 3-cell third harmonic (2.1 GHz) normal conducting cavity will be added to de-chirp the energy spread and to compensate its non-linearity. An additional normal conducting cavity will be added in LEReC Phase II (energies up to 5 MeV with an accelerator working in the ERL mode), which is not covered in this paper.

CAVITY DESIGN

The optimization of the cavities is performed using CST Microwave Studio®, and the final designs are simulated using ACE3P package.

A. 2.1 GHz Cavity RF Design

The 2.1 GHz cavity will deliver 200 kV accelerating voltage. It will dissipate about 7.5 kW in its walls and will be fed from a 10 kW solid state RF amplifier. The design frequency is 2.1107 GHz, and the beam pipe diameter is 1.37 inches.

* Work is supported by Brookhaven Science Associates, LLC under contract No. DE-AC02-98CH10886 with the US DOE. This research used the resources of the National Energy Research Scientific Computing Center (NERSC), which is supported by the US DOE under contract No. DE-AC02-05CH11231.
† binping@bnl.gov

A pillbox shape cell is adopted as a baseline bare cell in this design. Nose cones with the height *h*, shown in Figure 1(c), are used to improve the cavity shunt impedance. Cell-to-cell coupling is determined by slots in the walls between adjacent cells, as shown in Figure 1(b). In this design four slots are added. Each slot has a width of 8 mm and an azimuthal length *phi*. 50 degrees is chosen for *phi* to get 1.2% cell-to-cell coupling for a 3-cell design. Cells with different height *h* were simulated, with *h* varied from 3 to 6 mm with a 0.5 mm step size. For each simulation the value of R_d is optimized so that resonance frequency can be set at 2.1107 GHz for π mode. The simulations showed a maximum shunt impedance at *h* = 4 mm.

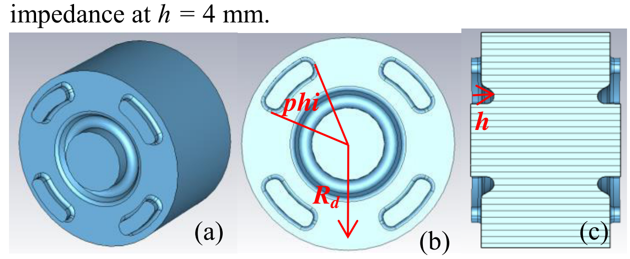

Figure 1: The 2.1 GHz bare cell: (a) perspective view; (b) front view; (c) side view.

This design provided a baseline for the 3-cell cavity. For the end cell with beam pipe, the *phi* value remains at 50 degree, the *h* value is re-optimized to maximize the shunt impedance, with a result of *h* = 4 mm.

For the center cell shown in Figure 2, a 30 mm diameter tuner is added at the bottom of the bare cell, with the tuner's penetration L_t to be negative while moving out of the cavity and to be positive while moving into the cavity. An FPC port is added opposite to the tuner. 134.42 mm × 25.04 mm JLab530 rectangular waveguide is used to deliver the RF power. This rectangular waveguide is connected to the cavity with a *WGHeight* + 5 mm long taper to a 25.04 mm × 25.04 mm coupling slot. 7.95 mm radius blending is applied to the transition edges. An RF window is not considered in this simulation and is added later to the 3-cell design. With *h* = 4 mm, *phi* = 50 degree, radius of the center cell R_d_c = 51.0 mm, the taper height *WGHeight* is chosen to be 92.0 mm to get the external quality factor Q_{ext}~3,300 from the FPC, so that the Q_{ext} for 3-cell cavity is about 10,000, with the assumption that the stored energy is evenly distributed between cells.

By assembling the two end cells (radius 52.5 mm and cone height 4 mm), and the center cell (radius 51.0 mm

CEBAF SRF PERFORMANCE DURING INITIAL 12 GeV COMMISSIONING*

T. Allison, R. Bachimanchi#, E. Daly, M. Drury, C. Hovater, G. Lahti, C. Mounts, R. Nelson, and T. Plawski, Jefferson Lab, Newport News, Virginia 23606

Abstract

The Continuous Electron Beam Accelerator Facility (CEBAF) energy upgrade from 6 GeV to 12 GeV includes the installation of eleven new 100 MV cryomodules (88 cavities). The superconducting RF cavities are designed to operate CW at an accelerating gradient of 19.3 MV/m with a Q_L of 3×10^7. Not all the cavities were operated at the minimum gradient of 19.3 MV/m with the beam. Though the initial 12 GeV milestones were achieved during the initial commissioning of CEBAF, there are still some issues to be addressed for long term reliable operation of these modules. This paper reports the operational experiences during the initial commissioning and the path forward to improve the performance of C100 (100 MV) modules.

INTRODUCTION

In March of 2014 eleven new eight cavity high gradient cryomodules were operated for the first time in the CEBAF accelerator. The cryomodule design is a culmination of the lessons learned from three preproduction high gradient cryomodules and the original 42 CEBAF cryomodules [2]. To meet the 12 GeV energy goals the cryomodules must have an energy gain of 98 MeV. With that as a performance must, the cryomodule and cavities were designed to achieve 108 MV. Each cryomodule consists of eight 7-cell elliptical cavities. The cavities are tuned to 1.497 GHz, and individually controlled by both a mechanical stepper motor and a Piezo tuner (PZT).

Additionally the RF system is completely new for these cryomodules [3, 4]. Each cavity is powered and controlled by a single klystron and LLRF system. The klystrons produce 12 kW of linear power and up to 13 kW saturated. Four high voltage power supplies power two klystrons at a time. The eight klystrons are self-protected with their interlocks as part of the high power amplifier system. The RF controls use a traditional heterodyne scheme and digital down conversion at an intermediate frequency. Each cavity field and resonance control PI algorithm is contained in two FPGAs. One FPGA is in the field control chassis, controlling a single cavity. The resonance control chassis contains the other and controls up to eight cavities. The RF controls are unique incorporating a digital self excited loop (SEL) to quickly recover cavities. Controls and interfaces for both the HPA and the LLRF are provided through EPICS.

RF SYSTEM/CRYOMODULE COMMISSIONING

RF System Commissioning

The RF systems and cryomodules were installed and commissioned between 2011 and 2013, while the CEBAF accelerator was off for the energy upgrade. Typically they are commissioned in series, first with the RF systems and then followed by cryomodule commissioning.

The RF power systems (circulators and waveguide directional couplers) were commissioned by powering the klystrons up to their saturated power level of 13 kW. The LLRF system (field control chassis (FCC), stepper motor chassis, cavity interlocks, Piezo amplifier and heater controls) was simultaneously tested and calibrated [3]. The new digital RF control has made testing much simpler and easier since it replaces the RF sources and analog phase lock loops used in the past.

Table 1: C100 Cryomodule Energy Gain

Cryomodule	Beam Measurement	During CEBAF Commissioning
C100-1	104 MV	94.01 MV
C100-2	122	93.8
C100-3	108	76.58
C100-4	93	79.24
C100-5	121	100.31
C100-6	111	101.8
C100-7	104	103.81
C100-8	110	100.17

CRAB CAVITIES: PAST, PRESENT, AND FUTURE OF A CHALLENGING DEVICE*

Q. Wu#, BNL, Upton, NY 11973, USA

Abstract

In two-ring facilities operating with a crossing-angle collision scheme, luminosity can be limited due to an incomplete overlapping of the colliding bunches. Crab cavities then are introduced to restore head-on collisions by providing the destined opposite deflection to the head and tail of the bunch. An increase in luminosity was demonstrated at KEKB with global crab- crossing, while the Large Hadron Collider (LHC) at CERN currently is designing local crab crossing for the Hi-Lumi upgrade. Future colliders may investigate both approaches. In this paper, we review the challenges in the technology, and the implementation of crab cavities, while discussing experience in earlier colliders, ongoing R&D, and proposed implementations for future facilities, such as HiLumi-LHC, CERN's compact linear collider (CLIC), the international linear collider (ILC), and the electron-ion collider under design at BNL (eRHIC).

INTRODUCTION

Adopting head-on collision scheme is a straight-forward option for providing the highest possible luminosity at a given beam intensity. However, the particles and the debris from collisions travel towards the next bunch in the opposing beam after the interaction point (IP) [1]. To avoid long-range beam-beam collisions and possible damage to the instrumentation and detectors, it is necessary to separate bunches from their original travel orbit over a very short time. Depending on the bunch repetition rate, the substantial separation requirement could be within nano seconds, which is challenging for the designing the interaction region.

A crossing angle is introduced into colliders to avoid such drawbacks of the head-on collision; however, it also decreases luminosity due to reducing the geometric overlap of the colliding bunches. As shown in Figure 1, θ_c is defined as the full crossing angle.

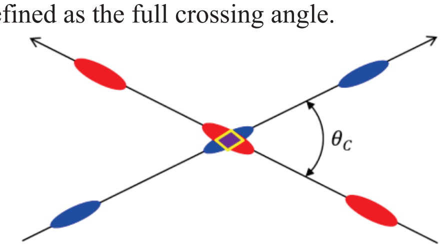

Figure 1: Beam collisions with crossing angle.

In 1988, Robert Palmer introduced the concept of crab cavity as a countermeasure to the geometric reduction in luminosity caused by the crossing angle in colliders [2]. The crab cavity imparts a transverse momentum kick, proportional to the longitudinal position of the particle. Transverse oscillation translates the longitudinally dependent kick to a transverse offset at IP. The offsets of the two beams cancel the reduction in luminosity caused by the crossing angle, and restore the head-on collision. Figure 2 illustrates the beam collision with the crab cavities [3]. The offset of the particles, x_{IP}, at the IP is a function of β_x at the crab cavity's location, $\beta_{x,cc}$, which is

$$x_{IP}=x'\sqrt{\beta_{x,cc}\beta_x^*}\sin\varphi$$

where φ is the phase advance from crab cavity to the IP.

The concept of the crab-crossing is appealing since it enables fast separation of the two colliding beam, has a compact interaction design, and small β^* at the interaction point (IP).

A few years after the concept was published, the first design of a superconducting RF (SRF) crab cavity started by KEK-Cornell University collaboration for CESR-B and later adopted at the High Energy Accelerator Research Organisation (KEK) in Japan for the electron-positron collider (KEKB). Since then, crab cavities have been added to many new collider designs as an essential element for pursuing higher luminosity.

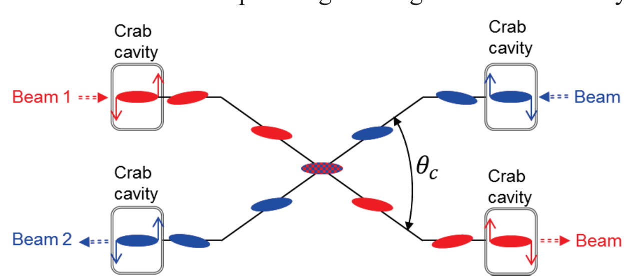

Figure 2: Beam collisions with crab cavity.

CRAB CAVITIES AT KEKB

In 2007, researchers at the KEKB demonstrated the first operational crab cavity, and observed a corresponding increase in luminosity [4][5].

The final configuration was a global crabbing scheme wherein a single cavity was used for each ring to compensate for a horizontal crossing angle of 22 mrad, Figure 3. In a global crabbing scheme, the crab cavity is installed at a particular location and generates transverse bunch oscillations around the ring. This scheme saved the cost by installing fewer cavities and utilization of the existing cryogenic system at Nikko.

THE AUTO-ALIGNMENT GIRDER SYSTEM OF TPS STORAGE RING

T.C. Tseng, H.S. Wang, W.Y. Lai, S.Y. Perng, M.L. Chen, H.C. Ho, C.J. Lin, K.H. Hsu, D.G. Huang, C.S. Lin, P.S. Chuang, C.W. Tsai, C.K. Kuan and J.R. Chen
National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract

To meet the stringent beam dynamic specs of TPS with high brilliance and low emittance characteristics, also to align the girders precisely and quickly with less manpower, the girder system for TPS (Taiwan Photon Source) storage ring is of an auto-tuning design. Each girder can be fine adjusted in 6 axes with 6 motorized cam movers of kinematic mounting design on 3 pedestals. With sensors between each girder, there are 72 girders to make up a whole ring auto-alignment girder system. All the sub-systems were carefully assembled and calibrated in a rented factory outside NSRRC during the civil construction period. Mock-up systems were set up and the auto–alignment processes were examined to modify interferences or mistakes between sub-systems. After the TPS building was nearly completed, the laser tracker alignment network was set up first and then the installation took place. When all the girders and sensors were installed into the tunnel, the auto-alignment procedures were carried out to fine tune all the girders. This paper describes the design, preparation, installation and implementation of this auto-alignment girder system for TPS storage ring.

INTRODUCTION

The TPS (Taiwan Photon Source) construction project started formally from 2006 while a feasibility study was initiated in 2004. It aimed to build a high brilliant and the very low emittance 3Gev ring with 518m circumference [1]. To meet the stringent beam dynamic specs, all the magnets should be located at precise positions and also firmly supported. However, considering the deformation of the floor and limited space in the tunnel also frequent earthquake in Taiwan, to align the girders precisely and quickly with less manpower is essential and an automatic-tuning girder system is thus proposed.

The design goal of the girders system for TPS is:

- To firm support and precise positioning of magnets
- Whole ring automatic alignment
- Precise resolution (μm)
- Beam based girder alignment (proposed)

In order to fulfill these challenging ambitions, a 6-axis motorized adjusting mechanism thus demanded. This girder system design is a modification from the girder system used in SLS (Swiss Light Source) by extending a 3 grooves type kinematic mounting from 3 balls to 6 balls and with a few major considerations:

- More contact points with locking system to raise natural frequency and reduce deflection.
- All contact points persist rolling contact when adjusting to reduce friction and remain high mobility.
- Contact stress is less than elastic limitation to reduce friction wear and keep high reliability.

In 2005, a preliminary study prototype bending section with 3 girders had been established for a test. This prototype proved the 6 axes adjustability with less than 1 μm resolution but the contact stress is exceed the elastic limitation due to point contact and wear occurred after a lifetime test [2-6].

In 2009, after the design stage of TPS is almost finished, a nearly real size testing mock-up system was set up in NSRRC fab for a system test and final examination [7-9]. After a few modifications, all hardware systems went into mass production processes.

From 2010, during the civil construction period, all the sub-systems were carefully assembled and calibrated in a rented factory outside NSRRC. A third mock-up system was set up again to modify interferences or mistakes [8-11].

After the tunnel completed, starting in January 2013, the pedestals were to be set out, anchor bolts drilling and installed with the accuracy around ±1mm. Upon completion of installation, the pedestals were grouted to the ground. There were 2 bending sections installed at July as an on-site mock-up testing system and the entire system installation began from October at a rate of 2 sections per week.

The whole storage ring girders were completed craned at March 2014 and finished control system installation test at May. In August, a whole ring girder automatic alignment was really performed the first time and it takes only 1900 seconds (32 minutes). In October, a second automatic alignment was performed to further minimize the deviations. Then, after the problem of high permeability booster vacuum chambers was discovered and solved, the commissioning of both rings were quick and accumulated beam took place at the end of 2014.

GIRDER SYSTEM DESIGN

According to the six-fold symmetric configuration DBA lattice design, 3 consecutive girders were used to accommodate one bending section magnets with the 2 dipole magnets assembled on side girders. With 4 bending sections to form a superperiod as in Fig. 1, there are 3 girder types and 72 girders total for the storage ring. With an electric levelling sensor (Leica Nevil 220) on each girder and touch sensors (Heidenhain Acanto AT1218 absolute length gauge) between consecutive girders in addition with a laser PSD (Position Sensitive Detector) system between straight section girders, a feedback controlled full ring automatic tuning girder system is established as in Fig. 2.

ION BEAM THERAPY WITH IONS HEAVIER THAN PROTONS: PERFORMANCE AND PROSPECTS

U. Linz, Forschungszentrum Jülich, D-52425 Jülich, Germany

Content from this work may be used under the terms of the CC BY 3.0 licence (© 2015). Any distribution of this work must maintain attribution to the author(s), title of the work, publisher, and DOI.

Abstract

This presentation focuses on two aspects of the therapy with ions heavier than protons: technical equipment and rationale for the choice of ion. The part on equipment concentrates on accelerator and gantry. Biophysical, medical, and economical considerations will be discussed in the part featuring the choice of the proper ion.

INTRODUCTION

Whereas all ions have Bragg peak and magnetic deflectability in common, ions heavier than protons are characterized by a narrower dose peak, less lateral scattering, and an increased biological effectiveness. All of these properties render them interesting as ions for therapy. However, with increasing atomic mass ions tend to fragment after nuclear collision. The resulting lighter ions and neutrons cause tailing of the Bragg peak with a higher dose in the exit zone. The increasing number of neutrons per projectile are also a reason for increased cost due to shielding requirements. Another cost factor is the size of the accelerator and the gantry. Both are directly correlated with the choice of the ion. The question *which is the optimum ion* or *which ions do we need* is therefore one that influences future facility design.

ACCELERATORS FOR ION BEAM THERAPY

An accelerator system for ion beam therapy (IBT) has to be highly reliable, easy to operate and to maintain. In order to be competitive with other clinical treatment systems, the cost for operation, maintenance, and follow-up should be low.

All active IBT centers that utilize ions heavier than protons have opted for carbon ions and all these centers have a normal-conducting slow-cycling synchrotron (SCS) as accelerator. They value the established slow extraction method and the high beam stability of this accelerator type. A first design study of a compact (ø 6-10 m), superconducting SCS has been published by Noda et al. of NIRS [1]. A superconducting isochronous cyclotron is under development by IBA and intended for ARCHADE in France [2]. Plans for other accelerators such as the rapid-cycling synchrotron were presented in the past [3] but have not yet been put into action in any therapy center.

NECESSITY OF A GANTRY

State-of-the art for proton therapy, a gantry should also be conceived for an IBT center using ions heavier than protons, even though it is a significant cost factor. From a clinical point of view, external irradiation should be carried out from the optimum angle to reduce unnecessary radiation exposure, and the radiation beam should be directed to the target not the target to the beam.

The first IBT center with a rotating gantry for carbon ions has been HIT in Heidelberg, Germany. The gantry is 25 meters long, has a diameter of 13 meters, weighs 600 tons, moves with an accuracy of ±0.3°, and has a braking distance of only 1°. It is an engineering masterpiece but as a standard for IBT it is prohibitive.

A superconducting gantry is under development at NIRS which provides the same ion range but has only half the length and weight of the HIT gantry. The aperture size will be somewhat smaller than at HIT, but with 20x20 cm^2 it should be compatible with 3D scanning [4].

The non-scaling fixed-field alternating gradient gantry claims a reduction of the weight of the beam line by approx. 2 orders of magnitude (1.5 t vs. 135 t) [5]. Unfortunately, a working prototype of such a slimmed-down gantry has not yet been put into practice.

THE OPTIMUM ION

From a clinical point of view, a therapeutic ion beam should display as little as possible (low-LET) radiation in the entrance channel or plateau region to spare normal tissue. In the Bragg peak or target area the radiation quality should preferably be high-LET and of high relative biological effectiveness (RBE). Minimum fragmentation, a low neutron dose, and a high benefit-cost ratio are further requirements that the optimum therapeutic ion should meet. Despite decades of clinical experience with protons and carbon ions in particular, or helium and neon ions on a smaller scale, systematic experimental studies to find the optimum ion are lacking.

Simulation experiments illustrate that only ions up to boron (Z=5) stay significantly below an ionization density of 20 keV/µm in the entrance channel of a spread-out Bragg peak (SOBP) [6]. This is considered the lower limit of high-LET radiation. Carbon is borderline and oxygen and all heavier ions show definite unwanted high-LET behavior in this area with healthy tissue that should not be damaged.

Beyond the SOBP, ions up to boron show an insignificant dose tail of low-LET fragments. Carbon exhibits a short high-LET dose tail of 2-3 centimeters. For heavier ions, this unwanted fragmentation tail is further pronounced.

COMPARISON OF BEAM DIAGNOSTICS FOR 3RD AND 4TH GENERATION RING-BASED LIGHT SOURCES

H. Maesaka#, RIKEN SPring-8 Center, Kouto, Sayo, Hyogo, 679-5148, Japan

Abstract

Beam diagnostics for the fourth generation ring-based light sources (4GLSs) with a multi-bend achromat (MBA) lattice are discussed in comparison to the third generation light sources (3GLSs). While the MBA lattice enables small natural emittance of typically 100 pm rad, it has large non-linear effect that makes the machine operation difficult. In addition, stability requirements for the X-ray photon beam of the 4GLSs are stringent due to the small beam size and divergence. Therefore, novel diagnostic techniques are needed, such as highly accurate and stable beam position monitors, high resolution beam size monitors, and bunch-by-bunch feedback systems. We review beam diagnostic technologies implemented for 3GLSs and their application to the 4GLSs. To maximize the performance of the 4GLSs, R&D toward the photon-beam-oriented diagnostics is discussed.

INTRODUCTION

The third generation light sources (3GLSs) have been indispensable sources of brilliant X-rays for various science applications [1]. Several years ago, X-ray Free Electron Lasers (XFELs) became available [2,3], which was a significant breakthrough for photon science. The XFEL has excellent transverse coherence and extremely high peak brilliance. The success of the XFEL has stimulated 3GLSs to evolve the pursuit of higher brilliance and coherence.

The natural emittance of a 3GLS ranges from 1 to 10 nm rad and the average brilliance around 10^{20} photons/sec/mm^2/mrad^2/0.1%BW. Higher brilliance radiation can be obtained by reducing the natural emittance of the electron beam, if the emittance is larger than the diffraction limit [4]. Therefore, the goal of the emittance reduction for a ring-based light source is to achieve the diffraction limit. The diffraction limit for 10 keV X-rays, for example, is 10 pm rad, which is two orders of magnitude smaller than 3GLSs.

In order to approach the diffraction limit, a new type of lattice design, multi-bend achromat (MBA), has been established. The MBA is motivated by the emittance scaling formula [5]:

$$\epsilon_0 \propto \gamma^2 \theta^3,$$

where ϵ_0 is the natural emittance, γ is the Lorentz factor of the electron beam, and θ is the bending angle for each dipole magnet. In order to reduce θ, MBA uses more than 3 dipoles for each achromat cell. By using MBA, the natural emittance of around 100 pm rad can be achieved and the brilliance can be increased to around 10^{22} photons/sec/mm^2/mrad^2/0.1%BW. In this article, we call the light source using the MBA lattice as a fourth generation light source (4GLS).

At this moment, there are two 4GLS facilities, MAX IV [6] and Sirius [7], under construction. Many other projects, such as ESRF Upgrade [8], SPring-8-II [9], APS Upgrade [10], Diamond-II [11], ALS Upgrade [12], PEP-X [13], BAPS [14] and TauUSR [15], have been proposed so far. The main parameters of these facilities are tabulated in Table 1.

In this article, the characteristics of 4GLSs and 3GLSs are compared, and requirements for beam diagnostics for the 4GLSs are discussed. Novel beam instrumentations developed for 3GLSs are briefly reviewed with prospects of 4GLSs. Finally, diagnostic challenges for 4GLSs are discussed.

Table 1: 4GLS Facility Examples. E is the beam energy in GeV, ϵ_0 is the natural emittance in pm rad and C is the circumference in meter.

Facility	E	ϵ_0	C	Lattice
MAX IV	3.0	330	528	7BA

TauUSR	9.0	3	6210	7BA

COMPARISON OF 4GLS AND 3GLS

Accelerator Beam Parameters

The MBA lattice used in a 4GLS has many technological challenges compared with a 3GLS (DB lattice). Typical beam parameters of the 4GLS and the 3GLS are summarized in Table 2.

The beam size of a 4GLS is approximately 20 µm (H) x 5 µm (V), which is determined by the horizontal (vertical) emittance of 100 (10) pm rad and the beta function of several meters. The beam orbit should be stable within 1/10 of the beam size in order to maintain the stable optical axis of a photon beamline. Thus, stringent orbit stability is required for the 4GLS.

RECENT TRENDS IN BEAM SIZE MEASUREMENTS USING THE SPATIAL COHERENCE OF VISIBLE SYNCHROTRON RADIATION

T. Mitsuhashi, KEK, Tsukuba, Japan

Abstract

The optical method of measuring the transverse beam profile and size using visible synchrotron radiation (SR) began with simple imaging systems. The resolution was limited by both diffraction and wavefront errors making it difficult to resolve beam sizes less than 50 µm. Instead of imaging, an interferometric method for measuring the beam profile and size using spatial coherence was introduced. The method is based on Van Cittert-Zernike's theorem, and can resolve 4-5 µm beam sizes with an error of only 0.5 µm. In this presentation, the principle of the measurement, the SR interferometer design, and some resent measurement results are reviewed. The incoherent field depth effect for the horizontal beam size measurement is also described with some recent results. Design study calculations for the SR interferometer at the LHC will be presented.

INTRODUCTION

The synchrotron radiation (SR) monitor based on visible optics is one of the most fundamental diagnostic tools in high energy accelerators. The monitor gives a static and dynamic observation for the visible beam profile, beam size and with a streak camera, the longitudinal profile. These diagnostics greatly improve the efficiency of commissioning and operation of the accelerator. The discipline of monitoring began with simple imaging systems [1]. The resolution in the imaging systems was limited by both the diffraction and wavefront errors making it difficult to resolve beam sizes less than 50 µm. Instead of imaging, a method for measuring the beam profile taking advantage of inherent spatial coherence was introduced [2].

Nowadays, the SR interferometer is recognized as a powerful tool to easily measure small beam sizes [3]. Recent efforts to improve the measurable range down to 3-4µm have been reported [4]. In recent few years, an imbalance input technique was developed to introduce magnification into the interferometer [4][5][6]. The principal of the measurement, and some resent results are reviewed in this paper.

PRINCIPAL OF THE MEASUREMENT

In visible optics, interferometry is one of the standard methods to measure the profile or size of very small objects. The principle of measuring the profile of an object by means of spatial coherence was first proposed by H. Fizeau in 1898 [7], and is now known as the Van Cittert-Zernike theorem [8]. In other hand, it is well known that A. A. Michelson measured the angular dimension (extent) of a star with his stellar interferometer in 1920 [9]. With interferometry, all free parameters such as wavelength distance between object and interferometer and separation of double slit are measured by interferometry and a ruler. Due to this self-consistently, this method is classified as an *absolute* measurement.

Considering an incoherent light source as an ensemble of the single, independent modes of the emitted light, according to the van Cittert-Zernike theorem, the intensity distribution of the object is given by the Fourier transform of the complex degree of 1st order spatial coherence [8]. Mathematically, if we let f denotes the two dimensional transverse intensity distribution of beam profile as a function of coordinates x, y, the 1st order complex degree of spatial coherence γ as a function of spatial frequency υ_x and υ_y is given by ,

$$\gamma(\upsilon_x,\upsilon_y)=\int f(x,y)\exp\{-2\pi i(\upsilon_x x+\upsilon_y\cdot y)\}dxdy$$

$$\upsilon_x=\frac{2\pi D_x}{\lambda R},\ \upsilon_y=\frac{2\pi D_y}{\lambda R} \qquad (1)$$

where R denotes the distance between the source and the double slit. We can therefore obtain the beam profile and thus beam size via the inverse Fourier transform of complex degree of 1st order spatial coherence as measured with a 2-slit interferometer.

SR INTERFEROMETER

In order to measure the 1st order spatial coherence of a SR beam, a wavefront-division type interferometer using polarized, quasi-monochromatic rays is used. An outline of the interferometer is shown in Fig. 1 [2][3].

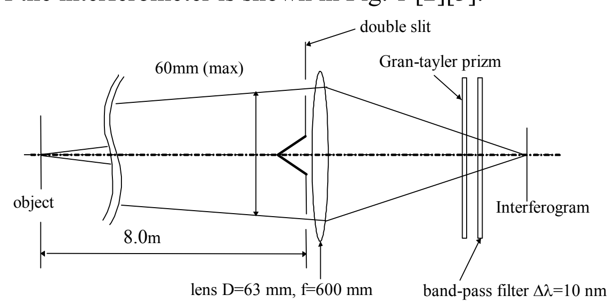

Figure 1: Outline of the 2 slit wavefront-division type of SR interferometer.

A diffraction-limited high quality lens (such as ED apochromat) is used to focus the beam onto the screen. In the vertical plane, there exists a π phase difference between the interference fringes relative to the σ-polarized fringes [2]. A Gran-Tayler prism is used to select the σ component of the SR. A band-pass filer is used for obtain quasi-monochromatic light. An eyepiece

THE CREATION OF THE PAC CONFERENCE SERIES*

Stan O. Schriber, Eagle, Idaho 83616, USA

Abstract

After much discussion in the early 1960s, the first Particle Accelerator Conference (PAC) was held in 1965 March at Washington, DC, using a particular format that the organizers determined should lead to a successful conference. In addition to focussing on all types of accelerators, the conference was organized to provide an environment for engineers, technologists, physicists and users/operators to interact and share information within an informal arrangement that promoted discussion and sharing information. The first conference was so successful that 50 years later we are using many of the concepts and procedures employed in the 1965 PAC, with improvements that have been added over the years. The initiation, development and operation/management of the successful PACs up to this 50th anniversary in 2015 are described in the following sections.

EARLY "TIMES"

With the advent of many accelerators being built and in operation in the USA, Europe and the Soviet Union, it was decided in the late 1950s to establish the International Conference on High Energy Accelerators – HEACC with sponsorship from the International Union of Pure and Applied Physics (IUPAP). Initially HEACCs were held every two years, but in 1971 this was changed to every three years. As an indication of the international nature of HEACCs, the 2nd was held at CERN in 1959, at BNL in 1961 and at Dubna in 1963. The author had the privilege of chairing the 16th HEACC in association with PAC'95 at Dallas, TX in March 1995. As chair, he worked with A.N. Skrinsky [1], Novosibirsk, Russian Federation for financial support from IUPAP to cover the costs for selected individuals to attend the conference from regions unable to provide funds for their attendance.

There are many excellent papers in the published records of this conference series, and several individuals in the accelerator community are investigating the possibility of having these conference records available through the popular Joint Accelerator Conferences Website (JACoW) [2].

Around 1960, the Institute of Electrical and Electronics Engineers (IEEE)[1] became more involved in various aspects of particle accelerators and their evolving technologies, especially for research and applications. For several years, the Technical Committee on Plasmas and the High Energy Physics sections of IEEE's Nuclear Science Group (precursor to the present IEEE-NPSS (Nuclear & Plasma Sciences Society)) was investigating ways to bring together individuals and teams interested in the technical and scientific aspects of particle accelerator design, engineering, construction, management and operations. At that time, there existed no opportunity for such accelerator specialists to forgather at one meeting covering all of these interrelated topics.

RATIONALE

Around 1963 a number of accelerator specialists felt that HEACC was becoming more of a dialogue between the high-energy facility designers and users. Because of this nature, they felt that an interdisciplinary conference (engineering/scientific) would complement the HEACC conference series, rather than create a conflict with it.

At the American Physical Society (APS)[2] meeting in Washington, DC in 1964, Louis Costrell [3,4], James E. Leiss [5,6] and H.W.(Bill) Koch [6,7] of NBS approached Robert S. Livingston [8] of ORNL regarding their desire to co-sponsor a particle accelerator meeting, using the decades old Scintillation Counter Symposium as a model for success. To achieve this interdisciplinary approach for the conference, with timely sharing of data/information, with ample time for discussion and with dissemination of important recent results, the program was organized to cover a large expanse of interests. In order to assist the broad accelerator community with the rapid development of scientific and technological advances, the following elements were considered important for success:

- To appeal to both scientists and engineers.
- To discuss the design of all sizes and types of accelerators, from the smallest to the largest.
- To include accelerators of both heavy and light particles.
- To review problems at both the input and output of the accelerator.
- To encourage participation of those who operate and build accelerators.

General Conference Layout

Many of the ideas and arrangements made for the first Particle Accelerator Conference (PAC) held in 1965 at the Shoreham Hotel in Washington DC have continued for the past 50 years, with some being modified to fit changes that have occurred within that timeframe, as described in later sections.

TOMOGRAPHY OF A HORIZONTAL PHASE SPACE DISTRIBUTION OF A SLOW EXTRACTED PROTON BEAM IN THE MedAustron HIGH ENERGY BEAM TRANSFER LINE

A. Wastl*, Atominstitut, Vienna, Austria
M. Benedikt, CERN, Geneva, Switzerland
A. Garonna, EBG MedAustron, Wiener Neustadt, Austria

Abstract

MedAustron is a synchrotron based hadron therapy and research center in Wiener Neustadt, Austria, which currently is under commissioning for the first patient treatment. The High Energy Beam Transfer Line (HEBT) consists of multiple functional modules amongst which the phase-shifter-stepper PSS is the most important module located where the dispersion from the synchrotron is zero and upstream of the switching magnet to the first irradiation room. The PSS is used to control the beam size for the downstream modules and for this scope rotates the beam in horizontal phase space by adjusting the phase advance. This functionality is used in this study to measure beam profiles for multiple phase space angles which act as input for a tomographic reconstruction. Simulation and measurement results are presented.

INTRODUCTION

The third order resonance slow extracted beam has a bar-like, non-gaussian phase space distribution in the plane of extraction (horizontal) called 'bar of charge' while in vertical phase space it has the usual distribution [1]. This particle distribution then propagates through the HEBT up to the PSS which is composed of six quadrupole magnets powered by independent power supplies. Its 'phase shifter' functionality adapts the horizontal phase advance μ_x keeping β_x at the end of the module (Fig. 1) constant while its 'shifter' function at the same time sets the needed variation of β_y.

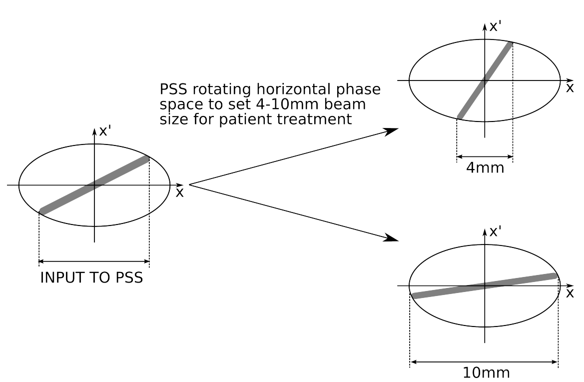

Figure 1: Adjusting the horizontal beam size [2].

Up to the entrance of the PSS the normalized strengths of optical components are independent of the required beam size at the beam line exit. Downstream the PSS 'telescope' modules project the adjusted beam size from the end of the PSS to the isocenter in the treatment room. This way the beam size is adapted to the required for patient treatment.

Using the PSS to rotate the bar in horizontal phase space and measuring the profiles downstream the module, the particle density distribution can be computed by a reconstruction techniques called tomography known from SPECT to compute the particle distribution at the monitor.

Figure 2 shows the horizontal and vertical β-functions for different horizontal phase advances and different β_y. In horizontal phase space the β-function at the PSS entrance and exit are identical. For medical purposes only four phase advance settings (representing 4mm, 6mm, 8mm and 10mm spot size at the isocenter in vacuum) are foreseen. For this study, MADX [3] was used to compute additional PSS magnet settings representing horizontal phase space rotation angles over a range of 180° (half a rotation) keeping β_y constant. Applying the different settings to the PSS, a scintillating fiber monitor SFX (64 fibers, 1mm resolution) downstream the PSS measured the different beam profiles.

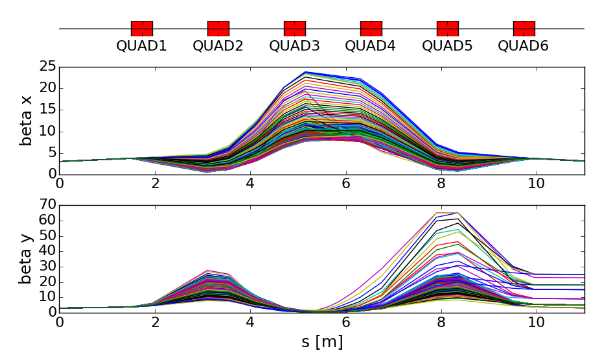

Figure 2: β_x and β_y for different beam sizes

RADON TRANSFORMATION

In modern medical diagnostics the computed tomography CT is a well-developed technique to recover information of the inner structure of the body. Density projections of a 2D 'slice' of the object of interest onto a 1D detector (the Radon transformation of the slice) performed from multiple angles around a perpendicular axis of rotation are taken as measurements and the inverse Radon transformation problem is solved to reconstruct an image of the inner structure. A medical CT performs the measurements by rotating an x-ray source and a detector around a patient who remains in place. In this study, this priciple is inverted using the PSS to rotate

SPACE CHARGE EFFECT ESTIMATION FOR SYNCHROTRONS WITH THIRD-ORDER RESONANT EXTRACTION*

M. T. F. Pivi#, A. Garonna, EGB MedAustron, Wiener Neustadt, Austria

Abstract

In proton and ion storage rings using the third-order resonance extraction mechanism, beam particles are slowly extracted from the ring when reaching the resonance stop-band. Typically at beam injection, the horizontal tune is set to a value close to the resonance value. The tune is then moved towards the resonance value to trigger beam extraction in a controlled way. The tune shift generated by space charge forces needs to be taken into account. For this, the incoherent space-charge tune shift for protons of the MedAustron accelerator main ring has been evaluated. This has been performed by multi-particle tracking using an optics model based on MADX, considering a realistic Gaussian beam distribution and exact non-linear space charge electric field forces. The MedAustron accelerator is in the beam commissioning phase and is planned to start medical commissioning at the end of 2015.

INTRODUCTION

The recently constructed MedAustron synchrotron based accelerator in Austria is one of the novel therapy accelerators intended to use protons and light ions for clinical treatment, as already operating accelerators as e.g. CNAO in Italy and HIT in Germany. A collaboration was set up with CERN, TERA (CNAO), GSI in Germany and Onkologie Institute in Czech Republic. The design is based on the PIMMS study [1]. A report of the actual MedAustron beam commissioning can be found in [2].

For the clinical treatment a beam extracted in a slow controlled process over a couple of seconds is necessary to facilitate the measurement and control of the delivered radiation dose. The third-order resonance extraction method [1] can be used to extract particles from a synchrotron over a large number of turns and in a spill time period of 1-10 sec.

Third Order Resonance Extraction

In the slow extraction process, a sextupole field is turned on to excite the resonance. The extraction is activated by accelerating the beam into the resonance with a so called betatron core. By this mechanism, the horizontal tune is effectively moved towards the third order integer resonance tune Qx = 1.666. Thus, a precise control of the beam tune at extraction is necessary.

Space charge forces, in particular for protons, may induce an incoherent tune shift that may perturb the extraction process.

Furthermore, the space charge tune shift at beam injection into the ring, when the beam energy is low, may induce resonance crossing and beam losses.

#mauro.pivi@medaustron.at

Previous space charge estimations for the main ring have been performed as part of the design studies [1]. The estimation has been revisited with the assumption of a transverse Gaussian beam distribution, by modelling the space charge electric field and forces that are highly non-linear and to take into account recently updated machine design parameters, in particular an injected beam energy of 7 Mev [3, 4].

Possible space charge mitigations are vertical emittance dilution at injection and adjustment of the chromaticity to partially compensate for beam losses [1].

SPACE CHARGE EFFECT ESTIMATION

MedAustron Accelerator Parameters

During a cycle, the phases concerning the main ring are essentially four: injection, beam capture, acceleration using synchrotron radio frequency (RF) and slow beam extraction from the ring to the irradiation rooms. Main proton beam parameters assumed for the estimation of the effect in the MedAustron accelerator are listed in Table 1.

Table 1: MedAustron Ring Optics Parameters Assumed

Parameter	Value
Circumference (m)	77.65
Energy at injection/extraction (MeV)	7.0 / 250.3
Max. num. of particles per extracted spill	2×10^{10}
Normalized emittance ε_x, ε_y (π m rad)	0.519×10^{-6}
Q_x - Horizontal design tune inject./extract.	1.739→1.666
Q_y - Vertical design tune inject./extract.	1.79/1.79
Q_x' - Natural horizontal chromaticity at inj.	-0.6
Q_y' - Natural vertical chromaticity at inj.	-1.9
D_x -Horizontal dispersion maximum (m)	8.44

Analytic Estimation

The incoherent tune shift can be estimated analytically.

For this, one can use a linear approximation of the beam electric field, as given by

$$E_x = \frac{\lambda}{2\pi\varepsilon_0}\frac{x}{\sigma_x(\sigma_x+\sigma_y)} \quad E_y = \frac{\lambda}{2\pi\varepsilon_0}\frac{y}{\sigma_y(\sigma_x+\sigma_y)} \quad (1)$$

where λ is the linear charge distribution and using SI units. Using the linear electric field approximation and assuming a Gaussian charge distribution in the transverse plane, it is possible to derive the incoherent linear vertical

BEST 70P CYCLOTRON FACTORY TEST

V. Sabaiduc, T. Boiesan, M. Carlson, D. Du, F. Grillet, F. Labrecque, B. Milton, L. AC Piazza
R. Ruegg, V. Ryjkov, M. Stazyk, S. Talmor, B. Versteeg, J. Zhu, R. Johnson, K. Suthanthiran
Best Cyclotron Systems Inc., Vancouver, BC, Canada
T. Evans, J. Harris, N. Matte, J. Panama, P. Zanetti, Best Theratronics Ltd., Ottawa, ON, Canada

Abstract

Best Cyclotron Systems Inc (BCSI) designed and manufactured a 70MeV compact cyclotron for radioisotope production and research applications. The cyclotron has been build at Best Theratronics facility in Ottawa, Canada for the INFN-LNL laboratory in Legnaro, Italy. The cyclotron has external negative hydrogen ion source, four radial sectors with two separated dees in opposite valleys, cryogenic vacuum system and simultaneous beam extraction on opposite lines. The beam intensity is 700μA with variable extraction energy between 35 and 70MeV. The beam acceleration to 1MeV results are reported as well as confirming the individual cyclotron systems performance.

ION SOURCE

The ion source for the BEST 70p cyclotron is a multi-cusp filament driven arc discharge ion source. The design parameters are chosen to closely follow, where possible, the published design parameters of the de facto reference design of this type of ion sources, the TRIUMF ion source [1]. Following the reference design, the walls of the plasma chamber contain 10-cusp magnetic structure confining the plasma to the centre portion of the chamber. The ion source emittance was found to be similar to that reported for the TRIUMF source as seen in Fig. 1. During the commissioning the ion source was operated at output currents greater than 8mA [3].

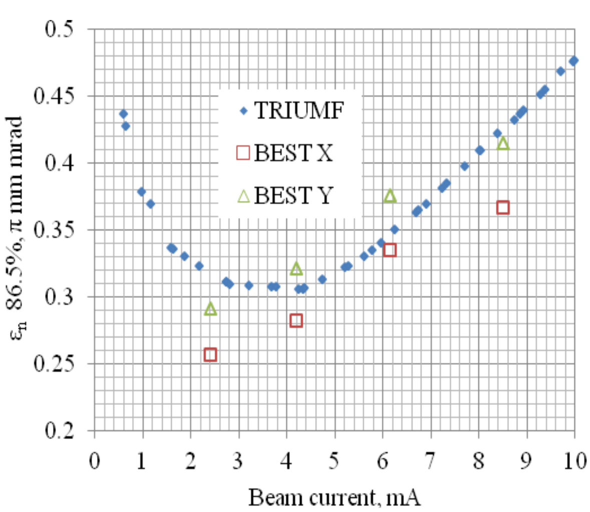

Figure 1: Emittance measurements (normalized emittance shown).

The ion source emittance was measured at the injection energy (40keV) in two perpendicular directions, one of them along the direction of the electron filter deflection. Sample emittance data is shown in Fig. 2, the "X" axis along the deflection direction. The dashed line boundaries outline emittance ellipses of 1σ, 4σ, and 9σ inclusion. While there are slight differences in the beam properties in x- and y- directions, they are not significant for transporting the beam through the injection line.

Further development of the ion source is continuing, a more detailed account of the ion source studies will be reported elsewhere.

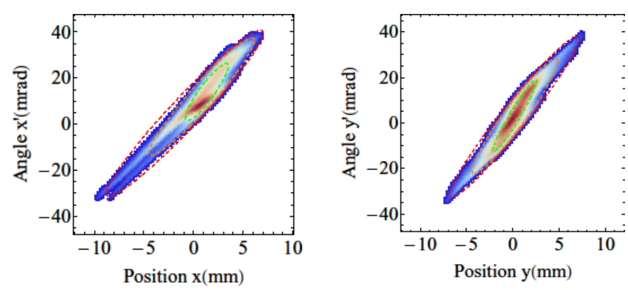

Figure 2: Ion source emittance at 6mA output (X and Y).

MAIN MAGNET

The magnet design has a good vertical focusing $\nu_z >$ 0.25 after the first few turns (0.4 at full extraction energy) and minimum magnet gap of 45mm to ensure low beam losses and high beam current acceleration. For a valley gap of 700mm the magnet operates with B Hill ≈1.6T and B Valley ≈0.12T.

The 70MeV magnet is shown in Fig. 3.

Figure 3: B70p Magnet.

THE SARAF-LINAC PROJECT FOR SARAF-PHASE 2

N. Pichoff, P. Bredy, G. Ferrand, P. Girardot, F. Gougnaud, M. Jacquemet, A. Mosnier, CEA/IRFU, Gif-sur-Yvette, France
P. Bertrand, M. Di Giacomo, R. Ferdinand, CEA/GANIL, Caen, France
D. Berkovits, J. Luner, J. Rodnizki, Soreq NRC, Yavne, Israel

Abstract

SNRC and CEA collaborate to the upgrade of the SARAF accelerator to 5 mA CW 40 MeV deuteron and proton beams (Phase 2). This paper presents the reference design of the SARAF-LINAC Project including a four-vane 176 MHz RFQ, a MEBT and a superconducting linac made of four five-meter cryomodules housing 26 superconducting HWR cavities and 20 superconducting solenoids. The first two identical cryomodules house low-beta (β_{opt} = 0.091), 280 mm long (flange to flange), 176 MHz HWR cavities, the two identical last cryomodules house high-beta (β_{opt} = 0.181), 410 mm long, 176 MHz, HWR cavities. The beam is focused with superconducting solenoids located between cavities housing steering coils. A BPM is placed upstream each solenoid.

INTRODUCTION

SARAF [1] is an Israeli national project, announced in 2001, managed by SNRC and aiming to deliver 5 mA beams at 40 MeV (deuteron) or 35 MeV (proton). Its phase 1 consisted of an ECR source, a low energy beam transport (LEBT), a 176 MHz four-rod radiofrequency quadrupole (RFQ) and a prototype superconducting (SC) module (PSM) containing 3 SC solenoids and 6 SC HWR cavities. Its phase 2 consists in increasing the energy to final one. In this context, SNRC solicited CEA (France) to contribute to this phase.

The present CEA proposal at 176 MHz is based on its experiences on the 88 MHz SPIRAL2 [2], the 175 MHz IFMIF [3] the 352 MHz IPHI [4], ESS [5] and LINAC4 [6] projects. Beginning of 2014, CEA presented a cost-optimized design to the SARAF International Steering Committee which concluded that no major risk was foreseen, but suggested to make the design more robust in order to compensate possible loss of performances during the machine life-time.

During 2014, a new linac design has been studied, discussed between SNRC and CEA and finally accepted by both parts (Fig. 1). This paper summarises this last design: the SARAF-LINAC reference design.

SARAF PHASE 2 PROJECT

CEA is in charge of studying, delivering, and commissioning the SARAF-LINAC made of:

- an optional 4-vane RFQ bunching and accelerating 5 mA-cw beams from 20 keV/u to 1.3 MeV/u,
- a MEBT measuring, cleaning and matching the beams,
- a superconducting linac accelerating the beams to final energies within the limited bean loss criterion for Hands-On maintenance,
- and the associated local control systems.

SNRC is in charge of providing:

- the source and LEBT,
- the HEBT,
- the building,
- the main control systems,
- the auxiliaries for the linac (RF power, electricity, water, liquid helium, compressed air…).

The final commissioning is planned for mid-2022.

Abstract

The IFMIF accelerator aims to provide an accelerator-based D-Li neutron source to produce high intensity high energy neutron flux for testing of candidate materials for use in fusion energy reactors. The first phase of the project, called EVEDA (Engineering Validation and Engineering Design Activities) aims at validating the technical options by constructing an accelerator prototype, called LIPAc (Linear IFMIF Prototype Accelerator) whose construction has begun [1], [2]. It is a full scale of one of the IFMIF accelerator from the injector to the first cryomodule. The cryomodule contains all the necessary equipment to transport and accelerate a 125 mA deuteron beam from an input energy of 5 MeV up to output energy of 9 MeV. It consists of a horizontal vacuum tank approximately 6 m long, 3 m high and 2.0 m wide, and includes 8 superconducting HWRs working at 175 MHz and at 4.45 K for beam acceleration. 8 Power Couplers provide RF power to the cavities up to 70 kW CW in the LIPAc case and 200 kW CW in the IFMIF case, with 8 Solenoid Packages acting as focusing elements. This paper gives an overview of the progress, achievements and status of the IFMIF SRF LINAC.

CRYOMODULE DESIGN

The SRF LINAC for the LIPAc phase mainly consists of a cryomodule designed to be as short as possible along the beam axis in order to meet the beam dynamics requirements [3]. Figure 1 shows the 12.5-ton cryomodule which consists of a rectangular section vacuum vessel, room temperature magnetic shield, MLI, thermal shield cooled down by GHe from the phase separator return line, and cold-mass wrapped in MLI.

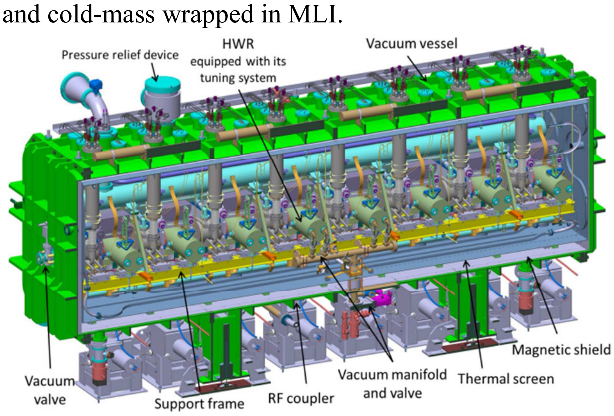

Figure 1: IFMIF LIPAc cryomodule cut view.

The cold mass is made up of the cylindrical phase separator; cryogenic circuit; titanium cavity support frame, attached to the vacuum vessel by TA6V rods ensuring lateral and horizontal positioning; 8 HWRs equipped with their frequency tuning system and power couplers; and 8 superconducting solenoids (see Figure 2). Due to their size and weight, the couplers are mounted vertically and connected to each HWR at their mid-plane.

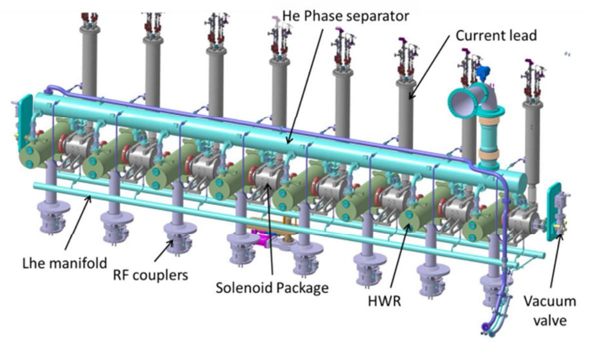

Figure 2: 3D view of the cold mass.

Several prototypes have been built during the design phase: One solenoid prototype was successfully tested [4]; the conditioning of the couplers was performed at room temperature by CIEMAT in April 2014, which qualified the design and fabrication respectively made by CEA and CPI for their use in CW mode up to 100 kW [5]; the superconducting HWR prototype, which was first equipped with a plunger for frequency tuning, was finally qualified in Dec. 2012 after removing the plunger and associated flanges [6], [7], [8], and replacing these with a more standard mechanical tuner including a disengagement system. Such a solution based on wall deformation of the half-wave resonator led to a lengthening of the cryomodule in order to accommodate it. The flange to flange length of the HWR was increased by 100 mm, and the total length of the cryomodule up to 5866 mm.

RISK MITIGATION STRATEGY

The new design of the cryomodule was submitted to a panel of international experts at a Detailed Design Review (DDR) held in June 2013 at Saclay. A detailed risk analysis taking into account the DDR remarks was also carried out. It highlighted the main risks which are related to safety, regulation, assembly, performance tests, connection, and transportation of the cryomodule. Mitigation measures to prevent the occurrence of the most

OPTIMIZATION OF MULTI-TURN INJECTION INTO A HEAVY-ION SYNCHROTRON USING GENETIC ALGORITHMS

S. Appel, O. Boine-Frankenheim, GSI, Darmstadt, Germany

Abstract

For heavy-ion synchrotrons an efficient multi-turn injection (MTI) from the injector linac is crucial in order to reach the specified currents using the available machine acceptance. The beam loss during the MTI must not exceed the limits determined by machine protection and vacuum requirements. Especially for low energy and intermediate charge state ions, the beam loss can cause a degradation of the vacuum and a corresponding reduction of the beam lifetime. In order to optimize the MTI a genetic algorithm based optimization is used to simultaneously minimize the loss and maximize the multiplication factor (e.g. stored currents in the synchrotron). The effect of transverse space charge force on the MTI has also been taken into account. The optimization resulted in injection parameters, which promise a significant improvement of the MTI performance for intense beams in the SIS18 synchrotron at GSI.

INTRODUCTION

The main goal during the design phase and later during operation of accelerators is to optimize and improve their performance. Unfortunately, accelerator problems are multi-dimensional, nonlinear, multi-objective and the quantities to be improved are often contradicting - improving one objective means worsening the others. A new approach to solve such difficult but realistic problems is the use of genetic algorithms (GA) [1,2]. The advantage of these optimization methods is that they allow finding globally optimal solutions with a large number of fit parameters, while showing the trade-offs in objective functions within a reasonable computing time. Over the years GA have been applied to optimize the performance of several accelerators.

In order to increase the space charge limit, heavy-ion synchrotrons are operated with intermediate charge state ions [3]. Therefore stripping injection is not an option and the MTI has to respect Liouville's theorem for the chosen charge state avoiding the already occupied phase space area. The MTI performance depends on various machine and beam parameters as well as on the contradicting quantities to be improved like multiplication of the injected current, the loss during injection and the required linac brilliance. Therefore, GA is well suited to optimize the injection.

GENETIC ALGORITHMS

Genetic algorithms are inspired by natural evolution. GA search for solutions using techniques such as *selection*, *mutation* and *crossover*. Due to the wide range of different algorithms GA are very flexible and can be adapted to a large range of different problems.

In GA terminology, a solution vector is called an *individual* and represents a set of variables; one variable is a *gene*. A group of individuals form a *population*, the following child populations are counted in *generations*. The first generation is created randomly. The crossover operator exchanges variables between two individuals - the parents - to discover with their offspring promising areas in the solution space. For the optimization within a promising area the mutation operator randomly changes the characteristics of individuals on the gene level. Reproduction of the individuals for the next generation involves selection. The *fitness* of an individual reflects how well an individual is adapted to the optimization problem and determines the probability of its survival for the next generation. The fitness is evaluated by the objective function, by a simulation code or by a real running system. During the single-objective optimization the most promising individuals are chosen to create the next generation. By allowing individuals with poor fitness to take part in the creation process the population is prevented to be dominated by a single individual. The most popular techniques are proportional selection, ranking and tournament selection [1,2].

In many real-life problems, multi-quantities have to be optimized. In addition, these quantities can be contradicting and there are more than one equally valid solutions. These solutions form a so-called *Pareto front* (PA front) in the solution space, see Figure 1. A solution is Pareto optimal if it is not dominated by any other solution. By using a non-dominated selection algorithm, one tries to find solutions near the optimal Pareto set. NSGA2 and SPEA2 are the most popular non-dominated selection algorithms.

As the SIS18 MTI model has been implemented in the particle tracking code pyORBIT - the python implementation of the ORBIT (Objective Ring Beam Injection and Tracking) code - and was carefully validated against experiments [4,5],

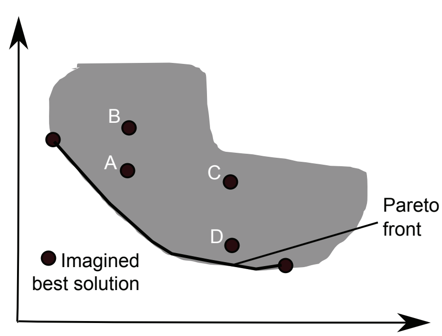

Figure 1: The Pareto front in the solution space. The solution A and D are be located near the Pareto front and non-dominated, while the solutions B and C are either dominates by the solution A or D. The solutions B and C do not dominate.

Abstract

To Meet the FAIR science requirements higher beam intensity has to be achieved in the present GSI-accelerator complex. An advanced upgrade program for the UNILAC aimed to meet the FAIR requirements is ongoing. Stripping is a key technology for all heavy ion accelerators. For this an extensive research and development program was carried out to optimize for high brilliance heavy ion operation. After upgrade of the supersonic N_2-gas jet (2007), implementation of high current foil stripping (2010 and 2011) and preliminary investigation of H_2-gas jet operation (2012), a new H_2-gas cell using a pulsed gas regime synchronized with arrival of the beam pulse was recently developed. An obviously enhanced stripper gas density at a simultaneously reduced gas load result in an increased stripping efficiency, while the beam emittance remains the same. A new record intensity (7.8 emA) for U^{28+} beams at 1.4 MeV/u has been achieved applying the pulsed high density H_2 stripper target, exploiting a high intensity U^{4+} beam from the VARIS ion source with a newly developed extraction system. The experimental results will be presented in detail.

STRIPPING OF HEAVY ION BEAMS

Suitable charge stripper technologies [1] are crucial to meet the challenging demands of state of the art heavy ion accelerator facilities. At FAIR - presently under construction at GSI - the existing linear accelerator UNILAC and the synchrotron SIS18 will serve as injector chain for the FAIR SIS100 synchrotron. Different approaches are investigated to increase the stripping efficiency of the heavy ion beam at 1.4 MeV/u and to generate higher charge states [2–5]. The stripper target at 1.4 MeV/u has to cope with a very high ion beam power of up to 1.5 MW for 18 emA U^{4+} beams during short beam pulses (100 µs) at low duty cycle (2.7 Hz rep. rate). Though for high beam powers gas or liquid strippers have clear advantages compared to foil strippers concerning durability and operational reliability, gas strippers lead to much lower equilibrium charge states due to the strongly reduced influence of the density effect [6–8] compared to solid strippers. Since electron capture cross sections of the heavy ions especially in the low-Z gases are considerably suppressed [8, 9], in particular hydrogen promises higher equilibrium charge states as compared to e.g. nitrogen, which is routinely used at the UNILAC gas stripper [10].

Thus a new setup, suitable for H_2 operation has been constructed. To enhance the gas density a pulsed gas injection [11] was implemented. This allows an increase of the maximum gas pressure and creates a high-pressure interaction zone for the stripping process. The time between two pulses is used to remove most of the gaseous particles from the system before injection of the next pulse.

UNILAC STRIPPER SECTION

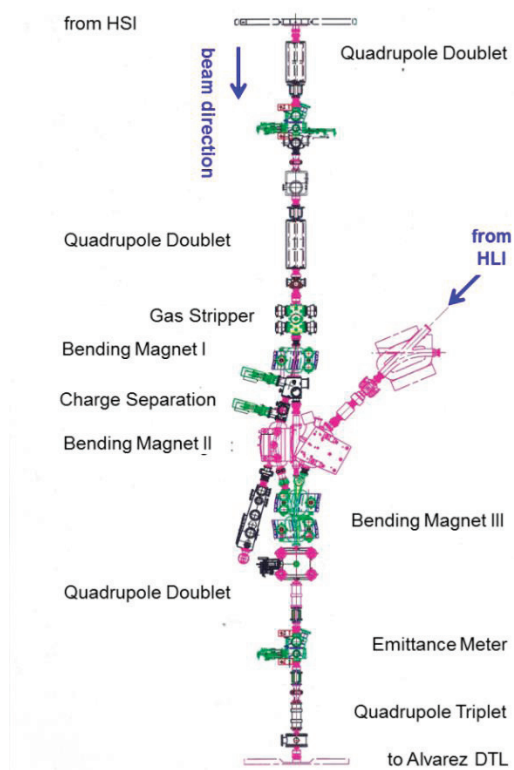

Figure 1: Layout of the 1.4 MeV/u stripper section; 14.0 m total length.

For the UNILAC a stripper section [12] was redesigned and installed in 1999 (Fig. 1). Charge separation and beam transport under highest space charge conditions and multi beam operation with pulsed magnets was established. A supersonic N_2-gas jet produced by a Laval nozzle crosses the ion beam in the central interaction region of the gas stripper chamber. Two sections of differential pumping upstream and downstream of the central region are pumped by four powerful turbo pumps (pumping speed 1200 l/s). The charge separator

PUMPING PROPERTIES OF CRYOGENIC SURFACES IN SIS100*

L. Bozyk, GSI, Darmstadt, Germany†
F. Chill, IAP, Frankfurt am Main, Germany,
O. Kester, IAP, Frankfurt am Main, Germany, GSI, Darmstadt, Germany,
P. Spiller, GSI, Darmstadt, Germany

Abstract

The synchrotron SIS100 of the planned FAIR facility will provide heavy ion beams of highest intensities. The required low charge states are subject to enhanced charge exchange processes in collisions with residual gas molecules. Therefore, highest vacuum quality is crucial for a reliable operation and minimal beam loss. The generation of the required low gas densities relies on the pumping capabilities of the cryogenic beam pipe walls. Most typical gas components in ultra high vacuum are bound by cryocondensation at LHe temperatures, resulting in ultimate low pressures with almost infinite pumping capacity. Hydrogen can not be cryconden-sated to acceptable low pressures. But if the surface coverage is sufficiently low, it can get bound by cryoadsorption. The pumping capabilities of cryogenic walls for Hydrogen have been investigated for SIS100-like conditions. The measurement results have been used in dynamic vacuum simulations at heavy ion operation. The simulation results are presented.

EXPERIMENTAL SETUP

An experimental setup to measure the mean sojourn time and the sticking probability has been built at GSI. It consists of two parts: The warm part is made of an upper and a lower recipient, vacuum diagnostics, pumps, a defined vacuum conductance, a gate valve, and a gas inlet. The cold part consists of a cryogenic vacuum chamber inside a cryostat, which is cooled by a cryocooler, type RDK-408E2 by Sumitomo. This chamber is connected to the warm part via a cold-warm-transition (CWT), which minimizes the heat load onto the cryogenic system while providing a maximal vacuum conductance. The cold chamber is coated with copper on the outside, resulting in a homogeneous temperature distribution. The whole vacuum system can be baked at 150 °C to reduce the background by outgasing of the chamber walls.

Design considerations and concepts of the measurements, as well as measurements with the warm part have been described in [1]. Figure 1 shows a sectional view of the whole test setup.

A minimal temperature of 7.2 K was reached on the vacuum chamber. Two calibrated temperature sensors (Lakeshore silicon diodes, type DT-670, typical sensor accuracy: ±12 mK) are mounted on the chamber, one close to the cryocooler, the other close to the cold-warm-transition. A difference of 190 mK is measured, i.e. the temperature of the cryogenic chamber is homogeneous within 200 mK. The reason for not reaching the expected 4.2 K is still under inves-

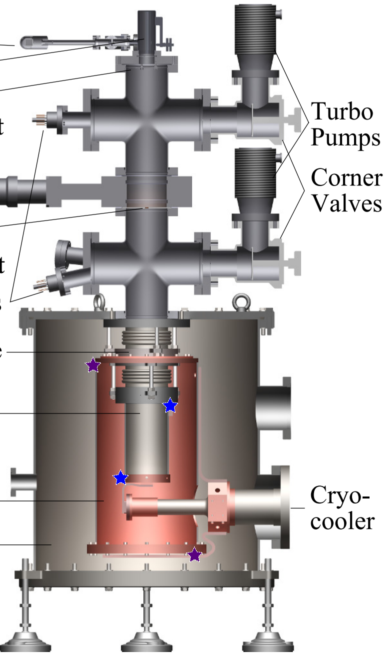

Figure 1: Sectional view of the experimental setup. Position of temperature sensors are marked with stars (blue: cryogenic vacuum chamber, purple: thermal shield).

tigation, a non-ideal connection to the cryocooler might be the reason. The thermal shield usually reaches a temperature of 36 K, measured with uncalibrated temperature sensors of the same type.

MEASUREMENTS OF CRYOGENIC PUMPING PROPERTIES

After evacuation of the UHV system, measurements are prepared by the following steps:

- Bakeout of the UHV system at 150 °C for about one week. Special care has to be taken to prevent damages by overheating of delicate components of the cold part. The cryocooler is removed during the bakeout. The cryostat is evacuated, the missing convection yields in a homogeneous temperature distribution.
- Cooldown to room temperature, meanwhile degassing of UHV diagnostics.
- Purging of the gas inlet system with hydrogen. Special care has to be taken to prevent the production of an explosive gas mixture in the exhaust system. The amount of gas in the gas pipes lasts for the whole measurements, the hydrogen bottle remains closed after purging.

SIMULATION AND EXPERIMENTAL INVESTIGATION OF HEAVY ION INDUCED DESORPTION FROM CRYOGENIC TARGETS*

Ch. Maurer†, D.H.H. Hoffmann, Institut für Kernphysik, TU Darmstadt, Germany
L.H.J. Bozyk, H. Kollmus, P.J. Spiller, GSI, Darmstadt, Germany

Abstract

Heavy-ion impact induced gas desorption is the key process that drives beam intensity limiting dynamic vacuum losses. Minimizing this effect, by providing low desorption yield surfaces, is an important issue for maintaining a stable ultra high vacuum during operation with medium charge state heavy ions. For room temperature targets, investigations show a scaling of the desorption yield with the beam's near-surface electronic energy loss, i.e. a decrease with increasing energy [1, 2]. An optimized material for a room temperature ion-catcher has been found. But for the planned superconducting heavy-ion synchrotron SIS100 at the FAIR accelerator complex, the ion catcher system has to work in a cryogenic environment. Desorption measurements with the prototype cryocatcher for SIS100 showed an unexpected energy scaling [3], which needs to be explained. Understanding this scaling might lead to a better suited choice of material, resulting in a lower desorption yield. Here, new experimental results will be presented along with insights gained from gas dynamics simulations.

MEASUREMENT OF CRYOGENIC DESORPTION

In this experiment, a cryogenic target is placed in a UHV environment and cooled by a coldhead. After the impact of a heavy ion beam, the resulting pressure evolution is measured. In combination with the beam intensity, a desorption yield η is calculated. It is defined as the number of desorbed gas particles divided by the number of impacting beam ions. A detailed description of the measurement setup can be found in [4].

While the beam's intensity can be measured with a beam current transformer, identifying the number of desorbed particles is more difficult. Up to now, the ideal gas law was employed to calculate this number by using the measured peak pressure after beam impact in a defined volume. A gas dynamics simulation can improve the analysis.

Another improvement compared to [4] is the extended range of experimental parameters, especially regarding the target. The target assembly is connected to a coldhead to facilitate a cryogenic environment and incorporates an optional thermal shield. Electrical insulation of the target is necessary to measure the ion current caused by the beam impact. It is achieved through a nonconducting tile, which unfortunately also limits the heat flow towards the coldhead. First results, obtained with a U^{73+} beam, an Al_2O_3-ceramic insulation plate, and a target made from gold coated copper have already been presented. Further experiments were conducted with a target made from uncoated stainless steel, but also without a thermal shield. In a later experiment, a Bi^{68+}-beam was used with the copper target and a thermal shield.

NEW EXPERIMENTAL RESULTS

Changing the target materials introduces several variations into the experiment. A modification in thermal conductivity leads to a shift of the thermal equilibrium between external heat load and heat transfer towards the coldhead. Thus, the lowest achievable temperature T_{min} rises when exchanging the copper target with a stainless steel target because copper has a higher thermal conductivity than steel.

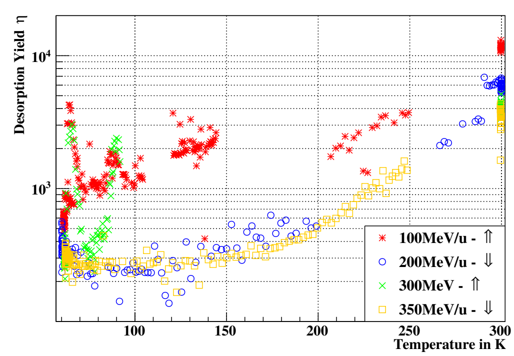

Figure 1: Temperature dependant desorption yield η for a U^{73+}-beam on a steel target.

The first modification was performed by exchanging the copper target with a stainless steel target. The results from this experiment are presented in Figs. 1 and 2.

The desorption yield decreases by an order of magnitude between room temperature and 100 K. The previously encountered desorption peak around 50 K can be found again when measuring with a deactivated coldhead on a rising temperature slope. After reaching room temperature, η again scales with $(\mathrm{d}E/\mathrm{d}x)^2$. Furthermore, a comparison of the absolute room temperature values with [1] and [3] shows a discrepancy by two orders of magnitude. The much higher η measured here might be a result of the milder bakeout process that had to be employed to protect the coldhead. Furthermore, the η measured with the copper target is twice as high as the η measured for the steel target at room temperature. This contradicts previous findings.

For cryogenic temperatures, the $(\mathrm{d}E/\mathrm{d}x)^2$ scaling can also be observed while the previously encountered, well

STATUS OF THE FAIR PROTON LINAC

R. Brodhage, W. Vinzenz, M. Vossberg, M. Kaiser, GSI, Darmstadt, Germany
U. Ratzinger, IAP, Universität Frankfurt, Germany

Abstract

For the research program with cooled antiprotons at FAIR a dedicated 70 MeV, 70 mA proton injector is required. The main acceleration of this room temperature linac will be provided by six CH cavities operated at 325 MHz. Within the last years, the assembly and tuning of the first power prototype was finished. The cavity was tested with a preliminary aluminum drift tube structure, which was used for precise frequency and field tuning. Afterwards, the final drift tube structure has been welded inside the main tanks and the galvanic copper plating has taken place at GSI workshops. This paper will report on the recent advances with the prototype as well as on the current status of the overall p-Linac project.

INTRODUCTION

The proton linac for FAIR is mechanically grouped in two sections, each having a length of about 9 m. Based on the actual design the first section will consist of 3 coupled CH-cavities. Between both sections there will be a diagnostics area with a rebuncher for longitudinal beam matching. Investigations have shown that a simplified layout of the 2nd section of the proton linac will be an improvement. Therefore, three simple CH cavities without a coupling cell will be used, reducing the triplet lens number by three and simplifying the layout and tuning of the cavities a lot.

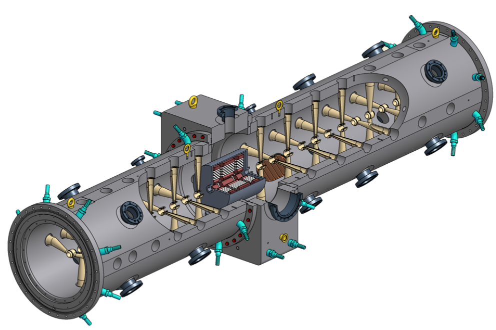

Figure 1: 3D-view of the coupled prototype cavity.

THE COUPLED PROTOTYPE CAVITY

Figure 1 shows the prototype cavity which corresponds to the second coupled cavity within the first section. The low energy part consists of 13 gaps, followed by the coupling cell and by the 14 gap high energy part. The whole cavity has an inner length of about 2.8 m and the cylindrical tanks have an inner diameter of about 360 mm. The coupling cell has a length of about $2\beta\lambda$ and hosts the focusing triplet lens within one large drift tube. The inter cavity tanks will also house triplet lenses and some beam diagnostics additionally (4 knob phase probes). They mechanically connect and support the neighbored cavities.

Table 1: Parameters of the Coupled CH Prototype Cavity

No. of gaps	13 + 14 = 27
Frequency [MHz]	325.2
Energy range [MeV]	11.7 - 24.3
Beam loading [kW]	882.6
Heat loss [MW]	1.35
Total power [MW]	2.2
Q_0-value	15300
Eff. shunt impedance [$M\Omega/m$]	60
Average $E_0T[MV/m]$	6.4 - 5.8
Kilpatrick factor	2.0
Coupling constant [%]	0.3
Aperture [mm]	20
Total inner length [mm]	2800
Inner diameter [mm]	360 / 434 / 364

Table 1 shows the main parameters of the prototype cavity. The prototype arrived at GSI in late 2013 and was prepared for galvanic copper plating. Unfortunately the plating process on long cavities with a complex inner structure is not trivial. Therefore lots of tests and investigations have been performed to realize a suitable copper layer. Figure 2 shows the final result after gavanic plating and polishing.

Figure 2: Picture of the copper plated inner surface of CH 3

This cavity is presently at the p-Linac RF test stand and is assembled with all tuners and the triplet lens. The first low level measurements were already performed and show a good accordance with theory and previous results. Copper plating and welding have not effected the performance and tolerances of the prototype. Further investigations and perturbation measurements of the field distribution will be performed within the next weeks.

STATUS OF THE HIGH ENERGY BEAM TRANSPORT SYSTEM FOR FAIR

F. Hagenbuck*, L. Bozyk, S. Damjanovic, A. Krämer, B. Merk, C. Mühle, S. Ratschow,
B.R. Schlei, P.J. Spiller, B. Walasek-Höhne, H. Welker, C. Will
GSI, Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany

Abstract

The overall layout of the High Energy Beam Transport (HEBT) System of the Facility for Antiproton and Ion Research (FAIR) [1] did not change since its last presentation in 2008 [2]. All necessitated adaptions as for example due to the introduction of the Modularized Start Version (MSV, module 0-3) of FAIR [3] could be smoothly implemented. In the meanwhile the HEBT system is in its realisation phase with the procurement of its main components in progress.

In the following adaptions of the system layout not yet covered in [2] are summarized and an overview of the technical system design and procurement status are presented.

ADAPTIONS OF THE HEBT SYSTEM LAYOUT

Since its last presentation in 2008 [2] it has been confirmed several times that the HEBT system will be able to fulfill all requirements imposed on it. A new direct connection from SIS18 to the CR was included into the HEBT system without difficulties. For this the section TSN1 was modified in a way that the beam coming from SIS18 can be either injected straight via TSR1 into the end part of the Super-FRS ring branch (which is connected to the CR via the sections TFC1 and TCR1) or guided directly to the NESR as before via TSN2, see Fig. 1, 2. The new connection to the CR was included into the planning of the MSV, whereas the beam line to the NESR belongs to module 6. Modifications in the building planning were not required.

The RESR is not part of the MSV. As mitigating measure the transfer line to the HESR starts now at the CR (THS1) which could be implemented smoothly. After RESR is built in module 5, THS1 will be removed and replaced by a new transfer line from CR to RESR and a new beam line from RESR to HESR (TRH1). All components from the transfer line from CR to HESR can be reused for the connection from RESR to HESR. Dipole magnets will be operated with different bending angles by means of field adaption, merely their vacuum chambers have to be replaced.

Plasma physics (PP) and atomic physics (AP) experiments will share a common building (APPA building), which replaces the former PP and AP caves and will contain two beam lines. The eastern beam line, see Fig. 1, serves atomic physics, biophysics and material research experiments, the western beam line plasma physics experiments. As before the PP beam line provides the option for a perpendicular beam from SIS18 onto the same target.

