COMMISSIONING AND OPERATION OF 12GeV CEBAF *

A. Freyberger† for the CEBAF Commissioning Team, JLab, Newport News, VA 23606, USA

Abstract

The Continuous Electron Beam Accelerator Facility (CEBAF) located at the Thomas Jefferson National Accelerator Laboratory (JLAB) has been recently upgraded to deliver continuous electron beams to the experimental users at a maximum energy of 12 GeV, three times the original design energy of 4 GeV. This paper will present an overview of the upgrade, referred to as the *12GeV upgrade*, and highlights from recent beam commissioning results.

INTRODUCTION

The Continuous Electron Beam Accelerator Facility, CEBAF, designed for 4 GeV continuous electron beams for nuclear physics, was the first large scale implementation of SRF technology. The CEBAF design included 42 cryomodules with each cryomodule containing 8 SRF cavities to achieve the design energy of 4 GeV. CEBAF reached design energy in 1995. The cryomodules were evenly divided among two linacs, North and South, connected by magnetic spreaders, arcs and recombiner sections. The energy reach of 6 GeV of CEBAF was establish in 2000; CEBAF operated at energies up to 6 GeV until 2012.

The beam parameters for 6 GeV configuration can be found in Table 1. CEBAF supported simultaneous beam delivery to three experimental end-stations; each end-station receiving beams with energy a multiple of the one-pass energy, beam currents from sub 1nA to 190 μA and beam polarization greater than 85%. During 6GeV operations 178 experiments were performed by the experimental users.

THE 12GeV UPGRADE

An experimental case to upgrade CEBAF to 12 GeV was made at the start of the 21st century. *Mission need* was granted in 2004 by the Department of Energy for Jefferson to develop a design for a 12 GeV capable CEBAF. This design was completed and construction started in 2009, construction overlapped with 6 GeV beam operations for work that did not impact CEBAF operations. Construction that did impact CEBAF was interleaved with 6 GeV operations, notably the arc magnet upgrade during the 2011 shutdown. 6 GeV beam operations terminated in 2012, and the accelerator tunnel portion of the upgrade was sufficiently complete by the end of 2013 to start of beam commissioning activities.

The 12GeV upgrade design retained the same footprint as the original 4GeV CEBAF allowing for the new accelerator to use the existing tunnel with the addition of the new extraction line transporting beam to the new end-station, Hall-D. In order to achieve the 12 GeV energy requirement, the design called for:

- A new Arc10 that would enable an additional pass of energy gain in the North linac, 11 linac traverses versus 10 traverses for 6 GeV CEBAF.
- Additional cryomodules in each linac contributing 500MeV of energy gain, increasing the total energy gain to 1100 MeV/linac from 600 MeV/linac.

The beam parameters from for the 12GeV design can be found in Table 1. The main difference with the 6GeV beam parameters, aside from beam energy, is the increase in beam emittance and energy spread due to the copious synchrotron radiation effects in the high energy arcs.

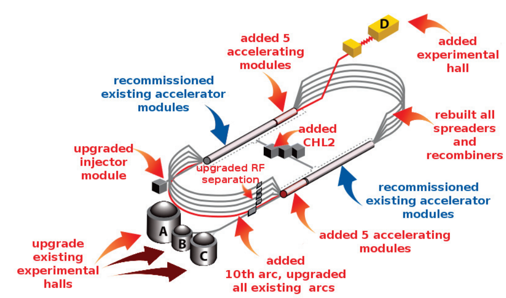

Figure 1: High level overview of the 12GeV upgrade

The scope of the accelerator upgrade is graphically presented in Figure 1.

Injector

The doubling of the CEBAF race-track energy requires that the injector energy be increased in order to maintain the same ratio of injection to one-pass energy. This energy increase was accomplished by replacing an original CEBAF cryomodule, denoted as C20, with a new cryomodule that provides 108 MeV in energy gain, denoted as C100. In addition the laser drive has been modified to allow for subharmonics of 499MHz in order to support the new 5-pass separation system. Details on the injector modifications and results of beam commissioning can be found in [1].

Linac

The ten cryomodules, C100s, that provide in total 1000 MeV per pass of additional energy gain were installed in five empty zones that existed at the end of each linac. The existing 20 cryomodules per linac from 6GeV CEBAF are an integral part of the new 12GeV CEBAF; 1200 MeV of energy is required from these modules to achieve the design energy of 12 GeV. During the upgrade, the linacs were warmed to 300 K to allow for the required cryogenic upgrades. Once the cryomodules were returned to the 2 K operating temperature

LHC COMMISSIONING AT HIGHER ENERGY

P. Collier, F. Bordry, J. Wenninger, CERN, Geneva, Switzerland

Abstract

The LHC has just come to the end of its first Long Shutdown (LS1) and preparations are underway to prepare for Run 2 data taking at 13 TeV centre of mass energy. After briefly recalling the major work undertaken during the 2-year long LS1, details will be given of the cool-down and hardware commissioning phase where each individual superconducting circuit is individually qualified for operation at nominal current. For the main dipole circuits this phase was completed with a quench training campaign in order to operate reliably at the required field. In parallel to the training campaign a rigorous cold checkout has been used to qualify the machine as an ensemble and to establish the conditions necessary for beam operation. The details of this phase will be given together with associated dry runs and beam injection tests. Finally, the latest news will be presented concerning the beam commissioning of the machine in preparation for first physics operation, which will hopefully begin in June.

INTRODUCTION

Between 2009 and early 2013 the LHC was delivering beam to the experiments almost continuously, with only relatively short end of year technical stops to perform essential maintenance. This mode of operation was triggered by the need for a major shutdown to consolidate the inter-magnet bus-bar splices before operation at nominal energy could be considered [1]. The time required to plan, prepare and organize this long shutdown (LS1) allowed three years of operation of the LHC at an intermediate energy, first at 3.5 TeV, then, in 2012, at 4 TeV.

During this first run a total of 30 fb^{-1} were delivered to the large general purpose experiments, using ~1400 bunches spaced by 50 ns to deliver a peak luminosity of over $7x10^{+33} cm^{-2}s^{-1}$. During this period there were also highly successful runs with Pb^{82+} heavy ion collisions as well as proton-lead operation during the final month.

LS1 lasted almost 26 months, beam-to-beam, and involved a huge amount of activity in the machine tunnel. Most activities were planned, but some were unexpected and others were added later [2]. Some of these are described below.

LHC LONG SHUTDOWN 1

The main priorities in LS1 were to prepare the machine for high-energy operation and to perform maintenance and consolidation to ensure reliable operation through the second long run, i.e. up to the next long shutdown scheduled for 2018. In addition to these main themes there were many additional activities to repair and upgrade individual systems. Major modifications to the control system itself as well as the operational software and databases were also foreseen. As a result it rapidly became clear that the LHC would be essentially a new machine when it restarted. Careful consideration was given from an early stage into the re-commissioning process and this was built into the overall planning.

Unfortunately only a few of the major planned and unexpected activities can be described here.

Super-Conducing Magnet and Circuit Consolidation (SMACC)

As soon as the machine was warm the SMACC activities could begin. Each interconnect in the machine was opened and the high-current bus-bars measured and inspected. Where necessary the joint was machined or repaired. Shunts were then applied across the joints and the whole junction encased in an insulating box. After suitable QA checks and measurements, the interconnect was re-closed [3]. With ~1700 interconnects and 10,170 high current splices this represented a huge workload over the shutdown, especially with an unexpectedly high number of splices (30%) needing to be completely re-made.

In addition to the splice repair a total of 18 cryo-magnets were removed from the machine and replaced by spares. These all had known unconformities: either showing high internal resistance, or having broken quench heaters. In total over 1 million hours were worked in the tunnel on these machine related activities.

Reliable Operation

During the first run of the LHC a problem with radiation-induced failures in electronic equipment was diagnosed and progressive mitigation measures used to keep single-event upsets at a reasonable level. During LS1 major works were undertaken to relocate, or shield electronics in several parts of the machine. The relocation often involved local civil engineering works, followed by major cabling campaigns to relocate the electronic equipment into more favourable locations. Over 100 control and power racks were moved. For the QPS system, which cannot be relocated, new cards were designed having a number of radiation-tolerant features and over 1000 cards in the tunnel were replaced [4].

To be reliable the major systems of the LHC needed maintenance. An example is the cryogenic system where some stations had been running for close to 5 years. A complete overhaul of the warm and cold compressors was undertaken as well as major interventions on the cryogenic lines and valve boxes. In addition, the opportunity was taken to repair several small leaks in the cryogenic feed lines (QRL).

An additional unexpected activity became apparent once the whole system had been warmed up. Several

COMMISSIONING OF NSLS-II*

F. Willeke, BNL, Upton, NY 11973, USA

Figure 1: Aerial view of NSLS-II.

Abstract

NSLS-II, the new 3rd generation light source at BNL was designed for a brightness of 10^{22} photons s^{-1} mm^{-2} $mrad^{-2}$ $(0.1\%BW)^{-1}$. It was constructed between 2009 and 2014. The storage ring was commissioned in April 2014 which was followed by insertion device and beamline commissioning in the fall of 2014. All ambitious design parameters of the facility have already been achieved except for commissioning the full beam intensity of 500mA which requires more RF installation. This paper reports on the results of commissioning.

NSLS-II OVERVIEW

The NSLS at BNL was the pioneer of the 3rd Generation Light Sources which provided a wealth of scientific results which have shaped the landscape of synchrotron radiation based science. However, the high demands on the performance of synchrotron light sources in the future motivated constructing a new machine which would enable spatial resolution of 1 nm and energy resolution of 0.1 meV. This mission was acknowledged by the Department of Energy in 2005 when the design of the new machine began. The goals require a beam brightness of B = 10^{22} photons s^{-1} mm^{-2} $mrad^{-2}$ $(0.1\%BW)^{-1}$. The corresponding beam parameters are a beam current of 500 mA, a sub-nm horizontal emittance with < 1% emittance ratio. Furthermore, state-of- the- art and beyond small gap undulators are needed to generate the ultra-bright photon beams. With full beam intensity, NSLS-II will be the brightest synchrotron at present.

The facility has the following topology: The ~800 m circumference ring building houses the accelerator tunnel (width 3.7m, height 3.2m) and the 17m wide experimental floor. Power supplies, vacuum equipment, diagnostics and controls are placed on the 86 cm thick tunnel roof. The ratchet shield wall is 100 cm thick.

* Work supported by DOE under contract No.DE-AC02-98CH10886.

The injector complex with the 200 MeV s-band LINAC and the 158 m circumference 3 GeV Booster Synchrotron is placed inside the ring. Also on the inside of the ring are five service buildings with mechanical utilities and HVAC systems as well as the RF-Cryogenic complex. The cooling tower and the central DI water system are in the center of the ring. On the outside of the ring building are five laboratory-office- buildings, each with 145 seats and several laboratory spaces. (See Figure 1.)

ACCELERATOR LATTICE

NSLS-II has a double bend achromat lattice with 30 cells on a 792 m circumference. The dipole magnets are long and weak (l = 3.69 m, B = 0.4 tesla) which allows obtaining close to DBA minimum beam emittance with moderate peak beta-values (30 m) and chromaticities >- 3. The gentle bends also imply low energy loss per turn (286 keV/e/turn). These are favorable conditions to increase radiation damping by adding six 3.4m long, 1.85 Tesla damping wigglers thereby increasing radiation damping and reducing emittance by more than a factor of two. The beam emittance obtained this way is only 0.9 nm rad. The straight sections for insertion devices alternate between long (9.3m, 3m vertical beta) and short (6.6m, 1m vertical beta). The damping wigglers weakly break the 15-fold symmetry to 3-fold symmetry. Three of the long straight sections are needed for injection and six superconducting RF cavities (including two passive units; for details see [1].)

TIMELINE

The mission of NSLS-II was acknowledged in 2005 by the DOE (CD-0) which was followed swiftly by the completion of the conceptual design and the establishment of a cost and schedule baseline (CD-1 in 2007 and CD-2 in 2008). Civil construction started in June 2009 after CD-3 was granted. Two years later, in the spring of 2011, the first part of the ring building was ready for accelerator installation which was completed by

HIGH BEAM INTENSITY HARP STUDIES AND DEVELOPMENTS AT SNS*

W. Blokland, ORNL, Oak Ridge, TN, USA

Abstract

The Spallation Neutron Source (SNS) Harp consists of 30 wires for each of the horizontal, vertical, and diagonal planes. The purpose of the harp is to measure the position, profile, and peak density of the high intensity beam coming out of the accumulator ring and going onto the spallation target. The data-acquisition hardware is now over ten years old and many of the electronics parts are obsolete. Occasionally, the electronics must be rebooted to reset the sample-and-hold circuitry. To evaluate options for a new system, the signals from the harp were studied. This paper will describe these studies' results, the design, and initial results of the new and simpler data-acquisition system.

INTRODUCTION

The harp was built as a removable instrument to measure the horizontal, vertical, and diagonal position and profile of an up to 1.4 MW, 1 GeV proton beam 10 meters in front of the target, using thirty 100 µm tungsten wires per plane, see Fig. 1 and [1,2].

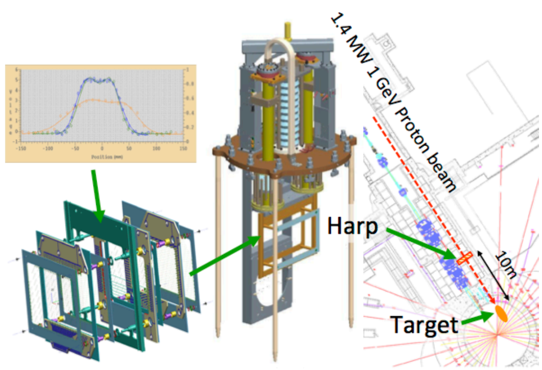

Figure 1: Harp actuator and profiles.

Initially, the harp was only to be inserted during tune-up, but the mechanism to insert and retract the harp was not strong enough and the harp is now left inserted at all times, allowing us to monitor the beam profile during full power production runs. The data-acquisition system consists of low-pass filters, amplifiers, and two sample-and-hold circuits per wire to integrate the charge intercepted and to integrate the baseline charge, followed by digitizer boards, see [3]. The analysis uses a single or double super-Gaussian function fit to derive the position and RMS width of the beam, see [4].

The data-acquisition electronics, designed and implemented by LANL, is now well over 10 years old and occasionally locks up and requires a manual reset. Many of the electronic parts are now obsolete and a redesign would be required to replace the electronics. Another issue is that the signal strength during production beam intensity saturates the sample-and-hold circuits. To avoid this saturation, we sample later, well into the signal decay to minimize the signal distortion.

STUDIES

To study the harp system and determine the requirements for a new data-acquisition system, we made the harp signal available for studies. An interconnect was placed between the diagonal plane cable from the harp and the electronics to allow us to temporarily disconnect a single wire from the electronics and route the signal to a scope for studies.

Wire Signal Strength

The first study was to determine the amount of charge intercepted by the wires to help define the requirements for a new data-acquisition system.

The instant current created by the proton beam charges up the long cable from the harp to the upstairs service building, while a 1 MOhm resistor discharges the charge as shown in Fig. 2.

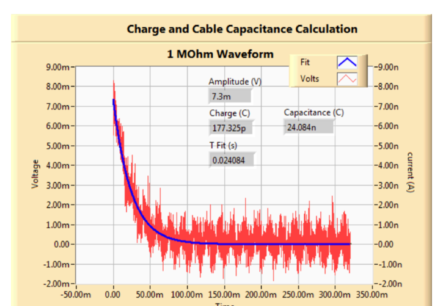

Figure 2: Wire charge measurement.

By fitting the discharge curve, we can approximate the total charge received, the peak voltage, and the capacitance of the cable. In this particular case, 2.5 µC beam, the measured charge was 177 pC, with a peak voltage 7.3 mV, giving a cable capacitance of C=Q/V=177pC/7.3 mV or about 24 nF. Given the beam pulse duration of 670 ns and assuming a flattop longitudinal profile, the instantaneous current is 0.26 mA.

We extrapolate the maximum expected voltage and current for the full intensity beam of 21 µC to be around 60 mV and 2.2 mA.

OVERVIEW OF BEAM INSTRUMENTATION FOR THE CADS INJECTOR I PROTON LINAC*

Y.F. Sui#, J.S. Cao, H.Z. Ma, L.D.Yu, Y. Zhao, Q.Y. Deng, J. He, X.Y. Zhao, Q. Ye, J.H. Yue, L. Wang, IHEP, 100049, China
Key Laboratory of Particle Acceleration Physics and Technology, IHEP, Chinese Academy of Sciences

Abstract

The injector I of China Accelerator Driven Subcritical system (C-ADS), which is composed of an ECR ion source, a low energy beam transport line (LEBT), a radio frequency quadrupole accelerator (RFQ), a medium energy beam transport line (MEBT) and cryomodules with SRF cavities to boost the beam energy up to 10 MeV. The injector linac will be equipped with beam diagnostics to measure the beam position, the transverse profile and emittance, the beam energy as well as beam current and beam losses. Though many of that are conventional design, they can provide efficient operation of injector linac. This paper gives an overview of C-ADS linac beam instrumentation.

INTRODUCTION

The Chinese ADS project is aimed to solve the nuclear waste problem and the resource problem for nuclear power plants in China. With its long-term plan lasting until 2030th, the project will be carried out in 3 phases: Phase I of R&D facility, Phase II of experiment facility and Phase III of industry demonstration facility. The driver linac of the CADS consists of two injectors to ensure its high reliability. Each of the two injectors will be a hot-spare of the other. Although the two injectors that are installed in the final tunnel will be identical, two different design schemes, named injector I and II respectively are being pursued in parallel by the Institute of High Energy of Physics (IHEP) and the Institute of Modern Physics (IMP). [1] The Injector I ion source is based on ECR technology. The beam will be extracted with an energy of 35 keV. The ion source will be followed by a Low Energy Beam Transportline (LEBT), which consists of 2 solenoids, a fast chopper system and a set of beam diagnostics including CTs and faraday cup. A Radio Frequency Quadrupole (RFQ) will accelerate the beam up to 3.2 MeV and will be followed by the first Medium Energy Beam Transport line (MEBT1), fully instrumented and also equipped. The next section is two cryogenic modules named CM1 and CM2 with seven cold beam position monitors in each, which accelerate beam up to about 10 MeV. The last section is the second Medium Energy Beam Transport line (MEBT2). The drift tubes between magnets provide the gap for diagnostics.

The injector I linac is equipped with beam diagnostics to measure the beam position, the transverse profile, the beam emittance, the beam energy as well as beam current and beam losses. This will provide efficient operation of drive linac and ensure the beam loss at a low level. A list of the different type of monitors using in the injector I linac is presented in Table 1.

Table 1: List of beam instrumentation in C-ADS linac

Device	Accuracy	Resolution	Quantity
Beam position monitor	±100um	30 um	25
Wire scanner	±0.5mm	50 um	4
Beam emittance unit	10%	-	2
Beam current monitor	1.5%	0.01mA	5
Beam loss monitor	1%	-	8
Beam energy monitor	±1deg	0.5deg	3
IPM	1mm	200 um	1
Electron scanner	1mm	300um	1

COMMISSIONING RESULTS OF THE NEW BPM ELECTRONICS OF THE ESRF BOOSTER SYNCHROTRON*

M. Cargnelutti, Instrumentation Technologies, Solkan, Slovenia
B. K. Scheidt, ESRF, Grenoble, France

Abstract

The 75 BPM stations of the Booster Synchrotron of the ESRF have been equipped with new RF electronics from December 2014. This new BPM system is based on the commercial Libera Spark system and now provides beam position data at various output rates, and with a possible time resolution even below that of the orbit-turn time (1 us). All modules are situated inside the Booster tunnel and powered by an Ethernet cable. This implies that the RF cables from the BPM blocks are less then 3m and only a single trigger signal in daisy chain is sufficient to keep the 75 stations in turn-by-turn phase over the full energy ramping (200 MeV to 6 GeV) time of typically 50 ms. The high sensitivity of the system yields excellent performance at very low beam currents down to 10uA. Full results of the system, including the application as a high quality betatron tune monitor, will be presented.

INTRODUCTION

This paper presents the measurements achieved during the commissioning of the new BPM electronics readout system for the ESRF booster synchrotron. The advantages of installing of the electronics in the tunnel and their integration in the control system are also described.

The ESRF booster ring accelerates the electron beam coming from the 200 MeV linear pre-injector up to the extraction energy of 6 GeV in a 50 ms period, with 10 Hz cycling frequency. In case of "long-pulse" operation mode, 352 bunches with a maximum current of 5 mA are injected in the storage ring, which operates with 200 mA current. Other operation modes enable multi-single bunch configurations with 1 to 5 bunches and currents up to 0.5 mA. The 300 m ring contains 75 BPM blocks with 60 mm diameter and four buttons with a diameter of 10 mm [1].

The 25 years old BPM electronics are now replaced with the Libera Spark system provided by Instrumentation Technologies. The instrument is a cost-effective network attached device which digitizes and buffers the 4 RF signals from the BPM with 14-bit 125 MHz ADCs. The raw data is later processed in the FPGA delivering position, sum, I&Q and strength signals at Turn-By-Turn rate (1 MSa/s) [2]. This enables the study of the beam properties over the full acceleration cycle, with optional time-domain processing for single-bunch fill pattern [3].

INSTALLATION IN THE TUNNEL

The decision to install all 75 units inside the Booster tunnel was taken after a series of radiation dosimetry, that showed globally low radiation doses as expected. The units are located underneath the girders of the dipoles by means of a simple support. At only a few locations, where radiation doses are stronger (i.e. injection & extraction zones) the unit will be protected against radiation damage by a (slightly) different position and additional Lead shielding. The RF cables (RG-223) are only 3 m long between BPM block and the unit. This installation inside the tunnel yielded a significant cost reduction for this RF cabling, and also an important increase of the sensitivity and resolution of the BPM system since the attenuation of otherwise long (typically 50 m) RF cables is avoided. The installation of cables and units was carried out in 2 weeks, according with the time slots when the tunnel was accessible and during the weekly machine stops.

Data acquisition from all 75 stations is triggered with a daisy-chained signal which travels around the machine in less than 2 µs. To align all the data acquisitions at the same ADC sample a delay setting in the FPGA is used. No machine reference signal is provided to the device since the short acceleration cycle doesn't call for a PLL to control the ADCs sampling rate over time. This simplifies the interface making the instrument affordable without compromising the TBT performance.

CONTROL SYSTEM INTEGRATION

Libera Spark can be accessed through a SCPI-like interface over Ethernet (100 MbE and 1 GbE). Every unit is integrated in the TANGO control system through individual Device Servers (DS) running on a dedicate server. On top of them a "grouping" server collects data from all the stations providing global attributes both for parameters and signals – see Fig. 1. GUIs and Matlab functions enable the end user to control the system.

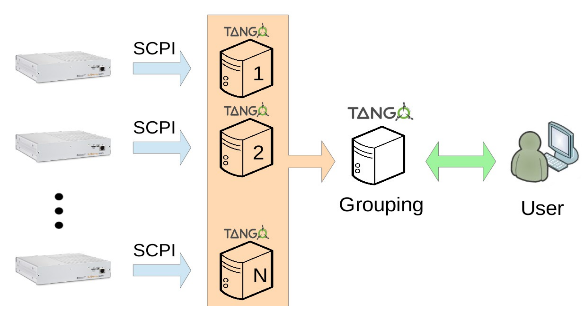

Figure 1: Control System integration architecture.

COMMISSIONING RESULTS

This chapter presents the data acquired from the ESRF booster ring with the new BPM electronics. Since 2 BPM blocks were dedicated to other measurements, only the acquisitions from 73 stations will be presented.

STATUS OF PROTON BEAM COMMISSIONING AT THE MEDAUSTRON ION BEAM THERAPY CENTRE

A. Garonna#, M. Kronberger, T. Kulenkampff, C. Kurfürst, L. Penescu, M. Pivi, C. Schmitzer, A. Wastl, F. Osmic, P. Urschütz, EBG MedAustron, Wr. Neustadt, Austria

Abstract

The MedAustron accelerator (Wiener Neustadt, Austria) will deliver clinical beams of protons (60 - 250 MeV) and carbon ions (120 - 400 MeV/n) to three ion beam therapy irradiation rooms (IR). Clinical beams and proton beams up to 800 MeV will be provided in a fourth IR, dedicated to non-clinical research. A slow-extracted proton beam of maximum clinical energy reached for the first time the IR3 in October 2014, thus providing the technical proof-of-principle of the entire accelerator chain. The main characteristics of the MedAustron accelerator system are presented, along with the results obtained along the ongoing commissioning.

INTRODUCTION

MedAustron is a synchrotron-based ion beam therapy centre. The accelerator supports beam rigidities up to 6.4 Tm. The accelerator layout is shown in Fig. 1. Its design [1] originates from those of PIMMS [2] and CNAO [3]. The injector produces beams of H_3^+ or C^{4+}, which are chopped with a fast electrostatic deflector, then bunched and pre-accelerated to 7 MeV/n with a Radiofrequency Quadrupole (RFQ) and an IH-DTL linac. In the Medium Energy Beam Transfer line (MEBT), the beam is stripped to H^+ or C^{6+} before injection into the synchrotron. The synchrotron has a superperiod of 2 with non-dispersive regions for injection and the Radiofrequency (RF) cavity. After acceleration, the beam is extracted via the third-integer resonance in the High Energy Beam Transfer Line (HEBT). Since last year [4-5], the installation of accelerator components for proton treatments in the two horizontal beam lines of IR2 and IR3 has been completed and a first beam of protons at 62.5 MeV reached IR3 in October 2014. Beam commissioning is currently resuming and passing the torch to medical commissioning.

INJECTOR AND MEBT

The commissioning of the beam from the source to the end of the MEBT has been completed at the end of 2014 with very positive results, in terms of intensity, transmission and stability. The main contributors to this progress have been: the extensive work on the IH stability (cooling and setpoint adjustment), optimization of the IH quadrupole strengths, steering at the source exit and in the matching section between RFQ and linac and finally, the increase of the RFQ output energy. The appropriate choice of the operation point of the linac was critical in stabilizing the energy of the beam injected into the ring. A summary is shown in Table 1.

adriano.garonna@medaustron.at

Table 1: Results of Commissioning up to the MEBT

Parameter	Performance
S1 current	650 μA
Linac exit current (H_3^+)	290 μA ± 3 %
Transmission through RFQ+Linac	45 %
MEBT exit current (H^+)	805 μA ± 2%
Transmission through MEBT	93 %
Energy Stability	± 0.1 %

SYNCHROTRON INJECTION

Multi-turn Injection

The injection in the ring is performed in 16 turns via a linearly decaying π orbit bump of 41 mm horizontal amplitude with 100 μs linear decay time. The resulting horizontal RMS geometric beam emittance is around 8 μm and the maximum injected number of particles is $6 \cdot 10^{10}$ protons, corresponding to 6 effective injection turns. Without orbit correction, the measured beam closed orbit errors are within ± 7 mm in the horizontal (H) plane and ± 2 mm in the vertical (V) plane.

RF Capture

The debuncher phase and amplitude were adjusted by measuring the time-of-flight coming from the phase probes in the MEBT and by maximizing the debunching time of a 1 μs injected beam pulse length. The results were confirmed by empty-bucket measurements and show that the RMS injected momentum spread can thus be decreased from $1.6 \cdot 10^{-3}$ to $0.5 \cdot 10^{-3}$.

The capture RF frequency (~ 470 kHz) was chosen by maximizing locally the signal on the current transformer and the sigma signal on the pickups. The voltage is adiabatically ramped to 170 V over 150 ms.

Beam Instability

With injected intensities over $1 \cdot 10^{10}$ protons (1 mA), erratic and strong beam losses were observed, with both unbunched and bunched beam. The variability of this effect is very strong in time. The common patterns are beam losses of nearly 90 % in around 100-300 ms, starting 0.1 to 3 s, when using an artificially prolonged injection flat-bottom (FB). These losses are correlated with coherent beam orbit oscillations in the V plane, with characteristic frequencies ~120 kHz and exponential rise times of 0.1 - 0.3 s, see Fig. 2.

FABRICATION OF TESLA-SHAPE 9-CELL CAVITIES AT KEK FOR STUDIES ON MASS-PRODUCTION IN COLLABORATION WITH INDUSTRIES

T. Saeki# and H. Hayano, KEK, 1-1 Oho, Tsukuba, Ibaraki, Japan

Abstract

The construction of the new Center-of-Innovation (COI) building started at KEK from 2014 for the studies of mass-production of Superconducting-RF (SRF) accelerators in collaboration with industries. The COI building is sitting next to the existing KEK-STF building and includes various SRF facilities like clean-room for cavity-string assembly, cryomodule-assembly facility, cryogenic system, vertical-test, cryomodule-test, input-coupler processing, cavity Electro-Polishing (EP) facilities, and control-room/office-rooms in the dimension of 80 m x 30 m. The purpose of these new SRF facilities is to establish a close collaboration between SRF researchers and industries in order to prepare for the upcoming small- and middle-scale SRF programs, and also large-scale future SRF projects, like ILC. This article reports the fabrication of four TESLA-shape 9-cell cavities for the commissioning of these new facilities the details of the new SRF facilities.