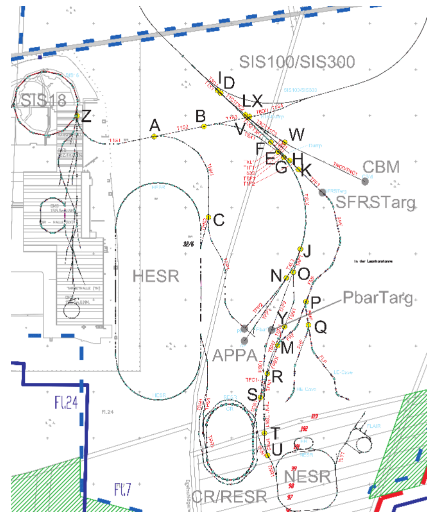

Figure 1: Top view of the beam line topology of FAIR (module 0-6).

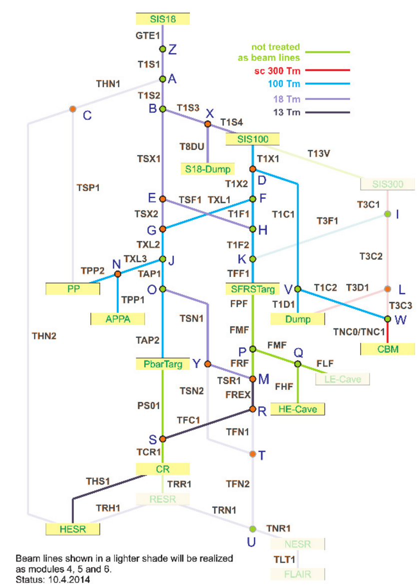

Figure 2: Beam line connection scheme.

The Super-FRS ring branch is not in line with the end of the Antiproton separator. The offset will be carried out now by use of in total four (module 0-6) dipole magnets similar to the ones used in the CR (different bending angle), which allows to use syneregies in magnet production, instead of two dipole magnets at two different bending angles, which turned out to be unpractical because their good field region

UNILAC PROTON INJECTOR OPERATION FOR FAIR

M. Heilmann*[1], A. Adonin[1], S. Appel[1], W. Barth[1,2], P. Gerhard[1], F. Heymach[1], R. Hollinger[1], W. Vinzenz[1], H. Vormann[1], and S. Yaramyshev[1]

Abstract

The pbar physics program at the Facility for Antiproton and Ion Research (FAIR) requires a high number of cooled pbars per hour [1]. The FAIR proton injector with coupled CH-cavities will provide for a high intensity (35 mA) pulsed 70 MeV proton beam at a repetition rate of 4 Hz [2, 3]. The recent heavy ion UNIversal Linear ACcelerator (UNILAC) at GSI is able to deliver proton as well as heavy ion beams for injection into the FAIR-synchrotrons. Recently GSI UNILAC could provide for a two orders of magnitude higher proton beam current in routine operation. A hydrocarbon beam (CH_3) from the MUCIS ion source [4] was accelerated inside the High Current Injector (HSI) and cracked in a supersonic nitrogen gas jet [5] into stripped protons and carbon ions. A new proton beam intensities record (3 mA) could be achieved during machine experiments in October 2014. Potentially up to 25% of the FAIR proton beam performance is achievable at a maximum UNILAC beam energy of 20 MeV and a maximum repetition rate of 2.7 Hz. The UNILAC can be used as a high performance proton injector for initial FAIR-commissioning and as a redundant option for the first FAIR-experiments [6].

INTRODUCTION

Two ion source terminals (PIG, MUCIS and MEVVA) deliver beam to a 36 MHz IH-RFQ and two IH-DTLs (up to 1.4 MeV/u). After acceleration the gas stripper and charge state separation four Alvarez DTL provide for end energies of 11.4 MeV/u; the eight installed Single Gap Resonators [7] could be used for energy fine adjustment. In the transfer line (TK) to the synchrotron SIS 18 [8, 9] a foil stripper and a second charge separator can be used.

The new FAIR proton linac delivers a high intensity proton beam with an energy of 70 MeV and a pulse current of up to 70 mA for injection into the SIS 18. The p-LINAC comprises of three new coupled CH-cavities with a compact and efficient design. The p-LINAC is connected to the TK (Fig. 1) by two 45 degree dipole magnets.

The first part of this machine experiment with the optimized mass spectrum (MUCIS), the gas stripper spectrum (HSI), emittance measurements and brillance for CH_3^+-operation are presented in [6].

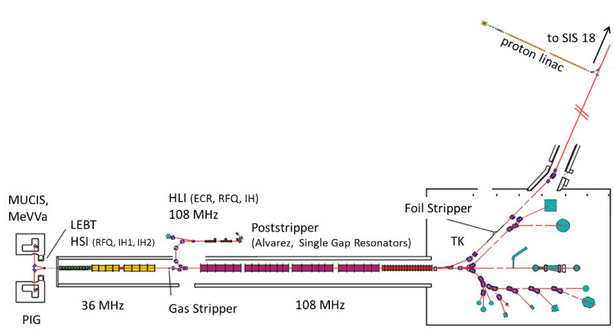

Figure 1: Schematic overview of the GSI UNILAC and FAIR proton linac.

RF CONTROL OPTIMIZATION

The proton acceleration with the current UNILAC implicates an optimization of the RF power control settings. The handling of low signal levels and in particular of the low level RF part (amplitude and phase control) is outside the predicable range of 100 kW up to 2 MW. The output power for the Alvarez tank (A3) is approximately 21 kW. The cavity voltage optimisation of a constant gap voltage (flat top) for the A3 (Fig. 2) was ensured with an adjustment of the rise time settings. While the beam pulse is passing the cavity, a flat top of the cavity voltage is required. The loop gain into to cavity has been optimized to increase up to a non-risky level.

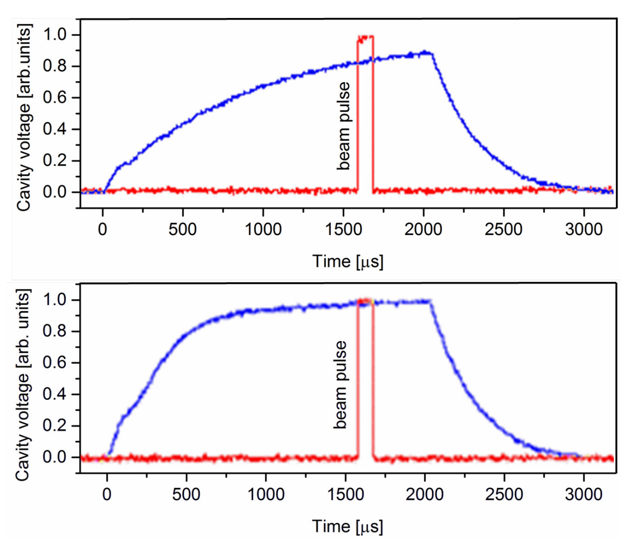

Figure 2: Shape of the cavity voltage before (top) and after (bottom) optimisation.

325 MHz HIGH POWER RF COUPLER FOR THE CH-CAVITIES OF THE FAIR p-LINAC

F. Maimone, R. Brodhage, M. Kaiser, W. Vinzenz, M. Vossberg
GSI, Planckstraße 1, 64291 Darmstadt, Germany

Abstract

In order to supply the input RF power to the Cross-bar H-mode (CH) cavities of the p-LINAC for FAIR an inductive RF coupler has been studied. The designed RF coupler, and its water cooled inductive loop, has to withstand up to a 3 MW pulsed power (at 325 MHz). At GSI a prototype has been manufactured and tests were performed. The prototype of the designed high power RF coupler is presented together with the results of the coupling measurements at the CH-prototype cavity.

INTRODUCTION

The Facility for Antiproton and Ion Research (FAIR) requires an intense proton beam at 70 MeV serving the SIS18. For this purpose a dedicated proton LINAC has been designed and will be produced by GSI. The room temperature DTL of the p-LINAC is composed by three coupled CH cavities, providing the acceleration up to 35 MeV, followed by three single CH cavities [1].

A prototype of the coupled CH cavity corresponding to the second accelerating unit, from 11.5 MeV to 24.2 MeV, has been manufactured, assembled and recently copper plated successfully at the GSI galvanic workshop [2-3]. The layout of the coupling cell for the coupled CH structures is designed to let it oscillate in an Alvarez E-mode at the same resonance frequency as the H-mode of the CH-cavities. In order to realize the coupling between the 6 1/8" coaxial line and the coupled CH-cavity, an inductive coupler has been studied. The advantage of an inductive coupler is the possibility to tune the coupling factor by rotating the loop inside the coupling cell. The design of the coupler inserted inside the coupling cell of the prototype of the CH cavity is shown in Figure 1. In the figure the coupler is oriented at 0° and the coupler area is perpendicular to the magnetic field lines.

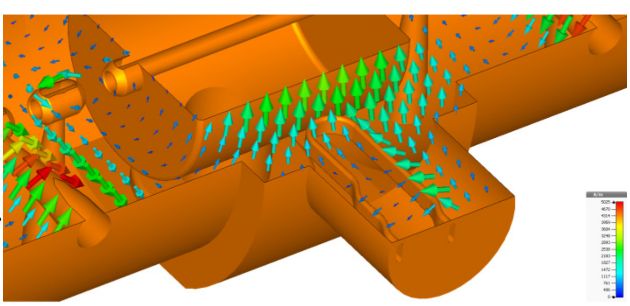

Figure 1: 3D-cut of the coupling cell of the second coupled CH cavity of the p-LINAC.

A prototype of the designed coupler has been assembled and tested. The mechanical construction steps of the prototype of the RF coupler are shown together with measurement results of the coupling to the coupled CH cavity.

INDUCTIVE COUPLER RF DESIGN

At GSI several inductive couplers are used for the UNILAC cavities at different frequencies (i.e. 36, 108 and 216 MHz) and also in other accelerator facilities (i.e. CERN Linac3, Heidelberg (HIT), Padova (CNAO) and at BNL). This design can be adapted to RFQs, IHs, Alvarez, Spirals and CH cavities covering a power range from some tens of kW up to 2 MW power (max 25% duty factor). Therefore a big number of flange-oriented types with respect to the dimensions of the used RF power lines can be realized [4]. The application of this type of coupler to the second coupled CH cavity of the p-LINAC has been studied with CST Microwave Studio. The coupling factor and the electromagnetic properties of the RF coupler insertion and rotation inside the coupling cell have been analysed for different effective loop areas [5]. However, the analysed solutions were not optimized to be used with a beam load. To take the cavity´s beam loading into account, the conventional parameter $\beta=Q_o/Q_{ext}$ has to be modified to include the contribution of the absorbed power by the beam:

$$\beta_{beam} = 1 + \frac{P_b}{P_{losses}} \tag{1}$$

Where P_{losses} is the average power dissipation at the cavity walls and P_b is the averagedelivered power to the beam as a function of the beam current [6]. For this reason the area of the loop was increased to enhance the coupling factor. Figure 2 shows the design of the inductive loop. The shape of the loop has been adopted in order to reduce the electric field between the coupler and the flange walls.

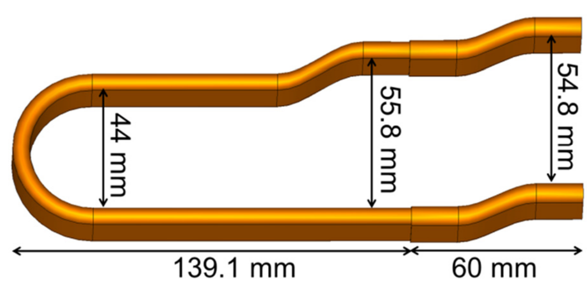

Figure 2: Inductive loop coupler.

STATUS OF THE FAIR HEAVY ION SYNCHROTRON PROJECT SIS100

P. Spiller, U. Blell, L. Bozyk, J. Ceballos Velasco, T. Eisel, E. Fischer, O. Kester, H.G. König, H. Kollmus, V. Kornilov, P. Kowina, J.P. Meier, A. Mierau, C. Mühle, C. Omet, D. Ondreka, N. Pyka, H. Ramakers, P. Rottländer, C. Roux, P. Schnizer, S. Wilfert
GSI, Darmstadt, Germany

Abstract

SIS100 is the main accelerator of the FAIR project. It is a worldwide unique heavy ion synchrotron dedicated to accelerate highest intensities of intermediate charge state heavy ion- and proton beams up to 100 Tm. From the technical point of view, most challenging issues are the fast ramped superconducting magnets and the acceleration of intense, intermediate charge state heavy ions beams. The latter required a unique lattice design (charge separator lattice) in combination with an ultra-high vacuum system based on distributed cryo-pumping with actively cooled magnet chambers, adsorption pumps and dedicated cryo-catchers for local suppression of gas desorption [1].

PROCUREMENT STATUS

The year 2014 was very much focused on completing, reviewing and finishing specifications and drawings for all kind of components. Finally, at the end of 2014, all contracts for the most demanding SIS100 components, the large series of superconducting magnets and RF systems, have been closed, which marks a major milestone in the project execution. This milestone corresponds to a bound value of about 50% of the SIS100 cost-book value. The last large in-kind contract regarding the quadrupole unit production has been successfully negotiated and closed with the Joint Institute for Nuclear Research (JINR, Dubna, Russia) and signed by the JINR, GSI and FAIR management at an official ceremony at JINR at 2015/02/20. This contract is accompanied by a number of contracts between GSI and JINR on quality assurance and magnet testing. Besides the major series with long production times, many other components have been tendered or contracted, e.g. the injection kicker system, the resonance sextupole magnets (awarded to DANFYSIK, Denmark) and the cryo-catcher system. The local cryogenics system will be delivered by the Wroclaw University of Technology (WrUT, Poland). The manufacturing design review for the first bypass line segment has been passed. The manufacturing design and preparation has been approved and the contract for the production of the bypass line has been awarded to the company KRIOSYSTEM, Poland.

BUILDING PLANNING

Detailed planning for the accelerator tunnel and the supply area (K0923A/T110) complex, including 3D DMU models of the accelerator and its technical infrastructure, has matured and is transitioning to execution planning, which will take place in 2015, see Figure 1. This will allow the finalization of the necessary building tendering documents and the start of the excavation in late 2015.

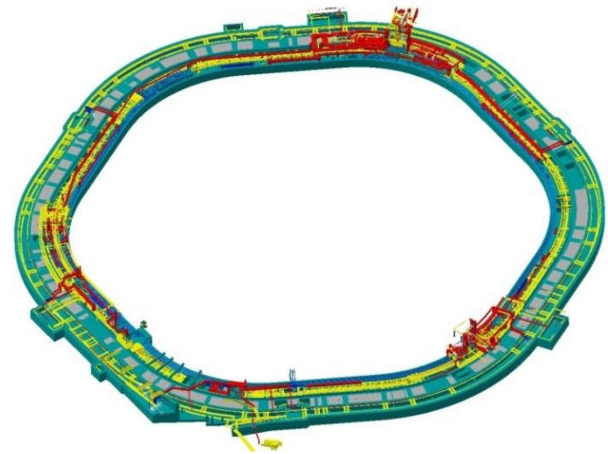

Figure 1: Design of T110, including the accelerator tunnel (outer tunnel) and the parallel supply tunnel (inner tunnel) with cable trays (yellow), cooling water supply lines (blue) and venting (red).

PROGRESS ON COMPONENT TENDERING AND DELIVERY

The first of the 109 superferric, 1.9 T dipole series magnets (FoS) [2] has already been delivered in June 2013 (Figure 2) and thoroughly tested under warm and cryogenic conditions. Although, the FoS dipole magnet has different to the previous prototype magnets, a completely new coil design and is operated at twice the electrical current, the quench training showed excellent behaviour. Nevertheless, the desired high beam currents allow only minimum mechanical errors in the series production of the yoke. Therefore, together with the manufacturer and the support by external experts, the production and welding process has been review and optimized. Meanwhile, significant progress in minimizing the deformation of the half yoke (before assembly) could be demonstrated by using a robot based laser welding. A new, mechanically further improved FoS yoke, providing the confidence in a high mechanical reproducibility of the series, will be produced and delivered until Q3/2015. In the frame of the side acceptance test of the FoS dipole, a number of precision measurement devices and technique could be developed, e.g. for high precision measurement of the inner magnet aperture (height, parallelism of pole surfaces, sag etc.), such that it will be able to release the

DESIGN STUDIES FOR THE PROTON-LINAC RFQ FOR FAIR

M. Vossberg, R. Brodhage, M. Kaiser, F. Maimone, W. Vinzenz, S. Yaramyshev,
GSI, Darmstadt, Germany

Abstract

The planned 27 m long Proton-Linac (p-Linac) for FAIR (Facility for Antiproton and Ion Research) comprises a RFQ (Radio-Frequency Quadrupole) and six crossbar H-Mode cavities to accelerate a 70 mA proton beam up to 70 MeV. The FAIR Proton-Linac starts with a 325.2 MHz, from 95 keV to 3 MeV RFQ accelerator. The main RFQ for this Proton-Linac will be a 4-Vane type RFQ. RF analytics with varying and constant transverse focusing strength for the electrode parameters will be used. CST MWS (Microwave Studio) [1] simulations will help to find cavity parameters for the working frequency. This paper presents the main cavity design concepts and simulation results.

INTRODUCTION

A new international accelerator-based science center (FAIR) will be built in the near future at GSI, Germany [2, 3]. The FAIR facility is designed to provide antiproton and ion beams of worldwide unique intensity and quality for fundamental physics research.

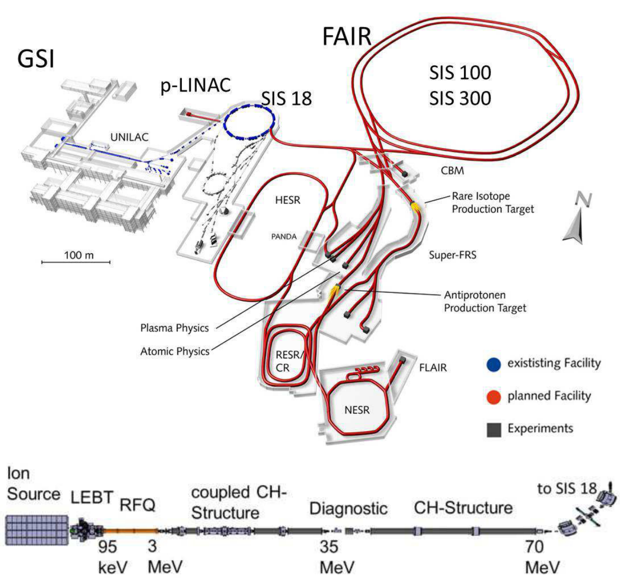

Figure 1: Layout of the FAIR facility and overview of the Proton-Linac.

Fig. 1 shows the planned Proton-Linac which is adjacent to the existing UNILAC. Both Linacs are injectors of the SIS 18 synchrotron, which delivers the SIS 100, the central accelerator component of FAIR. The Proton-Linac will mainly consist of an RFQ accelerator and two 9 m sections of Cross Bar H-Mode accelerators (CH structures) working at a frequency of 325.224 MHz. In the first section, there will be six CH cavities, which are pairwise RF-coupled. The second section consists of three separate long CH cavities. Each of those six cavities has its own klystron. It is required to provide a 70 MeV proton beam with a beam current up to 70 mA at a macro pulse length of 36 µs and a bunch length of 100 ps [4, 5]. The planned RFQ is between 3.2 m and 3.5 m long and will have an input energy W_{in} of 95 keV. After the acceleration in the RFQ the output energy W_{out} will be 3 MeV.

RFQ DESIGN STUDIES

One of the most important parameter for an RFQ design is the maximum electric field on the RFQ electrode surface. A high field is necessary for a reasonable and improved performance of the structure, but also a reliable and stable operation of the machine has a high priority [6]. The ongoing GSI Proton-Linac project requires such calculations for increased reliability.

Table 1: Design Requirements for the Proton-Linac RFQ for FAIR

Particle	proton (H^+)
Frequency	325.224 MHz
Input energy W_{in}	95 keV
Output energy W_{out}	3.0 MeV
Beam current (design)	70 mA
Length	> 3.2 m < 3.5 m
Kilpatrick factor	≤ 1.87
Rep. rate	≤ 4 Hz
Aperture (min)	≈ 2.2 mm
Modulation (max)	≈ 2
Average distance to beam	≈ 3.3 mm

The current design parameters for the Proton-Linac RFQ are listed in Table 1 [10]. These parameters are necessary for the beam dynamics design. For the RF-structure, a 4-Vane-RFQ is chosen [3]. The cavity geometry will be designed with the main parameters like aperture, modulation, frequency and the length of this cavity.

SIMULATION STUDIES OF PLASMA-BASED CHARGE STRIPPERS

O. S. Haas*, TEMF TU-Darmstadt, Darmstadt, Germany
O. Boine-Frankenheim, TEMF TU-Darmstadt, Darmstadt, Germany, and GSI, Darmstadt, Germany

Abstract

Calculations on the charge state distributions in different charge stripping media are presented. The main focus of this work is the width and peak efficiency of the final charge state distribution. For equal number densities fully-stripped plasma stripping media achieve much higher charge states than gas stripping media of the same nuclear charge. This is due to the reduced electron capture rates of free target electrons compared to bound target electrons. Furthermore, targets with low nuclear charge like hydrogen achieve higher charge states than targets with high nuclear charge like nitrogen in the case of both a plasma and a gas target. Equal final mean charge states can thus be achieved with lower density for plasmas and targets with low nuclear charge. The widths of the charge state distributions are very similar, slightly smaller for plasmas due to the different scaling of the dielectronic recombination rate. In comparison with calculations and measurements published in literature this work underestimates the width of targets with higher nuclear charge like, e.g., nitrogen gas. This is mainly due to the omission of multiple loss processes in the presented calculations. In the future we intend to expand the methods and models used in this work to improve the agreement with different measurements on charge state distributions in plasmas and gases.

INTRODUCTION

Charge stripping of heavy ion beams at high intensities is a major challenge in current and future facilities with high intensity heavy ion beams. Conventional stripping techniques are often limited in their applicability, e.g. solid carbon foils suffer from short lifetimes at high intensities and common gas strippers usually achieve only low charge states. One possible alternative is the use of a plasma as a stripping medium. The presented work focuses on theoretical studies of the interaction of an heavy ion beam with a plasma and gases and accompanying effects in possible charge strippers. The main interest in the presented studies is the final charge state distribution of the ion beam, which determines the efficiency of the charge stripper as an accelerator component.

BASICS

The main focus of this work is on the charge state distribution or $F_q(t_{\text{eq}})$, where the latter is the relative fraction of the beam in charge state q at time t. The beam loses or captures electrons in several different processes with rates

$$\alpha_{q(q\pm n)}(q) = v_{\text{r}} n_{\text{t}} \sigma_{q(q\pm n)}(q) \,, \tag{1}$$

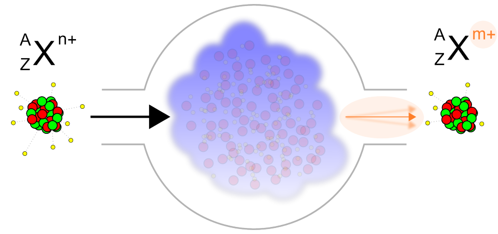

Figure 1: Sketch of a projectile getting stripped by a target.

where v_{r} is the relative velocity of projectile and target, n_{t} is the target density and $\sigma_{q(q\pm n)}(q)$ are the loss and capture cross sections. For every given beam energy the charge state distribution tends to an equilibrium. In the case of negligible multiple loss and capture rates the mean equilibrium charge q_{eq} is then given by

$$\alpha_{q(q+1)}(q_{\text{eq}}) = \alpha_{q(q-1)}(q_{\text{eq}}) \,. \tag{2}$$

Furthermore the rates can be approximated as $\alpha_{q(q\pm1)} \propto \exp(b_i(q - q_{\text{eq}}))$, leading to a Gaussian equilibrium charge state distribution with variance

$$\sigma^2_{q_{\text{eq}}} = \left(\left| \frac{\alpha'_{q(q+1)}(q_{\text{eq}})}{\alpha_{q(q+1)}(q_{\text{eq}})} \right| + \left| \frac{\alpha'_{q(q-1)}(q_{\text{eq}})}{\alpha_{q(q-1)}(q_{\text{eq}})} \right| \right)^{-1} \,, \tag{3}$$

where the prime denotes the derivative in respect to q. The peak efficiency is then given by $F_{q_{\text{eq}}}(t_{\text{eq}}) \approx 1/\left(\sigma_{q_{\text{eq}}}\sqrt{2\pi}\right)$. It should be noted that Eq. (3) implies that the width of the equilibrium charge state distribution does not depend on the absolute value of the rate, but on the scaling with the projectile charge q.

While the approximations above are useful for the discussions in this work, actual results in the presented work are calculated by solving the rate equations for the charge state evolution

$$\frac{\mathrm{d}F_q(t)}{\mathrm{d}t} = \sum_{q'} F_{q'}(t)\alpha_{q'q} - F_q(t) \sum_{q'} \alpha_{qq'} \,. \tag{4}$$

The system can be solved with a standard solver for differential equations, a Monte Carlo method or a matrix method (see Ref. [1]). The models used for the calculations of the rates are mostly summarized in Ref. [2] (which only includes single electron loss and capture) if not mentioned otherwise.

EQUAL DENSITY

As the basis of the theoretical discussion examples with parameters relevant for the GSI Unilac (see, e.g., Ref. [3]) are chosen. We assume an uranium projectile with energy $E = 1.4\,\text{MeV/u}$ in a fully-stripped hydrogen plasma and hydrogen, helium and nitrogen gas. For now the calculations

STATUS AND FIRST MEASUREMENT RESULTS FOR A HIGH GRADIENT CH-CAVITY *

Ali M. Almomani# and Ulrich Ratzinger, IAP, Frankfurt University, Germany

Abstract

The pulsed linac activity aims on compact designs and on a considerable increase of the voltage gain per meter. A high gradient CH – cavity operated at 325 MHz was developed and successfully built at IAP – Frankfurt. The mean effective accelerating field for this cavity is about 13.3 MV/m at β = 0.164. The results might influence the rebuilt and a later energy upgrade of the UNILAC – Alvarez section. Another motivation is the development of an efficient pulsed ion accelerator for significantly higher energies like 60 AMeV. The new GSI 3 MW Thales klystron test stand will be used for the cavity RF power tests. Detailed studies on two different types of copper plating can be performed on this cavity. The first measurement results of the frequency and the on axis electric field for this cavity will be presented.

INTRODUCTION

Conventional DTL's are limited in maximum field gain by thick walled drift tubes which are housing the focusing elements. Such geometries cause bigger parallel surfaces around the gaps which are loaded by high electric field levels. This leads to an increase of the stored field energies as well as the risk of spark damages on the cavity surfaces. Consequently, this results in reduced operable field levels.

Separated function DTL technology and strategies for a minimization of the consequences from transverse rf defocusing have been developed during the last decades of heavy ion linac development.

On the other hand, the combination between slim drift tubes and KONUS beam dynamics, in H – mode cavities allows to increase the effective field gain well above 10 MV/m. This has been tested successfully at CERN Linac 3, where the field gradient reached 10.7 MV/m at 1 ms pulse length and at low beam energy [1].

H – mode cavities profit very much from slim drift tubes (see Fig. 1), as they concentrate the electric field on the drift tube structure. Thus, the stored energy is reduced efficiently by a small outer drift tube diameter, reducing surface damages in case of sparking.

The development of CH – cavities towards a high field gradient [2-4] will be the main topic of this paper.

This aspect is important for cases, where a compact linac for low duty factor applications is needed. Also, for high current operation the high field acceleration provides the needed longitudinal focusing forces.

One main motivation of this work is to prepare the rebuilt and a later energy upgrade of the UNILAC – Alvarez section. Another motivation is the development of an efficient and compact ion accelerator for significantly higher energies for facilities like medical hospitals where available space is quite limited.

CH – CAVITY FABRICATION

A high gradient, 7 gap CH – cavity has been developed and successfully built at IAP – Frankfurt and was fabricated at NTG, Gleisbau, Germany [2-5]. This cavity (Fig. 1) is expected to have a mean effective field gradient of about 13.3 MV/m at β = 0.164.

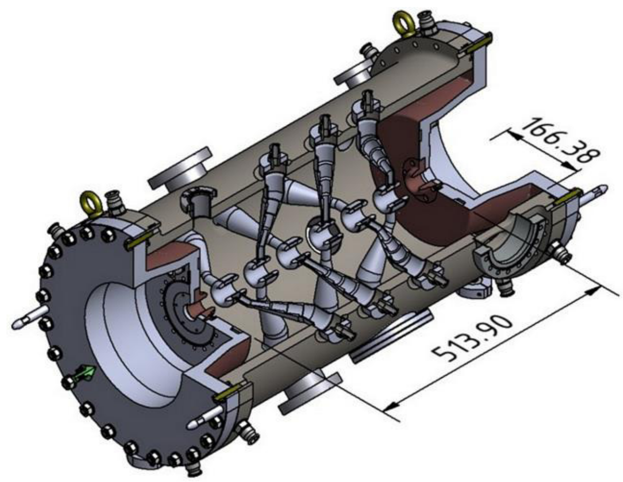

Figure 1: A 3D schematic view of the CH – cavity.

Table 1: Main Parameters of the High Field CH – cavity

Number of Gaps	7
Frequency (MHz)	325.2
Voltage Gain (MV)	6
Eff. Accel. Length (mm)	513.90
Mean eff. Accel. Field (MV/m)	13.3
Power Loss (MW)	1.76
Q_0 – value	12500
Effective Shunt impedance (MΩ/m)	52.15
Beam Aperture (mm)	27

The central part is a "monolithic" stainless steel element, where the drift tube structure was welded into a massive cylindrical tank. The drift tube stems with drift tubes are directly water cooled, the outer cylinder has eight cooling channels in longitudinal direction. The end plates have one cooling channel each, the quadrupole triplets will be positioned in the accessible outer volumes. Metal gaskets will be used at each bolted joint. Figure 2 shows the cavity tank, stems, end flanges and the massive drift tubes.

SURFACE ELECTRIC FIELD

The adaption of slim drift tubes for CH – cavity results in a very high sparking limit. The cavity geometry was

UPGRADE OF THE HSI-RFQ AT GSI TO FULFILL THE FAIR REQUIREMENTS

M. Baschke, H. Podlech
Institute for Applied Physics, Goethe University, Frankfurt am Main, Germany
Winfried Barth, GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany

Abstract

In Darmstadt/Germany the existing accelerator facility GSI is expanding to one of the biggest joint research projects worldwide: FAIR, a new antiproton and ion research facility with so far unmatched intensities and quality. The existing accelerators will be used as pre-accelerator and therefor need to be upgraded. In a first step the 36 MHz-HSI-RFQ for high current beams will obtain new electrodes to fulfill the FAIR requirements. First simulation results for capacity and multipole components will be presented.

INTRODUCTION

The existing HSI-RFQ is part of the linear accelerator UNILAC at GSI which has a length of 120 m and consists of the RFQ (up to 120 keV/u), two IH-DTL (up to 1.395 MeV/u), four Alvarez cavities (up to 11.4 MeV/u) and 15 shiftable single gap resonators [1].

The facility is expanding with the FAIR project to one of the biggest joint research projects worldwide. With the physics at FAIR questions of the evolution of the universe, the structure of matter and its constituent parts will be approached [2]. Therefor the existing cite should be used as pre-injector. To fulfill the requirements (i.e. a huge range of beam intensities and energies, highest beam quality) a lot of modifications and updates are needed.

The RFQ was built in 1996 [3] and modified in the past years. With the actual structure the emittance is too high for the following IH-DTL which leads to unwanted beam losses and a low brilliance. The planned upgrade of the electrodes should result an increase of the brilliance.

THE RFQ STRUCTURE

The RFQ is designed as an IH-RFQ, it has a length of nearly 10 m and consists of 10 modules with 10 stems each (see Fig. 1). The electrodes are mounted on rings where only two of them are at the same ring on one stem (like in every RFQ). To tune the RFQ and to get a better voltage distribution it is possible to change every single ring to vary the capacity by adding correction rings (see Fig. 2). The parameters for the existing RFQ are listed in Table 1 (where $\bar{A}$ is the average aperture to the beam axis along the complete electrodes).

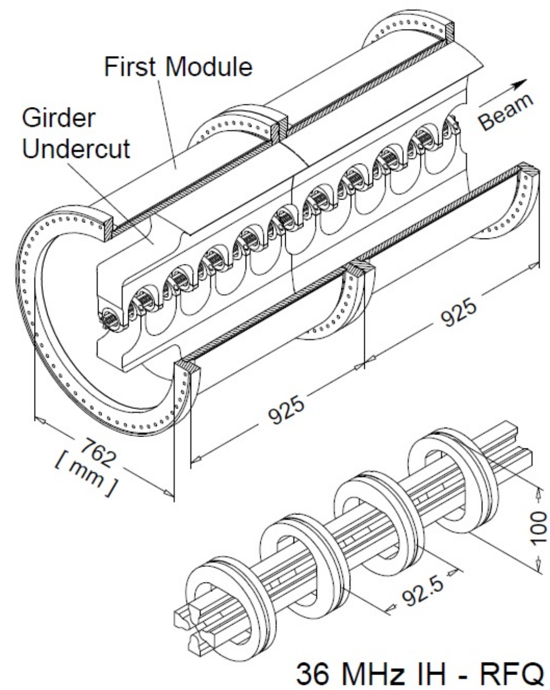

Figure 1: The IH-RFQ. [3]

Table 1: RFQ Parameters

parameter	value
$\bar{A}$	9.4 mm
R_0	4.2 mm
h	7 mm
L	14.8 mm

STRUCTURAL MECHANICAL AND RF MEASUREMENTS ON THE SUPERCONDUCTING 217 MHz CH CAVITY FOR THE CW DEMONSTRATOR AT GSI*

F. Dziuba[†,1], M. Amberg[1,3], K. Aulenbacher[3,4], W. Barth[2,3], M. Basten[1], M. Busch[1], H. Podlech[1], S. Mickat[2,3]

[4]KPH Mainz University, 55128 Mainz, Germany

Abstract

Together with the new horizontal cryomodule and two superconducting (sc) 9.5 T solenoids the sc 217 MHz Crossbar-H-mode (CH) cavity [1] represents the continuous wave (cw) demonstrator and brings sc rf technology to GSI. A reliable operability of the sc CH cavity is one major goal of the demonstrator project. Furthermore, the successful beam operation of the demonstrator will be a milestone on the way to a new sc cw linac at GSI for a competitive production of Super Heavy Elements (SHE) in the future. The production of the cryomodule and the solenoids is almost finished while the cavity has been completed except for the helium vessel. In this paper structural mechanical as well as related rf measurements on the sc 217 MHz CH cavity are presented.

INTRODUCTION

Currently, the production of the sc 217 MHz CH cavity [2] (see Fig. 1) for the cw demonstrator project is finished except for the titanium helium vessel. The cavity consists of 4 mm niobium sheets, has 15 equidistant arranged accelerating cells and a design gradient of 5.1 MV/m. It is equipped with nine static tuners, a 10 kW cw power coupler which is currently under development, several flanges for surface preparation and two fast frequency tuners. First performance tests of the cavity at 4 K with low rf power are expected in June 2015 at the Institute for Applied Physics (IAP), Frankfurt. As other sc cavities the 217 MHz CH structure is very susceptible to external influences like Lorentz-force detuning, microphonics or pressure variations as well. All caused mechanical deformations can change the resonance frequency of the cavity. Changes of the frequency due to evacuation and cooling down to 4 K have to be compensated by the static tuners during the respective production phase. Furthermore, the pressure sensitivity of the cavity is an important quantity regarding variations in the liquid helium bath as well as in the helium loop. These variations can be adjusted accordingly by the dynamic tuning system of the cavity [3]. Several rf measurements have been performed during each production step in order to adjust the cavity to its design frequency. Initially the frequency was designed higher than the operating frequency and lowered successively by reducing the end cap length and inserting static tuners. The following measurements have been performed before the last two remaining static tuners were welded into the cavity as the tuner ports were temporarily sealed with rings made from teflon.

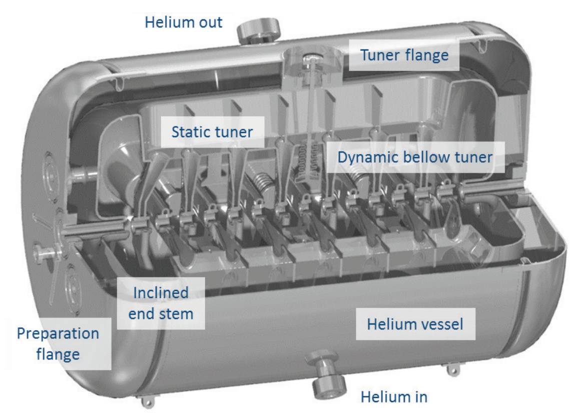

Figure 1: Layout of the sc 217 MHz CH cavity.

EVACUATION OF THE CAVITY

To study the cavity's resonance frequency change caused by evacuation and its pressure sensitivity, coupled structural - high frequency electromagnetic simulations [4] have been performed. For the analysis model the girders of the cavity were chosen as a fixed support while 1 bar pressure on the surface of the cavity walls was used as an applied load. These boundary conditions allow to simulate the mechanical behaviour of the self-supporting cavity during the evacuation process. The resulting deformations appear mainly at the central region of the cavity walls and at the end caps (see Fig. 2 top). As one can see, the results show that the maximum displacement at the end caps is around 0.23 mm while the deformation at the walls is about 0.17 mm. This leads to an increase of the resonance frequency and yields to a pressure sensitivity of 38 Hz/mbar. Additionally, the relative permittivity ϵ_r is decreasing during the evacuation pro-

DESIGN OF THE 325 MHz 4-ROD RFQ FOR THE FAIR PROTON LINAC*

B. Koubek†, H. Podlech, A. Schempp IAP,
Goethe University, Frankfurt, Germany

Abstract

Investigations on the 325 MHz 4-rod RFQ prototype for the FAIR proton linac have confirmed the feasibility of a 4-rod RFQ to work at frequencies above 300 MHz. This RFQ will accelerate protons from 95 keV to 3 MeV [1] within a length of 3.3 m and will be powered by a 2.5 MW klystron. The mechanical and rf design of this RFQ are presented in this paper.

325 MHz 4-ROD RFQ R & D

In simulations the dipole field, the fringe fields and higher order modes were investigated to find a solution for an rf design to fit a 4-rod RFQ to an operation frequency of 325 MHz. Based on this simulations a copper prototype was built and investigated as well. The results of the low level rf measurements confirmed the simulation work quite well and are presented in [2,3]. After the rf measurements the 6 stem prototype was power tested with 40 kW and a duty cycle of 0.3% that refers to a cw power of 400 W/m. At the FAIR project the 3.3 m RFQ will be powered at a duty cycle < 0.1% [4]. This tests have shown the feasability of the prototype to meet the FAIR requirements. Apart from this the input power was measured in comparison to the maximum electrodes voltage using gamma spectroscopy. From these measurements results the shunt impedance was determined and compared to other methods of determination of the shunt impedance to confirm their reliability. In summary these tests have demonstrated a working 325 MHz 4-rod RFQ without a dipole component that meets the FAIR requirements.

Challenges

Since higher frequencies refer to smaller dimensions of the resonant structure a 4-rod RFQ at 325 MHz becomes very small and sensitive with respect to parametric changes. This filigree and sensitive structure is very challenging for the engineering and requires very tight tolerances in manufacturing of every single part of the RFQ. In respect to rf this transversally small structure leads to a dipole component much stronger than at lower frequencies. In longitudinal direction the RFQ has a length above 3 m with approximately 60 rf cells. This leads to higher order modes in the region of the operation frequency that usually can be neglected at 4-rod RFQs. In addition this large number of rf cells makes the tuning procedure much more elaborate than usual.

ENGINEERING AND DESIGN

To reach a higher precision of the RFQ in the manufacturing process changes of the mechanical design, that worked very well over the last years on 4-rod RFQ at lower frequencies, were crucial. To reach a higher precision the idea was on the one hand to simplifiy all parts of the RFQ with respect to machining reasons and on the other hand to reduce the number of connected surfaces to increase the precision after assembly.

For example the stems and ground plate will be made of one piece of copper. This combination will be segmented in only few segments to form the support and resonant structure for the electrodes. To build this out of one or few pieces allow not only a higher precision in machining the surfaces that mount and connect the electrodes. In addition it provides also a better thermal and electrical connection of the single parts. Also the shape of the electrodes will be kept more simple to increase precision and stabillity of the filigree parts.

TUNING

General Tuning Process

In general the tuning of a 4-rod RFQ is an iterative process were a perturbance capacitor is placed on every single rf cell of the structure. From the frequency shift caused by this additive capacitance the longitudinal voltage distribution of the RFQ can be calculated. Then the tuning plates will be moved in such a way to minimize the longitudinal voltage deviation. This process has to be repeated several times to find a best match of the operating frequency and simultaneously a minimum longitudinal voltage deviation.

Additional to the large number of rf cells the frequency of 325 MHz causes a high sensitivity of the tuning plates that have to be placed very accurate (in sub millimeter range).

Simplification of the Tuning

In order to simplify and hence abbreviate the above mentioned process one can reduce the number of rf cells. This can be done by increasing the thickness of the stems but it only allows a limited reduction of the number of rf cells.

To reduce the sensitivity of the tuning plates the influence of plunger tuners instead has been investigated. While tuning plates change the inductivity of an rf cell by changing the length of the shortcut, plunger tuners are suppressing the field inside one rf cell. These kind of tuner have been used already as additional tuning possibilities at the FNAL RFQ [5]. Simulations of piston tuners have shown a strong reduction of the tuning range. The fact that the frequency is less sensitive on these plungers leads to a much higher precision of adjustment by keeping still enough frequency

MASSLESS BEAM SEPARATION SYSTEM FOR INTENSE ION BEAMS

O. Payir*, M. Droba, O. Meusel, D. Noll, U. Ratzinger, P. P. Schneider, C. Wiesner,
IAP, Goethe University, Frankfurt am Main, Germany

Abstract

The ExB chopper [1] in the Low Energy Beam Transport (LEBT) section of the accelerator-driven neutron source FRANZ [2] will form the required pulses with a repetition rate of 257 kHz out of the primary 120 keV, 50 mA DC proton beam. A following beam separation system will extract the deflected beam out of the beamline and minimize the thermal load by beam losses in the vacuum chamber. To further avoid an uncontrolled production of secondary particles, a novel massless septum system is designed for the beam separation.

The septum system consists of a static C-magnet with optimized pole shapes, which will extract the beam with minimal losses, and a magnetic shielding tube, which will shield the transmitted pulsed beam from the fringing field of the dipole. The magnetic field and the beam transport properties of the system were numerically investigated. A main deflection field of about 250 mT was achieved, whereas the fringing field was reduced to below 0.3 mT on the beam axis at 60 mm distance from the dipole. With this settings, the beam was numerically transported through the system with minimal emittance growth. Manufacturing of the septum system has started.

INTRODUCTION

The ExB chopper system in the LEBT section of FRANZ consists of a dipole magnet and a pulsed electric deflector. The fields are oriented in a Wien filter configuration. During the flat top of the HV pulse of the electric deflector, the electric deflection of the beam compensates the magnetic deflection and the beam is transmitted in forward direction. Between two deflector pulses, i.e. when the deflector voltage is zero, the beam is deflected about 10 ° by the dipole magnet. To minimize the energy deposition of the beam on the vacuum chamber walls without increasing the magnetic field on the beam axis, a following septum magnet is under construction. During the rise and fall of the deflector voltage pulse the beam sweeps between the full field region and the zero field region of the septum magnet and forms the required pulsed beam. To minimize secondary particle emission during the deflector pulses, the possibility of using a massless septum system was investigated [3]. The most promising design regarding longitudinal and transversal magnetic field distributions on the transmitted beam axis is shown in Fig. 1. Table 1 shows the current specifications.

The C-magnet is tilted 12 ° to match the deflection angle of the deflected beam and to further reduce the magnetic field on the transmitted beam axis. To minimize beam losses, the pole shoes were modified with additional fittings, so that the deflected beam is exposed longer to the maximum magnetic field in the gap. With this fittings the C-magnet will deflect the beam into a beam dump, while the shielding tube made of high permeable material (VACUFLUX 50) will shield the 60 mm distant beamline of the transmitted pulsed beam from the fringing field of the C-Magnet (see Fig. 2). The varying proportions of the tube along the beam axis, particularly the widening at the ends, serve a more effective shielding of the magnetic field. A slit on the side assures a lossless beam sweep during the rise and fall of the deflector pulse.

LEBT DYNAMICS AND RFQ INJECTION

P. P. Schneider*, M. Droba, O. Meusel, H. Niebuhr, D. Noll, O. Payir,
H. Podlech, A. Schempp and C. Wiesner
IAP, Goethe-University, Frankfurt am Main, Germany

Abstract

The Low Energy Beam Transport (LEBT) section at the accelerator-driven neutron source FRANZ [1] consists of four solenoids, two of which match the primary proton beam into the chopper. The remaining two solenoids are intended to prepare the beam for injection into the RFQ. In the first commissioning phase, the LEBT successfully transported a 14 keV He^+ beam at low intensities [2]. In the current commissioning phase, the beam energy is increased to the RFQ injection energy of 120 keV. In the upcoming step, the intensity will be increased from 2 mA to 50 mA.

Beam dynamics calculations include effects of different source emittances, position and angle offsets and the effects of space charge compensation levels. In addition, the behavior of the undesired hydrogen fractions, H_2^+ and H_3^+, and their influence on the performance within the RFQ is simulated.

INTRODUCTION

A LEBT can satisfy several tasks within an accelerator. While the most important task is the transport of the beam at low energy from the ion source into the downstream RFQ, which expects well defined beam properties at the injection point, another important aspect is the matching of the beam properties, the “RFQ injection parameters”, which are usally given by the twiss parameters α_{Twiss}, β_{Twiss}, γ_{Twiss} and the emittance ε.

A possible additional task within a LEBT is to apply a time structure to the beam. A time structure is necessary to reduce the duty cycle of the RFQ or to provide the time structure required for the experimental needs.

Furthermore, beam diagnostics are an important task to ensure the required specifications and quality of the beam.

If the desired beam ion cannot be delivered in one fraction from the ion source, as, for example, for hydrogen beams, the LEBT should separate the unwanted fractions. Otherwise, these would be lost in an uncontrolled way within the RFQ or the later beamline, where high loss rates are intolerable.

This work will focus on the fraction separation within the FRANZ LEBT and gives an outlook on planned projects at the MYRRHA LEBT. Additionally the sucessful separation of an hydrogen beam at a solenoidal separation channel will be described.

FRACTION SEPARATION

Proton sources usually provide three fractions of charged hydrogen: H^+, H_2^+ and H_3^+. However, an RFQ is able to accelerate only one mass-to-charge ratio. Therefore, the two unwanted fractions have to be filtered by the LEBT in order to reduce their impact on the further accelerator. To perform this task, there are several possible solutions.

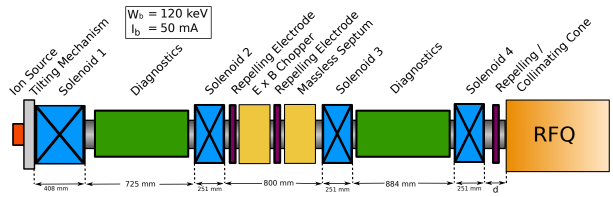

Figure 1: Schematic view of the FRANZ LEBT.

Dipole Separation

It is possible to separate the fractions with a dipole magnet, as is done for example at the SARAF LEBT [3].

⊕ separation efficiency up to 100 %
⊕ controlled dumping of separated beam possible

⊖ does not preserve beam symmetry
⊖ does not preserve space-charge compensation
⊖ small angle mismatches can lead to large offsets

Collimation System

Another possibility to separate the species is to exploit the momentum-dependent focusing of a solenoid in order to move every fraction to a different radius. A subsequent collimator system can scrape the fractions at high radii.

⊕ preserves beam symmetry
⊕ preserves space-charge compensation

⊖ separation efficiency always < 100 %
⊖ produces secondary particles
⊖ losses cause “hot spots”

Wien Filter

A third possibility is a Wien filter [4] composed of a magnetic dipole and an electric deflector. Particles that satisfy the Wien-ratio can pass, all others will be deflected.

⊕ preserves beam symmetry
⊕ controlled dumping of separated beam possible
⊕ separation efficiency up to 100 %

⊖ space-charge compensation is not preserved
⊖ complex to design and construct

FRANZ LEBT

The FRANZ LEBT (Fig. 1) consists of two sections. The first section ranges from the source to the chopper system, the second section from behind the chopper system to the entrance of the RFQ.

The first section has to transport the beam from the ion source into the chopper system. Between solenoid 1 and

[4]KPH, Johannes Gutenberg University, Mainz, Germany

Abstract

For future experiments with heavy ions near the coulomb barrier within the SHE (super-heavy elements) research project a multi-stage R&D program of GSI, HIM and IAP is currently in progress [1]. It aims at developing a superconducting (sc) continuous wave (cw) LINAC with multiple CH cavities as key components downstream the High Charge Injector (HLI) at GSI (Fig. 1). The beam dynamics concept is based on EQUUS (equidistant multigap structure) constant-β cavities. Advantages of its periodicity are a high simulation accuracy, easy manufacturing and tuning with minimized costs as well as a straightforward energy variation. The next milestone will be a full performance beam test of the first LINAC section, comprising two solenoids and a 15-gap CH cavity inside a cryostat (Demonstrator).

INTRODUCTION

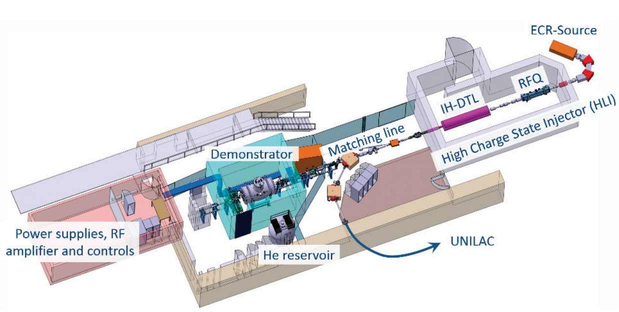

Figure 1: CH cavity test environment for a full performance test of the sc cw LINAC Demonstrator at GSI (first expansion stage with max. two cavities and one cryostat).

The beam dynamics concept for the sc cw LINAC is based on EQUUS, as proposed in [2]. It features high acceleration efficiency with longitudinal and transversal stability, as well as a straightforward energy variation. The latter can easily be achieved by varying the applied rf voltage (even down to "switched off" cavities) or the rf phase of the amplifier. Highly charged ions with a mass-to-charge ratio of up to 6 will be accelerated from 1.4 MeV/u up to 3.5 - 7.3 MeV/u. A typical ion species for acceleration is $^{48}Ca^{10+}$ (with an A/q of 4.8) as projectile for hot fusion reactions with actinide targets [3]. Energy variation whilst maintaining a high beam quality is the core issue with respect to beam dynamics. Therefore research has been started to optimize the present conceptual layout of a sc cw-LINAC by Minaev et al. [2].

BEAM DYNAMICS SIMULATIONS

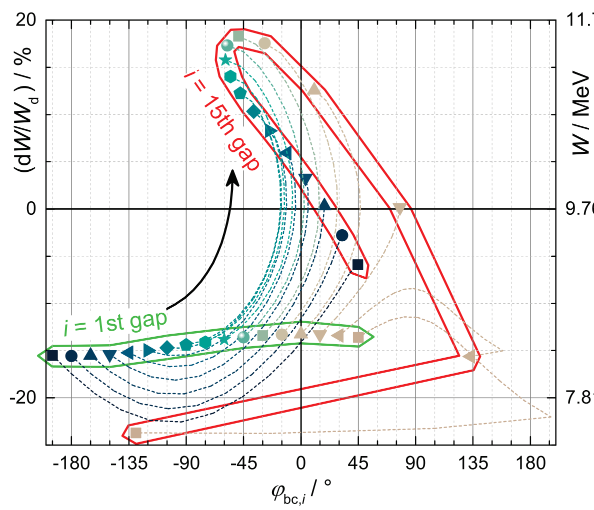

Figure 2: Movement of the bunch-center particle in longitudinal phase space in dependence of the initial phase $\varphi_{\mathrm{bc},1}$ while traversing the 15-gap CH cavity.

Inside an EQUUS cavity cell lengths are kept constant and are designed with a higher (geometrical) β than the one of the injected beam (also called "constant-β structure"). This leads to a sliding movement in longitudinal phase space. Trajectory and energy gain depend strongly on the initial phase at the first gap center $\varphi_{\mathrm{bc},1}$ and the difference between particle energy W and design energy W_{d}. Figure 2 shows this movement for the 15-gap CH cavity whose construction is nearly completed [4]. At $\varphi_{\mathrm{bc},1} = -30°$ the highest energy gain is achieved ($\Delta W = 3.1$ MeV), while at $-60°$ it has the highest symmetry. The corresponding emittance evolution is plotted in Fig. 3 showing a broad range of little growth. All simulations in this paper have been performed with LORASR [5] and will be prospectively benchmarked with TraceWin [6] and bender [7]. 10k particles with $q = 1$, $m = 6\,\mathrm{u}$ and $I = 0\,\mathrm{mA}$ were used as input distribution (Fig. 4), starting downstream the HLI IH-DTL (Fig. 5).

DEVELOPMENT OF A 325 MHz LADDER-RFQ OF THE 4-ROD-TYPE*

M. Schütt, U. Ratzinger
Institut für Angewandte Physik, Johann Wolfgang Goethe Universität, Frankfurt, Germany
R. Brodhage, GSI, Darmstadt, Germany

Abstract

For the research program with cooled antiprotons at FAIR a dedicated 70 MeV, 70 mA proton injector is required. In the low energy section, between the Ion Source and the main linac an RFQ will be used. The 325 MHz RFQ will accelerate protons from 95 keV to 3 MeV. This particular high frequency for an 4-ROD type RFQ creates difficulties, which are challenging in developing this cavity. In order to define a satisfactory geometrical configuration for this resonator, both from the RF and the mechanical point of view, different designs have been examined and compared. Very promising results have been reached with a ladder type RFQ, which has been investigated since 2013 [1, 2]. We present recent 3D simulations of the general layout and of a complete cavity demonstrating the power of a ladder type RFQ as well as measurements of a 0.8 m prototype RFQ, which was manufactured in late 2014 and designed for RF power and vacuum tests. The prototype manufacturing was completed and first measurements are shown.

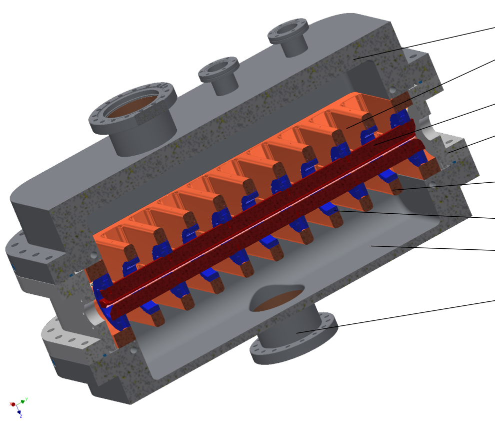

Figure 1: Isometric view of the Ladder-RFQ. The cooper carrier-rings (for a better view coloured in blue) guarantee the electrode positioning as well as the RF contact. The ladder structure consists of bulk copper components. Any brazing or welding processes are avoided.

INTRODUCTION

The idea of the Ladder-RFQ firstly came up in the late eighties [3, 4] and was realized successfully for the CERN Linac3 operating at 101 MHz [5] and for the CERN antiproton decelerator ASACUSA at 202 MHz [6]. Within the 4-ROD design the challange is to minimize dipole components and to have geometrical dimensions which are suitable for a mechanical manufacturing and assembling. At frequencies above 250 MHz the 4-Vane-type RFQ is used so far. Many versions for low and high duty factors have been realized successfully until now. Draw backs are the high costs per meter, the complexity as well as the challenging RF tuning procedure of that structure: The dipole modes tend to overlap with the quadrupole mode. Safe beam operation conditions result in ambitious mechanical vane tolerances. In the proposed ladder-RFQ version, the spokes show an extended width which increases the resonance frequency and which results in an homogeneous current flow towards the mini-vanes. The mini-vanes are embedded via precisely machined carrier rings into the copper shells (see Fig. 2). To proof the mentioned advantages and realizability of the Ladder RFQ a prototype was designed and built. The results of the simulation and comparision with the measurement are shown in this paper.

MECHANICAL LAYOUT

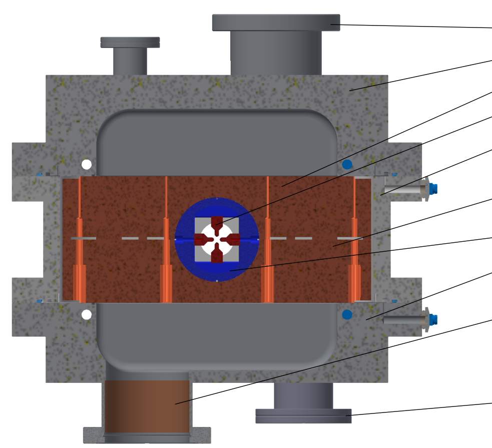

Figure 2: Sectional front view of the Ladder-RFQ.

The mechanical design consists of an inner copper ladder structure mounted into an outer stainless steel tank. The tank is divided into a base plate carrying the inner resonating structure, an intermediate part and the cover plate. The base will carry and adjust the position of the resonating structure. All parts are metal-sealed. Furthermore its task is to provide a vacuum at the level of 10^{-8} mbar. The rf is mainly determined by the resonating structure, while the dimensions of the tank have no significant influence to the frequency.

To lower the wall losses it is foreseen to copperplate the lower and upper half shells. The inner resonating structure consists of two symmetric half shells made of massive copper. They press and grout the carrier-rings in between. The

TEN GAP MODEL OF A NEW ALVAREZ DTL CAVITY AT GSI

Anja Seibel, IAP University of Frankfurt, Germany
Xiaonan Du, Lars Groening, Oliver Kester, Sascha Mickat, GSI, Darmstadt, Germany

Abstract

In order to meet the challenges of the FAIR project at GSI requiring highest beam intensities an upgrade of the existing Universal Linear Accelerator (UNILAC) is planned. The 108 MHz cavities will be replaced by new rf-structures of the same frequency. Simulations are done to improve the rf-properties. The geometry of the drift tubes is to be changed to a smoother curvature to reach a homogeneous surface field distribution and higher shunt impedances. To check the necessity of cooling channels, simulations on the temperature distribution at the drift tubes and stems are conducted. A test bench for low power rf-measurements with a 10 gap aluminum model (scale 1:3) is under construction. The modular mechanical design of the model will allow probing experimentally a wide range of drift tube and stem geometries. With the bead pull method the electrical field distribution will be measured as well as the field stability with respect to parasitic modes. Additionally, appropriate locations along the cavity to place fixed and dynamic rf-frequency tuners will be determined.

THE FAIR PROJECT

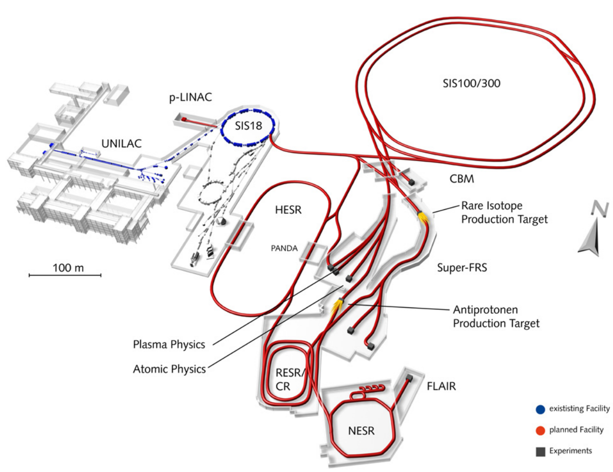

Figure 1: The FAIR facility in the full version [1].

The FAIR project (Fig. 1) will be a new international particle accelerator facility for antiprotons and heavy ions which is currently under construction [1]. This project will provide knowledge of still unknown subatomic components of matter in the Universe. In parallel the existing GSI facility is upgraded together with a new proton linear accelerator and will serve as pre-accelerator and injector for the new heavy ion synchrotron SIS100. The SIS100 beams are delivered to a complex of storage rings [2] and experimental stations reaching energies and intensities as required for FAIR [1].

As shown in Fig. 2, the existing HSI (high current injector) branch of the UNILAC consists of two ion source terminals, one RFQ, two IH cavities, a gas-stripper, and the poststripper with five Alvarez cavities and 10 single gap cavities. After the HSI the beam has an energy of 1.4 MeV/u. The operating frequency of the Alvarez DTL is 108.408 MHz accelerating the beam to the final energy of 11.4 MeV/u [3]. After almost 40 years in operation it is recommended to replace this section with an improved Alvarez DTL [4].

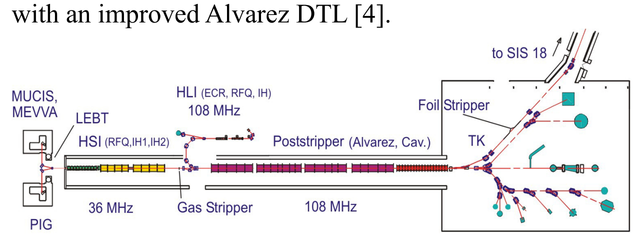

Figure 2: Existing UNILAC at GSI with the five Alvarez cavities working at 108.408 MHz [5].

DESIGN OF THE TEN GAP MODEL

A set of simulations has been performed using CST Microwave Studio [6] to improve the rf-properties of the existing Alvarez cavity [7]. Therefore a 1:3 scale ten gap model (Fig. 3) is simulated with a new design geometry inside. The frequency scales correspondingly to three times 108.408 MHz (= 325.224 MHz). To reach the exact frequency after fabrication, the tank is designed a bit larger in diameter, in accordance that the operating frequency is lower and can be shift up by tuners. The reasons for such procedure are small inaccuracies in fabrication which influence the frequency. The model design parameters are listed in Tab. 1.

The ten gap model with nine full and two half drift tubes at the end plate allows to vary the angle between the stems. With the rotating stem geometry the frequency of the TM011 mode (Fig. 4) can be pushed away in the simulations more than 5 MHz from the operating TM010 mode for the existing Alvarez 3 tank [7]. The stem configuration of each drift tube is used to damp parasitic modes and thus increase the field stability. In addition, the drift tube cabs are exchangeable to compare different drift tube geometries.

The goal is to optimize the rf-design geometry with respect to the field distribution stability. Therefore the above mentioned 10 gap aluminium model is under construction, to verify the simulated results using the bead pull method. The calculated electric field profile along the beam axis (Fig. 5) shows a flatness of better than 3 %.

CONCEPTUAL DESIGN OF A NOVEL RFQ FOR MEDICAL ACCELERATORS

R. Cee*, E. Feldmeier, T. Haberer, A. Peters, T. Winkelmann

Abstract

At the Heidelberg Ion Beam Therapy Centre HIT we operate a 4-rod RFQ as first stage of a 7 MeV/u injector linac followed by an IH-DTL. During the first years of patient treatment the injector performance was perfectly adequate, even though the transmission of the linac remained below the theoretical expectations. New developments in dose delivery technology already realised or to come in the future increase the demand on higher beam intensities which will finally result in shorter irradiation times. As measurements performed at our test bench have confirmed that there is a margin for higher transmissions especially for the RFQ we are currently preparing for a new RFQ design. While keeping the original design parameters, the new RFQ should be optimised with respect to the transmission of beams from different ion sources such as electron cyclotron resonance or electron beam ion sources. All parts of the RFQ will be put up for discussion including electrodes, stems, tank and the integrated rebuncher. The design work will profit from new concepts that have evolved at our own and other medical heavy ion facilities in operation and from the progress modern simulation tools have run through.

MOTIVATION

As a new field of application radio-frequency-quadrupoles (RFQs) are nowadays used in medicine as part of injectors for subsequent circular accelerators (synchrotrons). One of the world's leading facilities for the treatment of cancer patients with ion beams is the Ion Beam Therapy Centre of the Heidelberg University Hospital (HIT) [1]. It comes along with an ion accelerator designed for carbon ions with a maximum energy of 430 MeV per nucleon. The range of available ion species is not limited to carbon ions. Both heavier elements, such as e.g. oxygen, as well as lighter ions, such as hydrogen or helium, are accelerated. Since patient treatment was established in 2009 the capacity of HIT could be continuously increased up to 750 carbon and proton patients per year. A further rise of the patient number will essentially depend on the achievable beam intensity.

One known source of particle losses is the HIT-RFQ. Its maximum achievable transmission ranges between 30 % and 40 % depending on the ion species and beam intensity. Measurements carried out at other therapy facilities such as the one in Marburg (now Marburg Ion Beam Therapy Centre [2]) obtain consistent results. Obviously it is not possible to achieve higher transmissions with the current RFQ design in combination with beams from the ion sources in operation, the electron cyclotron resonance ion sources (ECRIS). In order to further increase the efficiency of our ion beam therapy facility, it is necessary to increase the transmission of the RFQ accelerator by a factor of about 2.5. This can be achieved by optimising the RFQ in terms of design, fabrication and adjustment. The medium term objective of this work is therefore the design, construction and testing of a highly efficient RFQ structure with high transmission (desirably 90 %) maintaining the parameters of the original RFQ.

* rainer.cee@med.uni-heidelberg.de

RFQ IN OPERATION

The RFQ currently in operation is a 4-rod type RFQ developped at the IAP Frankfurt [3]. It accelerates ions from 8 keV/u to 400 keV/u. Further design parameters can be found in Table 1. The resonant structure, as shown in Fig. 1, consists of four electrodes held by 16 stems which are electrically connected via tuning plates with variable height. As a peculiarity the rebuncher for longitudinal beam focusing into the subsequent IH drift tube linac (IH-DTL) is placed within the RFQ tank and is coupled to the resonant structure. This unique design was chosen for the sake of compactness and cost efficiency but is attended by a loss of variability during operation.

Table 1: RFQ Design Parameters

Parameter	Value
input energy	8 keV/u
output energy	400 keV/u
operating frequency	216.816 MHz
max. power consumption (pulsed)	200 kW
max. mass-to-charge ratio	3

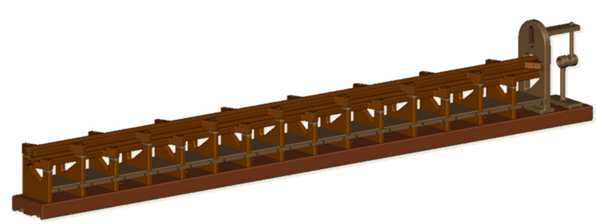

Figure 1: Resonant structure of the 4-rod RFQ with base plate, stems, tuning plates, electrodes and integrated rebuncher (beam direction from left to right).

CONCEPT FOR A NEW RFQ

Based on eight years of operational experience we see room for improvement for all major components of the RFQ.

Tank

The tank of the current RFQ essentially consists of a 250 mm diameter stainless steel tube equipped with sockets

PREPARATION OF AN ION SOURCE FOR AN EXTRA LOW ENERGY SYNCHROTRON

Ralf Gebel, Olaf Felden, Rudolf Maier, Sebastian Mey, Dieter Prasuhn
Forschungszentrum Jülich GmbH, IKP-4, Jülich, Germany

Abstract

ELENA is a compact ring for cooling and further deceleration of 5.3 MeV antiprotons delivered by the CERN Antiproton Decelerator (AD) down to 100 keV. Because of the long AD cycle of 100 s, it is foreseen to use a source for protons and H^- with a kinetic energy of 100 keV for commissioning and start-ups. The source, designed to provide 0.2 to 2.0 μs pulses with 3×10^7 ions, is based on a proven multicusp volume source used at the COSY/Jülich injector cyclotron. The source and its auxiliaries were refurbished, upgraded to $+/-100$ keV operation at the Forschungszentrum Jülich and have been set in operation at CERN in April 2015 for first tests of new equipments.

INTRODUCTION

CERN has approved in 2011 the construction of the Extremely Low ENergy Antiproton ring ELENA [1] due to the growing scientific demand for low-energy antiprotons. ELENA is a small synchrotron with an electron cooler for further deceleration of 5.3 MeV antiprotons delivered by the antiproton decelerator AD [2]. Electron-cooling of antiprotons of about 100 keV energy will produce a beam quality that allows delivery of pulses in electrostatic beam lines to experiments in the AD hall. The ELENA Feasibility Study [1] constitutes the scientific and technical basis of the project. ELENA is also an accelerator test platform for developing new generation sources for antiprotons which may start with FLAIR [3], an addition to FAIR at the GSI in Darmstadt [4]. CERN's AD with ELENA is going to be the world's sole source for low-energy antiproton physics for the near future. The Institute for Nuclear Physics (IKP-4) of Forschungszentrum Jülich [5] has committed, like other parties, to contribute significantly to ELENA with manpower and equipment. Setting-up ELENA and experiments is foreseen with a dedicated H^- and proton source. This enables making part of the commissioning independent of the CERN schedule. A 100 keV source can be installed in a section of the transfer beam line between AD, experiments and ELENA. The ion source provides higher intensity and more frequent injections than possible with AD, about one bunch every 100 seconds, and improves efficiency.

SYSTEM LAYOUT AND STATUS

The 100 keV H^-/proton ion source with auxiliaries has been prepared in Jülich for delivery in an early stage of ELENA installation. The source is one of the first components installed in the AD hall at CERN in April 2015. All systems are operational and the source can be useful for validation of equipment prior and during their installation.

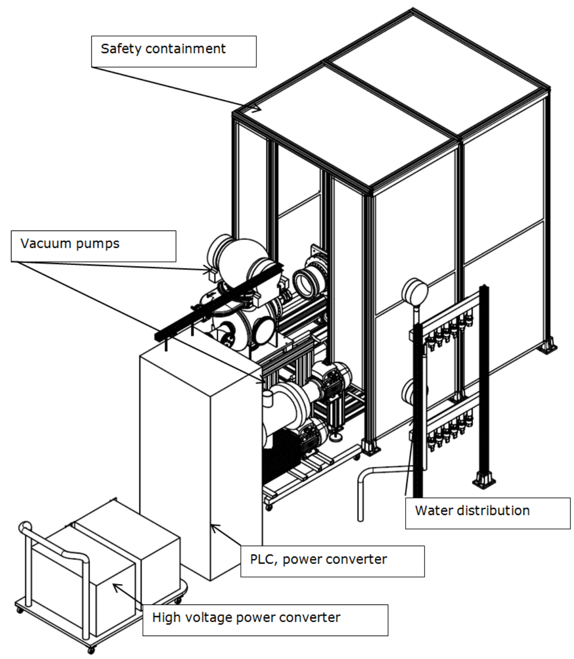

Figure 1: ELENA source set-up for commissioning, with its auxiliaries.

It is planned to test e.g. ion switch yard elements and diagnostic devices. In order to enable these activities the source has been delivered equipped with vacuum system, power converters, a local control computer and diagnostic tools. The ion source was successfully operated at 100 keV with both polarities in Jülich. Table 2 provides parameters first operation with 100 μA H^- and 150 μA proton ion beams. The first installation at CERN is very close to the opertional configuration used at Jülich. In a second step, after installation of the beam line elements between source to the ion switch after June 2015, the source is going to be installed at its final position. The faraday cage is already at its final position. The ion source system has been installed within the AD machine circumference and inside shielded areas. The position is fixed by the requirements of the switch yard for serving both ions and antiprotons to the ELENA ring and the experiments. The layout of the equipment integrates the HV cabinet which is enclosed inside a grounded safety cabinet of Faraday type and the ion source components. The ion source power supply is composed of four power supplies, filament driver to heat the filaments, arc power supply to create a discharge, two extraction power supplies for pulling out, or suppressing, ion beam and auxiliary power converters and high voltage solid state switches for pulsed operation.

ANTIPROTON ACCELERATION AND DECELERATION IN THE HESR

B. Lorentz[#], T. Katayama, A.Lehrach, R. Maier, D. Prasuhn, R. Stassen, H. Stockhorst, and R. Tölle
Forschungszentrum Jülich GmbH, D 52425 Jülich, Germany.

Abstract

The High Energy Storage Ring (HESR) is a part of the future Facility for Antiproton and Ion Research (FAIR) in Darmstadt [1,2]. The ring is used for hadron physics experiments with a pellet target and the PANDA detector, and will supply antiprotons of momenta from 1.5 GeV/c to 15 GeV/c. To cover the whole energy range a flexible adjustment of transition energy and the corresponding γ_{tr} value is foreseen. For injection and accumulation of antiprotons delivered from the CR at a momentum of 3.8 GeV/c (γ=4.2), the HESR optics will be tuned to γ_{tr}=6.2. For deceleration down to a momentum of 1.5 GeV/c this optic is suitable as well. Stochastic cooling at an intermediate energy is required to avoid beam losses caused by adiabatic growth of the beam during deceleration. For acceleration to 8 GeV/c (γ=8.6) the optics will be changed after accumulation of the antiproton beam to γ_{tr}=14.6. For momenta higher than 8 GeV/c the beam will be debunched at 8 GeV/c, optics will be changed to γ_{tr}=6.2, and after adiabatic rebunching the beam will be accelerated to 15 GeV/c (γ=16). Simulations show the feasibility of the described procedures with practically no beam losses.

INTRODUCTION

The High Energy Storage Ring HESR is dedicated to the field of high energy antiproton physics with high quality beams over the broad momentum range from 1.5 to 15 GeV/c to explore the research areas of hadron structure and quark gluon dynamics, e.g. non perturbative QCD, confinement, and chiral symmetry. An important feature of the new facility is the combination of phase space cooled beams with internal targets which opens new capabilities for high precision experiments.

Wide international collaborations (e.g. PANDA [3]) with a rich scientific program are working on new experiments with antiprotons in the energy range between the CERN Antiproton Decelerator AD and the Tevatron energies.

Special equipment enables the high performance of this antiproton machine, which will make high precision experiments feasible that are not possible up to now. Key tasks for the design work to fulfil these requirements are:

- multi harmonic RF cavities [4],
- high sensitivity stochastic cooling pickups for the frequency range 2-4 and 4-6 GHz,
- powerful beam cooling systems to counteract beam heating (from beam target interaction and intra beam scattering) to achieve high luminosity and high beam quality.

[#] b.lorentz@fz-juelich.de

Stochastic cooling will be used for the injection and accumulation process and to counteract the beam heating caused by the target of the PANDA experiment.

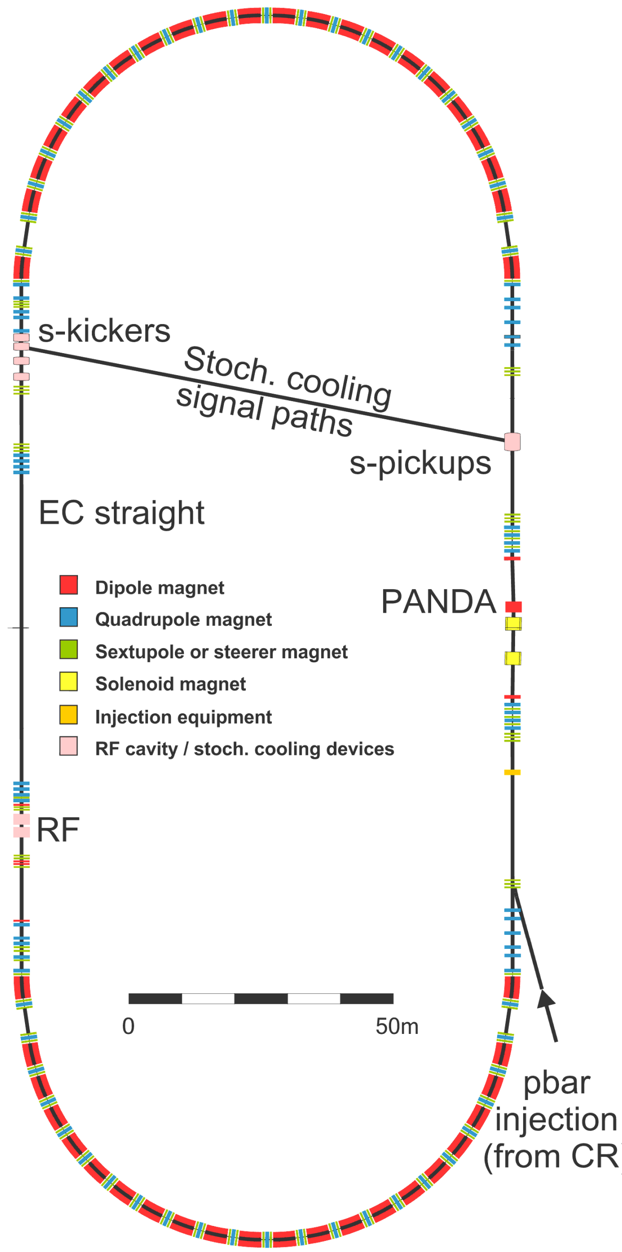

Figure 1: Schematic view of the HESR ring, the target position for PANDA is in the middle of the right straight section. Injection is placed on the bottom right, positions of stochastic cooling pickups and kickers are indicated.

TOWARDS AN RF WIEN-FILTER FOR EDM EXPERIMENTS AT COSY

S. Mey[1,2] and R. Gebel[1] on behalf of the JEDI Collaboration

[1]Institut für Kernphysik, Forschungszentrum Jülich GmbH, 52425 Jülich, Germany
[2]III. Physikalisches Institut B, RWTH Aachen, Otto-Blumenthal-Str., Aachen, 52074, Germany

Abstract

The JEDI Collaboration (Jülich **E**lectric **D**ipole **M**oment (EDM) Investigations) is developing tools for the measurement of permanent EDMs of charged, light hadrons in storage rings. The Standard Model predicts unobservably small values for the EDM, but a non-vanishing EDM can be detected by measuring a tiny build-up of vertical polarization in a beforehand horizontally polarized beam. This technique requires a spin tune modulation by an RF Dipole without any excitation of beam oscillations.

In the course of 2014, a prototype RF ExB-Dipole has been successfully commissioned and tested. To determine the characteristics of the device, the force of a radial magnetic field is canceled out by a vertical electric one. In this configuration, the dipole fields form a *Wien*-Filter that directly rotates the particles' polarization vector. We verified that the device can be used to continuously flip the vertical polarization of a 970 MeV/c deuteron beam without exciting any coherent beam oscillations. For a first EDM Experiment, the RF ExB-Dipole in *Wien*-Filter Mode is going to be rotated by 90° around the beam axis and will be used for systematic investigations of sources for false EDM signals.

MOTIVATION

The motion of a relativistic particle's spin in an electromagnetic storage ring ($\vec{\beta}\cdot\vec{B} = \vec{\beta}\cdot\vec{E} = 0$) with non vanishing EDM contributions is given by the generalized *Thomas-BMT* Equation, $\mathrm{d}\vec{S}/\mathrm{d}t = \vec{S}\times(\vec{\Omega}_{\mathrm{MDM}} + \vec{\Omega}_{\mathrm{EDM}})$ [1,2], with

$$\begin{aligned}\vec{\Omega}_{\mathrm{MDM}} &= \frac{q}{m}\left((1+\gamma G)\vec{B} - \left(\gamma G + \frac{\gamma}{\gamma+1}\right)\vec{\beta}\times\frac{\vec{E}}{c}\right)\\ \vec{\Omega}_{\mathrm{EDM}} &= \frac{q}{m}\frac{\eta}{2}\left(\frac{\vec{E}}{c} + \vec{\beta}\times\vec{B}\right)\end{aligned} \quad (1)$$

Here, the anomalous magnetic moment G is given by the particle's **M**agnetic **D**ipole **M**oment (MDM), $\vec{\mu} = 2(G+1)\frac{q\hbar}{2m}\vec{S}$. This corresponds to $G = -0.142$ for deuterons. As an analogue, the dimensionless factor η describes the strength of the particle's permanent EDM relative to its MDM. For a Standard Model prediction of $d = \eta\frac{q\hbar}{2mc}\vec{S} \approx 10^{-32}$ ecm its value is $\eta \approx 10^{-16}$.

In a purely magnetic storage ring, all the terms containing electric fields in Eq. 1 vanish and the EDM contribution due to the interaction with the motional electric field ($\vec{\beta}\times\vec{B}$) will lead to a tiny tilt of the spin's precession axis. This leads to a very slow oscillation of the vertical polarization, but for $\eta \approx 10^{-16}$ its contribution is far below measurable. Adding an RF *Wien*-Filter with vertical magnetic field orientation to the ring's lattice yields a modulation of the horizontal spin precession by means of a phase kick without disturbing the beam dynamics. Together with the EDM's interaction with the motional electric field in the rest of the ring, the frequency modulation can lead to a continuous buildup of vertical polarization in a horizontally polarized beam [3].

SETUP OF THE PROTOTYPE

While the above described approach could provide a measurable EDM signal, it doesn't provide an observable to characterize the RF *Wien*-Filter itself. Therefore, a first prototype with a radial magnetic field ($\vec{B} = (B_x, 0, 0)^T$) compensated by a vertical electric field ($\vec{E} = (0, E_y, 0)^T$) has been commissioned. Here, the magnetic field directly manipulates the vertical beam polarization. Expressing the electric field in Eq. 1 in terms of the magnetic field leads to a simple formula for the spin precession in an ideal *Wien*-Filter [4]:

$$\vec{\Omega} = \frac{q}{m}\left((1+\gamma G)\vec{B} - \left(\gamma G + \frac{\gamma}{\gamma+1}\right)\beta^2\vec{B}\right) = \frac{1+G}{\gamma}\vec{B}. \quad (2)$$

The particles sample the localized RF fields once every turn. Their contribution may be approximated by the integrated field along the particles' path assigned to a point-like device at an orbital angle θ:

$$b(\theta) = \int \hat{B}_x\,\mathrm{d}l\,\cos(f_{\mathrm{RF}}/f_{\mathrm{rev}}\theta + \phi)\sum_{n=-\infty}^{\infty}\delta(\theta - 2\pi n). \quad (3)$$

The resonance strength $|\varepsilon_K|$ of such a device is given by the amount of spin rotation per turn and can be calculated by the *Fourier* integral over one turn in the accelerator [5,6]:

$$\begin{aligned}|\varepsilon_K| &= \frac{f_{\mathrm{spin}}}{f_{\mathrm{rev}}} = \frac{1+G}{2\pi\gamma}\oint\frac{b(\theta)}{B\rho}e^{iK\theta}\,\mathrm{d}\theta\\ &= \frac{1+G}{4\pi\gamma}\frac{\int\hat{B}_x\,\mathrm{d}l}{B\rho}\sum_n e^{\pm i\phi}\delta(n - K \mp f_{\mathrm{RF}}/f_{\mathrm{rev}}).\end{aligned} \quad (4)$$

An artificial spin resonance occurs at all side-bands with a frequency corresponding to the spin tune:

$$K \stackrel{!}{=} \gamma G = n \pm f_{\mathrm{RF}}/f_{\mathrm{rev}} \;\Leftrightarrow\; f_{\mathrm{RF}} = f_{\mathrm{rev}}|n - \gamma G|;\; n \in \mathbb{Z}. \quad (5)$$

In the scope of the current JEDI experiments, deuterons with a momentum of 970 MeV/c are stored at COSY [7]. In this case, $\gamma = 1.126$ and the resulting spin tune is $\gamma G = -0.1609$. The fundamental mode is located at $f_{\mathrm{RF}} = 121$ kHz with $n = \pm 1$ harmonics at 629 kHz and 871 kHz.

Abstract

A strong hint for physics beyond the Standard Model would be achieved by direct measurements of charged particles' Electric Dipole Moments (EDMs). Measurements in magnetic storage rings using a resonant spin interaction of a radiofrequency Wien filter are proposed and needs to be scrutinized. Therefore, the calculation of phase space transfer maps for time-varying fields has been implemented into an extensions for the software framework COSY INFINITY. Benchmarking with measured data and analytical estimates for rf solenoid induced spin resonances are in good agreement. The dependence of polarization oscillation damping on the solenoid frequency could be confirmed. First studies of the rf Wien filter method reveal systematic limitations: Uncorrected Gaussian distributed misalignments of the COSY lattice quadrupoles with a standard deviation of $\sigma = 0.1$ mm generate a similar buildup as an EDM $d \approx 5 \cdot 10^{-19}$ e $\cdot$ cm using this method.

INTRODUCTION

The JEDI collaboration investigates the feasibility of electric dipole moment (EDM) measurements of protons and deuterons in storage rings. Methods requiring radiofrequency fields to create an EDM related measurement signal in a magnetic storage ring like COSY [1] are proposed [2,3] . Systematic tracking studies needs to be performed to explore the limits of these methods. This requires the fast tracking of particles in radiofrequency fields in presence of an EDM. The software framework COSY INFINITY [4] is used to calculate transfer maps of the magnetic elements and perform tracking. Recent efforts extend the code by the EDM contribution and by calculation of maps for time-varying fields. Benchmarking of the new algorithms using measured data and analytical estimations is carried out. Based on the results systematic limitations of the measurement methods can be deduced.

BENCHMARKING USING AN RF SOLENOID INDUCED SPIN RESONANCE

First benchmarking is performed using calculations and measurements for an rf-B solenoid induced spin resonance at COSY. Preceding studies of this process can be found in [5]. For these studies a vector polarized deuteron beam was injected, electron cooled and accelerated up to $p = 970$ MeV/c.

* m.rosenthal@fz-juelich.de

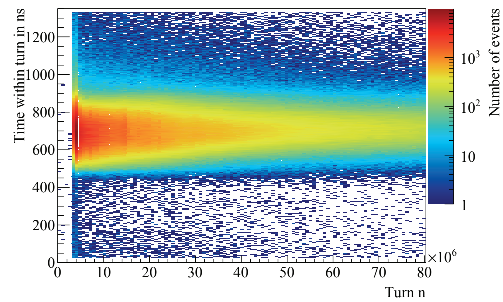

Figure 1: Event distribution within a turn vs. turn number for one measurement cycle.

The revolution time was roughly $T = 1332$ ns. After electron cooling had been turned off, a white noise electric signal was used to slowly extract the deuterons onto a carbon block target of the internal polarimeter. The scattering events were counted in four quadrants (up, down, left, right). The left-right-asymmetry is proportional to the vertical polarization. A more detailed description of the setup has been discussed in [6,7]. Figure 1 shows the event distribution during one measurement cycle. The timemarking system of the read-out electronics [6] allows to determine the event time with respect to the rf cavity period. The zero point is set to be shortly before the extraction starts. After about eleven million turns the rf-B solenoidal field was turned on:

$$B_{\text{sol}} = \hat{B}_{\text{sol}} \cos(2\pi\nu_{\text{sol}} + \phi_{\text{sol}}). \tag{1}$$

The spin tune for the particular setup is $\nu_s \approx G\gamma \approx -0.16$ [7], where G is the anomalous magnetic moment. The spin resonance condition for the solenoidal field is given by

$$\nu_{\text{sol}} = \nu_s + K, \quad K \in \mathbb{Z}. \tag{2}$$

Analytical estimations predict a vertical polarization $P_y(n)$ oscillation, which depends on the harmonic number K:

$$P_y(n) = \int_{-\infty}^{\infty} \rho(\hat{\tau}) S_y(n, \hat{\tau}) d\hat{\tau}, \tag{3}$$

$$S_y(n, \hat{\tau}) = \cos\left(\frac{\alpha_0}{2} \cdot J_0(C \cdot \hat{\tau}) \cdot n\right), \tag{4}$$

$$\alpha_0 = (1 + G)\frac{q}{p}\left(\hat{B} \cdot L\right)_{\text{sol}}, \tag{5}$$

$$C = \omega_{\text{rev}}\left(\nu_{\text{sol}} - \frac{G\gamma\beta^2}{\eta_{\text{ts}}}\right). \tag{6}$$

Here, S_y denotes the vertical spin component, $\left(\hat{B} \cdot L\right)_{\text{sol}}$ denotes the field amplitude times the length of the solenoid,

THE FIRST OPERATION OF 56 MHz SRF CAVITY IN RHIC*

Q. Wu#, S. Belomestnykh, I. Ben-Zvi, M. Blaskiewicz, L. DeSanto, D. Goldberg, M. Harvey, T. Hayes, G. McIntyre, K. Mernick, P. Orfin, S. Seberg, F. Severino, K. Smith, R. Than, A. Zaltsman, BNL, Upton, NY 11973, USA

Abstract

A 56 MHz superconducting RF cavity has been designed, fabricated and installed in the Relativistic Heavy Ion Collider (RHIC). The cavity operates at 4.4 K with a "quiet helium source" to isolate the cavity from environmental acoustic noise. The cavity is a beam driven quarter wave resonator. It is detuned and damped during injection and acceleration cycles and is brought to operation only at store energy. For a first test operation, the cavity voltage was stabilized at 300 kV with full beam current. Within both Au + Au and asymmetrical Au + He3 collisions, luminosity improvement was detected from direct measurement, and the hourglass effect was reduced. One higher order mode (HOM) coupler was installed on the cavity. We report in this paper on our measurement of a broadband HOM spectrum excited by the Au beam.

INTRODUCTION

The RF system installed in RHIC includes two main accelerating cavities at 28.15 MHz and five storage cavities at 197.05 MHz for each ring, all operating at room temperature. The 197 MHz cavities are used to store bunches, after they have been accelerated to the top energy, for many hours. To accommodate the long ion bunches into the storage cavity bucket, which is ~50% shorter than the bunch length, rebucketing is adopted in the RHIC ramping procedure. However, longitudinal emittance increase due to nonlinearity and hardware complications during rebucketing will result in a 30% loss in the particles. A 56.3 MHz superconducting RF (SRF) cryomodule was installed near the interaction point (IP) 4 in RHIC, Figure 1, during the first quarter of 2014, to provide sufficient RF acceptance to long bunches [1].

To save cost on cryogenic system, the cavity location is in the common section of RHIC, and it is shared by ion bunches from both rings. The two colliding beams are synchronized at each IP. Therefore to achieve identical longitudinal beam dynamic effect, the cavity is installed at 1.25λ (6.66 m) away from IP 4.

CAVITY

The 56 MHz SRF cavity is a quarter-wave resonator with beam passing through its symmetrical axis, as shown in Figure 2. The cavity is designed to provide 2 MV at the 8.5 cm single gap, and the operation temperature is 4.4 K. Detailed cavity parameters can be found in Ref. [2].

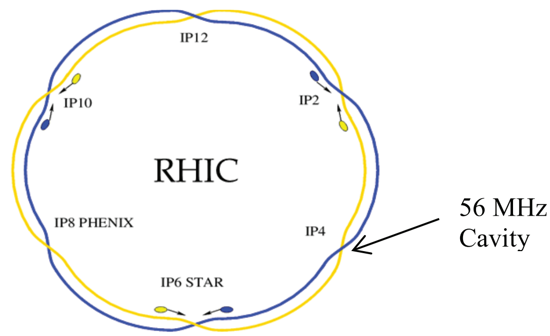

Figure 1: Location of the 56 MHz cavity in RHIC.

Mechanical tuning is achieved by pushing or pulling the end plate of the cavity that is close to the gap, as labeled in Figure 2 [3]. The tuning capability of this mechanism is 46.5 kHz, which is 60% of the revolution frequency of RHIC beam.

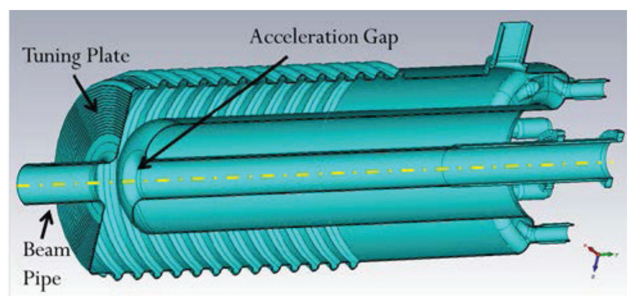

Figure 2: Crossection view of the 56 MHz SRF cavity.

Thirteen corrugations are added to the outer wall of the cavity to supress multipacting [4]. During the conditioning of the cavity, multipacting was encountered at 90 – 140 kV gap voltage, and was easily conditioned through after 30 minutes. During operation with beam, the cavity never encountered any multipacting issues.

Couplers

Since the cavity does not have sufficient tuning range to follow the large revolution frequency change during acceleration, it must be turned off during the energy ramp. In addition to full frequency detune from the tuning plate, a fundamental mode damper (FMD) is inserted into the cavity from a rectangular port. The port is opened perpendicular to the beam axis on the outer wall of the cavity, as shown in Figure 3. More information on the FMD can be found in Ref. [5].

Abstract

The High Energy Storage Ring for Antiprotons (HESR) is going to be built at FAIR in Darmstadt on the extended GSI campus. It will receive the antiprotons via the Collector Ring (CR). Using a barrier bucket, the circulating particles will be compressed into one half of the circumference. New particles have to be injected into the remaining half. Thus rise and fall time must not exceed 220 ns each with a flat top of 500 ns. A kick angle of 6.4 mrad is required at 13 Tm magnetic rigidity. The system must allow pole reversal for injection of positively charged particles. With a voltage lower than 40 kV a semi-conductor based pulser is going to be realized. Boundary conditions and the status of preparatory work are described. Simulation results and available measurements are presented.

INTRODUCTION

The HESR is a synchrotron and storage ring which is being built for FAIR on the GSI campus in Darmstadt in Germany. The Institute of Nuclear Physics 4 at Forschungszentrum Jülich (FZJ) has the overall responsibility for the complete HESR and will install it at the FAIR site when the buildings are ready. HESR will allow handling particles whose magnetic rigidity is in the range of 5 – 50 Tm. For protons or antiprotons this corresponds to momenta (energies) between 1.5 and 15 GeV/c (0.87 and 14.8 GeV), and for bare Uranium this corresponds to 579-5797 MeV/u/c. Injection is designed to operate at 3 GeV which is the production energy of antiprotons (12.76 Tm) to be injected via the collector ring CR which is needed for initial cooling. The injection equipment will be able to inject particles carrying positive or negative charge. For antiprotons each injected bunch might contain up to 10^8 particles, for heavy ions the intensity will be less.

INJECTION PROCESS

As the accumulator ring RESR will be postponed by several years, the proposed way of antiproton beam accumulation for the HESR is to use the already designed stochastic cooling system and the barrier bucket (BB) cavity of the HESR. The BB cavity of the HESR is used to separate the circumference of the HESR ring into two equal regions, one reserved for the injected beam and the other one for the accumulated beam. A beam bunch of 10^8 antiprotons delivered by the CR is kick-injected every 10 seconds into the central part of the two full wave barrier pulses (Fig. 1). The injection kicker rise time is 220 ns and the flat top time is 500 ns (Fig. 1). Just after beam injection the barrier voltages are switched off and the beam becomes coasting with a revolution period of 2 μs. Fast filter stochastic cooling is continuously applied during the whole accumulation process to avoid beam dilution due to Schottky noise diffusion. In the well cooled coasting beam again two full-wave barrier voltages are excited adiabatically and the right hand voltage moves to the injection position within the period of 0.5 sec. A new particle free gap with 1 μs duration for the injection of the next bunch is available. This procedure is repeated 100 times (1000 s) until 10^{10} antiprotons are accumulated. The beam accumulation and cooling processes have been studied in detail in [1, 2] and the corresponding proof of principle experiment has been successfully carried out at the GSI [3].

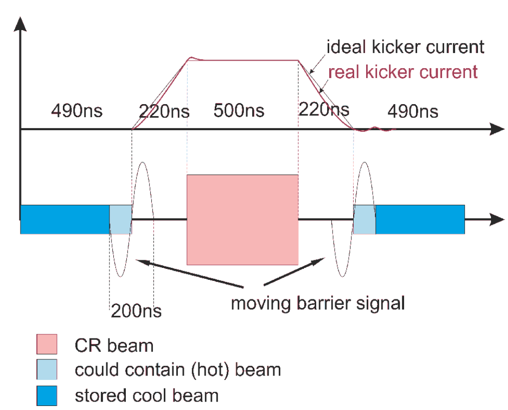

Figure 1: Injection timing of HESR.

SYSTEM DESIGN AND PARAMETERS

Preparatory studies at FZJ were carried out to specify mechanical properties, magnet properties and pulser properties. System design and the vacuum system are covered by FZJ, whereas the subsystems magnet and pulser are in the responsibility of the contractor. Requirements to build the coil (one single winding) with two horizontal slits on each side of the magnet and to make provisions to later install an eddy current strip (copper) into the slit in the bottom yoke have been accepted by the contractor (reduction of longitudinal impedance) [4]. The strip can be installed provided that in-vacuum dielectric tests are convincing.

The injection kicker system will have to deflect the incoming beam by 6.4 mrad using 4 individual 36 cm long

Abstract

As part of an injector system for FAIR, the GSI UNILAC has to meet high demands in terms of beam brilliance at a low duty factor. To accomplish this goal an extensive upgrade program has started.

To increase the beam intensity behind the UNILAC, it is aimed to increase the efficiency of the 1.4 MeV/u gas stripper. A modification of the stripper setup was developed to replace the N_2-jet with a pulsed gas injection, synchronized with the transit of the beam pulse. The pulsed gas injection lowers the gas load for the differential pumping system, rendering possible the use of other promising gas targets.

In recent measurements the performance of the modified setup was tested using an ^{238}U-beam with various stripper media, including H_2, He, and N_2. The data provide a systematic basis for an improved understanding of slow heavy ions passing through gaseous media. The stripping performance of the current N_2-jet was excelled by using H_2 at increased gas densities, enabled by the new pulsed gas cell.

INTRODUCTION

The GSI UNIversal LInear ACcelerator (UNILAC) will serve as part of an injector system for the future Facility for Antiproton and Ion Research (FAIR), currently under construction at GSI in Darmstadt, Germany. Therefore it has to meet high demands in terms of beam brilliance at a very low duty cycle (100 µs beam pulse length, 2.7 Hz repetition rate) [1]. To achieve this goal, an extensive upgrade program of the UNILAC has been started [2].

After acceleration in the UNILAC High Current Injector the ion beams are passing a gas stripper section at 1.4 MeV/u. The ions are stripped of electrons and the charge state of the ion beam is increased. After stripping, a charge state distribution results, and charge separation is accomplished by a system of dipole magnets; thus, only ions with the desired charge state are selected for further acceleration. The current gas stripper uses a laval nozzle at a back-pressure of 0.4 MPa to apply a super-sonic N_2-jet [3].

A key projectile for FAIR is ^{238}U [1]. In the gas stripper, the charge state of the U-ions is increased from 4^+, with 28^+ being needed for further acceleration. Measurements with the N_2-jet show equilibrated charge state distributions for U on N_2 with an average charge state between 26^+ and 27^+ [4]. To increase the stripping efficiency into the desired charge state (28^+), the use of other stripper gases is explored. To use other promising stripper gases at sufficient gas density, the back-pressure on the gas inlet has to be increased. The limitations of the differential pumping system connecting the stripper to the accelerator hinder this approach using the laval nozzle [5].

For working with increased gas density with the current pumping setup, the laval nozzle was exchanged by a pulsed valve, which is the basis for a pulsed gas cell. The valve opens only when a beam pulse passes the gas stripper and closes immediately afterwards. Given the low beam duty cycle, this enables the use of much higher back-pressures on the gas inlet, which is assumed to lead to higher gas densities in the interaction zone. With this modified setup, the use of other stripper gases at sufficient gas densities appears possible.

The new modified setup was first tested early in 2014 with a Bi-beam using N_2 as a stripper gas [6]. Recently, another measurement series was conducted using an U-beam on H_2, He and N_2 and a yet improved setup.

EXPERIMENTAL SETUP

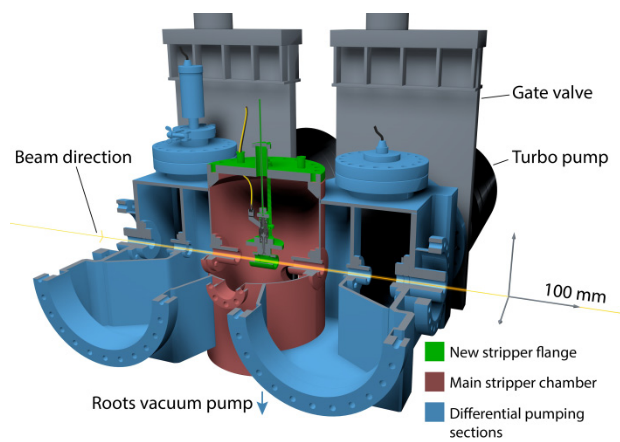

Figure 1: 3D model of the GSI UNILAC gas stripper.

The experimental setup that was used for these measurements is a modified version of the setup described in [6]. The basic parts of the GSI UNILAC gas stripper are depicted in Fig. 1. A four stage differential pumping system is used to achieve the required vacuum in the adjacent accelerator line. The major gas load is removed by a roots vacuum pump (2222 l/s) located directly below the main stripper chamber. The adjacent

A COMPACT CYCLOTRON FOR 35 MeV PROTONS AND 8 AMeV OF H_2^+

A. Calanna[1], T. Boiesan[2], L. Calabretta[1],
L. AC Piazza[2], R. Johnson[2], V. Sabaiduc[2]
[1] INFN-LNS, Catania, Italy
[2] BCSI, Vancouver, Canada

Abstract

The design characteristics and parameters of a compact cyclotron able to accelerate H^- ions up to an energy of 35 MeV and H_2^+ ions up to an energy of 8 AMeV are presented. This cyclotron is a 4-sector machine and its special feature is the possibility to modify the profiles of the sector hills to allow for the acceleration of the two different species. When equipped with two RF cavities and operated in harmonic mode 4, it accelerates the H- beam, which is extracted by stripping. The resulting proton beam is used for the commercial goal of radioisotope production. On the other hand, when equipped with four RF cavities, also operated in harmonic mode 4, it accelerates a high intensity H_2^+ beam that is of interest for the IsoDAR* experiment. Here, the presented cyclotron takes on the role of a prototype for the central region design of the final IsoDAR* cyclotron (60 A MeV H_2^+). By increasing the number of cavities, the energy gain per turn as well as the vertical focusing along the first orbit are increased, thereby optimizing the acceptance. Moreover, to minimize space-charge effects, the injection energy of H_2^+ is raised to 70 keV compared to the H- injection energy of 40 keV.

INTRODUCTION

A Memorandum of Understanding established a partnership between Best Theratronics Ltd. and LNS-INFN to develop a new high-power machine for proton and H_2^+. The study of this machine is based on the design of the central part of a bigger cyclotron studied for the DAEδALUS and IsoDAR experiments, respectively investigating the CP-violation and the existence of sterile neutrinos [1,2,3].

The primary goal of the project is the production of 1 mA proton beam at 35 MeV with cyclotron. The cyclotron here described and labelled B35P, accelerates H^- ions, which are extracted by stripping to deliver the proton beam. An additional feature of the cyclotron presented is the capability to accelerate ions with q/A=0.5 (H_2^+ hydrogen ionized molecule, deuteron and He^{++}) up to the maximum energy of 8 AMeV.

This feature is worth investigating, especially because one of the goals of the agreement is to check experimentally the acceleration of H_2^+ beams with currents up to 5mA. This feature is also of interest of Best Theratronics Ltd. because fine adjustments of the cyclotron central field and/or of the pole shims, allows the acceleration of He^{++} beams up to a maximum energy of 32 MeV (8 MeV/amu) and or deuteron beams up to 16 MeV.

The present magnetic circuit of the cyclotron is an evolution of the previous design presented at the Cyclotrons2014 [3]. The main differences are:

- the hill gap has been reduced to 5.4 cm from 6 cm;
- the maximum energy of H^- that has been increased from 28 MeV to 35 MeV;
- The iron size that was increased too;
- the coil sizes and the current to feed them have been optimized to reduce significantly the power consumption, which now is 7 kW;
- The stray field was significantly reduced to less than 20 Gauss on the cyclotron axis at a distance of 1.5 m from median plane, that is the position where the H^- source will be installed.

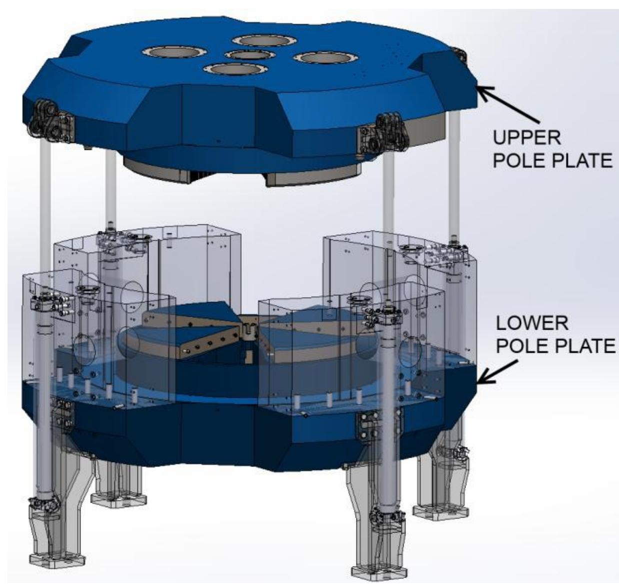

Figure 1: B35P layout.

These advantages have been achieved reducing the valley gap of the cyclotron from the previous value of 1400 mm to the present value of 1000 mm. The main change in respect to the September 2013 design is that the cyclotron here discussed is not a true dual machine for proton and H_2^+. That means, it is mandatory to open the cyclotron to switch from the proton operation mode to the H_2^+ mode.

Abstract

The INFN-LNS Superconducting Cyclotron (CS) has been working for about 20 years delivering ion beams from protons to gold in the wide energy range from 10 A MeV to 80 A MeV. The beam extraction is presently accomplished by means of two electrostatic deflectors and a set of magnetic channels. Recently, the experiment NUMEN [1, 2] has been highly recommended by the scientific community. The requirements on target are light ion beams (A<30 amu), within an energy range of 15-60 A MeV and a beam power of 5-10 kW, which means to increase the extracted power by a factor 10-100. To achieve this goal we have studied extraction by stripping using the existing extraction channel with an increased transversal section. In addition, a new extraction channel has been designed to broaden as much as possible the range of the extracted ions and energies. To allow the realization of these new channels, a new superconducting magnet is needed including a new cryostat. The major changes and the expected performances for the upgraded cyclotron, as well as the state-of-art of the design, are presented.

INTRODUCTION

The goal of this feasibility study is to investigate extraction by stripping in the Superconducting Cyclotron (CS) to achieve beam power intensity in the range 5-10 kW for light ions with A<30. Even if the NUMEN experiment, which proposes to measure the element of nuclear matrix using double charge exchange reactions [1, 2], is the main reason to increase the beam power, many other experiments currently accomplished at LNS will take advantage from this upgrade. These experiments make use of radioactive ions beam produced with in-flight technique at FRIBS@LNS [3]. Production of radioisotopes of medical interest can be considered too.

Presently, the vertical gap along the CS extraction channel is only +/- 12 mm, while the radial allowed beam dimension does not exceed +/- 5 mm. These mechanical constraints are not enough to plan an extraction of 5-10 kW of beam power. Moreover, a cold channel will be mandatory. For these reasons, we have to replace the whole cryostat. We have investigated the benefits of an increased cross-dimension of the existing channel as well as the feasibility of a complete new channel.

However, the CS peculiarity is its versatility, which has to be maintained since there is a consistent demand of beam types in a wide mass and energy range. For this reason, we plan to equip the CS with both extraction modes: extraction by stripping and extraction by electrostatic deflectors.

In this paper, we describe the approach and codes we used and we show few results that demonstrate we are ready to move towards the technical design. We have already committed to the Plasma Science and Fusion Centre of MIT a study on the feasibility of a new cryostat, which includes the new extraction channel. Some extract of the report they provided on the viability and costs have been reported too.

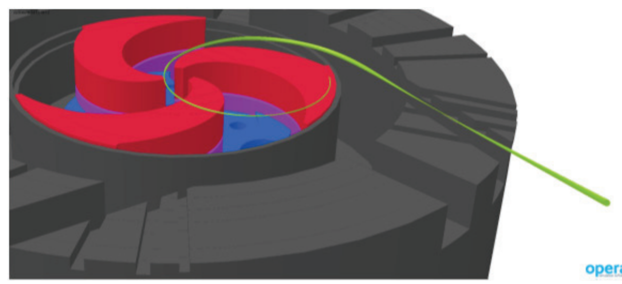

Figure 1: example of extraction trajectory of 12C at 45 AMeV achieved using the code OPERA.

TECHNICAL APPROCH

The main tools we used for this study of feasibility originate from two codes, GENSPE and ESTRAZ, developed at MSU by Gordon [4]. We updated them to suit and solve our needs. All the results have been validated and visualise through a FEM software, OPERA 3D.

Since this study is about an upgrade of an existing machine, measured magnetic maps are available. For this reason, we decided for an approach different from the usual. We created the magnetic model computing the components of the magnetic field outside the median plan solving the Maxwell equations. This 3D map can be visualised and analysed in the Post Processor module of OPERA 3D to track the particles both along the closed orbits and the extraction orbits.

Specifically, our procedure for each ion is now described.

At first, we identify the beam dynamics parameters along the closed orbits using GENSPE. Its input parameters are the magnetic map on the median plane, ion type, RF parameters, beam normalized emittance out of the inflector, which has been chosen to 1 π mm.mrad, about 2.5 larger than the value of the source emittance. The outputs of GENSPE give details on each closed orbit with a given step of energy. That means information on the radius, the radial component of the momentum, the isochronism, the phase slip and the axial and radial betatron oscillations.

RIB TRANSPORT AND SELECTION FOR THE SPES PROJECT

M. Comunian, A. Pisent, L. Bellan, INFN-LNL, Legnaro, Italy
A. D. Russo, INFN-LNS, Catania, Italy

Abstract

At LNL INFN is under construction a Rare Isotope Facility (SPES) based on a 35-70 MeV proton cyclotron, able to deliver two beams with a total current up to 0.5 mA, an ISOL fission target station and an existing ALPI superconducting accelerator as a post accelerator (up to 10 MeV/u for A/q=7). In this paper, some highlights are presented: the high resolution mass separator, the 5 MHz buncher performances and the voltage profile errors of the CW RFQ (80 MHz, 727 keV/u, internal bunching). The problems that have been solved during the design phase are partly common to all RIB facilities, like the necessity to have an high selectivity and high transmission for a beam of a very low intensity, plus the specific challenges related to the use of ALPI (with a reduced longitudinal acceptance) and related to the specific lay out. At present the design phase has been finalised, and the procurement procedure for the charge breeder, the transfer lines and the RFQ are in an advanced state.

INTRODUCTION

SPES, acronym of Selective Production of Exotic Species, is a CW radioactive ion beam facility under construction at LNL INFN in Italy. It will produce and accelerate neutron-rich radioactive ions, in order to perform nuclear physics experiments, which will require beams above Coulomb barrier.

The main functional steps of the facility are shown in Fig. 1: the primary beam delivered by the cyclotron, the beam from the fission target (as an example, up to 10^{10} particle/s of ^{132}Sn), the beam cooler, the separators, the charge breeder and the accelerator, the existing ALPI with a new RFQ injector. The use of the continuous beam from the +1 source, which can be of LIS, PIS, SIS type, maximizes the RNB efficiency but need a CW post accelerator (RFQ and ALPI); the charge breeder is chosen to be an ECR that woks in continuous. The energy on the transfer lines are determined by the chosen RFQ input energy (wRFQ=5.7 keV/u); for this reason, all the devices where the beam is approximately stopped (production target, charge breeder and RFQ cooler) lay at a voltage:

$$eV = (A/q)w_{rfq} \quad (1)$$

The charge state range (3.5<A/q<7) is bounded by the RFQ field level for the upper limit and by the minimum voltage on q=1 transport line. A full facility layout is shown on Fig. 2.

The beam preparation scheme satisfies various requirements:

- the zone with worst radiation protection issues is reduced by the first isobar selection (resolution R=1/200).
- after that an RFQ cooler reduces the beam energy spread and transverse emittance both for the isobar separation and to cope with the charge breeder acceptance (about 5 eV and 2 mm mrad rms normalized emittance).
- HRMS and MRMS (high and medium resolution mass separators, R=1/20000 and R=1/1000 respectively) are used to select the RNB (with good transmission) and to suppress the contaminants from the charge breeder source.
- both the HRMS and the MRMS are installed on a negative voltage platform, to decrease the beam geometrical emittance and the relative energy spread.
- the 7 m long RFQ is designed with an internal bunching and relatively high output energy; this easies the setting and allows 90% transmission into ALPI longitudinal acceptance.
- an external 5 MHz buncher placed 9 m before the RFQ will provide order of 100 ns beam length for specific experiments.
- the dispersion function is carefully managed in the various transport lines; where possible the transport is achromatic, otherwise the dispersion is kept low (in particular at RFQ input D=0).

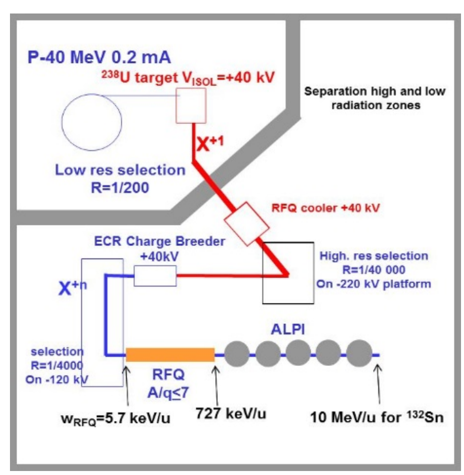

Figure 1: Functional scheme of the SPES facility. There are two main areas: the 1+ line and the n+ line, where 1+ and n+ indicates the beam charge state.

STABILITY STUDIES FOR J-PARC LINAC UPGRADE TO 50mA/400MeV

Y. Liu, T. Maruta, K. Futatsukawa, T. Miyao KEK/J-PARC, Ibaraki-ken, Japan
M. Ikegami, FRIB, East Lansing, USA
A. Miura, JAEA/J-PARC, Tokai-mura, Japan

Abstract

J-PARC linac applies the Equi-partitioning (EP) setting as the base-line design. And it is the first machine to adopt this approach at the design stage. EP condition is a natural solution for avoiding emittance exchange between transverse and longitudinal planes. At J-PARC linac it is also possible to explore off-EP settings. One of the motivations could be a lattice with relaxed envelope for mitigating the intra-beam stripping (IBSt) effects in high current H- beam. During and after the energy upgrade in Jan., 2014 and beam current upgrade in Oct., 2014, experiments were carried out to study the stability and emittance evolution for the EP and off-EP settings with high current H- beam at J-PARC linac for better choices of lattice and better understanding.

INTRODUCTION

The Japan Proton Accelerator Research Complex (J-PARC) is a high-intensity proton accelerator facility, which consists of a linac, a 3 GeV rapid cycling synchrotron (RCS), and a main ring synchrotron (MR).

The J-PARC linac consists of a 3 MeV RFQ, 50 MeV DTL (Drift Tube Linac), 181/190 MeV SDTL (Separate-type DTL) and 400 MeV ACS (Annular-ring Coupled Structure), as shown in Fig.1.

In Jan. 2014 the J-PARC linac energy was upgraded from 181 MeV to 400 MeV while the peak beam current was increased to 50 mA in Oct. 2014. These upgrades allowed the RCS to provide 1 MW equivalent beam powers, a major milestone in the development of J-PARC.

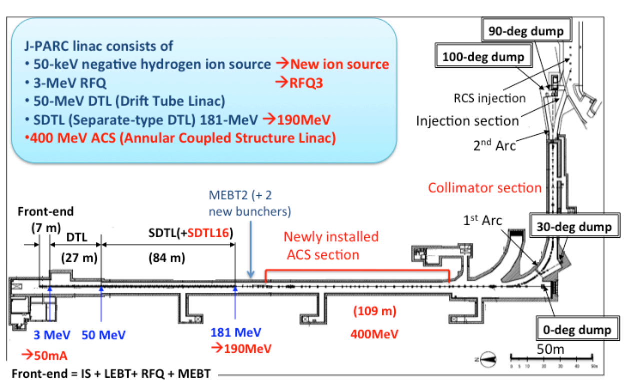

Figure 1: Layout of J-PARC linac.

During the design stage of J-PARC, there was sufficient evidence that an equi-partitioned (EP) lattice offers a natural solution for emittance conservation in high-intensity hadron accelerators, owing to pioneering work by R. A. Jameson, M. Reiser, I. Hofmann [1], and et al. J-PARC linac RF tank were arranged with consideration of a baseline design satisfying EP condition. It also has the flexibility for a wide range of off-EP operating points, offering the opportunities not only for investigating the basic physics principles but also for further optimizations of the machine operation.

As shown in Fig. 2, within the hardware capability, it is possible to set the DTL, the SDTL and the ACS in a wide range of Tx/Tz. Normally Tx=Ty is kept. Tx, Ty, Tz stand for the horizontal, vertical and longitudinal "temperature".

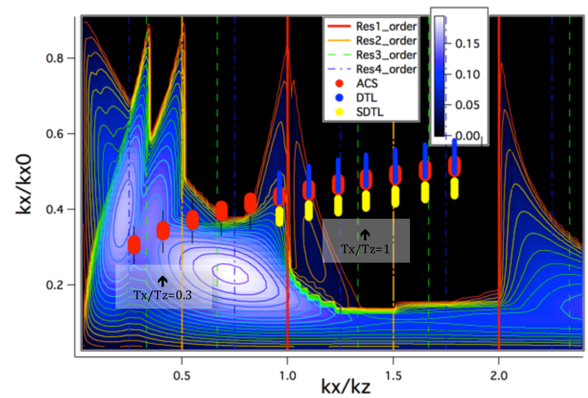

Figure 2: Tune-settings for J-PARC linac in Hofmann stability chart, at 50mA, with $\varepsilon_x / \varepsilon_z = 0.7$.

Tx/Tz is the ratio of oscillation energies in transverse and longitudinal plane, which is defined as,

$$\frac{T_x}{T_z} \equiv \frac{r_x^2 k_x^2}{r_z^2 k_z^2} = \frac{\epsilon_x k_x}{\epsilon_z k_z}. \qquad (1)$$

Here r stands for the beam rms envelop, ε the rms emittance, focusing is represented by the wave number k (with current) and k_0 (0-current). For instance settings to the left in Fig. 2 indicate less transverse focusing or more longitudinal focusing and vice versa. The EP condition generates largest stable area.

COMPLETION OF UPGRADES AND REMAINING QUESTIONS

Both energy [2] and beam current [3] upgrades were accomplished within the planned schedules with satisfying levels of beam loss and extinction rate. From 2015, J-PARC started ramping up of the RCS operation output power from 300 kW, in steps of 100 kW, towards the goal of 1MW in early 2016.

However, questions and difficulties remain. For example, the longitudinal measurement at MEBT2 was missing during the energy upgrade due to bunch shape monitor (BSM) vacuum problems. This measurement is

RECENT PROGRESS OF THE BEAM COMMISSIONING IN J-PARC LINAC

T. Maruta*, Y. Liu, K. Futatsukawa, T. Miyao, KEK, Tsukuba, Japan
M. Ikegami, FRIB, East Lansing, MI, USA
A. Miura, JAEA, Tokai-mura, Japan

Abstract

The injector linac of Japan Proton Accelerator Research Complex (J-PARC) is recently conducted a front-end upgrade to increase the feasible peak current to 50 mA. Together with the beam energy upgrade in year 2013, we are ready for challenge into design beam power of 1 MW operation at the 3 GeV Rapid Cycling Synchrotron (RCS). The 1st commissioning after the upgrade began at September 29th, and then we successfully realized 50 mA beam acceleration on October 15th. In this paper, recent progress of linac beam commissioning, especially for after the front-end upgrade is described.

INTRODUCTION

J-PARC is a MW-class multi purpose proton accelerator facility in Japan. The accelerator is comprised from a 400 MeV linac, a 3 GeV RCS and a 50 GeV main ring (MR). The MR is currently operating at 30 GeV. The linac consists of 50 keV negative hydrogen (H^-) ion source (IS), a 3 MeV Radio Frequency Quadruple (RFQ), a 50 MeV Drift Tube Linac (DTL), an 191 MeV Separate-type DTL (SDTL) and a 400 MeV Annular-ring Coupled Structure (ACS) linac as shown in Fig.1 [1]. There are three beam transport sections; MEBT1 is between RFQ and DTL, MEBT2 is in SDTL and ACS and L3BT is from ACS to 3 GeV RCS, respectively. The RF frequency is 324 MHz in RFQ, DTL and SDTL, and ACS is threefold frequency of 972 MHz.

Outline of the Linac Upgrade

In the linac, a beam power upgrade project had been conducted in year 2013 - 2014 to achieve the design beam power of 1 MW at the RCS extraction. Before this upgrade, the beam energy and the peak current were 181 MeV and 30 mA, respectively. The upgrade is divided in two periods. The 1st period is a beam energy upgrade from 181 MeV to 400 MeV by introducing ACS after the existing linac. The aim of this upgrade is the alleviation of the Laslett incoherent tune shift at RCS. Since the shift amount is inversely proportional to $\beta^2\gamma^3$ (β, γ : Lorentz factor), This energy extension reduces the shift amount to be < 1/3, and it is settled in an acceptable range even in 50 mA.

In the 2nd period of the intensity upgrade, the IS is replaced to an RF-driven type and RFQ (RFQ III) is also replaced to new one which is designed for 50 mA. To handle the higher beam power from the RFQ III, we also upgraded the RF chopper system placed in MEBT1; introduction of a tandem scraper configuration and new chopper cavity.

* tmaruta@post.j-parc.jp

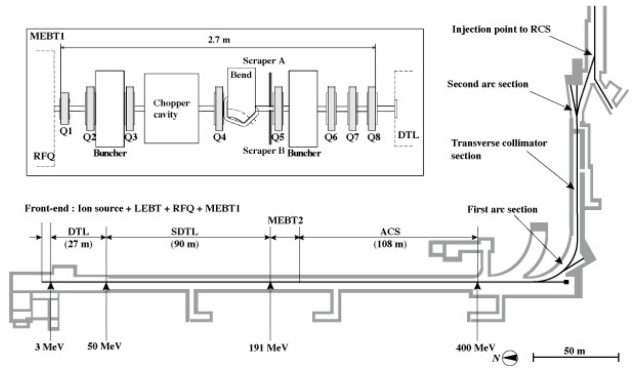

Figure 1: Outline of the J-PARC linac. The top-left Figure is the detail of MEBT1 between RFQ and DTL.

PROGRESS OF THE COMMISSIONING

The linac beam commissioning after the intensity upgrade began at September 29th, and continues till October 14th. There are main purposes; establishment of 400 MeV accelerator, a 50 mA tuning for a high power test and a 30 mA tuning for an user operation. We successfully accelerate a 50 mA beam at October 14th. In this section, the progress of the linac beam commissioning after the front-end upgrade is discussed.

MEBT1 Matching

It is needless to say that the replacement of the front-end results a variation of the beam distribution at RFQ exit, and this variation must be absorbed in MEBT1. Moreover, MEBT1 is the most severe matching section from the point of view of space-charge force due to its low energy. Therefore, an accurate matching is required for a beam halo mitigation. We firstly measured a transverse beam profile in MEBT1 by Q-scan. Then, the MEBT1 optics was determined from this measurement and simulated longitudinal profile at the RFQ III by PARMTEQM [2]. After setting a new lattice, we conducted a DTL acceptance scan [3] to check the consistency for longitudinal profile. We also measured a transverse beam profile at the SDTL entrance, because the beam profile at this region strongly depends on the accuracy of the MEBT1 matching.

The Q-scan is conducted by Q3 and the wire scanner monitor (WSM) between the RF chopper cavity and Q4 which is 0.62 m downstream from Q3. Since we turn off the chopper RF while a measurement, the lattice between them is quadrupole + drift. In the thin lens approximation, the square of beam size at the WSM (σ^2_{WSM}) is a 2nd order polynomial function described from the Twiss parameter at

RECTILINEAR COOLING SCHEME FOR BRIGHT MUON SOURCES*

Diktys Stratakis#, Brookhaven National Laboratory, Upton NY, USA

Abstract

A fast cooling technique is described that simultaneously reduces all six phase-space dimensions of a charged particle beam. In this process, cooling is accomplished by reducing the beam momentum through ionization energy loss in absorbers and replenishing the momentum loss only in the longitudinal direction rf cavities. In this work we review its main features and describe the main results.

INTRODUCTION

The initial muon beam occupies a relatively large phase-space volume which must be compressed by several orders of magnitude to obtain high-luminosity collisions. Furthermore, this phase-space reduction must be done within a time that is not long compared to the muon lifetime (2 μs in rest frame). Ionization cooling is currently the only feasible option for cooling a muon beam [1]. This technique is not very practical for protons, which would have frequent nuclear interactions, or electrons, which would have bremsstrahlung, but is practical for muons, and cooling rates compatible with muon lifetimes are possible. The main goal of this paper is to develop a potential baseline cooling lattice for a muon related applications and evaluate its performance. We also discuss a possible variant of this channel.

LATTICE DESIGN

Three different geometries for ionization cooling towards micron-scale emittances as required for a muon collider have been previously considered: (a) A ring, (b) a helix commonly known as a Guggenheim helix, and (c) a rectilinear channel. The common feature for all cases was that the solenoids were slightly tilted to generate upward dipole fields. In the third case, essentially the same cells from a ring or a Guggenheim, including their coil tilts and resulting upward dipole fields, are laid out in straight (rectilinear) geometry. The solenoid focusing is so strong, compared with the dipole deflections, that the closed orbits are merely displaced laterally, but continue down the now straight lattice. This rectilinear scheme was proposed for the first time by Balbekov [2] and is represented in Fig. 1. Despite its much simpler geometry, it was found [3] that its cooling performance was essentially the same as with rings or a helix. As a result, the rectilinear scheme will be considered our new baseline cooling lattice.

Figure 1(a) shows a cross section of a cell of the cooling rearly stage. The rf is at 325 MHz operating at 19 MV/m and a phase of approximately 41 degrees. The cell contains two coils of opposite polarity, yielding an approximate sinusoidal variation of the magnetic field in the channel with a peak on-axis value of 2.6 T. The coils are tilted in opposite directions by 0.9 degrees. Figure 1(b) shows a cell of a late cooling stage that is required to cool the beam transversely to ≤0.3 mm. The cell consists of six solenoids which surround four 650 MHz cavities in the cell center. As before, the geometry of the lattice is such that the absorber is located at beta minima (blue dashed curve).

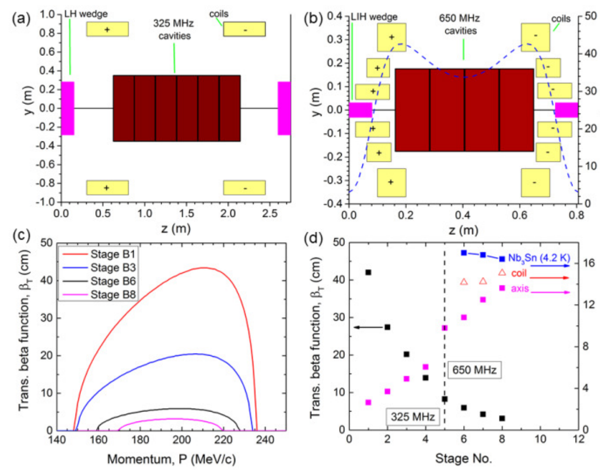

Figure 1: Lattice characteristics of the proposed rectilinear 6D cooling channel: (a) Early stage, (b) last cooling stage, (c) beta function for different stages, and (d) beta and maximum axial field per stage as well as allowable field limit for Nb_3Sn.

Figure 1(c) shows the transverse beta function at the absorber versus momentum for four stages out of the total 12 stages of the channel. Note that the transverse beta function becomes progressively smaller from stage to stage by scaling down the cell dimensions and raising the on-axis magnetic field [Fig. 1(d)]. As a result, the minimum beta function drops from 42.0 to 3.0 cm while the on-axis peak magnetic field increases from 2.6 to 13.6 T. This can become a challenge since the operating current in a superconducting magnet must be smaller than the critical current corresponding to the peak field in the coil. To highlight this last fact we also plot in Fig. 1(d) the maximum local fields in the coils for the last three stages (triangles) and compare them to the published maximum allowable field (squares) for the used coil current density, assuming a Nb3Sn conductor. Our findings indicate that the needed fields are consistent with the critical limits of existing conductor technology but the last stages are barely within the limits of Nb3Sn. A recent magnet feasibility study [4] revealed that for a more stable operation a 1.9 K operating magnet temperature is preferred for this stage. This would allow the Nb3Sn inner solenoids to operate at 85% of the load line at operational current.

PRELIMINARY STUDIES OF LASER-ASSISTED H⁻ STRIPPING AT 400 MeV

P.K. Saha*, H. Harada, M. Kinsho, T. Maruta, K. Okabe, M. Yoshimoto
J-PARC Center, KEK & JAEA, Tokai-mura, Naka-gun, Ibaraki-ken, Japan
Y. Irie, High Energy Accelerator Research Organization, Tsukuba, Ibaraki, Japan
T. Gorlov, Oak Ridge National Laboratory, Oak Ridge, TN, USA

Abstract

Laser-assisted H^- stripping is very essential to overcome real challenges of short lifetime and machine activation by using solid stripper foil for that purpose. Extensive studies on the laser stripping are in good progress at the Spallation Neutron Source (SNS) of Oak Ridge for an H^- energy of 1 GeV. It is therefore interesting to explore these studies for lower H^- energies. As an example, the 3-GeV Rapid Cycling Synchrotron (RCS) of Japan Proton Accelerator Research Complex (J-PARC) is considered, where H^- injection energy is 400 MeV. The present work is a preliminary study of the laser-assisted H^- stripping at this energy, where a set of optimized parameters are considered in order to realize a same level of stripping efficiency as in the SNS case. The feasibility and real challenges are discussed.

INTRODUCTION

Solid stripper foil is used for several hundred to thousand multi-turn H^- stripping injection in the proton accelerators in order to achieve MW-level beam power [1, 2]. However, lifetime and rapid foil failure due to overheating of the foil are serious concerns to maintain stable operation of the machine [3]. It is therefore a real challenge and may be the biggest limitation to realize a multi-MW user machine. Although continuous efforts on durable foil production made remarkable progress on the foil lifetime [4], it is still unclear how to deal with multi-MW beam. Other than foil lifetime, the residual activation near the stripper foil due to the foil scattering beam loss during multi-turn injection is also another uncontrollable factor and a serious issue for facility maintenance.

It is therefore essential that alternate technologies other than using solid foil for the charge-exchange injection have to be established in order to avoid these issues. The idea of laser-assisted H^- stripping, which is a three-step process of an H^- conversion to a proton (magnetic stripping + laser excitation + magnetic stripping) was originally proposed nearly two decades ago [5]. A schematic view of the concept is shown in Fig. 1. A little modified approach to reduce Doppler broadening in the second process of laser excitation was later proposed and also successfully demonstrated a proof-of-principle (POP) experiment at the Spallation Neutron Source (SNS) in Oak Ridge, achieving 90% stripping efficiency for a short pulse of 6 ns, 900 MeV H^- [6, 7]. Aiming for 3 orders of magnitude improvement by increasing

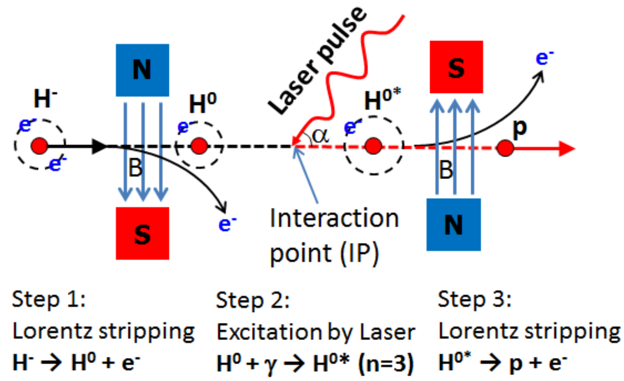

Figure 1: Schematic view of laser-assisted H^- stripping.

the H^- pulse length 5∼10 μs, preparations for the next experiment are in good stage and will be carried out in early 2016 [8, 9].

The present work is a preliminary study for laser-assisted H^- stripping at an energy quite lower that of SNS. For instance, the 3-GeV Rapid Cycling Synchrotron (RCS) of Japan Proton Accelerator Research Complex (J-PARC) is considered [1]. The injection energy is 400 MeV, while the extraction energy is 3 GeV. The designed beam power of the RCS is 1 MW at a repetition rate of 25 Hz. RCS beam power for the operation is 500 kW at present, while an equivalent beam power of 1 MW beam has already been demonstrated recently [10]. Although no foil failure occurred so far but based on measured foil degradation, it is worried that the real lifetime at 1 MW could be much shorter than expected. In order to realize further more than 1 MW beam power, it is therefor essential to study the possibility of laser-assisted H^- stripping at 400 MeV as foil may not survive beyond 1 MW. The present work has been done in the similar framework as in the SNS. The aim is to give an overview of the optimum parameters to realize laser-assisted H^- stripping at 400 MeV.

MAGNETIC FIELD STRIPPING

As shown in Fig. 1, the 1st and 3rd steps utilize Lorentz stripping by using high field magnets. In the former step, an H^- is stripped to an H^0, while H^0 excited by the laser is stripped to a proton by the 2nd magnet in the later step. The basic concept is similar to that already designed for 1 GeV H^- at SNS [11]. A detail is thus not discussed here. Figure 2 shows magnetic field configuration together with stripping functions. The magnetic field for each magnet is considered to be Gaussian shape with σ=0.03m for simplicity as shown

STATUS OF THE J-PARC 3 GeV RCS

M. Kinsho#, J-PARC, KEK&JAEA, Tokai-mura, Naka-gun, Ibaraki-ken, 319-1195, Japan

Abstract

Beam power of routine operation of the J-PARC rapid cycling synchrotron (RCS) increased gradually for the MLF user operation, beam power of 400 kW was achieved on 10th March, and 500 kW user operation has been stably performed from 14th April this year. Beam studies were also performed to demonstrate the capability of the RCS to operate at powers in excess of 1 MW. The study produced a beam intensity of 8.41×10^{13} protons during short time, an intensity equivalent to 1.01 MW operation on 10th January 2015.

INTRODUCTION

The J-PARC rapid cycling synchrotron (RCS) has been operated for the neutron and MLF users program from December 23rd, 2008. The RCS operations not only in support of the MLF but also were providing beam for the MR user program (Hadron experiment and/or Neutrino experiment). The RCS has been deliver stable beam of beam power of 300 kW to the MLS and the MR until December 2013 with the linac energy of 181 MeV [1]. To achieve the nominal performance of 1 MW at the RCS and 0.75 MW at the MR, the full energy (400 MeV) and higher peak beam current of the linac is necessary for the J-PARC facility. J-PARC has been done upgrade their linac from 181 MeV to 400 MeV with new ACS (annular coupled structure) linca, and user operation started from February 2014[2].

Beam injection energy of the RCS in J-PARC was increased from 181 MeV to 400 MeV, and user operation with beam energy of 300 kW for both the MLF and the MR was performed with high availability from February to Jun in 2014. Beam losses during beam injection period was decreased by reduction of space charge effect due to increase of beam injection energy. Since an ion source and an RFQ of the LINAC are replaced to realize 1 MW beam power at the RCS in summer maintenance period, injection beam peak current was increased from 30 mA to 50 mA. User operation was restarted from November with beam power of 300 kW. The beam power for user operation will be gradually increased after getting radiation safety permission from government. High intensity beam study was also performed and it was successfully to accelerate beam of 1MW equivalent with small beam losses. In this beam study it was cleared issues to realize 1MW routine operation in the RCS. Status of user operation and issues to realize high power routine operation in the RCS are presented in this paper.

#kinsho.michikazu@jaea.go.jp

ROUTINE OPERATION FOR USERS

The RCS could be delivered beam whose power was 300 kW to both the MLF and the MR for their user operation with an average availability of more than 95 % before the linac energy upgrade. Figure 1 shows output beam power and availability of the RCS from February 2014 to January 2015. Summer maintenance period is usually three months (from July to September), but it was four months last summer for replacement of front-end (ion source and RFQ) of LINAC. Beam studies were performed in spare moments from routine operation in the end of June, and end of December and middle of January which are sighed (1) and (2), respectively in Fig. 1. User operation resumed from 17th February 2014 with 110 kW beam only for the MLF after the linac beam energy upgrade (400MeV injection). The beam power gradually increased, and then beam power achieved 300 kW for the MLF users in 27th February 2014. Since the MR started user operation for neutrino experiment from middle of May, the RCS also started to deliver beam to both the MLF and the MR with beam power of 300 kW.

Beam power was limited 300 kW for the MLF due to government permission of radiation safety, but it was possible to be 1 MW beam routine operation at the RCS from December 2014 because we could get the permission from government. Beam power increased gradually for the MLF user operation, beam power of 400 kW was achieved on 10th March, and 500 kW user operation has been stably performed from 14th April this year. The beam power will be increased to 600 kW in the middle of May.

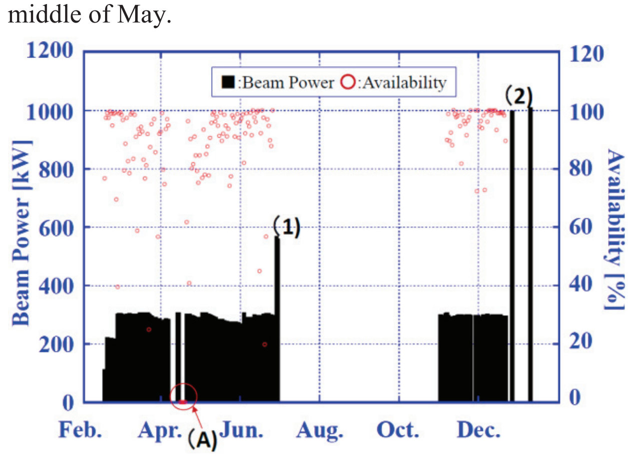

Figure 1: Output beam power and availability of the RCS from February 2014 to January 2015. Black line shows beam power and read circle shows availability. Beam studies were performed at the number (1) and (2) shown in this figure. Availability was zero at period of (A) shown in this figure due to failure of an oil cooling pump in the bending magnet choke transformer.

SIMULATION STUDY OF MUON ACCELERATION USING RFQ FOR A NEW MUON G-2 EXPERIMENT AT J-PARC

Y. Kondo*, K. Hasegawa, JAEA, Tokai, Naka, Ibaraki, 319-1195, Japan
M. Otani, T. Mibe, N. Saito, KEK, Oho, Tsukuba, 305-0801, Japan
R. Kitamura, U. Tokyo, Tokyo, 113-0033, Japan

Abstract

A new muon g-2 experiment is planned at J-PARC. In this experiment, ultra cold muons will be generated and accelerated using a linear accelerator. As the first accelerating structure, an RFQ will be used. We are planning to use a spare RFQ of the J-PARC linac for the first acceleration test. In this paper, simulation studies of this muon acceleration test are presented. A design study of a muon dedicated RFQ is also shown.

INTRODUCTION

The J-PARC E34 experiment aims to investigate particle physics beyond the standard model by measuring the muon anomalous magnetic moment (g-2) and the electric dipole moment (EDM) with precision of 0.1 ppm and $1 \times 10^{-21} e\cdot$cm, respectively [1]. E34 will be conducted at the H-line [2] of J-PARC muon science facility. This experiment needs a low-emittance muon beam, and to this end, the idea of reacceleration of cooled muon is utilized. The reacceleration of cooled muon is already proposed in [3], in which a wedge-shaped energy absorber is used to cool the muons. On the contrary, we are planning to use ultra cold muons (UCMs) generated by laser-ionization of thermal muoniums (Mu: μ^+e^-) form an silica-aerogel target [4]. Generated UCMs are accelerated using a muon linac. As the first step, a spare RFQ of J-PARC linac (RFQ II [5]) will be used as a front-end accelerator. The resonant frequency of RFQ II is 324 MHz.

Prior to construct the muon linac, we are planning to conduct a muon acceleration experiment using RFQ II at the H-line. The accelerated particle for E34 experiment is μ^+, however, the ultra cold muon source will not be available when the initial stage acceleration experiment will be performed. Therefore, we are developing a negative muonium (Mu^-) source [6], with witch the Mu^-'s are generated by decelerating the muons from the H-line using an aluminum degrader.

RFQ II is originally designed to accelerate H^-'s, and the mass of the $H^-$is nine times larger than that of muon. To accelerate muons using RFQ II, the power should be reduced to 1/80 of the design power; this is very inefficient. Therefore, we are planning to develop a muon dedicated RFQ (muRFQ), and replace RFQ II when the following accelerators are ready.

In this paper, simulation studies of muon acceleration using RFQs are described.

UCM ACCELERATION USING J-PARC RFQ II

For the simulation of J-PARC RFQ II, PARMTEQM [7] is used because it was used for the optics design of RFQ II. To accelerate muons, the original input file should be modified as follows; 1) The particle mass is defined as muon. 2) Input and output energy are converted from the βs of the H^-. The muon mass and the input and output energy are summarized in Table 1 together with the original parameters for H^- acceleration.

Table 1: Parameter Conversion from H^- to μ

Beam species	H^-	μ
Mass (MeV/c^2)	939.302	105.658
Injection β	0.010318	
Injection energy (keV)	50.000	5.625
Extraction β	0.079732	
Extraction energy (MeV)	3.000	0.337
Inter vane voltage (V)	82.879	9.324
Nominal power (kW)	330	4.177

In this simulation, a particle distribution simulated using GEANT4 [6] is used, as shown in Fig. 1. The phase distribution is assumed to be uniform.

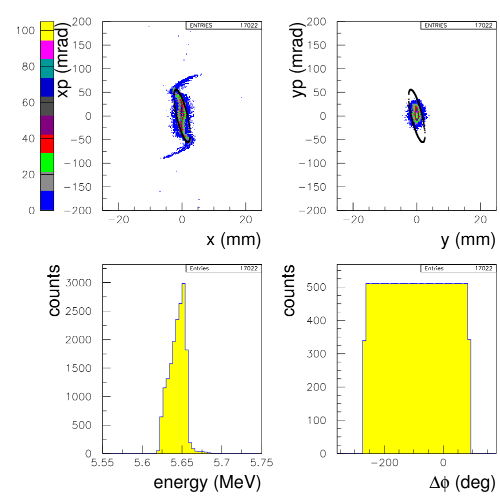

Figure 1: UCM distribution at the RFQ II entrance. The ellipses in upper figures represent the matched ellipses of $\varepsilon_{t,n,rms} = 0.167\pi$ mm mrad.

OPERATION OF THE RHIC INJECTOR CHAIN WITH IONS FROM EBIS*

BNL, Upton, NY 11973, USA

Abstract

Since 2012, gold and all other ions for the RHIC injector chain have been provided by an Electron-Beam Ion Source (EBIS). The source is followed by an RFQ, a short Linac, and a 30 m transport line. These components replace the Tandem van de Graaff and associated 840 m transport line. They provide ions at 2 MeV per nucleon (kinetic energy) for injection into the AGS Booster. The setup and performance of Booster and AGS with gold and other ions from the new source are reviewed.

INTRODUCTION

The RHIC injector chain, including both EBIS and Tandem, is shown in Figure 1 . Previous operation of the chain with ions from Tandem is documented in [1]. EBIS and associated components [2, 3] now provide essentially all ion species for both RHIC and the NASA Space Radiation Laboratory (NSRL), and allow both facilities to operate in parallel efficiently. Ions from EBIS are injected into Booster after acceleration by the RFQ and Linac. The EBIS, RFQ, and Linac output kinetic energies are 17 KeV, 300 KeV, and 2 MeV per nucleon, respectively. The nominal velocity of all ions at Booster injection is $c\beta$ where $\beta = 0.06505$. This gives a revolution period in Booster of 10.35 μs. EBIS delivers a short pulse of 10 to 40 μs, which amounts to 1-4 Booster turns.

The nominal un-normalized 95% transverse emittance of the beam at the end of the EBIS-to-Booster (ETB) transport line is 11π mm milliradians in both planes. This is an order of magnitude larger than the emittance of beams from Tandem, but with injection of EBIS beam occurring over just a few turns, the accumulated gross emittance after injection is somewhat less than that obtained with Tandem beam injected over some 60 turns. Injection proceeds by means of the same electrostatic inflector and four programmable dipoles that are used for Tandem beams. The dipoles move the closed orbit away from the inflector septum as beam is injected. In order to accommodate the larger emittance

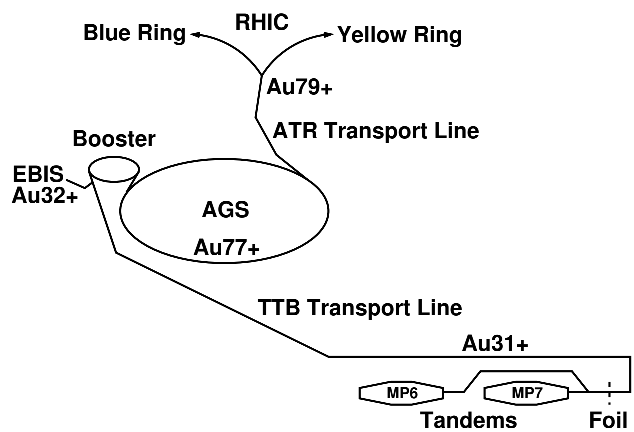

Figure 1: Acceleration of gold ions for RHIC.

of the incoming EBIS beam, the gap between the inflector cathode and septum was increased from 17 to 21 mm.

The number of gold ions delivered to Booster per EBIS pulse is roughly a factor of four less than that delivered per Tandem pulse. In order to make up for this shortfall, it is necessary to deliver 8 loads of Booster beam to AGS per AGS cycle instead of the usual 4 loads delivered for the setup with Tandem beams. Two bunch merges in Booster and two on the AGS injection porch are also required. One ends up with two bunches at AGS extraction, each of which contains 4 Booster loads. For the setup with Tandem one ends up with 4 bunches, each of which contains 1 Booster load. Thus, although there are half as many bunches at AGS extraction for the EBIS setup, each EBIS-setup bunch contains at least as many ions as each Tandem-setup bunch. The details of the setup with EBIS are given in the next section. Beam intensities and longitudinal emittances are discussed in the subsequent sections.

SETUP WITH IONS FROM EBIS

EBIS provided ions of Cu, Au, and U for Cu-Au and U-U collisions in RHIC during Run 12 [4], and for Au-Au collisions during Run 14 [5]. Helions (3He2+) were also provided for helion-Au collisions during Run 14. We focus here on the setup with gold ions. The setup is essentially

NEW SERIES OF RFQ VANE SHAPES

Y. Iwashita, Y. Fuwa, ICR, Kyoto University, Uji, Kyoto, Japan

Abstract

New series of RFQ vane shapes are under investigation by introducing more terms in addition to the two term potential. Because they can incorporate with the feature of the trapezoidal shape modulation with less multipole components, higher acceleration efficiency is expected.

INTRODUCTION

RFQs have basically been designed with so-called two term potential [1]. The two term potential has the simplest form that has minimum terms of acceleration and focusing:

$$U_2(r,\psi,z) = \frac{V}{2}\{X\left(\frac{r}{a}\right)^2 \cos 2\psi + AI_0(kr)\cos(kz)\},$$

where $A = \dfrac{m^2-1}{m^2 I_0(ka)+I_0(mka)}, X = 1 - AI_0(ka), k = \pi / Lc$

and a is the minimum radius at z=0 (see Fig. 1). The vane surface profile can be defined by the equipotential surface of U_2. These parameters are defined at each cell, which may make discontinuities between cells.

The acceleration term A and the focusing term X are the functions of only m and Lc/a, whose contour plots are shown in Fig. 2. They are not monotonic with m in the short cell length region. This is the main reason why m is limited up to 2 or 3 for practical cases. The effective acceleration factor should include the transit time factor.

Typical vane profiles based on this expression are shown in Fig. 3. As can be seen, the vane shape becomes ugly when the modulation factor m becomes large since the large modulation at Lc/a is not realistic. Fringe areas have to be truncated for real vanes in any case. This will be discussed later in this paper.

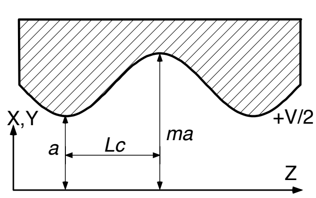

Figure 1: Definitions of vane parameter.

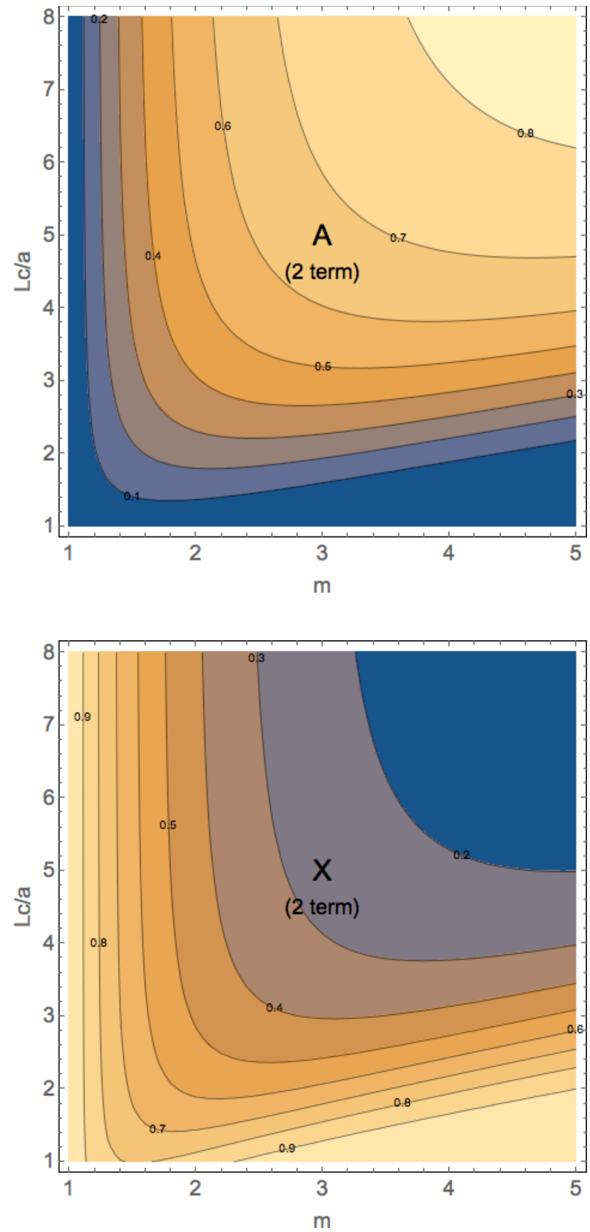

Figure 2: Acceleration term A and focusing term X.