INTRODUCTION

KEK and several industry companies: Mitsubishi Heavy Industry (MHI), Hitachi, Toshiba, Mitsubishi Electronic, Kyocera, Fujikura, etc. obtained a new budget from "Ministry of Education, Culture, Sports, Science and Technology of Japan" (MEXT) in 2012. The title of new budget is "New Project for Creating a Market for EARTH-CLEANER Products in Collaboration with Industries and Laboratories / Universities". In the program of the budget, we proposed to produce new innovations to realize sustainable societies on the earth by the accelerator science in collaboration among laboratories, universities, and industries. In order to keep the earth sustainable, we need to solve the serious problems such as "pollution of the earth", "warming of the earth", "energy crisis", "natural resources shortage", etc. Here, the situation created the needs for "new energy network system", "integration of power plant and water/air cleaner" and so on, which clean the environment of the earth. The new project by the budget utilizes the Superconducting Accelerator and Quantum Beam Technology, and create a new market for these "EARTH CLEANER" products. Finally, the goal of the project is to challenge the realization of global/sustainable environment on the earth. After the proposal and budget were successfully approved, we started the construction of new SRF building at KEK, which is so-called Center-of-Innovation (COI) building. Various SRF facilities were planned to be installed in the COI building to realize the innovations to create the EARTH-CLEANER products. We started the construction of COI building at KEK from 2014 and finished the construction in January 2015.

VARIOUS SRF FACILITIES IN COI BUIDING

Figure 1 shows the picture of the existing Superconducting Test Facility (STF) and new COI buildings, and the bird view of these two buildings at KEK.

Figure 1: The picture of STF and COI buildings and the bird view of these two buildings.

The new COI building includes various SRF facilities like clean-room for cavity-string assembly, cryomodule-assembly facility, cryogenic system, vertical-test, cryomodule-test, input-coupler processing, cavity Electro-Polishing (EP) facilities, and control-room/office-rooms in the dimension of 80 m x 30 m. The layout plan of these facilities in the COI building is shown in Figure 2.

AWAKE, THE PROOF-OF-PRINCIPLE R&D EXPERIMENT AT CERN

M. Bernardini, T. Bohl, C. Bracco, A. Butterworth, S. Cipiccia, H. Damerau, S. Doebert, E. Gschwendtner, V. Fedosseev, E. Feldbaumer W. Hofle, A. Pardons, A. Petrenko, J. Schmidt, M. Turner, H. Vincke, CERN, Geneva, Switzerland
P. Muggli, MPP Munich, Germany

Abstract

The Advanced Proton Driven Plasma Wakefield Acceleration Experiment (AWAKE) is a proof-of-principle R&D experiment at CERN. It is the world's first proton driven plasma wakefield acceleration experiment, using a high-energy proton bunch to drive plasma wakefields for electron beam acceleration. The AWAKE experiment will be installed in the former CNGS facility and will use the 400 GeV proton beam bunches from the SPS, which will be sent to a plasma source. An electron beam will be injected into the plasma cell to probe the accelerating wakefield. Challenging modifications in the area and new installations are required for AWAKE. First proton beam to the experiment is expected late 2016. The accelerating electron physics will start late 2017.

This paper gives an overview of the project from physics and engineering point of view, it describes the main activities and the milestones.

INTRODUCTION

In the baseline design of the AWAKE experiment at CERN, an LHC-type proton bunch of 400GeV/c (but with higher intensity of $3\cdot 10^{11}$ protons/bunch) will be extracted from the CERN SPS (see Fig. 1) and sent along the 750m long proton beam line towards a plasma cell, which will be installed in the former CNGS area.

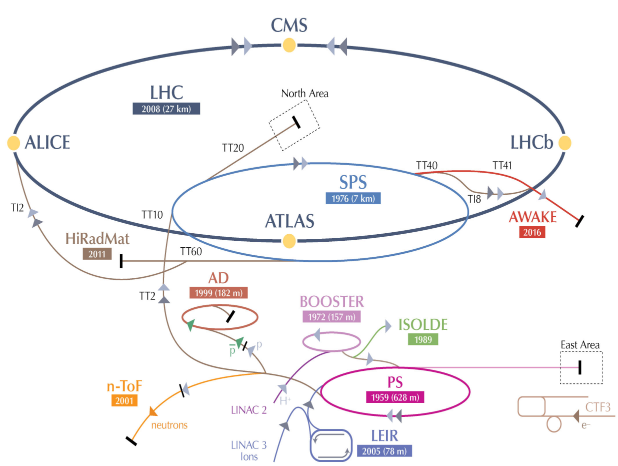

Figure 1: Layout of the CERN accelerator chain.

The proton beam will be focused to $\sigma_{x,y} = 200\,\mu$m near the entrance of the 10 m long Rubidium vapour plasma cell with an adjustable density in the 10^{14} - 10^{15} cm^{-3} range. When the proton bunch with an rms bunch length of $\sigma_z = 12$ cm (400 ps) enters the plasma cell, it undergoes the self-modulation instability (SMI) [1] i.e. the development a long bunch of protons into a series of micro-bunches that resonantly drive large wakefields. The effective length and period of the modulated beam is set by the plasma wavelength (for AWAKE typically λ_{pe} = 1mm). A high power (~4.5 TW) laser pulse [2] co-propagating and co-axial with the proton beam, will be used to ionize the neutral gas in the plasma cell and also generates the seed of the proton bunch self-modulation. Several diagnostics tools [3] will be installed downstream of the plasma cell to measure the proton bunch self-modulation effects. In the AWAKE master schedule the experimental evidence for the self-modulation instability corresponds to Phase 1, which foresees the following milestones: installation during 2015 until Q1 2016, hardware and beam commissioning in Q2/Q3 2016 and physics from Q4 2016.

In Phase 2 AWAKE aims at the first demonstration of proton driven plasma wakefield acceleration of an electron witness beam; an electron beam of $1.2\cdot 10^9$ electrons, which will be injected at 10 – 20 MeV/c into the plasma cell, will serve as witness beam and will be accelerated in the wake of the proton bunch and the accelerated electron bunch properties will be measured with an electron spectrometer. In Phase 2 the milestones are: installation during Q1 and Q2 2017, alternate with SMI physics, hardware and beam commissioning from Q3 to Q4, Physics from Q1 until the start of the CERN Long Shutdown 2 in Q3 2018.

AWAKE AT CERN

The AWAKE experiment is installed in the former CNGS facility. The conversion of the CNGS area into the AWAKE area started in January 2014 and challenging modifications are currently put in place. The following chapters describe the different activities and status of the systems of the AWAKE facility.

Proton Beam Line

The existing CNGS proton beam line is modified only in its last ~80 m, i.e. in the matching section and in the final focusing part in order to comply with the AWAKE requirements. The laser beam is merged with the proton beam at a distance of ~20 m from the plasma cell by adding a proton beam chicane to integrate the laser mirror. An offset of 19.9 mm exists between the proton and the laser beam axis, enough clearance to avoid intercepting protons and inducing losses. The proton and laser beams are made co-axial over the full length of the plasma cell, in particular the 3 σ proton beam envelope (~0.6 mm) must be contained in the 1σ laser spot size (~1

TOWARDS ULTRA-LOW BETA* IN ATF2

M. Patecki*, A. Aloev, D. Bett, M. Modena, R. Tomás, CERN, Geneva, Switzerland

K. Kubo, T. Okugi, T. Tauchi, N. Terunuma, KEK and SOKENDAI, Ibaraki, Japan

Abstract

The Accelerator Test Facility 2 (ATF2) has already demonstrated the feasibility of Final Focus Systems based on the local chromaticity correction scheme and its focusing capabilities by reaching a vertical beam size at the virtual Interaction Point (IP) of less than 50 nm. The level of chromaticity in ATF2 is comparable with the expected chromaticity in ILC, but 5 times lower than in a design of CLIC. ATF2 gives the unique possibility to test CLIC chromaticity level by reducing the vertical beta function at the IP by a factor of 4 (the inverse proportionality of chromaticity with beta function value at IP is assumed). The experience collected by tuning of a more challenging machine would be beneficial for both ILC and CLIC projects.

Simulations show that the multipolar errors and final doublet fringe fields spoil the IP beam sizes at ATF2. Either increasing the value of the horizontal beta function or installing a pair of octupole magnets mitigate the impact of these aberrations. This paper summarizes the studies towards the realization of the ultra-low beta* optics in ATF2 and reports on the progress of the construction of the octupoles.

INTRODUCTION

In the future linear colliders (CLIC [1], ILC [2]) the high collision rate is achieved by colliding the beams demagnified to the nanometer size in the interaction point (IP). Strong quadrupole magnets, called final doublet (FD), are used for the beam focusing at the IP, but they also introduce the chromatic effect which causes that the off-momentum particles are not focused exactly at the focal point, leading to larger spot sizes at the IP. In the ATF2 [3], which is a Final Focus System (FFS) test facility, the IP vertical beam size is expected to be 450 nm without correcting the chromaticity and 37 nm if the chromaticity is compensated. This shows the importance of the chromaticity correction.

A novel scheme [4], based on local chromaticity correction in the FD, is tested in ATF2. Its operating principle has been already experimentally validated by measuring a beam size of about 45 nm [5–7]. Therefore, the local chromaticity correction scheme is considered as a baseline for CLIC and ILC FFS. However, the level of chromaticity in ATF2 is comparable with the ILC expectation, but a factor 5 lower than in case of CLIC. For this reason, the ultra-low β^* [8] project is studied in ATF2, reducing the value of β^* by a factor 4, set the chromaticity to be comparable with CLIC (see Table 1). Larger tuning difficulties are expected under these more demanding conditions. Experiencing with higher chromatic lattice would benefit to both CLIC and ILC.

The chromaticity roughly scales as $\zeta_y \sim L^*/\beta_y^*$, so it can be increased by decreasing the β_y^* value, initially by a factor 2 to test a halfway moderated step and finally by a factor 4, which brings the chromaticity level close to CLIC. This will cause the β_y function increase in the FFS, especially in the FD which makes the beam more sensitive to the magnetic imperfections as e.g. multipolar errors, fringe fields, and other aberrations. Some of these issues were already addressed and mitigated in order to make the ultra-low β^* project feasible [9, 14].

MULTIPOLE COMPONENTS AND FRINGE FIELDS OF THE ATF2 MAGNETS

The decrease of the IP β_y value causes that the β_y function in the Final Focus region increases, as shown in Fig. 1. As a consequence, the beam size is larger in the FF and therefore the particles (especially in the tails) are more sensitive to any aberrations and imperfections. It was reported in [9] that carefully measured multipole components [10, 11] of the ATF2 magnets are setting the main limitation in reaching the low beam size for the ultra-low β^* optics. From the simulations, where all multipole components are represented as thin multipoles with integrated gradient corresponding to the measurements, the vertical IP beam size (in rms sense) is $\sigma_y^* = 27$ nm, which is not satisfactory. The impact of the magnetic multipole components was calculated using a MAPCLASS2 [12] code including a high-order transfer map given by PTC [13].

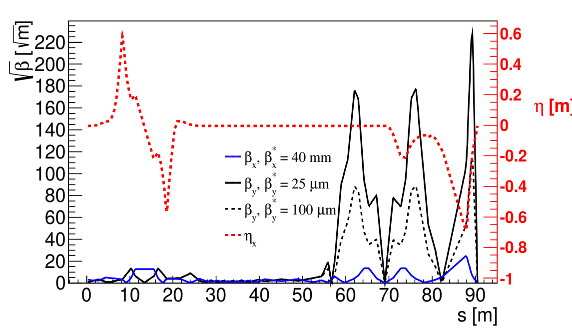

Figure 1: β functions and dispersion along the ATF2 beam line in case of nominal β_y^* and ultra-low β_y^* optics. β_x^* is increased by a factor 10 to minimize horizontal to vertical coupling.

Another limitation in reaching the low beam size in case of ultra low β optics is the magnetic fringe fields of the

HIGH-PERFORMANCE SIMULATIONS OF COHERENT SYNCHROTRON RADIATION ON MULTICORE GPU AND CPU PLATFORMS *

B. Terzić†, A. Godunov, K. Arumugam, D. Ranjan, M. Zubair
Old Dominion University, Norfolk, VA 23529, USA

Abstract

Coherent synchrotron radiation (CSR) is an effect of self-interaction of an electron bunch as it traverses a curved path. It can cause a significant emittance degradation and microbunching. We present a new high-performance 2D, particle-in-cell code which uses massively parallel multicore GPU/GPU platforms to alleviate computational bottlenecks. The code formulates the CSR problem from first principles by using the retarded scalar and vector potentials to compute the self-interaction fields. The speedup due to the parallel implementation on GPU/CPU platforms exceeds three orders of magnitude, thereby bringing a previously intractable problem within reach. The accuracy of the code is verified against analytic 1D solutions (rigid bunch).

INTRODUCTION

Coherent synchrotron radiation (CSR) can lead to a host of deleterious effects, such as increase in emittance and energy spread and microbunching instability. First step in mitigating these adverse effects is developing a code for high-fidelity numerical simulation of CSR. Numerical simulations of the CSR effects based on Greens function approach have proven to be extremely challenging because of the following features of simulation: (i) large memory requirement associated with storing the history of the beam bunch; (ii) difficulty to accurately account for retardation; (iii) large cancellation between $\boldsymbol{E}$ and $\boldsymbol{B}$ fields in Lorentz force; (iv) sensitivity to numerical noise, exacerbated by presence of gradients in relevant equations; (v) the manner in which self-interactions scale. In this paper, we present a new, 2D particle-in-cell code for modeling CSR and other collective effects in an electron beam using state-of-the-art computing platforms. The proposed method is optimized to run efficiently on different computing platforms such as GPUs, multicore CPUs and on hybrid CPU-GPU. This adaptation of the code design to the new computing architectures results in unprecedented efficiency and fidelity.

EQUATIONS OF MOTION

The dynamics of electron beams is captured by the Lorentz force:

$$\frac{d}{dt}(\gamma m_e \boldsymbol{v}) = e(\boldsymbol{E} + \boldsymbol{\beta}\times\boldsymbol{B}), \tag{1}$$

where the relativistic $\boldsymbol{\beta}$ and γ, velocity $\boldsymbol{v}$, electric field $\boldsymbol{E}$ and magnetic field $\boldsymbol{B}$ given as, respectively,

$$\boldsymbol{\beta} \equiv \boldsymbol{v}/c, \quad \gamma = \frac{1}{\sqrt{1+\boldsymbol{\beta}^2}}, \quad \boldsymbol{v}(\boldsymbol{p}) = \frac{\boldsymbol{p}/m_e}{\sqrt{1+\boldsymbol{p}\cdot\boldsymbol{p}/(m_e c)^2}}, \tag{2a}$$

$$\boldsymbol{E} = -\nabla\phi - \frac{1}{c}\frac{\partial \boldsymbol{A}}{\partial t}, \qquad \boldsymbol{B} = \nabla\times\boldsymbol{A}. \tag{2b}$$

ϕ and $\boldsymbol{A}$ the *retarded scalar and vector potentials*, respectively, which are computed by integration of the charge distribution ρ and charge current density $\boldsymbol{J}$ over the *retarded time* $t' = t - |\boldsymbol{r}-\boldsymbol{r}'|/c$:

$$\begin{bmatrix}\phi(\boldsymbol{r},t)\\ \boldsymbol{A}(\boldsymbol{r},t)\end{bmatrix} = \int_0^\infty \begin{bmatrix}\rho(\boldsymbol{r}',t-\frac{\boldsymbol{r}-\boldsymbol{r}'}{c})\\ \boldsymbol{J}(\boldsymbol{r}',t-\frac{\boldsymbol{r}-\boldsymbol{r}'}{c})\end{bmatrix}\frac{d^2\boldsymbol{r}'}{|\boldsymbol{r}-\boldsymbol{r}'|}, \tag{3a}$$

$$\begin{bmatrix}\rho(\boldsymbol{r},t)\\ \boldsymbol{J}(\boldsymbol{r},t)\end{bmatrix} = \int_0^\infty \begin{bmatrix}1\\ \boldsymbol{v}(\boldsymbol{p})\end{bmatrix} f(\boldsymbol{r},\boldsymbol{p},t)d\boldsymbol{p}. \tag{3b}$$

$\boldsymbol{r}$ are the particle coordinates, $\boldsymbol{p}$ the particle momentum and $f(\boldsymbol{r},\boldsymbol{p},t)$ is the beam's particle distribution function (DF) in phase space, m_e is electron mass, c the speed of light. It is important to note that $\boldsymbol{E} = \boldsymbol{E}^{\text{ext}}+\boldsymbol{E}^{\text{self}}$, $\boldsymbol{B} = \boldsymbol{B}^{\text{ext}}+\boldsymbol{B}^{\text{self}}$. $\boldsymbol{E}^{\text{ext}}$ and $\boldsymbol{B}^{\text{ext}}$ are external electromagnetic (EM) fields fixed by the accelerator lattice. $\boldsymbol{E}^{\text{self}}$ and $\boldsymbol{B}^{\text{self}}$ are the EM fields from the bunch self-interaction, which depend on the history of the bunch charge distribution ρ and current density $\boldsymbol{J}$ via the retarded scalar and vector potential ϕ and $\boldsymbol{A}$.

As can be seen from Eq. (3a), computation of the retarded potentials requires integration over the history of the charge distribution and current density. It points to the main computational bottlenecks of the CSR simulations: (i) data storage for the time-dependent beam quantities (ρ and $\boldsymbol{J}$); (ii) numerical treatment of retardation and singularity in the integral equation for retarded potentials; and (iii) accurate and efficient multidimensional integration in the equation for retarded potentials.

MODEL

Vlasov-Maxwell equations in CSR simulations can be solved either directly, by sampling the entire phase space of the DF, on a grid or in a appropriate basis [1], or by using a particle tracking approach (*e.g.*, [2, 3]). Computational requirements associated with sampling the entire phase space limit the direct solvers to low dimensions (usually 1D). Tracking methods are less restrictive owing to the fact that the sampling of the phase space is done only through simulation particles. This allows the study in higher-dimensional systems, which gives them a clear advantage and makes them a preferred method for modeling CSR effects [4]. We

ELECTRON LENSES FOR EXPERIMENTS ON NONLINEAR DYNAMICS WITH WIDE STABLE TUNE SPREADS IN THE FERMILAB INTEGRABLE OPTICS TEST ACCELERATOR*

G. Stancari†, K. Carlson, M. W. McGee, L. E. Nobrega, A. L. Romanov, J. Ruan, A. Valishev, Fermilab, Batavia IL, USA, D. Noll, IAP, Frankfurt am Main, Germany

Abstract

Recent developments in the study of integrable Hamiltonian systems have led to nonlinear accelerator lattice designs with two transverse invariants. These lattices may drastically improve the performance of high-power machines, providing wide tune spreads and Landau damping to protect the beam from instabilities, while preserving dynamic aperture. To test the feasibility of these concepts, the Integrable Optics Test Accelerator (IOTA) is being designed and built at Fermilab. One way to obtain a nonlinear integrable lattice is by using the fields generated by a magnetically confined electron beam (electron lens) overlapping with the circulating beam. The parameters of the required device are similar to the ones of existing electron lenses. We present theory, numerical simulations, and first design studies of electron lenses for nonlinear integrable optics.

INTRODUCTION

The study of neutrinos and rare processes in particle physics requires high-power accelerators to provide primary beams. The performance of these machines is limited by several factors, including tolerable losses and beam halo, space-charge effects, and instabilities. A possible path towards high-intensity rings includes these steps: developing theories and models describing high-intensity circular machines; carrying out related proof-of-principle experiments; and designing a new kind of rapid-cycling synchrotron based on nonlinear optics, wide tune spreads to suppress instabilities, and possibly self-consistent or compensated space-charge dynamics.

In particular, the Integrable Optics Test Accelerator (IOTA, Fig. 1) is a small storage ring (40 m circumference) being built at Fermilab [1–3]. Its main purposes are the practical implementation of nonlinear integrable lattices in a real machine, the study of space-charge compensation in rings, and a demonstration of optical stochastic cooling.

The concept of nonlinear integrable optics applied to accelerators involves a small number of special nonlinear focusing elements added to the lattice of a conventional machine in order to generate large tune spreads while preserving dynamic aperture [4]. The concept may have a profound impact in the design of high-intensity machines by providing improved stability to perturbations and mitigation of collective instabilities through Landau damping.

The effect of nonlinear lattices on single-particle dynamics will be investigated during the first stage of IOTA operations using pencil beams of electrons at 150 MeV with 10^9 particles/bunch, transverse rms geometrical equilibrium emittance in the range 0.01–0.04 μm, bunch lengths of a few centimeters, and a relative momentum spread of 1.4×10^{-4}. The goal of the project is to demonstrate a nonlinear tune spread of about 0.25 without loss of dynamic aperture in a real accelerator. The beam is generated by the photoinjector currently being operated at the Fermilab Advanced Superconducting Test Accelerator (ASTA) facility [5].

It was shown that one way to generate a nonlinear integrable lattice is with specially segmented multipole magnets [4]. There are also two concepts based on electron lenses: (a) axially symmetric thin kicks with a specific amplitude dependence [6–8]; and (b) axially symmetric kicks in a long solenoid [9, 10]. These concepts use the electromagnetic field generated by the electron beam distribution to provide the desired nonlinear transverse kicks to the circulating beam.

Electron lenses are pulsed, magnetically confined, low-energy electron beams whose electromagnetic fields are used for active manipulation of circulating beams [11, 12]. One of the main features of an electron lens is the possibility to control the current-density profile of the electron beam (flat, Gaussian, hollow, etc.) by shaping the cathode and the extraction electrodes. Electron lenses were developed for beam-beam compensation in colliders [13], enabling the first observation of long-range beam-beam compensation effects by tune shifting individual bunches [14]. They were used for many years during regular Tevatron collider operations for cleaning uncaptured particles from the abort gap [15]. One of the two Tevatron electron lenses was used for experiments on head-on beam-beam compensation in 2009 [16], and for exploring hollow electron beam collimation in 2010–2011 [17, 18]. Electron lenses for beam-beam compensation were built for RHIC at BNL, showing considerable improvements in luminosity [19–21]. Current areas of research on electron lenses include applications for the upgrades of the Large Hadron Collider: as halo monitors and scrapers [22], as charged current-carrying ‘wires’ for long-range beam-beam compensation [23, 24], and as tune-spread generators for Landau damping of instabilities before collisions.

In this paper, we describe the concept of electron lenses for nonlinear integrable optics and present the main design considerations for the Fermilab IOTA ring.

DEVELOPMENT OF HIGH GRADIENT RF SYSTEM FOR J-PARC UPGRADE

C. Ohmori, K. Hara, K. Hasegawa, M. Nomura, T. Shimada, F. Tamura, M. Toda, M. Yamamoto, M. Yoshii, KEK and JAEA J-PARC Center, 2-4 Shirakata-Shirane, Tokai, Ibaraki 319-1195, Japan
A. Schnase, GSI, 64291 Darmstadt, Germany

Abstract

A new 5-cell cavity has been developed for the upgrade of the J-PARC Main Ring. In the cavity, high impedance magnetic alloy, Finemet ®-FT3L, cores are loaded. The cavity was installed and has been used for the 320 kW beam operation. The cavity is operated with the RF voltage of 70 kV which is two times higher voltage than the present cavities. Eight more cavities will be assembled and installed in the next two years to increase the repetition rate of the Main Ring. This paper describes the status of cavity operation under the beam loading and status of the mass production of the cavities.

INTRODUCTION

We have been working for the development of magnetic alloy loaded RF system for high intensity proton ring for twenty years. In the first ten years, we have finished basic R&Ds on high field gradient [1], on the technique to control bandwidth [2], and on cut core configuration [3]. The water-proof coating [4] was developed to use magnetic alloys in water tanks. The high gradient RF systems were installed in the J-PARC RCS and MR [5, 6]. At the same time, the technology is also used for medical applications [7] and heavy ion acceleration [8].

In the last ten year, we have improved water-proof coating [4] and protection of cut surfaces of cut cores [9] to afford a stable operation. Now, J-PARC has delivered 500 kW beam to the Material and Life Science Facility and 320 kW for the T2K long base line neutrino experiment. We also worked for R&D of higher gradient RF systems to increase the repetition rate of the MR for the J-PARC upgrade. The key technology of high gradient RF is the development of magnetic alloy core with higher impedance to reduce the power consumption in the cavity. A magnetic annealing oven was constructed leasing a large spectrometer magnet from a high energy experiment during a short rental period of one year [10]. Based on the success of the proof-of-principle production of high impedance magnetic alloy cores, a dedicated magnetic annealing system was developed. The production by the dedicated system shows about 10 % improving on the core impedance because of an optimum magnetic field value and improvements of ribbon winding and insulation [11]. Although the magnetic oven which J-PARC made is designed for the production of large size cores, it is also reported that characteristics of the FT3L cores made by the oven is better than that of commercially available cores for medium size (330 mm) [12].

The dedicated magnetic annealing system was moved to a company according to the contract to produce FT3L in 2013. In these two years, 280 FT3L cores with the outer diameter of 800 mm were produced using the KEK-made production system. These 280 FT3L cores are manufactured for water-proof coating and cut core configuration. For the J-PARC upgrade to deliver 750 kW beam to the T2K experiment, all cavities in the MR will be replaced with new FT3L cavities to accelerate 2×10^{14} protons with 1.3 second cycle. Although the cavities are replaced, the final stage amplifiers and power supplies can be used. According to the power upgrade beyond 750 kW, the power supplies will be modified to increase the capability to drive the power.

5-CELL CAVITY

The first five-cell cavity was constructed and installed in 2014. Each cell consists of two sets of water tanks. Three cut cores are installed in a water tank. The cut core is covered by epoxy water-proof coating for the direct water cooling in the water tank. Between two water tanks, a ceramic gap for acceleration is located. The impedance of each cavity cell is 1450 Ω and it is higher than 1300 Ω of the proof-of-principle FT3L cell installed in 2012 because of the improvements of core impedance since the production of the FT3L cores in 2011 [11]. Before the installation, two sets of high power tests were performed with a total voltage of 80 kV for 1000 hours. It is a standard procedure to test a cavity with higher voltage and higher power dissipation for several hundreds hours before an installation to the tunnel. After the power test, the cavity was disassembled and status of the FT3L cores was investigated. The detail is described in the reference [13]. After re-assembling, the cavity was taken down to the MR tunnel by a crane as shown in Fig. 1 [13]. After the installation, the gap voltage of 14 kV has been generated. A total voltage of 70 kV which corresponds to two times higher voltage than the present cavity is generated.

Figure 2 shows the upgrade plan of the RF system. The upper figure shows the status before installation of the FT3L cavities. The lower figure shows the layout after replacement. Three sets of the 5-cell cavity will be installed in a long straight section where 4 sets of the present 3-cell cavity are installed. Two sets of FT3L cavity will be 4-cell type instead of 5-cell one to fit to short straight sections. Adopting the FT3L material for the cavity, the cavity impedance becomes about 40% higher and the length of the cavity cell is about 500 mm which is 90 mm shorter than the present cavity. The total length of the 5-cell cavity is about 700 mm longer than the present 3-cell cavity and 3 sets of the 5-cell cavity fit to

Abstract

Ionization cooling of intense muon beams requires the operation of high-gradient, normal-conducting RF structures in the presence of strong magnetic fields. We have measured the breakdown rate in several RF cavities operating at several frequencies. Cavities operating within solenoidal magnetic fields $B > 0.25$ T show an increased RF breakdown rate at lower gradients compared with similar operation when $B = 0$ T. Ultimately, this breakdown behavior limits the maximum safe operating gradient of the cavity. Beyond ionization cooling, this issue affects the design of photoinjectors and klystrons, among other applications. We have built an 805 MHz pillbox-type RF cavity to serve as an experimental testbed for this phenomenon. This cavity is designed to study the problem of RF breakdown in strong magnetic fields using various cavity materials and surface treatments, and with precise control over sources of systematic error. We present results from tests in which the cavity was run with all copper surfaces in a variety of magnetic fields.

INTRODUCTION

Strong, external magnetic fields have been shown to have an effect on the rate and extent of RF breakdown in normal-conducting cavities [1, 2]. The impetus for these studies was the design of ionization cooling channels for a future muon accelerator. Muons must be cooled quickly due to their relatively short lifetime. Ionization cooling – the only cooling method viable on muon-appropriate timescales – requires the operation of copper cavities in multi-Tesla external, solenoidal magnetic fields [3].

A model has been proposed to explain the effect of strong magnetic fields on RF breakdown rates [4]. In this model, field emission current from asperities (or other irregularities) on a cavity's surface is focused by the external solenoidal magnetic field into "beamlets" with current densities between 10^3 and 10^5 A/m^2 depending on field strengths, cavity geometry, etc. These beamlets may persist over multiple RF periods, causing cyclic fatigue and damage on cavity walls and contributing to an increased breakdown probability. Increases in solenoid field strength beyond some threshold value ($B \approx 0.5$ T in this context) produce negligible changes in beamlet current density due to space charge effects.

* Work supported by Fermilab Research Alliance, LLC under Contract No. DE-AC02-07CH11359.