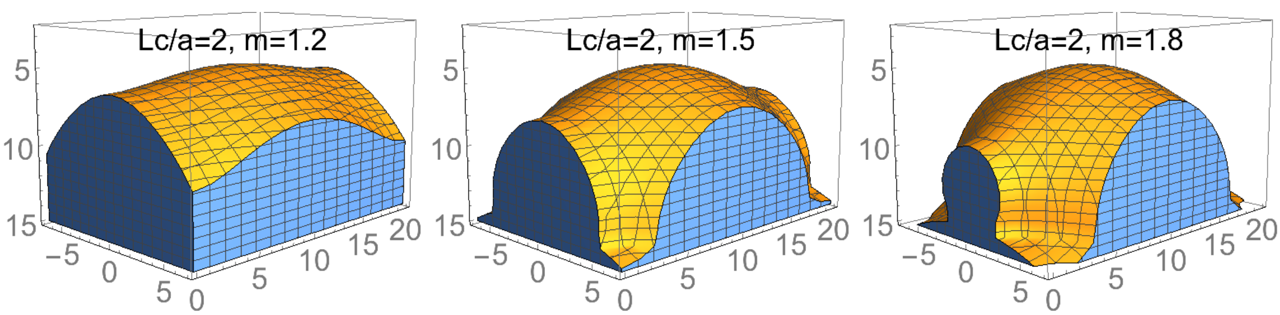

Figure 3: Typical vane profiles based on the two term potentials.

THE SIMULATION AND MANUFACTURE OF THE ROOM TEMPERATURE CROSS-BAR H TYPE DRIFT TUBE LINAC*

Jinhai Li#, China Institute of Atomic Energy, Beijing, China
Zhihui Li, Institute of Nuclear Science and Technology, Sichuan University, Chengdu, China

Abstract

The room temperature Cross-bar H Type Drift Tube Linac (CH-DTL) is one of the candidate acceleration structures working in CW mode. In order to optimize the parameters, the 3 dimensional electromagnetic field of the CH-DTL cavity is simulated. The method of parameter sweeping with constraint variable is better than the method of parameter sweeping with only one variable during the optimization. In order to simplify the manufacture, the drift tube surface can be designed as spherical shape. The effective shunt impedance of the CH-DTL cavity with cylinder end cup is better than that with cone cup.

INTRODUCTON

An industrial scale ADS will require a 10 MW proton beam having an energy between 600 and 1500 MeV. To achieve the required power at this energy will require an average beam current of ≥10 mA. In 2010, a study program was initiated to develop the design a 10 mA, 1.5 GeV, CW superconducting proton linac for ADS. The Institute of High Energy Physics (IHEP) and the Institute of Modern Physics(IMP) are both developing superconducting accelerating structures which would follow an RFQ [1].

Although low AC power consumption and a large aperture favour superconducting structures following a 2–3.5MeV RFQ, normal-conducting accelerating structures have some advantages [2–5]. While the technology for normal-conducting structures in the energy range from 2 to a few tens of MeV is relatively mature, superconducting structures in this energy range are still under development. Normal-conducting structures in this energy range are more efficient than superconducting cavities and, when located downstream of the RFQ, can serve as a beam filter to reduce the potential for beam loss at higher energies.

Under the support of the National Nature Science Foundation of China, we have initiated the design of a 10 MeV CW proton injector, based on normal-conducting Cross-Bar H-type (CH) structure. The CH structure, initially proposed by IAP, Frankfurt University [6–9] belongs to the π-mode family of accelerating structures and is typically characterized by a high shunt impedance, low stored energy and a stable geometry that is relatively easy to cool. We are evaluating this structure as a potential candidate for CW operation. In this paper we present the results of geometry optimization of the CH structure using the method of parameter sweeping with constraint variable (PSCV).

#lijinhai@ciae.ac.cn

OPTIMIZATION PHILOSOPHY

The final energy of modern proton RFQs is typically 3 MeV, corresponding to a relativistic velocity β=0.08. The room-temperature CH-DTL can be used to accelerate the beam starting at this velocity. The CH structure belongs to the π-mode family of structures in which the cells are βλ/2 long, the cell length at β=0.08 being about 37mm. To save simulation time, the geometry of a single cell was first optimized followed by the optimization of the complete multi-cell cavity. The parameters of a single cell are shown in Fig.1. The outer drift tube radius (TR) and the radius of the drift tube aperture (HR) are fixed during the optimization.

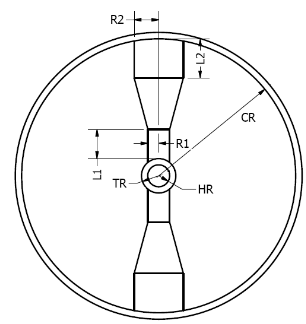

Figure 1: Geometry of a CH single cell.

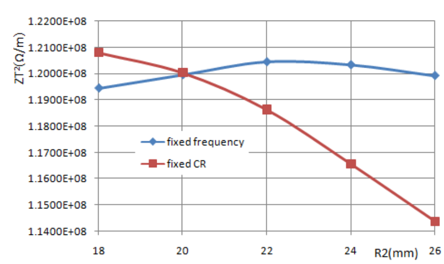

Figure 2: Shunt impedance as a function of outer stem radius using two methods of parameter sweeping

Typically we would sweep a single parameter while monitoring the cavity's RF properties. For example, we know that changing the length of a drift tube causes a corresponding change in the cavity's Q value [6]. However, by changing the length of a drift tube, the resonant frequency changes. Our objective is to optimize the cavity geometry at a fixed frequency (325 MHz). If the frequency changes during the optimization, the optimized value of the swept parameter will differ from the value corresponding to the correct frequency as shown in Fig. 2.

In Figure 2 we have swept the radius of the drift-tube stem base (R2) while fixing the cavity radius (CR). We see that the effective shunt impedance decreases with increasing R2 while the resonant frequency increases from 321.7 to 333.5 MHz. It is convenient to use the cavi-

APPLICATIONS OF BEAM PARAMETER MEASUREMENTS IN TRANSPORT LINES AT CSNS

Z. Li, Y. Li, J. Peng, DINS/IHEP, Dongguan, 523803, China
L. S. Huang, S. Wang, IHEP, Beijing, 100049, China

Abstract

Several XAL-based applications for parameter measurements in Medium Energy Beam Transport line (MEBT) and Linac to Ring Beam Transport line (LRBT) at China Spallation Neutron Source (CSNS) have been developed. Algorithms and functions of these applications are introduced in this paper. Real Machine tests are carried out in the MEBT commissioning.

INTRODUCTION

China Spallation Neutron Source (CSNS) [1] has an H- linear accelerator as an injector and a rapid cycling synchrotron (RCS) of 1.6 GeV. The linac part consists of an H- ion source, a low energy beam transport line (LEBT), a four-vane RFQ linac of 3 MeV, a medium energy beam transport line (MEBT) and a four tank DTL linac working at RF frequency of 324MeV. The linac to ring beam transport line (LRBT) connects the DTL linac and the RCS and it reserves the space for linac upgrading in the further .

XAL[2] is a Java-based application framework which is developed at the Spallation Neutron Source (SNS) at first, then many other accelerator laboratories join the collaboration, including CSNS. XAL provides an accelerator physics programming interface to the accelerator, and it allows creation of general-purpose applications dedicated to various parts of the accelerator and various kinds of the accelerators. Although most tools in XAL application package can be transplanted directly for the use of CSNS, work of developing new essential tools to meets the distinct requirements of CSNS is still necessary.

XAL TOOLS FOR TRANSPORT LINE

Since the first accelerator device of CSNS was installed last October, the installations of ion source, LEBT, RFQ and MEBT have been finished. The commissioning of the front end is proceeding well and the MEBT transport line is going to start soon after. Applications for MEBT commissioning are based on XAL and some new tools have been developed for CSNS. In this paper some of the new developed tools for transport line parameter measurement are introduced, including tools for measuring twiss parameters at MEBT entrance, fudge factor measurement and dispersion function measurement. We are running tests of there tools on the real machine during the commissioning. Algorithms and functions of these applications are presented as follow.

Twiss Parameters Measurement Tool

MEBT of CSNS linac is located between RFQ and DTL, one of whose major functions is for beam matching both transversely and longitudinally. Figure 1 gives the schematic drawing of MEBT.

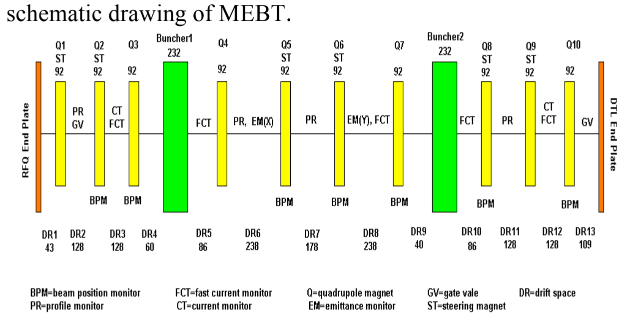

Figure 1: Schematic Drawing of CSNS MEBT.

The energy of MEBT is 3MeV and the peak current intensity is 15mA. Nonlinear space charge force must be considered seriously in the low-energy section of such a high intensity linac. Parmila[3] is an ion linac particle dynamics code. It is a versatile multi-particle code that generates the linac and transforms the beam, represented by a collection of particles, through a user-specified linac and/or transport system. It's widely used in linac designs and simulations, which have proved the accuracy in dealing with the low-energy optics calculation problems. To achieve good solution of MEBT optics matching, the twiss parameters at the MEBT entrance should be acquired first. By employing PARMILA code and 4 wire scanners devices installed in MEBT, a java-based tool was developed to fulfill this purpose. Figure 2 is the algorithm chart of the tool.

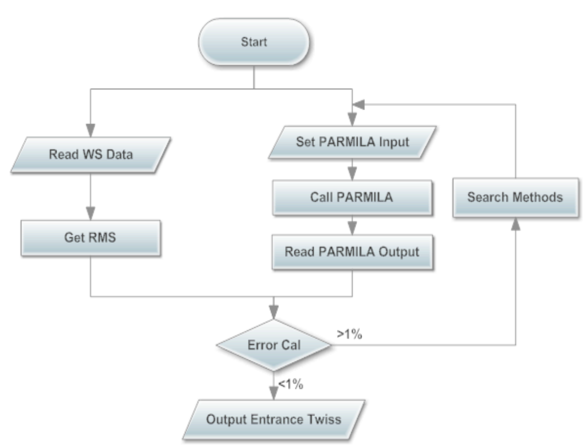

Figure 2: Algorithm Chart of Twiss Parameters Measurement Tool.

BEAM-BASED ALIGNMENT SIMULATION ON TRANSPORT LINE OF CSNS

Yong Li, L.S.Huang, Z.P.Li, Y.W.An, X.H.Lu, W.B.Liu, S.Wang
Dongguan Campus, Institute of High Energy Physics，Dongguan 523803 China

Abstract

The China Spallation Neutron Source (CSNS) is a high beam power proton machine which needs high precise alignment. Compared to traditional optical alignment, the beam-based alignment (BBA) technique can implement higher precise alignment. This technique with two implementations is applied to the transport line of CSNS to get the transverse misalignments of beam position monitor (BPM) and quadrupole magnet by measuring BPM data under different conditions. The corresponding control system application programs were developed based on CSNS/XAL platform. The result shows the fitted result is consistent with the input result.

INTRODUCTION

CSNS is a high power proton machine which is composed of accelerator, target and spectrometer [1]. The accelerator mainly contained a linac with a modest but upgradable energy and a rapid cycling synchrotron (RCS) of the fixed energy at 1.6 GeV. The installation and beam commissioning of the front end of linac has been finished. The beam commissioning for MEBT is upcoming.

The control of beam loss is quite strict for the reason of high power proton. Orbit correction should be done to decreasing the beam loss. Besides, the orbit correction is normally the first and the most important work during beam commission. Other tasks can easily carry out with very small and smooth orbit. But unfortunately, the measured and the true orbit have difference for the error of alignment and resolution of the magnet and BPM. It can't reach the expected purpose with big errors. The calibration of BPM and quadrupole can be achieved through BBA method. In this paper, two kinds of methods and the detailed simulation based on XAL platform is presented.

REVIEW OF BEAM BASED ALIGNMENT METHOD

The study and application of BBA technique can be seen in many laboratories at home and abroad [2-4] and the way of implementation is diversity. Two kinds of implementations will be introduced in this section.

The principle of the first method is very easy. When the beam passes through the center of the magnet, the BPM data is the relative offset of BPM to the quadrupole. We can change the beam position at the entrance of the quadrupole and scan the gradient of the field in the quadrupole and measure the BPMs' responses on both transverse directions. In many situations, the error of alignment for quadrupole is very small; the measured offset can be approximately considered the offset of BPM. However, this method takes too much time.

The second approach looked more promising, which can get the quadrupole and BPM transverse misalignments simultaneously. This method also need to change orbit and scans the gradient of the field of quadrupole. Meanwhile, the liner optics between all beam line elements must be known.

Fig 1 is the beam orbit with misalignments. Based on the liner optics transmission theory, the beam position measurement (m_i) at BPM-i is assumed to be the sum of all upstream beam kicks from quadrupole offset, correctors, incoming launch conditions and BPM offset as in (1) and (2).

$$m_i = (\mathbf{x_i})_1 - \mathrm{b_i} \tag{1}$$

$$\boldsymbol{x_i} = \mathbf{R}^{(\mathrm{B_1}:\mathrm{i})}\boldsymbol{x_1} + \sum_{\mathrm{j}}^{\mathrm{N_{Ci}}} \mathbf{R}^{(\mathrm{C_j}:\mathrm{i})}\mathbf{c_j} + \sum_{\mathrm{j}}^{\mathrm{N_{Qi}}} \mathbf{R}^{(\mathrm{Q_j}:\mathrm{i})}\left(\mathbf{I} - \mathbf{R}^{(\mathrm{Q_j})}\right)\mathbf{q_j} \tag{2}$$

where x_1, $\mathrm{c_j}$ and $\mathrm{q_j}$ are, respectively, the incoming launch position/angle vector at the first BPM in the beam line, a corrector kick angle vector, and a quadrupole position offset vector defined as

$$\boldsymbol{x_1} = \begin{bmatrix} x_1 \\ x_1' \end{bmatrix}; \quad \boldsymbol{c_j} = \begin{bmatrix} 0 \\ \theta_\mathrm{j} \end{bmatrix}; \quad \boldsymbol{q_j} = \begin{bmatrix} \mathrm{q_j} \\ 0 \end{bmatrix}; \tag{3}$$

R is the 2x2 transfer matrix from the first BPM, or from corrector-j, or from quadrupole-j to the BPM-i, or simply the matrix across quadrupole-j.

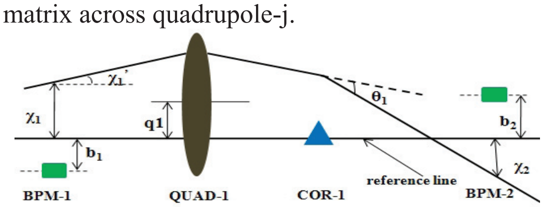

Figure 1: Beam based alignment scheme.

Based on Eq. 2, we can write a set of equations of each of BPM trajectory with different quadrupole strength settings and different incoming launch conditions. Quadrupole and BPM transverse misalignments can be calculated by the least square method.

SIMULATION RESULTS

This BBA application is developed based on the SNS/XAL [5], which is an open source development environment used for creating accelerator physics applications, scripts and services. There are many applications for beam commissioning like orbit correction, lattice calculation, lattice math and so on [6-7]. The result of XAL model for lattice calculation is consistent with the result used other accelerator code,

XAL DEVELOPMENT FOR CSNS/RCS COMMISSIONING

Y. An#, DINS/IHEP, Dongguan, 523803, P.R.C.
Y. Wei, S.Wang, Y. Liu, W. Liu, L. Huang, IHEP, Beijing, 100049, P.R.C.

Abstract

As a key component of the China Spallation Neutron Source (CSNS) Project, the Rapid Cycling Synchrotron (RCS) accumulates and accelerates the proton beam from 80MeV to 1.6GeV for extracting and striking the target with a repetition rate of 25Hz. A high level application programming framework code called XAL, based on Java Language with a well-performance online model, initially developed at the Spallation Neutron Source (SNS), has been installed as a part of control system via connection to EPICS for CSNS. Much of the applications have been initially established such as Tune Scan, Tune Monitor, Orbit Response Matrix Measurement, RCS Orbit Display, and Beta Function Measurement for preparing CSNS/RCS commissioning are showed in this paper.

INTRODUCTION

The CSNS accelerator consists of a low energy H^- Linac and high energy RCS. H^- beam with energy of 80MeV is scraped and transformed into proton beam by the carbon foil located in the injection region. After around four hundred turn accumulation, the proton beam is accelerated to 1.6GeV and then extracted to strike the target with the design power of 100kW. As a key component of CSNS, RCS consists of 4-fold symmetric structure, and each of which is constructed by a triplet cells. Table 1 shows the main parameters of RCS [1].

Table 1: Main Parameters of RCS

Parameters	Units	Values
Circumference	m	227.92
Repetition Rate	Hz	25
Average current	μA	62.5
Inj. Energy	MeV	80
Ext. Energy	GeV	1.6
Beam Power	kW	100
Quad		48
Dipole		24
Corrector		16/16
BPM		32/32
Nominal Tunes(H/V)	1	4.86/4.78

As a huge and complex accelerator, CSNS project needs a capable and well performance control system. As a high level application framework in control system, XAL is initially developed for SNS commissioning. After several years' development, and for better collaborating with other facilities and erasing the obsolete code, OPEN XAL formed out of XAL accelerator software about 5 years ago. Although XAL has capability, some modification or enhancement should be done to make the meets of the CSNS/RCS commissioning.

#anyw@ihep.ac.cn

XAL STRUCTURE AND FEATURES

As a device-oriented accelerator application based on java language, along with jython [2] and jruby [3] scripting languages, XAL provided numerous high level application frameworks with a common look and feel. However, the core of XAL is accelerator model. The hierarchy of accelerator model is initialized with a XML file, and that consists of a lot of accelerator sequences. The accelerator sequence is comprised of many ordered nodes which represent a kind of elements that affect the beam with different path, such as magnets, RF gap, and diagnosis elements and so on. The subclass of the nodes developed to distinguish the elements, like dipoles, quadrupoles, sextupoles, BPMs, CT and so on. XAL is also has capacity in doing real time physics simulation [4], and the online model is that application, and the accelerator parameters can be easily and quickly calculated from that.

XAL provides three principal java classes which are the application adaptor, document and document window [5], and all of which are extended from their corresponding abstract parent class. The application adaptor class is the main responsible for launching the main class and also receives the call back information. The document class is responsible for reading and writing the file as well as its associated main window. The document window class is responsible for creating and managing the views. However, in order to decouple the view and the controller as required by Model-View-Controller (MVC) compliance, the document window is now an optional for the developer after the bricks application frame [5] delivered, and that facilitates the application development.

APPLICATIONS

XAL tools have been used to create more than twenty applications in CSNS. And some of them, such that PV view, have been used to monitoring CT in LEBT (Low Energy Beam Transport Line) and MEBT (Medium Energy Beam Transport Line) to measure the beam current and beam energy for CSNS/RFQ tuning. However, we only discuss part of the applications framework for CSNS/RCS commissioning presented at next.

Tune Scan Application

As described in the previous paper, The Lattice of RCS is composed of 4 symmetric fold, and the nominal beta

STATUS OF THE SUPERCONDUCTING CAVITY DEVELOPMENT AT IHEP FOR THE CADS LINAC*

F.S. He#, J. Dai, J.P. Dai, H. Huang, X.F. Huang, L.H. Li, Z.Q. Li, H.Y. Lin, Q. Ma, Z.H. Mi, B.C. Ni, W.M. Pan, X.H. Peng, T.Z. Qi, P. Sha, G.W. Wang, Q.Y. Wang, Z. Xue, X.Y. Zhang, G.Y. Zhao, Key Laboratory of Particle Acceleration Physics and Technology, IHEP, CAS, Beijing, China

Abstract

IHEP (Institute of High Energy Physics) is developing a CW 10MeV proton injector and part of the 25MeV main linac for the CADS project. 14 SRF (superconducting radio frequency) spoke-012 cavities for the injector, as well as 6 SRF spoke-021 cavities for the main linac are to be beam commissioned before middle of 2016; meanwhile, VT (vertical test) of two more types of prototype cavities are to be finished with 2015, for the future phases of the project. In this paper, the VT statistics of 10 spoke012 cavities, 4 spoke021 cavities, and a 5-cell β0.82 elliptical cavity are reported; the cavity performance during beam commissioning of the TCM (test cryomodule) is reported as well.

INSTRUCTION

The C-ADS project is a strategic plan to help solve the nuclear waste problem and the resource problem for nuclear power plants in China [1]. For the first phase, the project goal is to build a CW proton linac of 25 MeV and 10 mA by about 2016. IHEP is developing one of the two 10-MeV injectors for the project, which is called Injector-I. The TCM, which contains two spoke-012 cavities, is under beam commissioning now. 8 more spoke0-12 cavities reached Ep of 60MV/m and Bp of 90 mT during VT, and 7 of them are being assembled to the CM1, which is the upstream cryomodule for the injector. 3 prototype spoke-021 cavities went through VT in 2014, and one more spoke-021 cavity for the cryomodule at the end of the 25MeV main linac reach specification during VT. Two spoke-040 cavities and two HMB cavities, which are 5cell β0.82 elliptical cavities, were fabricated, while one of the HMB cavities went through VT and reached specification. 8 more spoke-012 cavities and 7 more spoke-021 cavities are under fabrication now to catch up with the project schedule.

DESIGN AND FABRICATION OF THE CAVITIES

The Injector-I uses spoke012 cavities, which are 325MHz, β_0 of 0.14, single-spoke cavies. The main linac contains two types of 325MHz single-spoke cavities, i.e. spoke021 and spoke040, and two types of 650MHz multi-cell elliptical cavities, i.e. MB063 and HMB082. All types of cavities except for the MB063 have been designed and prototyped at IHEP, while three of them have reached the design specification during VT. The key parameters of these cavities are listed in Table 1.Note the effective length is defined as Leff = $\beta_0 \times \lambda$.for single-cell spoke cavities, while β_G is used for elliptical cavity instead of β_0.

Table 1: RF Parameters of the ADS SRF Cavities at IHEP

RF Parameters	Spoke -012	Spoke -021	Spoke -040	HMB 082
Frequency-MHz	325	325	325	650
β_0	0.14	0.24	0.46	0.82
Aperture-mm	35	40	50	100
Ep/Eacc	5.0	4.4	3.9	2.1
Bp/Eacc-mT/(MV/m)^2	6.9	9.4	9.2	4.1
G-Ω	60	71	104	236
R/Q-Ω	150	191	265	515
df/dp-Hz/mbar	+40	+0.6	+0.7	
df/dF-Hz/N	60	94	N/A	N/A
Leff -mm	129	221	424	945

The RF design of the spoke012 cavity was biased towards eliminating MP (multipacting); while stiffening rings and the helium vessel were designed to reduce pressure sensitivity. The spoke021 cavity was shaped to facilitate the fabrication, and the designed pressure sensitivity was significantly reduced by adopting a different helium vessel and tuner design. The spoke040 cavity is in the early phase of prototyping, and the RF properties are not fully optimized yet. The HMB082 cavity was designed to minimize surface field and to avoid MP. HOM (higher order modes) are not a concern for any type of these cavities.

The spoke012 cavities are in mass production phase now. The first two prototype spoke012 cavities were fabricated in 2012, and were VT in 2013. During the fabrication of the second batch of 4 cavities for TCM, the frequency errors of 2-4 MHz induced by inaccuracy in deep-drawing and machining were well understood and compensated by trimming the height of outer conductor. Though, a frequency scattering of 1.6 MHz induced by EBW were observed during the mass production of the third batch of 7 cavities for CM1 (see Fig. 1); since then the process flow of fabrication was adjusted to reduce the frequency error. The fourth batch of 8 cavities will be delivered from two vendors by September; they will be VT qualified after the He vessels are welded, and is

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing 100049, China

Abstract

The C-ADS accelerator is a CW (Continuous-Wave) proton linac with 1.5 GeV in beam energy, 10 mA in beam current, and 15 MW in beam power. C-ADS Injector-I accelerator is a 10-mA 10-MeV CW proton linac, which uses a 3.2-MeV normal conducting 4-Vane RFQ and superconducting single-spoke cavities for accelerating. The frequency of RFQ accelerator is 325 MHz. The test stand composed of an ECR ion source, LEBT, RFQ, MEBT and beam dump have been installed and the first stage of beam commissioning have been finished at IHEP in 2014 mid-year. At 90% duty factor, we got 11 mA proton beam at RFQ exit with 90% beam transmission efficiency, while 95% beam transmission efficiency at 70% duty factor. The energy after RFQ was measured by TOF method with FCTs. The transverse emittance measured by double-slits emittance meter was 0.135 π mm-mrad, which of detailed data analysis will be presented in this paper.

INTRODUCTION

The ADS project in China (C-ADS) is a strategic plan to solve the nuclear waste problem and the resource problem for nuclear power plants in China. For the C-ADS accelerator that is a CW proton linac with the proton beam of energy 1.5 GeV and current 10 mA [1]. The C-ADS accelerator uses superconducting acceleration structures, except for the RFQs and is composed of two major accelerating parts: the injector and the main linac. The rf frequencies for the main linac have been chosen as 325 MHz for the spoke cavity sections and 650 MHz for the elliptical cavity sections. However, two different designs employing different rf frequencies are pursued for the low-energy part of less than 10 MeV, namely, injectors in the technical developing phase, with 325 MHz for Injector Scheme-I [2] and 162.5 MHz for Injector Scheme-II.

For the first phase, the project goal is to build a CW proton linac of 25 MeV. The first phase itself will be executed progressively in several steps, with the first step to build two 5-MeV test stands of different front-end designs. Before the test stands of superconducting cavities, we have finished the first stage beam commissioning of the injector-I RFQ accelerator (Table 1), which composed of an ECR ion source, LEBT, RFQ, MEBT and beam dump line. There is an ACCT at the entrance of RFQ and a DCCT at the middle part of MEBT for transmission measurement, FCTs for energy measurement and double-slit for emittance measurement at the MEBT. Detailed analysis will be presented in this paper.

Table 1: Main RFQ design Parameters of Injector-I

Parameters	Value
RF Frequency (MHz)	325
Injection/Output energy (MeV)	0.035/3.2
Pulsed beam current (mA)	15
Beam duty factor	100%
Inter-vane voltage V (kV)	55
Average bore radius r0 (mm)	2.775
Maximum surface field (MV/m)	28.88 (1.62Kilp.)
Cavity power dissipation (kW)	272.94 (1.4*$P_{SUPERFISH}$)
Vane length (cm)	467.75

EXPERIMENTAL APPARATUS

The layout of the test stand is shown in Fig. 1. A 2.45 GHz electron cyclotron resonance (ECR) ion source was installed for the RFQ testing. The extraction energy is 35 keV and the typical pressure was 7.5×10^{-4} Pa. The low energy beam transport (LEBT) is equipped with two

RHIC ELECTRON LENSES UPGRADES *

X. Gu#, Z. Altinbas, D. Bruno, S. Binello, M. Costanzo, A. Drees, W. Fischer, D.M. Gassner, J. Hock, K. Hock, M. Harvey, Y. Luo, A. Marusic, C. Mi, K. Mernick, M. Minty, R. Michnoff, T.A. Miller, A.I. Pikin, G. Robert-Demolaize, T. Samms, T. C. Shrey, V. Schoefer, Y. Tan, R. Than, P. Thieberger, and S.M. White
Brookhaven National Laboratory, Upton, NY 11973

Abstract

In the Relativistic Heavy Ion Collider (RHIC) 100 GeV polarized proton run in 2015[1], two electron lenses [2] were used to partially compensate for the head-on beam-beam effect for the first time. Here, we describe the design of the current electron lens, detailing the hardware modifications made after the 2014 commissioning run with heavy ions. A new electron gun with 15-mm diameter cathode is characterized. The electron beam transverse profile was measured using a YAG screen and fitted with a Gaussian distribution. During operation, the overlap of the electron and proton beams was achieved using the electron backscattering detector in conjunction with an automated orbit control program.

INTRODUCTION

Figure 1 schematically depicts the layout of the electron lens in the operational synoptic display and the parameters that we used during the 2015 run. At the top of the figure, we show the layout of magnets and their names, including their current controls. Vacuum values and proton-beam losses are also given. At the bottom of the figure, the parameters for the electron beam current, the energy and timing control, as well as the statuses of the e-lens system and the proton beam are displayed.

While in the commissioning run[3] , the electron beam was modulated at the 78 kHz revolution frequency to allow parasitic commissioning with the e-lens acting on only a few ion bunches, for the e-lens operation during the 2015 100 GeV polarized proton run, we used a DC electron beam for beam-beam compensation.

We developed a new lattice for the proton beam based on ATS optics [4], which assures the correct phase advance between the E-lenses and the PHENIX experiment and reduces the second order chromaticity so providing larger dynamic aperture. The lattice has $\beta_{x,y}$ = 15 m at the center of each lens where the electron beam and proton beam collide head-on. We designed a new cathode for the electron beam with a larger radius of 7. 5 mm (formerly, it was 4.1 mm) [5] and machined it to match the size of the proton beam.

After improving the blue superconducting magnet inner cooling system, both the blue and yellow solenoids can run at the design of 6 tesla magnetic field using the RHIC helium system.

NEW CATHODE

For the 2015 polarized proton run, the new cathode with 7.5 mm radius was installed. This cathode is a dispenser cathode [6], which consists of a porous tungsten matrix, impregnated with a barium-based emission-enhancing material.
To activate the cathode material, the pressure near the cathode should be kept below 5×10^{-6} Torr. However, the cathode should in principle be kept at a higher temperature than the rest of the structure during bake-out to avoid the deposition of poisons that may come from out-gassing. These two requirements compete against each other because during the e-lens bake-out, the

THE SIMULATION STUDY OF SPACE CHARGE EFFECTS FOR CSNS LINAC

Y. Yuan[#,1,2], S. Wang[1,2], J. Peng[1,2], L. Huang[1,2]
[1]China Spallation Neutron Source, Institute of High Energy Physics, Chinese Academy of Sciences, Dongguan, China
[2]Dongguan Institute of Neutron Science, Dongguan, China

Abstract

China Spallation Neutron Source (CSNS) is a high intensity accelerator based facility. Its accelerator consists of an H- injector and a proton Rapid Cycling Synchrotron. The injector includes the front end and linac. The RFQ accelerates the beam to 3MeV, and then DTL accelerates it to 80MeV[1]. The space charge effect is the most important cause of emittance growth and beam loss due to the low beam energy and the high peak current. The paper performed simulation studies on the space charge effects at the LINAC by using three-dimensional code IMPACT-Z. The emittance evolution is studied in the point of view of the singe-particle dynamics and multi-particle dynamics with different peak beam current. The effect of mismatch is studied by simulation, and the emittance growth with different mismatch factor are given.

INTRODUCTION

The design beam power of the China Spallation Neutron Source (CSNS) is 100 kW at Phase Ⅰ, and it has upgrade potential of 500kW. Correspondingly, the design peak current of linac are 15mA and 30mA. In such a high intensity linear accelerator, the space chare effects is a very important research topic. The significance of the space-charge fields is not only that they reduce the effective focusing strength, but also the nonlinear terms, a consequence of the deviations from charge-density uniformity, cause growth of the rms emittance, which degrades the intrinsic beam quality. One consequence of space-charge-induced emittance growth is the formation of a low-density beam halo surrounding the core of the beam, which can be the cause of beam loss, resulting in radioactivation of the accelerating structure[2]. The interaction between a large number of charged particles is very complex, multi-particle tracking code provides a very effective means for the exploration of space charge effects. In this paper, three-dimensional code IMPACT-Z[3] is taken to study the space charge effects on MEBT and DTL, and this simulation also includes initial mismatch of beam.

SIMULATION STUDY OF SPACE-CHAREGE EFFECTS ON DTL

CSNS/DTL consists of four accelerating cavity with a total of 156 cell, the length among the cavities is designed to maintain longitudinal continuity. Transverse magnetic focusing lattice is FFDD, all quadrupole magnets arrangement can be approximated as periodic focusing structure. By tracking the position of the particle in phase space after each periodic structure, emittance growth can be analysed on microscopic view.

Beams that are in equilibrium in the focusing channel of a linac experience no emittance growth. Unfortunately, beams observed in linac numerical simulations are rarely in equilibrium. The space-chare force in high-current beams is typically the major cause of rms emittance growth. Four different space-charge mechanisms can be identified[4]: charge redistribution, the injected beam is not rms matched, space charge resonances that couple longitudinal and transverse oscillations, the periodic-focusing structure resonantly excite density oscillations in the beam.

Emittance Growth with Different Current

In the simulation, the initial distribution of particles is 6D water bag, the number of macro particles is 100,000, the currents of beams are respectively 0mA, 15mA and 30mA. Figure 1 is a comparison of the emittance evolution with different current of beam along linac.

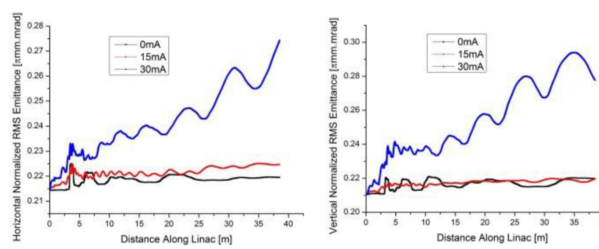

Figure 1: Left: beam horizontal RMS emittance growth along linac. Right: beam vertical RMS emittance growth along linac.

Figure 1 shows that beam's RMS emittance growth is very small with current of 15 mA , and oscillation of emittance is gradually levelling off. However, when the intensity reaches 30mA, emittance growth becomes apparent and increase the proportion of about 30%. In a strictly periodic focusing structure , without considering the impact of space charge effects, a single particle's trajectory after periodic cells is an ellipse in phase space. Because the particles are accelerated in DTL, the actual focusing structure is a quasi-periodic lattice. Therefore, without considering the space-charge effects, the trajectory of particles should be an approximation of an elliptical shape.

In the horizontal direction, for example, the position x and the spread angle x' of particles are normalized by

CADS 650 MHz BETA=0.63 ELLIPTICAL CAVITY STUDY

Liangjian Wen, Shenghu Zhang, Yongming Li*, Yuan He, IMP, Lanzhou, China

Abstract

The China Accelerator Driven Sub-critical System (CADS) is a high intensity proton facility to dispose of nuclear waste and generate electric power. CADS is based on 1.5 GeV, 10mA CW superconducting (SC) linac as a driver. The high-energy section of the linac is composed of two families of SC elliptical cavities which are designed for the geometrical beta 0.63 and 0.82. In this paper, the 650 MHz β=0.63 SC elliptical cavity was studied, including cavity optimization, multipacting, high order modes (HOM) and generator RF power calculation.

INTRODUCTION

China strives to develop the nuclear energy and the nuclear power of China will reach to 58 million kilowatts in 2020. The nuclear waste will also accumulate to 10400 tons [1]. The demand of nuclear energy will grow further with economic development. The disposal of nuclear waste and nuclear fuel shortage are increasingly more serious in China. Accelerator Driven Sub-critical System (ADS) is the optimal way to dispose of nuclear waste and solves the problem of shortage of nuclear fuel. CADS is promoted and constructed by Chinese Academy of Sciences (CAS), as a long-term energy strategy for China.

CADS is composed of a SC linac, a spallation target and nuclear reactor operating in subcritical mod. The 650 MHz β=0.63 elliptical cavities accelerate proton beams from 180 MeV to 360 MeV. This paper is mainly concerned with the RF properties, multipacting, damping of the higher order modes and required generator power of the elliptical cavity

CAVITY RF DESIGN

The following consideration is needed for high-current SC elliptical cavity design:

1) HOM damping is primarily concerned in high-current SC elliptical cavity design. The larger cavity aperture reduces the interaction between the cavity and beam and improve the cell-to-cell coupling to reduce potential for the rapped HOM and beam instability.

2) The accelerating efficiency improves by increasing the numbers of cells per cavity, but also make it difficult to extract and damp the HOM. Five cells per cavity compromises among the accelerating efficiency, the particle acceptance of TTF, and damping the HOM.

A 650 MHzβ=0.63 superconducting cavity was designed by Superfish. The achieved cavity RF and geometry parameters are listed in Table 1. The final β=0.63 five-cell cavity design is depicted in Figure 1.

ymli@impcas.ac.cn

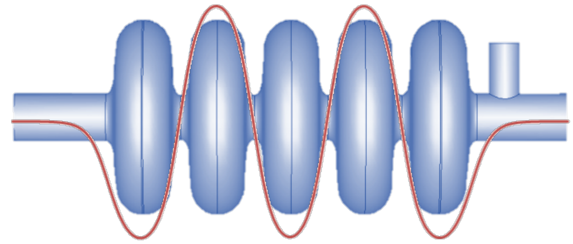

Figure 1: the final β=0.63 five-cell cavity design.

Table 1: The RF Parameters of the 650 MHz β=0.63 Elliptical Cavity

Parameter	unit	value
βg		0.63
frequency	MHz	650
equator diameter	mm	394.4
iris aperture	mm	90
beam pipe aperture	mm	96
cell-to-cell coupling	%	0.9
R/Q(βg)	Ω	333.5
G	Ω	192.7
Epeak/Eacc		2.34
Bpeak/Eacc	mT/(MV/m)	4.63

MULTIPACTING SIMULATION

Multipacting barriers restrict SC cavity performance and accelerating gradient enhanced since a great deal of electrons reach resonance and absorb RF power. Multipacting leads to temperature rise of SC cavity and eventually thermal breakdown. It is crucial to optimize the shape of cavity to eliminate the unexpected multipacting barriers. Multipac 2.1 code [2] was used to simulate the multipacting in the cavity. Fig. 2 shows the enhanced counter function. The result indicate that no hard multipacting was found and the cavity be processed by good cavity surface treatment.

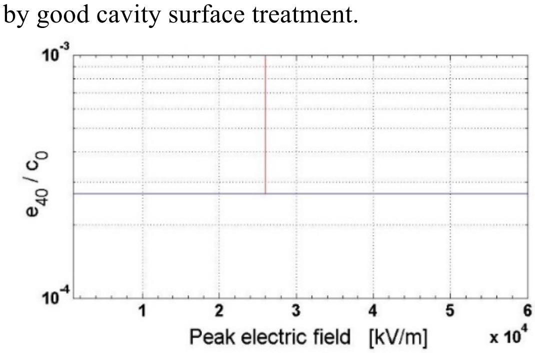

Figure 2: Enhanced counter function- ratio between the number of particles after the 40th impact and the initial number of particles.

THE EARLY RESULTS OF THE VERTICAL TEST FOR $\beta = 0.12$ HWR AT RISP

G.T. Park, H.C. Jung, Y.K. Kim, W.K. Kim, H.J. Cha, S. Choi, and H. Kim
Rare Isotope Science Project (RISP), Daejeon, Korea

Abstract

The facility for the vertical test at 2 K with the master frequency 81.25 MHz is being prepared at Rare Isotope Science Project (RISP) and the preliminary tests are being done as the preparation progresses. We briefly describe the vertical test system, the tests being done, and the future plan for the completion of the facility.

INTRODUCTION

At RISP [1], 4 different kinds of the superconducting cavities have been developed. Now the fabrication of the cavities is complete and their vertical test is being prepared. At the moment, as a beginning stage, the minimum facility is prepared with the prospect for further expansion and upgrade of the facility. For now, 4 K cryogenic system is prepared and no surface processing facility is available yet. The simple system check and the leak check at cryogenic temperature is examined and some RF measurement including critical coupling calibration and decay time measurement is made.

The future plan includes the construction for surface processing, the implementation of the magnetic shields, 2 K pumping station, LLRF system for the vertical test, adjustable coupler, radiation shields, and the interlock system.

SYSTEM PREPARATION

The vertical test stand consists of the cryostat, the pit, the test insert, the staging rack, and vacuum pump system.

The cryostat (See Fig. 1(a)) is made of the stainless steel STS304: The vacuum vessel is 3300 mm deep with 800 mm inner diameter. The helium vessel is 3000 mm deep 500 mm with inner diameter with about 250 L helium capacity. The helium vessel is surrounded by the thermal shield. The test insert was designed and fabricated. It consists of the top plate, the support cage, and the thermal baffle to reduce the static heat load through the conduction. The top plate is equipped with the pressure relief system, i.e., 8 cm diameter burst disk combined with a re-closable safety relief valve at a set pressure of 1 bar. The relief system is sized assuming complete helium vaporization due to a leak in insulating vacuum. It must also provide the various feedthroughs for the vacuum port (for the cavity), the temperature sensors, level sensors, N and SMA-type RF cables for the input and pick up couplers, LHe input port, and Gas output port. The vacuum pump system for the cavity evacuation was prepared. The system consists of the turbo molecular pump, the scroll pump, the controller, the compressor, the vacuum gauges (low range and the full range), and the residual gas analyzer (RGA) as shown in Fig. 1(c).

(a) Cryostat in the pit

(b) Test insert in the staging rack

(c) Vacuum pump system

Figure 1: Vertical test stand.

A simple cryogenic system to cool down the system to 77 K and 4 K using LN_2 and LHe, respectively, was prepared: The LHe dewar, GHe tank, LN_2 dewar, the thermometry sensors, the pressure transducer, and the level sensors. 2 K pump station will be added in near future.

The RF system is being installed to test the HWR with the resonant frequency of $f = 81.25$ MHz. The vertical test is generally done in critical coupling [2]. In the critical coupling, the bandwidths are very narrow and low power corresponding to the wall loss will be supplied.

The schematic of the RF system is given in Fig. 2. As shown in Fig. 2, the system consist of the signal generator, RF switch, the vertical test LLRF, the driving amplifier, the circulator, the directional coupler, the adjustable coupler, the power meters, and the oscilloscope with the diodes.

PRELIMINARY MEASUREMENTS

During the first cool down, the preliminary RF measurements were done using the vector network analyzer (VNA) only. Using the VNA, the frequency shift during the evacuation, the cool down (to 4 K), and the helium pressure pres-

PROTOTYPING PROGRESS OF SSR1 SINGLE SPOKE RESONATOR FOR RAON

H. J. Cha#, G. T. Park, H. Kim, W. Kim and H. J. Kim, IBS/RISP, Daejeon, South Korea

Abstract

We report the current status of prototyping of the SSR1 cavity (β = 0.3 and f = 325 MHz) for Korean heavy ion accelerator RAON. Simulation results on target frequency for vertical test of the cavity prototype are presented. Clamp-up tests for the cavity assembly are in progress.

INTRODUCTION

The RAON, an advanced heavy ion accelerator for basic sciences and multiple applications, is under construction in Daejeon, South Korea [1]. Based on the on-going technical designs, the prototyping for four different types of superconducting cavities (QWR [2], HWR [3], SSR1 [4], and SSR2) is in progress. In particular, the SSR1 cavities before the SSR2 section can reaccelerate the stable isotope heavy ion beams from the HWR cavities (β = 0.12) after the QWR section to higher energy (β = 0.3) with the resonant frequency of 325 MHz.

After completing the fabrication of the SSR1 cavity prototype, it will be qualified through vertical tests. Therefore, the target frequency considering the resonant frequency shifts by the followings: final electron beam welding (EBW) of an outer conductor with end walls, buffered chemical polishing (BCP), evacuation for ultra-high vacuum of the cavity, cooling to the temperature of 4 K and 2 K, and liquid helium (LHe) pressure acting on the cavity at the temperature should be determined before final trimming of the outer conductor and then EBW with end walls. The electromagnetic (EM) analyses with mechanical simulations will be given in the next section. In addition, the present status of clamp-up tests performing before final EBW is briefly introduced.

DETERMINATION OF TARGET FREQUENCY FOR VERTICAL TEST

The CST MWS and the CST MPhysics codes were utilized for predicting the target frequency of the SSR1 prototype. Figure 1 shows the variation of resonant frequency with respect to the width of the cylindrical outer conductor. Both sides of the outer conductor are simultaneously trimmed by the same length as shown in the inset. The positive sign at horizontal axis represents the decreasing width of the outer conductor and the negative one does the increasing that. Zero distance means the original design value of the outer conductor width. The slope was calculated to be -407.5 kHz/mm. It can be applied to the estimation of the resonant frequency shift by final EBW. Considering the shrinkage of 0.6 mm at each side in the case of niobium (Nb), the frequency shift by the EBW is -244.5 kHz.

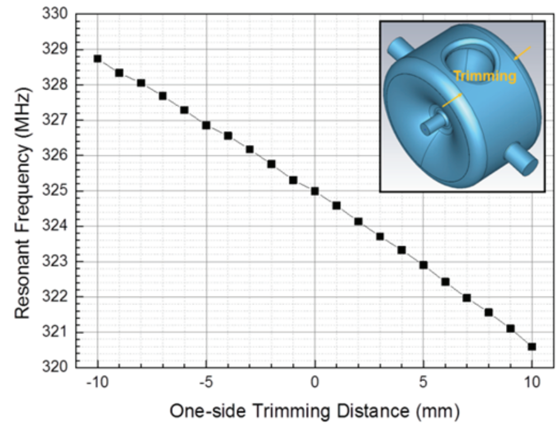

Figure 1: Variation of resonant frequency with changing the width of the outer conductor of the SSR1 cavity.

Figure 2 shows the variation of resonant frequency with respect to the BCP depth. Zero depth also means the original cavity design. The inset shows the simulation results in the narrower depth range. In both cases, it is expected that some fluctuations are caused by the limited mesh numbers. The frequency shift per unit depth calculated from linear fits of the data points is approximately -150 ~ -202 Hz/μm. For determining the target frequency, -150 Hz/μm was used.

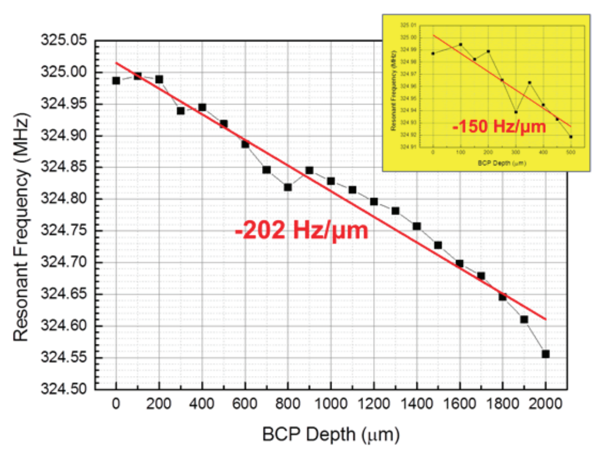

Figure 2: Variation of resonant frequency with changing the BCP depth of the SSR1 cavity.

The resonant frequency shift by vacuum in the cavity maintained during the vertical test should be considered. Figure 3(a) shows the deformation by pressure acting on the cavity due to the vacuum of the cavity inside. The pressure of 1 bar was assumed and the resultant maximum

BEAM OPTICS OF RISP LINAC USING DYNAC CODE*

Ji-Ho Jang#, Hyo-Jae Jang, Hyun-Chang Jin, In-Seok Hong, Hyung-Jin Kim, Dong-O Jeon,
RISP/IBS, Daejeon, Korea

Abstract

The RISP (Rare Isotope Science Project) [1,2] is developing a superconducting linac which accelerates uranium beams up to 200MeV/u with the beam power of 400kW. The linac consists of an injector which includes an ECR ion source and an RFQ, and superconducting cavities which include SCL1 with QWR (Quarter Wave Resonator) and HWR (Half Wave Resonator), and SCL1 with two types of SSR (Single Spoke Resonator). Multiple charge state beams will be accelerated to achieve the required beam power and the charge stripper will be used to obtain the higher acceleration efficiency. This work focuses on the beam dynamics by using the DYNAC code[3] in order to study a possibility that the code can be used as an online model of RAON linac. We compared the results with the calculation by TRACK code [4].

INTRODUCTION

The DYNAC code is a good candidate for the online model of RAON Linac because it can simulates multiple charge states and fast enough. The beam specification of RAON diriver linac is summarized in Table 1. We focus on the uranium beam in this study.

Table 1: Beam Specification for the Driver Linac

Parameters	H^+	O^{8+}	Xe^{54+}	U^{79+}
Energy [MeV/u]	600	320	251	200
Current [pμA]	660	78	11	8.3
Power on target [kW]	>400	400	400	400

LEBT

The injection energy of RAON RFQ is 10 keV/u and we need to inject two charge states, 33+ and 34+ of uranium beams in order to achieve 400 kW of beam power on target. We will use a multi-harmonic buncher (MHB) and velocity equalizer in RAON LEBT to achieve it. The MHB uses three harmonics with 40.645 MHz and its two higher harmonic frequencies. The particle distributions in Δϕ-ΔW/W are given in Fig. 1 just after MHB. The rms beam envelope is given in Fig. 2. We found that the profile is consistent with TRACK simulation except bending magnet region.

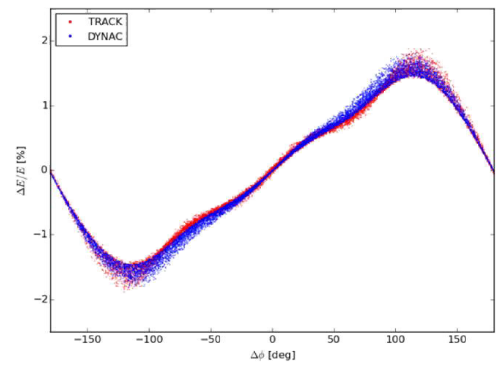

Figure 1: Particle distribution of DYNAC (blue) and TRACK (red) simulations in Δϕ-ΔW/W space.

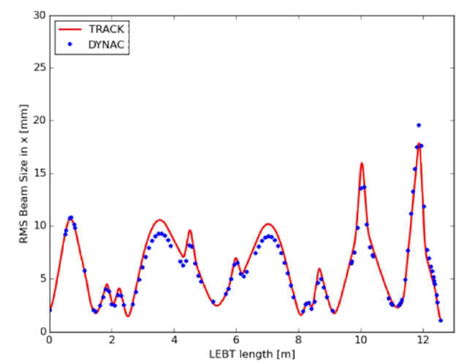

Figure 2: The rms beam envelope through RAON LEBT by DYNAC and TRACK codes.

The particle distribution at the entrance of the RFQ is given in Fig. 3 in the transverse phase space. The transverse beam parameters, twiss parameters and emittance, are summarized in Table 2.

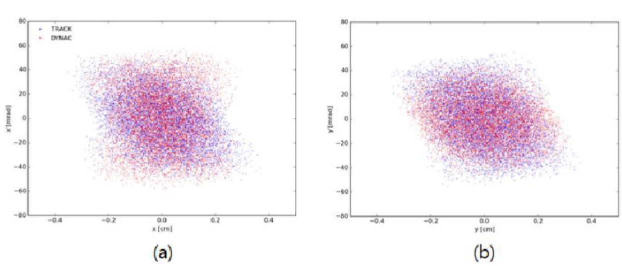

Figure 3: Particle distribution of DYNAC (blue) and TRACK (red) simulation results at the entrance of RFQ.

PROGRESS OF THE RAON HEAVY ION ACCELERATOR PROJECT*

Dong-O Jeon# representing the RAON
Institute for Basic Science, Daejeon, Republic of Korea

Abstract

Construction of the RAON heavy ion accelerator facility is progress in Korea with the In-flight Fragment (IF) and Isotope Separation On-Line (ISOL) facilities. Prototyping of major components and their tests are proceeding including the 28-GHz ECR ion source, RFQ, superconducting cavities, superconducting magnets and cryomodules. Superconducting magnets of the 28-GHz ECR ion source were fabricated and tested achieving 95% (80%) of design fields for the hexapole (solenoids) so far. Prototype superconducting cavities were fabricated through domestic vendors and delivered. Vertical tests showed good performance of the prototype cavities. Progress report of the RAON accelerator systems is presented.

INTRODUCTION

The RAON heavy ion accelerator facility is a unique facility that has the 400 kW In-flight Fragmentation (IF) facility and the 70 kW Isotope Separator On-Line (ISOL) facility providing wide range of rare isotope beams for users [1,2].

The driver accelerator for the IF facility is a superconducting linac (SCL) that can accelerate up to 200 MeV/u for the uranium beam delivering more than 400 kW of beam power to the IF target and various other targets. The driver for the ISOL facility is an H^- 70-MeV 1 mA cyclotron that delivers 70 kW beam power. The cyclotron has dual extraction ports with thin carbon foils for charge exchange extraction of H^- beam.

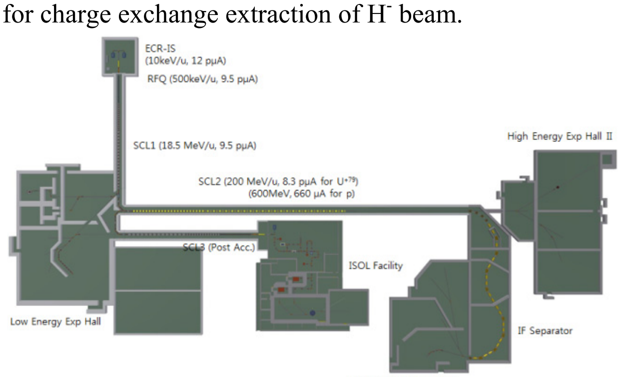

Figure 1: Plot of the RAON facility layout.

Rare isotope (RI) beams generated by the ISOL system is re-accelerated by a chain of post accelerators. The RI beams can be delivered to the low energy experimental hall or can be injected through P2DT to the SCL2 to accelerate to higher beam energy. The schematic layout of the facility is shown in Fig. 1.

The accelerator systems design is optimized to provide various high intensity stable ion beams and radioactive isotope (RI) beams from proton to uranium, while avoiding potential issues related with performance and operation.

Construction of the RAON heavy ion accelerator facility has begun December 2011 to be completed by December 2021. Detailed design of the accelerator systems has completed, and prototyping and testing of critical components and systems have been performed. In this paper, the status of the RAON accelerator systems is presented along with prototyping progress.

DRIVER LINAC

The driver linac consists of an injector (28-GHz ECR ion source, 500-keV/u RFQ) and SCL1 (QWR, HWR type), CSS (Charge Stripper Section) and SCL2 (SSR1, SSR2 type) that can accelerate a uranium beam to 200 MeV/u, delivering 400-kW beam power to the target. The driver linac can accelerate beams from proton to uranium.

Injector

28-GHz ECR ion source for the driver linac was designed [3] and its superconducting magnet assembly for the 28-GHz ECR ion source (ECRIS) was fabricated through domestic vendors. It consists of a saddle-type hexapole and four solenoids made of NbTi wires. Figure 2 shows the plot of the superconducting magnet assembly, the plot of ECRIS cryostat and actual ECRIS cryostat.

The cryostat for the 28-GHz ECRIS was put together and superconducting magnet tests have been carried out, achieving 95% (80%) of the design goal for the hexapole (solenoid) in a combined operation. Further magnet training is in progress. In parallel, beam extraction test is being prepared for of the 28-GHz ECRIS with a partial LEBT installed along with it.

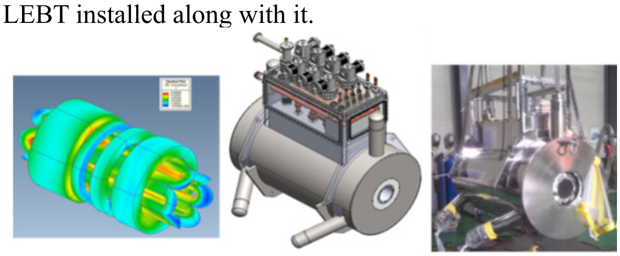

Figure 2: Plot of 28 GHz ECR ion source and its superconducting magnet assembly.

The 81.25-MHz RFQ is 5-meter long with a four-vane structure and its input and output beam energies are 10 keV/u and 500 keV/u respectively. RFQ prototype was successfully fabricated through a domestic vendor in September 2014, overcoming issues of the fabrication procedures and its photograph is shown in Fig. 3. The contract for the fabrication of the driver linac RFQ was

PROGRESS ON SUPERCONDUCTING LINAC FOR THE RAON HEAVY ION ACCELERATOR

H.J. Kim*, H.C. Jung, W.K. Kim, representing RAON, IBS, Daejeon, Korea

Abstract

The RISP (Rare Isotope Science Project) has been proposed as a multi-purpose accelerator facility for providing beams of exotic rare isotopes of various energies. It can deliver ions from proton to uranium. Proton and uranium ions are accelerated upto 600 MeV and 200 MeV/u respectively. The facility consists of three superconducting linacs of which superconducting cavities are independently phased. Requirement of the linac design is especially high for acceleration of multiple charge beams. In this paper, we present the RISP linac design, the prototyping of superconducting cavity and cryomodule.

INTRODUCTION

The RISP accelerator has been planned to study heavy ions in nuclear, material and medical science at the Institute for Basic Science (IBS). It can deliver ions from protons to uranium atoms with a final beam energy, for example, 200 MeV/u for uranium and 600 MeV for protons, and with a beam current range from 8.3 pμA (uranium) to 660 pμA (protons) [1, 2]. The facility consists of three superconducting linacs of which superconducting cavities are independently phased and operating at three different frequencies, namely, 81.25, 162.5 and 325 MHz.

SUPERCONDUCTING LINAC

Lattice Design

The configuration of the accelerator facility within the RISP is shown in Fig. 1. An injector system accelerates a heavy ion beam to 500 keV/u and creates the desired bunch structure for injection into the superconducting linac. The injector system comprises an electron cyclotron resonance ion source, a low-energy beam transport, a radio-frequency quadrupole, and a medium-energy beam transport. The superconducting driver linac accelerates the beam to 200 MeV/u. The driver linac is divided into three different sections, as shown in Fig. 2: a low-energy superconducting linac (SCL1), a charge stripper section (CSS) and a high-energy superconducting linac (SCL2). The SCL1 accelerates the beam to 18.5 MeV/u. The SCL1 uses two different families of superconducting resonators, i.e., a quarter wave resonator (QWR) and a half wave resonator (HWR). The SCL11 consists of 22 QWR's whose geometrical β is 0.047 and 22 quadrupole doublets. The resonance frequency of the QWR is 81.25 MHz. The cryomodule of the SCL11 hosts one superconducting cavity. The SCL12 consists of 102 HWR's whose geometrical β is 0.12 and 62 quadrupole doublets. The resonance frequency of the HWR is 162.5 MHz.

* hjkim@ibs.re.kr

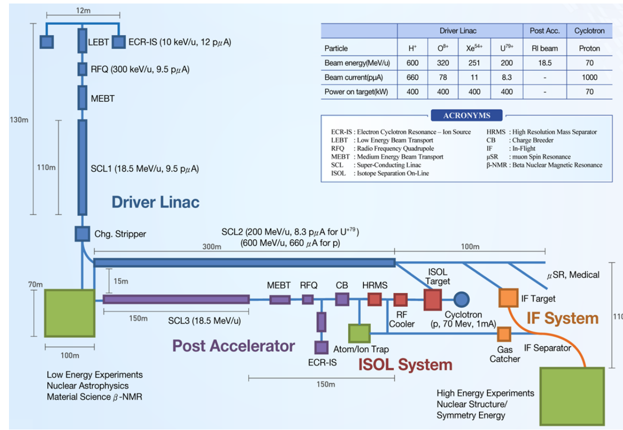

Figure 1: Layout of the RISP accelerator.

This segment has two families of cryomodules: one type of cryomodule hosts two superconducting cavities, and the other hosts four superconducting cavities. The CSS accepts beams at 18.5 MeV/u. The charge stripper strips electrons from the heavy-ion beams to enhance the acceleration efficiency in the high-energy linac section. The charge stripping section consists of normal conducting quadrupoles and room-temperature 45-degree bending magnets. The quadrupole magnets provide adequate transverse focusing and beam matching to the SCL2, and the bending magnet provides momentum dispersion for charge selection. The SCL2 accepts a beam at 18.5 MeV/u and accelerates it to 200 MeV/u. The SCL2 uses two types of single spoke resonators, i.e., SSR1 and SSR2. The SCL2 consists of the SCL21 and the SCL22, each with geometric β 0.30, resonance-frequency 325-MHz SSR and a geometric β 0.51, resonance-frequency 325-MHz SSR. The single-spoke-resonator type is chosen mainly because it can have a larger bore radius compared with the half-wave-resonator type, which is very important for reducing the uncontrolled beam loss in the high-energy linac section. The numbers of cavities in the SCL21 and the SCL22 is 69 and 138 respectively. The cryomodules of the SCL21 and SCL22 host 3 and 6 cavities, respectively. The SCL2 provides a beam into the in-flight fragmentation (IF) system via a high-energy beam transport (HEBT).

The post accelerator (SCL3) is designed to accelerate the rare isotopes produced in the ISOL (Isotope Separation On-Line) system. The SCL3 is, in principle, a duplicate of the driver linac up to low energy linear accelerator. The accelerated rare isotope beams are reaccelerated in the SCL2. Hence, the RISP accelerator provides a large number of rare isotopes with high intensity and with various beam energies.

PROTON BEAM OF 2 MeV 1.6 mA ON A TANDEM ACCELERATOR WITH VACUUM INSULATION*

S. Taskaev#, D. Kasatov, Novosibirsk State University, Russia
A. Kuznetsov, A. Makarov, I. Shudlo, I. Sorokin, BINP, Novosibirsk, Russia

Abstract

New type of charged particles accelerator, tandem accelerator with vacuum insulation, was proposed in BINP. The accelerator is characterized by fast acceleration of charged particles, long distance between ion beam and insulator (on which electrodes are mounted), big stored energy in the accelerating gaps and strong input electrostatic lens. High-voltage strength of vacuum gaps, dark currents, ion beam focusing, accelerating and stripping were investigated. Stationary proton beam with 2 MeV energy, 1.6 mA current has just been obtained. The beam is characterized by high-energy monochromaticity – 0.1%, and high current stability – 0.5%. Here we report the results of these investigations and discuss the proposal for obtaining 2.5 MeV 3 mA proton beam. The accelerator is considered to be a part of epithermal neutron source for boron neutron capture therapy and monoenergetic neutron source for calibration of dark matter detector.

INTRODUCTION

Currently, Boron Neutron Capture Therapy (BNCT) is considered as a promising technique for treatment of malignant tumours [1]. It provides selective destruction of tumour cells by prior accumulation inside them a stable boron-10 isotope and subsequent irradiation with epithermal neutrons. Because of the absorption of a neutron by boron, a nuclear reaction takes place with a large release of energy in the cell, leading to its death. Clinical trials on nuclear reactors showed that BNCT could treat glioblastoma, brain metastases of melanoma and several other tumours. For the widespread introduction of this technique in practice, compact sources of epithermal neutrons based on charged particle accelerators are required.

VACUUM-INSULATION TANDEM ACCELERATOR

The source of epithermal neutrons based on the original tandem accelerator with vacuum insulation and lithium neutron producing target was proposed and constructed in BINP [2]. Figure 1 shows the accelerator. Coming from the source *1* [3] negative hydrogen ion beam with 23 keV energy and 5 mA current is rotated in a magnetic field at an angle of 15 degrees, focused by a pair of magnetic lenses *2*, injected into the accelerator and accelerated up to 1 MeV. In the gas (argon) stripper *7*, which is installed inside the high-voltage electrode *5*, negative hydrogen ions are converted into protons. Then protons by the same 1 MV potential are accelerated to 2 MeV energy. The potential for the high-voltage *5* and five intermediate electrodes *6* of the accelerator is supplied by a high-voltage source *10* (most of the source is not shown) through the insulator *9*, wherein the resistive divider is set. Evacuation of gas is performed by turbomolecular pumps *8* mounted at the ion source and at the exit of the accelerator, and a cryogenic pump *4* via jalousies in the electrodes.

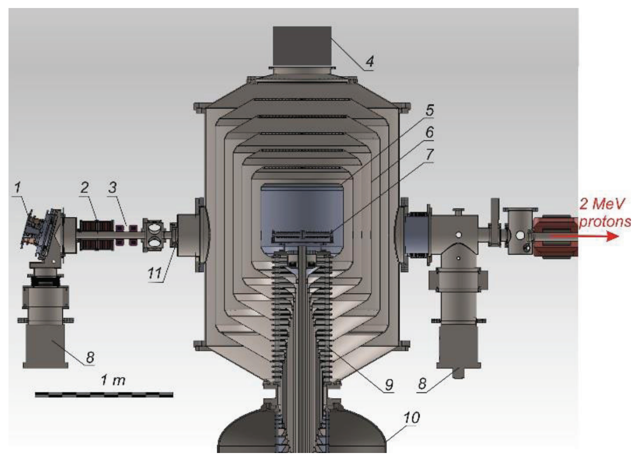

Figure 1: Tandem accelerator with vacuum insulation: *1* – source of negative hydrogen ions, *2* –magnetic lenses, *3* – correctors, *4* – cryogenic pump, *5* – high voltage electrode, *6* – intermediate electrodes, *7* – the gas stripper, *8* – turbomolecular pump, *9* – insulator, *10* – high-voltage power supply, *11* – inlet diaphragm.

A 50 kW sectitioned rectifier of industrial electron accelerator ELV is used as a high-voltage source providing voltage stability of 0.05% [4]. Vacuum part of the high-voltage feed-through insulator (Figure 2) is collected from 24 annular glass insulators with a diameter of 400 mm and a height of 35 mm, vacuum tightly strapped with intermediate electrodes through the rubber seals. The gas part of the insulator situated in a tank of a high voltage rectifier is composed of 14 ceramic rings with a diameter of 400 mm and a height of 60 mm, glued with their electrodes. The inner part of the feed-through insulator is filled with SF_6 gas at a pressure of 0.3 MPa, the high-voltage rectifier tank of 0.6 MPa. Maximum gradient along the surfaces of the insulators on the vacuum side is 12 kV/cm, on the sulfur hex side – 14 kV/cm, peak fields of the gaps in the gas region – 95 kV/cm.

THERMAL AND STRUCTURAL ANALYSIS OF THE 72.75 MHz LINCE RFQ*

A.K. Orduz, C. Bontoiu, A. Berjillos, J.A. Dueñas, I. Martel, University of Huelva, Spain
A. Garbayo, AVS, Elgoibar, Gipuzkoa, Spain

Abstract

The 72.75 MHz LINCE RFQ [1] is designed to function at room temperature. Effective operation of the RFQ cavity requires efficient water cooling in order to dissipate significant resistive power non-uniformly distributed on the copper walls and vanes. This amounts to about 10 kW for one 0.5 m long RFQ section. Cylindrical cooling channels have been designed and optimized by varying their diameter and position in order to minimize the frequency shift generated by thermal displacements. The article reports results of power loss simulations coupled with electromagnetic modelling studies and their consequences on the RFQ performance in terms of resonant frequency and thermal deformations.

INTRODUCTION

The four-vanes RFQ is designed for LINCE high intensity accelerator complex [2]. The structure provides a 72.75 MHz resonating mode with a 1.3 MHz margin controlled by the tuners [1]. The initial beam is made of 2 ns long bunches of 40 keV/u and the aim of the design is to achieve 500 keV/u. The modulation was simulated using the DESRFQ code [3] with 82 kV inter-vane potential on a vane tip tested in ANL [4].

A complete loop of coupled numerical studies is achieved as shown in Fig. 1. The **RF Analysis** has been carried with COMSOL [5] resulting in an estimate for the resistive power losses. These are scaled and coupled with **Heat Transfer** model in order to obtain a temperature map at the vanes surface. The next step is the optimization of the cooling system according to the heat map. Two optimization for channel position, channel diameter, fluid and velocity temperature are carried out. The final heat flux is coupled to a **Solid Mechanics** study to estimates the stress and displacements due to thermal expansion. The frequency shift is obtained through a new RF study of the deformed structure.

RF ANALYSIS

The first study has been done with DESRFQ and Track [6] codes. Eigenfrequency studies have been done using COMSOL software, as shown before [1]. For the last version of the study the whole structure with modulated vanes was simulated and a 73.25 MHz for the quadrupole mode TE_{211} resonance is obtained.

Heat Map

Resistive power losses are calculated and that show the maximum loses are in the window corners as it is show in

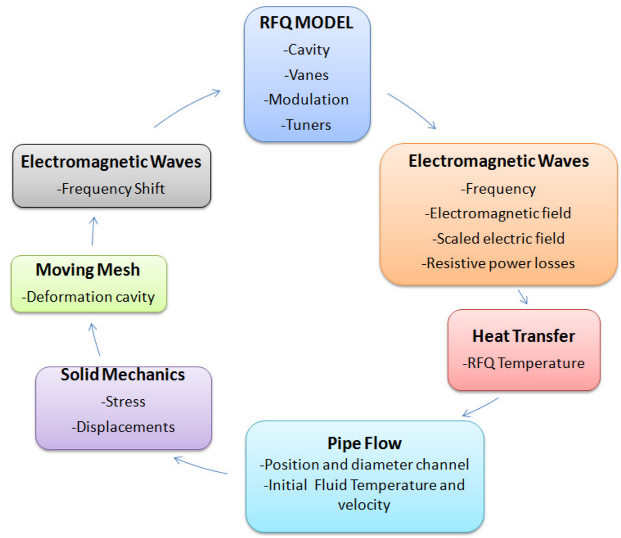

Figure 1: Study steps.

Fig. 2. This study is coupled with a non-isothermal pipe flow simulation in a quarter symmetry model (section) of the RFQ. The total resistive power dissipated by the RFQ working mode at 67.35 MHz is 10.67 kW. A cooling system must be design to control the heat dissipation in the RFQ.

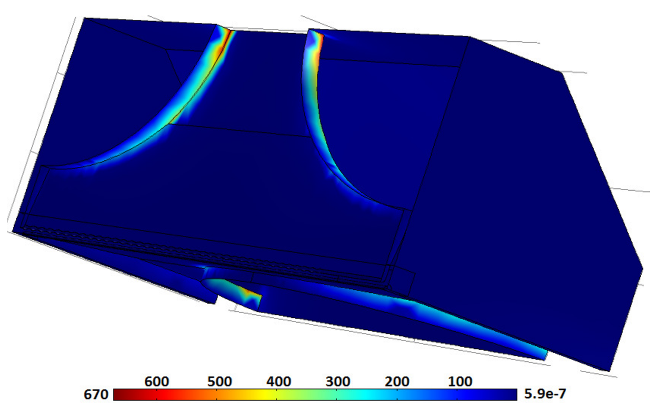

Figure 2: Resistive power losses [kW/m].

COOLING SYSTEM

According with the resistive power losses two models have been proposed as shown in Fig. 3. An initial cooling channel of rectangular profile has been considered due to its mechanical simplify as shown in Fig. 3(top) but proved unsatisfactory in the tip vanes. Therefore the second model Fig. 3(bottom) was studied whit better results.

PROPOSAL FOR A 72.75 MH¿ RFQ FOR THE LINCE ACCELERATOR COMPLEX *

A.K. Orduz, C. Bontoiu, A. Berjillos, J.A. Dueñas, I. Martel, University of Huelva, Spain
A. Garbayo, AVS, Elgoibar, Gipuzkoa, Spain

Abstract

The low-energy part of the LINCE facility [1] can be based on a 72.75 MHz normal-conducting RFQ designed to give a 450 keV/u boost for A/Q=7 ions in about 5 m length. The vanes have been electromagnetically designed to accommodate dedicated RF windows producing effective separation of the RFQ modes in an octagonal-shaped resonance chamber [2]. This article outlines the optimization of the quality factor of the cavity by using numerical methods for electromagnetic calculations. Experimental results of RF test carried out on a prototype are also discussed.

INTRODUCTION

RFQ development, as a whole device is a very complex project which requires many iteration loops between physical concepts and engineering practices. Within the physical aspects, the development is carried out setting beam quality and specifications first. Considering a design mass-over-charge ratio A/Q=7 the RFQ must yield 460 keV/u energy gain working at a maximum inter-vane voltage of 82 kV. Results of the RF modelling process carried out in COMSOL [3], are outlined along the design stages from the shape of the resonator to the final modulated vanes including windows and tuners.

CAVITY OPTIMIZATION

Considering only two RFQ sections, the vanes and windows geometry can be optimized in order to produce the highest quality factor with a resonant frequency around 70 MHz such that adding modulation and tuners [2] would raise it in the 8 sections layout to about 72.75 MHz. This can be achieved in two stages:

- choice of the vane height and thickness in 2D with a predetermined cross-section in the beam region;
- optimization of the elliptical RF windows in 3D;

2D Optimization

The 2D optimization is achieved by doing a parametrization of the vane height which consists of several geometric pieces, namely a trapezoid, a rectangle, a stem and a half disk, all added on the top of the inter-vane radius R_0 = 6.16 mm. While the disk radius r_1 = 4.8 mm and stem height h_{stem} = 14 mm are kept constant, the rectangle and trapezoid height shown in Fig. 1 are taking values between 45 mm and 125 mm in steps of 2.5 mm.

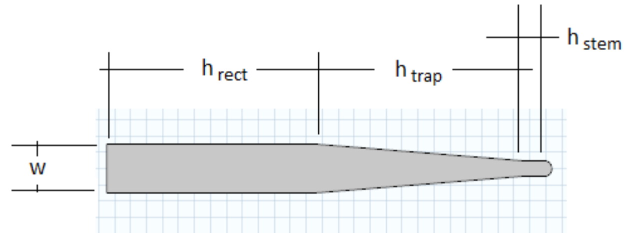

Figure 1: Transverse cross-section view of one vane.

Running the optimization process at three different values for the vane width w yields the quality factor and resonant frequency for the TM_{21} mode as shown in Fig. 2. For a given quality factor one must consider higher and thicker or shorter and thinner vanes. The trapezoid and rectangle heights are complementary in the sense that the same quality factor can be obtained decreasing any one of them and increasing the other one proportionally.

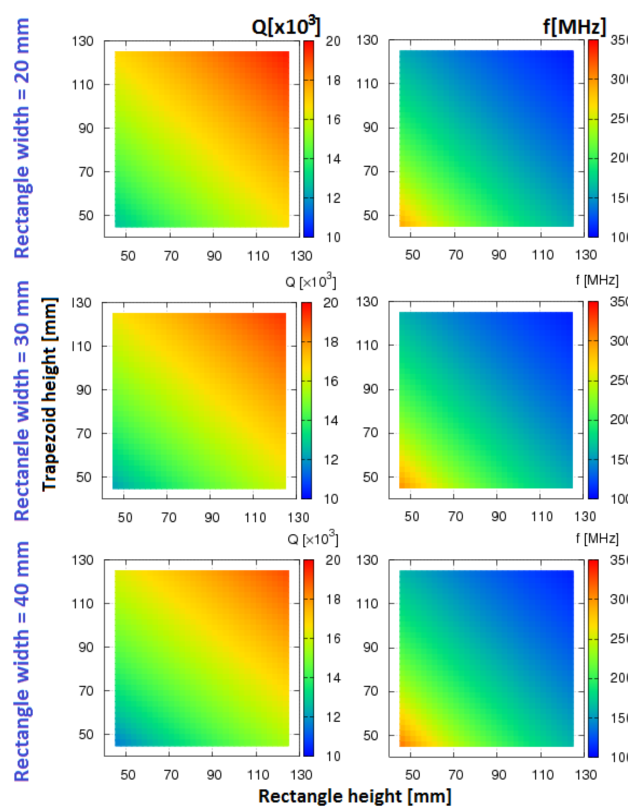

Figure 2: Evaluation of the quality factor and resonant frequency as function of rectangle and trapezoid height.

EFFECT OF THE FIELD MAPS ON THE BEAM DYNAMICS OF THE ESS DRIFT TUBE LINAC

R. De Prisco*, ESS, Lund, Sweden and Lund University, Lund, Sweden
M. Eshraqi, Y. I. Levinsen, R. Miyamoto, E. Sargsyan, ESS, Lund, Sweden
A. Karlsson, Lund University, Lund, Sweden

Abstract

In the beam dynamics design and modelling of the European Spallation Source (ESS) Drift Tube Linac (DTL) simplified models have been used for the focusing and accelerating elements. Since the high current requires precise control of the beam to analyze the losses it is useful to perform the beam dynamics simulations by using accurate field maps of the focusing and accelerating elements. In this paper the effects of the 3D-field maps on the beam dynamics of the ESS DTL are presented.

INTRODUCTION

The ESS DTL is an in-kind contribution from INFN/LNL [1]. Five Radio Frequency (RF) cavities (tanks) are used to accelerate a proton beam of 62.5 mA from 3.62 MeV to 89.68 MeV at 352.21 MHz; the transverse focusing system is composed by Permanent Magnet Quadrupoles (PMQs) arranged in a F0D0 lattice.

RF FIELD MAP OF THE ESS DTL

The design of the ESS DTL is defined in [2]. The cell numbers (and, consequently, the tank lengths) and the average electric accelerating field, E_0, are optimized simultaneously such that the sum of the power transferred to the beam, P_B, and the dissipated power on the internal tank surface, P_{Cu}, (including, on the last one, a factor 1.25 over the MDTfish computation) are slightly below 2.2 MW, that is the available RF power, P_{TOT}, per tank. The DTL parameters are summarized in Table 1 (E_{out} is the output energy of the beam at the end of each tank).

Table 1: DTL Parameters in Each Tank

Tank	1	2	3	4	5
E_0 [MV/m]	3.00	3.16	3.07	3.04	3.13
Cells	61	34	29	26	23
L_T [mm]	7618	7101	7583	7847	7687
P_B [kW]	1104	1114	1106	1064	1005
P_{Cu} [kW]	1088	1078	1090	1126	1190
P_{TOT} [kW]	2192	2191	2196	2189	2195
E_{out} [MeV]	21.29	39.11	56.81	73.83	89.68

Ideal and Nominal Accelerating Field

We define the average electric accelerating field, E_0, reported in the Table 1, as the *ideal* accelerating field, from now $E_{0,id}$. Even if all the cells, different in length, have the same frequency, *the accelerating field integral, cell by cell, is not constant* because of the imperfect mode matching between the adjacent cells. Thanks to algorithm presented in [3] it is possible to modify the geometry of the Drift Tubes (DTs) in order to calculate the electromagnetic field, solution of the Maxwell equations, inside each tank, such that the accelerating field is close to the ideal one. We call this field the *nominal* accelerating field, $E_{0,nom}$, shown in Fig. 1. From this moment all results are referred to the nominal accelerating field.

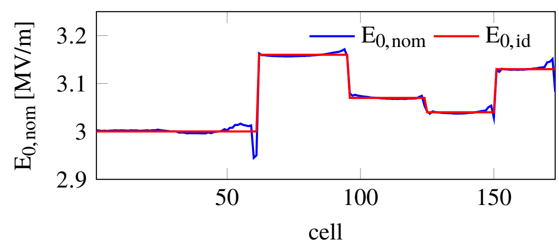

Figure 1: Nominal accelerating field in the DTL.

Self Perturbation Phenomena of the Post Couplers

The frequency perturbation due to the drift tube stems and the power couplers is compensated by tuning the cell face angles. Doing that the nominal accelerating field is achieved in the ESS DTL. Post Couplers (PCs) are used to stabilize the on axis accelerating electric field against tilts produced by mechanical errors (that, locally and randomly, change the resonant frequency of each cell). We define the *optimum lengths* of the PCs as the lengths for which there is the *confluence* [3]. The local frequency shift, due to the inserted PCs with their optimum lengths, must be compensated to avoid the *self perturbation* phenomena: uncompesated PCs produce, themselves, additional tilts of the accelerating electric field against which they are inserted.

FIELD MAP OF THE PMQs

The PMQ design is a modification of the segmented Halbach quadrupole.

The magnetic field into the beam pipe is given by the superposition of the magnetic fields of 16 parallelepiped permanent magnets of Sm_2Co_{17}. A transverse section of the PMQ is shown in Fig. 2. In each PMQ all the magnets (grey rectangles) have the same remanent magnetization along the appropriate direction.

The external radius of the PMQ housing is 30 mm. The transverse area of each of the 16 magnets is $w_m \times b_m$ =

A PLANNING AND SCHEDULING SYSTEM FOR THE ESS ACCELERATOR PROJECT

L. Lari, ESS, Lund, Sweden and CERN, Geneva, Switzerland
M. Conlon, H. Danared, L. Gunnarsson , G. Jacobsson, M. Jakobsson, M. Lindroos, E. Tanke
J.G. Weisend ESS, Lund, Sweden
P. Bonnal, CERN, Geneva, Switzerland

Abstract

Constructing a large, international research infrastructure is a complex task, especially when a large fraction of the equipment is delivered as in-kind contributions. A mature project management approach is essential to lead the planning and construction to deliver scientifically and technically.

The purpose of this paper is to present how the ESS accelerator project is managed in terms of planning and scheduling from the design phase until commissioning, keeping time, budgets and resources constraints, as well as creating and maintaining a strong and trust-based partnership with the external contributors.

INTRODUCTION

The European Spallation Source (ESS) is one of the largest science and technology infrastructure projects being built today. Bringing into successful operation this complex 1.8 billion-euro accelerator-based facility for neutron science implies collaborations among national institutions and nations. As a result, completing ESS, technically, financially and within schedule is strongly dependent from the capability of all the participants to meet delivery and performance specifications. In such a context of a complex project spanning over many years, a centralised project management team has been created in order to support the planning and scheduling activities of each macro project, such as the ESS Accelerator ones [1].

THE ESS CONSTRUCION PHASE

The ESS facility is currently under construction in Lund (Sweden). At present, the construction schedule is driven by the goals of producing neutrons by the end of 2019, completing the installation of the facility by the end of 2022 and installing/commissioning the neutron scattering instruments by the end of 2025.

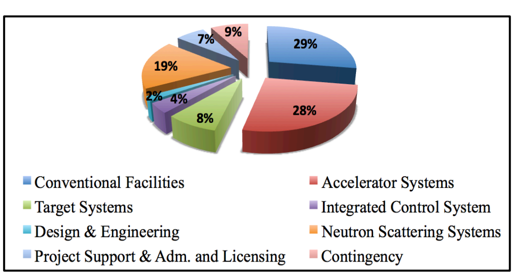

Figure 1: Distribution of the construction budget in % for the ESS macro-projects. The 510 million-euro accelerator project is shown in red.

The ESS construction phase is managed through seven macro project coordination schedules linked together. Five of the seven plans are machine and technically oriented, one is for tracking the civil engineering works, while two are used for administrative support (see Fig. 1). A centralized network-based is used for scheduling i.e. the Oracle's Primavera P6 software.

THE ESS ACCELERATOR PLAN

The ESS accelerator plan is a delivery oriented plan and an integrated cost-loaded multi-year and multi-level schedule. It covers from the start of the preliminary design of the accelerator components (2013) until the capability of delivering 2 GeV protons on Target (2022). It includes the design and industry preparation stages of the different accelerator systems, the development of the prototypes, the series production, the installation in gallery and tunnel buildings and the cold and beam commissioning of the ESS linac. The general services as well as the test stands for RF and cryomodules are also included in the accelerator budget and resource constraints of the schedule. The purpose of the plan is to give a complete and up-to-date picture of the whole Accelerator Project, including tracking the external partners contribution works.

The WBS of the ESS Accelerator Plan

A common Work Breakdown Structure (WBS) architecture is applied to all ESS projects during the construction phase. Work consists of activities and milestones, organized in a hierarchal structure (see Table 1). The WBS and levels do not necessary map in a one-to-one way the other breakdown structures, such as the ESS Product Breakdown Structure (PBS) of systems, sub-systems and components or the ESS Organizational Breakdown Structure (OBS).

Table 1: ESS Common WBS

WBS level	WBS element
1	ESS Programme
2	Projects
3	Work Packages (WP)
4	Work Unit (WU)
5	Activities/Milestones

Abstract

The European Spallation Source (ESS) is now under construction just outside in Lund in Sweden. The driver is a 5 MW linac operating at a duty factor of 4% and at 2 GeV. The detailed design of the buildings is just being completed, and the casting of the accelerator tunnel has started. The accelerator design is getting mature with the major parts under prototyping. A challenging aspect of the project is the large percentage of in-kind contributions. For the accelerator this is now reaching 50% in pre commitments by institutes and universities in the ESS member states. We will in this paper give an overview of the ESS accelerator design, the status of prototyping and the organization of the in-kind accelerator construction project.

THE ESS PROJECT

The ESS is a multi-disciplinary research centre based on the world's most powerful neutron source. This new facility will be 30–100 times brighter than today's leading facilities, enabling new opportunities for researchers in the fields of life sciences, energy, environmental technology, cultural heritage and fundamental physics. The facility is planned to have 570 MeV protons and first neutrons in 2019 and a user program starting in 2023.

ACCELERATOR BASELINE

The ESS accelerator high-level requirements are to provide a 2.86 ms long proton pulse at 2 GeV and a repetition rate of 14 Hz. This represents 5 MW of average beam power with a 4% duty cycle on target.

The ion source produces a proton beam that is transported through a Low Energy Beam Transport (LEBT) section to the Radio Frequency Quadrupole (RFQ) where it is bunched and accelerated up to 3.6 MeV. In the Medium Energy Beam Transport (MEBT) section the transverse and longitudinal beam characteristics are diagnosed and optimized for further acceleration in the Drift Tube Linac (DTL). The first superconducting section consists of 26 double-spoke cavities (SPK) with an optimum beta value of 0.50. The spoke cavities are followed by 36 Medium Beta Linac (MBL) elliptical cavities with β = 0.67 and 84 High Beta Linac (HBL) elliptical cavities, with β = 0.86. After acceleration the beam is transported to the target through the High Energy Beam Transport (HEBT) section and rastered on the target using an active fast magnet beam delivery system. A block diagram of the ESS accelerator design can be seen in Figure 1.

ACCELERATOR IN-KIND

Introduction

ESS is a new organization at a green field site set up in 2009. The design update of the ESS accelerator, undertaken from 2009 to 2013, was done in a collaboration including INFN in Italy, CEA and CNRS in France, ISA in Denmark, ESS-Bilbao in Spain, Uppsala University and Lund University in Sweden and the emerging ESS accelerator division. The design update resulted in a Technical Design Report [1] for the full facility, which has been the base of further negotiations for the funding of ESS. The funding for the construction is today secured but with a request from the member states for a very high proportion of in-kind financing. The target for the accelerator

ON THE SUITABILITY OF A SOLENOID HORN FOR THE ESS NEUTRINO SUPERBEAM

M. Olvegård, T. Ekelöf, R. Ruber, V. Ziemann, Uppsala University, Sweden
J.-P. Koutchouk, Uppsala University, Sweden and CERN, Geneva, Switzerland

Abstract

The European Spallation Source (ESS), now under construction in Lund, Sweden, offers unique opportunities for experimental physics, not only in neutron science but potentially in particle physics. The ESS neutrino superbeam project plans to use a 5 MW proton beam from the ESS linac to generate a high intensity neutrino superbeam, with the final goal of detecting leptonic CP-violation in an underground megaton Cherenkov water detector. The neutrino production requires a second target station and a complex focusing system for the pions emerging from the target. The normal-conducting magnetic horns that are normally used for these applications cannot accept the 2.86 ms long proton pulses of the ESS linac, which means that pulse shortening in an accumulator ring would be required. That, in turn, requires H- operation in the linac to accommodate the high intensity. As an attractive alternative, we investigate the possibility of using superconducting solenoids for the pion focusing. This solenoid horn system needs to also separate positive and negative pion charge as completely as possible, in order to generate separately neutrino and anti-neutrino beams. We present here progress in the study of such a solenoid horn.

INTRODUCTION

The European Spallation Source (ESS) will provide neutrons to a variety of experiments in the applied sciences, starting 2019. The spallation neutrons are generated by a 5 MW proton beam impinging at 2 GeV on a rotating tungsten target. This world-unique intensity attracts projects beyond the neutron sciences, one of which is the ESS neutrino superbeam study, ESSnuSB [1]. The ESSnuSB plans to use a 5 MW beam from the ESS linac to produce an intense neutrino beam in a separate target station, as shown with the sketch in Fig. 1. These neutrinos will be directed towards an underground detector several hundreds of kilometers from the ESS site, where the number of electron and muon neutrinos will be counted. Placed at the second neutrino oscillation maximum, the megaton water Cherenkov detector is expected to help settle the existence of CP violation in the leptonic sector, by recording and comparing the amounts of neutrinos and anti-neutrinos.

The nuclear reactions that occur as the proton beam hits the target generate a shower of hadrons, mostly pions. These pions are to be collected and focused so that they travel in the direction of the far detector before they decay into muons and muon neutrinos. The established way of hadron collection is with a magnetic horn [2], which consists of a toroidal magnet structure where the pions need to traverse a thin metallic conductor layer in order to reach the magnetic field region. The structure is powered by 350 kA [3], which leads to heavy ohmic heat dissipation in the conductor layer. As a result, the horn cannot accept the 2.86 ms proton pulse directly from the ESS linac, but an accumulator ring for pulse compression down to a few microseconds, is required [4]. For efficient injection into the ring the linac must support acceleration of H^- as well as the protons for neutron production, which has additional implications for the linac optics, and for the minimum curvature of transfer lines, etc. In addition, it requires an H^- source. In total, the horn requirements lead to an increase of the project complexity and cost and there are strong motivations for an alternative hadron collection scheme using superconducting magnets.

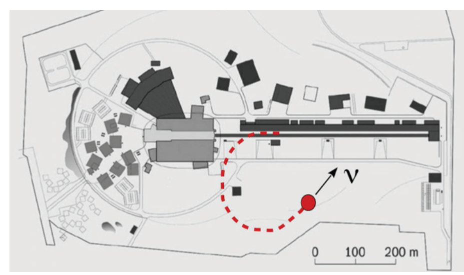

Figure 1: A sketch of the ESSnuSB layout at the ESS site.

BACKGROUND

An attractive alternative to the van der Meer horn is a superconducting solenoid. Earlier studies conducted for neutrino factories and muon colliders, as well as for neutrino superbeams, have shown that a solenoid horn could perform as well or better for certain neutrino energy ranges [5]. Here, we look specifically at the ESSnuSB case with a moderate proton beam energy of 2 GeV.

The pion distribution expected from the target was computed by N. Vassilopoulos for a van der Meer horn [3] and is shown in Fig. 2. We see a wide distribution both in total momentum and in emission angle θ with respect to the forward axis. The 2D distribution has its peak at around 500 MeV and 0.6 rad, which, with the strong tails, means that powerful collection directly at the target is necessary.

Figure 3 shows the decay scheme of the pions, whose life time in the rest frame is 26 ns. Since the detector cannot distinguish neutrinos from anti-neutrinos the pions of the wrong sign must be removed close to the source, before they have time to decay and contaminate the beam. Secondly, the length of the decay tunnel must be optimized so that the number of muons that have time to decay is mini-

CONSIDERATIONS ON THE FAST PULSED MAGNET SYSTEMS FOR THE 2 GEV BEAM TRANSFER FROM THE CERN PSB TO PS

T. Kramer, J.L. Abelleira, W. Bartmann, J. Borburgh, L. Ducimetière, L.M. Feliciano, B. Goddard, L. Sermeus, CERN, Geneva, Switzerland

Abstract

Under the scope of the LIU project the CERN PS Booster to PS beam transfer will be modified to match the requirements for the future 2 GeV proton beam energy upgrade. This paper describes considerations on the PSB extraction and recombination kickers as well as on the injection kicker(s) into the PS. Different schemes of an injection into the PS have been outlined in the past and are reviewed under the aspect of individual transfer kicker rise and fall time performances. Recent measurements on the recombination kickers are presented and subsequently homogenous rise and fall time requirements in the whole PSB to PS transfer chain are discussed. New options for the PS injection kicker(s) are outlined and compared to the previously presented concepts.

INTRODUCTION

CERN's accelerator complex is undergoing a massive upgrade program in the framework of the LHC Injectors Upgrade (LIU) project [1]. In the CPS complex the Proton Synchrotron Booster (PSB) will see an energy upgrade to 2 GeV to enable the limitation in intensity due to the space-charge tune shift in the PS to be overcome [2]. The extraction systems of the PSB, the recombination beam lines and beam transfer elements, as well as the injection system of the PS will all need to function at the new higher beam energy. At the same time, the rise and fall times of the kickers must be compatible with the required bunch lengths and filling schemes for future HL-LHC beams, and with the specifications to reach the present performance for the existing 1.4 GeV beams for fixed-target users in the PS complex and the SPS. Table 1 gives an overview of the basic machine parameters.

Table 1: PSB and PS Main Beam Parameters

Parameter	Present	LIU upgrade
Beam energy [GeV]	1.4	2.0
Beam rigidity [T.m]	7.14	9.28
PSB t_{rev} [ns]	571	552
PS t_{rev} [ns]	2286	2210

Considerations on the Kicker Rise Times

The kicker rise/fall times (along with gap field) are key parameters, and affect strongly the technical choices, cost and performance of the planned upgrades, plus the overall feasibility and risk. The bunch lengths and gaps between bunches in the two machines are a function of the harmonic numbers, of the beam momentum and also of the beam type (intensity and longitudinal emittance/RF voltage). To alleviate the space charge limitations in the PS, the LHC type beams will be transferred at 2.0 GeV with the maximum possible bunch lengths and imposes together with the machine harmonic numbers the kicker rise and fall times. Table 2 shows an overview of the individual requirements for the involved kicker systems.

PSB EXTRACTION

The four BE.KFA14L1 kickers (one per ring) eject the beam from the PSB. The rise time must be short enough to fit into the shortest gap between the two longest bunches which is 105 ns for operation with PSB harmonic number 2 and PS harmonic numbers 7 or 8. Note that the PS harmonic number determines this shortest gap, and not the PSB one.

PAINTING SCHEMES FOR CERN PS BOOSTER H- INJECTION

J. L. Abelleira, W. Bartmann, E. Benedetto, C. Bracco, G.P. Di Giovanni, V. Forte, M. Meddahi, B. Mikulec, G. Rumolo, CERN, Geneva, Switzerland; M. Kowalska, EPFL, Lausanne, Switzerland.

Abstract

The present 50-MeV proton injection into the PS Booster will be replaced by a H$^-$ charge exchange injection at 160 MeV to be provided by Linac4. The higher energy will allow producing beams at higher brightness. A set of kicker magnets (KSW) will move the beam across the stripping foil to perform phase space painting in the horizontal plane to reduce space charge effects. The PSB must satisfy the different users with very different beams in terms of emittance and intensity. Therefore, the KSW waveforms must be adapted for each case to meet the beam characteristics while minimizing beam losses. Here we present the results of the simulations performed to optimise the injection system. A detailed analysis of the different painting schemes is discussed, including the effect of the working point on the painted beam, and variations in the offset of the injected beam.

INTRODUCTION

In this paper we present a description of the injection process and its influence on the profile for different beams. We assume that each pulse coming from the Linac4 and reaching the 4 rings of the PSB has 6.5x10^{13} protons over a length of 400 μs with an average current of 26 mA. The number of injection turns needed for each PSB user is adjusted according to the required intensity, taking into account that the revolution period of the PSB at injection is $\sim 1\mu s$. We will describe the injection for two particular cases: LHC beam and High Intensity beam (HI). In the latter case, an injection over 100 turns has been considered, in order to build up a final intensity of 1.6×10^{13} p^+. This means injecting in the PSB twice as much intensity as we do today for this kind of beam. with twice as much intensity. Also the beam brightness of the LHC beams would be doubled. Two scenarios have been analyzed for the simulations. We have called tune 1 the baseline working point, with tunes Q_x=4.28 and Q_y=4.55. The second scenario, called tune 2, is intended to reduce space-charge blow up during acceleration and corresponds to a working point of Q_x=4.43 and Q_y=4.60.

Table 1 summarizes the beam characteristics of the two different LIU [1] beams studied in this paper and compares it with the present values in operation.

SIMULATIONS

We simulated the H$^-$ charge exchange process with the ORBIT code [2]. The stripping foil is made of Carbon with a density of 200 $\mu g/cm^3$ and a dimension of 32 mm [H] and 58 mm [V]. The simulations include a complete aperture model that allows to analyze the particle losses around the PSB ring. We have assumed a matched (including dispersion) 0.4 μm normalized emittance beam and we have injected in each case a total of 5×10^5 macroparticles. The space-charge effects have been taken into account as well as the edge focusing of the chicane magnets. For the case of HI beams, we have simulated also a phase space painting in the longitudinal plane.

Table 1: Characteristics of LHC and HI Beams (Present and LIU). Injection Energy, Extraction Energy, Beam Intensity per Ring and Normalized Emittance (Horizontal and Vertical)

	Present		LIU	
Beam	LHC	HI	LHC	HI
E_{inj} [MeV]	50	50	160	160
E_{ext} [GeV]	1.4	1.4	2.0	1.4
N [$x10^{12}$]	1.8	8.0	3.4	16
$\epsilon_{N,x}[\mu m]$	2.1	15	1.7	13
$\epsilon_{N,y}[\mu m]$	2.1	8	1.7	6

LHC BEAMS

Other studies have been carried out to define the optimal brightness in the PSB, characterizing a relation (curve) between beam intensity and target emittance [3]. We have studied how the H$^-$ injection is able to reproduce each point of the so-mentioned curve. For this purpose we have assumed a maximum intensity of 3.4×10^{12} p^+. For this beam intensity we need to inject over 21 turns.

To enlarge the emittance of $\epsilon_N = 0.4\mu m$ provided by Linac4, the injected beam is off-centered with respect to the circulating one. For the vertical plane, the offset is applied using the steerers in the transfer line. For the horizontal one, we have varied instead the circulating orbit with respect to the injected beam (which is located at $x = -35$ mm) with the help of the KSW magnets. We have observed that for the same initial conditions, different tunes give different final emittances, as the particle distribution turns by a different angle in the respective phase space. For this reason the position of the circulating beam at the stripping foil must be adjusted for each tune. We have placed the KSW bump at $x = -31.5$ mm for tune 1 and $x = -33.5$ mm for tune 2. The vertical offset of 3 mm gives similar results as the tune difference in this case is very small (~ 0.05). Assuming an ideal machine, we have attained for both working points the target emittances at the end of injection of $\sim 1.2\mu m$; that would leave some margin ($\sim 0.5\mu m$) for other sources of emittance growth such as optics mismatch or blow up from space charge during acceleration [4].

ProTec - A NORMAL-CONDUCTING CYCLINAC FOR PROTON THERAPY RESEARCH AND RADIOISOTOPE PRODUCTION

R. Apsimon*, G. Burt, J. Mitchell, S. Pitman, Lancaster University, Bailrigg, UK
H. Owen, University of Manchester, Manchester, UK
A. Degiovanni, CERN, Geneva, Switzerland

Abstract

The ProTec cyclinac proposes the use of a 24 MeV high-current cyclotron to inject protons into a normal-conducting linac pulsed at up to 1 kHz to give energies up to 150 MeV. As well as being able to produce radioisotopes such as ^{99m}Tc, the cyclinac can also provide protons at higher energy with beam properties relevant for proton therapy research. In this paper we present a comparison of linac designs in which S-band structures are used at lower energies, prior to injection into a high-gradient X-band structure; issues such as beam capture and transmission are evaluated.

INTRODUCTION

The ProTec cyclotron-linac, or cyclinac, is proposed as a multi-purpose facility which could simultaneously provide two proton beams [1]. Fed from a single high-current cyclotron that may generate extracted proton currents in excess of 500 μA to a single beamline, when that current is pulsed it may also feed a linac to obtain much higher energies albeit with lower currents. As such, such a facility could serve both as a regional site for production of medical radioisotopes whilst also being suitable for conducting research with higher-energy proton beams. In particular, we propose to utilise very high gradient X-band cavities to obtain 150 MeV protons suitable for testing methods and equipment to benefit particle radiotherapy. Whilst such research is possible at hospital proton therapy facilities, research time at such facilities is limited and this, a dedicated facility, provides much greater access.

We consider at present a cyclotron, such as the ACSI TR-24 [2], as a high-current cyclotron with multiple extraction ports which can obtain a suitably-high current for isotope production. One notable application is the volume production of ^{99m}Tc for nuclear medicine, in which a single c.1 mA cyclotron can, for example, provision sufficient numbers of technetium doses (around 250,000 per year per cyclotron) for about half of UK clinical demand [3, 4]. The TR-24 - similar to other multi-port cyclotrons - has two ports where we envisage providing up to four stations. Three of these are proposed to be at low energy to provide for radioisotope production; radiobiology research; irradiation experiments. The fourth station will feed the high-energy line that comprises both S- and X-band structures. S-band structures are proposed to accelerate the proton from 24 MeV up to ~100 MeV with an accelerating gradient of ~30 MV/m. High-gradient X-band structures will be used to further accelerate the beam to energies up to 150 MeV, with an accelerating gradient of at least ~50 MV/m.

We have chosen a cyclinac - that uses a cyclotron as its injector - for several reasons. Firstly, for protons energies up to 30 MeV and currents up to c.1 mA the cyclotron is a very mature technology that is compact, readily available commercially, and relatively inexpensive compared to alternative approaches such as linacs. Thus the low-energy stations can be obtained with minimal project risk. Although the extracted cyclotron beam is not naturally matched to the needs of a linac, the cyclinac concept has been explored at several institutions for a number of years and its technical issues have been well explored and addressed (see below). A summary of the extraction beam parameters of the TR-24 cyclotron are given in Table 1 [3, 5].

Table 1: TR-24 Extracted Beam Parameters

Parameter	Value
ε_x (90%, normalised)	10μm.rad
ε_y (90%, normalised)	17μm.rad
Beam energy	24 MeV
Energy spread (FWHM)	0.41 MeV
RF frequency	84.75 MHz
Bunch spacing	11.8 ns
Bunch length	2 ns

DESIGN CONSIDERATIONS

Transfer Line Optics

The 24 MeV protons extracted from the cyclotron must travel through a beam transfer system (BTS) some distance (~10 m) to the linac entrance. The protons have average relativistic parameters $\gamma_r = 1.026$ and $\beta_r = 0.222$; the velocity spread, σ_v, of the extracted bunches can be expressed in terms of energy spread, σ_E, as

$$\sigma_v = \frac{c\sigma_E}{\gamma_r^3 \beta_r mc^2}. \quad (1)$$

The velocity spread for low-energy bunches can therefore be quite large; which leads to ballistic (velocity) de-bunching that will lengthen the bunches from ~2 ns to ~3 ns. However, the bunches are then divided into sub-bunches in the higher frequency linac so this lengthening has no overall effect; the final pulse structure at the high-energy station will be insensitive to this.

BEAM COMMISSIONING OF LINAC4 UP TO 12MeV

V. A. Dimov, E. Belli, G. Bellodi, J.B. Lallement, A. M. Lombardi, CERN, Geneva, Switzerland
M. Yarmohammadi Satri, IPM, Tehran, Iran

Abstract

CERN Linac4 is made of a 3 MeV front end including a 45 keV source , a 3 MeV Radio Frequency Quadrupole (RFQ) and a fast chopper, followed by a 50 MeV Drift Tube Linac (DTL), a 100 MeV Cell-Coupled Drift Tube Linac (CCDTL) and a 160 MeV Pi-Mode Structure (PIMS). The Linac4 beam commissioning is performed in 6 stages of increasing energy. Movable beam diagnostics benches, with various instruments, are used at each step to allow the detailed characterisation of operational parameters that will play a key role in the overall future performance. The first three stages of the commissioning, up to 12 MeV beam energy, have been completed at the end of 2014. The RFQ and the chopper line at 3 MeV, as well as the first tank of the DTL at 12 MeV were fully characterised, using permanent diagnostic instruments and a movable diagnostic bench equipped with a spectrometer, a slit-grid emittance meter, a Bunch Shape Monitor, Beam Position Monitors and a laser-emittance device. This paper reports on the strategy and the results of the commissioning up to 12 MeV. It also presents the validation of the set-up strategy, which is essential for the next stages of commissioning.

INTRODUCTION

Linac4 is a normal conducting, 160 MeV H- ions accelerator that is being constructed within the scope of the LHC Injectors Upgrade project. Linac4 will be connected to the Proton Synchrotron Booster during the next long LHC shutdown and it will replace the current 50 MeV proton linac, Linac2. Linac4 is being commissioned progressively with the installation of the accelerating structures into the Linac4 tunnel.

The first three stages of commissioning, which focused mainly on the characterisation of the RFQ (3MeV), the validation of the chopping system and the characterisation of the first DTL tank (12MeV), have been successfully performed by the end of 2014. A temporary version of the ion source, which gives about 20mA of beam current, was used during each stage.

Figure 1: The Linac4 basic architecture up to 12MeV.

Figure 1 shows the Linac4 basic architecture up to 12MeV and Fig. 2 shows the movable diagnostic bench, which was used for the beam commissioning at 3MeV and 12MeV. The bench was consecutively used for the beam measurements after the RFQ, the Medium Energy Beam Transport (MEBT) line and the DTL tank1. In addition to the temporary diagnostic instruments on the bench, the permanent diagnostic instruments of the MEBT line and between the DTL tank1 and tank2 were also used where necessary.

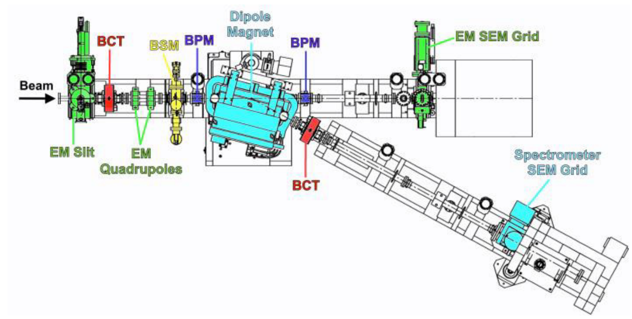

Figure 2: Movable diagnostic bench for 3MeV and 12MeV beam measurements.

During the 3MeV and 12MeV commissioning periods, the same beam properties were measured using different methods and instruments and then compared. In addition to the characterisation of the accelerating structures, these commissioning stages were particularly important for cross-calibration of the permanent diagnostic instruments with the temporary ones and validating the measurement methods, which are crucial for the high energy beam commissioning stages.

The following sections summarize the significant results of the 3MeV commissioning stage, with relevant references, and explain the measurement process and the results of the 12MeV commissioning in detail.

3MeV COMMISSIONING

During the 3MeV commissioning stage, many issues were addressed. The major ones were: confirming the RFQ performance, validating the chopping system operation and finding the RF phase and amplitude setting of the cavities on the MEBT line.

The performance of the RFQ and the calibration of the RF amplitude were confirmed by varying the power in the RFQ and measuring the transmission [1].

The chopping system is composed of four plates, followed by a cone shaped in-line dump. The correct operation of the chopping system was confirmed by measuring the transmission of the main and the chopped

A NEW HARDWARE DESIGN FOR PSB KICKER MAGNETS (KSW) FOR THE 35 mm TRANSVERSE PAINTING IN THE HORIZONTAL PLANE

L. Feliciano, C. Bracco, L. Ducimetière, A. Fowler,
G. Grawer, R. Noulibos, L. Sermeus,
W. Weterings, C. Zannini, CERN, Geneva, Switzerland

Abstract

The changeover from Linac2 to Linac4 in CERN's injector chain will allow increasing the injection energy into the PS Booster from 50 MeV to 160 MeV [1]. Transverse phase space painting will be performed in the horizontal plane, by means of four stacks of four KSW kicker magnets. The KSW magnets are located outside the injection region and will produce a 35 mm closed orbit bump, with falling amplitude during the injection to accomplish transverse phase space painting to the required emittance. New magnets with two different types of coils are being built using the existing design. The magnets are made of two halves, which are assembled together around a vacuum ceramic chamber. In order to reduce the beam impedance, the ceramic chamber is internally coated by a thin titanium layer. A new multiple-linear waveform generator has been developed to provide the high flexibility in the KSW kicker magnets current decay to fulfil the requirements of all the different users (LHC, nTOF, ISOLDE, CNGS, etc.).

INTRODUCTION

In the framework of the Linac4 – LIU (LHC Injectors Upgrade) project the European Organization for Nuclear Research (CERN) is designing a new layout for the transverse painting in the horizontal plane with kickers (KSW). The 160 MeV H^- ions beam from Linac4 will be distributed to four superposed rings of the PS Booster (PSB) and a new multi-turn H^- charge exchange injection system [2] will allow increasing the beam intensity in the PSB. A series of 4 horizontal kickers (KSW), outside the injection region, will produce a 35 mm closed orbit, with falling amplitude during injection, and uniformly fill the horizontal phase space (transverse painting) and move the circulating beam away from the stripping foil; this will allow the reduction of the emittance (ε_x) blow-up induced by space charge effects and scattering processes.

KICKER REQUIREMENTS

Two types of KSW magnets will be installed in the PSB layout to produce the transverse painting bump. Optics studies showed that, since the magnets are not symmetrically distributed around the stripping foil, each type of magnet has to give a slightly different kick to perfectly close the bump and prevent any orbit leakage around the ring. All the magnets will thus be individually powered.

A high flexibility in the KSW current decay waveform is needed to fulfil the requirements of all the different users. A multiple-linear waveform is chosen for the KSW generators as schematically shown in Fig 1.

For an "ideal painting" (red line in Fig 1), an initial fast decay over few turns (called in the following Slope 1) has to be followed by an almost constant slope (Slope 2) until the end of injection. This allows filling first the centre and then the outer area of the transverse phase space reducing the charge density in the core of the bunch and thus the space charge effects. Once injection is finished, the circulating beam is moved away from the foil (Slope 3), as fast as possible, until a negative bump of -9.2 mm (fixed for all the users) to avoid any further interaction with the foil. At this point also the chicane starts decaying and the KSW bump goes to zero in 1 ms.

For small emittance beams (i.e. LHC beams), no painting is applied during the full injection process, the bump stays constant at 35 mm (I_0 green line in Fig 1). This could vary between 10 μs and 20 μs, depending on the current delivered by Linac4. During injection, the deviation from the reference waveforms must be always kept smaller than 1%. After injection the beam has to be moved away from the foil as quickly as allowed by the HW. Studies with ORBIT [3] were performed assuming the fall of the injection bump from 35 mm to zero in 10 μs (cyan line in Figure 1; a 2 μs margin was considered to take into account possible delays induced by the eddy currents in the Titanium layer of the vacuum chambers as explained in above). Such decay speed allows keeping the number of foil crossings low enough to limit the emittance blow-up.

For the high intensity and large emittance beams (i.e. ISOLDE, nTOF, etc.) the "ideal painting" will be performed. In case of 40 mA average current delivered by Linac4 up to the PSB, the maximum target intensity (2.5×10^{13} protons per ring for ISOLDE) can be accumulated in 100 μs. The eventuality of a non-optimum performance of Linac4 (reduced current) and the consequent need to extend the injection process up to 150 μs to reach the target intensity is taken into account [4].

The envelope conditions for the KSW current decay (ΔI), depending on the user, are the following:

NEW SHAVING SCHEME FOR LOW-INTENSITY BEAMS IN THE CERN PS BOOSTER AND FEASIBILITY AT 160 MeV

M. Kowalska, CERN, Geneva, Switzerland, EPFL, Lausanne, Switzerland
E. Benedetto, CERN, Geneva, Switzerland
V. Forte, CERN, Geneva, Switzerland, Université Blaise Pascal, Clermont-Ferrand, France
B. Mikulec, G. Rumolo, CERN, Geneva, Switzerland

Abstract

The PS Booster (PSB) is the first synchrotron in the CERN proton accelerator chain, serving all downstream machines. As part of the LHC Injector Upgrade (LIU) Project, the PSB injection energy will increase from 50 MeV to 160 MeV and a new H^- charge-exchange injection scheme will be implemented. Beam losses are a concern due to the increased injection energy, and mitigation scenarios are under investigation.

On the other hand it is desirable for low-intensity beams to have the possibility to precisely tailor sub-micron beam emittances through controlled scraping (transverse shaving process) towards a suitable aperture restriction. Challenges are the higher activation potential of the beam and the smaller transverse beam sizes around 160 MeV as compared to 63 MeV, at which the shaving is presently done.

This paper describes the proposal of a new shaving scheme, more robust with respect to the steering errors and the choice of the working point, which localizes the scraping losses on the main PS Booster aperture restriction. The robustness of the new method, together with the results of simulations and measurements are discussed for the current (50 MeV) and future (160 MeV) situation.

INTRODUCTION

Shaving is presently the main method to control the beam emittance and beam intensity in the PS Booster. The beam is supposed to be scraped on the aperture restriction of the machine, located in period 8 – called Window Beam Scope (WBS) [1]. It is a carbon, 40 mm thick absorber. Its physical dimensions are: 28.6 mm and 50 mm in the vertical and horizontal plane, respectively.

The global aperture limitations in the lattice are built by the quadrupoles in the horizontal plane (57 mm) and at the scrapers that protect the dipoles in the vertical plane (29.7 mm). A small difference between the dipoles aperture and the WBS aperture makes the vertical place fragile for any uncontrolled orbit perturbation or variation of working point with respect to the nominal one while shaving. Figure 1 is an example of an unsuccessful shaving due to the introduced closed orbit error.

The current shaving method, which consists in inducing closed orbit oscillations by a single kick (Figure 1), causes losses around the machine. In order to localize the losses at the PS Booster aperture restriction – Window Beam Scope (WBS), a new shaving scheme based on a closed bump was proposed and tested.

The closed bump scenario was first studied in simulations and then tested during the 2014 machine run. Dedicated measurements were performed in order to investigate the robustness of the method. Measurements of intensity, beam profiles and orbit excursion were made for both scenarios: at the future, foreseen upgraded injection energy - 160 MeV - and for the existing operational situation, at 63 MeV, when shaving occurs.

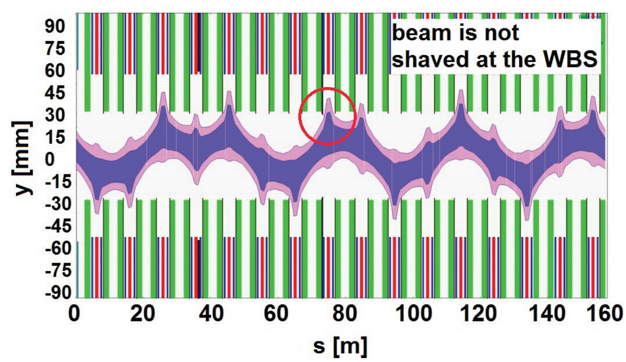

Figure 1: Lattice of the PSB and the illustration of the 3 sigma beam while conventional shaving. The 3-sigma beam is plotted in violet while 5 sigma is in magenta. The beam envelope is calculated for the vertical plane, with $Q_x = 4.37$ and $Q_y = 4.45$. Main lattice elements are shown in different colours: bending magnets in green, focusing quadrupoles in blue and defocusing quadrupoles in red. The scrapers are marked in maroon and WBS with the red circle.

EXISTING SITUATION IN OPERATION

Currently, operational shaving is performed by inducing a closed orbit global oscillation (Figure 1), using a single kick either in the horizontal or in the vertical plane. The vertical plane is preferred, mostly due to the absence of the dispersion and higher stability of the beam envelope in this plane. Closed orbit distortion (COD), induced during the shaving, depends strongly on the applied kick strength [2], which is adjusted independently for each type of the shaved beam. Moreover the shaving with the single kick is very sensitive to the working point and to steering errors.

CERN PS BOOSTER UPGRADE AND LHC BEAMS EMITTANCE

E. Benedetto, J. L. Abelleira, C. Bracco, B. Mikulec, G. Rumolo, CERN, Geneva, Switzerland,
V. Forte, CERN, Geneva, Switzerland, and Université Blaise Pascal, Clermont-Ferrand, France

Abstract

By increasing the CERN PS Booster injection energy from 50 MeV to 160 MeV, the LHC Injector Upgrade Project aims at producing twice brighter beams for the LHC. Previous measurements showed a linear dependence of the transverse emittance with the beam intensity and space-charge simulations confirmed the linear scaling. This paper is discussing in detail the dependence on the longitudinal emittance and on the choice of the working point, with a special attention to the H^- injection process and to the beam dynamics in the first 5 ms, during the fall of the injection chicane bump.

INTRODUCTION

As part of the LHC Injectors Upgrade Project (LIU), the CERN PS Booster (PSB) will undergo an upgrade program [1], which includes the increase of injection energy from 50 MeV to 160 MeV and the implementation of an H^- charge-exchange injection from the new Linac4. Compared to the other rings with H^- injection and characterized by similar space-charge tune spreads at low energy ($\Delta Q \sim 0.5$ [2]), the peculiarity of the PSB is the required small transverse emittance. This needs to be produced and preserved in order to provide high brightness beams to the LHC. Being the first circular accelerator in the LHC proton injector chain, the PSB defines the minimum normalized transverse emittance.

The paper will review the measurements done in 2012 to characterize the operational LHC type beams in the PSB [3], which show a linear dependence of the transverse emittance with the beam intensity. The increase of injection energy with LIU should give about a factor $(\beta\gamma^2)^{160\mathrm{MeV}}/(\beta\gamma^2)^{50\mathrm{MeV}} = 2.04$ reduction of the space-charge tune spread for the present beams. Assuming the same tune spread as of today, which is in our baseline [4], with Linac4 it will be possible to inject twice the intensity in a given emittance (or to reduce the emittance by the same amount), i.e. the brightness curve should scale down by a factor 2. Simulation results will be presented to confirm these estimates and to discuss the dependence on the working point and on the longitudinal emittance of the minimum emittance achievable for a given intensity. Finally, the H^- injection scheme to produce in a controlled way 1-1.5 μm emittances will also be discussed.

MEASUREMENTS

Figure 1 shows the linear dependence of the transverse emittance on the beam intensity, found with the measurements done in 2012 for the LHC-type operational beams [3]. Two sets of points are plotted in the figure, for the standard LHC beam (LHC25ns) which has a required longitudinal emittance of 1.20 eVs (matched area at extraction), and for the so called BCMS LHC beam [5], which undergoes a special RF gymnastics in the downstream machine, the PS, and needs to be provided to the PS with a longitudinal emittance of maximum 0.9 eVs.

Different beam intensities have been produced by increasing the number of injected turns from 1 to 4 and by optimizing the injection parameters including the tune to minimize the transverse emittances. The horizontal and vertical profiles have been measured at extraction in Ring 3, which featured the best performances as the result of a careful optimization.

Additional measurements [3] showed that, provided that the working point is optimized all along the cycle, the transverse normalized emittance is constant during acceleration (however measurements at injection are difficult to read due to scattering at the wires, inducing 10% blow-up during the measurement itself). This indicates that the final values of the transverse emittance are dominated by space-charge effects at injection energy and by the multi-turn injection process itself.

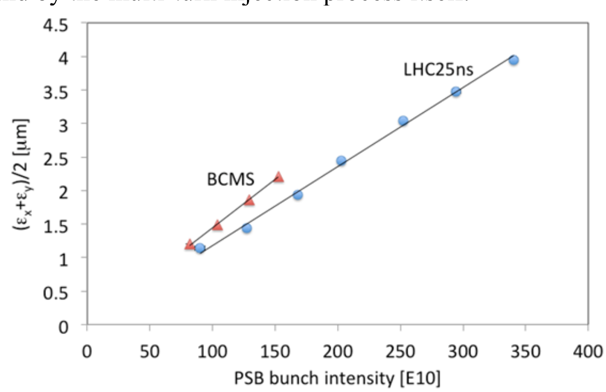

Figure 1: Emittance vs intensity curve for the LHC25ns beam (1.20 eVs) and the BCMS beam (0.86 eVs). Measurements of 2012 [3].

MINIMUM EMITTANCE SIMULATIONS

Simulations with PTC-Orbit [6] have been done to confirm the predictions of a factor 2 improvement in the brightness curve, assuming that the space-charge effects at injection energy in combination with machine errors are the cause of emittance blow-up.

The errors included in the model are the perturbations at the chicane magnets due to edge effect and Eddy currents [7]. Those provide the excitation of the half-integer and 20% vertical beta-beating, which is corrected down to a few % by special trims on two lattice quadrupoles. In addition to that, they induce the excitation

BEAM TRANSFER TO THE FCC-hh COLLIDER FROM A 3.3 TeV BOOSTER IN THE LHC TUNNEL

W. Bartmann, M.J. Barnes, M. Fraser, B. Goddard, W. Herr, J. Holma, V. Kain, T. Kramer, M. Meddahi, A. Milanese, R. Ostojic, L.S. Stoel, J. Uythoven, F. Velotti, CERN, Geneva, Switzerland

Abstract

Transfer of the high brightness 3.3 TeV proton beams from the High Energy Booster (HEB) to the 100 TeV centre-of-mass proton collider in a new tunnel of 80–100 km circumference will be a major challenge. The extremely high stored beam energy means that machine protection considerations will constrain the functional design of the transfer, for instance in the amount of beam transferred, the kicker rise and fall times and hence the collider filling pattern. In addition the transfer lines may need dedicated insertions for passive protection devices. The requirements and constraints are described, and a first concept for the 3.3 TeV beam transfer between the machines is outlined. The resulting implications on the parameters and design of the various kicker systems are explored, in the context of the available technologies. The general features of the transfer lines between the machines are described, with the expected constraints on the collider layout and insertion lengths.

MACHINE PROTECTION LIMITS

Present investigations of the feasibility of absorber blocks for the LHC injection protection for High Luminosity-LHC (HL-LHC) beam parameters show two limitations. The foreseen high brigthness beams could cause mechanical stresses in the absorbers beyond their damage level. Also, attenuation of primary particles to provide protection of downstream elements would not be guaranteed with the present design [1–3]. The beam energy at the HEB to FCC transfer is a factor 130 higher than in case of the SPS to LHC transfer. Thus, a staggered transfer of batches with a reduced number of bunches is envisaged. The reachable bunch filling as a function of the injection kicker rise time for different transferred beam energies is shown in Fig. 1. In order to fill 80% of FCC and assuming 5 MJ as maximum energy per transfer leads to a required kicker rise time of less than 0.28 μs. A total of 120 batches with 90 bunches each need to be transferred. In case of LHC as HEB, there would be 4 times 30 batches of 90 bunches. The time between batch transfers is dominated by the synchronisation between the HEB and FCC and beam quality checks. Between each transferred batch both machines have to be synchronised on the common frequency:

$$f_c = \frac{f_{rev,HEB}}{C_{FCC}} = \frac{f_{rev,FCC}}{C_{HEB}} \tag{1}$$

In case of LHC as HEB the common frequency is about 111Hz which defines the required recharging frequency of HEB extraction and FCC injection kickers. With a total number of about 30 transferred batches from LHC the minimum injection time for one full LHC beam injected into FCC is 0.5 s.

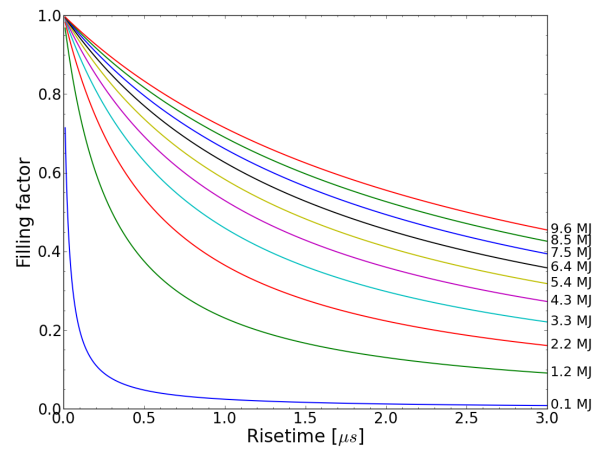

Figure 1: FCC bunch fill factor vs injection kickers rise time for different transferred beam energies. The foreseen filling of 80% is reached for HL-LHC energies (about 5 MJ) for a rise time of 0.28 μs.

INJECTION SYSTEM LAYOUT

The proposed injection system uses a Lambertson septum to deflect the beam horizontally onto the FCC orbit. The injected beam enters the septum with an offset in angle and position in both planes with respect to the ring orbit, Fig. 2. The vertical angle is reduced by off-centre passage through a quadrupole and finally compensated by a fast kicker system. In order to estimate the required kick angles we assume that the beam clearance at the level of the quadrupole is

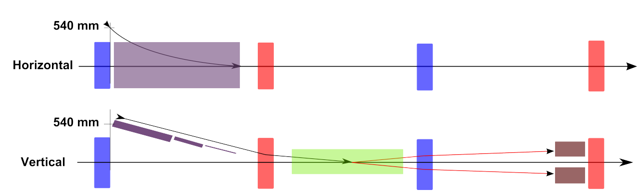

Figure 2: Layout of the injection system. Focussing (red) and defocussing (blue) quadrupoles build a FODO lattice. The Lambertson septum (violet), which is vertically aligned with the incoming trajectory angle, deflects the beam horizontally onto the orbit, and the kicker (green) compensates for the remaining angle in the vertical plane. The injection dump (brown) intercepts miskicked beam (red).

Abstract

CERN's Proton Synchrotron Booster (PSB) is undergoing a major upgrade program in the frame of the LHC Injectors Upgrade (LIU) project. During the first long LHC shutdown (LS1) some parts of the upgrade have already been implemented, and the machine has been successfully re-commissioned. More work is planned for the upcoming end-of-year technical stops, notably in 2016/17, while most of the upgrade is planned to take place during the second long LHC shutdown (LS2). We report on the upgrade items already completed and commissioned, the first Run 2 beam performance and give a status of the ongoing design and integration work.

INTRODUCTION

The upgrade of the PS Booster consists of two major parts. With the connection of Linac4, the injection scheme will be upgraded to charge exchange injection of H- ions. This change will significantly reduce beam loss in the injection area and allow for tailoring the transverse emittance by means of phase space painting. At the same time, the injection energy will be increased from 50 MeV to 160 MeV [1]. With this increase of beam energy the relativistic $\beta\gamma^2$ factor increases by a factor of 2. The incoherent space charge tune shift at Booster injection can be expressed as

$$\Delta Q_x = \frac{R_p N_b}{2\pi^{3/2}\gamma^3\beta^2\sigma_z}\oint\frac{\beta_x(s)ds}{\sigma_x(s)[\sigma_x(s)+\sigma_y(s)]}$$

$$\Delta Q_y = \frac{R_p N_b}{2\pi^{3/2}\gamma^3\beta^2\sigma_z\sqrt{\varepsilon_y}}\oint\frac{\sqrt{\beta_y(s)}ds}{\sigma_x(s)+\sigma_y(s)}$$

where R_p is the classical proton radius and N_b is the number of protons per bunch. With the increase of injection energy the space charge tune shift decreases by a factor 2, thus doubling the intensity that can be accumulated within a given emittance. The second component of the upgrade program is the increase of the extraction energy from presently 1.4 GeV to 2.0 GeV. The underlying idea is to reduce space charge effects at injection into the downstream Proton Synchrotron (PS), thus removing this bottleneck. The expected gain can again be deduced from the ratio of the $\beta\gamma^2$ factor at 1.4 GeV and 2.0 GeV, which is 1.63 and corresponds to an intensity increase of 60% within given emittance values.

LS1 WORK

While most of the upgrade activities are scheduled to be implemented during LS2, a number of LIU activities could be performed in the PSB during LS1 in 2013/14. Activities that could be completed comprise:

- implementation of the new digital RF controls
- installation of 5 additional prototype Finemet cavity cells (Fig. 1)
- upgrade of diagnostics (new beam loss monitors, new orbit measurement, new pick-ups and transformers in the transfer lines)
- renovation of the multipole power supplies
- installation of a new external dump
- limited cabling campaign and identification of obsolete cables
- controls upgrades (change of many front-end computers)
- consolidation of handling and lifting equipment
- new hardware interlock at extraction (Beam Interlock System - BIS)

Figure 1: Prototype Finemet cavity modules installed in Ring 4 of the PSB.

COMMISSIONING OF UPGRADE ITEMS

The PS Booster was re-started after LS1 in June 2014. Unlike in previous years, much more than standard

DETAILED STUDIES OF BEAM INDUCED SCRUBBING IN THE CERN-SPS

H. Bartosik, T. Bohl, B. Goddard, G. Iadarola*, G. Kotzian, K. Li, L. Mether,
G. Rumolo, E. Shaposhnikova, M. Schenk, M. Taborelli (CERN, Geneva)

Abstract

In the framework of the LHC Injectors Upgrade (LIU) project, it is foreseen to take all the necessary measures to avoid electron cloud effects in the CERN-SPS. This can be achieved by either relying on beam induced scrubbing or by coating the vacuum chambers with intrinsically low Secondary Electron Yield (SEY) material over a large fraction of the ring. To clearly establish the potential of beam induced scrubbing, and to eventually decide between the two above options, an extensive scrubbing campaign is taking place at the SPS. Ten days in 2014 and two full weeks in 2015 are devoted to machine scrubbing and scrubbing qualification studies. This paper summarizes the main findings in terms of scrubbing efficiency and reach so far, addressing also the option of using a special doublet beam and its implication for LHC.

INTRODUCTION

The electron cloud effect has been identified as a possible performance limitation for the SPS since LHC type beams with 25 ns spacing were injected into the machine for the first time in the early years of 2000. At that time a severe pressure rise was observed all around the machine together with transverse beam instabilities, significant losses and emittance blow-up on the trailing bunches of the train [1]. Since 2002, scrubbing runs with 25 ns beams were carried out almost every year of operation in order to condition the inner surfaces of the vacuum chambers and therefore mitigate the electron cloud. Extensive machine studies showed that by 2012 the conditioning state of the SPS was such to avoid any possible beam degradation due to electron cloud on the cycle timescale for 4 batches of 72 bunches with $N \approx 1.35{\times}10^{11}$ p/b and normalized transverse emittances of about 3 μm [2]. For higher intensities ($N \approx 1.45{\times}10^{11}$ p/b injected) a seemingly electron cloud driven transverse instability was observed after the injection of the third and the fourth batch, leading to emittance blow up and particle losses on the trailing bunches of the injected trains. Since the SPS was never scrubbed with such high beam intensities, an additional scrubbing step might be required for suppressing these effects. If scrubbing is not sufficient for suppressing the electron cloud effect with the high beam intensity and small transverse emittance produced with LIU, or in case the reconditioning process is very slow after large parts of the machine are vented (like during a long shutdown), the inner surface of the SPS vacuum chambers might have to be coated with a low Secondary Electron Yield (SEY) material. The solution developed at CERN is to produce a thin film of amorphous Carbon (a-C) using DC Hollow Cathode sputtering on the inner walls of the vacuum chamber [3]. The suppression of electron cloud in coated liners equipped with electron cloud strip monitors was already proved with beam in the SPS. An additional four SPS half cells (including quadrupoles) have been coated with a-C during Long Shutdown 1 (LS1), seeking for further experimental evidence of the coating efficiency with beam operation in Run 2.

The total or partial coating of the SPS machine with a-C is a major task, which requires careful preparation and planning of resources. The decision whether or how much of the SPS needs to be coated has therefore to be taken no later than mid 2015. After LS1, a first scrubbing run took place during the whole Week 45 in 2014 with the main goal of recovering the operational performance, as it was expected that the good conditioning state of the SPS will be degraded due to the long period without beam operation, partial venting, and the related interventions on the machine. Two and a half additional days of scrubbing in Week 50 were also used to start exploring the SPS behaviour with 25 ns beams with higher intensity as well as accelerated doublets and other LHC beam variants [4]. Two more weeks for scrubbing will be performed in the first half of 2015 in order to assess the potential to fully scrub the machine for high intensity 25 ns beams or the limitations of this approach. Only after collecting all the additional experience and the important information from the extensive experimental scrubbing from post-LS1 operation, the final choice between coating and scrubbing will be made in mid-2015.

WEEK 45: RECOVERY OF THE PRE-LS1 PERFORMANCE

The goals of the SPS scrubbing run in Week 45 were:

- Recover the 2012 performance with LHC 25 ns beams;
- Qualify the machine behaviour with LHC beams after long shutdown and extensive machine venting;
- Test doublet beams for SPS scrubbing and as preparation for LHC scrubbing in 2015.

In oder to make scrubbing efficient, the pressure interlocks on the injection kicker MKP-S and the beam dump (TIDVG), exchanged during LS1, had to be raised. The summary plot showing the maximum current per cycle (in

EUROPEAN SPALLATION SOURCE LATTICE DESIGN STATUS

Y. Inntjore Levinsen*, H. Danared, M. Eshraqi,
R. Miyamoto, A. Ponton, R. de Prisco, E. Sargsyan, ESS, Lund, Sweden
H. Dølrath Thomsen, S. Pape-Møller, ISA, Aarhus Uni., Denmark

Abstract

The accelerator of the European Spallation Source (ESS) will deliver 62.5 mA proton beam of 2.0 GeV onto the target, offering an unprecedented beam power of 5 MW. Since the technical design report (TDR) was published in 2013, work has continued to further optimise the accelerator design. We report on the advancements in lattice design optimisations after the TDR to improve performance and flexibility, and reduce cost of the ESS accelerator.

INTRODUCTION

The ESS project is an ambitious project, which aims to provide a world leading 5 MW spallation neutron source, planned to be commissioned in 2019 [1]. The ESS is constructed in Lund, Sweden, in a collaboration between 17 partner countries. The neutrons are produced by shooting a high power proton beam onto a spallation target. The current accelerator design is assuming operation at 14 Hz, with 2.86 ms long pulses, corresponding to a duty cycle of 4 %. The accelerator can accelerate the beam up to 2 GeV, and a beam current of 62.5 mA is thus needed to reach the 5 MW requirement. The overall layout is shown in Fig. 1.

Since the TDR was published in 2013 [2], the beam energy has been reduced from 2.5 GeV to meet the budget requirements. Correspondingly the beam energy increased from 50 mA to 62.5 mA in order to keep the beam power constant. This was discussed last year in [3]. The high level parameters described within this reference remain unchanged this year.

The accelerator design is currently mainly limited by the amount of power that can be fed to the cavities (energy), beam loss limits (intensity), and space charge effects at low energy.

There has been ongoing work to further optimise and finalise the design of the lattice optics in the last year, and various error studies have been performed to better understand the limitations of the lattice and providing valuable input for the design constraints. The lattice and optics presented here will in the future be referenced to as the “2014 Baseline”.

FRONT END

The front end of the ESS linac will accelerate the high intensity beam from the 75 keV ion source and up to 90 MeV at the exit of the last DTL tank, before the beam is injected into the superconducting part of the linac. With a high power superconducting linac, it is important to provide a high quality beam to the superconducting section so as to minimise the losses (machine protection). In addition, it is important to generally keep the losses low, to reduce activation and keep a good machine reliability.

* yngve.levinsen@esss.se

Ion Source, LEBT, and RFQ

The proton beam is generated with a Microwave Discharge Ion Source (MDIS), delivering a 75 keV beam energy and more than 70 mA proton beam current to the low energy beam transport (LEBT) [4]. The LEBT is a 2.4 m long section matching the beam to the RFQ using two solenoids. In between the solenoids a chopper is installed to remove the transient of the beam pulse.

The four-vane RFQ acclerates and bunches the continuous pulse from the source into bunches at 352.21 MHz. The output beam energy of the RFQ is 3.62 MeV. The RFQ has a relatively long bunching section to allow for a higher transmission.

In Fig. 2, we show the transmission through the LEBT+RFQ for different strengths of the two solenoids in the LEBT lattice. The optimal setting found in this simulation is to have the two solenoids at 0.238 T and 0.244 T, providing a transmission of 97.8%. The working point is shown by the large dot in the figure.

MEBT and DTL

Between the RFQ and the start of the drift tubes, there is a section of 3.6 m called the Medium Energy Beam Transport (MEBT). Recent advancements in the MEBT layout was described in [5, 6]. The purpose of this section is to match the beam coming out of the RFQ to the drift tube linac, and to measure the beam properties with various beam diagnostics. The MEBT has 11 quadrupoles for the focusing of the beam, with one BPM per quadrupole. Three scrapers will be installed to clean the transverse halo, which will reduce the losses in the DTL and superconducting part of the linac [7].

A fast chopper is installed in the MEBT, which main purpose is to chop off the bad quality bunches at the beginning and end of the pulse which could not be removed by the LEBT chopper due to the space charge compensation recovery time. Both the LEBT and the MEBT choppers have a secondary purpose of providing an additional level of beam protection. The MEBT chopper is the last location where the beam can be dumped before the superconducting section.

The last accelerating section of the warm linac is the drift tube linac (DTL). The DTL consists of 5 tanks which brings the beam energy from 3.6 MeV to 90 MeV. The DTL has undergone a design optimisation since the TDR was published in 2013. One tank was added, and the output beam energy thus increased from the original 77.5 MeV to 90 MeV [8].

The FODO lattice is realised using permanent magnet quadrupoles (PMQ) in every second drift tube. There are also three horizontal, three vertical steerers, and three BPMs in each tank. The optimised locations of the steerers and BPMs are currently being studied [9].

LHC INJECTORS UPGRADE (LIU) PROJECT AT CERN

M. Meddahi*, J. Coupard, H. Damerau, A. Funken, S. Gilardoni, B. Goddard, K. Hanke, I. Kobzeva, A. Lombardi, D. Manglunki, S. Mataguez, B. Mikulec, G. Rumolo, E. Shaposhnikova, M. Vretenar, CERN, Geneva, Switzerland

Abstract

CERN is currently carrying out an ambitious improvement programme of the full LHC Injectors chain in order to enable the delivery of beams with the challenging HL-LHC parameters. The LHC Injectors Upgrade project coordinates this massive upgrade program, and covers a new linac (Linac4 project) as well as upgrades to the Proton Synchrotron Booster, the Proton Synchrotron and Super Proton Synchrotron. The heavy ion injector chain is also included, adding the Linac3 and Low Energy Ion Ring to the list of accelerators concerned. The performance objectives and roadmap of the main upgrades will be presented, including the work status and outlook. The machine studies and milestones during LHC Run 2 will be discussed and a preliminary Long Shutdown 2 installation planning given. Finally, for the LHC Run 3, the beam performance across the full injector chain after all the upgrades will be estimated and the required commissioning stages outlined.

INTRODUCTION

The goal of the LHC Injectors Upgrade project (LIU) is to increase the intensity/brightness in the injectors in order to match the High Luminosity LHC (HL-LHC) requirements [1]. For protons, the Linac4/PSB/PS/SPS chain will be enabled to produce higher intensity beams (based on efficient production schemes, space charge and electron cloud mitigation, impedance reduction, feedback systems, hardware upgrade and improvement). For heavy ions, an important upgrade of the injector chain (Linac3, LEIR, PS, SPS) is planned to reach the beam parameters at the LHC injection that can meet the luminosity goal. In addition, the LIU project should ensure the increased injectors reliability and lifetime to cover the HL-LHC era (until 2035). This part, closely related to the CONSolidation, project [2], concerns the upgrade/replacement of ageing equipment (power supplies, magnets, RF) and the improvement of radioprotection measures (shielding, ventilation).

The timeline of the LIU project is sketched in Fig. 1. The simulation studies, beam measurements and equipment procurement will take place during Run 2 until the start of Long Shutdown 2 (LS2). During this time, key dates for pending decisions have been set in order to define the baseline program of all the interventions by end of 2016. All LIU installations and hardware works will then take place during LS2. For some of these installation activities, it is checked if they could be anticipated to Year-End-Technical-Stop (YETS) or Extended-Year-End-Technical-Stop (EYETS). Commissioning of LIU beams will take place in 2020 for the Pb ion beams, as the full beam performances are already needed for the 2020 ion run. The proton beam commissioning up to the LIU beam parameters will gradually be performed during Run 3 to be ready after LS3. This strategy would as well allow performing any further hardware corrective actions during the Run 3 technical stops or LS3, if needed.

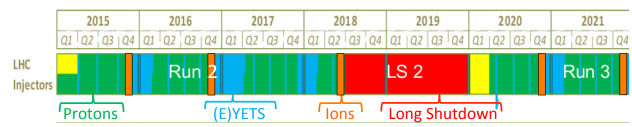

Figure 1: LHC (upper row) and Injectors (lower row) operation schedule (green: proton operation, blue: technical stops, orange: ion operation, red: long shutdown -LS).

LIU IONS

The main target of the LIU-IONS can be described in a simplified form as reaching 7 times the design peak luminosity [3]. This also translates into multiplying by about a factor 3 the peak luminosity extrapolated from beam parameters achieved during the 2013 p-Pb run. Table 1 summarises the desired versus achieved ion performance. The bunch intensity was already at the limit on the SPS flat bottom during the 2013 p-Pb run in terms of acceptable intra-beam scattering and space-charge effects. It is therefore needed to accumulate a larger number of bunches in LHC.

Table 1: Ion Beam Parameters at LHC Injection

	N (10^8 ions/b)	$\epsilon_{x,y}$ (μm)	Bunches
Achieved	1.4	1.2	358
HL-LHC (tbc)	1.4	1.2	960

The means to achieve the LIU-IONS target luminosity are the following:

- Increase the beam current from the source and Linac3 by improving both source and Low Energy Beam Transport (LEBT). This requires identifying and removing bottlenecks with the aid of beam dynamics simulations and beam measurements, and by installing new diagnostics. The increase of the injection rate from 5 to 10 Hz will allow injecting more intensity into LEIR, while keeping the same magnetic cycle duration;
- Increase the beam current out of LEIR by both increasing the amount of injected beam (compatibly with the electron cooling capabilities) and mitigating

POSSIBLE REUSE OF THE LHC AS A 3.3 TeV HIGH ENERGY BOOSTER FOR HADRON INJECTION INTO THE FCC-hh

B.Goddard, W. Bartmann, M. Benedikt, W. Herr, M. Lamont,
P. Lebrun, M. Meddahi, A. Milanese, M. Solfaroli Camillocci, L.S. Stoel
CERN, Geneva, Switzerland

Abstract

One option for the injector into a 100 TeV centre-of-mass energy frontier proton collider FCC-hh [1] in a new tunnel of 80–100 km circumference is to reuse a suitably modified LHC as 3.3 TeV High Energy Booster (HEB). The changes that would be required to the existing LHC insertions are described, including the types and numbers of new magnets and circuits. The limitations on the maximum LHC ramp rate and minimum cycle time discussed. The key question of the minimum FCC filling time achievable with technically possible upgrades is examined, together with the issues of decommissioning for the elements which would need to be removed from the machine. The potential performance reach of the modified LHC as 3.3 TeV HEB is quantified, and implications for FCC-hh discussed.

MAIN DESIGN CONSIDERATIONS

Initial studies have shown that beam transfer from both LHC P1 and P8 is preferable to optimise the orientation of the collider with respect to the local geology in the Geneva area and to minimise the length and overall bending angles of the new transfer lines. It is desirable to minimise changes to the LHC lattice and machine configuration, avoiding changes to highly activated zones. Beam parameters are summarised in Table 1. The low number of bunches per transfer is determined by the damage potential of the 3.3 TeV beam [2].

Table 1: Parameters of Beams to Inject into FCC-hh

Parameter	Unit	Value (option)
Beam energy	TeV	3.3
Bunch spacing	ns	25 (5)
Bunch population		1.0 (0.2)$\times 10^{11}$
H/V emittance (norm.)	mm.mrad	2.2 (0.44)
RMS bunch length	cm	8.0
Bunches per transfer		50-100
Turnaround time	h	5.0

Transfer Energy

The injection energy of the FCC-hh collider is assumed to be 3.3 TeV, based on the ratio of injection to collision dipole field. In view of possible changes to the baseline HEB energy e.g. as a result of the collider dipole magnet aperture optimisation, the LHC machine layout changes have been made to reach as high an energy as possible compatible with all other constraints.

Number and Length of Rings, and Crossing Points

The use of both LHC rings is assumed, both to decrease the filling time by a factor two and to minimise the length of transfer lines required (or avoid polarity reversal). The cost will be in the duplication of many circuits and instruments, higher complexity and lower availability. The lengths of the two rings should be identical to simplify the RF manipulations and re-phasing required for transfer to the collider, and from the SPS to the HEB. There thus need to be at least two crossings placed azimuthally opposite, which do not need to be at the centre of the respective LHC long straight sections. The lengths of both rings should be the same as the existing LHC 26.659 km, to maintain the present ratio of 27/7 with the 6.912 km circumference of SPS.

Machine System Locations

Injection should remain in P2 and P8, to avoid additional civil engineering for 450 GeV beamlines. With the layout proposed and only two crossings the injections would need to be into the inner rings, which is feasible but entails some reorganisation of the layouts in P2 and P8. The beam dump system should remain in P6, to avoid decommissioning of the highly active dump blocks, and to avoid additional civil engineering for the dump lines and dump caverns. The two collimation systems (betatron and momentum cleaning) are assumed to remain in their locations in P7 and P3 respectively. This avoids the issue of decommissioning or moving the highly activated systems, and having to modify the accelerator and its infrastructure in these activated areas. The 400 MHz RF accelerating system is assumed to remain in its present location in P4.

Extraction Towards FCC Collider

The two extraction systems for transfer of the beams to the FCC-hh collider are assumed to be located in P1 and P8. For an overall layout where the 100 km collider intersects the LHC machine, LHC Beam 1 would be extracted from P1 and Beam 2 from P8, Fig. 1 (top). For a layout where a 80 km collider does not intersect the LHC ring, the direction of extraction from these two points is inverted. Integration of the extraction system in P8 together with the existing injection is feasible for 3.3 TeV but is likely to rely on the HEB extraction energy being lower than 7 TeV. In P1 the accommodation of the extraction with crossing dipoles will also be likely to limit the transfer energy.

LIMITS ON FAILURE SCENARIOS FOR CRAB CAVITIES IN THE HL-LHC *

A. Santamaría García, H. Burkhardt, K. Hernández Chahín, A. Macpherson, K. Sjobak, D. Wollmann, B. Yee-Rendón, CERN, Geneva, Switzerland

Abstract

The High Luminosity (HL) LHC upgrade aims for a tenfold increase in integrated luminosity compared to the nominal LHC, and for operation at a levelled luminosity of 5×10^{34} cm^{-2}s^{-1}, which is five times higher than the nominal LHC peak luminosity. Crab Cavities (CCs) are planned to compensate the geometric luminosity loss created by the increased crossing angle by rotating the bunch, allowing quasi head-on collisions at the Interaction Points (IP). The CCs work by creating transverse kicks, and their failure may have short time constants comparable to the reaction time of the Machine Protection System (MPS), producing significant coherent betatron oscillations and fast emittance growth. Simulations of CC failure modes have been carried out with the tracking code SIXTRACK [1], using the newly added functionality called DYNK [2], which allows to dynamically change the attributes of the CCs. We describe these simulations and discuss early, preliminary results.

INTRODUCTION

In order to produce ten times more collisions during the HL-LHC lifetime, the nominal levelled luminosity will be 5×10^{34}cm^{-2}s^{-1}. An increase in luminosity entails an increase in proton collisions per bunch crossing (pile-up) and a rapid decay of the beam current due to proton burning. In order to optimize the experimental detectors' efficiency, the pile-up has to be maintained at an acceptable level and the luminosity should remain constant over the length of the fill. It has been proposed to maintain the luminosity constant by reducing the transverse beam size by means of reducing β^*, called β^* levelling. A smaller beam size at the IP implies larger beam sizes in the triplet quadrupole magnets, which will need a larger aperture. The implementation of low β^* collision optics will be carried out with the Achromatic Telescopic Squeeze (ATS) scheme [3]. A smaller β^* requires a larger crossing angle θ, which in turn causes a reduction of the geometrical luminosity. The crossing angle will be increased by a factor of two for HL-LHC, causing a significant loss in luminosity and therefore delaying the integrated luminosity goal. CCs have been proposed to counteract this effect. They generate transverse electromagnetic fields, which rotate each bunch longitudinally by $\frac{\theta}{2}$ such that the bunches collide effectively head-on, compensating the geometric luminosity loss. CCs allow access to the full performance reach of the small β^* values offered by the ATS scheme and the larger triplet quadrupole magnets [4, Chapter 1].

* Research supported by the High Luminosity LHC project.

THE MPS AND CRAB CAVITY FAILURES

A variety of processes can cause unavoidable beam losses during normal and abnormal operation. Because of the high stored energy of the HL-LHC beams, above 700 MJ, the beams can be highly destructive. Even a local beam loss of a tiny fraction of the full beam into a superconducting magnet can cause a quench, and large beam losses can cause damage to accelerator components. Because of this, the MPS is designed with very high reliability to prevent an uncontrolled release of the energy and damage due to beam losses [4, Chapter 7].

With the installation of CCs, new failure scenarios that could cause beam losses have to be considered. Voltage or phase changes of the CCs will happen with a time constant τ, which is proportional to the time it takes to dissipate the energy stored in the cavity through the coupler when the RF sources are turned off (external Q factor):

$$\tau = \frac{2 \cdot Q_{\text{ext}}}{\omega},$$

where ω is the angular frequency of the CCs. For the HL-LHC parameters of $f_{\text{cc}} = 400.79$ MHz and $Q_{\text{ext}} = 3 \times 10^5 - 5 \times 10^5$, CC failures could happen with a time constant as fast as $\tau = 238 - 397$ μs $\approx 2 - 4$ LHC turns. These ultrafast failures are potentially dangerous, which motivates detailed studies as there may not be enough time to extract the beam in a controlled way [5].

SIMULATION SETTINGS

Tracking simulations have been carried out with the collimation version of SIXTRACK and the DYNK module, in order to estimate the beam loss distribution around the ring in case of CC failures. These simulations were carried out for Beam 1 and IP1, considering one bunch represented by 9.6×10^5 particles at collision energy. The relevant HL-LHC parameters considered are summarized in Table 1. Further studies including IP5 are foreseen.

Baseline Optics and Layout

The optics used for the whole machine is the HLLHCV1.0 collision optics, which includes the new Nb_3Sn triplet (140 T/m, 150 mm) with all the additional magnets needed to be compatible with $\beta^* = 0.15$ m and implementing the ATS scheme [6].

Crab Cavities

The HLLHCV1.0 optics include the installation of three CCs per IP, per side and per beam (n_{cc}). To simplify the opening and closing of the crab bump, the groups of $n_{\text{cc}} = 3$

ORIGIN OF THE DAMAGE TO THE INTERNAL HIGH ENERGY BEAM DUMP IN THE CERN SPS

V. Kain, K. Cornelis, B. Goddard, M. Lamont, I. Leitao, R. Losito, C. Maglioni, M. Meddahi, F. Pasdeloup, G. Steele, F. Velotti, CERN, Geneva, Switzerland

Abstract

The high energy beam dump in the SPS has to deal with beams from 105 to 450 GeV/c and intensities of up to 4×10^{13} protons. An inspection during the last shutdown revealed significant damage to the Al section of the dump block. This paper summarizes the results of the analysis revealing the most likely cause of the damage to the beam dump. The implications for future SPS operation will also be briefly discussed, together with the short-term solution put in place.

INTRODUCTION

The SPS can provide a large variety of ion and proton beams in an energy range from 14 GeV to 450 GeV. The most demanding beams are the high intensity proton beams that are accelerated to 400 or 450 GeV with intensities of more than 4×10^{13} protons per shot. The characteristics of the high intensity proton beams relevant for the discussion in this paper are summarized in Table 1.

Table 1: Normalized emittance in horizontal and vertical plane, protons per bunch, number of bunches and cycle length of the achieved high intensity proton beams in the SPS: Fixed Target (FT) and CNGS beams are accelerated to 400 GeV and LHC beams to 450 GeV.