Breakdown probabilities may therefore be reduced by careful surface preparation, which reduces the number of defects causing surface electric field enhancement. Note also that the problem is mitigated by using cavity materials with long radiation lengths, such as beryllium. Low-Z materials should allow beamlets to exit the cavity without depositing energy in cavity walls and contributing to material fatigue and damage.

Breakdown behavior consistent with this model has been observed in several RF cavities. The relevant methodology and results are described here.

EXPERIMENTAL SETUP AND RF MEASUREMENTS

Work was performed at the MuCool Test Area (MTA) at the south end of the Fermilab Linac. The MTA is an experimental hall optimized for R&D related to muon ionization cooling [5]. RF power is available in the hall at 201 MHz (4.5 MW) and at 805 MHz (12 MW). RF structures can be operated at high power inside the 44 cm diameter bore of a 5 Tesla superconducting solenoid. A data acquisition system (DAQ) automates the collection of data from six oscilloscopes and a wide array of instrumentation [6]. The DAQ also detects breakdown sparks in real time by examining (a) the time derivative of a cavity pickup probe voltage signal; (b) the time derivative of power reflected from the cavity; and (c) light from a spark, transmitted through an optical fiber and detected by a photomultiplier tube. Cavities are prepared and inspected inside a class-100 portable clean room.

A spark rate of 1 in 10^5 RF pulses defines the maximum "safe" operating gradient of a cavity. Higher breakdown probabilities lead to lower cooling channel efficiencies.

The All-Seasons Cavity

RF breakdown may be suppressed by pressurizing cavities with gas, which gas can also serve as an ionization cooling medium [7]. Furthermore, for "traditional" evacuated cavities, there is some interest in studying the dependence of breakdown probabilities on cavity materials and surface preparations [4, 8]. Muons, Inc. has designed, built, and tested a cavity suitable for R&D on these various ideas – "a cavity for all seasons" [9]. The so-called All-Seasons cavity (ASC) is shown in Fig. 1. It has replaceable walls, can be pressurized up to 100 atm or evacuated to 3×10^{-8} Torr, and is fed with a coaxial power coupler.

RELATIVE ALIGNMENT WITHIN THE MAX IV 3 GeV STORAGE RING MAGNET BLOCKS

J. Björklund Svensson*, M. Johansson, MAX IV Laboratory, Lund, Sweden

Abstract

Unlike the discrete magnet scheme of previous 3rd generation light sources, the magnet elements of the MAX IV storage rings are integrated in precision-machined magnet blocks. By analyzing the rotating coil measurements made by the magnet suppliers, we determined the relative alignment between consecutive magnet elements, which was found to be <10 μm RMS for all magnet block types in both horizontal and vertical direction. This article presents our analysis and results for the full magnet production series.

INTRODUCTION

The MAX IV synchrotron radiation facility [1], currently being built on the outskirts of Lund, Sweden, will house two electron storage rings; one smaller and one larger, at 1.5 and 3 GeV, respectively [2]. The magnet design concept [3], with magnet blocks containing several different magnets, will be used for both storage rings. The two halves of these magnet blocks are each CNC machined out of a single block of iron (2.3-3.4 m long), and together, they work as both supporting structure and return yoke for the magnets, see Figure 1. The different magnet block types for the 3 GeV ring are called M1, U1, U2, U3, U4, U5 and M2 and are placed in that order in the achromats. The production of these magnet blocks, including all field measurements, was entirely outsourced to industry[1], based on a technical specification and full set of drawings [4] provided by MAX-lab.

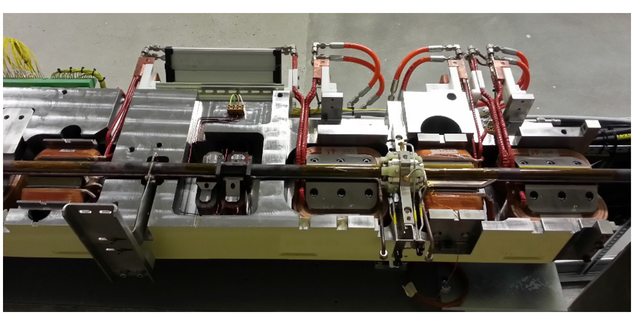

Figure 1: U3 bottom yoke half in achromat 16 with vacuum chamber in place, upstream side, viewed from the outside of the ring. Magnet elements from right to left (particle direction): QF, SFi, QF, Corr y/x, SD.

The MAX IV magnet block design assumes that the magnetic center location for each magnet depends only on the position of the pole surfaces [3]. This means that the alignment accuracy of individual magnets within each block is given by the mechanical tolerances of the top and bottom yoke halves (±0.02 mm over the whole block length), the loose quadrupole pole tips (±0.01 mm) and the sextupole and octupole yoke halves (±0.02 mm), as well as the respective assembly tolerances. Based on this assumption, no requirement of measuring magnetic center locations relative to the mechanical reference surfaces with high accuracy was made in the technical specification. However, from the provided field measurements, we could calculate the relative alignment between consecutive magnet elements within each magnet block.

The technical specification required measurement of the magnetic field strength as well as the harmonic content to characterize the magnets. Both magnet manufacturers decided to measure the harmonic content with rotating coils, and because of limited accessibility inside the magnet blocks they produced rotating coil shafts fitted with multiple coils placed at different positions along the shaft. These were used to measure several consecutive magnets, which then allowed us to evaluate the relative alignment since the magnets could be considered to have been measured within a common local coordinate system defined by the shaft. Several different rotating coil shafts were produced because of the differences in magnet layout between block types. A brief summary of the elements measured by each rotating coil shaft can be found in Table 1.[2]

Table 1: Elements Measured by Each Rotating Coil Assembly

Coil assembly	Magnet elements
"M1/M2 long"	OXX - QFe - OXY - QDe
"M1/M2 short"	OYY - SDe
"U3"	QF - SFi - QF - SD
"U1..U5 long"	QFm - SFm - QFm/ QF - SFo - QF
"U1..U5 short"	SD

MAGNETIC CENTERS FROM ROTATING COIL MEASUREMENTS

Displacements from Harmonic Content

To calculate the displacement of the rotating coil axis from the magnet center, one can use the feed-down of the main magnetic field components. Eq. 9.72 in [5] relates the

PRELIMINARY DESIGN OF THE HIGH-LUMINOSITY LHC BEAM SCREEN WITH SHIELDING*

V. Baglin, C. Garion, R. Kersevan, CERN, Geneva, Switzerland

Abstract

A new beam screen is needed in the High-Luminosity LHC (HL-LHC) final focusing magnets. Such an essential vacuum component, while operating in the range 40-60 K, has to ensure the vacuum performance and to prevent the beam-induced heating from reaching the cold bore which is at 1.9 K. In addition, it has to shield the cold mass from physics debris coming from the nearby beam collision points. To such purpose, energy absorbers made of tungsten alloy are installed onto the beam screen in the vacuum system. In this contribution, the proposed mechanical design is shown; it covers different thermomechanical aspects such as the behaviour during a magnet quench and the heat transfer from the tungsten absorbers to the cooling tubes. Assembly and manufacturing tolerances are also considered to evaluate the impact on the aperture. Results obtained with a short prototype assembly test are discussed.

INTRODUCTION

The beam screen is a complex object with a variety of functions [1]. HL-LHC beam screens are to be inserted into the separation dipole (D1) and the inner triplet (IT) quadrupoles (Q1 to Q3) of the LHC long straight sections 1 and 5. The main purpose is to intercept the beam induced heat load before it reaches the cold mass. It has also to shield the cold bore inner surface from direct particle impingement, which would lead to important outgassing while assuring high effective pumping speed on the cold bore toward pumping slots to fulfil vacuum requirements. It is equipped with shielding made of tungsten alloy to absorb the particle debris generated in the collision points [2].

The beam screen with shielding has to withstand the Lorentz' forces induced by eddy currents during a quench. The temperature of the beam screen must be actively controlled in a given temperature range: 40-60 K, where vacuum stability is guaranteed [1]. The system must be compatible with the global LHC impedance and with the machine aperture.

DESIGN OF THE BEAM SCREEN WITH SHIELDING

Preliminary design relied on the soldering of the absorbers made of tungsten alloy (Inermet® 180) on the beam screen shell [3]. This concept raises few critical aspects:

- Feasibility: how to accommodate the large differential thermal contraction between the tungsten alloy (around 0.09% at 50 K) and the beam screen shell in stainless steel (around 0.29 % at 50 K).
- Manufacturing: the brazing has to be done under vacuum and requires therefore a long furnace. The risk to have a bad brazing of one element is not negligible and would lead to the reject of the whole beam screen.
- Assembly: The tolerances obtained after brazing are not well managed. In addition, the beam screen obtained after the brazing of the tungsten alloy blocks would be very stiff and difficult to insert into the cold bore. This would require large assembly tolerances.

A concept based on a mechanical assembly of the tungsten absorbers is proposed here (Fig. 1). As for the standard LHC beam screen, the shell is perforated with oblong holes to provide sufficient pumping speed of the desorbed gas. The cooling is provided by four tubes, whose diameter depends on the type of magnet (external diameter of 16 mm and 10 mm for the Q1 and Q2-D1, respectively). The tungsten blocks are positioned on the beam screen by pins, welded onto the shell. Dedicated slots are used on one side of the block to allow differential thermal contraction; an overlap is used to reduce the number of pins. Elastic rings, in titanium grade 5, block the tungsten shields onto the beam screen. Copper strips are installed between the absorbers and the cooling tubes to assure a good heat transfer.

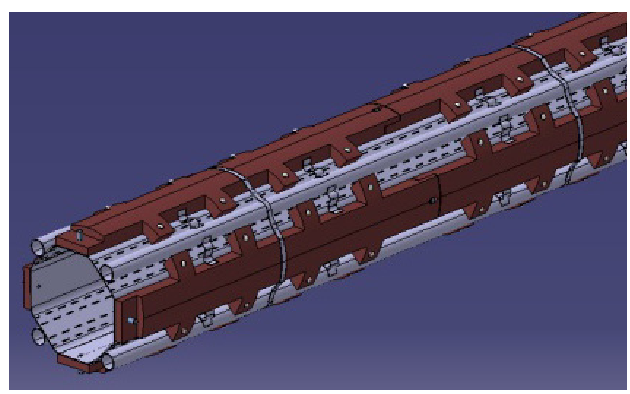

Figure 1: New beam screen design.

THERMAL MECHANICAL BEHAVIOR OF THE BEAM SCREEN

Self-weight Deformation

The weight of the tungsten absorbers is rather high (53 kg/m for the Q1 beam screen). The self-weight deformation has been assessed. The vertical deformation

Abstract

The LHC high luminosity project envisages the use of the crabbing technique for increasing and levelling the LHC luminosity. Double Quarter Wave (DQW) resonators are compact cavities especially designed to meet the technical and performance requirements for LHC beam crabbing. Two DQW crab cavities are under fabrication and will be tested with beam in the Super Proton Synchrotron (SPS) at CERN by 2017. This paper describes the design and prototyping of the DQW crab cavities for the SPS test.

INTRODUCTION

The LHC luminosity upgrade would significantly increase the potential to discover new physics from rare events. Bunch crabbing is one of the proposed techniques for increasing and levelling the LHC luminosity [1].

The first phase of the crab cavity program was to validate the design by demonstrating the nominal deflecting voltage. The first prototype of a DQW crab cavity was successfully cold tested at BNL in 2014 [2].

The next phase of the program envisages testing of the crab cavities with proton beams in SPS by 2017. A prototype cryomodule will host two fully dressed DQW crab cavities. The tests will try to crab bunches of proton beams for the first time ever.

DQW CRAB CAVITY FOR SPS TESTS

Optimization of the cavity body and port tubes was discussed in previous papers [3,4] and focused on reducing residual accelerating voltage and peak surface fields while respecting clearance requirements for the adjacent LHC beam pipe.

Position of the flanges has been carefully chosen to reduce the dissipative losses in the copper RF-seal gaskets while respecting space constraints of the cryomodule.

Figure 1 shows a bare DQW crab cavity with flanges and preparatory rings. Table 1 summarizes the main geometric and electromagnetic properties of the SPS DQW crab cavities.

DEVELOPMENT OF A 9 MHz 15 kW SOLID-STATE CW AMPLIFIER FOR RHIC

Shane Dillon, Tomco Technologies, Adelaide, Australia

Abstract

This paper describes the technical details of the development of a high-power solid-state amplifier for Brookhaven Laboratory. The amplifier must withstand short duration events of 100% full-power reflection, and also must guarantee delivery of continuous power into any load impedance at any angle.

INTRODUCTION

This paper describes some of the technical considerations in the design of a 9MHz 15kW CW amplifier for use in RHIC at Brookhaven National Laboratory (BNL). A total of six of these 15kW amplifiers will be commissioned, driving "gap cap" cavities [1].

The amplifier uses modular solid-state architecture and 6th Generation LDMOS power transistors. In the 15kW system, six 2.5kW amplifier units are combined via a 6:1 combiner unit to give a single 15kW output. The RF amplifier rack is located within the accelerator tunnel close to the cavity, and the associated switchmode DC power supply is located remotely to minimise the risk of damage due to ionizing radiation. A failsafe opto-isolated interlock link was designed to accommodate this requirement. The amplifier system has extensive control and monitoring functions and is equipped with three different control interfaces: it can be controlled locally via front panel push-buttons, or remotely via a wired parallel (PLC) interface or an Ethernet connection.

DESIGN CONSIDERATIONS

The major specifications of the amplifier are listed in Table 1. The requirement for the amplifier to supply significant amounts of forward power to mismatched loads presented a number of design challenges: Since circulators are not an option at 9MHz, the amplifier had to be capable of withstanding the mismatch in its own right, while remaining stable and well behaved under all load conditions.

To meet these specifications several key design factors had to be simultaneously optimised, namely: forward power, thermal management, stability, and parts count.

Forward Power

As a first approximation, the maximum power that a push-pull transistor pair can produce is limited to $2V_{dc}^2/R_L$, where V_{dc} is the DC supply voltage (fixed at 50 volts), and R_L is the load resistance presented across the transistor drains. Thus, if R_L is very large it becomes impossible to achieve the required output power. At the other extreme, if R_L is very small the available output power becomes very large, but as described later, there is a risk of destroying the device due to excessive die temperature. The various measures that were taken to address this issue are described in the following paragraphs.

Table 1: Basic Specifications

<table>
<tr><td>Frequency</td><td colspan="8">9MHz ±10% minimum</td></tr>
<tr><td>Power</td><td colspan="8">15kW CW minimum</td></tr>

<tr><td>Load transients</td><td colspan="8">Withstands 100% reflection at full rated power for at least 100µs</td></tr>
</table>

Thermal Management

Reflected power acts to disrupt the operating point of the transistor and affect its efficiency. For example, it can result in a very low impedance load being presented to the transistor, forcing the transistor to carry high current whilst simultaneously having a large voltage across it. This results in very high heat dissipation in the silicon die, which unless properly managed can lead to overheating and permanent destruction of the transistor. Safe operation hinges on minimising the thermal resistance between the power transistor and the cooling water. Therefore, a great deal of care was taken in the mechanical design to ensure a very low thermal resistance and a solid electrical connection from the flange to the earth.

Stability

Since the amplifier is required to operate into all phase angles of any possible VSWR, there is significant potential for amplifier instability. There is also a risk of that circuit elements might form high Q resonances with the load reactance. This can produce large gain variations and possible oscillations if any suitable feedback path exists. It can also result in damage to components such as harmonic filter capacitors or coupling capacitors.

Parts Count

In order to maximize the expected MTBF of the system, every effort was made to minimise the parts

INSTABILITY THRESHOLDS AND TUNE SHIFT ESTIMATION FOR SIRIUS

F. H. Sá*, L. Liu, X. R. Resende, N. Milas, LNLS, Campinas, Brazil

Abstract

In this work we present the evaluation of longitudinal and transverse instability thresholds as well as tune shifts for Sirius using time and frequency domain codes that are being developed in-house and take into account various effects on the beam instability, such as bunch by bunch feedback system, quadrupolar impedances from undulator chambers and tune spreads.

INTRODUCTION

This contribution is a continuation of the work presented at IPAC14 [1], where we detailed the construction of the impedance budget for Sirius and used a frequency domain code based on the solution of the Linearized Vlasov Equation for equally spaced Gaussian bunches [2, 3] to calculate thresholds for single and coupled bunch instabilities. After analyzing the results we concluded that: a) Due to the strength of the coupled bunch instability induced by the chamber wall, a transverse bunch by bunch feedback system will operate from start for safety; b) With a small positive absolute chromaticity (maximum of 1.5 in both planes) it is possible to get a strong damping of the chamber wall instability. This motivated us to include this value in our dynamic aperture and lifetime optimizations [4]; c) The thresholds for intra-bunch instabilities in the three planes are relatively low and can compromise some operation modes.

The last item motivated us to implement a single bunch tracking code to better characterize the intra-bunch dynamics. Even though the chromaticity and the interplay between coupled and single bunch instabilities were taken into account in the frequency domain code, other important effects such as potential well distortion, third harmonic cavity, tune shift with amplitude, quadrupolar impedances and the bunch by bunch feedback were not considered. The simultaneous action of these forces changes significantly the behavior of each bunch, which can increase or decrease the thresholds.

The effects described above also influence the multi-bunch dynamics and consequently the coupled bunch motion. However, they are generally of a stabilizing nature due to the introduction of tune spreads. For this reason we decided to focus on the single bunch dynamics first. The implementation of a multi-bunch tracking code will be performed later.

SINGLE BUNCH TRACKING CODE

The single bunch tracking code is presently implemented using MATLAB® but an implementation using C/C++ is planned to gain speed in the simulations.

* fernando.sa@lnls.br

Haissinski Equation Solver

The code is organized in two parts. First an equilibrium distribution in four dimensions is generated. In the transverse plane an exponential distribution of emittances and a uniform distribution of phases are used. In the longitudinal plane there are two options: a) generate energy deviations with a Gaussian distribution with the input value of the energy spread and longitudinal positions following the distribution determined by the input potential well (which can be arbitrary); b) solve the Haissinski equation, taking into account the input potential well and wakes to get the new equilibrium distribution to generate the particle's longitudinal positions and the new potential well.

The Haissinski equation solver may also change the value of the energy spread, because its algorithm first tries to solve the equation with the input value. If convergence is not achieved, it increases the value of the energy spread by a small amount and iterates again. This procedure is repeated until an equilibrium state is found [5, 6]. The new value of energy spread is then used to generate the energy deviation distribution.

Macro Particles Tracking

The second part of the code is the tracking itself. The one turn map is approximated by the following set of equations:

$$\begin{aligned}
J &= \frac{(x-\eta_x\delta)^2}{\beta_x} + (x'-\eta_x'\delta)^2\,\beta_x \\
\phi &= 2\pi\left(\nu_0 + \xi\delta + AJ\right) \\
\begin{pmatrix} x \\ x' \end{pmatrix} &= \begin{pmatrix} \cos\phi & \beta_x\sin\phi \\ -\frac{1}{\beta_x}\sin\phi & \cos\phi \end{pmatrix}\begin{pmatrix} x-\eta_x\delta \\ x'-\eta_x'\delta \end{pmatrix} + \begin{pmatrix} \eta_x \\ \eta_x' \end{pmatrix}\delta \\
\tau &= \tau - T_0\alpha\delta \qquad (1)\\
\delta &= \delta + \frac{V(\tau)}{E_0} + K_{W_L}(\tau) \\
x' &= x' + K_{W_T}(x,\tau) + K_F(\langle x\rangle)
\end{aligned}$$

where J is the transverse action, A is the tune shift with the action coefficient, τ is the relative position of the particle ahead of the synchronous particle and K_{W_T}, K_{W_L} and K_F are the collective kicks generated by the transverse and longitudinal wakes and the feedback system, respectively. The other terms have the usual interpretation. When the longitudinal dynamics is solved with the Haissinski equation solver and the effect of the longitudinal wakes is considered in the longitudinal potential used in the tracking, K_{W_L} is zeroed to be consistent.

The wakes are generated from the Fourier Transform of the impedances, multiplied by the betatron function at the point where the kick is given, summed and passed to the tracking code as a table for interpolation. However,

TRANSITION TO SPACE-CHARGE LIMITED FLOW IN CROSSED-FIELD DEVICES *

S. Marini†, F. B. Rizzato, and R. Pakter, UFRGS, Porto Alegre, Brazil

Abstract

This work presents a fully kinetic description to model the electron flow in the electronic crossed-field configuration observed in a smooth-bore magnetron. Through this model, it has been observed that, according to the electromagnetic field, the injection temperature and the charge density, the electron flow can be classified in two different stationary modes: magnetic insulation mode where most of the electrons returning to the cathode after a transient time and Child-Langmuir mode where most of the electrons reach the anode after a transient time. Focusing on magnetic insulated mode, it has been found that charge density and injection temperature define whether electrons are accelerated (accelerating regime) or decelerated (space-charge limited regime) on the cathode. Besides, when the injection temperature is relatively low (high), a small charge increase causes (does not cause) an abrupt transition between accelerating and space-charge limited regime. Basing on the results, it was possible to identify a critical temperature that separates abrupt and continuous behavior. The results have been verified by using self-consistent computer simulations.

INTRODUCTION

Describing the electron flow in presence of crossed electric and magnetic fields is fundamental for the development of several advanced applications in areas ranging from microwave sources [1] to space propulsion [2]. The study of the electron dynamics in such field configuration was pioneered by Hull [3] who showed that a magnetic field might limit the particle flow from the cathode to the anode. This result was based on a single-particle model that assumes given external electromagnetic fields. Nowadays, a large number of papers have investigated the equilibrium and stability of these systems by explicitly taking into account the particles self-fields [4–6]. The self-fields may play a major role in the dynamics since they can also limit the particles flow from the cathode to the anode as the current density exceeds a certain threshold and a space-charge limited (SCL) regime emerges [7, 8]. However, given the complexity that long ranged self-fields add to the problem, the large majority of the theoretical analysis done so far are based on models that assume the electron flow is either completely cold or is a fluid with postulated equation of state. These fluid models might not properly take into account thermal effects. Because of it, recently we have developed a fully kinetic model to investigate thermal effects in crossed-field configuration observed in a smooth-bore magnetron [9]. Here, we review the theoretical framework and compare it against simulations with different injection distributions at the cathode.

THE PHYSICAL MODEL

The model and field configuration of a smooth-bore magnetron is shown in Fig. 1. There are two plates separated by a distance L along the y axis. The one localized at $y = 0$ is a thermionic cathode kept at zero electrical potential and the one localized at $y = L$ is an anode kept at V_0 electrical potential. As consequence of the electrical potential difference in the gap region between the plates, there is an uniform electric field $\mathbf{E}_0 = -(V_0/L)\hat{\mathbf{y}}$. Besides, in gap region there is an uniform constant magnetic field $\mathbf{B}_0 = -B_0\hat{\mathbf{z}}$, consolidating the crossed-field configuration.

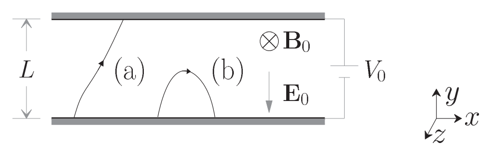

Figure 1: Model and field configuration of a smooth-bore magnetron. The curves correspond to the trajectories of test electrons emitted from the thermal cathode with vanishing velocities. In the case (a) $V_0 > V_H$ and in the case (b) $V_0 < V_H$.

At instant of time $t = 0$, the thermionic cathode starts to emit electrons, which enter in gap region. These are accelerated by the electric field $\mathbf{E}_0$ along the y direction while they are deflected along clockwise direction on $x-y$ plane by the magnetic field $\mathbf{B}_0$. In Fig. 1 is also shown two trajectories of test electron under external fields influence. Assuming the test electron enters the gap region with vanishing velocities, it is observed that, whether electrical potential satisfies the condition $V_0 > V_H$– where $V_H = eB_0^2L^2/2m$ is called potential Hull and m and e are the mass and electric charge of the electron– the test electron has enough energy to reach the anode, as illustrated in detail (a) of the Fig. 1. On the other hand, whether $V_0 < V_H$ the test electron has not enough energy to reach the anode and the magnetic field deflects the test electron to cathode, as illustrated in detail (b) of the Fig. 1. In the smooth-bore magnetron system, there is a spatial symmetry and it is assumed the thermal cathode emits infinite charges sheets parallel to $x - z$ plane instead of single particles. Consequently, the particle distribution function on phase space $f(\mathbf{r}, \mathbf{p}, t)$ only depends on the y spatial coordinate and its evolution is dictated by Vlasov equation [10]

$$\frac{df}{dt} = \frac{\partial f}{\partial t} + \frac{\partial H}{\partial p_y}\frac{\partial f}{\partial y} - \frac{\partial H}{\partial y}\frac{\partial f}{\partial p_y} = 0, \tag{1}$$

Abstract

A new adaptive Particle-in-Cloud (AP-Cloud) method for obtaining optimal numerical solutions to the Vlasov-Poisson equation has been proposed. The traditional particle-in-cell (PIC) method, commonly used for solving this problem, is not optimal in terms of the balance of errors of the differential operator discretization and source integration; it is also inaccurate when the particle distribution is highly non-uniform. Our method replaces the Cartesian grid in the traditional PIC with adaptive computational nodes or particles, to which the charges from the physical macroparticles are assigned by a weighted least-square approximations. The partial differential equation is then discretized using a generalized finite difference (GFD) method and solved with fast linear solvers. The density of computational particles is chosen adaptively, so that the error from GFD and that from the source integration are balanced and the total error is approximately minimized. The method is independent of geometrical shape of computational domains and free of artificial parameters. Results of verification tests using electrostatic problems of particle beams with halo and comparison of accuracy and solution time of the AP-Cloud method with the traditional PIC are presented.

ERROR ANALYSIS OF TRADITIONAL PIC METHOD

Particle-in-cell [1] (PIC) is the traditional method for solving both the Vlasov-Poisson and Vlasov-Maxwell problems. In this work, we focus on the Vlasov-Poisson equation using an example of the electrostatic space charge problem for particle beams.

In PIC, the charge density at grid point $\rho(x^j)$ is estimated from the distribution of particles by interpolating particle charges to mesh nodes. Then the Poisson equation

$$\Delta\varphi = \rho \tag{1}$$

subject to a Dirichlet or Neumann boundary condition is discretized on the mesh. Performing error analysis of the PIC method, we can show that the total error is

$$O\left(\sqrt{\frac{\rho(x^i)}{Nh^D}} + \rho(x^i)h^2\right),$$

where N is the number of physical macroparticles, h is the cell size, and D is the space dimension. The error is minimized if

$$h = O\left(\frac{1}{N\rho(x^j)}\right)^{\frac{1}{4+D}},$$

which is impossible if a uniform mesh is used for a highly nonuniform particle distribution.

AP-CLOUD METHOD

Adaptive Particle-in-Cloud (AP-Cloud) method can be viewed as a meshless and adaptive version of PIC. We use computational particles instead of Cartesian grid, the distribution of which is derived using an error balance criterion. Instead of the finite difference discretization of the Laplace operator, we use the framework of weighted least squares approximation, also known as the generalized finite-difference (GFD) [2]. The framework includes interpolation, least squares approximation, and numerical differentiation on a stencil in the form of cloud of computational particles in a neighborhood of the point of interest. It is used for the charge assignment scheme, numerical differentiation, and interpolation of solutions.

The Particle-in-Cloud method operates as follows:

- Given a distribution of physical macro-particles, optimally select a subset of computational nodes (particles) from this distribution by constructing an octree and applying the error balance criterion
$$h = O\left(\frac{1}{N\rho(x^j)}\right)^{\frac{1}{2k+D-2}}$$
where h is the local averaged distance between computational macro-particles and k is the order of interpolation polynomial in the GFD method.
- Place computational particles on the boundary
- Enforce the 2:1 balance of inter-particle distances in the case of extreme density changes. The 2:1 balance requires that the difference between the levels of refinement of two neighbors is at most one, improving the smoothness in the placement of computational particles.
- Assign physical states to computational nodes and approximate differential operators in the location of computational nodes using GFD.
- Solve the corresponding linear system using a

REFORMULATION OF THE ACTION AND PHASE JUMP METHOD TO OBTAIN MAGNETIC ERRORS IN THE LHC IRS*

Alba-Carolina Garcia-Bonilla , Javier Fernando Cardona†
Universidad Nacional de Colombia, Bogotá, Colombia

Abstract

One of the major problems when doing the commissioning of an accelerator is to identify and correct the linear components of magnetic errors. The Action and Phase Jump Technique is one of the available methods to perform this task. For this method to work, it is necessary to have one BPM measurement at the Interaction Region (IR), the region where the magnetic error is evaluated. In some cases, this BPM measurement become the biggest source of uncertainty when the action and phase jump technique is used. In this paper, a new formulation based on this method is presented. This new formulation doesn't make any use of BPM measurements at the IR, thereby allowing more robust error estimations. Quadrupole errors in the LHC lattice are estimated with this new formulation, using both, simulated data and LHC experimental data. A comparison with the previous formulation is included. The results on simulated data show that the reformulation leads to a reduction in the uncertainty, while for the experimental case, the reduction is not so clear. Explanations for this behavior and possible remedies will also be discussed.

INTRODUCTION

One of the main goals during commissioning of accelerators like LHC is to reduce the magnetic errors. The Action and Phase Jump Analysis Technique, also called Action and Phase method, or just APJ, is one of the available methods to perform magnetic error corrections. This method is based on the theoretical principle of preservation of the Action and Phase variables in absence of a magnetic error. The corrections are made locally and specially at the Interaction Regions (IR) of an accelerator. Its theoretical development is presented in the first part of [1].

Experimental studies using this method have been already presented. Different tests were run at RHIC in Brookhaven, for example using closed-orbit [2] or first turn orbit [3] data. In LHC, preliminary analysis had been done using turn-by-turn (TBT) orbits, these are [4] and [5].

In this paper, a reformulation of the APJ technique for linear error corrections will be presented. First, theoretical expressions will be shown and then a comparison between the previous and the new formulation, using simulated orbits, will be discussed. Finally, the results of proposed corrections using LHC data are reported.

THEORETICAL REFORMULATION FOR THE ACTION AND PHASE ANALYSIS

With the APJ method, the variables of Action (J) and Phase (δ) are measured from orbit data around the accelerator and then three regions are identified: the region which contains the magnetic error, a region (or subsection of the accelerator) before the error, and a region after the error. To calculate the magnetic errors the method uses the J and δ from the region before and after the error, and one transverse position from the error region.

The transverse position at the error region is inferred from one BPM measurement at the IR as described in [6]. In some cases, this BPM measurement can become the biggest source of uncertainty when the action and phase jump technique is used, because it is a single measurement while the other quantities involved to estimate the magnetic error are obtained from multiple measurements.

Keeping the theoretical framework of the Action and Phase method, given in [1], new equations are introduced that mainly start by changing equation (15) from that paper (the strength of the magnetic error), and ends in new equations for the magnetic errors estimations, which changes equations (22), (25) and (26).

The reformulation implies the following procedure. Equation (15) in [1] is

$$\sqrt{2J_0 + 2J_1 - 4\sqrt{J_0 J_1}\cos(\delta_1 - \delta_0)}/\sqrt{\beta_{z,i}(s_\theta)} = \theta_z \quad (1)$$

where J_n, δ_n are the average of the Action and Phase variables, for the region before $n = 0$ and after $n = 1$ the error, θ_z is the strength of the magnetic error, and $\beta_{z,i}(s_\theta)$ is the beta-function at the longitudinal position of the error. In addition, in terms of the multipolar components of the magnetic field, the strength of the magnetic error is written as equations (19) and (29) from [1], these are:

$$\begin{aligned}
\theta_x &= \mathbf{B}_0 - \mathbf{B}_1 x(s^\varepsilon) + \mathbf{A}_1 y(s^\varepsilon) + 2\mathbf{A}_2 x(s^\varepsilon) y(s^\varepsilon) + \\
&\quad + \mathbf{B}_2[-x^2(s^\varepsilon) + y^2(s^\varepsilon)] + \ldots \\
\theta_y &= \mathbf{A}_0 - \mathbf{A}_1 x(s^\varepsilon) + \mathbf{B}_1 y(s^\varepsilon) + 2\mathbf{B}_2 x(s^\varepsilon) y(s^\varepsilon) + \\
&\quad + \mathbf{A}_2[x^2(s^\varepsilon) - y^2(s^\varepsilon)] + \ldots.
\end{aligned} \quad (2)$$

where $\mathbf{B}_i$ and $\mathbf{A}_i$ are quantities related with the multipolar expansion of the magnetic field, and $x(s^\varepsilon)$, $y(s^\varepsilon)$ are the transverse coordinates of the orbit at the error position.

When several errors are present, equation (1) can be rewritten as:

$$\sqrt{2J_0 + 2J_1 - 4\sqrt{J_0 J_1}\cos(\delta_1 - \delta_0)} = \sum_i [\theta_{z,i}\sqrt{\beta_{z,i}(s_\theta)}] \quad (3)$$

COMPARISON BETWEEN DIGITAL FILTERS AND SINGULAR VALUE DECOMPOSITION TO REDUCE NOISE IN LHC ORBITS USED FOR ACTION AND PHASE JUMP ANALYSIS*

Alba-Carolina Garcia-Bonilla, Javier Fernando Cardona†, UNAL, Bogota, Colombia

Abstract

One of the initial difficulties to apply the Action and Phase Jump (APJ) analysis to LHC orbits was the high level of noise present in the BPM measurements. On the other hand, the unprecedented number of turns for LHC allows us to use all sort of filters. In this paper, we evaluate the effectiveness of digital filters like the band-pass filter and compare them with a filter based on Singular Value Decomposition, when magnetic error estimations are made using a recent version of the APJ method. First, mainly results on simulated orbits with noise are presented, and then, plots and results are shown for the filters effect on experimental data. The analysis indicates that a combination of filters leads to measurements with the least uncertainty.

INTRODUCTION

The Large Hadron Collider (LHC) is a machine designed to have two beams of particles, which encounter each other in four points along a ring of 26.7 Km. The LHC system is capable of running and measuring all 2808 bunches of the beam. For this task, the Beam Position Monitors (BPMs) have a much wider bandwidth than previous colliders [1].

A requirement for optical measurements is that each beam uses only one single bunch for security reasons. Therefore, with the wide bandwidth of the BPMs, the measurements have a considerable amount of noise when compared to others accelerators.

On the other hand, the unprecedented number of turns available per measurement in the LHC allows us to use all sort of filters to drastically reduce such noise, some of which have been already presented [2–5].

In this paper, we evaluate the effectiveness of digital filters like the band-pass filter and compare them with a filter based on Singular Value Decomposition, which is currently used in the LHC. First, the results of the filters and its combinations on simulated orbits are presented, and then, results from experimental data with the same filters are shown.

The technique used to measure the magnetic errors is the Action and Phase Jump Analysis (APJ), in particular, the new formulation, explained in [6].

DIFFERENT WAYS TO REDUCE NOISE

During this investigation, initially, we studied the effectiveness of the dual band-pass filter (described in [2]) in reducing the noise. This, by using the signal-to-noise (STN) ratio quantity, which is independent of the technique used to obtain the magnetic errors. Trials to separate the noise from the signal were performed, like taking the difference of the orbit with and without noise after using the filter. Generally, the filters change the output signal amplitude, so we applied the filter for both, the signal before adding noise and the signal with noise to have a comparison.

It was found that generally the noise is reduced more faster than the amplitude, as the bandwidth ($\Delta\omega$) of the dual pass-band filter decreases. Sometimes there was an optimum $\Delta\omega$ which was different depending on the magnetic error[1].

Also, we developed studies for the sensitivity of the band-pass filter with frequency. Initially, fictitious sinusoidal signals with fraction frequencies between 0.0 and 0.5 (like in the real accelerator) were used, and it is found that the filter is effective at any of these frequencies. Actually, the filter changes a bit the Fourier frequency at the points closer to the central band but this is not a problem to obtain the magnetic errors as proposed. Later this was corroborate with some Mad-X simulations for the LHC.

Therefore, the most convenient way to apply the band-pass filter is to do a simulation curve to establish a range for the optimal band-width according to the experimental conditions. The type of curves proposed are discussed later.

To reduce noise on turn-by-turn orbits in the LHC, the filters that have been used are: a filter based on the average of many orbits (*Prom*) [3], a dual band-pass filter (*Band*) [2], and a filter based on singular value decomposition (*Svd*) [4], Combinations of these filters can be built and the following cases are analyzed:

1. Prom
2. Band
3. Svd
4. BandProm
5. SvdProm
6. BandSvdProm
7. SvdBandProm

Composed names like "BandProm" means that the band-pass filter is applied and then the "Prom" filter.

RESULTS ON SIMULATIONS

The comparison between the studied filters are based on the exactness and precision of the measurements obtained from LHC orbits using the APJ method.

Although it is not possible to compare a simulation with the experimental data because not all what is happening in reality can be modeled in the simulation, a simulation close

CORE-HALO LIMIT AS AN INDICATOR OF HIGH INTENSITY BEAM INTERNAL DYNAMICS

P.A.P. Nghiem*, M. Valette, N. Chauvin, N. Pichoff, D. Uriot
CEA/DSM/IRFU, Centre de Saclay, 91191 Gif-sur-Yvette cedex, France

Abstract

The dynamics of high-intensity beams is mainly governed by their internal space charge forces. These forces induce emittance growth and halo generation. They contribute to shape the beam density profile. As a consequence, a careful analysis of this profile can help revealing the internal dynamics of the beam. This paper recalls the precise core-halo limit determination proposed earlier, then studies its behaviour through a wide range of beam profiles and finally shows its relevance as an indicator of the limit separating the two specific space charge field regimes of the core and the halo.

INTRODUCTION

In high intensity accelerators, the outermost part of the beam, although tenuous, is often the object of great attention. Indeed, the halo is the main contributor to particle losses downstream, which must be maintained under specified levels. There is nevertheless no consensus on a definition of the halo [1]. Yet there is a real need of precisely and quantitatively defining halo. Simulations of halo generation and halo growth all need to know how much halo has been generated or how much it has grown. For halo measurement or halo cleaning there is a need to know what to measure and what to clean.

In this paper, we first recall the existing definitions of halo and study their relevance through a great variety of different density profiles. Then we point out the particular relevance of the definition we proposed earlier by showing that it is a good indicator of the beam internal dynamics.

EXISTING DEFINITIONS

Halo definitions often consist in comparing beam characteristics somewhere "far from" and "close to" beam centre. Are considered the ratio of particles contained in n times rms emittance to those contained in rms emittance, or the ratio of emittance containing x% of particles to rms emittance, with generally n>3 and x> 90%. But to be relevant, n or x must be adjusted to each particular density profile, according to visual inspection in most cases. This makes difficult studies of halo evolution that comes with beam shape evolution.

To our knowledge, there exist only two definitions able to be applied to any density profile.

The first one, widely used, stated that halo can be characterised by the parameter h, defined as ratio of the fourth to the square of the second invariant moment [2]. This corresponds to the profile kurtosis or "peakedness". Thus, the higher the kurtosis is, the larger the halo would be. This definition, valid for a 1D projection, was later extended to a 2D phase space [3].

The second definition started from considering the extreme case of a uniform core surrounded by a tenuous halo, where the core-halo limit is indisputably at the foot of the discontinuity in density ρ, i.e. where there is an infinite change in the slope of ρ. For a more general case of continuously varying density, it is proposed that the core-halo limit is where there is the biggest change in slope, that is where the second derivative ρ" is maximal [4, 5]. Once this limit precisely known, it is then possible to define the parameters PHS and PHP, which are respectively the Percentage of Halo Size and Percentage of Halo Particles.

The relevance of the parameters h, PHS and PHP can be studied through their behaviour for a great variety of different density profiles.

FOR DIFFERENT DENSITY PROFILES

For this study, without lack of generality, it is enough to consider the cases of cylindrically symmetric beam where the density profile depends only on the radius, ρ(r). For the sake of comparison, we state that the beam external limit is where density decreases down to 10^{-6} of its maximum.

Let us consider first the large family of density profiles described by the Generalized Gaussian functions:

$$\rho(r) = \rho_0 e^{-\left|\frac{r}{\alpha\sqrt{2}}\right|^{\beta}}. \tag{1}$$

For given parameters ρ_0 and α (both fixed to 1 here), different profiles can be described by varying continuously β from ∞ (uniform) to 2 (Gaussian), and even ≤ 1 (sharply convex). The first six graphs of Fig. 1 shows some typical examples of such profiles ρ together with its second derivative ρ" of which the location of maximum marks the core-halo limit (black curves). The first graph of Fig. 2 gives the corresponding h, PHS, PHP. The regular decrease of all these parameters would let us think that h on one side and PHS, PHP on the other are compatible for this type of density profile [6]. The h parameter would combine the two information of halo size and halo particles, while PHS and PHP can analyse them separately. However, for more particular profiles like triangular or parabolic ones (two last graphs of Fig. 1), the kurtosis of the first profile is three times bigger than that of the second, while PHS=PHP=0 for both profiles, meaning no halo, as expected for profiles decreasing abruptly to zero.

The cases of a core and a halo described by the sum of two Gaussians can also be examined:

THE SARAF-LINAC BEAM DYNAMICS

N. Pichoff, B. Dalena, D. Uriot, CEA/IRFU, Gif-sur-Yvette, France

Abstract

SNRC and CEA collaborate to the upgrade of the SARAF Accelerator to 5 mA CW 40 MeV deuteron and proton beams (Phase 2). This paper presents the beam dynamics in the reference design of the SARAF-LINAC, from the 4 m long 176 MHz RFQ to the HWR Superconducting linac's end. The beam losses, mostly in longitudinal direction, estimated from error studies, are compared with acceptable losses defined for hands-on maintenance.

INTRODUCTION

Israeli's SNRC solicited CEA (France) to contribute to the development of phase 2 of the SARAF accelerator [1].

In order to deliver 5 mA beams of deuteron up to 40 MeV and protons up to 35 MeV, CEA proposed a SARAF-LINAC reference design made of:

- an optional 4-vane RFQ bunching and accelerating 5 mA-cw beams from 20 keV/u to 1.3 MeV/u,
- a MEBT measuring, cleaning and matching the beam to
- a superconducting linac accelerating the beams to 40 MeV deuteron or 35 MeV proton,
- and the associated local control systems.

This design is based on beam dynamics calculations made with TraceWIN codes package developed at CEA [2] where the beam is represented by about 1M macro-particles.

RFQ SIMULATIONS

The initial beam will be delivered by SARAF's source and LEBT built during phase 1. Measurements 1.4 m upstream the RFQ exhibit that the beam RMS normalized emittance is around (and even below) 0.2 π.mm.mrad [3]. Therefore, we considered as simulation input deuteron and proton beams of 0.2 π.mm.mrad rms emittance with a Gaussian distribution truncated to ±4 sigmas (Fig.1). In the reference design [1], the 3.85 m long, 4-vane RFQ proposed by CEA is considered. It has:

- a constant 4 mm average radius R0, except at entrance and exit where it is increased to 6 mm in a few cells to reduce the input/output beam con/divergence.
- a constant voltage limited to 70 kV corresponding to a peak field of 1.6 Kp,
- a maximum sine vane modulation of 2.

The input energy is 20 keV/u and the output energy is 1.3 MeV/u. The matched beams density profiles are plotted on Fig. 2. The exit beam phase-space distribution of deuteron beam is plotted in Fig. 3. Please note that all the densities plotted in this paper are in logarithm scale.

Good transmission, low longitudinal emittance (Table 1) and no transverse emittance growth are observed.

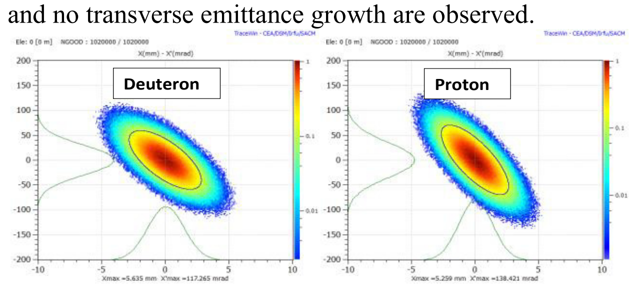

Figure 1: Input beam (x,x') distributions (matched to RFQ).

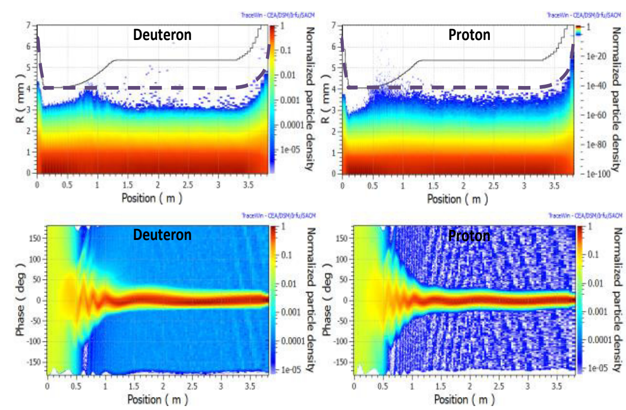

Figure 2: Matched beam density profiles in the RFQ.

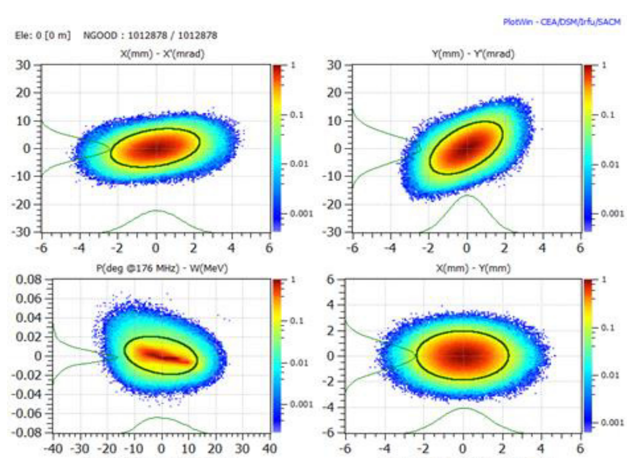

Figure 3: Deuteron beam phase-space distributions at RFQ exit.

Table 1: RFQ Performances

Particle	Transmission	Long. Rms emittance π.mm.mrad (π.°.keV/u)
Deuteron	99.3% (70 kV)	0.161 (31.8)
Proton	99.9% (50 kV)	0.194 (38.4)

STATUS OF TRACEWIN CODE*

D. Uriot#, N. Pichoff
CEA-Saclay/DSM/Irfu/SACM, Gif-sur-Yvette, France

Abstract

Well known in the community of high-intensity linear accelerators, the transport code TraceWin is able to simulate a beam from the source to the target using either simple linear model or multiparticle simulations including 2D or 3D space-charge. Continuously developed at CEA Saclay since 15 years, it is today the reference code for projects such IFMIF, ESS, MYRRHA, SPIRAL2, IPHI, SARAF... The accuracy of his predictions associated with an original and powerful GUI and its numerous features have made its success, with a community of 200 users worldwide in 45 laboratories. It is now used on a larger perimeter that its initial skills. The aim of this paper is to summarize the TraceWin capabilities, including implemented last ones.

INTRODUCTION

The TraceWin code was initially developed to fulfil the special requirement of high intensity linear accelerators. It has been maintained by CEA Saclay, France for more than 15 years. Since 2009, it is distributed under a CEA commercial license, required for each identified user to pay an annual symbolic financial contribution. Due to this special status allowing users to request specific developments and our willingness to help them as fast as possible, the code has been gradually enriched with new features and advanced tools to finally become a global tool box oriented to accelerator design and realistic simulations.

One of the main specificity of TraceWin, probably unique in the plethora of existing codes, is to make possible to run different models with various levels of sophistication. Thus, model complexity can be gradually increased from envelope optic with hard edge linearized elements and space-charge to massive tracking 3D simulations using PIC space-charge, field maps, and use of automatic tuning procedures in realistic (imperfect) accelerators.

MAIN FEATURES

Software

Six versions of the software are available for 32 and 64 bits Mac, Linux and Windows operating systems. They all use common very powerful GUI, figure 1, allowing to compute, print and plot all quantities of interest of the accelerator and the beam. A free limited version for test or the last full version release can be downloaded at http://irfu.cea.fr/Sacm/logiciels/index3.php. Six associated batch versions and a dedicated server allow automatic run of the code on a multicore computer network.

*http://irfu.cea.fr/Sacm/logiciels/
#didier.uriot@cea.fr

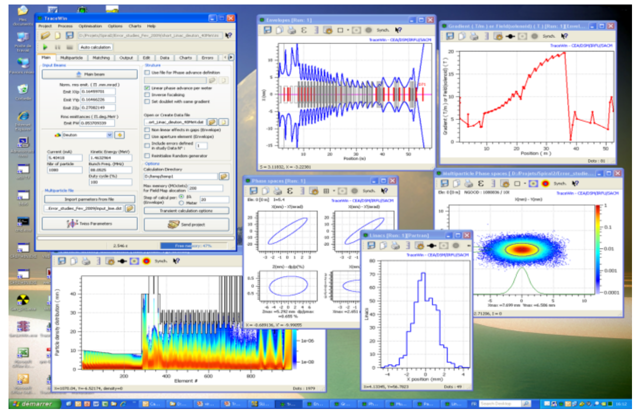

Figure 1: TraceWin screenshot example.

Even if originally dedicated to high intensity proton linacs, it is today used for more exotic applications, like electron machine, spectrometer, ILC IP [1]… A simulation with up to 10^8 particles can be easily made on a multicore desktop in one day.

TraceWin Main Features

Here are the main features of TraceWin code:

- a full documentation including examples,
- electrons and ions transport, with distribution generated/red in several format,
- envelopes and macro-particle tracking modes on multi-core machines,
- fully compatible with the free independent beam plot/analysis tool: PlotWin [2],
- a wide range of elements (see next page) with possible user-defined ones,
- linear and PIC 2D and 3D space-charge routines with possible user-defined ones,
- automatic beam tuning procedures (possibility to use diagnostics),
- dynamics charts allowing to visualize machine and beam behaviors during matching and tuning,
- beam scattering on residual gas,
- H- stripping on residual gas or in magnetic field,
- possible transport of two beams in the same structure,
- exhaustive error studies using a Monte-Carlo approach, based on a client/server architecture and a statistical analysis module,
- Halo [3] and beam loss analysis with location of particle loss.
- transient time module (figure 2),
- acceptance calculation,
- Hofmann stability diagram.

Abstract

Electron beams with moderate energy ranging from 4 to 50 MeV can be used to produce x-rays through the Channeling Radiation (CR) mechanism. Typically, the x-ray spectrum from these sources extends up to 140 keV and this range covers the demand for most practical applications. The parameters of the electron beam determine the spectral brilliance of the x-ray source. The electron beam produced at the Fermilab new facility Advanced Superconducting Test Accelerator (ASTA) meets the requirements to assemble an experimental high brilliance CR x-ray source. In the first stage of the experiment the energy of the beam is 20 MeV and due to the very low emittance ($\approx$ 100 nm) at low bunch charge (20 pC) the expected average brilliance of the x-ray source is about 10^9 photons/[s-(mm-mrad)^2-0.1%BW]. In the second stage of the experiment the beam energy will be increased to 50 MeV and consequently the average brilliance will increase by a factor of five. Also, the x-ray spectrum will extend from about 30 keV to 140 keV.

INTRODUCTION

Channeling radiation (CR) is generated by charged beams (typically electrons or positrons) passing through a crystal parallel with a crystallographic plane [1]. Electrons may oscillate perpendicular to the plane and generate CR which propagates in the same direction as the incident beam. The frequency of the CR is given by $\omega = 2\gamma^2\omega_0/(1+\gamma^2\theta^2)$ and depends on beam energy (the relativistic factor γ) on crystal lattice (ω_0) and on the observation angle θ. Due to $\propto \gamma^2$ beam energy dependence the CR can reach the x-ray domain even for moderate electron energy (4 to 50 MeV) which means that relatively small accelerators can be used to build compact x-ray sources [2].

For beam energies below about 100 MeV, the X-ray spectrum consists of discrete lines and an accurate description of the CR requires a quantum mechanical calculation. Still, some of the classical interpretations are valid and offer an understanding of the requirements for the incident electron beam. In planar channeling the beam electrons oscillate quasi harmonically perpendicular to a certain crystal plane. Since the electron oscillation amplitude is limited by the inter-planar distances, the kinetic energy associated with the transverse motion can be related to the maximum potential energy V_{max}. The angle of the incident electrons is limited by a critical channeling angle related to V_{max}: $\Psi_c = \sqrt{\frac{V_{max}}{pv}}$ where p and v are electron momentum and velocity respectively. With diamond as the crystal material, the depth of the potential in the (1,1,0) channeling plane is 23.8 eV. Hence the critical angle at 20 MeV is 1.54 mrad while at 50 MeV, it is 0.98 mrad. The value of the critical angle measured at SLAC [3], for diamond and electron beam energy of 23 GeV is 44 μrad. Scaling this value with beam energy as $E^{-1/2}$ yields 0.94 mrad at 50 MeV, in good agreement with the theoretical value.

The figure of merit of the CR x-ray source is given by the spectral brilliance $B = dN/[(d\omega/\omega)\cdot d\Omega\cdot dA\cdot dt]$ defined as the number of photons per second emitted within solid angle $d\Omega$, from area dA, and within a relative spectral bandwidth $d\omega/\omega$. The expression for spectral brilliance in terms of electron beam parameters [4] can be written as::

$$B_{av} = \frac{I_{av}}{e}\cdot\frac{\gamma^2 Y\cdot\sigma_e'^2\times 10^{-3}}{\epsilon_n^2\cdot\Delta E_\gamma/E_\gamma}Erf[\frac{\psi_C}{\sigma_e'}] \quad (1)$$

where I_{av} is the average electron beam current, e elementary electron charge, γ Lorentz factor, Y photon yield per electron and unit solid angle, σ_e', electron beam angular spread, ϵ_n normalized transverse emittance and $\Delta E_\gamma/E_\gamma$ relative spectral bandwidth and the error function accounts for the fraction of the beam within the critical angle.

The average current (over one second) I_{av} in Eq. 1 is proportional with charge per micro-pulse q, laser sampling rate f_L, RF duration pulse ΔT_{RF} and the RF repetition rate R:

$$I_{av} = q\cdot f_L\cdot\Delta T_{RF}\cdot R \quad (2)$$

In this paper we briefly present the relevant components of Fermilab ASTA beamline, preparations for the experiment and the expectations for CR properties as they are derived from theoretical models applied to our specific beam properties. Previous high brightness channeling experiments were reported [5] from the Elbe facility at Helmholtz-Zentrum Dresden-Rossendorf (HZDR) in Germany.

EXPERIMENTAL SETUP

At ASTA the nominal values for the parameters in Eq. 2 are: bunch charge q = 3.2 nC, laser sampling rate f_L = 3 MHz, macro-pulse duration ΔT_{RF} = 1.0 ms and repetition rate T = 5 Hz. The nominal energy is 50 MeV but in the first stage of the experiment "CAV1" (Fig. 1) will not be installed and the kinetic energy will be about 20 MeV. The

EMITTANCES OF THE CORE AND OF THE HALO

Matthieu Valette, Phu Anh Phi Nghiem, CEA/IRFU, Gif-sur-Yvette 91191 France

Abstract

In high intensity accelerators, the beam is often space charge dominated. The density profile then takes a shape very different from a Gaussian one, with a more or less sharp core and a more or less compact halo. Furthermore, the core and the halo can be differently focused and thus differently oriented in the phase spaces. In these conditions, classically characterizing the beam by a global set of RMS values, namely Emittance and Twiss parameters, is not enough meaningful. This paper extends the core-halo limit defined earlier in 1D real space [1] to the 2D phase space, allowing to define for the very first time Emittances and Twiss parameters for the core and the halo separately. Applications to some typical beam distributions are given as an example of more appropriate beam characterization for high intensity linacs.

THE CORE-HALO ISSUES

In high intensity linacs, the space charge induces strong self-repelling electric forces on the particle beam. These nonlinear internal forces can lead to emittance growth and halo formation, two linked phenomena leading to an increased beam size and particle losses on the beam pipe. As beam power increases with beam energy and intensity, the beam power rapidly increases in high intensity linacs; furthermore, with increasing halo proportion, the power stored in it can become significant. A special attention should thus be brought to the halo behaviour and not only to the beam core. Halo quality is also important in high intensity machines.

A common practice in the design or the tuning of an accelerator is to minimize global emittance growth, but halo quality is also important in high intensity machines. Halo scraping equipment is frequently installed to limit the extension of the halo. However a widespread definition of what and where the halo is has yet to be agreed upon [2]. It is also true that a definition for halo has to suit each experiment's application, constraint and typical beam profile.

Regarding beam dynamics, the central dense core and the surrounding thinner halo are subject to different space charge force regimes [3]. As a consequence their dynamics are different and need to be studied separately.

Gaussian-like beam distributions are very common in accelerators and defining the halo as particles further than a certain number of standard deviations in this case is only natural. In high intensity linacs though, the low energy and thus high perveance makes the beam sensible to space charge effects. As a consequence beam distributions are often far from Gaussian.

A precise determination of the core-halo limit is thus needed and was proposed in [1, 4]. Such a limit allows to know whether a particle is part of the halo or not and to study the specific characteristics of the core and the halo.

A PRECISE DETERMINATION OF THE CORE-HALO LIMIT

We will here recall the one dimensional criterion defined to determine the precise location of the core-halo limit. This criterion originated from considering the extreme case of a uniform core surrounded by a tenuous halo, where the core-halo limit is indisputably at the foot of the discontinuity in density ρ, i.e. where there is an infinite change in the slope of ρ. For a more general case of continuously varying density, it is proposed that the core-halo limit is where there is the biggest change in slope, that is where the second derivative ρ'' is maximal [1, 4]. Once this limit precisely known, it is then possible to define the parameters PHS and PHP, which are respectively the Percentage of Halo Size and Percentage of Halo Particles.