Beam	ε [μm]	ppb [10^{10}]	#bunches	T_{cycle} [s]
LHC 25 ns	2.6	12	288	21.6
LHC ultimate	3.5	17	288	21.6
FT	12/8	1.07	4200	14.4
CNGS	12/8	1.07	4200	6

The SPS Beam Dumping System

The beam dump system of the SPS is housed in the long straight section LSS1 along with the injection system. It is connected to the SPS interlocking system and has to be able to receive all types of SPS beam at all energies. The system consists of horizontal and vertical kicker magnets that are triggered together to move the beam down and then to sweep it across the beam dump block as indicated in Fig. 1. Due to limitations on the reachable minimum voltage for the kicker switches, two beam dump blocks are installed in long straight section LSS1. The low energy beam is dumped on the low energy beam dump TIDH. Beam above 102.2 GeV is dumped on the high energy beam dump, called TIDVG.

Whereas the concept of the SPS beam dump system is valid for all current and future beams in terms of aperture and

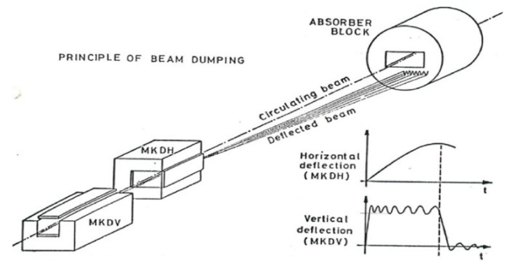

Figure 1: Principle of SPS beam dumping system.

technical feasibility for required kick strength, the radiation level in LSS1 due to the internal beam dump system and the robustness of the TIDVG dump block itself for high power loads have become a concern. In fact the TIDVG has suffered from beam induced damage during the years of the CNGS run.

TIDVG DAMAGE OBSERVATION

The absorber block of the high energy beam dump TIDVG is made of 2.5 m of Graphite, 1 m of Aluminum, 0.5 m of Copper and 0.3 m of Tungsten. The TIDVG Cu core is cooled with water and the absorber blocks are cooled through contact with the Cu core. Further information can be found in [1]. It was installed in 2006 before the CNGS run.

During the SPS shutdown from spring 2013 to September 2014 the equipment in LSS1 was dismantled and re-installed afterwards. When the TIDVG was ready to be re-connected, chunks of Aluminum close to its downstream end were detected. An endoscope inspection was carried out and the first Al block was found to have had melted and re-solidified, see Fig. 2. The damaged TIDVG was removed and the spare installed before the SPS start-up. The spare TIDVG absorber consists of the same materials as the original one, only that the graphite part is 2.7 m long and the Aluminum 0.8 m. As a consequence an analysis campaign was launched to understand the origin of the damage.

The TIDVG used between 1999 to 2005 was inspected as well. Also here the Al part of the absorber showed signs of damage.

SIMULATION RESULTS FOR ROBUSTNESS LIMITS

In 2009 possible power load limitations of the TIDVG absorber were investigated in simulation [2]. The weakest material in the sandwich absorber block is Aluminum with a melting point of only 660°C. With the assumptions used in the study for the thermal contact conductance of the Aluminum part, the maximum allowed temperature in

FEASIBILITY STUDY OF A NEW SPS BEAM DUMP SYSTEM

F.M. Velotti, J.L. Abelleira, M.J. Barnes, C. Bracco, E. Carlier, F. Cerutti, K. Cornelis, R. Folch, B. Goddard, V. Kain, M. Meddahi, R.F. Morton, J. A. Osborne, F. Pasdeloup, V. Senaj, G.E. Steele, J. Uythoven, H. Vincke, CERN, Geneva, Switzerland

Abstract

The CERN Super Proton Synchrotron (SPS) presently uses an internal beam dump system with two separate blocks to cleanly dispose of low and high energy beams. In view of the increased beam power and brightness needed for the LHC Injector Upgrade project for High Luminosity LHC (HL-LHC), the performance of this internal beam dump system has been reviewed for future operation. Different possible upgrades of the beam dumping system have been investigated. The initially considered solution for the SPS Beam Dump System is to design a new, dedicated external system, with a dump block in a shielded cavern separated from the machine ring. Unfortunately this solution is not feasible with the present technology. In this paper, the design requirements and the possible solutions are investigated, including considering a new internal beam dump in the Long Straight Section 5 (LSS5).

INTRODUCTION

The internal SPS beam dump system (SBDS) is a concern for the upcoming HL-LHC upgrade and also, after the recent observed damage [1], during current operation. The system has been designed for very different beam parameters, compared to those that will be used after the Long Shut-down 2 (LS2). As shown in [2] the internal high-energy absorber block (TIDVG) will not survive the nominal HL-LHC beam, and hence an upgrade is necessary to fulfil the requirements.

The internal SBDS is installed in LSS1. It is composed of two kicker systems (MKDV to vertically deflect the beam onto the absorber blocks and MKDH to dilute it), two main absorber blocks (TIDVG and TIDH for high and low-energy beams respectively) and three displaced quadrupoles (dog-leg) [3]. The presence of the dump system in LSS1 makes this area the most activated in the SPS. The TIDVG receives the highest beam power (Fig. 1) of all the SPS absorbers, which causes severe material and air activation, as well as radiation triggered material damage (cables, beamlines equipment, etc.) in its surroundings. Therefore, the post-LS2 high-brightness beam requirements and the heavy radiation related problems caused by the dump system in LSS1, translate into investigating an external dedicated solution, or an upgraded internal one.

The design of a completely dedicated external beam dump could profit from the existing extraction channels in LSS4 and LSS6. In [4], these two possibilities have been documented and both considered unsuitable due to the operational and civil engineering complexity.

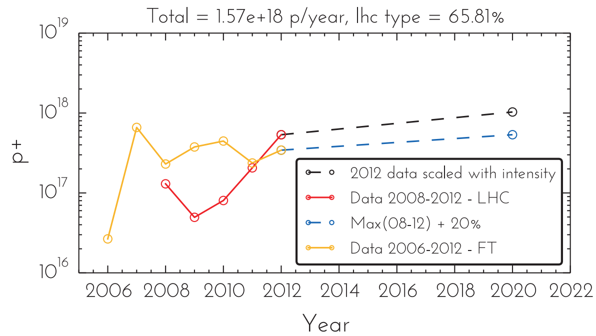

Figure 1: Extrapolation of the expected intensity to be dumped per year for post-LS2 era based on available data.

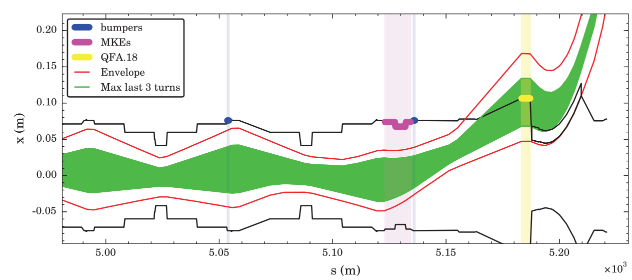

Figure 2: Proposed extraction channel in LSS5 using the same elements as in LSS4. In green the envelope of the last three turns trajectory of the particle with the maximum allowed amplitude at the extraction electrostatic septum ZS2 is shown. In red the beam envelope calculated as $A(s) = (D\delta_p + 1.2 \times \max\{6\sqrt{\epsilon\beta}, x_{3turns}\})1.1 + 6mm$.

It has also been studied to install a new external beam dump in LSS5 in order to fulfil all the requirements for a new beam dump. However this option suffers, as the other cited above, from the small extraction septum aperture and hence it will not be able to fulfil the design requirements within the time-line of the project.

In this paper the feasibility studies and main outcomes of an external dump using a new extraction system in LSS5 are presented. The design of a new internal system in LSS5 is also documented, covering most of the aspects that could undermine the feasibility of such a concept.

EXTERNAL SBDS IN LSS5

An extraction system for a beam dump exhibits several differences with respect to the classical fast extraction from the SPS, for example:

SPS-TO-LHC TRANSFER LINES LOSS MAP GENERATION USING PYCOLLIMATE

F. M. Velotti[1,2], W. Bartmann[1], C. Bracco[1], M. A. Fraser[1], B. Goddard[1], V. Kain[1], M. Meddahi[1],
[1]CERN, Geneva, [2]EPFL, Lausanne, Switzerland

Abstract

The Transfer Lines (TL) linking the Super Proton Synchrotron (SPS) to the Large Hadron Collider (LHC) are both equipped with a complete collimation system to protect the LHC against mis-steered beams. During the setting up of these collimators, their gaps are positioned to nominal values and the phase-space coverage of the whole system is checked using a manual validation procedure. In order to perform this setting-up more efficiently and more reliably, the simulated loss maps of the TLs will be used to validate the collimator positions and settings. In this paper, the simulation procedure for the generation of TL loss maps is described, and a detailed overview of the new scattering routine (`pycollimate`) is given. Finally, the results of simulations benchmark with another scattering routine are presented.

INTRODUCTION

The SPS is the last accelerator of the LHC injector chain. The SPS and LHC are directly connected through two ≈3 km long TLs which allow the injection of the required 450 GeV beam.

Both transfer lines (TI2 and TI8) are equipped with a complete passive protection system; it is composed of three graphite (R4550 in 1.2 m of active length) collimators per transverse plane (TCDIs). TI2 differs from TI8 because it is also equipped with a momentum collimator installed at the beginning of the line.

Such collimation system is designed to protect the LHC aperture and the LHC injection septa, in case of any kind of failures of the TLs active elements, as well as the SPS extraction systems.

The complete phase-space coverage is ensured by placing the three collimators, on each plane, at about $\pi/3 + n\pi$ phase-advance from each other. They are located at the end of the TLs and are single-stage protection devices. In case of failure in the upstream part of the TL, only one TCDI will be completely hit by the beam; therefore, every collimator has to guarantee an attenuation of the beam intensity to a safe level for accelerator components, i.e. 2×10^{12} [1].

Phase-space Coverage

The main aim of the TL collimators is to ensure adequate protection of the LHC cold apertures. From the LHC Design Report [2], the minimum available aperture in the arc is $7\,\sigma$, hence this represents the target protection for the TL collimation system.

In order to define the collimator jaws aperture needed to guarantee the above cited protection, all possible sources of error have to be taken into account. All the considered errors are listed in Table 1; summing these contributions linearly, considering a typical beam size of 0.5 mm, the total error is $\approx 1.4\,\sigma$ [1]. The maximum escaping amplitude in a "three-phase" collimation system is given by pure geometrical considerations, i.e. $A_{max} = A_{jaw}/\cos(\pi/6)$; where A_{jaw} is the required jaw position, including errors. For the LHC $A_{max} = 7\,\sigma$, so the collimator half-gap has to be $A_{jaw} = 4.5\,\sigma$.

As an example, Fig. 1 shows the horizontal Poincaré portrait at the septum at the end of TI2 (MSI2). Here, all three collimators are sketched at their ideal position, i.e. $4.5\,\sigma$, together with the surviving particles at the MSI2 for two different amplitudes, 4.6/4.9 σ.

Table 1: Errors for the TL Collimator Jaws [1]

Error type	Unit	Value
Inter-jaw parallelism	μm	50
Jaw axis wrt tank	μm	100
Tank axis wrt beam size	μm	180
Surface flatness	μm	50
Knowledge of bema position	μm	44
Beam size errors	σ	0.5

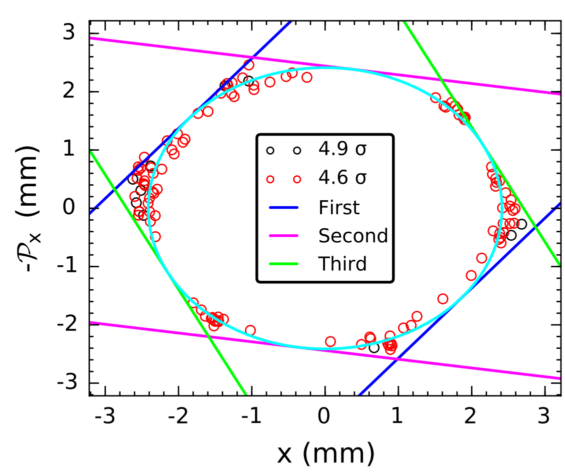

Figure 1: Horizontal phase-space at the LHC injection septum (MSI) downstream TI2.

Validation Methodology

In order to ensure the required protection, after setting up the TL collimators at their nominal apertures and centring them with respect to the measured beam trajectory,

UPGRADE OF THE SPS ION INJECTION SYSTEM

J. Uythoven, J. Borburgh, E. Bravin, S. Burger, E. Carlier, J.-M. Cravero, L. Ducimetière, S. Gilardoni, B. Goddard, J. Hansen, E.B. Holzer, M. Hourican, T. Kramer, F. Maciariello, D. Manglunki, F.-X. Nuiry, A. Perillo Marcone, G. Steele, F. Velotti, H. Vincke, CERN, Geneva, Switzerland

Abstract

As part of the LHC Injectors Upgrade Project (LIU) the injection system into the SPS will be upgraded for the use with ions. The changes will include the addition of a Pulse Forming Line parallel to the existing PFN to power the kicker magnets MKP-S. With the PFL a reduced magnetic field rise time of 100 ns should be reached. The missing deflection strength will be given by two new septum magnets MSI-V, to be installed between the existing septum MSI and the kickers MKP-S. A dedicated ion dump will be installed downstream of the injection elements. The parameter lists of the elements and studies concerning emittance blow-up coming from the injection system are presented. The feasibility of the 100 ns kicker rise time and the small ripple of the septum power converter are presented. Material studies of the ion dump are presented together with the radiation impact.

INTRODUCTION

The ALICE experiment in the LHC will be implementing a detector upgrade to reach higher luminosities with ion operation. The foreseen ALICE peak luminosity in Pb-Pb runs is 7×10^{27} Hz/cm^2. As part of the LHC Injector Upgrade Project (LIU), an upgrade of the LHC ion injection chain is ongoing to reach this ambitious goal [1]. The LIU ion project consists of upgrades throughout the ion injector complex and also of the injection system for the ions in the SPS, see Fig. 1.

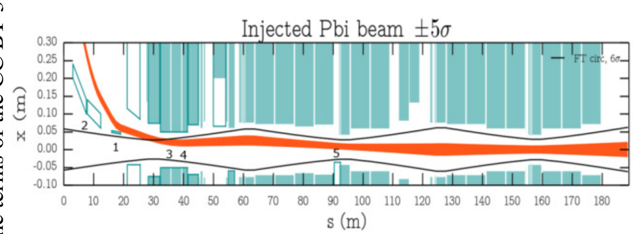

Figure 1: Trajectory and 5σ envelope of the injected ion beam together with the proposed layout: the new MSI-V septum (1), the existing septum MSI (2), the fast injection kickers MKP-S (3) and the slower injection kicker MKP-L (4) together with the new ion injection dump (5).

The new injection system for ions will allow a spacing of 100 ns between the ions batches in the SPS, due to an upgrade of the SPS injection kicker MKP, obtaining a faster pulse rise time. The resulting reduced kick strength will be compensated by the installation of an additional septum MSI-V. As the trajectory of the injected beam is different from the one of the protons, a new injection dump for ions will be installed. A new beam observation screen will be placed in front of the dump and additional beam loss monitors will be added. Details of some of the new or modified elements will be given below.

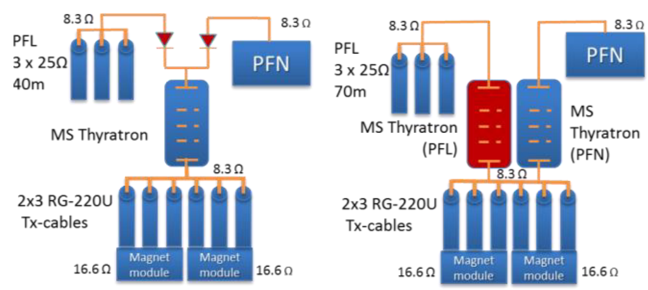

Figure 2: MKP 100 ns test set-up: Configuration 1with diode for separation between PFL and PFN (left) and configuration 2 with one thyratron per branch (right).

INJECTION KICKER UPGRADE

The upgrade of the existing SPS ion injection system by adding an additional PFL in parallel to the existing MKP-S PFN generators is outlined in [2]. In order to proof the feasibility of the 100 ns rise time (2-98%) and to validate the preliminary PSpice simulations a test stand for the 100 ns MKP-S upgrade was set up. Two basic options for a low impedance connection of the existing PFN to the PFL and the transmission cables, as shown in Fig. 2, were developed. Whilst configuration 1 considers only one main switch (MS) thyratron connected to the six parallel transmission cables (50 Ω RG-220U, 3 per magnet module) and separated for operation by two diode stacks, the same functionality is obtained in configuration 2 by using a 2nd thyratron for the PFL branch.

Measurements with the test system in configuration 1 have been performed and showed a significant increase of rise time due to the additional diode stack in the PFL branch. Rise times of around 350 ns were measured with a first test setup using switch tank connected to the spare MKP-S magnet via short transmission cables. Whilst optimization of the circuits (filters) would bring large improvements, it will not stay below the specified 100 ns rise time.

Activities will now focus on tests for configuration 2 which however requires mechanical modification on both switch tanks. Also more detailed PSpice simulations will be necessary to optimize the filter circuits mainly to

THE ACCUMULATOR OF THE ESSnuSB FOR NEUTRINO PRODUCTION

E. Wildner, B. Holzer, M. Martini, I. Papaphilippou, H. Schönauer, CERN, Geneva, Switzerland
M. Eshraqi, ESS, Lund, Sweden
T. Ekelöf, M. Olvegård, R. Ruber, Uppsala University, Uppsala, Sweden

Abstract

The European Spallation Source (ESS) is a research center based on the world's most powerful neutron source currently under construction in Lund, Sweden. 2.0 GeV, 2.86 ms long proton pulses at 14 Hz are produced for the spallation facility (5MW on target). The possibility to pulse the linac at higher frequency to deliver, in parallel with the spallation neutron production, a very intense, cost effective and high performance neutrino beam. Short pulses on the target require an accumulator ring. The optimization of the accumulator lattice to store these high intensity beams from the linac (1.1 10^{15} protons per pulse) has to take into account the space available on the ESS site, transport of H^- beams (charge exchange injection), radiation and shielding needs. Space must be available in the ring for collimation and an RF system for the extraction gap and loss control. We present the status of the accumulator for the ESS neutrino facility.

NEUTRINO PRODUCTION AT ESS

The European Spallation Source (ESS) [1] presently being built in Lund, Sweden, is a research centre that will have the world's most powerful neutron source. It is based on a 2.0 GeV superconducting linac, giving 2.86 ms long proton pulses at 14 Hz for the spallation facility (5MW on target). By pulsing the linac at 28 Hz, additional interleaved H^- pulses sent to a neutrino production target system, would give an opportunity to produce neutrino beams with unprecedented intensity [2]. The corresponding number of protons on target per year would be 12.7 10^{23}. However, the horn based hadron collector can not, for the time being, handle 2.86 ms long pulses due to ohmic heating of the magnet system current leads. Therefore the linac pulse has to be accumulated in a storage ring to produce pulses, a few μs long, on the neutrino production target.

THE ESS LINAC

The duty cycle of the ESS superconducting linac is relatively low (4%). This fact opens a possibility to add pulses in between those used for the spallation neutron production and use them to produce neutrinos. The linac would then be pulsed at 28 Hz, resulting in a total linac power of 10MW. The additional 5 MW that have to be provided for the neutrino production require an upgrade of the ESS linac, in particular of systems related to the acceleration of the H^-- beams needed for charge exchange injection into the accumulator. An additional H^--source would be added, probably including also additional LEBT, RFQ and MEBT sections for matching the H^--beam and the proton beams separately [1]. It is foreseen that focussing and steering elements necessary to tune the H^- beam may change setting between proton and H^- pulses. The ESS construction has started, therefore an urgent preliminary feasibility evaluation of the needed equipment and infrastructure upgrades has taken place, in particular concerning water, cryogenic distribution and capacity, radio frequency couplers, klystron modulators, and electric transformers and power capacity.

To fill the accumulator ring with 1.1 10^{15} protons is a challenging task and the possibility to split the 2.86 ms linac pulse in shorter linac pulses with the same current, still keeping the 5 MW total power for the neutrinos, would be a possibility to fill the accumulator with less number of particles but more often. The option of accelerating, for example, four shorter linac pulses for the neutrino production would make the Linac pulse at 70 Hz giving one 2.86 ms pulse for neutrons and four 0.72 ms pulses for neutrino production, see Fig. 1. 5MW beam power needs 13.3 MW wall plug power for one 2.86 ms long pulse. 4 pulses of 0.72 ms would need 17 MW power consequently there is an operational overhead for this option. To increase the duty cycle may lead to collective effects, which may limit the maximum usable duty cycle in the cavities. Extensive ongoing testing and future operational experience will show if higher duty cycles can be accepted. The aim is to operate the linac at the lowest possible frequency. The final design considerations and cost optimization of the accumulator will decide the optimal repetition rate.

The accumulator will be designed in order to profit from a possible linac upgrade to higher energy by designing the transfer line from the linac to the accumulator for 2.5 GeV and placing the extraction point in the contingency region of the linac, situated between the end f the linac and the spallation target region, where 2.5 GeV could be reached after adding more accelerating modules.

THE ACCUMULATOR

A preliminary lattice of 376 m circumference is described in [3] and summarized in Table 1. The accumulator has to be installed on the ESS site including the transfer lines and the target station. For the H^- beam transfer line the allowed minimum bending radius is limited by the Lorenz stripping of the H^--ions. The criterion we have used to design the transfer line is to have a beam loss corresponding to less than 0.1 W/m heat deposition. With a 66% dipole filling factor in the transfer line we would get, for 2.5 GeV, a radius of about 110 m (see [4]). The baseline layout for the accumulator, target, transfer lines, and the neutrino beam can be seen in

DESIGN OF A PROTON TRAVELLING WAVE LINAC WITH A NOVEL TRACKING CODE

S. Benedetti[#], TERA, Novara, Italy and EPFL, Lausanne, Switzerland
A. Grudiev, A. Latina, CERN, Geneva, Switzerland
U. Amaldi, TERA, Novara, Italy

Abstract

A non-relativistic proton linac based on high gradient backward travelling wave accelerating structures was designed using a novel dedicated 3D particle tracking code. Together with the specific RF design approach adopted, the choice of a 2.9985 GHz backward travelling wave (BTW) structure with 150° RF phase advance per cell was driven by the goal of reaching an accelerating gradient of 50 MV/m, which is more than twice that achieved so far.

This choice dictated the need to develop a new code for tracking charged particles through travelling wave structures which were never used before in proton linacs. Nevertheless, the new code has the capability of tracking particles through any kind of accelerating structure, given its real and imaginary electromagnetic field map. This project opens a completely new field in the design of compact linacs for proton therapy, possibly leading to cost-effective and widespread single room facilities for cancer treatment.

INTRODUCTION

A collaboration between TERA Foundation and CLIC was established to study a novel linear accelerator for proton therapy. The main goal of the collaboration is to transfer the knowledge acquired by the CLIC group, mostly in terms of RF design, high-gradient limitations and linac optimization, to a medical linac.

Funds of the Knowledge Transfer group of CERN permitted the construction of a prototype based on the design discussed in [1]. High power RF test of this accelerating structure is under preparation at the present time, to validate its capability to reach the maximum accelerating gradient of 50 MV/m.

A backward travelling wave linac was never used for accelerating protons. Moreover, a medical linac has a certain number of peculiarities with respect to high energy physics linacs, as for instance the need to vary the kinetic energy of particles over a wide range to reach tumour tissues at different depth into the patient body. So it was decided to develop a completely new tracking code, called *RF-Track*. The main features of such code will be discussed in the present paper, together with the results of the benchmark study and a preliminary BTW linac design.

RF-TRACK

In order to evaluate and maximise the transmission through backward-travelling accelerating structures, a new *ad-hoc* tracking code was developed: *RF-Track*. The decision to develop a new code was motivated by the need to perform accurate tracking of continuous, unbunched, inherently relativistic beams of protons or ions (with beta = ~0.35 for the protons, even less for the ions), through 3D field maps of BTW structures. No code in our knowledge featured the required flexibility and had the capability to handle real and imaginary field maps of travelling-wave RF structures (forward or backward).

RF-Track can input and combine the 3D phasor maps of both electric and magnetic fields, in order to represent an RF field in all its complexity, as 3D solvers such as HFSS [2] generate. This possibility allows the accurate representation of (backward) travelling-wave structures, differently from most of the codes, which can only input static field maps or can only simulate standing wave structures (and require to overlap two standing waves to mimic a travelling wave).

RF-Track performs full 6D transport and maintains the proper time of each particle. This allows computing the correct timing of the RF fields felt by each particle. It must be noticed that, thanks to this strategic choice, the code is not bounded by the notion of "bunch" or "reference particle" and can track continuous beams consistently. It implements exact transfer maps for drifts, quadrupoles and sector bends in both the transverse plane and the longitudinal planes, with the exception of the quadrupole longitudinal map, which features a second-order expansion of the path length to take into account the particle's incoming position and angles. The approximated solution of the longitudinal quadrupole map (already better than the standard "drift-like" map adopted by many codes) doesn't undermine the tracking accuracy, because each element can be integrated in an arbitrary number of steps, recovering accuracy whenever a second-order tracking is not sufficient.

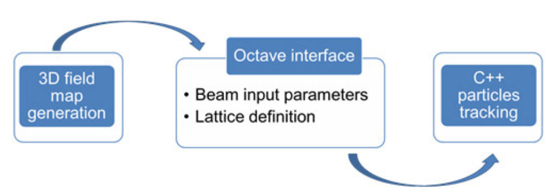

Figure 1: Simplified scheme of *RF-track* software architecture.

The code is written in modern, fast, parallel C++ that exploits multi-core CPUs. Its fast computational core is accessible by the user through a powerful SWIG Octave interface [3,4], which permits to write complex, yet readable and concise, simulation scripts that can directly benefit from a large number of optimization toolboxes

VERIFICATION OF THE NEUTRON MIRROR CAPABILITIES IN MCNPX VIA GOLD FOIL MEASUREMENTS AT THE EIGER INSTRUMENT BEAMLINE AT THE SWISS SPALLATION NEUTRON SOURCE (SINQ) *

R.M. Bergmann†, U. Filges, S. Forss, E. Rantsiou, D. Reggiani, T. Reiss, U. Stuhr, V. Talanov, M. Wohlmuther
Paul Scherrer Institut, Villigen, Switzerland

Abstract

The EIGER triple-axis thermal neutron spectrometer beamline contains “supermirror” neutron guides, which preferentially reflect low-energy neutrons toward the EIGER spectrometer that come from the ambient temperature, light water neutron source in SINQ. Gold foil measurements have been performed at the EIGER beamline in 2013. This process can be modeled from incident proton to thermal neutron exiting the EIGER beamline by using the neutron mirror capabilities of MCNPX, which should be more accurate than simulations with simplified neutron source distributions and geometry representations. The supermirror reflectivity parameters have been measured previously and are used in MCNPX 2.7.0 to reproduce the activity measured from the gold foil irradiation, verifying the neutron mirror modeling capabilities in MCNPX 2.7.0.

INTRODUCTION

EIGER is a triple-axis thermal neutron spectrometer that looks at the light water scatterer inside SINQ, a spallation neutron source driven by a continuous 590 MeV proton beam at the Paul Scherrer Institut in Villigen, Switzerland. The incoming protons impinge on a lead target cooled with heavy water, producing high energy neutrons. These neutrons are moderated by the tank of D_2O surrounding the target. The “water scatterer” is a set of seven vertical aluminum tubes 25 cm away from the center of the target that contain ambient temperature light water. These tubes act as a scattering medium to send thermal neutrons streaming through low pressure nozzles towards neutron instruments.

The neutron guide that delivers thermal neutrons from the water scatterer towards the EIGER instrument is internally covered with neutron “supermirrors”. These mirrors are reflective to low-energy neutrons, and allow the guide to transport neutrons with small divergence instead of only neutrons with trajectories parallel to the guide axis, increasing neutron extraction efficiency. The reflectivity of the mirrors are described by Eq. 1 where R_0 is nominal reflectivity, Q_c is the critical momentum transfer, m is the angular extension parameter, α is reflectivity declination parameter, and W is the reflectivity edge width [1].

The reflectivity parameters of EIGER's supermirrors have been measured previously and determined to be $R_0 = 0.995$, $Q_c = 2.17 \times 10^{-2}$Å^{-1}, $m = 3.6$, $\alpha = 3.99$Å, and $W = 10^{-3}$Å^{-1} [2]. The guide is rectangular, tapers in the horizontal plane from 80 mm wide near the moderator tank to 30 mm wide at the guide exit, and is a constant 150 mm tall in the vertical plane. There is a 10 cm thick sapphire crystal near the moderator tank which acts as a neutron filter to preferentially scatter neutrons above 0.1 eV out of the beam [3].

$$R(Q) = \begin{cases} \text{if } Q > Q_c : \\ \frac{R_0}{2}\left\{1 - \tanh\left(\frac{Q-mQ_c}{W}\right)\right\}\{1-\alpha(Q-Q_c)\} \\ \\ \text{if } Q \le Q_c : \\ R_0 \end{cases} \tag{1}$$

This reflectivity model is used by McStas and has been previously implemented in patched version of MCNPX 2.5.0 [1]. The patch has recently been ported to MCNPX 2.7.0 [4] and debugged for MPI parallelism. The parallelized reflectivity capabilities now allow the neutron flux gains to be completely modeled in MCNPX 2.7.0. This capability is demonstrated by comparing the calculated activation of an array of gold foils exposed to the EIGER beam to experimental results.

GOLD FOIL MEASUREMENT

The vertical array of six gold foils shown in Figure 1 were exposed to the EIGER beam in December, 2013.

Figure 1: Gold foil array used in the measurements.

The foils were placed near the monochromator position at EIGER. The foils are 25 mm in diameter and 30 mm center-to-center. The blue marker lines in the figure show the approximate extent of the neutron guide. The average current on the SINQ target during the irradiation was 200μA, and the foils were exposed for 5 minutes. After irradiation, activation analysis was performed using a gamma spectrometer.

Abstract

The design and production studies of the proton beamline of SPP, which aims to acquire know-how on proton accelerator technology thru development of man power and serves as particle accelerator technologies test bench, continue at TAEK-SANAEM as a multi-phase project. For the first phase, 20 keV protons will be accelerated to 1.3 MeV by a single piece RFQ. Currently, the beam current and stability tests are ongoing for the Inductively Coupled Plasma ion source. The measured magnetic field maps of the Low Energy Beam Transport solenoids are being used for matching various beam configurations of the ion source to the RFQ by computer simulations. The installation of the low energy diagnostics box was completed in Q1 of 2015. The production of the RFQ cavity was started with aluminum 7075-T6 which will be subsequently coated by Copper to reduce the RF (Ohmic) losses. On the RF side, the development of the hybrid power supply based on solid state and tetrode amplifiers continues. All RF transmission components have already produced with the exception of the circulator and the power coupling antenna which are in the manufacturing and design phases, respectively. The acceptance tests of the produced RF components are ongoing. This work summarizes the design, production and test phases of the above-mentioned SPP proton beamline components.

INTRODUCTION

Turkish Atomic Energy Authority (TAEK) started the construction of a proton beamline at its Sarayköy Nuclear Research and Training Center, SANAEM. The SANAEM Prometheus Project (SPP) is designed and engineered with local resources enabling accelerator physicists to acquire know-how and it will serve as a particle accelerator technologies test bench. Currently some of the components are being manufactured (e.g. the single piece RFQ) or being assembled (e.g. the hybrid RF PSU). In the meantime, the stability tests and measurements continue with the already installed components such as the ion source, the LEBT line and the low energy diagnostics box (Fig. 1). The rest of this note details the ongoing work on the components of the SPP beamline.

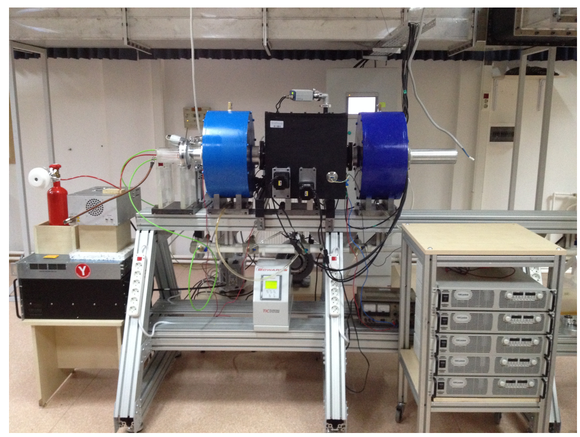

Figure 1: Currently installed parts of the SPP beamline.

ION SOURCE

An Inductively Coupled Plasma (ICP) type ion source was selected for its low production cost and its ability to match the relatively modest proton current requirements of the SPP project. Initially, a water cooled plasma chamber with 8 multicusp magnets was produced with an internal RF antenna [1]. Later, plasma generation method was changed because of the high voltage sparking between the alumina coated copper internal RF antenna and the high voltage plate. In the new design, a quartz tube with a gas injection nose is used as the plasma chamber. A 3.5 turn external RF antenna is used to produce hydrogen plasma and to prevent sparking. This RF antenna is sandwiched between the quartz plasma chamber and the plexi-glass water cooling chamber. With this setup, the ICP ion source is found to be suitable for longtime operation without overheating at an RF power below 500 W. The impedance matching between the RF antenna and the 13.56 MHz RF power supply was achieved using a matching network. The RF power coupling to the plasma was easily accomplished for a chamber diameter of 30 mm at 10^{-3} mBar.

DESIGN OF A SCALED HIGH DUTY FACTOR HIGH CURRENT NEGATIVE PENNING SURFACE PLASMA SOURCE

D. Faircloth, S. Lawrie, T. Rutter, M. Whitehead, T. Wood
STFC/RAL/ISIS, Chilton, Oxfordshire, OX11 0QX, UK
V. Dudnikov
Muons Inc, Batavia, IL 60510, USA

Abstract

The Front End Test Stand (FETS) at the Rutherford Appleton Laboratory (RAL) requires a 60 mA, 2 ms, 50 Hz H^- beam. The present source can only deliver the current and pulse length requirements at 25 Hz. At 50 Hz there is too much droop in the beam current. To rectify this, a scaled source is being developed. This paper details the new source design and the experiments conducted that are guiding the design.

FETS

The FETS project aims to produce a very high quality, perfectly chopped H^- ion beam as required for high power proton drivers. The beam parameters are 3 MeV energy and 60 mA beam current at 50 Hz repetition rate and up to 2 ms pulse duration.

DUTY CYCLE LIMIT

FETS uses a Penning Surface Plasma Source (SPS) [1] (Fig. 1). The current FETS source uses the same plasma electrodes, and has the same plasma volume, as the ISIS operational source. The operational source has successfully delivered beam for ISIS operations for 30 years. It runs with a 760 µs discharge pulse length at a 50 Hz repetition rate.

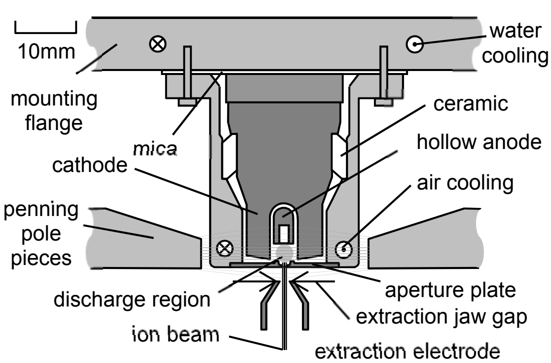

Figure 1: Existing FETS Penning SPS schematic.

FETS specifies a 2 ms 50 Hz 60 mA H^- beam. To cleanly extract a 2 ms beam it is necessary to produce a 2.2 ms long discharge pulse in the ion source. This gives the plasma 0.2 ms to stabilize before beam extraction begins. With increased cooling the maximum discharge pulse lengths achievable with the standard ISIS electrode geometry are 1.2 ms at 50 Hz or 2.2 ms at 25 Hz [1]. Beyond these duty cycles there is too much droop in the extracted beam current.

Although adequate for FETS commissioning, extra development work is required in order to meet the full FETS duty cycle requirements. ISIS is also interested in developing sources with longer lifetimes for ISIS operations.

NEW DESIGN

Scaled Source

Previous work [2,3] indicates that increasing the surface area of the electrodes presented to the plasma should solve the duty cycle limitations. Increasing the surface area will also reduce the sputtering rate and should yield longer source lifetimes. The proposed new design is shown in Fig. 2.

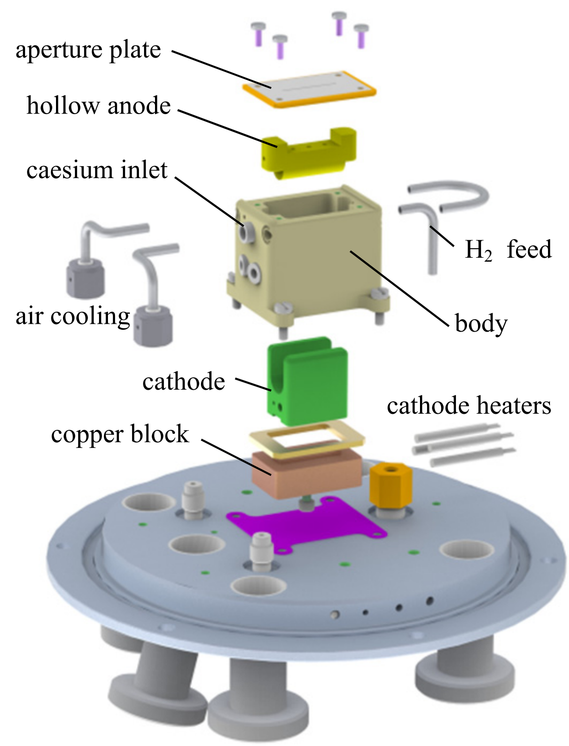

Figure 2: Scaled source exploded view.

The basis of the design is to double the plasma volume in each dimension, creating an 8 fold increase in plasma volume. Meanwhile, the external dimensions of the source are kept as compact as possible, limited by the

Abstract

The Front End Test Stand (FETS) under construction at RAL is a demonstrator of front end systems for future high power proton linacs. Possible applications include a linac upgrade for the ISIS spallation neutron source, new future neutron sources, accelerator driven sub-critical systems, high energy physics proton drivers etc. Designed to deliver a 60mA H-minus beam at 3MeV with a 10% duty factor, FETS consists of a high brightness surface plasma ion source, magnetic solenoid low energy beam transport (LEBT), 4-vane 324MHz radio frequency quadrupole and medium energy beam transport (MEBT) containing a high speed beam chopper and non-destructive laser diagnostics. This paper describes the current status of the project and future plans.

FRONT END TEST STAND

FETS was originally conceived as a chopper beam test facility but has since expanded its objectives to become a generic test stand for high power proton accelerator front end technologies. Applications include but are not limited to ISIS upgrades, future Spallation Neutron Sources, a Neutrino Factory, Muon Collider, Accelerator Driven Sub-critical Systems as well as exploitation of the low energy beam.

FETS has been extensively described elsewhere [1][2]. It consists of an H- ion source, magnetic low energy beam transport (LEBT), 324 MHz 4-vane Radio Frequency Quadrupole accelerator (RFQ), medium energy beam transport and chopper line (MEBT) and comprehensive diagnostics. The rest of this paper describes the status and future plans for each component of the test stand.

ION SOURCE

FETS uses a Penning Surface Plasma Source (SPS) [3]. A programme of continuous development over many years has resulted in source performance which is very close to the demanding FETS specification [4].

Having previously commissioned a new high voltage extraction power supply capable of 25 kV at the full 10% duty factor [5] and a redesigned downstream post-acceleration system which resulted in a considerably less divergent beam entering the LEBT, a beam emittance of 0.35 π mm mrad rms normalised was measured. The ion source systems have now been decommissioned to allow infrastructure installation and development has turned to the VESPA plasma test stand [6] where progress is being made towards a scaled version of the source capable of operating continuously at the full duty factor [7].

LEBT

The FETS LEBT consists of three identical magnetic solenoids with maximum on axis field of 0.4 T. Previous studies had shown high beam currents of up to 60 mA at the end of the LEBT with a reasonably small rms-emittance. However, large offsets of ~10mm in position and ~10 mrad in angle were observed in both transverse planes. These were traced to a lack of repeatability in mounting the ion source assembly following source changes or maintenance. An improved datum and alignment system has largely corrected this and although a perfect alignment cannot be achieved due to the length of ~2 m, minor offsets can be corrected with the dipole steerers integrated into the solenoids.

An extensive parametric evaluation of the LEBT has shown that a well aligned, well matched beam can be delivered to the RFQ injection point [8][9].

The LEBT is currently decommissioned to allow for infrastructure installations.

RFQ

The FETS RFQ is a 324 MHz, 4-vane type with a final energy of 3 MeV and a total length of ~4.0m. It employs a bolted, braze-free construction with a 3D O-ring for the vacuum seal and RF finger contacts [10]. The 4m long cavity consists of 4 sections each made up of 2 major and 2 minor vane segments.

Manufacturing of the RFQ is nearing completion. Inspection of the first section delivered to RAL showed a manufacturing error resulting in a transverse and longitudinal shift of the vane modulations. This error was traced to a changed datum setting in the 5-axis CNC machine. Simulations showed that the effect on the beam dynamics would have been acceptable however the resulting resonant frequency shift was beyond that which could be compensated for. Fortunately the internal surfaces have been re-machined and both major and minor vane segments recovered. Inspection of the second section showed a small (100 μm) curvature due to internals stresses introduced during rough machining. The outer datum surface was re-machined flat before finalising the internal surface. Similar corrective action will be performed on sections 3 and 4.

Resonant frequency measurements of section 1, including the error, showed good agreement with

REVIEW OF LINAC UPGRADE OPTIONS FOR THE ISIS SPALLATION NEUTRON SOURCE

C. Plostinar, C. Prior, G. Rees, STFC/ASTeC, Rutherford Appleton Laboratory, UK

Abstract

The ISIS Spallation Neutron Source at Rutherford Appleton Laboratory has recently celebrated 30 years of neutron production. However, with increasing demand for improved reliability and higher beam power it has become clear that a machine upgrade is necessary in the medium to long term. One of the upgrade options is to replace the existing 70 MeV H^- injector. In this paper we review the ongoing upgrade programme and highlight three linac upgrade scenarios now under study. The first option is to keep the existing infrastructure and replace the current linac with a higher frequency, more efficient machine. This would allow energies in excess of 100 MeV to be achieved in the same tunnel length. A second option is to replace the current linac with a new 180 MeV linac, requiring a new tunnel. A third option is part of a larger upgrade scenario and involves the construction of an 800 MeV superconducting linac.

ISIS UPGRADES

Over the last three decades, the ISIS spallation source has been delivering neutrons to generations of scientists from all over the world, creating a key centre for physical and life sciences research at Rutherford Appleton Laboratory in the UK. The accelerator consists of a 70 MeV H^- injector and an 800 MeV synchrotron delivering a total of ~200 kW beam power to two target stations. The injector starts with an H^- ion source, followed by a three solenoid low energy beam transport line (LEBT) and a 665 keV, four-rod RFQ operating at 202.5 MHz. A Drift Tube Linac (DTL) accelerates the beam to 70 MeV. The DTL consists of four tanks which have been recycled from previous high energy physics projects. Tanks 2 and 3 were commissioned in the 1950s for the RAL Proton Linear Accelerator, while tanks 1 and 4 were copies of the Fermilab DTL built in the 1970s, originally intended for the Nimrod accelerator, but first used in ISIS [1], [2].

While ISIS has been the most successful pulsed neutron spallation source in the world, it is also one of the oldest and the necessity for an upgrade has been made clear for some time. This involves not just maintaining or improving the current machine reliability, but also increasing its capabilities. With new facilities like the SNS in the USA and J-PARC in Japan now delivering MW class beams, a major power upgrade for ISIS has become a key strategic goal in the medium to long term.

Small upgrades are already taking place aimed mainly at improving the machine reliability and maintaining the current level of performance. A programme designed to improve the ion source lifetime, beam current, pulse length and reliability has been successfully taking place as part of the Front End Test Stand project [3]. The old Cockcroft-Walton linac injector was replaced a few years ago with a 665 keV, 202.5 MHz RFQ, the structure of choice for most modern proton injectors, while efforts are now underway to replace the fourth DTL tank, a structure soon to celebrate its 60th anniversary. In the ring, the installation of a dual harmonic system has taken place. By employing a combination of harmonic numbers two and four RF cavities, the stable area of longitudinal phase space can be lengthened, allowing more beam to be injected and accelerated, thus overcoming the old machine intensity space charge limit of $2.5\cdot10^{13}$ protons per pulse. Beam powers of ~240 kW have already been demonstrated [4].

In terms of major upgrades, the addition of a second target station at the end of 2008 saw the machine capabilities and user base greatly expanded. However, for power upgrades, the construction of new accelerators is necessary. There have been several proposals for a power increase ranging from injector to synchrotron upgrades, as well as for a multipurpose facility where a high power proton accelerator would be used both for a spallation source and as a driver for a neutrino factory [5].

Regarding linac developments, it has become clear that a major upgrade will be necessary. While plans for a new machine are welcomed, any proposal has to take into account several factors, of which two are essential. The first requirement is that any upgrade work should consider the high likelihood of a phased upgrade. This simply means that any design choice should be made as part of a broader, long term plan, such that later upgrade efforts are not hampered by early choices. The second requirement takes into account the wider context of neutron science in Europe. With several experimental reactors due to be retired and with ESS not being fully operational for another decade, ISIS remains the main source of neutrons. Indeed, demand for beam time is at an all time high. This makes machine availability the dominant user requirement and as a result, potential upgrades with minimum user disruption should be proposed. In this context, three linac upgrades routes will be further outlined.

100 MeV LINAC

A straightforward and by far the most economical upgrade is a new linac in the existing tunnel to replace the existing 70 MeV injector. By reusing the existing infrastructure, the civil engineering costs are dramatically reduced, the only constraint being the overall length restriction of ~50 m. By operating at a higher frequency, increased accelerating gradients and redesigning the RF structures for increased efficiency, energies in excess of 100 MeV can be achieved in the same length as the

QUALITY AND STABILITY STUDIES OF THE BEAMS IN THE ELENA RING TRANSFER LINES

J. R. Hunt, O. Karamyshev, J. Resta-López, C. P. Welsch
Cockcroft Institute and The University of Liverpool, UK

Abstract

The Extra Low Energy Antiproton (ELENA) ring will initially provide eight different experiments at CERN with extra low energy (~100 keV) antiprotons by utilising electron cooling techniques. As a result, a system of transfer lines is being designed to ensure each experiment receives a beam consistent with specified properties. In this paper, particle tracking simulations are performed to explore the effects of different lattice imperfections, e.g. element misalignment, electric field errors and matching errors, on the beam quality and orbit stability. Specific values for the upper limits of inaccuracies are obtained as a guide for the construction of the transfer lines, and will enable further optimization.

INTRODUCTION

ELENA is a low energy storage ring designed to increase the efficiency of the antimatter experiments at CERN [1]. Currently under construction, ELENA will accept antiprotons from the Antiproton Decelerator (AD) [2] and employ the use of an electron cooler to further decelerate them from a kinetic energy of 5.3 MeV to 100 keV. At these lower energies, fewer antiprotons will be lost to degrader foils at the end of the deceleration process and as a result the anti-hydrogen experiments will receive higher intensity beams.

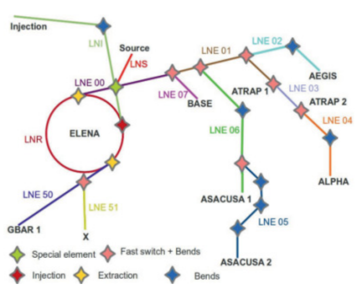

Figure 1: Schematic layout of transfer lines.

A system of transfer lines will carry these extra low energy beams to eight different locations within the AD hall. The low beam energy after ejection from ELENA allows the use of electrostatic elements. Reasons for this design choice include cost of construction, low power consumption, easy operation and good possibilities for shielding elements against stray magnetic fields. [1]

Nine separate lattices make up the transfer lines, two of which are directly connected to ELENA. The studies undertaken in this paper focus on the lattice 'LNE00' as it is connected directly to ELENA and the beams for all but one experiment will pass through this section,see Fig. 1. The only working optical elements present along LNE00 in these simulations are the quadrupoles in a configuration used to pass the beam through to LNE01.

TRACKING CODE

For this study Polymorphic Tracking Code (PTC) [3] was used to track a series of beams through a complete MAD-X [4] model of LNE00 obtained from [5]. For each simulation, a Gaussian beam of 10,000 particles with initial ε_x and ε_y = 1 mm·mrad, momentum spread = 5×10^{-4} and no x-y coupling, was generated using Monte-Carlo methods. After tracking, the beam data was passed to a custom Matlab code for analysis.

ELEMENT POSITION OFFSETS

The positions of the quadrupoles were offset in the x and y planes separately. Monte-Carlo methods were used to offset each element by a random amount corresponding to a Gaussian spread. The magnitude of the offsets was increased and the effect on the particle losses in the beam was observed (Fig. 2). For each point the result of 10 runs with varying random offsets were averaged to capture overall effect of the position errors.

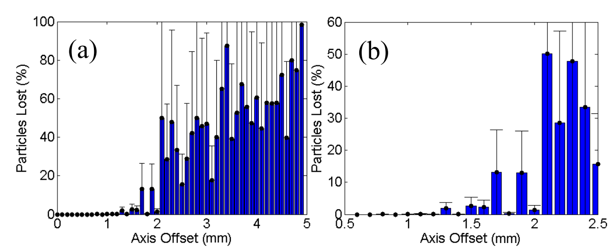

Figure 2: Horizontal losses at the end of LNE00 for increasing quadrupole offsets. The vertical losses results have similar features. (a) shows the full scan and (b) shows more detail around 1.5 mm.

The effects of the quadrupole offsets on the beam losses at the end of the transport line remain steady until they significantly increase around 1.8 mm, with the average reaching just below full beam loss by 5 mm. The first significant losses occur at 1.3 mm where for one particular run almost 18% of the beam was lost, however the other 9 runs lost only 0.56% in total, bringing the average down.

As this simulation only includes the physical aperture and we would expect a dynamic aperture at a smaller

EBIS CHARGE BREEDER AT ANL AND ITS INTEGRATION INTO ATLAS

A. Perry#, A. Barcikowski, G. Cherry, C. Dickerson, B. Mustapha, P. N. Ostroumov,
Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

An Electron Beam Ion source Charge Breeder (EBIS-CB) has been developed to charge breed CARIBU radioactive beams at ATLAS and it is now in the final stages of off-line commissioning. Within the next year, the EBIS-CB will replace the existing ECR charge breeder to increase the intensity and improve the purity of reaccelerated radioactive ion beams. The integration of the new EBIS-CB requires:

a. Building a new electrostatic low energy beam transport line (LEBT) from CARIBU to the EBIS-CB that will ensure successful seeding into the trap.
b. Modifications to the existing ATLAS LEBT to accommodate the injection of the charge bred ions into the post accelerator.

In this paper we will describe the beam line design and present beam dynamics simulation results.

INTRODUCTION

The CAlifornium Rare Isotope Breeder Upgrade (CARIBU) facility is capable of generating a wide variety of rare isotope beams (RIB) of heavy ions in the 80-160 mass range from the fission fragments of a ^{252}Cf source [1]. After thermalization in a helium gas catcher the ions are mass-separated using a magnetic spectrometer, charge bred in an electron-cyclotron resonance (ECR) ion source, and then injected into the Argonne Tandem Linear Accelerator System (ATLAS) for post acceleration. Plasma-surface interactions in the ECR chamber results in significant contamination of the extracted beams, which subsequently obscures the signature of low intensity RIBs. To address this, a charge breeder based on the electron beam ion source (EBIS) concept has been developed at ANL for the CARIBU system [2]. Higher breeding efficiency and most importantly, much better purity of radioactive ion beams are expected with the EBIS charge breeder. The CARIBU EBIS-CB utilizes technology recently developed at Brookhaven National Laboratory (BNL) [3].

The offline commissioning of the EBIS-CB is now approaching its final stages and 20% breeding efficiency into ^{133}Cs^{27} within 23 ms has already been demonstrated [4]. The integration into ATLAS is scheduled to commence later this year. This paper will focus on beam dynamics studies for the beam transport line from CARIBU to the EBIS-CB and from the EBIS-CB to ATLAS.

BEAM TRANSPORT FROM THE EBIS-CB TO ATLAS

The beam transport line from the EBIS-CB to the ATLAS RFQ is shown in Figure 2. In this section of the beam line it is necessary to separate the desired radioactive beams from the residual gas contaminants. The residual gas spectrum was measured during the EBIS offline commissioning and is depicted in Figure 1. Radioactive beams delivered from CARIBU will be charge-bred to a charge-to-mass ratio in the range $1/6 \leq Q/A \leq 1/4$ in every 10-30 ms breeding cycle. This corresponds to a dipole current between 36 A and 45 A in the figure. The intensity of the O^3 peak which lies in that range is estimated at $\sim 10^5$ ions per pulse. This should be compared to the intensity of radioactive beams delivered by CARIBU which will be in the order of 10^3-10^4 ions per pulse.

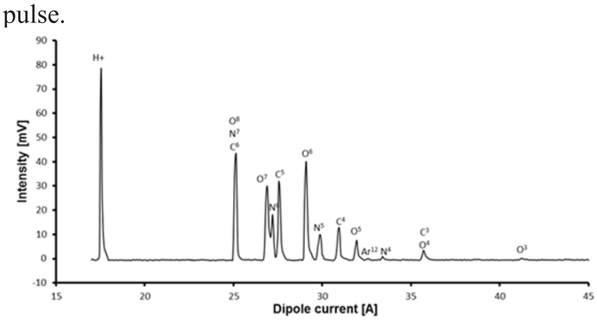

Figure 1: Residual gas spectrum after 30ms breeding.

It has already been noted by several authors that electron beam ion sources tend to generate beams with significant energy spreads [5]. This is due to heating of the ions in the trap by the electron beam [6], ionization heating [7], and heating by plasma instabilities [8] or as a result of the extraction process [9]. In order to handle the significant energy spread Nier-type spectrometers are usually employed, so the beam width at the mass selection slit does not depend on the energy spread at the first order [10]. However, in our case it was decided not to employ a Nier-type spectrometer due to the cost of replacing one of the existing dipole magnets with an electrostatic deflector capable of handling beams with relatively high electric rigidities (up to ~200 kV). Furthermore, the residual magnetic dispersion would prohibit the possible upgrade to a multi user facility, where beams with different magnetic rigidities will be transported simultaneously [11]. Instead, it was decided to use the existing dipoles and make the 180° bend doubly achromatic with the mass selection performed between the 90° dipoles. In addition, it was required that after the 180° bend the beam will be symmetric and focused into the small aperture of the Multi Harmonic Buncher (MHB)

OFFLINE TESTING OF THE CARIBU EBIS CHARGE BREEDER*

C. Dickerson#, S. Kondrashev, P.N. Ostroumov, R. Vondrasek, ANL, Argonne, IL 60439, USA
A. Perry, IIT, Chicago, IL 60616, USA

Abstract

In 2015 an electron beam ion source (EBIS) will be installed at the ATLAS facility to charge breed radioactive beams from the Californium Rare Isotope Breeder Upgrade (CARIBU). Currently an ECR ion source is used to charge breed CARIBU beams. The EBIS will provide beams with much less contamination and higher breeding efficiencies. In preparation for its installation at ATLAS the EBIS has been successfully commissioned offline. The EBIS was configured in the offline facility to closely mimic the conditions expected in the ATLAS installation, so commissioning results should be representative of its performance with CARIBU. The EBIS breeding efficiency was tested with pulses of $^{133}Cs^{1+}$ from a surface ionization source, and for multiple operational modes relative breeding efficiencies greater than 25% could be achieved. After transmission losses the total efficiency of the system was 15-20%. The contaminants were expectedly very low for a UHV system with nominal pressures of ~1 – 3 x 10^{-10} Torr.

INTRODUCTION

Acceleration in the ATLAS facility requires an $A/q \leq 7$, so the ions produced by the CARIBU ^{252}Ca source in the mass range 80 – 160 amu with 1+ and 2+ charge states require charge breeding [1]. Presently an electron cyclotron resonance ion source (ECRIS) breeds the radioactive ion beams (RIB) from CARIBU. The combination of capture, breeding, and transport efficiencies of the ECR for CARIBU RIBs is typically 8-15%, but extracted beams can contain significant contamination which can be problematic for experiments with low intensity radioactive ions.

Later this year an electron beam ion source (EBIS) charge breeder will replace the ECRIS. Based on the performance achieved during offline testing and reported here, the EBIS will increase the intensity and reduce the contamination of RIBs accelerated in ATLAS.

OFFLINE CONFIGURATION AND OPERATING CONDITIONS

To take advantage of the higher breeding efficiencies an EBIS can reach when operated in a pulsed mode, ions from CARIBU will be cooled and bunched in a Radio Frequency Quadrupole (RFQ) prior to injection into the CARIBU EBIS. The offline configuration, shown in Figure 1, was designed to be able to closely match the injected ion beam expected in the final ATLAS installation. Instead of RIBs from CARIBU, pulses of stable $^{133}Cs^{1+}$ were created from a DC beam by pulsing the voltage of a deflector near the surface ionization source. Injected ion bunches were trapped, bred, extracted, and finally analysed with a 70° dipole magnet. Ion intensities were measured with standard Faraday cups and a Tektronix 3032B oscilloscope. Peak heights from the oscilloscope traces were recorded, and could be converted from voltage to charge with the measured capacitance of the cable and cup.

During commissioning two main operating modes were established. The EBIS was first operated in mode 1, for this was the initial commissioning configuration. Mode 1 was generally lower power; using a lower trap magnetic field, lower electron beam current, and lower trap current density. When it was clear better performance would be needed, the mode 2 configuration was established. The operating parameters for both modes are listed in Table 1.

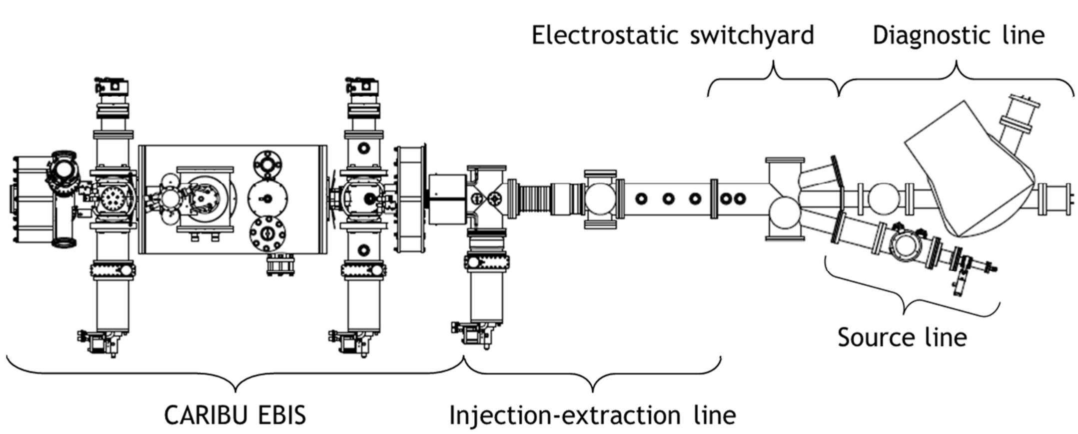

Figure 1: Offline EBIS configuration.

A NEW BEAM INJECTION SCHEME FOR THE FERMILAB BOOSTER *

C. M. Bhat#
Fermilab, Batavia, IL 60510, USA

Abstract

A new beam injection scheme is proposed for the Fermilab Booster to increase beam brightness. The beam is injected on the deceleration part of the sinusoidal magnetic ramp and capture is started immediately after the injection. During the entire capture process we impose $\dot{P} = 0$ in a changing B field. Beam dynamics simulations clearly show that this method is very efficient with no longitudinal beam emittance dilution and no beam loss. As a consequence of preserved emittance, the required RF power on a typical Booster cycle can be reduced by ~30% as compared with the scheme in current operation. Further, we also propose snap bunch rotation at extraction to reduce dP/P of the beam to improve the slip-stacking efficiency in MI/RR.

INTRODUCTION

The Fermilab Booster is one of the oldest rapid cycling proton synchrotron [1, 2] in the world. It uses a 15 Hz sinusoidal magnetic ramp for beam acceleration. The Booster receives H^- beam of 400 MeV kinetic energy from the LINAC while it is at B_{min} (minimum of the magnetic field ramp). H^- charge exchange injection scheme is adopted to accumulate multi-turn proton beam in the ring. Depending on the number of Booster Turns (BT), the duration of the beam injection varies in the range of 2-40 μsec. Ever since the Booster came into operation, the beam injection was carried out in the region of fairly constant magnetic field of the ramp i.e., close to B_{min}. The beam is allowed to debunch for a period of about 60-200 μsec and then captured with the help of a 37 MHz RF (para-phase) system. Since the magnetic field is continuously changing throughout this period, the beam is captured as quickly as possible with a considerably large RF bucket. This led to substantial beam filamentation in the RF bucket leading to longitudinal emittance dilution. Additional issue in the Booster is the observed jitter in B_{min} relative to the beam injection time which is of the order of 50 μsec. This jitter mainly arises from ComEd power-line frequency fluctuation. Further, the beam capture and acceleration found to partly overlap during this part of the cycle as shown in Fig. 1. A combination of all these effects led to undesirable decreased in beam capture efficiency. Over the years many improvements have been implemented to make the capture more efficient. Yet, the best capture efficiency observed so far is <95% with a longitudinal emittance dilution ≈50%.

Around 2000, the Fermilab long range accelerator program planning started focusing on increasing the beam power on targets for neutrino beams. A staged improvement approach is undertaken to inject beam on all of the Booster cycles and increase the BT per cycle [3, 4]. In this context, the Booster is found to play a significant role in the near future of Fermilab. In 2007, I started investigating possible advantages of beam injection on the deceleration part of the magnet ramp in the Booster and thereby, increase the beam brightness at extraction.

Tests of beam injection on the deceleration part of the magnet ramp in the Booster had been attempted in the past [5]. However, the beam transmission efficiencies turned out to be were very poor and the root causes of the problem were not understood at that time.

This paper proposes a fully developed *Early Beam Injection scheme* which has many advantages over the scheme in current operation. The general principle of the method, beam dynamics simulations and results of the proof of principle experiments are presented. Multi-particle beam dynamics simulations applied to the Booster injection convincingly validates the concepts and the proposed scheme's feasibility.

PRINCIPLE OF THE EARLY INJECTION SCHEME AND SIMULATIONS

Schematic views of the newly proposed early injection scheme (EIS) along with the currently used scheme (CIS) are shown in Fig. 1. In EIS, the beam is injected at about 150 μsec prior to $\dot{B} = 0$. Following the completion of the injection, the Booster RF system is turned on at a *matched* frequency. Debunching of the beam prior to the start of beam capture is eliminated. The RF capture voltage is increased by changing the para-phase angle from 180^0 to 0^0 in ≈ 260 μsec imposing $\dot{P} = 0$ to guarantee iso-adiabatic beam capture in stationary RF buckets with synchrotron oscillation period varying in the range of 125 μsec to 40 μsec. In an ideal case, one demands much longer capture time. Since, the magnetic field is continuously changing the capture time cannot be increased much further. Differential relationship between magnetic field B and the radius R of the orbit is given by, $\Delta R = (R/\gamma_T^2)(\Delta B/B)$ where, γ_T=5.47, $\Delta B/B = 3.74E-4$ and $R = 75.41$ m for the Booster. Then the radial displacement of the beam due to change in magnetic field is ≈0.9 mm, which is << the diameter of the RF cavity beam pipe (57.2 mm). However, the corresponding change in the RF frequency is ≈13.7 kHz. This RF frequency variation should be taken in to account during beam capture.

We have demonstrated the feasibility of the EIS in the Booster that includes i) beam capture with no emittance growths and no beam losses, ii) beam acceleration from injection energy to the extraction energy and iii) bunch rotation. The 2D- particle tracking simulation code ESME

ENERGY SPREAD OF THE PROTON BEAM IN THE FERMILAB BOOSTER AT ITS INJECTION ENERGY *

C. M. Bhat#, B. E. Chase, S. J. Chaurize, F. G. Garcia, K. Seiya,
W. A. Pellico, T. M. Sullivan, A. K. Triplett, Fermilab, Batavia, IL 60510, USA

Abstract

We have measured the total energy spread (≈ 99% energy spread) of the Booster beam at its injection energy of 400 MeV by three different methods - 1) creating a notch of about 40 nsec wide in the beam immediately after multiple turn injection and measuring the slippage time required for high and low momentum particles for a grazing touch in line-charge distribution, 2) injecting partial turn beam and letting it to debunch, and 3) comparing the beam profile monitor data with predictions from MAD simulations for the 400 MeV injection beam line. The measurements are repeated under varieties of conditions of RF systems in the ring and in the beam transfer line.

INTRODUCTION

The Booster is the oldest proton synchrotron in the Fermilab accelerator complex, operating at 8 GeV extraction energy since May 1971 [1, 2] (it was tested for 10 GeV extraction energy for a short time). Though it is a rapid cycling synchrotron (sinusoidal magnet ramp at 15 Hz with a frequency variation of ≈ 0.2% variation) the beam is not delivered on all of its cycles, all the time. Many improvements have been made over the past four decades to increase the beam intensity per Booster *batch* and to increase its average beam power to the down-stream accelerators and to the low energy neutrino program — full potential of the Booster is yet to be realized. One of the important goals of the "Proton Improvement Plan" at Fermilab [3] is to extract the beam at 15 Hz rate from the Booster all the time. Long range plan of Fermilab [4] is to increase the Booster beam delivery cycle rate from 15 Hz to 20 Hz. Hence, the current Booster plays a very significant role in the near future of the Fermilab.

In support of the proposed upgrades to the Fermilab facilities, a thorough investigation on the properties of the beam at the injection energy is extremely valuable. In the past, many attempts have been made in this regard (e.g., ref. [5]), in bits and pieces, often only soon after major upgrades in the upstream hardware. Nevertheless, we realized that a systematic and coherent set of measurements on beam properties at injection is highly needed to understand the beam dynamics.

The Booster receives 400 MeV (kinetic energy) proton beam from the LINAC with 200 MHz bunch structure, while it is at its minimum of sinusoidal ramp. The injection line is equipped with an 800 MHz debuncher cavity to reduce the energy spread of the injected beam. After the injection the beam is quickly captured with the help of a 37 MHz RF system. Typically the capture efficiency is < 97 %. Between the injection and RF capture the beam is debunched for ~100 µs. In this report, we primarily focus on the measurement of energy spread at this time of the beam cycle as a function of beam intensity which is measured in terms of Booster Turns (BT) (1BT ≈ 0.33× 10^{12} protons).

SIMULATIONS AND MEASUREMENTS

In the absence of any RF field, injected bunched beam into the synchrotron debunches (shears) forming a DC beam and maintains its initial energy spread. The energy spread of such a beam can be measured by producing a gap (notch) in the beam with the help of a fast kicker and measuring the time T_{Graz} required for a grazing touch of two sides of its line-charge distribution. Then the energy spread ΔE is given by,

$$\Delta E = \frac{\beta^2 E_s}{|\eta|} \frac{W_{notch}}{T_{Graz}} .$$

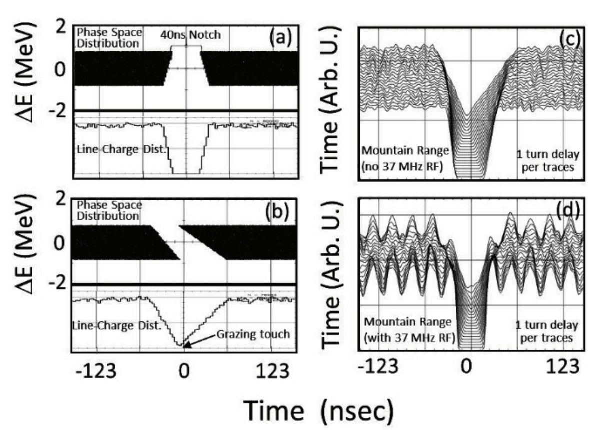

Figure 1: ESME[6] simulations for a) initial beam phase space distribution with a notch in the beam (top) and its line-charge distribution (bottom) b) same as "a" but at grazing touch, c) mountain range without 37 MHz RF and c) similar to "c" but with 37 MHz RF turned on at 25kV.

Where β, E_s, η and W_{notch} are relativistic velocity (0.713 for 400 MeV proton), synchronous energy of the beam (1338.3 MeV), slip factor (-0.4583) and the width of the notch in seconds (≈40 nsec), respectively. We have performed longitudinal beam dynamics simulations for the Booster injection scenario using the machine parameters [2] and for a notch of ≈40 ns width to understand the notch filling mechanism. Figure 1 depicts the predicted dynamics of the beam particle distribution

PIP-II STATUS AND STRATEGY

Stephen Holmes, Paul Derwent*, Valeri Lebedev, Shekhar Mishra, Donald Mitchell,
Vyacheslav P. Yakovlev, Fermi National Accelerator Laboratory, Batavia IL 60510, USA†

Abstract

Proton Improvement Plan-II (PIP-II) is the centerpiece of Fermilab's plan for upgrading the accelerator complex to establish the leading facility in the world for particle physics research based on intense proton beams. PIP-II has been developed to provide 1.2 MW of proton beam power at the start of operations of the Long Baseline Neutrino Facility (LBNF), while simultaneously providing a platform for eventual extension of LBNE beam power to >2 MW and enabling future initiatives in rare processes research based on high duty factor/higher beam power operations. PIP-II is based on the construction of a new 800 MeV superconducting linac, augmented by improvements to the existing Booster, Recycler, and Main Injector complex. PIP-II is currently in the development stage with an R&D program underway targeting the front end and superconducting RF acceleration technologies. This paper will describe the status of the PIP-II conceptual development, the associated technology R&D programs, and the strategy for project implementation.

OVERVIEW

The Proton Improvement Plan-II (PIP-II) is a high-intensity proton facility being developed to support a world-leading neutrino program over the next two decades at Fermilab. PIP-II is an integral part of the U.S. Intensity Frontier Roadmap as described in the Particle Physics Project Prioritization Panel (P5) report of May 2014 [1]. PIP-II is focused on upgrades to the Fermilab accelerator complex capable of providing a beam power in excess of 1 MW on target at the initiation of Long Baseline Neutrino Facility [1, 2] operations and is a part of a longer-term concept to achieve multi-MW capabilities at Fermilab. PIP-II is anticipated to be a Department of Energy project following the critical decision (CD) process and guidelines of DOE Order 413.3b [3]. At the present time, PIP-II is still in the development phase and is not a formal construction project.

Design Criteria and Considerations

The existing Fermilab accelerator complex could be upgraded using a number of different approaches in order to achieve beam power in excess of 1 MW on the LBNF target. The challenge is to identify solutions that provide an appropriate balance between minimizing near-term costs and maintaining the flexibility to support longer-term physics goals. In order to constrain consideration to a modest number of options the following criteria are applied to possible solutions:

- support the delivery of at least 1 MW of proton beam power from the Main Injector to the LBNF target at energies between 60-120 GeV.
- provide support to the currently envisioned 8 GeV program, including the Mu2e and g-2 experiments, as well as the suite of short-baseline experiments [4, 5].
- provide a platform for eventual extension of beam power to LBNF to more than 2 MW.
- include a future capability to support rare processes experiments with high duty factor and high beam power.

The ideal facility meeting the above criteria would be a modern 8 GeV superconducting linac for injection either into the Main Injector or Recycler as described in the Project X RDR [6], or the pairing of an ~2 GeV SRF linac with a modern Rapid Cycling Synchrotron. These options provide performance that would significantly exceed the first design criteria, and would meet all subsequent criteria, but also significantly exceed the likely available funding.

Design Approach

The goal of Proton Improvement Plan-II is to enhance the capabilities of the existing accelerator complex at Fermilab to support delivery of 1.2 MW beam power to the LBNF production target, while simultaneously providing a platform for subsequent upgrades of the accelerator complex to multi-MW capability. High-level goals, and supporting beam performance parameters, for PIP-II and their comparison to current Proton Improvement Plan (PIP) [7] parameters are given in Table 1. The central element of PIP-II is a new 800 MeV superconducting linac accelerating H- ions and located in close proximity to the existing Booster as shown in Figure 1. This siting offers several advantages in terms of minimizing cost while retaining options for future development; in particular, the site affords direct access to significant electrical, water, and cryogenic infrastructure.

The concept for PIP-II is described in a Reference Design Report [8] and includes the following scope:

- An 800 MeV superconducting linac (SC Linac), constructed of CW-capable accelerating structures and cryomodules, operating with a peak current of 2 mA and a beam duty factor of 1.1%.
- Beam transport from the end of the SC Linac to the new Booster injection point, and to a new 800 MeV beam dump.
- Upgrades to the Booster to accommodate 800 MeV injection, and acceleration of 6.5×10^{12} protons per pulse.

FERMILAB BOOSTER INJECTION UPGRADE TO 800 MeV FOR PIP-II*

D.E. Johnson, V. Lebedev, I. Rakhno, Fermilab, Batavia, IL., USA.

Abstract

Fermilab is proposing to build an 800 MeV superconducting linac which will be used to inject H⁻ ions into the existing Booster synchrotron as part of the proposed PIP-II project. The injection energy of the Booster will be raised from the current 400 MeV to 800 MeV. Transverse phase space painting will be required due to the small linac transverse emittance ($\varepsilon_{ring}/\varepsilon_{linac}$ ~ 10) and low average linac current of 2 mA. The painting is also helpful with reduction of beam distribution resulting in a reduction of space charge effects. The injection will require approximately 300 turns corresponding to ~ 0.5 ms injection time. A factor of seven increase of the injected beam power (relative to present operation) requires an injection waste beam absorber. The paper describes the requirements for the injection insert, its design, and plans for transverse painting.

THE FNAL BOOSTER

The 40+ year old Booster contains 24 periods and can be described as a FoDooDoF lattice utilizing gradient magnet pairs (FD or DF) mounted on a girder with long straight sections (5.68 meters) between the defocusing gradient magnets and a short straight section (0.5 meters) between the F and D gradient magnets. Horizontal beta function varies from about 6 meters in the long straight to 33 m in the short straights while the vertical beta function varies from 20 m in the long straights to ~5.3 m in the short straights. The horizontal dispersion varies between approximately 1.8 (in the long straights) and 3.6 meters. The "nominal" ring optics is shown in Fig. 1.

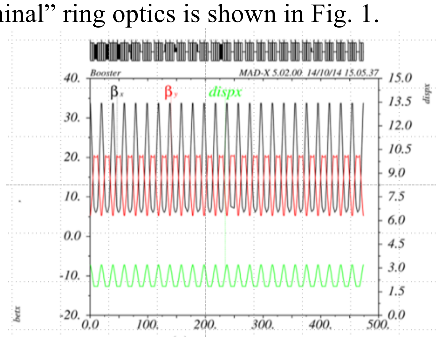

Figure 1: Booster lattice functions.

The current injection insert is located in one of the long straight sections (Long 1). The injection [1,2] is based on a three dipole (powered by a single supply) horizontal orbit bump moving the closed orbit by about 45mm onto a carbon stripping foil to match a trajectory of injected H⁻ beam for the duration of injection. The multi-turn injection time is $N_{turns}*\tau_{Booster}$ ~35μs for N_{turns}=16. Since the transverse emittance of the current 400 MeV linac is close to the Booster acceptance, no transverse phase space painting is used. Figure 2 shows the lattice functions for the injection straight with locations of the gradient and injection bump magnets shown at the top of the plot and the injection trajectories shown in the inset.