The interest of such a limit is that it corresponds to a transition from two different space charge fields [3].

A TWO DIMENSIONAL EXTENSION OF THE METHOD

The work presented here is an extension of the previously mentioned criterion to two dimensional distributions $\rho(x,y)$ in any phase space. The general algorithm used to determine such a two dimensional core-halo limit is detailed and applications to some examples are displayed.

The two dimensional distribution is first converted into a two dimensional histogram. The "good" number of bins is given by: $NbBins = SizeRatio * \sqrt[4]{NbParticle}$, where *SizeRatio* was fixed to 3.0 by calibration of the algorithm on various distributions. This allows keeping statistical noise to a constant level, as explained in [5].

Several zooms or rescaling are then performed in order to maximize resolution. The Twiss parameters (for a phase-space distribution) or covariance matrix (for a general case) are calculated and the histogram is shifted to normalised coordinates in order to have a round beam. Another set of zooms and rescaling is then done before starting the so called “wheel” algorithm.

Around the centroid of the beam, cross sections of the beam with regular angles in normalised coordinates are performed. This would allow having iso-density curves perpendicular to the cross sections in case of elliptically symmetric beams. The length of the cross section on each side of the centre is then adjusted to maximise resolution. The interpolated local densities are converted to a one-dimensional histogram with the same number of bins as

THE DAMPING OF TRANSVERSE COHERENT INSTABILITIES BY HARMONIC CAVITIES

F. Cullinan*, R. Nagaoka, Synchrotron SOLEIL, Gif-sur-Yvette, France
G. Skripka, P. F. Tavares, MAX IV Laboratory, Lund, Sweden

Abstract

At nonzero chromaticity, the threshold current due to transverse coupled bunch instabilities in an electron storage ring is defined by intrabunch head-tail motion of higher than zeroth order. Multibunch tracking simulations predict that this threshold can be increased to several times its original value through the introduction of bunch lengthening harmonic cavities. One previously suggested explanation is the narrower spectra of the elongated bunches but reliable estimates for the threshold currents are not obtainable for anything other than rigid beam motion since the usual Sacherer formalism is not directly applicable to beams in a non-harmonic potential. A new scheme has been developed in which the decay time of a higher than zeroth order transverse head-tail mode may be estimated by taking into account the synchrotron tune spread generated by the harmonic cavity potential. This scheme is presented along with the results of numerical simulations performed in order to confirm the analytical predictions and justify the assumptions made. The extension of the scheme to more complex scenarios is also discussed.

INTRODUCTION

Many present and future light sources based on an electron storage ring make use of passive or active harmonic cavities (HCs) [1] [2] [3]. In most cases, these are used to lengthen the electron bunches, thus reducing the impact of intrabeam scattering and allowing for a higher beam current while maintaining the same small transverse emittance. HCs work by modifying the radio frequency (RF) potential in which the electron bunches are confined longitudinally. Since the potential is no longer quasi-harmonic, the synchrotron tune of a single particle is no longer approximately independent of its amplitude of synchrotron oscillation. The stronger amplitude dependence results in a large tune spread within a bunch and Landau damping of longitudinal instabilities [4].

The use of harmonic cavities has important consequences in the transverse plane, particularly regarding head-tail motion. A head-tail mode describes coherent motion within a bunch. At the lowest order ($m = 0$), this is a dipole oscillation of the whole bunch while at higher order, there is a change in betatron phase along the bunch so that there is some longitudinal structure to the transverse oscillation with nodes and antinodes. The effect of nonzero chromaticity is to add a further modulation of the transverse motion at the chromatic frequency, shifting its spectrum in the frequency domain. Head-tail motion is important for multibunch instabilities since the collective motion of multiple bunches is strongly linked to the overall motion of each individual bunch.

A HC lengthened bunch corresponds to a narrower range of frequencies and so a small positive chromaticity is more effective in decoupling the zeroth order head-tail mode from the damaging impedance at negative frequency, so called head-tail damping. Frequency domain calculations therefore show a significant improvement in coupled bunch instability threshold currents for the $m = 0$ mode [5]. As the chromaticity is increased further, for a single RF system, the threshold current would then be limited by the presence of a first order head-tail mode which is not damped since its spectrum peaks at a negative frequency. However, because of the synchrotron tune spread from the HC-modified potential, the higher than zeroth order head tail modes will no longer remain coherent indefinitely as they would in a harmonic potential. Studies of this regime with HCs are therefore, at present, limited to multiple particle tracking and although these simulations show that an improvement in the current threshold is maintained [6], it can no longer be attributed solely to the lengthening of the bunch. This paper attempts to quantify the contribution of the synchrotron tune spread.

THEORY

The position of a particle in longitudinal phase space can be expressed using cartesian coordinates τ and δ where the former is the arrival time with respect to the synchronous particle ($\tau > 0$ refers to the head of the bunch) and the latter is the energy deviation normalised by the design energy. Using, as an approximation, a sinusoidal oscillation at synchrotron tune Q_s, the motion of a particle in longitudinal phase space can be expressed as

$$\tau = \hat{\tau}\cos(\omega_s(\hat{\tau})t + \psi_0) \quad (1)$$

$$\delta = -\frac{\dot{\tau}}{\alpha_c} = \frac{\omega_s(\hat{\tau})}{\alpha_c}\hat{\tau}\sin(\omega_s(\hat{\tau})t + \psi_0) \quad (2)$$

where $\hat{\tau}$ is the synchrotron amplitude, ψ_0 is the synchrotron phase at $t = 0$, α_c is the momentum compaction factor and $\omega_s = Q_s\omega_0$ is the angular synchrotron frequency for angular revolution frequency ω_0. ω_s has been expressed as a function of the amplitude $\hat{\tau}$ so that the equations can approximate nonharmonic potentials, ignoring the inevitable harmonics that these introduce.

Longitudinal phase space can be normalised and converted into convenient polar coordinates (r, θ) by multiplying the δ coordinate by $\alpha_c/\omega_s(r)$. A particle's synchrotron amplitude and phase can then be determined from its position in synchrotron phase space. Under the current approximation, $\hat{\tau} = r$ and $\psi_0 = \theta - \omega_s(\hat{\tau})t$ [7].

STUDY OF OPTIMAL MBA LATTICE STRUCTURES FOR THE SOLEIL UPGRADE

R. Nagaoka, P. Brunelle, F. Cullinan, X.-N. Gavaldà, A. Loulergue, A. Nadji, L.S. Nadolski, M.-A. Tordeux, Synchrotron SOLEIL, Gif-sur-Yvette, France

Abstract

Within the context of a future upgrade of SOLEIL, the present paper reports on the low emittance lattice design studies made using 7BA and 6BA cells in the SOLEIL ring. With this combination of the MBA lattices, it is found that the horizontal emittance in the range below 200 pm·rad can be achieved by basically keeping the optical functions in the straight sections unchanged as in the previous 5BA-4BA solutions. In particular, a solution giving the horizontal emittance of 145 pm·rad with the use of longitudinal gradient bends (LGBs) is shown. On the other hand, the required transverse gradients in quadrupoles and combined dipoles as well as the chromaticities increase significantly as anticipated. Future directions including the ways to improve the encountered difficulties are considered.

INTRODUCTION

SOLEIL is the French third generation light source routinely operated for users since 2007 with a low emittance electron beam of 3.91 nm·rad in high intensity multibunch and temporal structure (e.g. 8 bunches) modes (cf. Table 1) [1]. After nearly 9 years of successful operation, a series of feasibility study is launched towards a possible future upgrade of the lattice with a significantly lower emittance. The approach taken is to employ whatever useful methods in lowering the emittance by fully respecting the geometric constraints such as the circumference of the ring and the available straight sections, so not to impact the existing insertion device based beamlines.

Table 1: Main SOLEIL Parameters as of Today

Energy	2.75 GeV
Circumference	354.097 m
Nominal current	430 mA (multibunch mode), 8×12 mA (8-bunch mode)
Horizontal emittance ε_x	3.91 nm rad
Adjusted emittance ratio	1%
Betatron tunes (ν_x, ν_z)	(18.174, 10.232)
RF frequency f_{RF}	352.2 MHz

As a first of such studies, the use of longitudinal field variations of superbends was attempted in a 4BA cell, finding a zero dispersion solution with the horizontal emittance ε_x of 0.98 nm·rad [2]. A particularity of SOLEIL is the short straight sections (SDCs) inserted between the dipoles of half of the 16 double-bend (DB) cells, to provide 8 additional straight sections for users. The SDCs however tend to limit the number (M) of dipoles introduced in those cells. Here we shall refer to cells with and without SDCs as SDM-SDC-SDM and SDL-SDM, respectively. In the second studies, a combination of 5- and 4BA was followed [3,4], where the use of longitudinal gradient bends (LGBs) allowed the emittance to reach 440 pm·rad [4]. In the framework of developing an optimal MBA lattice for SOLEIL, the axis towards the limit of the achievable lowest emittance must also be pursued. An approximate formula for the theoretical minimum emittance (TME) in a ring composed of alternating M_1BA and M_2BA cells may be given by

$$\varepsilon_x^{TME} = \frac{1}{8\sqrt{15}}\frac{C_q\gamma^2}{J_x}\theta_0^3\cdot\left\{\frac{1}{\left[2+(M_1-2)3^{1/3}\right]^3}+\frac{1}{\left[2+(M_2-2)3^{1/3}\right]^3}\right\}, \quad (1)$$

where θ_0 denotes the total bending angle per cell and other symbols have their usual meanings [5]. The above expression extends the derivation found in Ref. 6 for a MBA cell composed of 2 outer dispersion suppressing dipoles and (M-2) inner dipoles, all having the same field but differing in length between the two groups. The TME condition is imposed on each dipole. The optimal ratio between the inner and outer dipoles lengths to minimize the emittance is found to be $1/3^{1/3} \approx 0.69$ and is applied in the formula. Plotting the emittance for several different values of M_1 and M_2 in proportion to the relation given by Eq. 1, by normalizing the $M_1 = M_2 = 2$ case to the present SOLEIL value, suggests that an emittance lower than 200 pm·rad could be reached if a combination of 7BA and 6BA is considered (Fig. 1).

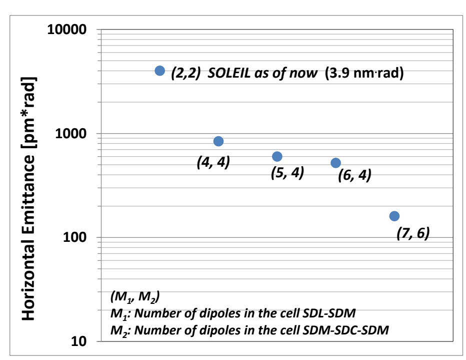

Figure 1: An estimate of attainable emittance in a lattice composed of alternating M_1BA and M_2BA using Eq. 1.

In the following, application of a 7BA-6BA lattice in the SOLEIL ring and obtained solutions are presented.

LATTICE STRUCTURE CONSIDERED

As already said, the SOLEIL ring with its extended DB lattice is optimized to provide as much as 46% of its

MODELING AND MEASUREMENTS OF SPIN DEPOLARIZATION

N. Carmignani, F. Ewald, L. Farvacque, B. Nash, P. Raimondi, ESRF, Grenoble, France

Abstract

An electron bunch in a storage ring becomes spin polarized due to the Sokolov-Ternov effect. The beam may then be depolarized by applying a horizontal magnetic field oscillating in resonance with the spin tune. This technique has been used to measure the electron energy at numerous synchrotrons. In this paper, we report on modeling and measurements of the polarization and depolarization process at the ESRF. We report the results of a Matlab based parallelized spin tracking code that we developed for these studies. We show the change in depolarization resulting as different physical effects are added to the model.

SPIN DYNAMICS

Each electron in a beam has a spin which may be represented as a point on a sphere $\vec{S}_j$. The polarization of the beam may then be defined as $\vec{P} = \frac{1}{N}\sum_j \vec{S}_j$, where N is the number of particles.

An electron beam becomes spontaneously polarized due to the Sokolov-Ternov effect in which spin flips induced by synchrotron radiation cause preferentially polarization in the direction opposite to the magnetic field of the dipole magnets [1].

As the electron passes through magnetic fields it receives transverse orbital kicks $\theta_{x,y,\mathrm{orbit}} = (-\Delta y', \Delta x')$ [1]. The corresponding spin kick is then given by

$$\Delta\theta_{x,y,\mathrm{sp}} = a\gamma\Delta\theta_{x,y,\mathrm{orbit}} \tag{1}$$

where $a = (g-2)/2 = 0.0011596$ with g the anomalous magnetic moment of the electron and γ is the relativistic energy factor. Thus the net result of the dipoles in one revolution around the ring is to rotate the spin vector about the y axis by the spin tune $\nu_{sp} = a\gamma$.

After equilibration, the spins in the ring will continue to precess at the spin tune frequency. We now consider adding a vertical oscillating magnetic kicker to the ring with the goal of depolarization. The vertical orbit kick is given by

$$\theta_{orbit} = \theta_k \cos(\omega_k t) \tag{2}$$

Then, using Eqn (1), we get the kick to the spin by an angle

$$\theta_{x,sp} = a\gamma\theta_k \cos(\omega_k t) \tag{3}$$

Here we may also define the tune of the kicker, by dividing the kicker frequency by the revolution frequency

$$\nu_k = \frac{\omega_k}{\omega_0} \tag{4}$$

[1] Note that we use the coordinates (x, y, z) where y is vertical, z is the direction of the particle orbit, and x points out of the ring.

The polarization reduces the scattering cross section of the electrons and increases the Touschek lifetime. This latter can be calculated via:

$$\frac{1}{\tau_t(|\vec{P}|)} = \frac{1}{\tau_t(0)} + Q|\vec{P}|^2 \qquad Q < 0 \tag{5}$$

where the expression for Q can be found in reference [2] and depends on the lattice functions and momentum acceptance. The polarization evolves with time as:

$$\vec{P}(t) = \vec{P}_{max}\left(1 - e^{-\frac{t}{\tau_p}}\right) \tag{6}$$

with τ_p being the polarization time.

POLARIZATION AND DEPOLARIZATION AT THE ESRF

For the ESRF, the theoretical polarization time is τ_p = 15.6 min (using equation 4 in section 2.7.7 in reference [1]). If we assume the Sokolov-Ternov maximum polarization of $P_{ST} = 0.9238$ and a constant momentum acceptance of 2.5%, we obtain a lifetime increase of 15.1%.

The polarization at the ESRF was measured using the Touschek lifetime, as given by equation (5) and (6). The result is shown in figure 1. Fitting the curve, we obtain $\tau_p = 15.9 \pm 0.6$ min and $\Delta\tau_t/\tau_t = 0.150 \pm 0.005$ [3]. These values are very close to the theoretical ones, which is an indication that the final polarization P_{max} is close to the Sokolov-Ternov value.

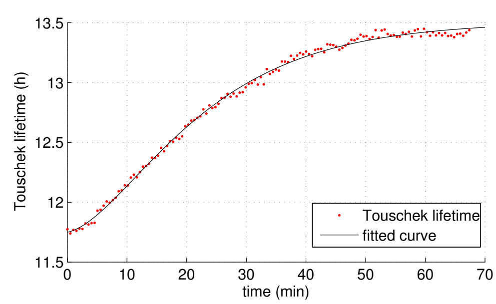

Figure 1: Polarization measurement at the ESRF via Touschek lifetime. The Touschek lifetime has been normalized to account for current and bunch length change and the measured vacuum lifetime has been subtracted.

The method of resonant spin depolarization allows a precise measurement of electron beam energy [4] [5]. We tried to apply this technique at the ESRF, however, the observed frequency range leading to depolarization was orders of magnitudes wider (~ 20 kHz) than expected (few Hz), see figure 2. This result and the difficulty of defining the correct experimental parameters motivated a more careful analysis of the depolarization process. A code based on AT [2] was written

[2] ATfastring function [6] was used for tracking speed.

NEW FUNCTIONALITY FOR BEAM DYNAMICS IN ACCELERATOR TOOLBOX (AT)

B.Nash, N.Carmignani, L.Farvacque, S.M. Liuzzo,
T.Perron, P.Raimondi, R.Versteegen, S.White, ESRF, Grenoble, France

Abstract

Accelerator Toolbox is a widely used code for beam dynamic simulations based on Matlab. To continue the development of the code in a collaborative manner, a SourceForge project and SVN repository called *atcollab* has been established. Here we describe the contributions to *atcollab* from the ESRF beam dynamics group. Additional modules have been developed: general matching (*atmatch*), improved plotting (*atplot*), Touschek lifetime computation via the Piwinski formula, nonlinear dynamics computations such as resonance driving terms, improved reporting of lost particles and improvements and additions to the integration routines. One example of the latter includes diffusion due to quantum fluctuations. Modeling of collective effects may now be performed using pass methods representing a variety of impedance models. Finally, routines to replace the full ring with a compact representation have been developed, facilitating studies in which many turns and many particles are required.

INTRODUCTION

Accelerator Toolbox (AT) is a Matlab [1] based tool box for accelerator simulation originally created by Andrei Terebilo during the late 1990's at SLAC [2, 3]. The latest release of AT from SLAC is 1.3. AT is widely used at accelerator facilities around the world. We describe the status of the developments made by the ESRF beam dynamics group, outlining our approach and some of the additions since AT 1.3. We have made an effort to maintain backwards compatibility throughout these changes.

WORKING WITH LATTICE STRUCTURES

Consistent with the original design of AT, a storage ring lattice is a Matlab structure where each element contains a link to a pass method[1] together with the relevant data to describe the element. Particles may then be tracked through the lattice structure using the function called *atpass* which is a compiled C language Mex Function for purposes of speed.

Element Creation Functions

Element creation functions exist to aid in the creation of a valid lattice structure. Previous versions of AT included many of these, but within a global variable structure. These have been modified to allow direct output of the lattice elements. As an example, QF=atquadrupole('QF1',0.94,0.39,'QuadMPoleFringePass') produces a quadrupole element structure with length 0.94 m and $k = \frac{1}{B\rho}\frac{\mathrm{d}B_y}{\mathrm{d}x} = 0.39m^{-2}$ using the pass method QuadMPoleFringePass. These elements may then be strung together to create a lattice structure.

[1] A pass method, or integrator is a function that maps initial phase space to final phase space in an element.

Class Field

The field 'Class' has been added to each element to facilitate element finding. The classes are 'Drift', 'Bend', 'Quadrupole', 'Sextupole', 'Multipole', 'ThinMultipole', 'Wiggler', 'KickMap', 'RFCavity', 'QuantDiff', 'Aperture', 'Monitor', 'Corrector', 'Solenoid', 'Matrix66', 'RingParam'. As an example, the indices of all sextupoles may be simply found using the command 'indsext=findcells(ring,'Class','Sextupole')'. The 'RingParam' element may contain global parameters describing the ring such as the electron energy or the ring periodicity, in case only one period is represented in the structure.

Lattice Manipulation Functions

We create functions to make changes to a lattice. Examples include misalignments and multipole errors. Additional function for setting elements properly include functions for setting cavities, turning radiation on and off, etc. The element creation functions output a lattice element directly. The lattice manipulation functions work directly with lattice structures. Working this way, rather than with a global variable THERING or FAMLIST as in AT 1.3, allows multiple ring structures to be stored simultaneously and more easily compared.

Plotting

A new plotting routine has been developed called *atplot*. It allows the plotting of arbitrary functions around the ring, together with the lattice synoptic. Examples are shown in Fig. 1 and 2. In Fig. 1, we see a plot of the varying dipole strength in sliced dipoles, together with the $\mathcal{H}_x$ function. This visualization allows understanding of how emittance may be minimized. In Fig. 2, we plot the geometric Hamiltonian driving terms throughout a lattice cell for the ESRF upgrade lattice. These have been computed using code from Elegant [4] interfaced to AT via MEX.

Matching

The function *atmatch* [5] allows general linear and nonlinear matching of an AT lattice structure. For optics matching the routine uses the function *atlinopt* (with a single call for all matching conditions), however generic Matlab functions may be used both to define variables (matching knobs) or conditions to be achieved, such as emittance reduction,

LATTICE CORRECTION USING LOCO FOR THE THOMX STORAGE RING*

I. Chaikovska†, C. Bruni, S. Chancé, A. Variola, J. Zhang
Laboratoire de l'Accélérateur Linéaire, CNRS-IN2P3, Université Paris-Sud XI, Orsay, France
A. Loulergue
SOLEIL, Gif-sur-Yvette, France

Abstract

ThomX is a compact Compton based X-ray source under construction at LAL in Orsay (France). The ThomX accelerator facility is composed by a 50-70 MeV linac driven by 3 GHz RF gun, a transfer line and a 18 meters long Storage Ring (SR). The Compton backscattering at each revolution between the 1 nC electron bunch and the ~25 mJ laser pulses stacked in the Fabry-Perot cavity results in the production of $\sim 10^{13}$ photons per second with energies in the X-ray regime. This high flux of the X-rays strongly depends on the quality (beam sizes) of the electron beam at the interaction point. To guarantee this, a good knowledge and quality of the linear lattice of the ThomX SR are required. Nowadays, LOCO (Linear Optics from Closed Orbits) is a well-known and widely used algorithm to measure and restore the linear optics of the SRs and ensure the designed performances. Comparing the measured and model orbit response matrices, the linear lattice can be restored by retuning the quadrupole gradients. In this paper, we report on the LOCO analysis of the ThomX SR taking into account simulated misalignment, calibration and field errors.

INTRODUCTION

ThomX is a demonstrator proposed by a collaboration of French institutions and one company to build an accelerator based compact X-ray (up to 90 keV) source in Orsay [1]. The main goal of the project is to deliver a stable and a high energy X-ray flux generated by the Compton backscattering process. Low energy, compactness and lack of the operation experience make such type of the machine very difficult to operate and, especially, to commission. At present, the ThomX machine is under construction. Layout of the ThomX accelerator facility including the Photoinjector, Transfer Line, Storage Ring (SR) and Extraction Line is shown on Figure 1.

First, to ensure a high flux X-ray production, linear optics of the ThomX SR has to be measured and controlled. Broken symmetry of the optics due to the field, calibration and misalignment errors usually leads to the resonant excitation which can strongly affect the beam dynamics and so the X-ray generation in the ring. Therefore, it is very important to identify and correct the linear optics (quadrupole gradient) errors in the ThomX SR.

In this framework, the analysis of the machine optics is usually performed by using the trajectories or closed orbit information organized in terms of the Orbit Response Matrices (ORM).

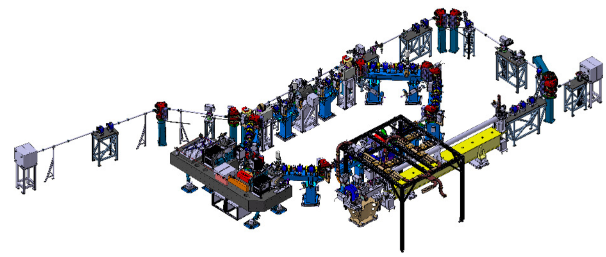

Figure 1: Layout of the ThomX facility.

THOMX STORAGE RING

ThomX SR design is based on a Double Bend Achromat (DBA) optics with a two-fold symmetry including eight 45° dipoles, 24 quadrupoles and 12 sextupoles (see Figure 2). This design accommodates two long straight sections and two short sections between the dipoles where potentially two interaction points can be located. Some of the ThomX SR parameters are listed in Table 1.

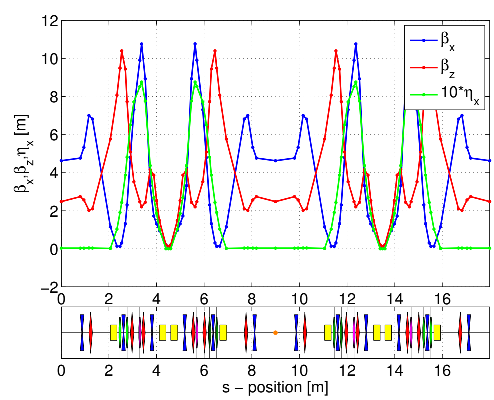

Figure 2: ThomX storage ring nominal optics: horizontal beta function (blue), vertical beta function (red), and horizontal dispersion (green).

The SR has 12 Beam Position Monitors (BPMs) and 12 correctors integrated in the sextupoles for both the horizontal and the vertical planes. The 24 quadrupoles are divided in 6 families and foreseen to have individual power supplies.

The Linear Optics from Closed Orbit (LOCO) code [2] is widely used to correct errors in the linear optics of the storage rings and transport lines. This paper will describe

Abstract

The electron ring of the compact Compton-backscattering X-ray source ThomX which is being built at LAL featured with a small circumference of 18 meters and a low beam energy 50-70 MeV, and its long term single particle dynamics is dominated by the non linear effects in the transverse and longitudinal planes. In this paper, we study the feasibilities to reduce the sextupole resonances and then increase the dynamic aperture and momentum aperture of the ThomX ring, using octupoles correctors.

INTRODUCTION

The compact Compton-backscattering X-ray source ThomX is under construction by a collaboration of seven institutes and an industry partner at LAL-Orsay, France. The accelerator part of this X-ray source is composed of an electron photon-gun, a linac, and a ring; and is featured with the compact size of 10 m long and 7 m wide, and the high average flux of 10^{11} to 10^{13} photons/second. However, the small size of the ring of 18 circumference and the low electron beam energy 50-70 MeV determine that the beam dynamics in the ThomX ring is dominated by the non-linear effect, which is a common issue for the future generation circular accelerators, like the low emittance light sources and the high luminosity colliders. For such type of accelerators, the dynamic aperture (DA) is normally smaller than the vacuum chamber size, and the momentum aperture (MA) is limited by the non linear motions of the off momentum particles.

DA AND MA OF THE THOMX RING

Quadrupole fringe fields (FFs) show no obvious effects on the beam dynamics, but the sextupole-like second order dipole FFs contribute greatly to the vertical chromaticities [1], and the sextupoles and the multipole field errors in the main magnets (dipoles, quadrupoles, sextupoles) in the ring are the main sources of the non linear effects of the ThomX machine, and they reduced the DA and the MA which have nontrival effects on the injection efficiency and the beam storage time in the ring.

In the final version of the ThomX ring lattice, there are 12 sextupoles which are composed of one family focusing sextupoles and two families defocusing sextupoles. The DA is reduced to around 15 mm in the horizontal plane x and 20 mm in the vertical plane z, which are respectively 30 times of the horizontal beam size σ_x and 57 times of the vertical beam size σ_z at the injection point of the ring; the MA is around ±3%, which is much larger than the final beam energy spread 0.6% after 20 ms storage time.

Table 1: Relative systematic multipole field errors in the ThomX ring, with the unit 10^{-4} at 18 mm radial position. From the OPERA-3D simulations.

Pole N	Inner dip.	Outer dip.	Quad.	Sext.
6	+8.5	-16	-	
8	+0.1	-0.7	-	
10	+3	-6	-	
12	-	-	+2	-
18	-	-	-	-4
20	-	-	-6	-
28	-	-	-9	-
30	-	-	-	-0.9

Furthermore, the engineering construction of the magnets introduces high order magnetic field errors, which deteriorate the DA and MA of the ThomX ring. With the systematic multipole field errors shown in Table 1 [2], the DA is reduced to around 13 mm (25 times of σ_x) in x and to 10 mm (29 times of σ_z) in z, which is smaller than the physical vacuum chamber size of 20 mm in x and 14 mm in z, while larger than the scaled chamber size of 12 mm in x and 7 mm in z; the MA is reduced to -1.8% and 2% (Fig. 1 and 2), which is comparable to the energy momentum acceptance ±2% limited by the vacuum chamber size.

Although from the simulation, the DA and MA (Fig. 1 and 2) seems to be sufficient for the operation mode of the ThomX ring with sextupoles and systematic multipole field errors, in the real ThomX machine, there will be other sources of perturbations that can reduce the DA and MA, such as the random multipole field errors, the systematic and random misalignment errors, power supply ripples, ground vibrations, thermal expansions of the ring, etc. As a result, one needs to further optimize the DA and MA of the machine.

HAMILTONIAN AND SEXTUPOLE RESONANCE TERMS

To optimize the DA and MA of the ThomX ring, one powerful method is the analysis of the Hamiltonian resonance

DESIGN STATUS OF THE ESSνSB SWITCHYARD

E. Bouquerel* on the behalf of the ESSνSB Collaboration
IPHC, Université de Strasbourg, CNRS/IN2P3, F-67037 Strasbourg, France

Abstract

The feasibility of the distribution of 5 MW proton beam power pulsed at 70 Hz onto a 4-target station for the production of neutrino super beams is discussed. To deflect and focus the beam having a magnetic rigidity of 11.0 Tm onto the targets, different configurations of beam switchyard are proposed and compared. The number of dipoles and quadrupoles composing this system is defined for each scenario. The length, the aperture, the magnetic fields and the field gradients of these optical elements are determined. The code TraceWin is used to simulate and optimize the envelopes of the beam along the beam lines. The transverse emittances at the exit of the system are shown.

INTRODUCTION

The next generation of neutrino beams are based on multi MW scale proton drivers. The proposal for the ESSνSB (European Spallation Source Neutrino Super Beam) project has been submitted to H2020 Design Study and is led by the Neutrino Group of the IPHC (Institut Pluridisciplinaire Hubert Curien) of Strasbourg and the University of Uppsala. It foresees the use of the ESS linac currently being constructed at Lund, to accelerate H^- ions (2.5 GeV, 5 MW, 70 Hz) and produce neutrino super beams [1]. It succeeds the studies made by the FP7 Design Study EUROν [2], regarding future neutrino facilities. The primary proton beam-line completing the linac will consist of an accumulator ring and a switchyard to distribute the protons onto the different targets composing the horn system (4 targets of 15 mm radius). The BSY (beam switchyard) is one of the key systems of the project. Its efficiency and reliability directly impact the production of yields of secondary particles.

Table 1: Beam Parameters for EUROν and ESSνSB [1]

Parameter	EUROν	ESSνSB
Particle	H^-	H^-
Proton kinetic energy (GeV)	4.5	2.5
Pulse intensity (mA)	40	62.5
Avg beam power (MW)	4	5
Beam rigidity (Tm)	17.85	11.02
Macro-pulse length (linac) (ms)	2.86	0.715
Pulse length (accu.) (μs)	1.5	1.5
Pulse repetition rate (Hz)	50	70

Preliminary studies were done on such system within EUROν [3]. Although the horn requires similar conditions as for EUROν, the parameters of the primary beam being different from those used for this previous project (Table 1) implies considering an upgrade or even new solutions for the distribution of the protons onto the horn system.

*Elian.Bouquerel@iphc.cnrs.fr

SPLITTING AND DISTRIBUTING THE PROTONS

Different Configurations Investigated

Besides the configuration studied for EUROν (labelled "config1" in this paper), other scenarios to deflect the beam onto the horn system have been recently under considerations. Among several layouts, two new configurations, in addition to config1, could be seriously retained for further detailed studies. These new solutions will be labelled "config2" and "config2a" respectively. The selection criteria relied on the number of magnetic elements necessary, on the type of operation (i.e. simple or bi-polar devices) and on the prospective of beam dump requirements.

Deflecting Elements

Although kicker technology was raised for config1 in the framework of the EUROν Design Study, the rise and fall times of few ms and the repetition rates of 17.5 Hz (35 Hz according to the configuration) needed by each device would actually allow the use of simple classical dipoles (O- and H-types), to deflect the protons onto the 4 target axes [4]. This would have the advantage of making easier the design of both the magnets and the power supplies, thus reducing their cost.

BEAM FOCUSSING SYSTEM

Beam Parameter Definition

The normalised rms transverse emittances of the beam extracted from the ESS linac are foreseen to be 0.33 μm [5]. The charge exchange injection with high power beam requires a modest number of foil hits during the phase space painting, resulting in a larger emittance than the injected beam. Therefore transverse emittances at the exit of the accumulator will be much larger than the one at the end of the ESS linac. Current studies suggest the emittances of the beam coming from the accumulator to be of several tenths of μm [6]. In the following, the normalised transverse emittances of the proton beam are assumed to be 225 μm (99.7%) and the rms momentum dispersion 0.1%. The required beam size at the target station is 4 mm rms.

LOSS FACTOR AND IMPEDANCE ANALYSIS OF WARM COMPONENTS OF BERLINPRO*

H.-W. Glock[1,2], M. Abo-Bakr[1], J. Kolbe[1], F. Pflocksch[1], C. Potratz[2], Andreas Schälicke[1]
[1] Helmholtz-Zentrum Berlin für Materialien und Energie (HZB), BESSY II, Berlin, Germany
[2] Compaec e.G., Rostock, Germany

Abstract

The ongoing component design for the HZB 50 MeV, 100 mA ERL project bERLinPro is accompanied by loss factor and impedance computations. A list of accelerator components that are likely to induce geometric wake fields including bellows, collimators, tapers, shutter valves etc. is given. Loss factors and impedance spectra, both calculated using CST-ParticleStudio®, are presented. Scaling of the loss factors with respect to the bunch length is calculated on base of the numerical simulations and is used to extrapolate down to a rms bunch length of 0.6 mm, which is hard to reach directly in numerical simulations.

INTRODUCTION

Future single-pass accelerators, in particular high-brilliant next-generation light sources or colliders for high-energy physics, will demand for beam power levels hardly to be maintained by classical set-ups, which dump the beam with most of its kinetic energy. This led to the "energy recovery linac" concept with a recirculation of the used beam through the accelerating cavities, where it is decelerated by a proper choice of the beam-to-field-phase to a small fraction of its maximum kinetic energy. Thus the beam feeds back the accelerating cavity mode, which in turn accelerates a fresh beam. Such a mode of operation will be most effectively applied to a high current, continuously operated (cw) accelerator with low loss, i.e. super-conducting cavities. It is the aim of the bERLinPro project [1] (cf. Fig. 1), now under construction at HZB, to demonstrate energy recovery operation with a cw (1.3 GHz repetition rate), 50 MeV, 100 mA, $\sigma_t < 2$ ps bunch length, low-emittance beam.

This demands for a careful analysis of all beam line components according to their potential to excite wake fields. This paper is focussed on so-called geometric wakes; effects of coherent synchrotron radiation (CSR), resistive walls or surface roughness are only cited for comparison. Since the bunch spectrum reaches far above 100 GHz most wakes are able to propagate through the machine, in principle causing a strong rf-coupling between individual components. It would demand for excessive supercomputing capabilities to compute the field interaction with each other and the beam for such a long chain of coupled components, which – even if available – would not be practicable for any design optimisation. Thus the two following figures of merit, computable for every single component, were used (cf. Fig. 2, Tab. 1): a) the loss factor; b) the impedance close to the beam-harmonic frequencies of N·1.300 GHz.

SIMULATION TECHNIQUE

All simulations were performed with the wakefield solver of CST ParticleStudio® [2], running on a dedicated workstation (2x Intel Xeon E5 2643v2-6-core, 3.50 GHz, Intel S2600 board, 256 GB of DDR3-1866 RAM). The solver uses an explicit time stepping scheme on a hexahedral mesh. In most cases 15 mesh lines were applied longitudinally per bunch rms length $\sigma_s = c\cdot\sigma_t$ of Gaussian shaped bunches. σ_s usually was chosen as 1 mm (computed impedance spectra up to 100 GHz), 3 mm and 5 mm. The number of mesh cells was in most cases up to a few 10^8, largest possible meshes reached $1.3\cdot10^9$ cells. Indirect wake integration was used (option "indirect interfaces"), mostly applied to on-axis beams. As a trade-off between spectral resolution versus grid dispersion error and computation time typically a wake length of 10 m was computed for at least one of the three bunch lengths. In most cases two more runs were performed with a wake length of 200 mm, which is sufficient for the program to determine the loss factor.

LOSS FACTOR DEPENDENCY ON BUNCH LENGTH

Due to its infinitely extended spectrum, which cannot be handled numerically, it is not possible to compute a point charge's wake potential (at least not with bandwidth-limited discretizing approaches). Instead the wakes of Gaussian shaped bunches were simulated, giving wake potentials and loss factors depending on the bunch rms length. Computing various objects (many of them not shown here) and comparing their bunch-length dependent loss factors in a double-logarithmic viewgraph heuristically led to the observation of a loss factor scaling according to:

$$k_{loss}(\sigma) = k_{loss}(\sigma_0)\left(\frac{\sigma}{\sigma_0}\right)^{-\alpha} \tag{1}$$

STATUS OF THE ROBINSON WIGGLER PROJECT AT THE METROLOGY LIGHT SOURCE

T. Goetsch*, J. Feikes, M. Ries, G. Wüstefeld, HZB, Berlin, Germany

Abstract

The beam lifetime in electron storage rings concerns machines running in decay mode as well as machines doing top-up. A standard procedure to increase the lifetime is via bunch lengthening as the lifetime depends on the electron density in the bunch. Bunch lengthening is typically achieved with higher harmonic (Landau) cavities. As noted in [1], there are several advantages in using a different approach: it is possible to increase the bunch length by installing a Transverse Gradient (Robinson) Wiggler, which allows to transfer damping between the horizontal and the longitudinal plane. While increasing the bunch length, the horizontal emittance is being reduced yielding advantages regarding the source size depending on the magnet optics. At the Metrology Light Source, a primary source standard used by Germanys national metrology institute (Physikalisch-Technische Bundesanstalt) [2], such a scheme is being investigated. The current state of the project including dynamic aperture effects and synchrotron radiation issues of the device is being presented in the following.

INTRODUCTION

The lifetime at the MLS is Touschek dominated and it is 6 h for a beam current of 150 mA. To improve the lifetime, the prospects of installing a Robinson Wiggler (RW) are being investigated. The RW transfers damping between the horizontal and the longitudinal plane. Therefore, it will allow tuning of the energy spread σ_δ, and by that the bunch length σ_s as $\sigma_s \propto \sigma_\delta$. Hence, the bunch density can be decreased via bunch lengthening, resulting in an increased lifetime. Increasing the bunch length is usually achieved by installing higher harmonic (Landau) cavities. Installing a RW at the MLS is an option, as the users of the synchrotron radiation are not as sensitive to an increased energy spread as in other facilities.

THEORY

The damping partition number D describes how the damping is divided between the horizontal and the longitudinal plane. It is the ratio between the fourth and the second synchrotron radiation integral, I_4 and I_2:

$$D = \frac{I_4}{I_2}, \tag{1}$$

$$I_2 = \oint \frac{1}{\rho^2} \mathrm{d}s, \tag{2}$$

$$I_4 = \oint \left(\frac{\eta_x}{\rho^3} + \frac{2\eta_x k_1}{\rho} \right) \mathrm{d}s, \text{ with } k_1 = \frac{1}{B\rho} \frac{\partial B_y}{\partial x}, \tag{3}$$

* tobias.goetsch@helmholtz-berlin.de

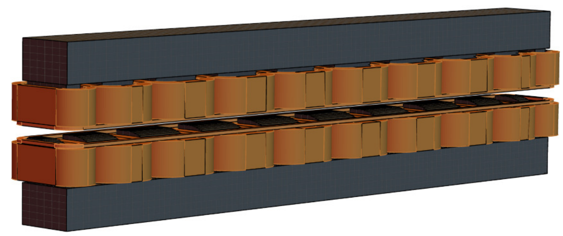

Figure 1: Robinson Wiggler as described in RADIA [3]. The poles have a hyperbolic shape in the horizontal direction, giving rise to a linear, horizontal field gradient (comp. Fig. 4). Field and gradient depend on the current in the coils.

where ρ is the bending radius, η_x is the horizontal dispersion function and k_1 is a horizontal gradient to the field. The damping partition D can be manipulated by introducing a magnetic field B and a gradient $\partial B/\partial x$ simultaneously in a dispersive section. The contribution to I_4 is negative when choosing B and $\partial B/\partial x$ to be of opposite sign (for a positive dispersion). Chains of alternating combined function magnets yield such fields (compare Fig. 1).

In Fig. 2 the development of σ_x, the averaged beam width along the circumference, the hor. emittance ε_x, the bunch length σ_s (and with that the energy spread σ_δ) and the beam lifetime $\tau_{1/2}$ are shown as a function of the damping partition D. The lifetime includes gas lifetime, the different quantum lifetimes and the Touschek lifetime. The gas lifetime was assumed to be constant with a value of $\tau_{\mathrm{gas}} = 25$ h, which is the result of measurements performed in 2013.

The lifetime is calculated for two scenarios: τ_1 represents the lifetime calculated for a constant vertical source size, independent of the horizontal emittance; τ_2 represents the lifetime as it would be for a constant emittance coupling between the horizontal and the vertical plane of $\varepsilon_y/\varepsilon_x = 0.5$ %. The graphs show that for $D = -1.75$, a lifetime improvement between 60 % (τ_2) and 100 % (τ_1) seems achievable.

DESIGN STATUS

Number of Poles and Drift Correction

As the available space for the device is limited to 1740 mm, the maximum length of an individual pole is defined by the number of pole pairs. The longer a pole, the higher the achievable fields. But the longer the poles the larger the particles amplitude. Taking the constraints at the MLS into account, the optimum seems to be 9 to 10 poles (including end poles). In order to preserve the aperture, it is worthwhile to have the beam oscillating around the central

LONGITUDINAL STABILITY OF SHORT BUNCHES IN STORAGE RINGS WITH STRONG LONGITUDINAL FOCUSING*

P. Kuske#, Helmholtz-Zentrum Berlin, Germany

Abstract

In the BESSY VSR project, the variable bunch length storage ring, two high gradient accelerating structures at 1.5 and 1.75 GHz will be phased such that long and short bunches can be stored simultaneously. The longitudinal stability of the short bunches is investigated taking into account the shielded CSR- and a purely inductive impedance. Multi particle tracking studies and numerical solutions of the Vlasov-Fokker-Planck equation show that threshold currents for short bunches do not follow the simple scaling law which was found for long bunches. The inductive impedance can even lower the thresholds for the instability. With an 80 times increased accelerating gradient and reasonable assumptions on the inductive impedance for shorter bunches stable operation can be expected with bunches 1.8 ps long (RMS-value) and 0.8 mA current. According to the calculations and operating in a dedicated low-α mode will produce stable 40 μA bunches with 400 fs length.

INTRODUCTION

At the 3rd generation synchrotron radiation light source BESSY II shorter light pulses are requested by a growing number of users. Laser slicing is operated routinely and produces pulses as short as 100fs FWHM. Operating in the short bunch, low-α mode delivers bunches shorter than 6 ps FWHM. This is offered for up to 3 weeks per year. Slicing and low-α mode suffer both from a too low intensity. One way to increase the intensity of light pulses, or overcome the quite low stable bunch currents, is the increase of the longitudinal RF-focusing. This produces shorter bunches and shifts threshold currents to higher values. A neat way to produce short bunches without sacrificing flux or brilliance for other users was proposed by G. Wüstefeld, et al. [1]: long and short bunches can be stored simultaneously with proper phasing of two super-conducting high gradient accelerating structures operating at 1.5 and 1.75 GHz, 3 and 3.5 times the fundamental 500 MHz-RF-system. Most of the charge will be stored in long bunches producing most of the photon flux and, at the same time, a few short bunches carrying charge just below their instability threshold will emit the desired short light pulses. The purpose of this paper is to analyse the longitudinal stability of these short bunches.

MODEL OF SHIELDED CSR

For very short bunches the coherent synchrotron radiation (CSR) is dominating the longitudinal beam dynamics. In the calculations presented here the model of the steady-state CSR theory for bunches moving on a circle with radius ρ is used. This is justified by the fact that the BESSY dipoles are long enough so that the light emitted from a trailing electron at the entrance of the dipole can overtake the bunch and interact with the electrons at the head of the bunch [2] already inside the dipole magnet. The slippage length is a factor of 3 to 14 longer than the length of the investigated bunches. Bunches are not yet short enough to assume that the interaction takes place in free-space. Shielding effects of the nearby dipole vacuum chamber have to be taken into account. This is done with the wake function derived by J. Murphy, et al. [3] for the model of two perfectly conducting infinite parallel plates separated by 2h.

Some of the results of the simulations and also the observations are easier to understand within the impedance picture of the shielded CSR-interaction first derived by R. Warnock [4] and later expressed in scaled parameters by Y. Cay [5]. The resulting CSR-impedance is presented in Figure 1. The plates suppress the impedance at low frequencies and at higher frequencies the impedance approaches the free-space values. In between a resonance-like enhancement appears. The frequency of the maximum as deduced from the Olver expansion of the impedance [6] is located around $n_{max} = \omega/\omega_0 = \omega\rho/c = 2/3^{1/2}(\pi\rho/2h)^{3/2}$. This broad resonance has features of a broad-band resonator and can create similar instabilities.

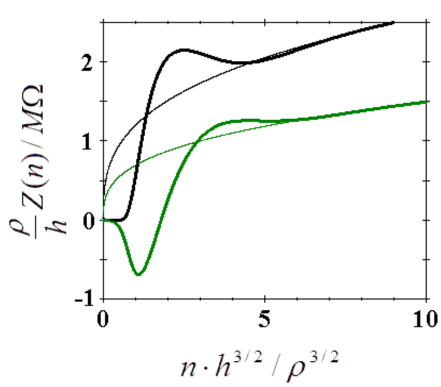

Figure 1: Scaled real part (black) and imaginary part (green) of the CSR impedance in free space (thin lines) and shielded by two infinite perfectly conducting parallel plates (thick lines).

Based on the shielded CSR-model, K. Bane, et al. [7] found a very simple scaling law valid for a large range of parameters, except for bunch lengths with 1/σ in the neighbourhood of this resonance. In this region the strong instability turns into a weak instability and threshold currents are dramatically reduced. BESSY VSR will produce bunches with a length in the critical region.

TRANSVERSE RESONANCE ISLAND BUCKETS AT THE MLS AND BESSY II

M. Ries *, J. Feikes, T. Goetsch, P. Goslawski, J. Li, M. Ruprecht, A. Schälicke, G. Wüstefeld †
HZB, Berlin, Germany

Abstract

By operating the Metrology Light Source (MLS) near horizontal resonances (ΔQ_x = 1/2, 1/3 or 1/4), two, three or four resonance island buckets may be populated for beam storage. This paper presents experimental results and operational experience such as tuning the machine for high current, controlling inter-bucket diffusion rates, improving overall lifetime and extraction of radiation pulses with sub-revolution repetition rate. First approaches to transfer this mode of operation to the BESSY II storage ring will also be presented.

INTRODUCTION

The MLS is an electron storage ring operated as a dedicated light source for metrology applications of the Physikalisch-Technische Bundesanstalt (PTB). By design, it is equipped with additional families of sextupole and octupole magnets to manipulate nonlinear beam dynamics [1, 2]. Therefore, the MLS is ideally suited to investigate nonlinear beam dynamics in the transverse plane.

Transverse resonance island buckets form when a machine is operated in the vicinity of a resonance and suitable amplitude dependent tune shift is present. The existence of these island buckets is well known and described for long time, e.g. [3]. An application is multi-turn extraction at CERN [4]. However, island buckets are not yet exploited for user operation at electron storage rings.

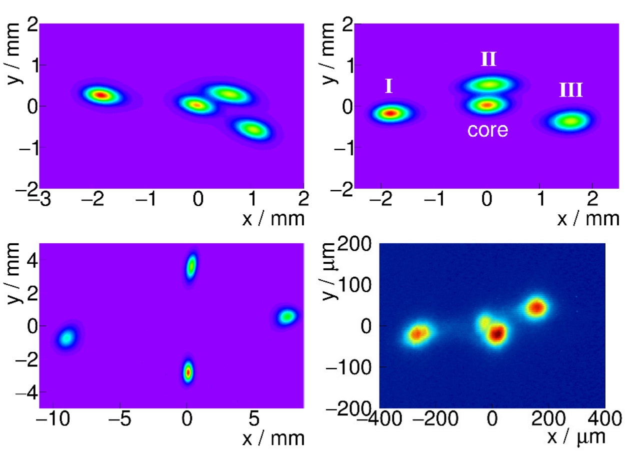

Figure 1: Source point imaging measurements from island bucket operation near horizontal resonances ΔQ_x = 1/3 (top) and 1/4 (bottom left) at the MLS and BESSY II (bottom right).

* markus.ries@helmholtz-berlin.de
† gwuestefeld@gmx.de

Figure 1 exemplarily shows transverse electron distributions measured using a source point imaging system. The MLS was successively operated near horizontal resonances $\Delta Q_x = f_x/f_{\text{rev}} = 1/3$ (top) and 1/4 (bottom left). Skew quadrupole magnets were used to introduce vertical separation for the purpose of visualization. The upper measurements were taken simultaneously at two different locations along the circumference. The position of the islands can be manipulated by changing quadrupole and sextupole currents. Islands stored near the ΔQ_x = 1/4 resonance are shown bottom left, with large off-axis fixed points. The core beam was not populated.

Studies for island bucket operation are also performed at the BESSY II storage ring, an example measurement is shown in the bottom right part. Resonance island buckets may provide an elegant way of beam separation – see next section – for the BESSY VSR project [5].

MULTIPLE BEAMS & SEPARATION

Two intrinsic characteristics of island buckets seem to be of special interest for application at light sources. First, island buckets offer the possibility to store two distinct user beams simultaneously, e.g. homogeneous fill and pseudo single bunch. Second, island bucket and core beams are separated in space and/or in angle in the plane corresponding to the resonance.

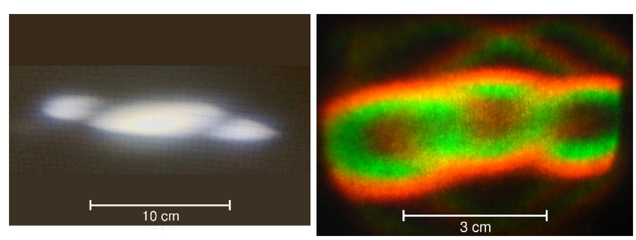

Figure 2: Photon beam separation in divergent parts of user beamlines shown for bending magnet radiation (left) and undulator radiation (right).

The separation in electron phase space translates to the generated photon beams. Figure 2 shows photon beams generated by island buckets in a bending magnet (left) and an undulator straight (right) in divergent parts of the user beamlines. The former image was taken with simultaneously populated island bucket and core beam. In contrast, the latter image was measured with exclusively populated island buckets. At the position of the undulator two islands are characterized by fixed points at ($x_{\text{FP}} \approx 0, \pm x'_{\text{FP}}$), whereas the third island is at ($x_{\text{FP}}, x'_{\text{FP}} \approx 0$). The achieved photon beam separation is in the order of cm, which is an accessible range

INFLUENCE OF TRANSIENT BEAM LOADING ON THE LONGITUDINAL BEAM DYNAMICS AT BESSY VSR*

M. Ruprecht†, P. Goslawski, A. Jankowiak, A. Neumann, M. Ries, G. Wüstefeld,
HZB, Berlin, Germany
T. Weis, TU Dortmund University, Dortmund, Germany

Abstract

BESSY VSR, a scheme where 1.7 ps and 15 ps long bunches (rms) can be stored simultaneously in the BESSY II storage ring has recently been proposed [1]. The strong longitudinal bunch focusing is achieved by superconducting high gradient RF cavities. If the bunch fill pattern exhibits a significant inhomogeneity, e.g. due to gaps, transient beam loading causes a distortion of the longitudinal phase space which is different for each bunch. The result are variations along the fill pattern in synchronous phase, synchrotron frequency and bunch shape. This paper presents investigations of transient beam loading and depicts the consequences on bunch length, phase stability and longitudinal multi-bunch oscillations for the projected setup of BESSY VSR.

INTRODUCTION

The upgrade proposal BESSY VSR [2] is based on the idea that the superposition of the voltage of two different higher harmonic cavity systems will allow to store short and long bunches simultaneously. In order to separate the synchrotron radiation from single bunches by means of a mechanical chopper, they need to be placed in the center of gaps in the bunch fill pattern. Therefore, the fill pattern is proposed to have two 100 ns gaps as depicted in Fig. 2, which gives rise to potentially strong transient beam loading.

TRACKING CODE

A tracking code written in C++ has been developed which uses one macro-particle per bunch for the calculations presented here. The cavity-bunch interaction is calculated by means of phasor addition and active cavities are controlled by a feedback loop which does not act within a revolution but acts quickly from one revolution to another. This simplified method is sufficient to evaluate the effects of beam dynamics discussed in this paper. Related studies, with a focus on RF control are given in [3].

Experimental Verification at BESSY II

Transient beam loading can readily be observed at BESSY II as it is typically operated with a 200 ns gap in the fill pattern and the 1.5 GHz Landau cavities set to bunch lengthening mode. Figure 1 shows an example of measurements at BESSY II compared to simulations performed with the tracking code used in this paper. Both, the data of the synchronous phase position of each bunch, measured in ps with respect to the nominal equidistant bucket reference, and the individual synchrotron frequencies was taken by the diagnostics of bunch-by-bunch feedback systems [4].

The agreement of simulation and measurement can be considered satisfying. Despite some deviation, all major features, such as magnitude of phase transient, magnitude and shape of the synchrotron frequencies are predicted by the simulation. The deviations are expected to stem from uncertainties from both the measurements and the input parameters to the simulation, such as quality factors Q, the shunt impedances R_s^c and the tuning settings. Investigations towards identification and improving the accuracy are ongoing.

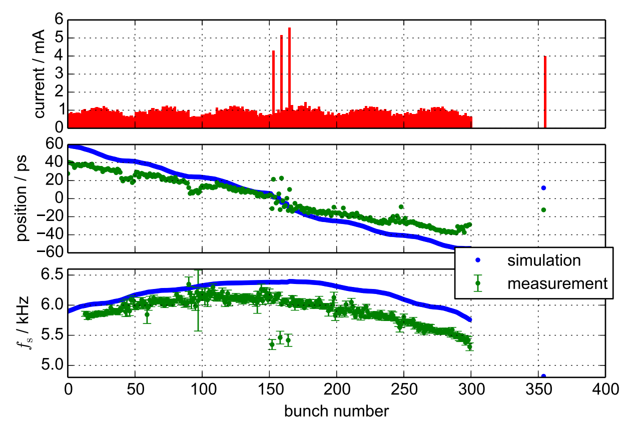

Figure 1: Comparison between simulation and measurements of synchronous phase position of each bunch (center), measured in ps w.r.t. the nominal equidistant bucket reference, and synchrotron frequency (bottom) at BESSY II for a given fill pattern (top). Error bars show a statistical error only.

BESSY VSR SETUP

In BESSY VSR, the storage ring will be equipped with four 5-cell SC cavities, two at 1.5 GHz and two at 1.75 GHz. In this simulation, the normalized shunt impedance[1] is set to $R_s^c/Q = 250\,\Omega$ per cavity. In order to accelerate the approach of the equilibrium state in this simulation, the quality factor of the cavities is set to $Q = 4 \times 10^5$ and the radiation damping time to $\tau = 4 \times 10^{-4}$ s. The 1.5 GHz and 1.75 GHz system are tuned to $\Delta f = -11.3$ kHz and $\Delta f = 15.3$ kHz respectively to compensate for the average

PRESERVING INFORMATION OF THE THREE SPATIAL ELECTRON BEAM DIMENSIONS IN ONE STREAK CAMERA MEASUREMENT *

M. Switka and W. Hillert, ELSA, Bonn, Germany

Abstract

At the pulse stretcher and storage ring ELSA a streak camera is used for the analysis of visible synchrotron radiation. It functions as fast time resolving beam diagnostic apparatus, capable of visualizing dynamics down to the picosecond time regime. The optical beamline splits the photon beam into two parts and projects both electron beam images onto the streak camera, one of them with transversely perpendicular orientation and slight displacement. Thereby it provides simultaneous imaging of both transverse planes. Thus, the information of bunch and beam dynamics of all three dimensions is preserved and can be observed in slow sweep or synchroscan operation. Characteristics and exemplary measurements, demonstrating the capabilities and limits of this technique, are presented.

INTRODUCTION

Since commissioning of the ELSA streak camera beamline was completed in 2013 [1], the natural reduction of three-dimensional spatial information to two dimensions due to the streaking action turned out to be of hindrance as both, horizontal and vertical beam responses were of interest. In the initial setup the change of the observation plane was possible by insertion of a Dove prism. However, simultaneous observation of both transverse planes could not be performed. Therefore a dual imaging beamline was installed and initially tested [2] by coupling a horizontal and a vertical beam image onto the streak camera's input optics. Due to the promising results, attention was drawn to the addition of two beamline extensions. First, the possibility to adjust the difference of photon propagation time between the two imaging beams was added. Secondly, independent remote positioning of both photon beams enabled to account for transverse electron beam orbit displacements. The remote positioning capability also ensures optimum utilization of the available space on the CCD matrix, especially in synchroscan mode.

THE OPTICAL SYSTEM

The evacuated synchrotron radiation (SR) beamline frontend is approximately 12 m long and serves as differential vacuum pumping section in order to achieve a pressure 1-2 orders of magnitude below synchrotron vacuum. As the primary reflecting mirror is fully exposed to the x-ray beam, mirror surface reactions with residual gas are suppressed [3]. The mirror couples the visible part of the SR spectrum out of the accelerator's plane through a vertical chicane onto an optical table housing the optical components. An overview of the beam optics assembly is given in Fig. 1.

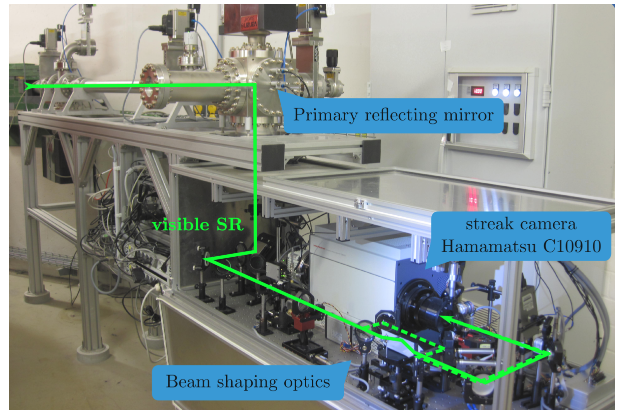

Figure 1: Photograph of the optical diagnostics beamline's back-end including the vertical chicane and the optical setup. The optical path (green) is guided through beam shaping optical elements half-way around the streak camera.