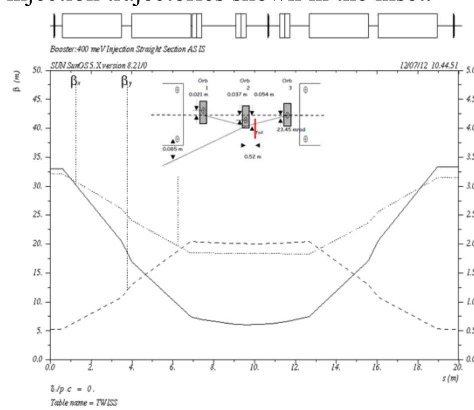

Figure 2: Current Booster injection straight section lattice.

800 MeV INJECTION

The goal of this effort is to verify that we can inject the PIP-II linac beam into the existing Booster at twice higher energy and to find the major issues to be addressed. The major challenges of the new injection system are related to (1) the ability to incorporate a well shielded injection absorber in the current straight section length to handle the factor of 7 increase in injection beam power (17 kW), (2) to introduce a dipole chicane capable to move the closed orbit onto the injection foil, and (3) to support both horizontal and vertical painting based on the control of closed orbit during injection. We also strive to limit the peak field in the single-turn ferrite loaded chicane dipoles to 3 kG due to ferrite saturation near the coils [3].

INITIAL CONCEPTUAL DESIGN

The initial conceptual design for the new injection insert, as described in the PIP-II RDR [4], utilizes an existing straight section (Long 11) with a flange-to-flange length of 5.68 m. The insert is located between gradient magnets and includes a vertical three bump chicane as shown in Fig. 3. The injection stripping foil is located after the two central chicane dipoles. Here, the vertical chicane dipoles not only move the closed orbit onto the foil, but serve as vertical painting magnets as well. The bending angle of each of the chicane dipoles is approximately 40 mrad. Horizontal painting magnets are located in the short straight sections on either side of the injection straight. The last injection line dipole located over the upstream gradient magnet directs the incoming H⁻ ions onto the foil. As the injected H⁻ beam passes

TRANSFER LINE DESIGN FOR PIP-II PROJECT*

A. Vivoli#, J. Hunt, D. E. Johnson, V. Lebedev, FNAL, Batavia, IL 60510, USA

Abstract

The recent U.S. Particle Physics Community P5 report encouraged the realization of the Proton Improvement Plan II (PIP-II) project to support future neutrino programs in the United States. PIP-II includes the construction of a new 800 MeV H$^-$ Superconducting (SC) Linac at Fermilab and an upgrade of its current accelerator complex mostly focused on upgrades of the Booster and Main Injector synchrotrons. The SC Linac will initially operate in pulsed mode at 20 Hz. The design should be compatible with upgrades to CW mode and higher energy. A new transport line will connect the Linac to the Booster. This line has to provide adequate collimation and be instrumented for beam parameter measurements. In addition, to support beam based Linac energy stabilization, the line should provide a mechanism to redirect the beam from the dump to the Booster within one pulse. In this paper we present the design of the transport line developed to meet the above requirements. Tracking simulations results are reported to confirm the validity of the design.

INTRODUCTION

PIP-II [1] immediate goal is to provide more than 1 MW of beam power on the target at the start of LBNF operations [2], maintaining the flexibility of the Fermilab accelerator complex necessary to support long-term neutrino physics and being cost-effective. The main limiting factor for an increase of beam power to LBNF is the current Linac/Booster system. Increasing the injection energy from the current 400 MeV to 800 MeV, together with some modifications in the existing Booster, Recycler and Main Injector, would allow higher beam intensity and power. To provide the 800 MeV proton beam, PIP-II assumes the construction of a new SC Linac operated in pulsed mode but built with CW-capable accelerating structures and cryomodules, minimizing the cost of a future upgrade to CW mode. The SC Linac will accelerate a 2 mA H$^-$ beam, requiring a multi-turn strip-injection in the Booster. The repetition frequency will be 20 Hz and the beam duty factor of 1.1%.

TRANSFER LINE DESIGN

The siting of the SC Linac has been selected because of its proximity to existing electrical, water and cryogenic infrastructure and the possibility it offers for future development. To connect the end of the Linac to the injection position in Booster a new beam line has been designed. Figure 1 shows a layout of the Fermilab site together with the existing beam lines. In green the footprint of the PIP-II SC Linac and Transfer Line are presented. In cyan the footprint of the alternate design is shown. The alternate design is around 24 m shorter than the baseline.

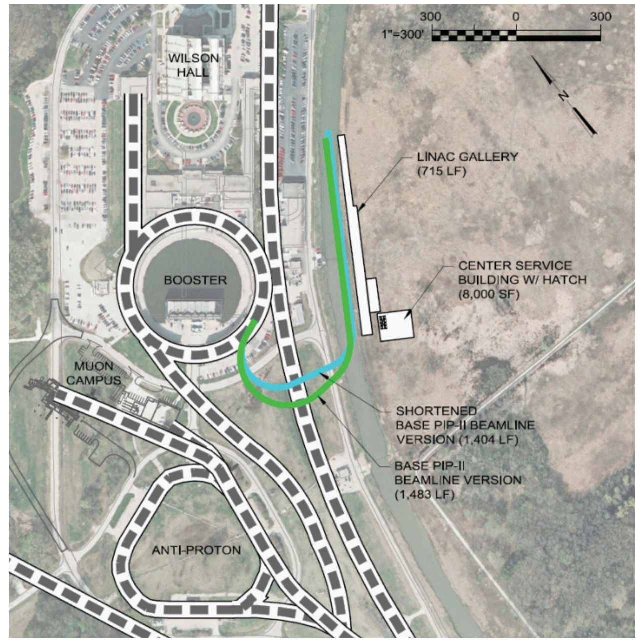

Figure 1: Layout of Fermilab site with PIP-II beam lines.

The direction of the Linac forms an angle of 217 deg. with the direction of injection in the Booster. In order to avoid Lorentz stripping, the magnetic field used to bend the beam has been chosen to be 2.36 kG, corresponding to a loss rate of $3{\cdot}10^{-13}$ m^{-1}. With these parameters the total bending angle can be completed with 32 bending dipole magnets of 2.45 m length (baseline) or with 24 dipoes 3.27 m long (alternate). To fit into the geometrical constraints of the site, the Transfer Line has been divided into a first matching straight section, a first arc, a second straight section, a second arc and an injection line to the Booster. The optics chosen for the transport is a FODO lattice for all the line but the first matching straight section, in which a doublet focusing system similar to the one in the Linac is used, and the injection line. The cell length has been determined by the geometrical constraints resulting in 12 m for both the options. The strength of the quadrupoles has been chosen to determine about 90 deg. phase advance per cell both horizontally and vertically. With this choice, the first arc is composed of 4 cells and the second arc of 12 or 8 cells for the baseline and alternate design respectively. Such choice assures achromaticity of the arcs. The vacuum chamber will be manufactured from 1.5” stainless steel pipe, leaving a transverse aperture of 17 mm for the beam. Figure 2 presents the optical functions of the Transfer Line (baseline) computed with the code OPTIM [3].

DESIGN OF THE LBNF BEAMLINE*

V. Papadimitriou#, R. Andrews, J. Hylen, T. Kobilarcik, G. Krafczyk, A. Marchionni, C. D. Moore, P. Schlabach, S. Tariq, Fermilab, Batavia, IL 60510, USA

Abstract

The Long Baseline Neutrino Facility (LBNF) will utilize a beamline located at Fermilab to carry out a compelling research program in neutrino physics. The facility will aim a wide band neutrino beam toward underground detectors placed at the SURF Facility in South Dakota, about 1,300 km away. The main elements of the facility are a primary proton beamline and a neutrino beamline. The primary proton beam (60-120 GeV) will be extracted from the MI-10 section of Fermilab's Main Injector. Neutrinos are produced after the protons hit a solid target and produce mesons which are subsequently focused by magnetic horns into a 204 m long decay pipe where they decay into muons and neutrinos. The parameters of the facility were determined taking into account the physics goals, spacial and radiological constraints and the experience gained by operating the NuMI facility at Fermilab. The initial proton beam power is expected to be 1.2 MW, however the facility is designed to be upgradeable to 2.4 MW. We discuss here the design status and the associated challenges as well as plans for improvements before baselining the facility.

INTRODUCTION

The Beamline is a central component of LBNF and its driving physics considerations are the long baseline neutrino oscillation analyses. On January 8, 2010 the Department of Energy approved the "Mission Need" (CD-0) for the Long Baseline Neutrino Experiment (LBNE) and on December 10, 2012 the conceptual design (CD-1). As of January 2015, the LBNE experiment had evolved to the Deep Underground Neutrino Experiment (DUNE) which uses the LBNF Facility at the Fermilab and Sanford Underground Research Facility (SURF) sites. Because of the increased scope for LBNF/DUNE we are preparing for a "CD-1 refresh" review in July 2015. For the Beamline, the change of scope consists of being ready to accept beam power of 1.2 MW (instead of 700 kW) at day one of operations.

The beamline facility is expected to be fully contained within Fermilab property. The primary proton beam, in the energy range of 60-120 GeV, will be extracted from the Main Injector's (MI) [1] MI-10 section using "single-turn" extraction. For 120 GeV operation and with the MI upgrades implemented for the NOvA experiment [2] as well as with the expected implementation of the accelerator Proton Improvement Plan, phase II (PIP-II) [3], the fast, single turn extraction will deliver all the protons (7.5 x 10^{13}) in one MI machine cycle (1.2 sec) to the LBNF target in 10 μs. The beam power is expected to be 1.03 to 1.20 MW in the energy range of 60 to 120 GeV [3]. The charged mesons produced by the interaction of the protons with the target are sign selected and focused by two magnetic horns into the decay pipe towards the far detector. These mesons are short-lived and decay into muons and neutrinos. At the end of the decay region, an absorber pile is needed to remove the residual hadrons remaining at the end of the decay pipe. The neutrino beam is aimed 4850 ft underground at SURF in South Dakota, about 1300 km away.

A wide band neutrino beam is needed to cover the first and second neutrino oscillation maxima, which for a 1300 km baseline are expected to be approximately at 2.4 and 0.8 GeV. The beam must provide a high neutrino flux at the energies bounded by the oscillation peaks and we are therefore optimizing the beamline design for neutrino energies between 0.5 and 5 GeV. The initial operation of the facility will be at a beam power incident on the production target of 1.2 MW, however some of the initial implementation will have to be done in such a manner that operation at 2.4 MW can be achieved without retrofitting. Such a higher beam power is expected to become available in the future with additional improvements in the Fermilab accelerator complex [4]. In general, components of the LBNF beamline system which cannot be replaced or easily modified after substantial irradiation at 1.2 MW operation are being designed for 2.4 MW. Examples of such components are the shielding of the target chase and the decay pipe, and the hadron absorber.

The LBNF Beamline design has to implement as well stringent limits on the radiological protection of the environment, workers and members of the public. The relevant radiological concerns, prompt dose, residual dose, air activation and water activation have been extensively modeled and the results are incorporated in the system design. A most important aspect of modeling at the present design stage is the determination of the necessary shielding thickness and composition in order to protect the ground water and the public and to control air emissions.

This paper is a snapshot of the present status of the design, detailed in the 2012 Conceptual Design Report [5] and the more recently published LBNE science document [6].

STATUS OF THE DESIGN

Figure 1 shows a longitudinal section of the LBNF beamline facility. At MI-10 there is no existing extraction enclosure and we are minimizing the impact on the MI by introducing a 15.6 m long beam carrier pipe to transport the beam through the MI tunnel wall into the new LBNF enclosure. The extraction and transport components send the proton beam through a man-made embankment/hill

OUT-OF-TIME BEAM EXTINCTION IN THE MU2E EXPERIMENT*

E.J. Prebys, S.Werkema, Fermilab, Batavia, IL 60510, USA

Abstract

The Mu2e Experiment at Fermilab will search for the conversion of a muon to an electron in the field of an atomic nucleus with unprecedented sensitivity. The experiment requires a beam consisting of proton bunches 250 ns FW long, separated by 1.7 μ sec, with no out-of-time protons at the 10^{-10} fractional level. Satisfying this "extinction" requirement is very challenging. The formation of the bunches is expected to result in an extinction on the order of 10^{-5}. The remaining extinction will be accomplished by a system of resonant magnets and collimators, configured such that only in-time beam is delivered to the experiment. Our simulations show that the total extinction achievable by the system is on the order of 10^{-12}, with an efficiency for transmitting in-time beam of 99.6%.

INTRODUCTION AND REQUIREMENTS

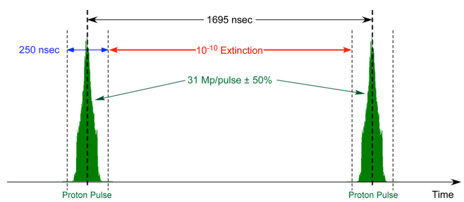

Figure 1: The proton bunch structure required by the Mu2e experiment.

The goal of the Mu2e experiment [1] is to search for the conversion into an electron of a muon which has been captured by a nucleus ($\mu N \rightarrow eN$). This manifestly violates the conservation of charged lepton flavor number, and therefore its observation would be an unambiguous indicator of physics beyond the Standard Model.

A key component of the experimental technique is the proton beam structure [2], which is illustrated in Figure 1. The primary beam consists of short (250 ns FW) proton bunches with 8 GeV kinetic energy, separated by approximately 1.7 μs, which are used to produce muons. To suppress backgrounds, it's vital that the interval between the bunches be free of protons at a level of at least 10^{-10}, relative to the beam in the bunches [3]. This will be achieved in two steps. The first step will be in the formation of the bunches, which - as we will show - we expect to achieve an extinction on the order of 10^{-5}. The remaining extinction will be provided by a system of resonant magnets and collimators in beam line, configured such that only the in-time beam is transmitted to the target. This system is designed to provide an additional extinction factor of below 10^{-7}. There is thus a safety margin of two orders of magnitude, which we feel is appropriately conservative, given the importance of the issue.

In the interest of minimizing radiation damage and secondary activation, we have also imposed the specification that less that 1% of the in-time beam be lost on the collimator.

BUNCH FORMATION

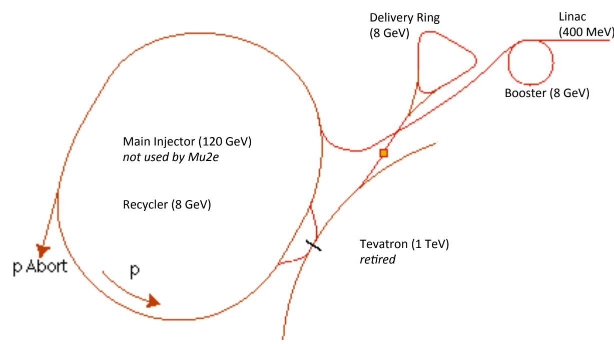

Figure 2: The parts of the Fermilab Accelerator Complex used for the Mu2e Experiment. The “Delivery Ring" was formerly the Antiproton Debuncher

The parts of the Fermilab accelerator complex which are required are shown in Figure 2.

Protons with 8 GeV of kinetic energy will be transferred from the Booster to the Recycler, an 8 GeV permanent magnet storage ring developed for the Tevatron program. In the Recycler, beam will be re-bunched into 2.5 MHz bunches. These will be transfered one at a time to the 8 GeV “Delivery Ring" (formerly the Antiproton Debucher"). Beam will then be resonantly extracted from this ring, which has a period of 1.7 μs, thus producing the bunch structure needed by the experiment.

BEAM LINE EXTINCTION

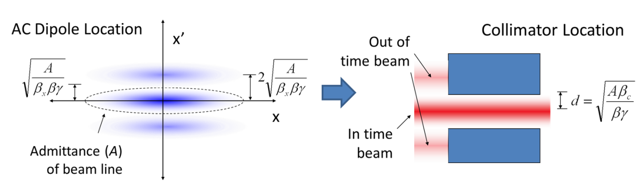

Figure 3: Effect of the AC dipole field in phase space. Beam line admittance A is indicated by the ellipse.

The AC dipole/collimator system and it's optimization has been described in detail elsewhere [4]. The principle is shown in Figure 3. A bending dipole deflects out-of-time beam, such that it will be absorbed by a collimator located 90° downstream in betatron phase advance. If the

THE STATUS OF MICE STEP IV

D. Rajaram*, Illinois Institute of Technology, Chicago, IL, USA
V. C. Palladino, INFN-Napoli, Napoli, Italy
on behalf of the MICE collaboration

Abstract

Muon (μ) beams of low emittance provide the basis for the intense, well-characterised neutrino beams of the Neutrino Factory and for lepton-antilepton collisions at energies of up to several TeV at the Muon Collider. The International Muon Ionization Cooling Experiment (MICE) will demonstrate ionization cooling – the technique by which it is proposed to reduce the μ phase-space volume. MICE is being constructed in a series of Steps. At Step IV, MICE will study the properties of liquid hydrogen and lithium hydride that affect cooling. A solenoidal spectrometer will measure emittance up and downstream of the absorber vessel into which a focusing coil will focus muons. The construction of Step IV at RAL is nearing completion. Its status will be described together with a summary of the performance of the principal components. Plans for the commissioning and operation and the Step IV measurement programme will be described.

INTRODUCTION

Stored muon beams for facilities such as a Neutrino Factory or a Muon Collider originate from decays of pions created in proton-target interactions. At production, occupy a large volume in phase space. For efficient acceleration the phase space volume (emittance) must be reduced (cooled) significantly. Due to the short lifetime of the muon, ionization cooling is the only practical technique by which to cool beams of muons.

In ionization cooling, a muon beam passes through an absorber material losing momentum in both transverse and longitudinal dimensions. Subsequently the muons are re-accelerated whereby only the longitudinal momentum is restored. This results in a net reduction of the transverse emittance. The dependence of the normalized 2D transverse emittance on path length in a medium is given by [1]:

$$\frac{d\varepsilon_N}{ds} \approx -\frac{1}{\beta^2}\frac{\varepsilon_N}{E_\mu}\left\langle\frac{dE}{ds}\right\rangle + \frac{1}{\beta^3}\frac{\beta_\perp(0.014\ \text{GeV})^2}{2E_\mu m_\mu X_0}, \qquad (1)$$

where ε_N is the normalized transverse emittance, β the velocity in units of c, E_μ the energy in GeV, $\beta_\perp$ the transverse betatron function, m_μ the muon mass in GeV/c^2, and X_0 the radiation length of the material. The first term on the right describes reduction of emittance per unit length ("cooling") while the second term describes the effect of multiple scattering ("heating"). Equilibrium emittance is reached when the terms are equal and an ideal cooling channel would provide the smallest equilibrium emittance.

* durga@fnal.gov

The Muon Ionization Cooling Experiment (MICE) [2] sited at the Rutherford Appleton Laboratory (RAL) will be the first demonstration of muon ionization cooling. A single cell of a realistic cooling channel will be built and its performance studied under a variety of conditions. The experiment was designed to be built and operated in a staged manner. In the first stage (Step I), which ended in 2013, the muon beamline was commissioned [3] and characterized [4]. The next stage – Step IV – will study the change in normalized transverse emittance using LH_2 and lithium hydride (LiH) absorbers under various optical configurations. Two 201 MHz rf cavities and a second focus-coil module will then be added to the Step IV configuration to allow the demonstration of ionization cooling.

STEP IV

A schematic layout of MICE Step IV is shown in Fig. 1. An absorber (LH_2 or LiH) is placed within a superconducting absorber/focus-coil (AFC) module.

The AFC module is sandwiched between two superconducting solenoids instrumented with scintillating-fiber trackers. The spectrometers measure the emittance of the beam upstream and downstream of the absorber precisely. Particle identification, to reject the small pion contamination in the MICE Muon Beam, upstream of the absorbers is performed using two time-of-flight hodoscope (TOF) stations, and two threshold Cherenkov (Ckov) counters. Downstream of the absorber, contamination from decay electrons is rejected using a TOF, a pre-shower calorimeter (KL) and a fully active scintillator calorimeter (EMR). More detailed descriptions and status of the components follow.

Diffuser

The diffuser is designed to allow varying the input emittance by inserting material into the beam. It sits just inside the upstream end of the first spectrometer solenoid and consists of four irises of different thicknesses, two made of brass and two of tungsten. The irises are pneumatically controlled from the MICE control room and provide 16 possible settings for the diffuser.

Spectrometer Modules

Two superconducting spectrometer solenoid magnets, one upstream and the other downstream of the absorber, house the scintillating fiber trackers. Each magnet consists of five coils wound on a common aluminum mandrel. A cross-sectional view of the magnet assembly is shown in Fig. 2. The center coil along with the end coils provide a uniform 4 T field over a 1 m long, 30 cm diameter volume. The two

MODELING PROTON- AND LIGHT ION-INDUCED REACTIONS AT LOW ENERGIES IN THE MARS15 CODE*

I.L. Rakhno#, N.V. Mokhov, Fermilab, Batavia, IL 60510, USA
K.K. Gudima, Institute of Applied Physics, National Academy of Sciences, Chisinau, Moldova

Abstract

An implementation of both ALICE code and TENDL evaluated nuclear data library in order to describe nuclear reactions induced by low-energy projectiles in the Monte Carlo code MARS15 is presented. Comparisons between results of modeling and experimental data on reaction cross sections and secondary particle distributions are shown.

INTRODUCTION

Correct prediction of secondary particles, both neutral and charged ones, generated in proton-nucleus interactions below a few tens of MeV is required for various applications. The latter include, e.g., radiation studies for front-end of many proton accelerators, energy deposition studies for detectors, residual activation and radiation damage calculations, etc. In medical accelerators, low energy primary proton or deuteron beams are used either directly or as a tool to generate secondary neutron beams. Cascade models of various flavours fail to properly describe this energy region (see Fig. 1). Therefore, we opted to use the TENDL library developed by the Nuclear Research and Consultancy Group [1]. The evaluated data is provided in the ENDF/B format in the projectile energy range from 1 to 200 MeV, and the library is annually updated since 2008. In addition, a much more time-consuming approach utilized in a modified code ALICE [2] was also looked at. For both the options, the energy and angle distributions of all secondary particles are described with the Kalbach-Mann systematics. The following secondaries are taken into account: gammas, neutrons, protons, deuterons, tritons, ^{3}He and ^{4}He. The energy and angular distributions of all generated residual nuclei—including unstable ones—are accounted for as well.

DETAILS OF THE IMPLEMENTATION AND FORMALISM

TENDL Library

The TALYS-based evaluated nuclear data library (TENDL) contains data for direct use in both basic physics and applications. The evaluations were performed for practically entire periodic table except for hydrogen and helium. The library contains data for both stable and unstable target nuclei—all isotopes which live longer than 1 second were taken into account. At present, the list includes about 2400 isotopes. In fact, the TENDL library contains data not only for protons as projectiles, but also for light ions (d, t, ^{3}He, ^{4}He), neutrons and gammas. In current implementation, the data for protons and light ions are used when modelling low-energy inelastic reactions in MARS15 code [4-5]. For every interaction the following information is extracted from the library: (i) total inelastic cross section; (ii) energy and angular distributions of all above mentioned secondary particles and residual nuclei; (iii) yields of all the secondaries.

The TENDL library is a collection of files in both ENDF/B and ACE format. We opted to use the source—ENDF/B format—because it is more easily readable which is a very important feature at the development and debugging stages. At the same time, there is little difference between the two formats with respect to computer memory requirements.

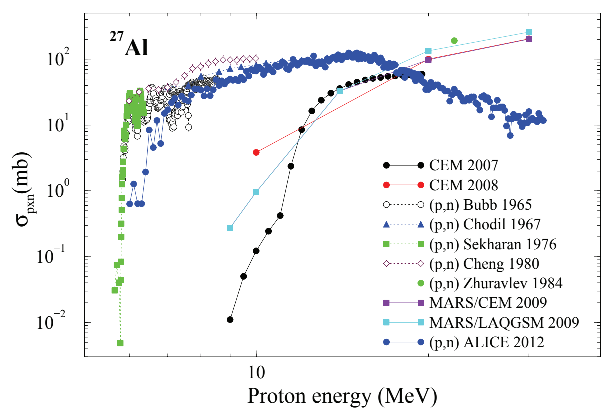

Figure 1: Calculated and measured [3] neutron production cross section on aluminum at low energies.

ALICE Code

An alternative approach—using an event generator—was explored as well. For this purpose, the nuclear model code ALICE [2] based on a hybrid model of pre-compound decay, Weisskopf-Ewing evaporation and Bohr-Wheeler fission models was employed. It was re-designed in order to be used as an event generator for nucleon, photon and heavy-ion nuclear reactions at incident energies from 1 to 20-30 MeV matching CEM and LAQGSM at energies above 20-30 MeV in MARS15. At present, this option looks much more time consuming, but potentially it can offer some advantages for applications where accuracy of the full exclusive modeling is of major importance, e.g. when modeling a detector performance.

Kalbach-Mann Systematics

Nowadays, continuum energy-angle distributions of secondary particles generated in low energy interactions

ENERGY DEPOSITION AND RADIOLOGICAL STUDIES FOR THE LBNF HADRON ABSORBER*

I.L. Rakhno#, N.V. Mokhov, I.S. Tropin, Fermilab, Batavia, IL 60510, USA
Y.I. Eidelman, Euclid TechLabs, LLC, Solon, OH 44139, USA

Abstract

Results of detailed Monte Carlo energy deposition and radiological studies performed for the LBNF hadron absorber [1] with the MARS15 code [2] are described. The model of the entire facility, that includes a pion-production target, focusing horns, target chase, decay channel, hadron absorber system – all with corresponding radiation shielding – was developed using the recently implemented ROOT-based geometry option in the MARS15 code. Both normal operation and accidental conditions were studied. Results of detailed thermal calculations with the ANSYS code helped to select the most viable design options.

INTRODUCTION

The Long-Baseline Neutrino Facility (LBNF) at Fermilab is supposed to provide the world's highest-intensity neutrino beam for the US and international programs in neutrino physics [1]. The corresponding incoming proton beam power can ultimately be as high as 2.4 MW, and the underground beam absorber at the end of the decay channel with related infrastructure is supposed to operate with little or no maintenance for about 20 years. Such a combination of long operation time and high deposited power imposes strict limitations on design.

UNIFIED COMPUTER MODEL

A very detailed model of the entire facility which includes a pion-production target, focusing horns, target chase, decay channel, and hadron absorber system was developed. A drawing that describes an elevation view of the entire facility and a fragment of the entire MARS model which shows the absorber hall are presented in Fig. 1. In the Figure, light blue and gray colors refer to air and concrete, respectively, and green color means soil. As a result of thorough optimization studies with MARS code, the system now consists of a spoiler aluminum block, five aluminum mask blocks, nine sculpted aluminum blocks, four solid aluminum blocks, and four central steel blocks, and all that is surrounded with sophisticated steel and concrete shielding. Total weight of the aluminum and steel is 39 and 2,500 ton, respectively. Volume of poured concrete is 24,000 ft^3.

BEAM PARAMETERS AND SCENARIOS

Table 1 summarizes the beam parameters used to study both the normal operation and two most severe credible accident scenarios. The beam starts at z=-7.3 m (this location is labelled as MC0 in Table 1) and emittance ε_{95} is 20π mm-mrad. The tilt downward is 0.101074 radian.

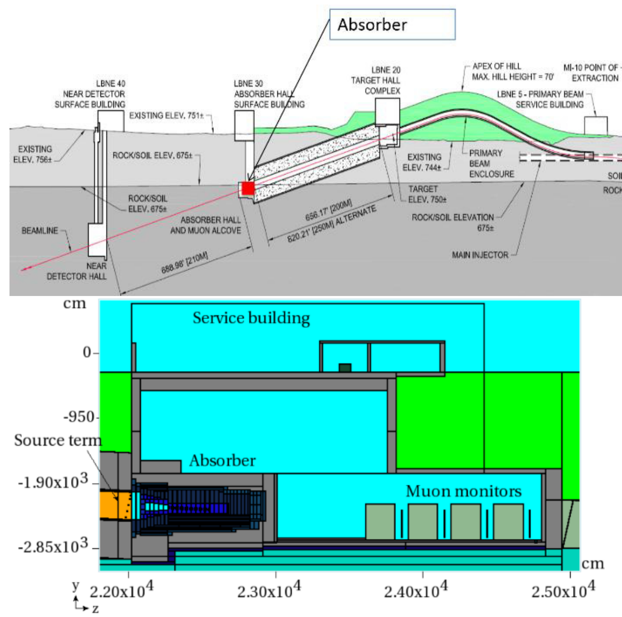

Figure 1: Elevation view of the entire facility (top) and a fragment of the MARS model that shows the hadron absorber and muon monitors in the hall with a service building above (bottom).

Table 1: Beam Parameters and Studied Scenarios

Parameter	Normal Operation	No-Target Accident On-Axis	Off-Axis Accident§
E_p(GeV)	120 60	120	120
P(MW) or Q(MJ)	2.40 MW 2.06 MW	2.88 MJ	2.88 MJ
σ_0 (mm) at MC0	1.7 1.7	2.4	2.4
β_0 (m) at MC0	110.8837 55.44	221.03	221.03
Cycle (s)	1.2 0.7	1.2	1.2

MARS TRACKING SIMULATIONS FOR THE MU2E SLOW EXTRACTED PROTON BEAM*

V. Nagaslaev#, I. Rakhno, Fermilab, USA

Abstract

Particle tracking taking into account interactions with fields and materials is necessary for proper evaluation of the resonant extraction losses and geometry optimization for the extraction beam line. This paper describes the tracking simulations for the Mu2e Resonant Extraction and discusses the geometry choices made based on these simulations.

INTRODUCTION

Mu2e experiment [1] uses the third integer resonant extraction from the Fermilab Delivery Ring to deliver the 8kW proton beam to the production target. Beam losses at the extraction location are a very serious concern of the design. Heavy in-tunnel shielding will be needed even for localized beam losses as low as 1% in order to keep prompt radiation dose levels on the surface within acceptable range and to reduce the residual doses in the tunnel to facilitate the machine maintenance. Another consequence of high beam losses is activation of hardware, which makes its servicing more difficult. Extraction channel geometry needs to be optimized for best extraction efficiency. We define the extraction channel here as the section of the beam line including two Electrostatic Septa (ESS) straddling a focusing quad Q203, defocusing quad Q204 and two magnetic septa straddling the large aperture quad Q205. The layout of this section is shown in Fig. 1. Extracted beam is separated from the circulating beam and deflected horizontally in the ESS and vertically in the Lambertson and the C-magnet. Quads Q204 and Q205 provide additional horizontal and vertical kicks outwards due to their defocusing and focusing functions correspondingly.

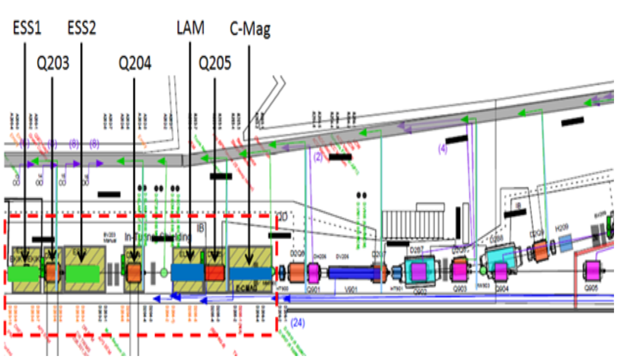

Figure 1: Extraction beam line, plan view. Extraction channel is marked by the red dashed line. Hatched yellow blocks are the in-tunnel shielding around the most activated elements.

* Work supported by Fermi Research Alliance, LLC, under contract No. DE-AC02-07CH11359 with the U.S. Department of Energy
#vnagasl@fnal.gov

The process of beam passage through the extraction channel and generation of losses in the ESS has been studied using tracking simulations with MARS program [2]. MARS provides a very detailed description of particle interaction with materials as well as tracking in the fields. Also MARS provides calculation of the prompt dose and residual activation maps, which are not discussed here.

MARS MODEL

Most of the beam line elements were described in the model using MARS "extended" and "nonstandard" types of geometry. Mixing these two types has to be done with care and should be avoided in volumes with thin objects. It is important that tracking in the ESS handles correctly transitions in and out the tiny foil strips, therefore only "extended" objects are used there. The volume recognition is verified in Fig. 2 that shows the proton beam crossing through the foil plane. Red dots on the plot indicate locations of the ends of steps along the particle path. The points are random outside the foil plane but in the plane they concentrate on the foil boundaries; this demonstrates that the volume transitions are properly recognized. The ESS planes are formed by the W/Re 50μ thick foils, of 1mm width, spaced at 2.6mm centre-centre. The foil shapes in Fig. 2 are exaggerated by the strong compression in z-direction along the beam path.

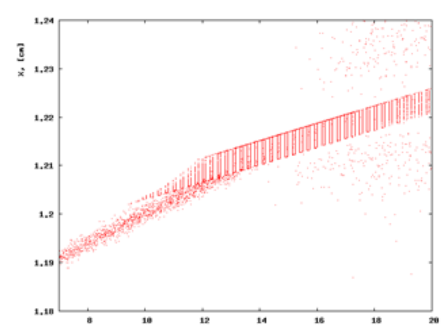

Figure 2: Beam tracking through the foil plane. Red dots show stopping points between two consecutive steps of a particle. They "light up" the foil strips boundaries.

Particle samples for the MARS tracking have been provided from the resonant extraction simulation in the Delivery Ring made with the Synergia program [3,4]. The phase space of two such samples is shown in Fig. 3. The green sample (Sample 1) represents particles at the entrance of the ESS1 that arrive beyond the nominal position of the septum foil plane in X - these are the extracted particles. The red sample (Sample 2) represents the outmost parts of the beam that still circulate in the ring but will be extracted after the next 1, 2 and 3 turns.

PXIE LOW ENERGY BEAM TRANSPORT COMMISSIONING*

L. Prost#, M. Alvarez, R. Andrews, J.-P. Carneiro, B. Hanna, V. Scarpine, A. Shemyakin, Fermilab, Batavia, IL 60510, USA
R. D'Arcy, University College London, London, WC1E 6BT, UK
C. Wiesner, IAP, Goethe University, Frankfurt am Main, Germany

Abstract

The Proton Improvement Plan II (PIP-II) at Fermilab is a program of upgrades to the injection complex [1]. At its core is the design and construction of a CW-compatible, pulsed H^- superconducting RF linac. To validate the concept of the front-end of such machine, a test accelerator (a.k.a. PXIE) is under construction [2]. It includes a 10 mA DC, 30 keV H^- ion source, a 2 m-long Low Energy Beam Transport (LEBT), a 2.1 MeV CW RFQ, followed by a Medium Energy Beam Transport (MEBT) that feeds the first of 2 cryomodules increasing the beam energy to ~ 25 MeV, and a High Energy Beam Transport section (HEBT) that takes the beam to a dump. The ion source and LEBT, which includes 3 solenoids, several clearing electrodes/collimators and a chopping system, have been built, installed, and commissioned to full specification parameters. This report presents the outcome of our commissioning activities, including phase-space measurements at the end of the beam line under various neutralization schemes obtained by changing the electrodes' biases and chopper parameters.

LEBT DESCRIPTION

The present layout of the PXIE beam line is shown on Fig. 1. It consists of an H^- Volume-Cusp Ion Source [3], capable of delivering up to 15 mA DC at 30 keV, 3 solenoids, a chopping system, Electrically Isolated Diaphragms (EID) (water-cooled, except for EID #4), an electrically isolated, water-cooled, vertical scraper assembly (a.k.a. "LEBT scraper"), and diagnostics [4]. Details about most of these components can be found in Ref. [5]. There is also a set of 4 electrically isolated scraper jaws (up, down, left and right) temporarily installed between the first two solenoids (not water-cooled). The LEBT only missing component is a switching dipole magnet which will eventually allow selecting between two ion sources (in PIP-II).

The EIDs can be biased to up to + 50V in order to prevent background ions from moving from one section of the LEBT to another. Depending on the relative potential of these electrodes, different neutralization patterns may be produced. The EIDs also act as scrapers to eliminate transverse tails particles and as a diagnostic tool for beam size and position measurements [4].

The chopper consists of two parallel plates. When the beam is interrupted, -6kV is applied to the bottom ('kicker') plate, and the beam is directed to the upper ('absorber') plate. In addition to the chopping system, a modulator was added to the ion source extraction electrode. Both can produce 1 μs-16.6 ms pulses at up to 60 Hz. Thus, for commissioning of the SRF modules, the initial nominal operation scenario will be to create 5-10 μs pulses with the LEBT chopper out of milliseconds-long ion source pulses. Then, the duty factor will be increased by extending the chopped pulse as the beam line is better understood.

One key aspect of the PXIE warm front-end is its vacuum management approach. For the RFQ, it was decided to keep the vacuum level in the 10^{-7}-10^{-6} Torr range, hence limiting the gas load allowed from the LEBT. The idea is that better vacuum will improve reliability and lifetime of the RFQ, which operates CW. Also, because of the relative proximity of the first superconducting structure, it is important to limit the number of fast neutrals that could potentially reach it.

A direct consequence from this choice is the design of a long (2.2 m) LEBT with extensive pumping to effectively isolate the inherently high pressure found near the ion source from the low pressure required in the RFQ. In measurements made with a configuration similar to the one shown on Fig. 1, the base pressure at the chopper assembly with the plasma on but without extracting beam is found to be < 10^{-7} Torr. With the entire beam being deflected onto the absorber, the vacuum remained < 2 × 10^{-7} Torr for beam currents of up to 6 mA DC.

Maintaining a low vacuum pressure also implies long neutralization times from the background ions; therefore the beam parameters may vary dramatically throughout the pulse, which in turn can cause large beam losses. In part to alleviate this issue, an atypical transport scheme has been proposed [6], where the major portion of the LEBT is kept neutralized while positive ions are cleared in the last ~1 m of the beam line before the RFQ by applying -300V DC voltage to the kicker plate.

A drawback foreseen with this scheme was the probable emittance growth that would result from the un-neutralized transport portion of the LEBT. However, simulations that used the ion source measured parameters indicated that the final emittance would remain within the RFQ specifications. In addition, the LEBT lattice is compatible with a fully neutralized transport solution, should the scheme with the un-neutralized section be found to be too detrimental to the beam quality.

COMMISSIONING MILESTONES

The LEBT was assembled and commissioned in phases, adding components as they were available [5].

SCHEME FOR A LOW ENERGY BEAM TRANSPORT WITH A NON-NEUTRALIZED SECTION*

A. Shemyakin**, L. Prost, Fermilab, Batavia, IL 60510, USA

Abstract

A Low Energy Beam Transport (LEBT) line is the part of a modern ion accelerator between an ion source (IS) and a Radio-Frequency Quadrupole (RFQ). Its typical design includes 1-3 solenoidal lenses for focusing and relies on transport with nearly complete beam space charge neutralization over the entire length of the LEBT. In this paper, we discuss the possibility and rationality of imposing an un-neutralized transport in a portion of the LEBT adjacent to the RFQ. For estimations, we will use the parameters from PXIE [1], a test accelerator presently being constructed at Fermilab.

REASONING FOR A LEBT WITH AN UN-NEUTRALIZED SECTION

Often, a LEBT either operates with a pulsed ion source or is capable of creating pulses from an initially DC beam. Because the ionization process is not instantaneous, the front of the beam pulse is not neutralized as it propagates through the LEBT. Thus for long-pulse operation, when the accelerator optics is tuned for neutralized transport in the LEBT, the space charge at the beginning of the pulse may result in increased losses in the following beam line. In the case of PXIE, several microseconds pulses envisioned for tuning would not provide a representative envelope for CW operation.

Remedies include working at relatively high pressure to speed up the neutralization process, which, in turn shortens the time for the beam parameters to reach a steady state, and moving the chopping system as close as possible to the RFQ in order to decrease the distance that beam travels with full space charge and low energy. In both cases, reliability of the RFQ may suffer because of higher pressure and/or increased irradiation of the RFQ vanes during chopping.

Here we consider an alternative scheme, where the ion source works in the DC mode and the beam propagates through the first, 'high pressure' part of the LEBT being neutralized, but neutralization is stopped right upstream of an electrostatic chopper. Hence, in the ideal case with zero density for the neutralizing ions in the downstream part of the LEBT, the beam envelope is time-independent.

Applicability of such scheme depends on several factors, most importantly, the beam perveance $P_b = I_b / U_{IS}^{3/2}$, where I_b is the beam current and U_{IS} is the ion source bias voltage. If the perveance exceeds a certain limit, an un-neutralized beam simply cannot be transported in a LEBT with lumped focusing even in the linear approximation. In addition, even for a lower perveance, non-linear space charge effects can dramatically increase the beam emittance, making it not suitable for an accelerator.

LINEAR SPACE CHARGE EFFECT

To estimate the maximum perveance theoretically allowing lumped focusing, let's consider the space-charge dominated transport of a non-relativistic, round, completely un-neutralized H$^-$ beam with uniform transverse distribution of the charge density, i.e. neglecting the beam emittance and potential drop across the beam. The maximum length that the beam can propagate between two thin focusing elements while remaining within radius r_b can be expressed (using, for example, formulae from Ref. [2]) as

$$\frac{L_m}{r_b} = \sqrt{2.33\frac{\sqrt{2e/M_i}}{P_b}} = \sqrt{\frac{3.59\,\mu A/V^{3/2}}{P_b}}, \quad (1)$$

where e is the electrical charge and M_i the ion mass. In real-life, for a typical solenoid, the magnetic lens inner radius is at least twice the beam radius and its length is roughly equal to its inner diameter. One can argue that the maximum allowable perveance corresponds to the case when the minimum possible physical distance between lenses exceeds their length by only a factor of 2-3 (with a factor of '1' meaning that the lenses would be touching). Taking a factor of 3 for the lenses' distance-to-length ratio implies $L_{m\_sc}/r_b \approx 12$ and a value of the maximum allowable perveance of

$$P_{bm} \approx \left(\frac{L_{m\_sc}}{r_b}\right)^{-2} \cdot 3.59\,\mu A/V^{3/2} \approx 0.025\,\mu A/V^{3/2}. \quad (2)$$

In the case of PXIE's LEBT, the perveance of the 10mA, 30 kV H$^-$ beam is $1.9\cdot10^{-3}$ μA/V$^{3/2}$, significantly lower than the estimation from Eq. (2). Therefore, for these parameters, un-neutralized transport is not excluded in this simplest model.

NONLINEAR SPACE CHARGE EFFECT

A significantly more important limitation is an emittance growth due to space charge. For a beam with a Gaussian current density distribution, the space charge force is highly non-linear outside of the beam core. The tail particles experience a lower radial kick, which distorts the beam phase portrait and increases the beam emittance.

An obvious solution to avoid emittance dilution due to space charge is to create a beam with constant radial

ACCELERATOR PHYSICS AND TECHNOLOGY RESEARCH TOWARD FUTURE MULTI-MW PROTON ACCELERATORS *

V. Shiltsev#, P. Hurh, A. Romanenko, A. Valishev, R. Zwaska, Fermilab, Batavia, IL 60510, USA

Abstract

Recent P5 report [1] indicated the accelerator-based neutrino and rare decay physics research as a centrepiece of the US domestic HEP program. Operation, upgrade and development of the accelerators for the near-term and longer-term particle physics program at the Intensity Frontier face formidable challenges. Here we discuss accelerator physics and technology research toward future multi-MW proton accelerators.

MULTI-MW ACCELERATORS: ISSUES

The 2014 Particle Physics Project and Prioritization Panel (P5) provided an updated strategic plan for the US HEP program necessary to realize a twenty-year global vision for the field. The near-term program of HEP research at the Intensity Frontier continuing throughout this decade includes the long-baseline neutrino experiments and a muon program focused on precision/rare processes. It requires: a) double the beam power capability of the Booster; b) double the beam power capability of the Main Injector; and c) build-out the muon campus infrastructure and capability based on the 8 GeV proton source. The long-term needs of the Intensity Frontier community are expected to be based on the following experiments: a) long-baseline neutrino experiments to unravel neutrino sector, CP-violation, etc.; and b) rare and precision measurements of muons, kaons, neutrons to probe mass-scales beyond LHC.

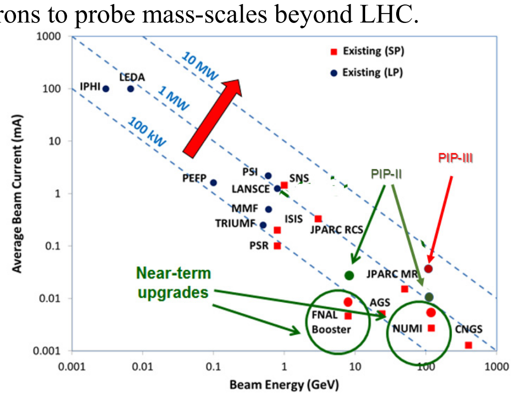

Figure 1: Accelerator beam power landscape.

Construction of the PIP-II SRF 800 MeV linac [2] is expected to address the near-term challenges. PIP-II will increase the Booster per pulse intensity by 50% and allow delivery 1.2 MW of the 120 GeV beam power from the Fermilab's Main Injector, with power approaching 1 MW at energies as low as 60 GeV, at the start of DUNE/LBNF operations ca 2023. It will also support the current 8 GeV program, including Mu2e, g-2, and the suite of short-baseline neutrino experiments; provide upgrade path for Mu2e and a platform for extension of beam power to DUNE/LBNF to multi-MW levels.

The P5 report sets longer-term sensitivity goals for the US long-baseline neutrino program. Those goals require an exposure of 600 kT*MW*yr (the product of the detector mass, beam power on target and exposure time). PIP-II offers a platform for the first 100 kt*MW*yr as in Table 1.

Table 1: Neutrino Physics Program Requirements

PIP-II Beyond PIP-II (mid-term)

	1st 10 years	2nd 10 years		
To Achieve :	100 kT-MW-year	500 kT-MW-year		
We combine :		Option 1	Option 2	Option 3
Mass	10 kT	50 kT	20 kT	10 kT
Power	1 MW	1 MW	2.5 MW	5 MW

The mid-term strategy towards an additional 500 kT*MW*yr after PIP-II depends on the technical feasibility of each option (see the Table) and the analysis of costs/kiloton of detector versus costs/MW of the beam power on target. To make an informed choice, extensive medium-term R&D on the effective control of beam losses in significantly higher current proton machines and on multi-MW targetry is needed [3].

There are two approaches for the multi-MW proton machine (currently tagged as PIP-III, see Fig. 1) – rapid cycling synchrotron and SRF linac. Attainment of the required beam intensities in synchrotrons is only possible with greatly reduced particle losses stemming from space-charge forces and coherent and incoherent beam instabilities. Modern SRF proton linacs can accelerate the needed currents but their cost/performance ratio needs to be significantly reduced compared to, e.g., the Project X facility [4] to be financially feasible. For both avenues, high-power targetry technology needs to be considerably enhanced to contribute to the cost and feasibility of any multi-MW superbeam facility.

In 2014-15, the HEPAP subpanel has developed *"A Strategic Plan for Accelerator R&D in the US"* [5] which recommends three R&D activities toward next step intensity frontier facility:

a) experimental studies of novel techniques to control beam instabilities and particle losses, such as integrable beam optics and space-charge compensation at IOTA ring at Fermilab;
b) exploration of the SRF capital and operating cost reductions through transformational R&D on high-Q cavities and innovative materials such as Nb-Cu composites, Nb films and Nb_3Sn; cavity performance upgrades through novel shapes and field emission elimination;

Abstract

Muon beams of low emittance provide the basis for the intense, well-characterised neutrino beams necessary to elucidate the physics of flavour at the Neutrino Factory and to provide lepton-antilepton collisions at energies of up to several TeV at the Muon Collider. The International Muon Ionization Cooling Experiment (MICE) will demonstrate ionization cooling, the technique by which it is proposed to reduce the phase-space volume occupied by the muon beam at such facilities. In an ionization-cooling channel, the muon beam passes through a material (the absorber) in which it loses energy. The energy lost is then replaced using RF cavities. The combined effect of energy loss and re-acceleration is to reduce the transverse emittance of the beam (transverse cooling). A major revision of the scope of the project was carried out over the summer of 2014. The revised project plan, which has received the formal endorsement of the international MICE Project Board and the international MICE Funding Agency Committee, will deliver a demonstration of ionization cooling by September 2017. In the revised configuration a central lithium-hydride absorber provides the cooling effect. The magnetic lattice is provided by the two superconducting focus coils and acceleration is provided by two 201 MHz single-cavity modules. The phase space of the muons entering and leaving the cooling cell will be measured by two solenoidal spectrometers. All the superconducting magnets for the ionization cooling demonstration are available at the Rutherford Appleton Laboratory and the first single-cavity prototype is under test in the MuCool Test Area at Fermilab. The design of the cooling demonstration experiment will be described together with a summary of the performance of each of its components. The cooling performance of the revised configuration will also be presented.

INTRODUCTION

Stored muon beams have been proposed as the source of neutrinos at the Neutrino Factory and as the means to deliver multi-TeV lepton-antilepton collisions at the Muon Collider [1]. In such facilities the muon beam is produced from the decay of pions produced in the bombardment of a target by a high-power proton beam. The tertiary muon beam occupies a large volume in phase space. To optimise the muon yield while maintaining a suitably small aperture in the muon-acceleration systems requires that the muon-beam phase space be reduced (cooled) prior to acceleration. The short muon lifetime makes traditional cooling techniques unacceptably inefficient when applied to muon beams. Ionization cooling, in which the muon beam is passed through material (the absorber) and subsequently accelerated, is the technique by which it is proposed to cool the beam [2, 3].

The experimental configuration with which the MICE collaboration will study ionization cooling has been revised in the light of the recommendations of the US Particle Physics Projects Prioritization Panel [4] and subsequent national and international reviews of the project. This process culminated in November 2014 when the project was formally rebaselined to deliver the configuration presented in Fig 1. The cooling cell is formed of a central lithium-hydride (LiH) absorber sandwiched between two "focus-coil" (FC) modules. Acceleration is provided by two 201 MHz cavities. The emittance is measured upstream and downstream of the cooling channel by solenoidal spectrometers. Further instrumentation upstream and downstream of the magnetic channel serves to select a pure sample of muons passing through the channel and to measure the phase at which each muon passes through the RF cavities. The schedule for the rebaselined project shows that the initial demonstration of ionization cooling will be performed by the end of US fiscal year 2017, while preserving MICE measurements at Step IV [5] scheduled in 2015.

This paper describes the novel lattice configuration adopted for the MICE demonstration of ionization cooling and presents its performance.

LATTICE FOR COOLING DEMONSTRATION

The lattice that will be used for the demonstration of ionization cooling is shown in Fig. 1. The lattice has been optimised to maximise the reduction in transverse emittance using the primary (central) and secondary LiH absorbers. With this configuration, a small betatron function at the position of the primary absorber can be achieved together with an acceptable beam size at the position of the 201 MHz cavities. The spectrometer solenoids (SSs) house high-precision scintillating-fibre

BEAM STUDIES FOR THE PROTON IMPROVEMENT PLAN (PIP) - REDUCING BEAM LOSS AT THE FERMILAB BOOSTER *

K. Seiya#, C. M. Bhat, D. E. Johnson, V. V. Kapin, W. A. Pellico, C. Y. Tan, R. J. Tesarek, FNAL, Batavia, IL 60510, USA

Abstract

The Fermilab Booster is being upgraded under the Proton Improvement Plan (PIP) to be capable of providing a proton flux of 2.25E17 protons per hour. [1] The intensity per cycle will remain at the present operational 4.3E12 protons per pulse, however the Booster beam cycle rate is going to be increased from 7.5 Hz to 15 Hz. One of the biggest challenges is to maintain the present beam loss power while the doubling the beam flux. Under PIP, there has been a large effort in beam studies and simulations to better understand the mechanisms of the beam loss. The goal is to reduce it by half by correcting and controlling the beam dynamics and by improving operational systems through hardware upgrades. This paper is going to present the recent beam study results and status of the Booster operations.

700 kW OPERATION

Fermilab is going to provide 700kW proton beam to the NOvA experiment. Booster is a 15 Hz resonant circuit synchrotron and accelerates proton beams from 400 MeV to 8 GeV. The required intensity in the Booster for NOvA is 4.3E12 ppp, the same as it was for 400 kW operation. [2] However, the cycle rate will be increased from ~7.5 Hz to 15 Hz to accommodate both NOvA and other users. The RF system and utilities are being upgraded to 15 Hz operations and are nearing completion. The plan is to start 15 Hz operations in FY15.

The beam loss limit has been set to 525W to allow workers to maintain all elements in the Booster tunnel without excessive radiation exposure. Figure 1 shows the historical beam loss in the Booster versus protons per hour. The total loss depends on the beam intensity.

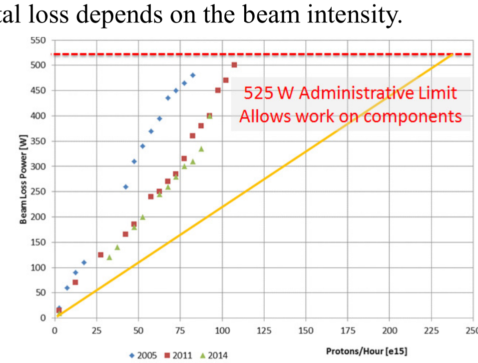

Figure 1: Beam power loss for 3 year operations (blue: 2005, red: 2011 and green: 2014).

*Work supported by Fermilab Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the United States Department of Energy.

#kiyomi@fnal.gov

The present operational beam intensity at injection is about 5E12 ppp and extraction is 4.5E12 ppp. The total energy loss is 0.075 kJ in one Booster cycle and hence 1150 W when the cycle rate is 15Hz. The loss has to be reduced to half by 2016. Figure 2 shows the intensity and loss during normal operations. Beam studies and upgrades that will be done to reduce the beam losses will be discussed in this paper.

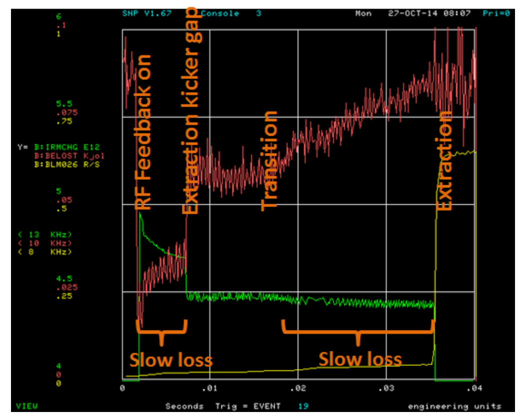

Figure 2: Beam intensity (green), energy loss (red) and extraction loss (yellow) signals.

COLLIMATORS

Two-stage collimator system which had horizontal and vertical primary collimators and three secondary collimators was installed in Booster in 2004. The primary collimators haven't been used and the secondary collimators have been used as single-stage collimators because the system never worked or implemented as designed which created much larger scatter than we expected from the simulation results.

Ramped corrector magnets, installed in the Booster during the 2007/2009 shutdowns, allowed us to control the beam orbit. In 2013, realignment of the main dipole magnets based on aperture scans and simulation increased aperture. RF Cogging changed the radial positon from cycle to cycle and it was replaced with Magnetic Cogging in 2015 which kept beam on central orbit. With the better understanding and control of the orbit, the operating parameters for the collimators will be optimized based on simulations and measurements.

A simulation was developed using MADX to replace an earlier STRUCT simulation and better optimize the material and thickness of the primary collimators. Assuming that 10^4 particles at the edge of horizontal

TEXTURED-POWDER BI-2212/AG WIRE TECHNOLOGY DEVELOPMENT*

J.N. Kellams[#], K. Damborsky[1], P.M. McIntyre, J. Vandergrifft, Texas A&M University, College Station, TX 77840, USA
L. Motowidlo, Supramagnetics, Inc., Plantsville, CT 06479, USA
N. Pogue, Paul Scherrer Institute, Villigen, Switzerland

Abstract

Progress is reported in developing of textured-powder Bi-2212 cores as a new approach to Bi-2212/Ag wire technology. The process builds upon earlier work in which Bi-2212 fine powder can be highly textured in its a-b plane orientation and fabricated into square-cross-section bars. The current work concerns an Enhanced Textured Powder (ETP) process, in which silver nanopowder is homogeneously mixed with the Bi-2212 powder. We report studies of the effect of the addition on the phase dynamics near melt temperature. ETP cores are being prepared for compounding into a billet to fabricate multi-filament wire.

STATE-OF-ART: OPIT BI-2212 WIRE

Bi-2212 is the only one of the high-temperature superconductors that has been successfully fabricated into multi-filament round wire. The state-of-art fabrication route is oxide-powder-in-tube (OPIT), in which fine-powder ~phase-pure Bi-2212 is loaded into Ag or Ag alloy tubes, the tubes are drawn, stacked, and re-drawn to make multi-filament wire [1]. The wire is then cabled and wound into final-form windings, and the windings are subjected to a 'partial melt' (PM) heat treatment at ~887 C during which the Bi-2212 solid particles are fully melted and then gradually re-crystallized. Several properties of this PM heat treatment lead to difficulties and until recently limited engineering current density to je~200 A/mm^2:

- The void space among particles in the powder becomes bubbles in the liquid (porosity), and capillary forces coalesce the bubbles to form macro-voids that can block current transport.
- The liquid is chemically aggressive, and etches along grain boundaries in the silver matrix. This creates dendritic bridging among filaments (good and bad).
- Connectivity among grains remains a limit to performance.

A dramatic improvement in performance to je~800 A/mm^2 was obtained last year using overpressure processing at ~5-10 MPa during the formation heat treatment [2,3]. However, overpressure processing remains a challenging proposition for long dipoles of a future hadron collider.

TEXTURED POWDER BI-2212

We began several years ago to develop an alternative method for fabricating the Bi-2212 cores for wire, in which fine-powder Bi-2212 was uniaxially pressed to form square-cross-section rods [4]. The pressing aligns the orientation of the a-b planes in the micaceous powder to a remarkable degree. The motivation of the development is to achieve connectivity among textured grains of Bi-2212 within a core using solid-phase diffusion at a temperature slightly below melt. Conductivity is 100x greater in the a-b plane than in the c-axis, In a non-melt heat treatment the transition to liquid is never made and the favorable texture is preserved.

The procedure is summarized in the photos of Fig. 1: fine-powder Bi-2212 is loaded into the 4x150 mm^2 aperture of a female forming die. The male die is inserted into the aperture above the powder, the die assembly is loaded into a hydraulic press, and the powder is compressed by 200 MPa. Bi-2212 is micaceous, and therefore the powder particles are flat flakes, and they naturally align when compressed to yield ~80 % texture as measured using X-ray diffraction [4].

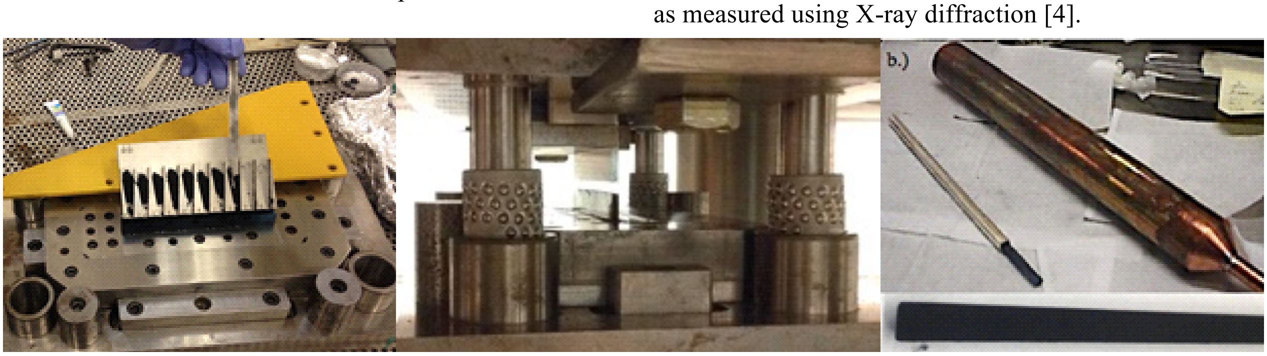

Figure 1: Fabrication of square-cross-section textured-powder Bi-2212 core a) load fine-powder Bi-2212 into rectangular die in oxygen atmosphere; b) compress to 200 MPa; insert bar into square hole in silver tube.

MAGNET DESIGN AND SYNCHROTRON DAMPING CONSIDERATIONS FOR A 100 TeV HADRON COLLIDER*

S. Assadi, D. Chavez, J. Gerity, T. Mann, P. McIntyre#, N. Pogue[1], A. Sattarov,
Texas A&M University, College Station, TX 77845, USA
M. Tomsic, Hypertech, Columbus, OH 43228 USA

Abstract

A conceptual design is presented for a 100 TeV hadron collider based upon a 4.5 T NbTi cable-in-conduit dipole technology. It incorporates a side radiation channel to extract synchrotron radiation from the beam channel so that it does not produce limitations from heating on a beam liner or gas load limits on collider performance. Synchrotron damping can be used to support 'bottom-up' stacking to sustain maximum luminosity in the collisions.

INTRODUCTION

The importance of extending searches for new gauge fields by another order of magnitude has led to the suggestion by CERN to develop a Future Circular Collider (FCC) that could contain a 100 TeV hadron collider [1]. We report on development of a particular design for such a collider, motivated by a systematic optimization of its two major cost drivers – the dual ring of superconducting magnets and the tunnel. The two drivers optimize oppositely as a function of the choice of magnetic field.

The tunnel cost depends strongly upon the choice of site for the collider. An optimum case was the siting of the SSC near Dallas, for which the actual cost for the 39 km of completed 4 m diameter tunnels was \$3,300/m (1992). The advance rate for the tunnels averaged 40 m/day, the fastest rate of advance on any recorded large-bore tunnel project in history [2]. The favourable cost was the result of a favourable choice of rock: the Austin Chalk and Taylor Marl formations permit rapid excavation using tunnel boring machines and are self-supporting so that lining can be installed in coordination with excavation schedule [3].

The same site could accommodate a circular tunnel up to 270 km circumference and still remain entirely within those favourable rock strata. A 270 km circumference would require B_0 ~4.5 T to produce hadron collisions at 100 TeV. The tunnel cost today for a 100 TeV collider can be estimated from the SSC tunnel costs using the Construction Cost Index [4]: (270 km)(\$3,300/m)(2.04) = \$1.8 billion. Since this cost is almost certainly less than that of a superconducting magnet ring, it is reasonable to take 270 km as a working choice for collider design and to optimize the design of a superconducting dipole suitable for 4.5 T operating field.

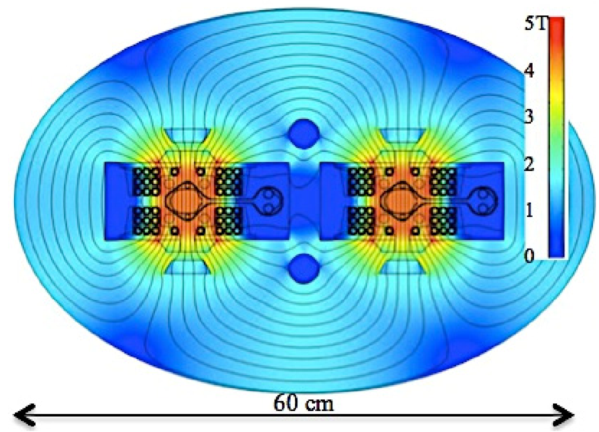

Figure 1: 4.5 T dipole for 100 TeV hadron collider.

4.5 T CABLE-IN-CONDUIT DIPOLE

Figure 1 shows the magnetic design of a 4.5 T dual dipole suitable for use in a 100 TeV hadron collider. The design uses a block winding of round NbTi cable-in-conduit (CIC). The design is inspired by the simplicity of the CIC dipoles that were developed at JINR for use in SIS-100 and FAIR [5]. Each dipole is configured in a C geometry so that the horizontal fan of synchrotron radiation exits the beam tube through a slot aperture and is absorbed in a separately cooled radiation channel as shown in Figure 2.

The main parameters of the dipole are summarized in Table 1. For a dipole field strength of 4.5 T, the C geometry shown requires no more superconductor than would a conventional dipole. A main benefit of the CIC conductor is that it simplifies the fabrication and support of end windings, as shown in Figure 2.

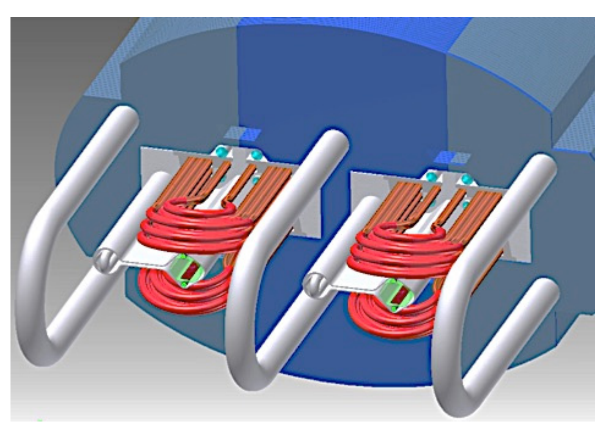

Figure 2: View of end windings in the CIC dipole.

OPTIMIZATION OF ORBITS, SRF ACCELERATION, AND FOCUSING LATTICE FOR A STRONG-FOCUSING CYCLOTRON

K. Melconian#, J. Gerity, J. Kellams, P. M. McIntyre, A. Sattarov, S. Assadi, Texas A&M University, College Station, TX 77845 USA
N. Pogue, Paul Scherrer Institute, Villigen, Switzerland

Abstract

The strong-focusing cyclotron is an isochronous sector cyclotron designed to accelerate >10 mA CW beams of protons and ions up to >500 MeV/u with low loss and high efficiency. Superconducting RF cavities are used to provide enough energy gain per turn to fully separate orbits, and arc-shaped beam transport channels in the sector dipole apertures provide strong focusing of all orbits. A design methodology is being developed to optimize the sector dipoles, the focal lattice, and the SRF cavities so that betatron tunes can be locked to favorable operating point. Provision is made for correction of dispersion and chromaticity. The methodology will provide a framework on which we can then proceed to study and optimize the nonlinear beam dynamics for high-current transport.

INTRODUCTION

The Accelerator Research Laboratory at Texas A&M University is developing a strong-focusing cyclotron (SFC) for applications requiring high-current beams or micro-emittance beams [1]. Applications include an 800 MeV, >10 mA proton driver for accelerator-driven fission to destroy the transuranics and burn to completion the depleted uranium in spent nuclear fuel [2], a 100 MeV, >10 mA p/α driver for cost-effective production of medical isotopes [3], and a 100 MeV spallation driver for fast neutron damage studies [4].

A 100 MeV SFC is shown in cutaway in Figure 1. It contains 4 superconducting RF cavities [5] that provide enough energy gain to fully separate successive orbits (Δr>6 cm). Each sector dipole consists of a warm-iron flux return with a pair of cold-iron flux plates suspended in the mid-plane gap to define the magnetic field B(r) required for isochronicity [6]. An array of arc-shaped beam transport channels (BTCs, shown as blue in Figure 1) are located in the aperture between the flux plates, each aligned to define the equilibrium trajectory for one orbit in that sector [7]. Each BTC contains an F-D quadrupole doublet and a dipole correction winding, all fabricated as wire-wound superferric windings on a square beam channel. 80% of the 6 cm orbit spacing is available for particle trajectories.

In a previous study [8], we made a first design for a 100 MeV SFC and simulated several aspects of single-bunch dynamics of high-current proton bunches. That study validated that the SFC should be capable of accelerating >10 mA of CW beam without limitations from the effects that are known to limit beam current at PSI.

*This work supported by the George and Cynthia Mitchell Foundation.
#KarieMelconian@tamu.edu

The SFC design builds upon an earlier design for a separated-orbit cyclotron, TRITRON [9], which also used SRF cavities and quadrupole channels. Although TRITRON successfully demonstrated transport of beam through several orbits, the orbit separation was small (10 mm) and the fraction of aperture with usable field quality for orbits was ~40%. In order to avoid this limitation, the beam transport channels in the SFC have been designed with > 6 cm orbit separation and 4 cm good-field aperture in each BTC.

Table 1: Main Parameters of the SFC Design

Proton energy (inj/ext)	13/100	MeV
RF frequency	117	MHz
Orbit radius (inj/ext)		m
Dipole field (inj/ext)	0.60/0.45	T

BEAM DYNAMICS OPTIMIZATION OF FRIB FOLDING SEGMENT 1 WITH A SINGLE TYPE OF REBUNCHER CRYOMODULE

Z. He*, Y. Zhang, T. Xu, Q. Zhao, M. Ikegami, F. Marti
FRIB, Michigan State University, USA

Abstract

The Facility for Rare Isotope Beams (FRIB) uses a charge stripper in folding segment 1 to increase the number of charge states of particles to enhance the acceleration efficiency. To control possible emittance growth after the charge stripper, the 3-dimensional on-stripper beam size should be as small as possible. The original 2-cavity-HWR (HWR stands for half wave resonator) rebuncher cryomodule is responsible for the longitudinal focusing before stripper. In order to accept and transport the beam downstream to linac segment 2, another kind of 3-cavity-QWR (QWR stands for quarter wave resonator) rebuncher cryomodule is baselined after the stripper. However, two kinds of cryomodules would increase the cost in design, therefore would be quite inefficient. In this paper, the FRIB lattice with only single-type 4-cavity-QWR rebuncher cryomodule in folding segment 1 is discussed. Positions of lattice elements are adjusted to accommodate the new type of cryomodule. Beam dynamics is optimized to meet the on-stripper beam requirement. The lattice is then adjusted and rematched.

INTRODUCTION

In the FRIB [1] baseline design of linac segment 1 (LS1) and folding segment 1 (FS1), there are two types of rebuncher cryomodules, one type is the 2-cavity-HWR rebuncher, and another is the 3-cavity-QWR rebuncher.And There are two rebuncher cryomodules for each type, two 2-cavity-HWR rebunchers and two 3-cavity-QWR rebunchers. The baseline design aims at decreasing the total number of RF cavities, however, further cost optimization favored the choice of decreasing the type of rebuncher cryomodules to a single type 4-cavity-QWR rebuncher, which can save design and manufacturing cost. A proposal was made to reduce the type of rebunchers from 2 to 1. And the feasibility of the new lattice with new type of rebuncher from beam dynamics point of view is studied and described in this paper.

NEW LATTICE DESIGN CONFIGURATION

This section mainly provides information on the new type of 4-cavity-QWR rebuncher and the two criteria of lattice design:

New Type of 4-cavity-QWR Rebuncher

Some pre-study shows that a single type of 4-cavity-QWR rebuncher is capable of replacing the two types of rebunchers. The drawing of the new 4-cavity-QWR rebuncher can

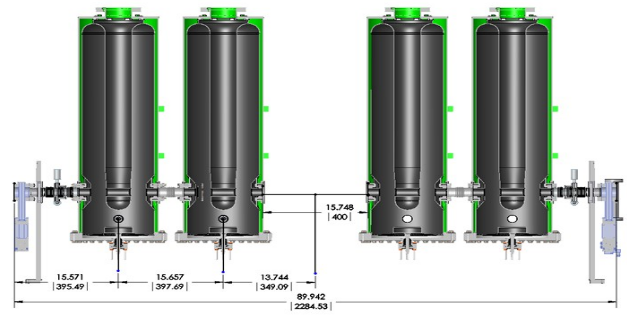

Figure 1: Mechanical drawing of the new 4-cavity-QWR rebuncher.

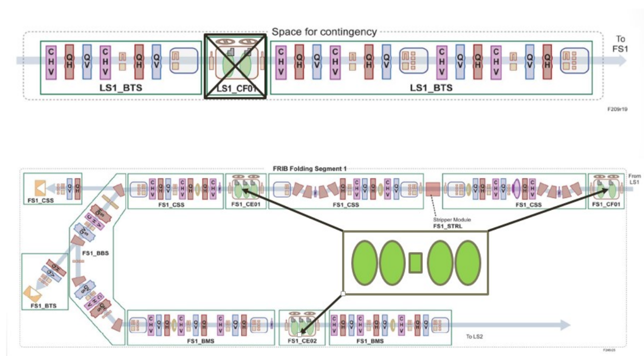

Figure 2: New lattice design with a single type of 4-cavity-QWR rebuncher (Criterion 1) [2].

be seen in Fig. 1. There are 4 $\beta = 0.085$ QWRs in one rebuncher cryomodule, and a 0.4 m reserved space at the center of the cryomodule for heat exchanger. The total length of the new rebuncher cryomodule is 2.285 m.

New Lattice Design Criterion 1

The first criterion of a new lattice design with a single type 4-cavity-QWR rebuncher can be seen in Fig. 2. The 2-cavity-HWR rebuncher LS1-CF01 is deleted, and the remaining rebunchers FS1-CF01, FS1-CE01, FS1-CE02 are changed into the 4-cavity-QWR rebuncher. In order to preserve cryogenic port position, center position of each rebuncher cryomodule is fixed.

The original 2-cavity-HWR rebuncher is 1.243 m long and the 3-cavity-QWR rebuncher is 1.589 m long, both kinds of old rebunchers are smaller in size. In order to accommodate the new rebuncher, lattice elements should be shifted around and drift spaces must be compressed to make room for the new rebuncher.

BEAM DYNAMICS EFFECTS OF HIGH ORDER MULTIPOLES IN NON-AXISYMMETRIC SUPERCONDUCTING RF CAVITIES

Z. He*, Y. Zhang, J. Wei, FRIB, Michigan State University, USA

Abstract

Non-axisymmetric superconducting RF cavities have been widely used in accelerator facilities. Because of the geometry, electric and magnetic multipole components, including steering terms, quadrupole terms, and higher order terms, would arise and have potential effects on beam dynamics. In this paper, we start with a simple linac periodic structure to study the effects of higher order terms. The action is defined as a figure of merit to quantify the effects. After that, we move to a more realistic situation of FRIB linac segment 1 (LS1). Multipole terms of quarter wave resonators (QWRs) are firstly calculated using multipole expansion scheme. Then, the scheme is tested using the FRIB linac lattice with QWRs, and the effects of higher order terms on FRIB LS1 are estimated.

INTRODUCTION

The non-axisymmetric geometry of the superconducting RF cavities would produce all kinds of multipole components. In 1992, Marco Cavenago firstly described dipole and quadrupole terms in a non-axisymmetric QWR [1]. Then, Alberto Facco came up with an analytical approach to calculate steering terms in 2001 [2]. Later works [3–5], based on the idea of field multipole expansion, made several attempts to study the cavity multipole components under different scenarios. Even though efforts have been made to extract the higher order terms by multipole expansion, the beam dynamics effects coming from it have never received systematic study. In this paper, we are going to develop a systematic scheme to estimate beam dynamics effects coming from multipole components, and the scheme is then applied to FRIB LS1.

FIGURE OF MERIT

It is well known that the particle action, described in Eq.1, is a constant for a linear lattice with no error.

$$J = \frac{1}{2\beta}[y^2 + (\beta y' + \alpha y)^2]. \tag{1}$$

The transformation between action-angle coordinate system and x-x' phase space coordinate system is decribed in Eq.2. It can be easily found out that, the beam envelope of a beam bunch can be determined by the beta-function and the maximum particle action.

$$\begin{cases} y = \sqrt{2\beta J}\cos\psi \\ y' = -\sqrt{\frac{2J}{\beta}}[\sin\psi + \alpha\cos\psi] \end{cases} \tag{2}$$

Therefore, particle action can be chosen as the figure of merit [6–8].