Table 1: ELSA & Source Point Parameters

Parameter	Value
Beam energy E	0.5–3.5 GeV
Revolution period T_{rev}	548 ns
Cavity RF frequency f_{RF}	499.67 MHz
Natural emittance ϵ_x	18–900 nm· rad
Bunch length σ_s	14–91 ps
Beam size ($8\sigma_x$ at source point)	3.1–21.9 mm

Requirements for Image Magnification

ELSA's electron beam dimensions are in the order of millimeters transversely and several ten picoseconds longitudinally. The accelerator properties and the resulting source point parameters are listed in Table 1.

Since longitudinal resolution capabilities are intrinsic properties of any streak camera, the aforegoing beamline is designed to provide sufficient resolution of transverse beam dynamics. The optics therefore match the expected electron beam size with the smallest field stop aperture which is identified as the photocathode of the operating streak camera Hamamatsu C10910 with a size of $0.15 \times 4.41\,\text{mm}^2$ [4]. The requirement for minimum beam demagnification at the photocathode is therefore

$$M_{\text{cathode}} \lesssim h_i/h_o \approx 10^{-2},$$

where $h_i = 150\ \mu\text{m}$ is the maximum allowable field size due to the aperture and $h_o \approx 22$ mm the maximum expected source size. The inequation takes into account that transverse beam oscillations enlarge the effective source size.

ESTIMATION OF THE ION DENSITY IN ACCELERATORS USING THE BEAM TRANSFER FUNCTION TECHNIQUE*

D. Sauerland†, W. Hillert, ELSA, Bonn, Germany
A. Meseck, Helmholtz-Zentrum Berlin, Germany

Abstract

The ELSA stretcher ring of Bonn University serves external hadron physics experiments with a quasi continuous electron beam of up to 3.2 GeV energy. Ions, being generated by collisions of the circulating electrons with the residual gas molecules, accumulate inside the beam potential, causing *incoherent* tune shifts and *coherent* beam instabilities. Detailed measurements were carried out in which ion dynamics is studied in dependence of beam energy and current, filling patterns and bias voltages of the ion clearing electrodes. By measuring the beam transfer function using a broadband transversal kicker, we were able to derive an estimate of the average ion density from the shift and broadening of the tune peak. In this contribution first results of these measurements are presented.

INTRODUCTION

The **El**ectron **S**tretcher **A**ccelerator (ELSA) is a three stage electron accelerator, consisting of a linear accelerator, a booster synchrotron, and the fast-ramping stretcher ring (see Figure 1). It is capable of providing polarized and unpolarized electrons with an energy of up to 3.2 GeV for hadron physics experiments.

An energy dependent equilibrium beam emittance in the stretcher ring is caused by damping due to synchrotron radiation. Thus the resulting transversal beam dimensions are scaling with the beam energy as well, which is shown in Table 1 in which also important operating parameters of the stretcher ring are presented. This energy dependency has an observable impact on the occurrence of transversal beam instabilities when storing high beam currents. Investigations have shown that these instabilities are mainly caused by trapped ions [1]. Since the dynamics of ion generation and motion in circular accelerators is i.a. influenced by the size of the beam, these instabilities arise in the horizontal and in the vertical plane at different beam energies. The growth rates of these instabilities scale with the ion density and may lead to beam losses during operation. In order to reduce the density of trapped ions, several ion clearing measures are applied at ELSA. To evaluate their efficiency, it is essential to develop a technique to estimate the average ion density. For this purpose an approach using beam transfer functions (BTF) was developed and will be discussed in this contribution.

1-σ bunch length	18.5 to 80 ps
Pressure (avg.)	$5.5 \cdot 10^{-8}$ mbar

ION EFFECTS IN CIRCULAR ACCELERATORS

Production, Accumulation and Impact of Ions

In an accelerator the passing electron beam continuously produces charged ions. Their composition mainly depend on the partial pressures of the different residual gas species and their corresponding ionization cross-sections. The electron beam forms an attractive potential wherein the positively charged ions can be trapped.

Once the ions are trapped, the beam's repulsive electrical field caused by space charge is reduced by the superimposed space charge field of the accumulated ions, while the focussing magnetic field generated by the beam remains constant as the ions are moving nonrelativistic. This results in a decreased defocussing of the electrons whose strength is dependent on their position inside the bunch. Thus an accumulation of ions causes an *incoherent* tune shift in the transversal planes which increases for higher ion densities.

Additionally trapped ions perform transversal oscillations inside the beam's potential around the barycenter of the

SIMULATION OF LASER COOLING OF HEAVY ION BEAMS AT HIGH INTENSITIES

L. Eidam*, TEMF, TU Darmstadt, Germany
O. Boine-Frankenheim, GSI Helmholtzzentrum für Schwerionenforschung GmbH (GSI), Germany
D. Winters, GSI Helmholtzzentrum für Schwerionenforschung GmbH (GSI), Germany

Abstract

In the past the principle of Doppler laser cooling was investigated and verified in storage rings in the low energy regime. Within the FAIR project the laser cooling will be applied to high intensity and high energy beams for the first time. The laser cooling results in a further increase of the longitudinal phase space density and in non-Gaussian longitudinal beam profiles. In order to ensure stable operation and optimize the cooling process the interplay of the laser force and high intensity effects has to be studied numerically. This contribution will identify constrains of the cooling scheme for an efficient reduction of momentum spread. For high beam energies the scattering of photons has to be treated stochastically instead of using averaged forces. The modeling of the laser force in a particle in cell tracking code will be discussed.

INTRODUCTION

Laser cooling produces ultra cold ion beams by intersecting laser light anti parallel with the particle beam. The momentum kick of the absorbed photon always points in direction of the laser beam, whereas the emission is isotropically distributed. For many scattering events the effect of the emission vanishes and the directional force of the absorption remains as shown in Fig. 1. Indeed this process requires a precise matching of the laser wavelength in the particle frame to the energy of the atomic transition. For available laser light sources this fact assigns a constrain on the beam velocity depending on the chosen transition as discussed in ref. [1].

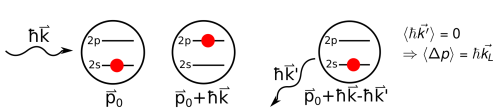

Figure 1: Sketch of a scattering event. Directional absorption and isotropic emission of photons leads to net force used for laser cooling.

The laser force requires a counteracting force to cool an ion beam. A second laser in opposite direction is the most efficient way for ion traps and low energy storage rings. For higher beam energies the best solution is given by capturing the particles in a rf bucket. The narrow laser force does not interact simultaneously with all ions in a hot particle bunch. Therefore the position of the laser force is scanned in order to damp continuously the synchrotron oscillation of all particles as shown in Fig. 2.

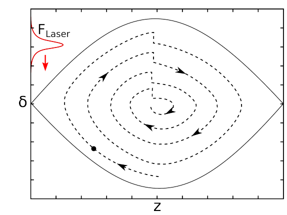

Figure 2: Sketch of the cooling process for a hot ion beam in a rf bucket. The laser force is scanned to damp continuously the synchrotron oscillation of all particles.

MODELING OF THE LASER FORCE

The influence of the laser force on the particle dynamic cannot be described by a cooling rate because of its strong non-linearity. In order to determine cooling equilibriums and optimize the general cooling process the longitudinal particle dynamics are solved numerically. For simplicity, the study contains only longitudinal dynamics assuming that the transverse motion is unaffected by the laser cooling.

The cooling force in the laboratory frame (LF) is given by the momentum change of one scattering event times the scattering rate.

$$F^{cool} = \Delta p^{LF} \cdot k \tag{1}$$

As shown in Fig. 1 the momentum change is given by the difference of the momentum of the incoming and outgoing photon:

$$\begin{aligned} \Delta p^{LF} &= \Delta p^{LF}_{in} - \Delta p^{LF}_{out} && (2)\\ &= -\frac{\hbar\omega^{LF}}{c_0} - \frac{\hbar\omega^{LF}}{c_0}\frac{U_i+\beta}{1-\beta} && (3)\\ &= -\frac{\hbar\omega^{LF}}{c_0}\gamma^2(1+\beta)\cdot(1+U_i) && (4) \end{aligned}$$

Where U_i is a random number between -1 and 1 that describes the projection of the isotropically radiated photon on the longitudinal axes. Note that the Lorentz boost of the outgoing photon provides a kick that is approximately $2\gamma^2$ higher than the incoming photon.

The scattering rate is given by the occupation of the excited state divided by its lifetime:

$$k = \frac{1}{\tau} \cdot \rho_{ee} \tag{5}$$

For simulations the ion-photon interaction is reduced to an atomic two level system in an electromagnetic mode and

DEMONSTRATION OF FLAT ION BEAM-CREATION AND -INJECTION INTO A SYNCHROTRON

L. Groening, S. Appel, L. Bozyk, Y. El-Hayek, M. Maier, C. Xiao, GSI, 64291 Darmstadt, Germany

Abstract

An ion beam with different horizontal and vertical emittances has been created from a beam with initially equal emittances. This round-to-flat adoption has been accomplished without any beam loss. In the set-up the beam passes through a stripping foil placed inside a solenoid followed by a skewed quadrupole triplet. The amount of beam flatness has been controlled by setting the solenoid field strength only. Increase of the product of the two transverse emittances is purely due to the stripping process that occurs anyway along an ion linac. Beams with different amounts of flatness were injected into a synchrotron applying horizontal multi-turn injection. The efficiency of injection increased as smaller as the horizontal emittance was set by the round-to-flat adaptor.

INTRODUCTION

For heavy-ion synchrotrons an efficient Multi-Turn Injection (MTI) from the injector linac is crucial in order to reach the specified currents using the available machine acceptance. The FAIR Heavy-ion synchrotrons are operated with intermediate charge state ions in order to increase the space charge limit. Therefore, stripping injection is not an option and the MTI has to respect Liouville's theorem for the chosen charge state - avoiding the already occupied phase space area. To achieve the space charge limit the multiplication of the injected current should be as large as possible. The beam loss during the MTI must not exceed the limits determined by machine protection and by the vacuum requirements. Especially for low energy and intermediate charge state ions, the beam loss can cause a degradation of the vacuum and a corresponding reduction of the beam lifetime.

One consequence of single-plane MTI is that the effective acceptance in the injection plane (usually the horizontal one) is reduced w.r.t. the acceptance in the other transverse plane. However, the two transverse emittances of the injected beam are generally similar to equal. The case may rise that the injected beam emittance is within the vertical acceptance budget but not within the horizontal acceptance budget for high MTI performance, although the product of its two emittances is lower than the product of the two effective acceptances. The MTI performance is thus reduced due to a not favourable emittance partitioning of the injected beam rather than by the product of its two emittances. Re-partitioning of the beam emittances, i.e. round-to-flat transformation would help to eliminate this reduction in injection efficiency. The latter has been proposed already for electrons by [1].

FLAT BEAM CREATION

Strict definition of rms-emittances is given through the transverse beam second moments matrix

$$C = \begin{bmatrix} \langle xx \rangle & \langle xx' \rangle & \langle xy \rangle & \langle xy' \rangle \\ \langle x'x \rangle & \langle x'x' \rangle & \langle x'y \rangle & \langle x'y' \rangle \\ \langle yx \rangle & \langle yx' \rangle & \langle yy \rangle & \langle yy' \rangle \\ \langle y'x \rangle & \langle y'x' \rangle & \langle y'y \rangle & \langle y'y' \rangle \end{bmatrix} \tag{1}$$

with

$$\epsilon_u := \sqrt{< u^2 >< u'^2 > - < uu' >^2}, \tag{2}$$

where u stands either for x or y as the particle coordinate. The prime denotes the derivative w.r.t. the longitudinal coordinate. The eigen-emittances [2] are the two emittances to which the rms-emittances can be reduced if all inter-plane correlation moments are removed:

$$\varepsilon_1 = \frac{1}{2}\sqrt{-tr[(CJ)^2] + \sqrt{tr^2[(CJ)^2] - 16det(C)}} \tag{3}$$

$$\varepsilon_2 = \frac{1}{2}\sqrt{-tr[(CJ)^2] - \sqrt{tr^2[(CJ)^2] - 16det(C)}}, \tag{4}$$

where

$$J = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & 0 \end{bmatrix}. \tag{5}$$

The square root of the determinant of C (Equ. 1) is equal to the 4d-rms-emittance of the beam and equal to the product of the two eigen-emittances. The amount of inter-plane correlation is quantified through the coupling parameter

$$t = \frac{\varepsilon_x \varepsilon_y}{\varepsilon_1 \varepsilon_2} - 1 \geq 0\,. \tag{6}$$

Figure 1 depicts the EMittance Transfer EXperiment (EMTEX) beam line that performs the desired round-to-flat adoption. It comprises two doublets to provide a small double waisted beam spot in the center of a subsequent solenoid where a charge state stripping foil is inserted. It causes

Abstract

The accelerators of the FAIR facility will be operated using a new control system presently under design at GSI. One of its major components, the module for settings generation and management is based on the framework LSA developed at CERN. Its task is the provision and administration of set values for all devices in the FAIR facility. The set values for any accelerator are derived from a machine model, implemented by accelerator physicists using the features of the LSA framework. In view of the large number of accelerators in the FAIR facility, the aim is to develop a generic model, applicable to any of those machines. This requires the introduction of an additional logical layer on top of the LSA framework, ensuring the coherence of the modeling strategy across all accelerators. Following this design concept, a prototype of the FAIR settings management system has been realized at GSI, providing support for a large number of operation modes relevant for the later operation of FAIR. The prototype has been used extensively during recent machine experiments with the synchrotron SIS18, performed both to benchmark the machine model and to support further machine developments for FAIR.

INTRODUCTION

The FAIR facility comprises ten circular accelerators and a large number of beam transport lines. The planned operation schemes require a coordinated activity of the accelerators in order to achieve a high degree of parallel operation to optimize the facility's duty cycle. Consequently, each circular accelerator must be represented by a suitable machine model parameterized in terms of the physics parameters describing the functionality of the machine. The machine models have to be integrated into the control system to allow for the calculation of set values and timing events consistent with the planned operation schemes.

The FAIR control system will employ the software framework LSA developed at CERN to implement the settings generation and management component. The machine models will therefore be implemented using the features of the LSA framework. LSA itself, as a data-driven framework, provides excellent support for the storage of data related to devices and ion optical layout of accelerators. Moreover, it comes with generic concepts for the implementation of machine models as well as algorithms for the generation, modification, and persistance of set values. However, within the limits of the framework, it is completely up to the users of the framework to choose a particular representation for a certain machine.

At CERN, this freedom has, mostly for historical reasons, led to the existence of a heterogeneous collection of machine models (basically one model per machine) employing different philosophies and using the LSA structures in different ways. In essence, this means that each model is defined and maintained by a different group of machine experts. For FAIR, we aim at creating generic machine models that can be used for any circular accelerator. This is possible since the same fundamental principles of accelerator physics apply to each ring. Special features of individual rings can then be added on top of the common structures. This strategy will greatly reduce the implementation and maintenance effort for the machine models for FAIR. In addition, the machine experts implementing the models automatically share a common knowledge about all machines, which increases the resources for troubleshooting during operation.

In this paper, we first discuss our strategy for implementing generic machine models using LSA, giving two important examples. Then, we report on recent results obtained using a prototype of the settings management system for FAIR to control the existing synchrotron SIS18.

GENERIC MODELS

In the context of an accelerator control system, we define a *machine model* loosely as the collection of all input parameters and algorithms used to implement the calculation of hardware set values, according to the desired operation of the machine and based on a theoretical description in terms of accelerator physics equations. The input parameters of the machine model should allow the control of the accelerator in terms of physics quantities (e.g., tunes, magnet strengths, bucket size). This is particularly important in a facility like FAIR, where beams of different mass, charge states and energies are routinely produced in alternating cycles.

The LSA framework provides generic structures for implementing machine models. Physics quantities and hardware set values are represented as *parameters*. Parameters are grouped according to their *parameter type*, describing the physics category of the parameter. For instance, each quadrupole magnet has a strength value represented by a parameter of the same parameter type KL. A *setting* is a value of a parameter associated with a certain machine cycle. The task of the machine model is the calculation of hardware settings from the settings of the physics parameters.

The rules for calculations among the parameters are expressed explicitly in terms of *relations* between pairs of parameters, i.e., *parent* and *child*. A set of relations between parameters is called a *parameter hierarchy*. There is typically one parameter hierarchy per accelerator or beam trans-

RESONANCE COMPENSATION FOR HIGH INTENSITY BUNCHED BEAM

G. Franchetti, S. Aumon, F. Kesting, H. Liebermann, C. Omet, D. Ondreka, R. Singh
GSI, Darmstadt, Germany

Abstract

Mitigation of periodic resonance crossing induced by space charge is foreseen via classic resonance compensation. The effect of the space charge is, however, not obvious on the effectiveness of the compensation scheme. In this proceeding we report on the experimental campaign performed at SIS18 to investigate experimentally the effect of space charge on the resonance compensation. The experimental results and their consequences are discussed.

INTRODUCTION

Long term beam loss are due to several factors, but lattice nonlinearities and high intensity certainly rank among the main causes for long term beam loss. In fact, numerical and experimental studies have shown that periodic resonance crossing induced by space charge in a bunched beam is a deleterious effect for beam survival [1,2]. The focus in the mentioned studies was on one dimensional resonances: in Ref. [1] with $4Q_x = 25$, and in Ref. [2] with $3Q_x = 13$. The underlying mechanism leading to beam loss is explained, for 1D resonances, in terms of instantaneous stable islands in the two-dimensional phase space and their crossing of particles orbits [3].

Detailed studies for SIS100 have shown that in the injection scenario of the uranium ions, random components of magnet nonlinearities excite a significant web of resonances including 2D resonances [4], the simpler of which is the $Q_x + 2Q_y = N$. The details of the periodic resonance crossing induced by space charge for coupled resonances have never been studied due to its complexity. In fact, while for 1D resonances the mechanism is relatively well understood, for 2D resonances it is not, as the dynamics is now fully 4-dimensional in phase space. Indication of this complexity have been observed in the experimental campaign at the CERN-PS in 2012, where space charge studies near the resonance $Q_x + 2Q_y = 19$ have shown that beam profiles for some machine tunes acquired an anomalous asymmetry. In this scenario new nonlinear dynamics objects called fix-lines play a similar role as the fixed points for the crossing of the 1D resonances. A full study of the fix-lines is reported in Ref. [5].

In SIS100 operational requirements do no allow beam loss to exceed ~ 5%, and the issue of whether a resonance compensation may be carried out for a long term storage of a high intensity bunched beam or not is of high relevance. Recent numerical studies have shown that resonance compensation in simulations using a *frozen space charge* model has a beneficial effect on long term beam loss [4,6,7]. However, it remains to be established if this procedure is effective in a real high intensity bunched beam. In fact, resonance compensation is obtained by creating an artificial driving term that counteract the driving term of the machine nonlinearities. This procedure relies on the assumption that a resonance is excited mainly by a single harmonics. While this assumption works well in standard operational regimes for low intensity beams, it is not obvious what are the consequences for multiple periodic resonance crossing induced by space charge. For these reasons at GSI a campaign for testing the effectiveness of a resonance compensation in presence of space charge has been undertaken.

THIRD ORDER RESONANCE MITIGATION

Figure 1 shows the resonance chart of SIS18 after the recent re-alignment of the accelerator magnets. The apparent mismatch of some of the resonance lines with the theoretical solid lines is due to small systematic tune-shifts present in the machine model used by the control system. The third

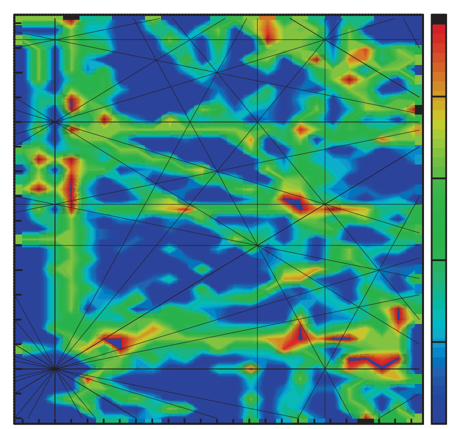

Figure 1: Resonances of SIS18 measured on the 16/7/2014 after the magnets re-alignment. This picture have been obtained by using SISMODI control system.

order resonance $Q_x + 2Q_y = 11$, visibly excited, is of particular interest because a similar resonance will affect the SIS100 for the preliminary working point for ions (example for the uranium beam scenario at the working point $Q_x = 18.84, Q_y = 18.73$) and fast extraction [8].

This resonance strength was estimated by measuring beam loss while the resonance is crossed with linear ramp from $Q_y = 3.45$ to $Q_y = 3.35$ in 1 second keeping $Q_x =$

INVESTIGATIONS OF THE SPACE-CHARGE-LIMITED EMISSION IN THE L-BAND E-XFEL PHOTOINJECTOR AT DESY-PITZ*

Y. Chen†, E. Gjonaj, A. Tsakanian, H. De Gersem, T. Weiland
TEMF, Technische Universitaet Darmstadt, Schlossgartenstrasse 8, 64289 Darmstadt, Germany
C. Hernandez-Garcia, M. Krasilnikov, F. Stephan
Deutsches Elektronen-Synchrotron DESY, Platanenallee 6, 15738 Zeuthen, Germany

Abstract

This paper discusses the numerical modelling of electron bunch emission for an L-band normal conducting RF photogun. The main objective is clarifying the discrepancies between measurements and simulations performed for the European X-ray Free Electron Laser (E-XFEL) injector at DESY-PITZ. An iterative beam dynamics simulation procedure is proposed for the calculation of the total extracted bunch charge under the assumption that the emission source operates at the space-charge limit of the gun. This algorithm has been implemented in the three-dimensional full electromagnetic PIC Solver of the CST Particle Studio ő (CST-PS) [1]. Simulation results are in good agreements with measurements for a series of operation parameters. Further comparisons with a conventional Poisson-solver-based (PSB) tracking algorithm demonstrates the great significance of transient electromagnetic field effects for the beam dynamics in high brightness electron sources.

INTRODUCTION

For the operation of Free Electron Lasers (FELs), high quality electron beams characterized by high brightness and extremely low transverse emittance, are required. An L-band normal conducting (copper) RF photoinjector was particularly designed and optimized at PITZ for the generation of such high quality electron beams for the European X-ray Free Electron Laser (E-XFEL) and the Free Electron Laser in Hamburg (FLASH) [2]. Hereby, a crucial role plays the modelling of electron bunch emission as well as the simulation of the space-charge dominated beam dynamics in the gun.

It has been previously reported [3] that for specific machine conditions, comparatively large discrepancies between simulations and measurements are found. In particular, the total extracted bunch charge at an RMS beam size of 0.3 mm is much higher than predicted in the simulations. One source of discrepancy was identified in [4]. It was shown that in conventional Poisson-solver-based (PSB) tracking codes, the magnetic space-charge field contribution is neglected. For high current beams, this contribution becomes important due to the fast electron bunch expansion during emission. In order to take into account the impact of these magnetic space-charge fields, beam dynamics simulations based on the solution of the full set of Maxwell equations are necessary. Yet another important modelling issue, however, is the computation of the total charge extracted from the cathode when the injector is operated close to or at the space-charge limit. This quantity depending on various machine parameters is not a priori known. In this paper we propose a self-consistent simulation procedure which is able to predict very accurately space-charge field dominated photoemission in RF electron sources.

Investigations of the space-charge-limited emission will be performed specifically with parameters of significance experimentally obtained for the PITZ photoinjector project. The main components of the PITZ injector are a 1.6 cell copper RF gun cavity with a cesium-telluride photocathode, CDS booster cavity, cathode laser system, and multiple beam diagnostic systems. The electron beam is extracted as the photocathode is illuminated by the UV laser pulse at the wavelength of 257 nm, and then accelerated by a 1.3 GHz RF field excited in the gun cavity. A main solenoid and a bucking solenoid are additionally applied for beam focusing and space-charge emittance compensation. A detailed description of this setup can be found in [2].

BUNCH EMISSION MODELLING AT THE SPACE-CHARGE LIMIT

A sketch of the total bunch charge extraction based on experimental observations [3] is shown in Fig. 1. The top curve shows the total space-charge-limited bunch charge at each gun launch phase when operating the emission source exactly at the space-charge limit. As for below the space-charge limit, the emission becomes a combination of two emission regimes, the space-charge-limited (SCL) and the quantum-efficiency-limited (QEL). The QEL regime in the combined emission case is marked out by the trapezoid area. The total charge in this regime depends on conditions of the emission source instead of the applied RF field at the cathode. As shown, the maximum extracted charge is apparently given by the flat-top region in the gun phase range. However, the charge extraction below this flat level (i.e., the rise / fall edge) is still limited by the space-charge field. This is because the space charge limits there are lower than the maximum total charge produced by the emission source.

In the following we propose a self-consistent simulation procedure specifically to calculate the total SCL bunch charge extracted from the cathode. Using a set of gun launch phases, the bunch emission simulation is performed initially with a sufficiently large total bunch charge depending on specific machine parameters (f.i., 2 nC in this paper). After

SIMULATIONS OF ELECTRON CLOUD LONG RANGE WAKEFIELDS *

F.B. Petrov, O. Boine-Frankenheim, TEMF, TU-Darmstadt, Darmstadt, Germany

Abstract

A typical approach to electron cloud simulations is to split the problem in two steps: buildup simulations and instability simulations. In the latter step the cloud distribution is usually refreshed after each full interaction with the bunch. This approach does not consider multibunch effects. We present studies of the long range electron cloud wakefields generated in electron clouds after interaction with relativistic proton bunch trains. Several pipe geometries - relevant to CERN accelerators - with and without external magnetic field are considered. Using simple examples we show that the long range wakefields depend significantly on the secondary emission curve as well as on the pipe geometry. Additivity of electron cloud wakefields is studied as well.

INTRODUCTION

Relativistic bunches penetrating electron clouds induce transverse and longitudinal wakes. Transverse wakefields cause instabilities and emittance growth [1]. Whereas longitudinal wakefields are responsible for energy loss and synchronous phase shift [2, 3]. In many cases researchers look for the first unstable bunch in bunch trains. For this purpose one performs scans over electron cloud density. Typically, the electron cloud is assumed to be a very nonlinear object. Thus, most of the beam tracking studies utilize particle-in-cell electron cloud distributions.

In this contribution we investigate the parameters of transverse and longitudnal electron cloud wakefields for CERN-like conditions. We compare the results of 2D and 3D codes. We investigate single-bunch electron cloud wakefields induced by transversely perturbed proton bunches. Moreover, we investigate multi-bunch electron cloud wakefields induced by $k = 0$ bunch mode in bunch trains. The aim is to identify possible regimes where electron cloud representation can be simlified for future beam tracking simulations.

SIMULATION MODEL

For our simulations we utilize two codes: openECLOUD [4] and commercial Vsim [5]. The first code is the electron cloud buildup code from TU-Darmstadt. It utilizes 2D Poisson solver; electron cloud is represented as a 2D slice; the interaction with the beam is purely transverse; stainless steel and copper material models are implemented according to Ref. [6]. For all the simulation we assume rigid, frozen bunches. We take pipe parameters of the super proton synchrotron (SPS) and the large hadron collider (LHC) (set Table 1).

Table 1: Simulation Parameters

Parameter	Value
Bunch length, $\sigma_z[m]$	0.1
Bunch radius, $\sigma_r[m]$	0.01
Bunch spacing, $T[ns]$	25
Bunch population, N_i	10^{11}, 2×10^{11}
Round pipe radius, $R[m]$	0.02
LHC pipe dimensions, $l_x/l_y[m]$	0.044/0.036
SPS MBB dimensions, $l_x/l_y[m]$	0.1218/0.0485
Dipole field, $B[T]$	0.1
Wall materials	copper, stainless steel

SINGLE-BUNCH WAKEFIELDS

In this section we investigate the single-bunch electron cloud wakefields for several bunch parameters. The aim is to indicate the conditions where electron coud wakefields show any linearity.

Figure 1 shows the comparison between the wakefields calculated with openECLOUD and Vsim (3D electromagnetic). The bunch is offcentered as a whole ($k = 0$ head-tail mode), electron cloud fills the cylindrical pipe uniformly. The left plot shows the transverse wakefields obtained directly from the simulations. The right plot shows the longitudinal wakefields. In case of openECLOUD this field is obtained during the data postprocessing. For this purpose we take the derivative of 2D potential with respect to z. One can see that the agreement between the two codes is very good.

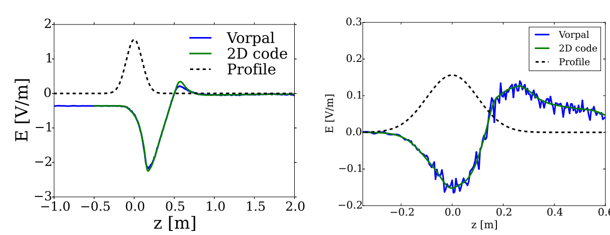

Figure 1: Electron cloud transverse (left) and longitudinal (right) wakefields simulated with Vsim and openECLOUD codes for $N_i = 2 \times 10^{11}$.