ACTION KICK FOR SINGLE HIGH ORDER TERMS

Particle action is a constant for perfect linear lattice, however, when a non-linear high order kick occurs, particle action changes. The action kick coming from high order terms can be estimated by Eq.3 [7], where J represents particle action, $B_0\rho$ is the magnetic rigidity. B_{ref} and R_0 are reference magnetic field and radius. n is the multipole order. a_n is multipole coefficient, which can be both normal term or skewed term.

$$\frac{\Delta J_{x,y}}{J_{x,y}} \sim \frac{(2J)^{\frac{n-1}{2}}}{4\pi B_0\rho}\frac{B_{ref}}{R_0^n}\int a_n\beta_{x,y}^{\frac{n+1}{2}} \tag{3}$$

Subsequently, we take the specific example of sextupole to derivate the maximum action kick. Assume the sextupole kick is small, and take horizontal direction as an example, we can get Eq.4:

$$\begin{aligned}\Delta J_x &\sim \sqrt{2\beta_x J_x}\sin\psi_x\cdot g_2(2\beta_x\cos^2\psi_x - 2\beta_y J_y\cos^2\psi_y) \\ &\leq 2\sqrt{2}\beta_x^{\frac{3}{2}}J_x^{\frac{3}{2}}g_2\sin\psi_x\cos^2\psi_x\end{aligned} \tag{4}$$

Furthermore, we test Eq.4 using a simple lattice, which can be seen in Fig. 1(a). A sextupole kick is induced at 4.28 m with strength $g_2 = 0.05$. The red-plus line indicates the predicted maximum action after sextupole kick, which agrees pretty well with particle tracking result. Fig. 1(b) shows the predicted maximum action kick vs sextupole strength. Blue line is the result coming from 10000 particle tracking. The green star is the result coming from the model. We can see that, two results agree with each other pretty well.

ACTION KICK FOR MULTIPLE HIGH ORDER TERMS

Reference [7] has pointed out that, if phase advance can be neglected, multiple high order terms, after scaled by β-function, can be added up directly. However, in a superconducting linac, higher order multipoles caused by RF cavities would usually separate with each other by a certain phase advance. As a result, high order terms would not cancel out even with same absolute value and opposite sign.

We derive the formulism for multiple high order kicks separated by a non-negligible phase advance. We start with magnetic field and electric field can be treated similarly. We'll still based on the idea of small kick approximation and

NONLINEAR OPTICS OF SOLENOID MAGNETS*

Steven M Lund†
Facility for Rare Isotope Beams, Michigan State University, East Lansing, MI , USA 48824

Abstract

Solenoid magnets are often employed for focusing in low energy beam transport lattices in the front-end of a machine. We derive a relatively simple analytic formula for the nonlinear angular focusing kick imparted to particles traversing the solenoid. Few approximations are made. The formula provides a clear expression of the well-known *Scherzer's Theorem* from electron optics that all nonlinear terms of an axisymmetric magnetic field provide more focusing and that nonlinear terms are non-removable. The formula suggests that for beam transport, little can be done to reduce nonlinearities in solenoid-type magnets other than take a simple design without abrupt changes as a function of axial coordinate and appropriately choose the aspect ratio (characteristic bore radius over axial length) of the magnet system and the beam filling factor within the aperture to limit nonlinear effects. Illustrative applications of the formula characterize nonlinear focusing effects in iron-free and iron type solenoid magnets.

INTRODUCTION

Solenoid magnets are appealing due to their simple field structure in idealized form. However, as the level of detail of the model description increases, the cross-coupled structure of the equations of motion describing particle focusing in a solenoid become increasingly complicated and difficult to analyze. In this study, we derive a closed analytic formula for the radial angular impulse imparted to a particle traversing an axisymmetric solenoid magnet including both linear and *all* nonlinear field components. The only approximation made is the paraxial approximation. The formula applies to particles with arbitrary (conserved) canonical angular momentum. This is important because in many cases particles are born from a source immersed in a magnetic field, and consequently, the particles can have finite canonical angular momentum. Near the source, particles are typically transported downstream using an axisymmetric solenoid focusing lattice where the particle canonical angular momentum is conserved. The surprisingly simple formula obtained for the focusing impulse provides insight on the nonlinear focusing properties of solenoid magnets. The formula is applied to better understand nonlinear focusing effects in solenoids, both as the radius of the particle within the magnet aperture increases and as the aspect ratio and structure of the solenoid is varied. The formula should be possible to exploit in future studies to estimate how statistical rms beam emittance (quality) evolves during transport in a nonlinear solenoid lattice.

DERIVATION

We consider the a single particle of charge q and mass m evolving in an axisymmetric ($\partial/\partial\theta = 0$) applied solenoid field $\mathbf{B}^a$ and employ r,θ,z cylindrical-polar coordinates. Because the magnetic field only bends particle trajectories, the kinetic energy of the particle is constant, or equivalently, the exact relativistic gamma factor ($\gamma = 1/\sqrt{1-\beta^2} = \text{const}$) and beta factors ($\beta = \text{const}$) are conserved. The applied magnetic field of the solenoid is assumed axisymmetric, so the particle evolves with a conserved angular momentum $P_\theta \equiv [\mathbf{x}\times(\mathbf{p}+q\mathbf{A})]\cdot\hat{\mathbf{z}} = r(p_\theta + qA_\theta) = \text{const}$. Here, $\mathbf{x}$ and $\mathbf{p} = m\gamma\dot{\mathbf{x}}$ are the coordinate and mechanical momentum of the particle, $\dot{} \equiv \frac{d}{dt}$ denotes a derivative with respect to the time t, and $\mathbf{A}$ is the vector potential that generates the applied field (i.e., $\mathbf{B}^a = \nabla\times\mathbf{A}$). Applying Stoke's theorem to the expression for P_θ obtains the so-called Bush's theorem expression [1, 2]

$$P_\theta = \gamma m r^2\dot{\theta} + \frac{q\psi}{2\pi} = \text{const.} \qquad (1)$$

Here, $\psi = \int_r d^2x\ B_z^a(r,\theta) = \oint_r \mathbf{A}\cdot d\ell = 2\pi r A_\theta$ is the magnetic flux bounded by a circle of radius r. In general, one cannot take $P_\theta = 0$ for orbits that do not go through the origin $r = 0$ (i.e., P_θ cannot in general be zeroed by coordinate choice for all particles) which corresponds to the axis of symmetry of the solenoid.

The static field Maxwell equations $\nabla\cdot\mathbf{B}^a = 0$ and $\nabla\times\mathbf{B}^a = 0$ allow $\mathbf{B}^a = \hat{\mathbf{r}}B_r(r,z) + \hat{\mathbf{z}}B_z(r,z)$ to be expanded as [1, 2]

$$\begin{aligned} B_r(r,z) &= \sum_{\nu=1}^{\infty} \frac{(-1)^\nu}{\nu!(\nu-1)!}\frac{\partial^{2\nu-1}B_{z0}(z)}{\partial z^{2\nu-1}}\left(\frac{r}{2}\right)^{2\nu-1}, \\ B_z(r,z) &= \sum_{\nu=0}^{\infty} \frac{(-1)^\nu}{(\nu!)^2}\frac{\partial^{2\nu}B_{z0}(z)}{\partial z^{2\nu}}\left(\frac{r}{2}\right)^{2\nu}, \end{aligned} \qquad (2)$$

where $B_{z0}(z) \equiv B_z(r=0,z)$ is the on-axis field. Thus, the 3D field of the axisymmetric magnet with all nonlinear terms can be regarded as specified by the on-axis ($z = 0$) field. The lowest-order terms in the sums in Eq. (2): $B_r \simeq -\frac{1}{2}\frac{\partial B_{z0}}{\partial z}r$ and $B_z \simeq B_{z0}$ provide linear focusing. All higher terms provide nonlinear focusing [1, 2].

The radial component of the Lorentz force equation for the particle evolving in the magnetic field $\ddot{\mathbf{x}} = [q/(\gamma m)]\mathbf{x}\times\mathbf{B}^a$ can be expressed as

$$\ddot{r} = r\dot{\theta}^2 - \frac{qr\dot{\theta}B_z^a}{\gamma m}. \qquad (3)$$

UNIQUE ACCELERATOR INTEGRATION FEATURES OF THE HEAVY ION CW DRIVER LINAC AT FRIB*

Y. Yamazaki#, N. Bultman, M. Ikegami, F. Marti, E. Pozdeyev, J. Wei, Y. Zhang, Q. Zhao, FRIB/MSU, East Lansing, MI 48824, USA
A. Facco, INFN-Laboratori Nazionali di Legnaro, Legnaro (Padova), Italy and FRIB/MSU, East Lansing, MI 48824, USA

Abstract

The FRIB driver linac is a front runner for the future high power hadron linacs, making full use of CW, superconducting acceleration from very low β. accelerator driven nuclear waste transmutation system (ADS), international fusion material irradiation facility (IFMIF), Project-X type proton accelerators for high energy physics and others may utilize the technologies developed for the design, construction, commissioning and power ramp up of the FRIB linac. Although each technology has been already well developed individually (except for charge stripper), their integration is another challenge. In addition, extremely high Bragg peak of uranium beams (several thousand times as high as that of proton beams) gives rise to one of the biggest challenges in many aspects. This report summarizes these challenges and mitigations, emphasizing the commonly overlooked features.

INTRODUCTION

The continuous wave (CW) heavy ion linac with a beam energy over 200 MeV/u and a beam power of 400 kW for Facility for Rare Isotope Beams (FRIB) [1] is a driver to produce various isotope species for nuclear physics study. The linac is to accelerate all the stable ions from proton to uranium by making full use of superconducting (SC) RF acceleration technology from a very low beam energy of 0.5 MeV/u. The linac is to use 330 SC cavities with four different types; β = 0.041 quarter wave resonator (QWR), β = 0.085 QWR, β = 0.29 half wave resonator (HWR) and β = 0.53. Most of the SC cavities are housed together with focusing SC solenoid magnets in 44 acceleration cryomodules (CMs), while the remaining 14 SC cavities in 5 rebuncher (matching) CMs (Recently, the rebuncher CMs and cavities therein were further optimized [2]). Needless to say, manufacturing of a great number of SC cavities and CMs of different kinds is one of the biggest challenges in this project. Also, it should be emphasized that the FRIB CMs equipped with the focusing SC solenoids and beam position monitors (BPMs) are much more complicated than those of SNS linacs and many electron SC linacs without the solenoids and BPMs inside. Furthermore, each of the FRIB CMs is equipped with many fundamental mode input couplers (FPCs) and each solenoid is with two SC corrector steering dipoles. The development of these FRIB SC technologies is detailed in Ref. [3, 4].

This driver is the first heavy ion linac to join the beam power front of an order of 1 MW as mentioned in Ref. [5], in which beam physics challenge in the FRIB driver linac is detailed. This article is a continuation of Ref. [5] in a sense that accelerator physics integration features of the FRIB driver linac is discussed.

MPS AND BEAM DUMPS

In order to contrast heavy ion beams against proton ones, take uranium beams as the most extreme example. One of the striking difference of the uranium beams from proton ones is their extremely high Bragg peak, that is, energy loss density dE/dx in materials. The uranium one is typically by several thousand times [5] as high as the proton one, depending upon their energy. The range is by several ten times smaller [5]. As a result heavy ion beam loss damage is significantly larger than proton one by this factor, while the radiation arising from the uranium beam loss is by several ten times lower than that of the proton one. The latter implies that the uranium beam loss is very hard to detect, in particular, at an energy below 100 MeV/u. It is one of the biggest challenges how to protect accelerator components from the beam impinge damage. For this reason, Machine Protection System (MPS) [6, 7] implements a redundant, multi-layer scheme, responding to fast events and slow losses.

The extremely high beam loss energy density gives rise to many technical challenges in the FRIB, like liquid lithium charge stripper [8], the target [9], the charge selector and others. In order to show the difficulty arising from high beam damage, take the beam dump design here as an example.

The linac beam dump is used for beam commissioning and beam tuning. For this purpose, we are going to use a beam pulse length of 50 μs and a repetition rate lower than 1 Hz in most cases in order to minimize the beam dump cost. However, after the commissioning and/or tuning, we have to increase the beam duty to CW. The difference between the 50 μs beam and the CW beam is the beam loading. Since the stored energy of SC cavities is very large, no beam loading can be observed with the 50 μs beam. In order to ramp up the beam to CW, we need to confirm the beam loading well compensated with low level RF control system. Since the filling time of the FRIB SC cavities is typically of 5 ms, we need the beam with a pulse length several times as long as this filling time, like 20 ms, in order to confirm the beam loading

DESIGN OF A COMPACT ALL-PERMANENT MAGNET ECR ION SOURCE INJECTOR FOR REA AT THE MSU NSCL*

Alfonse N. Pham†, Daniela Leitner, Patrick Glennon, Jack Ottarson, Don Lawton, Mauricio Portillo, Guillaume Machicoane, John Wenstrom, Andrew Lajoie
Michigan State University National Superconducting Cyclotron Laboratory
East Lansing, MI 48824-1321, USA

Abstract

The design of a compact all-permanent magnet electron cyclotron resonance (ECR) ion source injector for the ReAccelerator Facility (ReA) at the Michigan State University (MSU) National Superconducting Cyclotron Laboratory (NSCL) is currently being carried out. The ECR ion source injector will augment the electron beam ion trap (EBIT) charge breeder as an off-line stable ion beam injector for the ReA linac. The objective of the ECR ion source injector will be to provide CW beams of heavy ions from hydrogen to masses up to ^{136}Xe within the ReA charge-to-mass ratio (Q/A) operational range from 0.2 to 0.5. The ECR ion source will be mounted on a high-voltage platform that can be adjusted to provide the required 12 keV/u injection energy into a room temperature radio-frequency quadrupole (RFQ) for further acceleration. The beam line consists of a 30 kV tetrode extraction system, mass analyzing section, and optical matching section for injection into the existing ReA Low Energy Beam Transport (LEBT) line. The design of the ECR ion source and the associated beam line are discussed.

INTRODUCTION

The Facility for Rare Isotope Beams (FRIB) is currently under construction at MSU [1]. FRIB consists of a heavy ion driver linac, target station to produce rare isotope, and fragment separator to purify the beam to be delivered to three large experimental areas for rare isotope nuclear physics research. The fast beam experimental area where the shortest-lived rare isotope beams (RIB) at energies >100 MeV/u are sent, and a stopped beam experimental area where RIBs are thermalized either in a gas cell or a cyclotron gas stopper before being transported to the trap and laser spectroscopy area or re-accelerated for low energy nuclear physics experiments with ReA [2]. Utilizing the modularity of the superconducting RF cyromodules, ReA currently re-accelerate thermal heavy ion beams from the gas stopper to 0.3–3 MeV/u for Q/A of 0.25 and up to 6 MeV/u for Q/A of 0.5. In its final configuration, ReA will reach kinetic energies of up to 12 MeV/u for the heaviest ions (e.g. ^{238}U) and 24 MeV/u for light ions (e.g. ^{4}He).

With the addition of an all-permanent magnet off-line ECR ion source, the existing beam delivery capabilities at ReA will be significantly expanded by providing a source of continuous-wave stable heavy ion beams for commissioning, beam preparation, detector testing, and stable beams experiments. The robust ECR ion source will be integrated with existing facility capabilities to allow for independent tuning of the linac with stable beams while optimizing the EBIT charge breeder during radioactive ion beam development for experiments.

Beam Current	~ 1–3 $e\mu$A
Optical Matching	$\alpha_x = 0.7$, $\beta_x = 8.4$ m/rad
Conditions	$\alpha_y = -1.1$, $\beta_y = 0.9$ m/rad

ECR ION SOURCE DESIGN

The design of the all-permanent magnet ECR ion source presented is based on a reference design developed at CEA-Grenoble, and later built for Oak Ridge National Laboratory and SOLAIRE [3]. The design allows for a compact, cost-effective ECR ion source with low power consumption that is optimized for the production of multiply charged heavy ions. A cross-sectional diagram of the ECR ion source is shown in Fig. 1 and Table 1 summarizes the injector requirements. The ECR ion source comprises of the injection, magnetic confinement, and extraction system to confine ions long

HIGH INTENSITY SOURCE OF He NEGATIVE IONS

V. Dudnikov #, Muons, Inc., Batavia, IL 60510, USA, V. Morozov, Jefferson Laboratory, Newport News, VA 23606, USA and A. Dudnikov, BINP, Novosibirsk, Russia

Abstract

He- ion can be formed by an attachment of additional electron to the excited metastable 2^3S_1 He atom. Electron affinity in this metastable He^- ion is A=0.08 eV with excitation energy 19.8 eV. Production of He^- ions is difficult because the formation probability is very small but destruction probability is very high. Efficiency of He- ions generation was improved by using of an alkali vapor targets for charge exchange He^- sources. Low current He^- beams were used in tandem accelerators for research and technological diagnostics (Rutherford scattering). The development of high-intensity high-brightness arc-discharge ion sources at the Budker Institute of Nuclear Physics (BINP) has opened up an opportunity for efficient production of more intense and more brighter He- beam which can be used for alpha particles diagnostics in a fusion plasma and for realization of a new type of a polarized $^3He^−$ ion source. This report discusses the high intense He- beams production and a polarized $^3He^−$ ion source based on the large difference of extra-electron auto-detachment lifetimes of the different $^3He^−$ ion hyperfine states.

INTRODUCTION

The parameters of the Electron-Ion Collider projects that are being actively developed by BNL and JLab are discussed in Ref. [1]. Advanced spin control techniques used in these projects should provide very good polarization preservation including ^3He and D polarization. This means that the final beam polarization after acceleration will be determined by the beam polarization extracted from the ion source which must be made as high as possible. Polarized ^3He ions are particularly important for efficient electron-ion collider operation.

A review of the polarized ^3He ion beam production has been presented in Ref. [2]. Early ion sources have polarized ^3He ion beam intensities of nA scale. Since the efficiency of experiments is proportional to the square of the polarization, P^2, having the highest possible degree of polarization is very important. For polarized $^3He^{++}$ production, it was proposed to use ionization of nuclear-polarized $^3He^0$↑ by electrons in an electron beam ion source (EBIS) [2, 3]:

$$^3He^0\uparrow + e \rightarrow {}^3He^{++}\uparrow + 3e$$

The expected beam intensity is about $2.5\cdot10^{13}He^{++}$/pulse with nuclear polarization P >70 %.

For polarized $^3He^{++}$ production, one can also use the high-current arc-discharge source (developed at BINP [4] and used in the BNL OPPIS upgrade [5]) with pulsed injection of nuclear-polarized $^3He^0$↑ atoms (polarized by optical pumping) into an arc-discharge plasma source [6]. For protection of the nuclear polarization during the step-by-step ionization, a strong magnetic field can be used.

Another proposed technique [7] is to use resonant charge-exchange ionization of polarized $^3He^0$↑ in a storage tube by an incident $^4He^+$, $^4He^{++}$ plasma jet produced by an arc-discharge ion source [4]:

$$^3He^0\uparrow + {}^4He^{++} \Rightarrow {}^3He^{++}\uparrow + {}^4He^0$$

The proposed methods of polarized ^3He ion production were discussed but were never tested.

POTENTIAL OPTIONS FOR PRODUCTION OF POLARIZED $^3He^-$ IONS

An intense beam of polarized $^3He^−$ ions could be produced using the high-brightness arc-discharge ion source with geometrical focusing and low gas consumption developed at BINP and used in the BNL OPPIS upgrade [8]. Earlier this arc-discharge source was used for high-intensity (12 mA) $He^−$ beam production [9]. A schematic of this device is shown in Fig. 1. An intense high-brightness flow of He^+ ions is generated in the arc-discharge source (1) and formed into an ion beam by a multi-grid multi-slit flat extraction system of 4 cm in diameter. This intense space-charge-compensated beam is focused by a magnetic lens (2) into a sodium jet charge-exchange target (3). A part of He^+ ions captures two electrons from Na atoms and forms metastable $He^−$ ions. The beam of He^- ions is deflected from the more intense beams of He^+ and He^0 in an analyzing magnet (4) and detected by a FC (5). The secondary electron emission is suppressed by a suppression electrode. The beam profiles are controlled by profile monitors (6) and (7). Under the optimal conditions at the energy of 12 keV, up to 1.5% of He^+ ions were converted into He^- producing a 12 mA $He^−$ beam. The estimated He^+ beam intensity transferred to the FC is ~ 0.8 A. With a modern spherical multi-aperture extraction system, it is possible to have He^+ beam with an intensity of ~ 2 A.

With a 2 A $^3He^+$ beam current, up to 0.1 A of a $^3He^−$ beam can be produced by charge exchange in an alkali vapors target yielding up to 2 mA of highly polarized $^3He^−$ ions [4, 6].

A pulsed gas valve [10] can provide low gas consumption, which is important because ^3He gas is very expensive. The basic idea of this proposal can be traced back to the alpha particle diagnostics that is being developed for the ITER project in France.

Abstract

Existing RF Ion Sources for accelerators have specific efficiencies for H^+ and H^- ion generation ~3- 5 mA/cm^2 kW, where about 50 kW of RF power is typically needed for 50 mA beam current production. The Saddle Antenna (SA) SPS described here was developed to improve H^- ion production efficiency, reliability and availability. In SA RF ion source the efficiency of positive ion generation in the plasma has been improved to 200 mA/cm^2 kW. After cesiation, the current of negative ions to the collector was increased from 1 mA to 10 mA with RF power ~1.5 kW in the plasma (6 mm diameter emission aperture) and up to 30 mA with ~4 kW RF. Continuous wave (CW) operation of the SA SPS has been tested on the test stand. The general design of the CW SA SPS is based on the pulsed version. Some modifications were made to improve the cooling and cesiation stability. CW operation with negative ion extraction was tested with RF power up to ~1.2 kW in the plasma with production up to Ic=7 mA. Long term operation was tested with ~0.8 kW in the plasma with production of I_c=5 mA, I_{ex} ~15 mA. A stable long time generation of H^- beam without degradation was demonstrated in RF discharge with AlN discharge chamber.

INTRODUCTION

Development of the saddle antenna RF surface plasma source (SA RF SPS) was proposed for improve efficiency of H- ion production and improve SPS reliability and availability [1-6]. RF SPS for accelerators have the efficiency of H- ion generation ~1 mA/kW and RF power ~ 50 kW is needed for 50 mA beam current production [7-8]. The high RF power required for the sources as well as triggering of the pulsed discharge can create problems for very long term operation. In tested version of SA RF SPS the specific efficiency of positive ion generation was increased to ~200 mA/ cm^2 kW and a specific efficiency of H- production was increased up to ~ 20 mA/cm^2 kW from previous ~2.5 mA/ cm^2 kW.

The total efficiency of the surface plasma produced fraction of the H^- beam is a product of the probability of secondary emission of H^- caused by plasma bombardment of the collar surface around the emission aperture, the probability of extraction of emitted H^-, and the rate of bombarding plasma flux [9-12].The coefficient of secondary emission of H^- is determined by surface properties (proper cesiation) and the spectrum of the plasma particles bombarding the collar surface around the emission aperture.

The cesiation was improved recently [7] and appears to be nearly optimal. The probability of extraction of H^- emitted from the collar surface is dependent on the surface collar shape [9-11], which was optimized recently to improve H^- emission [6]. The problem of efficient plasma generation is being addressed by the development of new RF plasma generators with higher plasma generation efficiency and better concentration of useful plasma flux onto the internal surfaces of the collar around the emission aperture for lower RF power [1-6]. In this project, we use the saddle antenna, which has its RF magnetic field transverse to the source axis, combined with an axial DC magnetic field, to concentrate the plasma on the collar where the negative ions are formed by secondary emission [1-6, 9-11].

SA SPS DESIGN

The schematic of a large RF SA SPS with the AlN ceramic discharge chamber, saddle antenna, and DC solenoid is shown in Fig. 1. The chamber has an ID=68 mm. The saddle antenna in this SPS with inductance L=3.5 µH is made from water cooled copper tube. RF assisted triggering plasma gun (TPG) is attached to discharge chamber from left. An extraction system is attached from right side.

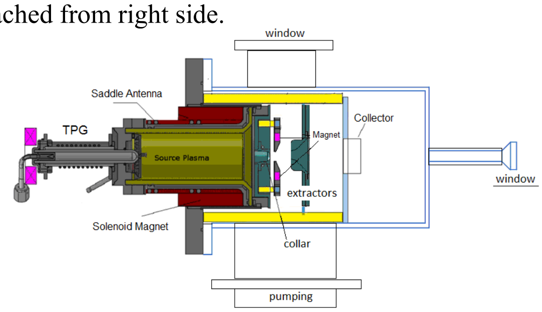

Figure 1: A schematic of the SA SPS with an extraction system and a collector.

A schematic of the extraction system is shown in Fig. 2. The strong transverse magnetic field (up to 1 kG) is created in the collar by permanent magnets (arrows) inserted into water cooled extractor attached to the plasma plate through ceramic insulators.

ANALYSIS OF FEL-BASED CEC AMPLIFICATION AT HIGH GAIN LIMIT*

G. Wang#, V. N. Litvinenko and Y. Jing, BNL, Upton, NY 11973, U.S.A.

Abstract

An analysis of Coherent electron Cooling (CeC) amplifier based on 1D Free Electron Laser (FEL) theory was previously performed with exact solution of the dispersion relation, assuming electrons having Lorentzian energy distribution [1]. At high gain limit, the asymptotic behaviour of the FEL amplifier can be better understood by Taylor expanding the exact solution of the dispersion relation with respect to the detuning parameter [2, 3].

In this work, we make quadratic expansion of the dispersion relation for Lorentzian energy distribution [1, 4] and investigate how longitudinal space charge and electrons' energy spread affect the FEL amplification process.

INTRODUCTION

FEL instability plays a key role in a FEL-based CeC system: it determines the cooling force, the effective bandwidth, as well as the saturation level of the system[5]. An analytical analysis based on numerically solving the exact 1-D FEL dispersion relation had been previously performed for a warm electron beam with Lorentzian energy distribution [1]. Although the analysis in [1] is based on an exact solution of the FEL dispersion relation and takes into account both the warm beam and longitudinal space charge effects, the final solutions involve an inverse Fourier transformation that can only be evaluated numerically. During analysing and optimizing a CeC system, it is often beneficial to have analytical time-domain solutions, which provides scaling laws as well as more intuitive insights.

Recently, an analysis of CeC based on 1-D FEL at high gain limit has been performed [2] for cold electron beam. In the analysis, the solutions of 1-D FEL dispersion relation have been Taylor expanded up to the quadratic terms with respect to the detuning parameter. The approximation is valid if the FEL gain is large enough such that the beam spectrum is dominated by the components with small detuning parameter. The approximation significantly simplified the final results and allow for an analytical expression for the time-domain solution of the cooling force.

As an attempt to extend the analysis of [2], we start with the 1-D FEL dispersion relation of a warm electron beam as adopted in [1], and take the Taylor series of its solutions up to the quadratic terms in detuning as the approximate solutions. Similar to the results obtained in [2], the approximation leads to an electron density wave-packet with a Gaussian envelope in the time domain. Both the amplitude and the RMS width of the Gaussian envelope depend on the longitudinal space charge parameter and the energy spread parameter of the electron beam, which makes it possible to investigate how these beam parameters affect the cooling process.

The contents are organized as follows. In section II, we present the set of equations to be used to find the approximate solutions to the dispersion relation for arbitrary space charge and energy spread parameters. We then solve the equations for zero space charge parameter in section III, and investigate how energy spread parameter alone affects the gain and coherent length of the cooling force. For arbitrary space charge and energy-spread parameter, numerical method is required to solve the set of equations and we present our results in section IV. Section V consists our summary.

SOLUTION OF 1-D FEL DISPERSION RELATION AT HIGH GAIN LIMIT

Assuming the following energy distribution of the electron beam*: $\hat{F}\left(\hat{P}\right)=\hat{q}\Big/\left[\pi\left(\hat{P}^2+\hat{q}^2\right)\right]$, the 1-D FEL dispersion relation reads

$$s\left[\left(s+\hat{q}+i\hat{C}\right)^2+\hat{\Lambda}_p^2\right]=i \quad , \tag{1}$$

where s is the complex growth rate of 1-D FEL instability in unit of Γ, $\Gamma\equiv\left[\pi j_0\theta_s^2\omega\big/\left(c\gamma_z^2\gamma I_A\right)\right]^{\frac{1}{3}}$ is the 1-D gain parameter, $\hat{\Lambda}_p\equiv\sqrt{4\pi j_0\big/\left(\gamma_z^2\gamma I_A\right)}\Big/\Gamma$ is the normalized space charge parameter, $\hat{P}\equiv\left(E-E_0\right)/\left(\rho E_0\right)$ is the normalized energy deviation of an electron with energy E, ρ is the Pierce parameter, $\hat{q}$ is the normalized energy spread parameter, I_A is Alfven current, $\theta_s\equiv K/\gamma$ is the trajectory angle of electrons' motion, K is the undulator parameter, $\hat{C}\equiv\left[k_w-\omega\big/\left(2c\gamma_z^2\right)\right]\Big/\Gamma$ is the normalized detuning parameter and $\gamma_z=\gamma\Big/\sqrt{1+K^2}$.

Let the growing root of eq. (1) to be

$$s_1=\lambda_0+\lambda_1\Delta\hat{C}+\lambda_2\Delta\hat{C}^2+\ldots \tag{2}$$

where $\Delta\hat{C}\equiv\hat{C}-\hat{C}_0$ and $\hat{C}_0$ is the detuning corresponding to the maximal growth rate, i.e.

$$\left.\frac{d\,\mathrm{Re}\left(s\right)}{d\hat{C}}\right|_{\hat{C}_0}=0 \; . \tag{3}$$

Inserting eq. (2) into eq. (1) and using eq. (3) leads to

$$\lambda_0=\lambda_R+i\lambda_I \quad , \tag{4}$$

SPIN COHERENCE TIME LENGTHENING FOR A POLARIZED DEUTERON BEAM USING SEXTUPOLE FIELDS

G. Guidoboni, University of Ferrara and INFN, Ferrara, Italy

Abstract

The possibility to use sextupole fields to increase the in-plane (ring plane) polarization lifetime of a deuteron beam is part of the feasiblity studies for a search for an electric dipole moment (EDM) of charged particles in storage rings. This experiment requires ring conditions that can ensure a lifetime of the in-plane polarization (spin coherence time, SCT) up to 1000 s. At the COoler SYnchrotron (COSY) located at the Forschungszentrum Jülich, the JEDI collaboration has begun to examine the effects of emittance and momentum spread on the SCT of a polarized deuteron beam at 0.97 GeV/c. The set of data presented here shows how second-order effects from emittance and momentum spread of the beam affect the lifetime of the horizontal polarization of a bunched beam. It has been observed that sextupole fields can correct for depolarizing sources and increase the spin coherence time up to hundreds of seconds while setting the chromaticities equal to zero.

INTRODUCTION

The spin coherence time (SCT) measurements presented here are part of feasibility studies [1, 2] for a new project searching for the electric dipole moment (EDM) of charged particles in storage rings. The EDM is a permanent charge separation within the particle volume, aligned along the spin axis. The EDM violates both parity conservation and time reversal invariance. Thus, assuming the validity of the CPT theorem, the EDM represents a source of CP violation that could explain why the universe evolved to a matter-dominated state. The Standard Model (SM) does not explain the observed baryon asymmetry and predicts unobservably small EDMs (*e.g.*, for the proton, $|d_p|_{\mathrm{SM}} < 10^{-32}\ e\cdot$cm). Models beyond the SM predict values within the sensitivity of current or planned experiments (for proton and deuteron $|d_{p,d}| \geq 10^{-29}$ e·cm), but no EDM has been observed yet. If an EDM is found within the present experimental limits it would be a clear and clean probe of new physics.

Since the EDM lies along the spin axis, the new detection method requires observing the polarization precession in an electric field while the charged particles are trapped in a storage ring. While keeping the horizontal component of the beam polarization along the velocity direction during the storage time, the EDM signal can be detected as a rotation of the polarization from the ring plane toward the vertical direction due to the interaction with the inward radial electric field that is always present in the particle frame. In a magnetic storage ring, the polarization will undergo a rotation relative to the velocity described by the Thomas-BMT equation [3]:

$$\vec{\omega}_a = \vec{\omega}_s - \vec{\omega}_c = -\frac{q}{m}\left\{G\vec{B} + \left[G - \left(\frac{m}{p}\right)^2\right]\frac{\vec{\beta}\times\vec{E}}{c}\right\} \quad (1)$$

where it is assumed that $\vec{\beta}\cdot\vec{B} = \vec{\beta}\cdot\vec{E} = 0$ and the EDM component has been omitted. $\vec{\omega}_s$ is the spin precession in the horizontal (ring) plane, $\vec{\omega}_c$ is the particle angular frequency and $G = \frac{g-2}{2}$ is the anomalous magnetic moment. In the deuteron case, where $G = -0.14$, the spin alignment along the velocity ($\vec{\omega}_a = 0$ in Eq. 1) is achieved with a combination of magnetic and outward electric fields. In order to reach a sensitivity of 10^{-29} e·cm, a good compromise for the experiment requires a polarimeter sensitivity of 10^{-6} rad and a horizontal polarization lifetime (SCT) of 1000 s. The SCT represents the time available to observe the EDM signal as a polarization precession toward the vertical direction. The aim of the feasibility studies made at COSY (COoler SYnchrotron at the Forschungszentrum Jülich, Germany) is to demonstrate the possibility to reach an SCT of 1000 s using sextupole field corrections and a dedicated beam preparation including beam bunching and electron cooling.

EXPERIMENTAL SETUP

The EDM feasibility studies started at COSY in 2012 using a polarized deuteron beam with a momentum of 0.97 GeV/c. The beam polarization was initially aligned along the vertical direction (orthogonal to the ring plane) and then rotated to the horizontal (ring) plane by exciting the $(1 - G\gamma)$ spin resonance with an RF-solenoid, where G is the anomalous magnetic moment and γ is the relativistic factor. With the development of a DAQ (Data AcQuisition system) capable of measuring the rapidly precessing polarization (≈ 120 kHz) in the ring plane [4], it was possible to continuosly measure the horizontal polarization as a function of time by slowly extracting the beam onto a thick carbon target and observing elastic scattering events at forward angles in the EDDA detector [5]. The beam was bunched at the first harmonic in order to remove the first order momentum spread ($\Delta p/p$) as a cause of the in-plane spin decoherence.

The SCT studies aimed to investigate the decoherence sources represented by the finite transverse beam size (emittance) and the second order momentum spread of the beam, ($(\Delta p/p)^2$), arising from synchrotron oscillations. With the combination of electron cooling, bunching and white noise applied to electric field plates, it was possibile to prepare different beam setups to separately study the single contributions. The sequence of doing electron cooling first, then bunching without cooling, was used to study the effect of $(\Delta p/p)^2$ alone. In another setup, electron cooling and

INCREASING THE BEAM BRIGHTNESS OF A DUOPLASMATRON PROTON ION SOURCE*

Y.K. Batygin#, I.N. Draganic, C.M. Fortgang, LANL, Los Alamos, NM 87545, USA

Abstract

The LANSCE accelerator facility operates with two independent ion injectors for H^+ and H^- particle beams. The H^+ ion beam is formed using a duoplasmatron source followed by a 750 keV Cockroft-Walton accelerating column. Formation of an optimal plasma meniscus is an important feature for minimizing beam emittance and maximizing beam brightness. An experimental study was performed to determine optimal conditions of extracted H^+ beam for maximizing beam brightness. Study was based on measurements of beam emittance versus variable beam current and extraction voltage. Measurements yielded 0.52 as the best ratio of beam perveance to Child - Langmuir perveance for maximizing beam brightness. As a result of optimization, beam brightness was increased by a factor of 2.

ION SOURCE AND BEAMLINE

The existing H^+ ion source is a duoplasmatron with a Pierce extraction geometry [1]. The source (see Fig. 1) has been operated successfully for many years at LANSCE [2]. Originally developed for production of 50 mA proton beam, the source was modified for production of a less intense, but brighter beam [3]. The Pierce anode was replaced with a modified electrode with an aperture radius of R = 2.5 mm. The extraction electrode was moved closer to the ion source. The extraction distance is now d =10.78 mm. Details of internal structure of LANSCE duoplasmatron are given in [2, page 28]. Presently the source delivers a proton beam current of I = 15 mA at 60 Hz x 625 μsec pulse length using 1.3 std cc/min gas flow. The source is mounted on a Cockroft-Walton accelerating column at 750 kV potential with respect to ground. The H^+ beamline (see Fig. 2) is equipped with two slit-collector emittance measurement stations. TAEM1 station is placed after the 750 keV Cockroft-Walton accelerating section, while TAEM2 is placed after the 81° bending magnet. An additional emittance measurement station, TDEM1, is common for both H^+ and H^- beams and is placed in front of Drift Tube Linear accelerator. Beam current is measured with 5 beam current monitors along the beamline. The beamline is operated at typical pressure of $9 \cdot 10^{-7}$ Torr.

CHARACTERISTICS OF EXTRACTED BEAM

Optimal operation of the accelerator facility critically depends on the emittance of the beam extracted

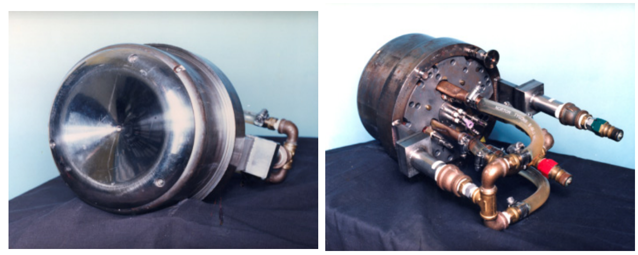

Figure 1: Side view of assembled LANSCE duoplasmatron ion source with Pierce electrode.

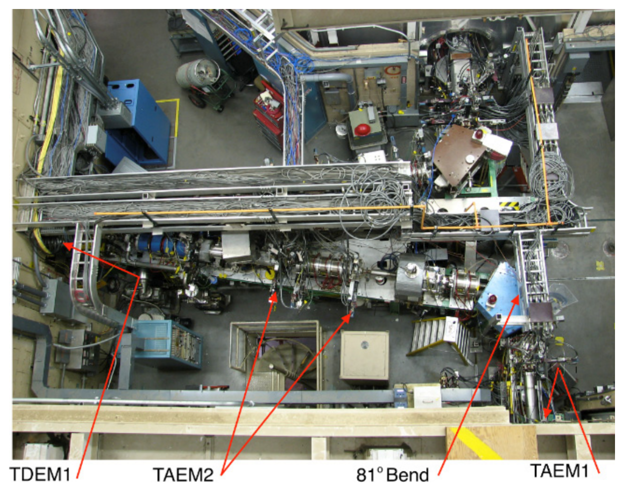

Figure 2: Layout of 750 keV H^+ Low Energy Beam Transport of LANSCE.

from the ion source. An intrinsic limitation in particle-source beam-emittance comes from the finite value of plasma temperature in the ion source and from the value of longitudinal magnetic field at extractor. Normalized emittance of the beam, extracted from a particle source with aperture radius R and plasma ion-temperature T with magnetic field B at extractor is estimated as [4]

$$4\varepsilon_{rms} = 2R\sqrt{\frac{kT}{mc^2} + \left(\frac{eBR}{4mc}\right)^2} \quad . \tag{1}$$

Besides emittance determined by Eq. (1), additional sources contributing to beam emittance are:

• irregularities in the plasma meniscus extraction surface
• aberrations due to ion-source extraction optics
• optical aberrations of the focusing elements of the Low Energy Beam Transport
• non-linearity of the electric field created by the beam space charge
• beam fluctuations due to ion-source instability or power regulation.

LANSCE H$^+$ RFQ STATUS*

R. W. Garnett#, Y. K. Batygin, C. A. Chapman, I. N. Draganic, C. M. Fortgang, S. S. Kurennoy, R. C. McCrady, J. F. O'Hara, E. R. Olivas, L. J. Rybarcyk, and H. R. Salazar, LANL, Los Alamos, NM 87544, U.S.A., B. Koubek, A. Schempp, IAP, Goethe University, Frankfurt am Main, Germany, J. Haeuser, Kress GmbH, Biebergemuend, Germany

Abstract

The LANSCE linear accelerator at Los Alamos National Laboratory provides H$^-$ and H$^+$ beams to several user facilities that support Isotope Production, NNSA Stockpile Stewardship, and Basic Energy Science programs. These beams are initially accelerated to 750 keV using Cockcroft-Walton (CW) based injectors that have been in operation for over 37 years. To reduce long-term operational risks and to realize future beam performance goals for LANSCE we are completing fabrication of a 4-rod Radio-Frequency Quadrupole (RFQ) and design of an associated beam transport line that together will eventually become the modern injector replacement for the existing obsolete H$^+$ injector system. A similar H$^-$ system is also planned for future implementation. An update on the status and progress of the project will be presented.

INTRODUCTION

The present dual-beam CW-based injector scheme for the LANSCE linac is shown in Fig. 1. The two beam species are merged into a common beam transport line and bunched before injection into the drift-tube linac (DTL). The proton beam (H$^+$) is presently accelerated to 100 MeV for isotope production. The H$^-$-ion beam is accelerated to 800 MeV and used to produce neutrons for a wide variety of applications. Assessment of failure modes of our CW injectors revealed the potential for significant disruption of beam operations at LANSCE [1], primarily due to catastrophic failure of major components and unavailability of spare parts.

Our strategy to reduce operational risks associated with the current CW-based injector systems involves the eventual replacement of these systems with modern radio-frequency quadrupole (RFQ) based injectors. This approach is expected to improve reliability due to reduced overall complexity of the systems and by modernization. RFQ accelerators are employed worldwide and have demonstrated stable and reliable operation.

To meet both present and future, anticipated beam-delivery requirements, implementation of several RFQ-based injectors will be required at LANSCE [2]. Due to funding constraints and to minimize facility and operational impacts, this will be done in a phased manner with development of the H$^+$ RFQ having highest priority due to its impact on our near-term high-power performance goals [3, 4].

The RFQ is required to operate at a high duty factor of up to 15% and must meet strict beam performance requirements. Complementary simulations using the TRACE 2-D/3-D, PARMTEQM and PARMILA codes [5], Beampath [6], the CST Studio suite of codes [7] including Particle Studio, and the ANSYS [8] code were used to validate the design results prior to fabrication.

To ensure mechanical and operational robustness of the RFQ, several technical evaluations were completed prior to acceptance of the design [9]. These included: addressing potential structure cooling issues, evaluation of tuning range, impact of stem spacing on frequency and field flatness, impact of vane cross-section and stem geometry on dipole fields, and investigation of end-region field effects on emittance growth and final output energy.

The final physics design of the 4-rod RFQ was completed and verified through a joint effort between the Institute of Applied Physics (IAP) at Goethe University, Frankfurt, Germany, and Los Alamos in 2011[10]. A final mechanical design review was held in April 2013. Fabrication of the RFQ began in April 2014 in Germany by our project partner Kress, GmbH and was completed in December 2014.

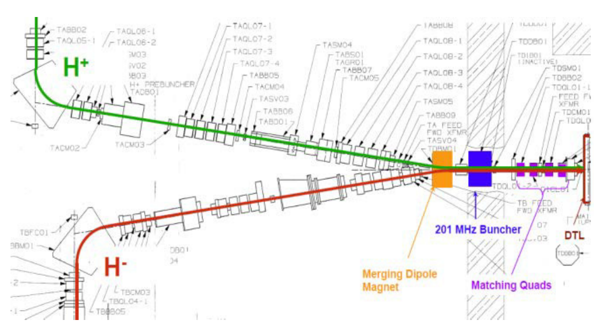

Figure 1: Present H$^+$/H$^-$ CW injector layout.

The H$^+$ RFQ and planned beam-transport layout will replace the existing H$^+$ CW injector and beam line, requiring no changes beyond the merging dipole upstream of the common H$^+$/H$^-$ beam transport section (See Fig.1). This enables early implementation of the new H$^+$ system, independent of the longer-term plans to implement multiple RFQ injectors. It is still our current plan to operate and commission the RFQ/beam transport system on a separate test stand prior to integration at the front end of the LANSCE linac. Figure 2 shows a preliminary layout of the new RFQ/ beam line configuration.

The RFQ has been delivered to Los Alamos. High-power RF testing is planned next. The ion source and high-voltage platform are being assembled in preparation for full assembly of an RFQ Test Stand that will include the ion source, low-energy beam transport (LEBT) to

ELECTROMAGNETIC MODELING OF 4-ROD RFQ TUNING

S.S. Kurennoy, L.J. Rybarcyk, LANL, Los Alamos, NM 87545, USA

Abstract

Modern codes make possible detailed electromagnetic (EM) 3D modeling of RFQ accelerators. We have recently analyzed two 201.25-MHz 4-rod RFQs – one commissioned at FNAL [1] and a new design for LANL [2] – with CST Studio using imported manufacturer CAD files. The RFQ EM analysis with MicroWave Studio (MWS) was followed by beam dynamics modeling with Particle Studio as well as other multi-particle codes. Here we apply a similar approach to study the process of RFQ tuning in 3D CST models. In particular, the results will be used to better understand tuning the voltage flatness along the new LANL 4-rod RFQ.

INTRODUCTION

Radio-frequency quadrupole (RFQ) accelerators are now standard in front ends of modern ion linacs. They are usually designed with codes that rely on electrostatic field approximations, e.g., Parmteq [3]. While this is justified for classical 4-vane RFQs having perfect quadrupole symmetry, many modern RFQs contain elements that break such a symmetry. Additional RF field effects can be introduced by asymmetric elements like vane windows in split-coax designs or stem supports in 4-rod RFQs. Such effects are more complicated and can't be easily taken into account in electrostatic calculations, even in 3D, but can influence beam dynamics in some cases. We have discussed 3D RF effects in 4-rod RFQs in [4].

LANL is moving forward with replacing one of its aging Cockcroft-Walton injectors with an RFQ-based front end for the LANSCE proton linac [5]. The LANL H^+ RFQ, operating at 201.25 MHz at a duty factor up to 15%, with 35-keV injection and 750-keV final energy, should satisfy special requirements when incorporated into the existing medium-energy beam transfer that works with multiple beam species. The 4-rod type RFQ design was developed in collaboration between IAP (Frankfurt) and LANL. The RFQ was manufactured by Kress GmbH and recently delivered to LANL. The CAD files from Kress were imported into CST Studio [6] to create an RFQ model that was used to evaluate its performance [2].

4-ROD RFQ TUNING

RFQ CST Model

The imported CAD model was simplified by removing details nonessential for EM analysis such as external supports, etc. The RFQ cavity walls were also removed, leaving only the resonator vacuum volume in the CST model. The resulting model is shown in Fig. 1. Here the RFQ vacuum vessel, in gray-blue, is 175-cm long (wall-to-wall), 34-cm wide, and 30-cm high (along the stem direction, *z*). The model includes a frequency slug tuner (cyan cylinder) and two 5-cm-long beam pipes of radius 2 cm attached to the vacuum vessel, but other ports are ignored. The RFQ vanes are supported by 24 stems that are spaced longitudinally with variable period, 75 mm in the center and 69.5 mm for three periods near each end. There are 23 tuners that electrically short two adjacent stems and can be moved along them (in *z* direction) to adjust the mode frequency and voltage profile (flatness) along the structure length. The variable stem spacing simplifies tuning the voltage flatness along the structure. Our RFQ model uses the CAD model coordinates: *x* is along the RFQ axis, and the beam is moving in *-x* direction (right to left in Fig. 1).

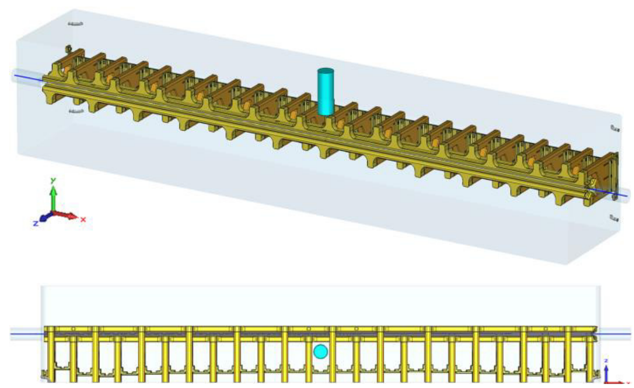

Figure 1: CST model of the LANSCE H^+ RFQ (top) and its side view (bottom).

One can see in Fig. 1 (bottom) that the tuners are at different heights: they are adjusted in the model to make the inter-vane voltage flat within ±1%. However, even with all tuners at the same height, the voltage is flat within ±5%, due to the variable stem spacing, see below.

RF Field Calculations with MWS

The fields in the RFQ model are calculated using the hexahedral AKS eigensolver; it approximates complicated surfaces well but is slow due to minimal parallelization. The efficient tetrahedral eigensolver fails to mesh the imported RFQ CAD model. The inter-vane voltages are obtained by integrating the electric field of the operating mode along short segments located in the middles of the RFQ stem periods between the vanes. The voltages calculated in different locations along one stem period show some variation (scalloping). The RFQ-model frequency is tuned to 201.226 MHz when all tuning plates are positioned at the same height, *h*=27.15 mm, from the ground plate. The voltage profiles calculated from the MWS eigenmode solution are plotted in Fig. 2 versus stem period number *n*; *n* = 0 is the middle of RFQ, negative *n* values correspond to the downstream end (left in Fig. 1). There are two profiles: V_y is calculated by integrating the field on both sides from the axis and averaging the two voltages to minimize errors – this is our usual procedure; for V_z the voltages are calculated

3D ELECTROMAGNETIC AND BEAM DYNAMICS MODELING OF THE LANSCE DRIFT-TUBE LINAC

S.S. Kurennoy and Y.K. Batygin, LANL, Los Alamos, NM 87545, USA

Abstract

The LANSCE drift-tube linac (DTL) accelerates the proton or H- beam to 100 MeV. It consists of four tanks containing tens of drift tubes and post-couplers; for example, tank 2 is almost 20 m long and has 66 cells. We have developed 3D models of full tanks [1] in the DTL with CST Studio to accurately calculate the tank modes, their sensitivity to post-coupler positions and tilts, tuner effects, and RF-coupler influence. Electromagnetic analysis of the DTL tank models is performed using MicroWave Studio (MWS). The full-tank analysis allows tuning the field profile of the operating mode and adjusting the frequencies of the neighboring modes within a realistic CST model. Beam dynamics is modeled with Particle Studio for bunch trains with realistic initial beam distributions using the MWS-calculated and tuned RF fields and quadrupole magnetic fields to determine the output beam parameters and locations of particle losses.

INTRODUCTION

The drift-tube linac (DTL) structure, proposed by Alvarez in 1946, became the most popular type of low-energy proton linac for many decades. The DTL structure employs long cylindrical resonators (tanks) operating in the TM_{010} mode and containing a sequence of drift tubes (DTs) installed along the beam axis. DTL accelerators achieve their best efficiency for particle velocities from approximately 10% to 35% of the speed of light, i.e. $\beta = v/c = 0.1\text{-}0.35$. The Los Alamos Neutron Science Center (LANSCE) 201.25-MHz DTL covers a wide velocity range from $\beta = 0.04$ to 0.43, which corresponds to the proton energies from 750 keV to 100 MeV. The LANSCE DTL consists of four tanks. Some relevant parameters of the DTL tanks are listed in Table 1, where N_{DT} is the number of full DTs and N_{pc} is the number of post-couplers in the tank.

Table 1: LANSCE DTL Design Parameters [2]

Parameter	Tank 1	Tank 2	Tank 3	Tank 4
Energy in, MeV	0.75	5.39	41.33	72.72
β, in-out	0.04	0.107	0.287	.37-.43
Length L, m	3.26	19.688	18.75	17.92
N_{DT}	30	65	37	29
N_{pc}	0	65	37	29
Aperture r_b, cm	0.75	1-1.5	1.5	1.5
Grad. E_0, MV/m	1.6-2.3	2.4	2.4	2.5
Aver. ZT^2, MΩ/m	26.8	30.1	23.7	19.2

DTL TANK MODELS AND FIELDS

We have built 3D models of all four DTL tanks using CST Studio [3]. The EM fields in the tank models were calculated with CST MicroWave Studio (MWS), see [1, 4] for details. The CST model of tank 2 (T2) is shown in Fig. 1. This is the longest DTL tank (19.7 m) that contains 65 full DTs and two half-DTs on the end walls. The full DTs are supported by vertical stems. The tank cavity of radius 45 cm is shown in Fig. 1 as the blue-gray cylinder. Two upper insets in Fig. 1 show side views near the tank entrance (blue) and exit (green). The stabilizing post-couplers (gray) with rotating tabs can be seen in the end view of the tank in the right-bottom inset.

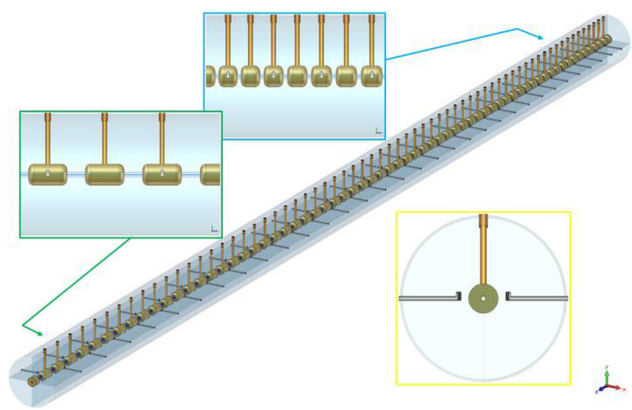

Figure 1: CST model of the LANSCE DTL tank 2. The cavity outer walls are removed for better view.

The shortest tank of the DTL, tank 1 (T1), does not have post-couplers, and its accelerating field is ramped: the average on-axis cell field E_0 increases along the tank from 1.6 to 2.3 MV/m. In T2-T4, the accelerating gradient E_0 is constant. Its flatness was tuned in the CST models by adjusting spacing between post-couplers and DTs, cf. [1, 4]. The RF fields in the tank models were calculated using primarily the MWS tetrahedral eigensolver. For accuracy, the meshes were refined locally, especially inside the DT apertures; details can be found in [4].

BEAM DYNAMICS

The MWS-calculated RF fields of the tuned operating mode in the tanks were used to study beam dynamics. The fields in the beam region were exported from MWS as text files in a format that can be imported into various multi-particle codes. We mainly use the CST Particle Studio (PS) particle-in-cell (PIC) solver. The static magnetic fields of the focusing quadrupoles, produced in Matlab as text files based on the hard-edge quad design values, were also imported into PS as external fields.

THE DOE LONG-TERM ACCELERATOR R&D STEWARDSHIP PROGRAM*

E. Colby#, M. Zisman, DOE Office of High Energy Physics
E. Lessner, DOE Office of Basic Energy Sciences
M. Farkhondeh, DOE Office of Nuclear Physics

Abstract

Since the Accelerators for America's Future (AfAF) Symposium in 2009, the U. S. Dept. of Energy's Office of High Energy Physics (DOE-HEP) has worked to broaden its accelerator R&D activities beyond supporting only discovery science to include medicine, energy and environment, defense and security, and industry. Accelerators play a key role in many aspects of everyday life, and improving their capabilities will enhance U.S. economic competitiveness and the scientific research that drives it. Funded for the first time in 2014, the DOE Office of Science Accelerator Stewardship Program has launched initiatives to facilitate access to DOE accelerator infrastructure, develop innovative accelerator technologies that solve critical problems, and catalyze new partnerships across the accelerator user community. We will discuss the formulation and evolution of the Accelerator Stewardship program, the current status of initiatives, and plans for engagement with the accelerator and user communities for future stewardship activities.

INTRODUCTION

The mission of the DOE Long-Term Accelerator R&D Stewardship Program is to:

- Support fundamental accelerator science and technology R&D, and
- Disseminate accelerator knowledge and training.

This mission is implemented through:

- Facilitating access to national laboratory accelerator facilities and infrastructure† for industrial and U.S. government agency users and developers of accelerators and related technology,
- Developing innovative solutions to critical problems, to the benefit of both the broader user communities and the DOE discovery science community,
- Serving as a catalyst to broaden and strengthen the community that relies on accelerators and accelerator technology.

First funded in FY 2014 by redirection, the Stewardship program launched with two primary program elements: (1) a dedicated accelerator R&D user facility, and (2) a university-based R&D program. In response to (1), the Brookhaven Accelerator Test Facility ("ATF") was identified as a dedicated, central Accelerator Stewardship user facility. The initial university R&D program was created by redirecting ten university grants already awarded in the HEP General Accelerator R&D program.

The Brookhaven ATF [1] has for more than two decades supported experimental accelerator science that has led to world-first demonstrations of new high-gradient acceleration methods, SASE, HGHG, and Compton Scattering radiation generation, new beam diagnostic techniques, and more. The ATF supported 24 experiments in 2014, with a significant proportion of the experiments being funded by federal agencies other than High Energy Physics, and 25% led by industrial partners (primarily small businesses). In 2014, the Accelerator Stewardship program designated the Brookhaven ATF as a dedicated Stewardship accelerator R&D facility, broadening its mission to include accelerator technology development in addition to accelerator science. In 2015 the ATF's broad role has been recognized by the Office of Science by designating it as an Office of Science User Facility. This designation is a formalization of the merit-based approach to facility management that has been ATF's tradition, and raises the visibility of the facility to potential users.

This versatile facility provides medium energy electron beams (80 MeV) of very high quality, and high power CO_2 laser beams (up to 1 TW) together with an expert staff that supports the users. To accommodate the steadily growing demand for the ATF, an upgrade is also being funded through the Stewardship program which will result in a significantly expanded facility (~3x the space) with increased beam energy (~2x) and increased laser energy (~100x). The upgrade, dubbed "ATF-II", is planned to open for new users in 2018.

The ten redirected university grants for launching the Stewardship program were selected after discussions with the Offices of Basic Energy Sciences and Nuclear Physics to identify those with particular strategic long-term interest. The awards included fundamental R&D in beam physics, accelerator simulation codes, advanced superconductors, and cryogenics, with an emphasis on fundamental R&D that would have broad impact across multiple programs.

As a new program in the Office of Science, it is vital that the Accelerator Stewardship program demonstrate success in the near-term. As Accelerator Stewardship, by its definition, serves the needs of stakeholders other than High Energy Physics, it is essential that those stakeholders express an active interest in the R&D, and choose to make use of the results of the R&D when it is

ADVANCES IN CW ION LINACS*

P.N. Ostroumov#
ANL, Argonne, IL 60439, U.S.A.

Abstract

Substantial research and development related to continuous wave (CW) proton and ion accelerators is being performed at ANL. A 4-meter long 60.625-MHz normal conducting (NC) CW radio frequency quadrupole (RFQ) and a 4K cryomodule with seven 72.75-MHz quarter-wave resonators (QWR) and superconducting (SC) solenoids have been developed, built, commissioned and operated as an upgrade of the CW ion linac, ATLAS, to achieve higher efficiency and beam intensities [1]. Currently we are engaged in development of the first cryomodule for a CW H$^-$ linac being built at FNAL [2]. This work is well aligned with the development of a 1 GeV 25 MW linac as the driver of a sub-critical assembly for near-term spent nuclear fuel disposal.

The new CW RFQ and cryomodule were fully integrated into ATLAS and have been in routine operation for more than two years and one year, respectively. New design and fabrication techniques for QWRs resulted in the achievement of record accelerating voltages and low cryogenic losses. Since the very beginning the cryomodule provided 17.5 MV accelerating voltage or 2.5 MV per cavity. A 2K cryomodule with eight 162.5-MHz SC half wave resonators (HWR) and eight SC solenoids is being developed for FNAL and scheduled for commissioning in 2017. The testing of the first 2 HWRs demonstrated remarkable performance. Experience with the development and reliable operation of new NC and SC accelerating structures is an essential precursor for the future large scale high power CW accelerators.

INTRODUCTION

Technology required for both CW RFQ and SC RF accelerators was successfully developed for a recent ATLAS upgrade. This upgrade achieved greater efficiency and beam intensities than were previously obtained at ATLAS and in some cases a 10× improvement is observed [1]. Developments here can be applied to future high-power CW accelerators such as drivers for the production of rare isotope beams or for Accelerator Driven Systems (ADS). In this paper we present the description of major breakthroughs in technologies for CW linacs which have resulted in excellent performance in both normal conducting and SC accelerating structures. Details of our research and developments can be found in numerous conference publications and journal articles published by members of ANL's Physics Division. To save space only key publications will be referenced in this paper.

CW ION LINACS

CW linear accelerators can be divided into two main categories: (1) low intensity ion linacs capable of accelerating the majority of ion species from hydrogen to uranium and (2) high intensity light ion linacs, primarily for acceleration of protons and/or deuterons. The linacs in the first category are not affected by the beam space charge and can deliver several hundred kilowatts of beam power; as is the case for FRIB or RAON [3,4]. There are many operational low energy (up to ~25 MeV/u) CW linacs worldwide which are being used for fundamental nuclear physics experiments. Currently, no high-power CW linac exists. Substantial research and development work has been performed in the past decade for several high-power CW linac projects worldwide [2,5-8] and the ability to accelerate several milliamp CW proton beams with SC cavities has been demonstrated in the prototype cryomodule at SARAF [9].

As we discussed in the recent review paper [10], independent of ion species, a CW hadron linac includes a room temperature RFQ accelerator. The transition energy from NC to SC structures depends upon the ion species and the beam intensity. A transition from NC to SC structures is accompanied with significant changes of two main accelerator lattice parameters: (1) the focusing period becomes longer and (2) higher accelerating gradients, E_{ACC}, are readily achievable when using SC cavities. These changes, if not mitigated, can easily lead to strong coupling of the transverse and longitudinal motions and may result in large emittance growth and beam halo formation. In heavy-ion linacs, the higher accelerating gradients available from SC cavities can be effectively used above ~300 keV/u. In high intensity proton linacs, the transition energy from normal conducting to SC structures must be pushed as high as possible not only to avoid transverse-longitudinal coupling but to supress space charge effects. Depending on the proton beam current, the transition energy can be in the range from 2 to 7 MeV/u and it is limited by the cost and complexity of CW RFQs.

CW RFQ

Starting in the 1990's, the ATLAS heavy ion linac included 48 MHz SC resonators capable of accelerating pre-bunched ions with an initial velocity of 0.008c. Due to the high velocity gain in the first 4 SC resonators, a significant distortion of both transverse and longitudinal emittance occurred and resulted in reduced beam transmission through the linac. To address this issue, we have developed and built a CW RFQ capable of accelerating any ion species from 30 keV/u to 295 keV/u. Several innovative ideas have been implemented in this CW RFQ. By selecting a multi-segment split-coaxial

THE LUMINOSITY UPGRADE AT RHIC*

G. Robert-Demolaize, Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

Starting with the high energy heavy ion run for Fiscal Year 07 (Run7), the Relativistic Heavy Ion Collider (RHIC) underwent a series of upgrades in all three tiers of its activities: machine hardware, lattice design and operational efficiency. The following presents a review of these upgrades and how their combined contributions to heavy ion operations lead to average store luminosities that exceed the initial RHIC design by a factor of 25.

INTRODUCTION

RHIC's main objective is to increase its ability to recreate quark-gluon plasma and study the rare processes associated with it. Run7 marked the first efforts towards the implementation of the components aimed at improving the design average store luminosity by a factor of 10. With Run14, all equipments designed for the heavy ion luminosity upgrade have been successfully commissioned with beam and used operationally. Table 1 presents an overview of the main performance parameters of all high energy heavy ion runs from Run7 to Run14, and includes the design, enhanced design and Run4 values as a reference point to the pre-upgrade machine conditions. When looking at the performances of the Au-Au runs alone, the average store luminosities have been improved by a factor of 25 from Run4, reaching a consistent $L_{avg.}$(Run14)=50.0x10^{26}cm^{-2}s^{-1} while keeping the beams for physics for twice as long. Figure 1 shows the evolution of the integrated luminosity of heavy ion runs at 100 GeV/u from Run1 to Run14 [1], where it can be seen that Run14 outperformed Run4 by over an order of magnitude.

Such a significant improvement can be attributed to the RHIC-II upgrade plans [2]. The next section will highlight the most signifcant changes and achievements in machine hardware and subsystems. New magnet settings for lattice design that allow for larger dynamic aperture and dynamic β^* squeeze for the STAR and PHENIX experiments are then presented. A review of the changes in machine operations and how the store-to-store turnaround time is pushed to maximize beam time in physics is also included.

HARDWARE AND SYSTEM UPGRADES

Injectors

The RHIC-II luminosity upgrade included plans to update the source where heavy ions are generated, from the Tandem Van de Graaf to a new Electron Beam Ion Source (EBIS) followed by an RFQ and a short linac [3]. This new, versatile source allows switching rapidly between various ion species while providing per-bunch intensities similar to the Au ion ones. EBIS was successfully commissioned in 2010 and has

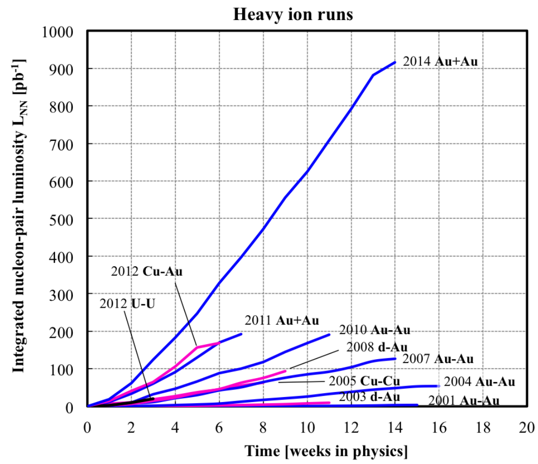

Figure 1: Integrated luminosity of the RHIC heavy ion runs at 100 GeV/nucleon as a function of the number of weeks in physics. The data is presented for the nucleon-pair luminosity $\mathcal{L}_{\text{N-N}}=N_1 N_2 \mathcal{L}$ from Run1 to Run14, where $\mathcal{L}$ is the luminosity and N_1,N_2 are the number of nucleons for the species in each beam. From [1].

since delivered beams to both RHIC and the NASA facility without slowing down operations for either programs. The ion species other than Au that have been used for RHIC physics are (to date) Cu, U and polarized ^{3}He.

Part of the limitations on the intensity of the heavy ion bunches injected into RHIC came from beam instabilities when crossing transition, due to impedance and electron clouds effects [4–6]. However starting with Run10 the intensity threshold was raised thanks to scrubbing runs with high intensity proton beams in 2009 and 2012, as evidenced by the new highs in bunch intensity reported in Table 1.

Stochastic Cooling

It is clear from the data shown in Table 1 that the main limitation to the luminosity lifetime comes from intrabeam scattering (IBS) which induces emittance blow-up during physics stores. The RHIC Stochastic Cooling (SC) system [7–9] was designed to counter this mechanism and reduce the beam emittance: for each of the three planes of motion, it uses a pickup and kicker magnet pair separated by a multiple of $\pi/2$ phase advance. The longitudinal SC system was installed for Run7, while the transverse one was implemented in stages: vertical plane only for Run10, both planes for Run11.

With a fully operational 3D SC system, the average store luminosity jumped by a factor 2.5 from Run7 to Run11 to 30.0x10^{26}cm^{-2}s^{-1} while reducing the transverse emittance in both planes by over 30%. Further upgrades were brought to all pickups and kickers prior to Run14, mainly for reliability purposes [10]. Figure 2 shows the improvement in transverse cooling efficiency from Run7 to Run14.

THE HIGH LUMINOSITY LHC PROJECT[1]

O. Brüning, CERN, Geneva, Switzerland

Abstract

This presentation reviews the status of the high luminosity LHC project, and highlights the main challenges from the technology and beam physics point of view. It will mention the outcome of the 2015 Cost and Schedule review for the HL-LHC project and summarizes the status of the high field quadrupole and crab cavity development.

HL-LHC PERFORMANCE GOALS AND SCHEDULE

The Large Hadron Collider (LHC) was successfully commissioned in 2010 for proton-proton collisions with a 7 TeV centre-of-mass energy and delivered 8 TeV centre-of-mass proton collisions from April 2012 to the end of 2012. The LHC underwent from 2013 to 2015 a general consolidation of the magnet bus bar interconnections and started the second operation phase, the LHC RunII, in 2015 with beam energies of 6.5 TeV (→ CM collision energy of 13 TeV).

The full exploitation of the LHC is the highest priority of the European Strategy for particle physics. This strategy has been adopted by the CERN Council, and is a reference point for the Particle Physics Strategy of the USA and, to a certain extent, Japan. To extend its discovery potential, the LHC will need a major upgrade in the 2020s to increase its luminosity (and thus event rate) by a factor of five beyond its design value. The integrated luminosity goal is a ten-fold increase of the nominal design value (300 fb^{-1} → 3000 fb^{-1}). The required machine modifications require new technologies and novel operation concepts. These include among others: cutting-edge 11-12 tesla superconducting magnets; very compact with ultra-precise phase control superconducting crab cavities for beam rotation; new technology for beam collimation; long high-power superconducting links with zero energy and the operation with novel optics schemes and leveled luminosity. The necessary developments require substantial prototyping and testing.

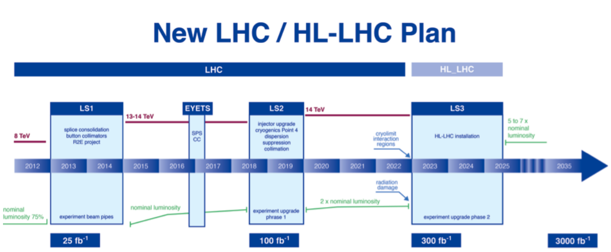

Figure 1: The LHC Baseline Program until 2025.

Figure 1 shows schematically the LHC baseline program until 2025 and Fig. 2 shows the potential evolution of the peak and integrated luminosities. After entering into the nominal energy regime of 13-14 TeV centre-of-mass energy in 2015, it is expected that the LHC will reach the design luminosity of $L = 10^{34}$ cm^{-2}s^{-1}. This peak value should give a total integrated luminosity of about 40 fb^{-1} per year. In the period from 2015 to 2022 the LHC will hopefully further increase the peak luminosity by exploiting upgrades implemented during the second long shutdown LS2. These upgrades include the Phase I upgrade of the LHC experiments and a full implementation of the LHC Injector complex Upgrade (LIU) project, opening the door to an operation beyond nominal bunch intensities and beam brightness. Margins in the design of the nominal LHC are expected to allow, in principle, about two times the nominal design performance.

After 2020 the statistical gain in running the accelerator without a significant luminosity increase beyond its design value will become marginal. The running time necessary to halve the statistical error in the measurements will be more than ten years after 2020. Therefore, to maintain scientific progress and to explore its full capability, the LHC will need to have a decisive increase of its luminosity.

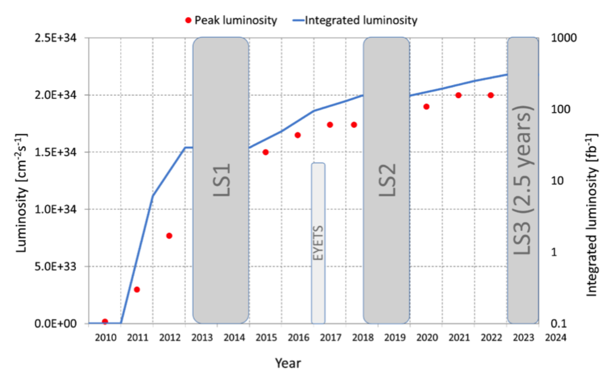

Figure 2: The projected evolution of peak and iterated luminosities over the LHC and HL-LHC project phases.

LHC LIMITATIONS AND HL-LHC CHALLENGES

The performance reach of the LHC beyond that of RunIII is limited by six fundamental limitations:

- Technical Bottle Necks
- Insertion Magnets: Lifetime and Aperture
- Crossing Angle and geometric reduction factor: Crab Cavities
- Performance optimization: Event rate and pileup density
- Beam power and particle losses
- Machine efficiency and availability

HIGH POWER PROTON FACILITIES: OPERATIONAL EXPERIENCE, CHALLENGES, AND THE FUTURE*

S. Cousineau, ORNL, Oak Ridge, TN 37830, USA

Abstract

High power proton accelerators are increasingly popular as drivers for secondary beams with a large variety of applications, such as neutron sources for materials science and neutrino factories for high energy physics. In the last few decades, average beam powers have increased substantially, giving rise to an array of challenges centered on providing high beam power and availability while maintaining low activation levels. This talk summarizes the current status of high power proton accelerators. It discusses recent operational experiences and lessons learned, and identifies the primary hardware and beam dynamics limitations. A brief review of planned next generation facilities and driving technologies is also presented.

INTRODUCTION

Modern day high power proton facilities are employed primarily in the production of secondary and sometimes tertiary particle beams for various applications. In the past quarter of a century, the number of high power proton facilities and the range of applications have increased dramatically [1]. This has been driven in part by the desire for a new generation of high power neutron sources with various pulse structures for materials and life science applications, and in part the emerging focus in HEP on "intensity frontier" applications such as neutrino beam production.

The average beam power is a combination of both the energy and average beam current, and these parameters are optimized to suit the desired application. In general, HEP applications require higher energies in the 10^2 GeV range for production of particles such as neutrinos, while materials science applications require mid-range energies on the order of a few GeV for neutron production. In the last quarter century, beam powers for these types of facilities have increased approximately an order of magnitude, as demonstrated by Figure 1, which shows beam powers for several facilities in the era 1988-1993 compared with operational beam powers today. A number of advances in accelerator technology and accelerator physics have enabled this evolution, including H- charge exchange injection, phase space painting, superconducting linear accelerators, massively parallelized simulations, and liquid targets.

Regardless of the end application, all high power proton facilities are designed and operated with the goal of providing stable beams with minimal beam loss and activation that allow for hands-on maintenance. In addition, user facilities such as neutron sources place a high degree of emphasis on machine reliability. While reliability is most often tied to hardware performance, activation levels are tied to beam dynamics challenges. Increases in beam power have to respect the reliability and activation goals, and therefore require troubleshooting of present limitations rather than "turning the knob up" on either beam current or energy.

This paper discusses the operational experience of today's highest power proton accelerator facilities, and the challenges that limit increases in beam power. Finally, it summarizes the high power horizon with a preview of future facilities and their driving technologies.

OPERATIONAL EXPERIENCE

Operational Metrics

Table 1 shows the operational metrics for eight high power proton accelerator facilities. Sustained operation at high power relies on preventative hardware maintenance and tight control over beam losses. Most facilities shown in the table operate for 4000-4500 hours per year, which allows for one to two extended maintenance outages.

For user based facilities, reliability, as defined by the ratio of the number of hours operated divided by the number anticipated, is the highest figure of merit, trumping even the average beam power. The reliability metrics in Table 1 are averages over the last 2-3 years. As seen, the spread is small with all facilities operating between 80-92%. In practice, it is very difficult to break the 90-92% threshold, possibly because much of the accelerator hardware is R&D in nature, or operating near technological limits.

Perhaps the parameter of highest interest to accelerator physicists, because it is closely tied to beam control, is activation. The gold standard for beam loss in an accelerator is considered to be 1 Watt/meter, on average. In practical terms, activation levels should not exceed roughly 100 mrem/hr in order to allow for routine hands on maintenance of the accelerator. Table 1 shows the typical and peak activation levels for six high power machines. Note that the activation levels include facility-specific nuances in terms of measurement time and distance, and a direct comparison between values is not meaningful. However, one can draw a few general conclusions from the survey data. First, the activation in linacs is 30 to 60 times lower than in rings. Second, typical activation levels fall below the threshold for hands on maintenance. Third, peak activation levels are roughly an order of magnitude higher than typical levels. The peak activations levels occur in localized regions, usually injection or extraction, where measures can be taken to provide extra shielding and work-practice controls. Even so, peak activation levels can limit the beam power.