Next we analyze the wakefields due to the harmonically excited bunches. All the following simulations are performed using the openECLOUD code. The transverse displacement as a function of longitudinal coordinate is given as follows:

$$\Delta x_k = A_x \sin \frac{2k\pi z}{\lambda_z} \quad (1)$$

, where k is the mode number, A_x is the amplitude, z is the longitudinal coordinate, λ_z is the bucket length. Figure 2 shows the transverse electric fields induced by several

A NEW APPROACH FOR RESISTIVE WAKEFIELD CALCULATIONS IN TIME DOMAIN

A. Tsakanian#, E. Gjonaj, H. De Gersem, T. Weiland, TU-Darmstadt/TEMF, Darmstadt, Germany
M. Dohlus, I. Zagorodnov, DESY, Hamburg, Germany

Abstract

We report on a new numerical technique for the computation of the wakefields excited by ultra-short bunches in the structures with walls of finite conductivity. The developed 3D numerical method is fully time domain. It is based on special Staggered Finite Volume Time Domain (SFVTD) method and has no numerical dispersion in all three axial directions simultaneously. The resistive boundary model applies Surface Impedance Boundary Condition (SIBC) evaluation in time domain and covers boundary effects like frequency dependent conductivity, surface roughness and metal oxidation. A good agreement between numerical simulation and perturbation theory is obtained.

INTRODUCTION

Electromagnetic wakefields due to the finite conductivity of cavity walls are one of the main concerns in the design of electron accelerators. These so called resistive wall wakefields are the largest contributor to beam coupling impedances in the high energy sections of the accelerator where extremely short electron bunches are operated [1]. For an estimation of these contributions one relies (almost) exclusively on numerical simulations, since wakefield measurements within the high-vacuum accelerator chamber are very cumbersome.

Conventional methods for the solution of Maxwell's equations in the time domain, however, will usually fail for this class of problems. This is primary due to the extremely high frequency of wakefields resulting in large numerical dispersion errors. These errors tend to accumulate in the course of the simulation as, e.g., short electron bunches of μm-length propagate over several meters within the accelerator.

To cope with this problem, specialized low-dispersion techniques have been proposed [2]. The SFVTD method introduced in [3] is one of them. It represents a volume-integral based formulation with very appealing numerical properties. The dispersion error of SFVTD is substantially smaller than that of the conventional FDTD technique. The crucial property, however, is that the method can be operated at a maximum stable time step corresponding to the 1D-CFL stability limit. Applying SFVTD at this so called 'magic' time step provides the exact, dispersion-free solution for all electromagnetic waves propagating along the three main axis directions (cf. [3]).

In order to take into account resistive and/or rough wall wakefields in such simulations, however, an appropriate implementation of broadband SIBC for SFVTD is needed. In the following, this task is accomplished by combining the ADE technique with a particular time stepping scheme. This latter allows to maintain the numerical dispersion and stability properties of the original SFVTD which are necessary for this type of simulations.

THE SFVTD METHOD

The basic idea of the SFVTD discretization is depicted in Fig. 1. Fields and currents are allocated component-wise on the faces of a Cartesian mesh. For each of these components a unique control volume enclosing the corresponding mesh face is introduced. Alternatively, one may think of three secondary, staggered meshes which are obtained by shifting the original mesh along the x-, y- and z-directions, respectively.

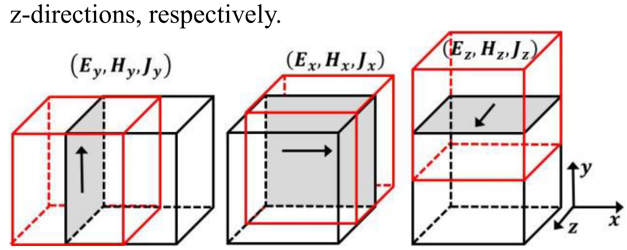

Figure 1: Allocation of fields and currents on mesh cells (black) and corresponding control volumes (red) of SFVTD.

A discretization of Maxwell's equations is obtained by applying the generalized Stokes' theorem for each of the 6 field components on the corresponding control volumes. A detailed derivation of these equations is given in [3]. Here, we begin with the semi-discrete form of SFVTD:

$$\boldsymbol{M}_\mu \frac{d\boldsymbol{h}}{dt} = -\boldsymbol{C}\boldsymbol{e} \ , \tag{1}$$

$$\boldsymbol{M}_\varepsilon \frac{d\boldsymbol{e}}{dt} = \boldsymbol{C}^T \boldsymbol{h} - \boldsymbol{j} \, . \tag{2}$$

In (1), (2), $\boldsymbol{e}$, $\boldsymbol{h}$ and $\boldsymbol{j}$ represent volume averages over the control volumes of the electric, magnetic and current field components, respectively. The matrices, $\boldsymbol{C}$, $\boldsymbol{M}_\varepsilon$ and $\boldsymbol{M}_\mu$ are the *curl*- and *mass*-operators of the method resulting from this particular choice of integration volumes on the mesh. The particular form of these matrices determines the numerical properties of the SFVTD method such as the low numerical dispersion and the large bound of stability.

In figure 2 are presented the numerical phase velocity behavior of the plane wave versus its propagation direction. Both, SFVTD and conventional FDTD methods are evaluated at their stability limits, i.e. FDTD - $c\Delta t_{2D} = \Delta/\sqrt{2}$, $c\Delta t_{3D} = \Delta/\sqrt{3}$, SFVTD - $c\Delta t_{2D,3D} = \Delta$.

ASPECTS OF SRF CAVITY OPTIMIZATION FOR BESSY-VSR UPGRADE*

T. Galek†, J. Heller, K. Brackebusch, T. Flisgen, U. van Rienen, Universität Rostock, Germany
B. Isbarn, B. Riemann, M. Sommer, T. Weis, Technische Universität Dortmund, Germany

Abstract

In this work we present a preliminary study of a long chain of cavities and some aspects involved in the optimization procedure. It is important to numerically model and optimize the SRF cavities with respect to external quality factors of the most dangerous higher order modes. BESSY-VSR is an upgrade scheme for the existing BESSY II storage ring aiming to simultaneously support variable electron pulse lengths. Currently, BESSY II supports long 15 ps bunches in the standard user optics configuration and short 1.5 ps bunches in a so-called low-α optics mode. In order to develop BESSY II into a variable electron pulse length storage ring, additional two sets of SRF higher-harmonic cavities will be installed. The present RF acceleration system operates at 0.5 GHz and the additional 3rd harmonic and 3rd sub-harmonic cavities will operate at 1.5 GHz and 1.75 GHz, respectively. These cavities are essential to produce short 1.5 ps bunches with a design current of up to 0.8 mA per bunch. The total current in the storage ring is limited by the higher order mode damping capabilities of the SRF cavities.

END-GROUP OPTIMIZATION

The design of the cavity used in this work is similar to the bERLinPro [1] energy recovery linac main cavity. It is characterized by spline-nose cavity to beam-pipe transition and threefold waveguide higher order mode (HOM) couplers. One of the waveguide HOM couplers is replaced by a coaxial input coupler as shown in Fig. 1. The Cornell mid-cell based on TESLA design and used in the bERLinPro cavity was selected for this study. The mid-cell design was scaled to the operational frequency of 1.5 GHz and 1.75 GHz. The results of a comparison between Cornell mid-cell and other mid-cell designs were discussed previously elsewhere [2].

Field Flatness in Cavities

Usually, in the optimization procedure of the end-groups of a superconducting radio frequency (SRF) cavity one can aim at multiple optimization targets like minimum magnetic and electric surface fields, operational frequency, maximum accelerating gradient (R/Q) and field flatness. In this work the optimization focused only on the operational frequency and field flatness. Typically the E-field flatness is of a concern. The E-field flatness on the beam axis is defined as [3]

$$\eta_{E_z} = \left(1 - \frac{\sigma_{E_{z,\text{peak}}}}{\mu_{E_{z,\text{peak}}}}\right) \times 100\%, \tag{1}$$

where $\mu_{E_{z,\text{peak}}}$ is the mean value of the peak electric field component $E_z(z)$ on the beam axis in the direction of the beam in every cell and $\sigma_{E_{z,\text{peak}}}$ is the standard deviation.

The BESSY-VSR higher harmonic cavities will not operate close to the maximum achievable electric field gradient, thus the electric peak surface fields and field assisted emission become less of a concern. This allows to focus on peak magnetic surface fields that contribute to magnetic quenches. The H-field flatness is even more of an issue in cavities with mid-cell designs that have relatively large iris

YACS - A NEW 2.5D FEM EIGENMODE SOLVER FOR AXISYMMETRIC RF-STRUCTURES *

B.D. Isbarn†, B. Riemann, M. Sommer, T. Weis
TU Dortmund University (DELTA), Center for Synchrotron Radiation, Dortmund, Germany

Abstract

Most feasibility studies for modern accelerator concepts, including superconducting multicell RF-cavity-resonators in circular accelerators, depend on computing a large number of eigenmode frequencies and field patterns to obtain typical figures of merit. This task includes computationally intensive studies. To obtain the full eigenfrequency spectra most of these studies are performed in 3D, require a great amount of computation resources and thus are limited to a few hundred or thousand eigenmodes. To overcome this issue, some codes make use of the axisymmetric geometry of most of the RF-cavity-resonator structures and solve the problem in 2D. Solving in 2D however reduces the eigenmode spectra to eigenmodes with no azimuthal dependencies (so called monopole modes). Due to the lack of freely available and easy to use 2.5D eigenmode solvers which are able to solve for the full 3D field in a reduced 2.5 dimensional problem, we developed yet another cavity solver (Yacs), a simple FEM based solver capable of solving for the full 3D eigenmodes of axisymmetric problems while only requiring a fraction of the computation resources required by most modern 3D codes.

INTRODUCTION

Numerical calculation of resonant eigenmodes with the eigenfrequency $\omega \in \mathbb{C} \setminus \{0\}$ in a rf-structure usualy involves solving the vector Helmholtz equation for the electric field that arises from the Maxwell equations in a bounded domain $\Omega \subset \mathbb{R}^3$

$$\nabla \times \left(\underline{\mu}^{-1} \nabla \times \boldsymbol{E}\right) - \omega^2 \underline{\epsilon} \boldsymbol{E} = \boldsymbol{0} \,. \tag{1}$$

Closed-form solutions of (1) can only be obtained for simple geometries like cylindrical or spherical resonators.

The Sparse Eigenvalue Problem

In the case of an axisymmetric problem domain we may use spherical coordinates and expand the azimuthal component of the electric field by a Fourier series

$$\boldsymbol{E}\left(\boldsymbol{r}\right) = \sum_{m=0}^{\infty} \boldsymbol{E}_m^{(c)}\left(r,z\right) \cos\left(m\theta\right) + \boldsymbol{E}_m^{(s)}\left(r,z\right) \sin\left(m\theta\right) \,. \tag{2}$$

Due to the pairwise orthogonality of the Fourier basis functions we receive a decoupled problem and can solve for each mulipole mode m individually. Applying the finite element method on the problem stated in (1) together with the azimuthal fourier series expansion (2) we can approximate (1) with a sparse generalized eigenvalue system. This has allready been discussed thoroughly in earlier works [1]. The resulting sparse generalized eigenvalue system is described by

$$\begin{pmatrix} \underline{\boldsymbol{K}}^{pp} & \underline{\boldsymbol{K}}^{p\theta} \\ \underline{\boldsymbol{K}}^{p\theta^T} & \underline{\boldsymbol{K}}^{\theta\theta} \end{pmatrix} \begin{pmatrix} \hat{\boldsymbol{E}}_p \\ \hat{\boldsymbol{E}}_\theta \end{pmatrix} = \omega^2 \begin{pmatrix} \underline{\boldsymbol{M}}^{pp} & 0 \\ 0 & \underline{\boldsymbol{M}}^{\theta\theta} \end{pmatrix} \begin{pmatrix} \hat{\boldsymbol{E}}_p \\ \hat{\boldsymbol{E}}_\theta \end{pmatrix} \tag{3}$$

$$\underline{\boldsymbol{K}} \hat{\boldsymbol{E}} = \omega^2 \underline{\boldsymbol{M}} \hat{\boldsymbol{E}} \tag{4}$$

with

$$\begin{aligned}
\underline{\boldsymbol{K}}_{ij}^{pp} &= \langle \mu_\theta^{-1} r \nabla_p \times \boldsymbol{\phi}_i, \nabla_p \times \boldsymbol{\phi}_j \rangle + m^2 \langle \mu_p^{-1} r^{-1} \boldsymbol{\phi}_i, \boldsymbol{\phi}_j \rangle \\
\underline{\boldsymbol{K}}_{ij}^{p\theta} &= m \langle \mu_p^{-1} r^{-1} \boldsymbol{\phi}_i, \boldsymbol{\nabla}_p \psi_j \rangle \\
\underline{\boldsymbol{K}}_{ij}^{\theta\theta} &= \langle \mu_p^{-1} r^{-1} \boldsymbol{\nabla}_p \psi_i, \boldsymbol{\nabla}_p \psi_j \rangle \\
\underline{\boldsymbol{M}}_{ij}^{pp} &= \langle \epsilon_p r \boldsymbol{\phi}_i, \boldsymbol{\phi}_j \rangle \\
\underline{\boldsymbol{M}}_{ij}^{\theta\theta} &= \langle \epsilon_\theta r^{-1} \psi_i, \psi_j \rangle
\end{aligned}$$

where $\underline{\boldsymbol{K}}$ and $\underline{\boldsymbol{M}}$ are typically referred to as stiffness- resp. mass-matrices, p (in-plane) denotes operations and vectors with respect to the $\hat{\boldsymbol{r}}$ and $\hat{\boldsymbol{z}}$ direction, while $\boldsymbol{\phi}_x$ together with ψ_x refer to the global mapping of the basis functions with $\boldsymbol{\phi}_x$ referring to the vector-valued in-plane component and ψ_x referring to the out of plane scalar component.

IMPLEMENTATION

The primary part of the FEM code has been developed in C++ using state-of-the-art numerical libraries to achieve maximum performance and reliability. The meshing of the problem domain is performed with Triangle [2], general dense and sparse algebra is done using Eigen v3 [3] and solving the sparse generalized eigenvalue problem has been realized with ARPACK [4] in conjunction with UMFPACK [5]. The latter is used for solving sparse linear systems. In this first iteration of Yacs we solely use first order basis functions for expanding the trial and test functions.

Boundary Conditions

In the case of solving multipole modes, we artifically introduce PEC boundary conditions on the rotation axis and thus force the electrical field parallel to the rotation axis to vanish. In order to avoid the singular terms for $r = 0$ in (3), we use a Gauss quadrature scheme that only evaluates points inside the domain and avoids those points on the boundary of the domain.

BENCHMARK

All the benchmarks presented in the following were performed on a simple $\nu = 500\,\mathrm{MHz}$ pillbox cavity for which

COUPLED-BUNCH INSTABILITY SUPPRESSION USING RF PHASE MODULATION AT THE DELTA STORAGE RING*

M. Sommer†, M. Höner, B. Isbarn, S. Khan, B. Riemann, T. Weis
Center for Synchrotron Radiation (DELTA), TU Dortmund University, Dortmund, Germany

Abstract

In this paper, a feedback-based method to measure the damping rates of multibunch modes at the 1.5-GeV electron storage ring DELTA operated by the TU Dortmund University is presented and the influence of an RF modulation on these damping rates is analyzed. For this purpose, the amplitude as well as the frequency of the modulation was varied. The suppression of coupled-bunch instabilities could be observed with a modulation frequency slightly below twice and three times the synchrotron frequency. However, the determination of damping rates for high modulation amplitudes using the presented method is problematic.
In addition, the decrease of beam quality using RF phase modulation was investigated and the increase of bunch length was measured as a function of the modulation amplitude.

INTRODUCTION

The upcoming upgrade of BESSY II, called BESSY-VSR [1], involves the utilization of superconducting multicell RF-resonators to provide short and long bunches simultaneously. The residual impedances of the cavities may cause collective multibunch instabilities at the frontier of stability available from current bunch-by-bunch feedback systems. Hence, other damping methods have to be considered, e.g. a modulation of the radio frequency (RF) of the accelerating cavity. The effects of RF phase modulation in circular accelerators date back to the early 1990's [2] [3]. In 2008, a modulation had been applied at the 1.5-GeV electron storage ring DELTA operated by the TU Dortmund University (see Fig. 1 and Table 1) in order to suppress longitudinal instabilities [4] [5]. In 2011, a digital bunch-by-bunch feedback system [6] was installed for beam diagnostics purposes [7]. This system is able to suppress the aforementioned instabilities succesfully, without the application of the RF phase modulation. During user operation, the RF modulation is routinely in operation to increase the beam lifetime by up to 20% due to the reduction of the mean electron density and, thus, the rate of Touschek scattering [8]. To get a deeper understanding of the suppression of instabilities by RF phase modulation, the bunch-by-bunch feedback system is used to determine the damping rates of all coupled-bunch modes.

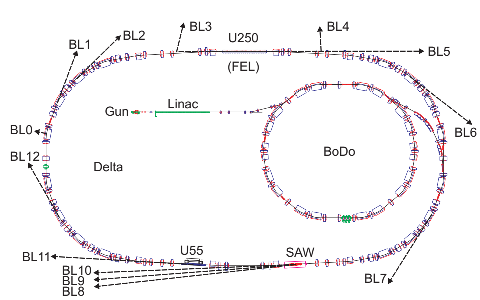

Figure 1: Overview of the DELTA facility including the storage ring and its booster synchrotron BoDo.

Experimental Setup

To extract the horizontal, vertical and longitudinal position of every bunch, a combination of a beam position monitor and a hybrid network is used. The horizontal and vertical differential signals as well as the sum signal are sent to the feedback frontend, where they are filtered, attanuated and digitized. By applying a 24-tap FIR filter on consecutive input data, the output signals are created, which are converted to analog signals driving the power amplifiers and the corresponding kicker structures. In addition, the processing units include a frequency generator, which allows to send a dedicated RF signal to the beam, for example to excite a specific multibunch mode [9].
The modulation of the RF phase of the accelerating cavity is realized by an external system. It mainly consists of electrical phase shifters and a signal generator with variable frequency and amplitude (for detailed information see [5]).The signal modulation of the DELTA RF master generator is given by

$$U_{\mathrm{RF}}(\omega) = U_0 \sin\left(\omega_{\mathrm{RF}} t + a \cdot \sin\left(\omega_{\mathrm{mod}} t\right)\right)$$

with the amplitude U_0, the RF frequency ω_{RF}, the modulation amplitude a and the modulation frequency ω_{mod}. At the signal generator, the modulation frequency $f_{\mathrm{mod}} = \omega_{\mathrm{mod}}/2\pi$ can be set directly and the modulation amplitude a can be set via input signal U_{mod} from 0 V up to 3 V. The standard settings for user operation are $U_{\mathrm{mod}} = 0.7$ V and $\omega_{\mathrm{mod}} \approx 2 \cdot \omega_s$, with the synchrotron frequency $f_s = \omega_s/2\pi$.

Table 1: Storage Ring Parameters

parameter	value
revolution frequency	2.6 MHz
RF frequency	500 MHz
nominal RF power loss	26 kW
maximum beam current (multibunch)	130 mA
maximum beam current (single bunch)	20 mA
synchrotron frequency	15.2 - 16.4 kHz
fractional horizontal tune	0.10 - 0.20
fractional vertical tune	0.20 - 0.30

TWO GENERAL ORBIT THEOREMS FOR EFFICIENT MEASUREMENTS OF BEAM OPTICS

B. Riemann*, A. Ferrarotto, P. Hartmann, B.D. Isbarn, S. Koetter, M. Sommer, P. Towalski, T. Weis
DELTA, Dortmund, Germany

Abstract

Closed-orbit perturbations and oscillating beam solutions in storage rings are closely related. While techniques exist to fit accelerator models to closed-orbit perturbations or to oscillation data, the exploitation of their relation has been limited. In this work, two orbit theorems that allow an efficient computation of optical parameters in storage rings with older hardware are derived for coupled linear beam motion. The monitor theorem is based on an uncoupled case study described by the author in an earlier work [1] and has been generalized as well as simplified in mathematical abstraction to provide a reliable and computationally stable framework for beam optics measurements. It is based on a closed-orbit measurement utilizing 4 dipole correctors (2 for each plane). The corrector theorem allows to obtain parameters of these dipole correctors using two turn-by-turn monitors at almost arbitrary positions in the ring (which do not need to be located in a drift space), so that it possible to uniquely resolve closed orbits into optical parameters without sophisticated lattice models.

INTRODUCTION

To express the orbit theorems in a reasonable and straightforward way, we need to describe coupled optics in the linear phasor model, instead of the polar-like Courant-Snyder parameters. Then, the two orbit theorems are formulated and verified by experimental data obtained using the mapping method, a diagnostic method containing both theorems.

LINEAR PHASOR MODEL

In a storage ring, a closed orbit exists. For any working setup, the particle motion around this orbit is bound and undamped in good approximation. From these assumptions, we can linearize the bound motion around the orbit as a $M = 3$-dimensional harmonic oscillator. In the following, we will not consider synchrotron motion ($M = 2$).

Beam Oscillation (Turn-by-Turn)

The deviations $\vec{r}$ from the closed orbit at each turn n at a given longitudinal position s_j can be modeled [2] as ($\Re$: real part)

$$\vec{r}_n(s_j) = \sum_m^M \Re\left\{\vec{R}_{jm} e^{in\mu_m}\right\}, \tag{1}$$

where the phase advances μ_m correspond to betatron tunes, while $\vec{R}_{jm}$ are vectors of complex oscillation amplitudes (phasors) that we will call *monitor vectors* in the following. The monitor vectors are related to the Mais-Ripken parameterization of beam optics [3] [4] and are a fully coupled representation of spatial linear beam motion.

Closed-Orbit Perturbation (Orbit Response)

The closed orbit can be defined by a fixpoint of the linear transfer map at a given position. The map has a zero-order term $\vec{t}_k$, which corresponds to a dipole kick, and a first-order term which is the transfer matrix $\mathbf{T}_k$. If we assume that the kick is located directly before the corrector, we obtain the closed orbit vector $\langle\vec{r}\rangle$ at position $\tilde{s}_k$ by the equation system

$$\vec{t}_k = (\mathbf{1} - \mathbf{T}_k)\langle\vec{r}\rangle_{jk}$$

A computation [2] including the knowledge that the spatial parts of the eigenvectors of $\mathbf{T}$ are indeed the forementioned monitor vectors $\vec{R}_{jm}$, while the eigenvalues are $e^{i\mu_m}$, leads to a phasor expression for the closed-orbit perturbation

$$\langle\vec{r}\rangle_{jk} = \Re\left\{\sum_m \vec{R}_{jm} E^*_{jkm} D^*_{km}\right\}, \tag{2}$$

The phase jump coefficients $E_{jkm} = \exp\{i\mu/2\ \mathrm{sign}(s_j - \tilde{s}_k)\}$ hold numbers on the complex unit circle. These coefficients occur as closed orbits are ring-periodic, and may be interpreted as correcting the "fractional tune" of the betatron oscillations. The corrector parameter D_{km} is a complex quantity that represents the coupling of a given dipole error or corrector k to each oscillation mode m.

ORBIT THEOREMS

Both orbit theorems are based on solving systems of equations for all monitors $1 \le j \le J$, or the subset of all turn-by-turn capable monitors $1 \le f \le F$, and correctors k. In brief, the first theorem obtains the corrector parameters D_{km} from closed-orbit perturbations turn-by-turn data at monitors f. Then, the second theorem is used to obtain $\vec{R}_{jm}$ at all monitors j.

Corrector Theorem

In a first step towards the knowledge of spatial optical parameters at all BPMs, we state that

- it is possible to compute D_{km} from a set of closed orbit data and turn-by-turn data at $F \ge 2$ turn-by-turn capable monitors

STATUS OF INJECTION STUDIES INTO THE FIGURE-8 STORAGE RING

J.F. Wagner*, A. Ates, M. Droba, O. Meusel, H. Niebuhr, D. Noll, U. Ratzinger
Goethe University, Frankfurt am Main, Germany

Abstract

The ongoing investigations on the design of the Figure-8 Storage Ring [1] at Frankfurt University focus on the beam injection. The research includes simulations as well as a scaled down experiment. The studies for an optimized adiabatic magnetic injection channel, starting from a moderate magnetic field up to a maximum of 6 Tesla, with a realistic field model of toroidal coils due to beam dynamics with space charge will be shown. For the envisaged ExB-kicker system the simulations deal with beam potential constraints and a multi-turn injection concept in combination with an adiabatic magnetic compression. To investigate the concept of the beam injection into a toroidal magnetic field, a scaled down room temperature experiment is implemented at the university. It is composed of two 30 degree toroidal segments, two volume ion sources, two solenoids and two different types of beam detectors. The experiment is used to investigate the beam transport and dynamics of the laterally injected and "circulating" beam through the magnetic configuration. To set up the injection experiment, theoretical calculations and beam simulations with bender [2] are used.

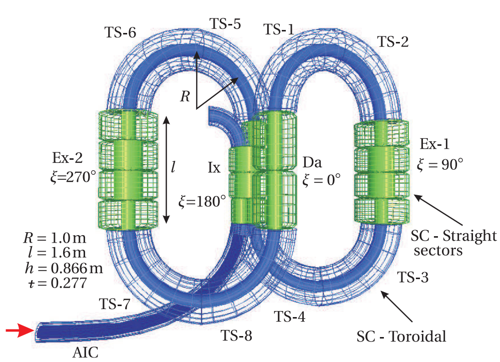

Figure 1: Figure-8 Storage Ring with the proposed adiabatic injection channel (AIC).

INTRODUCTION

The Figure-8 storage ring (*F8SR*) concept is under development at Frankfurt University. Different from traditional storage rings, a guiding longitudinal magnetic field confines the charged particle beam continuously with high transverse momentum acceptance. Due to the strong magnetic field level (B=6 T), high current low energy proton (W~150 keV) and ion beams of several amperes can be confined. Many characteristic features and key components were developed in the past. The current developments are concentrated on the design of a realistic injection system and test campaign in scaled down experiments.

* j.wagner@iap.uni-frankfurt.de

SIMULATIONS OF THE INJECTION SYSTEM

An injection system composed of an adiabatic magnetic compression channel and an **E**×**B**-kicker was designed and 3D multi particle simulations with realistic static magnetic and electric fields were performed.

The shape of the injection channel follows the curve of a hyperbolic spiral $R(\theta) = \frac{a}{\theta}$ within the interval of the parameter $\theta \in [\frac{\pi}{3} : \pi]$, see Fig. 1 (AIC). The channel has a length of L=4 m and a minimum radius R_1 of 1 m, hence a=π. The chosen channel geometry was implemented in the design code *segments* with solenoidal coils of decreasing distance $\sim \frac{1}{\theta}$ and constant current . The results of a Biot-Savart solver delivers a smooth ascending magnetic field, see Fig. 2 (blue). Concerning the curvature κ the channel

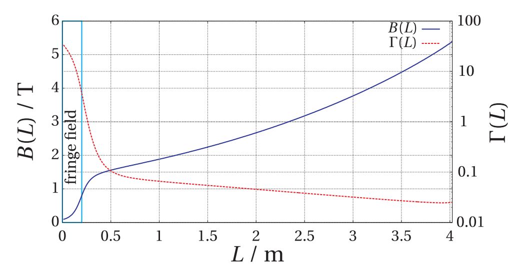

Figure 2: Rise of the magnetic flux and the adiabatic condition, on axis along the injection channel.

provides a small value at the entrance to avoid an instant kick to the injected beam. At the junction to the ring a high curvature keeps the perturbation of the ring flux low. For an adiabatic magnetic compression the magnetic field has to obey the condition for the parameter Γ in Eq. (1)

$$v_{\parallel}\frac{\Delta B}{\Delta s} < B\frac{\omega_c}{2\pi} = \frac{|q|B^2}{2\pi m} \rightarrow \Gamma = v_{\parallel}\frac{\Delta B}{\Delta s}\frac{2\pi m}{|q|B^2} < 1 \qquad (1)$$

The calculated Γ shows that this condition is fulfilled along the whole proposed injection channel. The only exception can be found at the magnet fringe at the beginning. Single particle tracking in *segments* with protons at E_{kin}=150 keV injected on axis show an expected rise of the transversal velocity $v_{\perp}$ due to the $\mathbf{R} \times \mathbf{B}$-drift with an acceptable ratio to the parallel velocity. The off plane drift amounts to 17 mm. Field maps of the whole injection system area were exported to the multi-particle code *bender* and simulations were qualitatively confirmed, see Fig. 3.

Further, an $\mathbf{E} \times \mathbf{B}$-kicker system with two fixed and two movable electrodes with a total length of 1170 mm, at a gap width of 30 mm and 90 kV voltage, i.e. E=3 MV/m, were integrated into the simulations. Single particle tracking shows the velocity components in Fig. 4. The increase in $v_{\perp}$ occurs respectively to the shift of the magnetic flux due to the

MIRROR SYMMETRIC CHICANE-TYPE EMITTANCE EXCHANGE BEAMLINE WITH TWO DEFLECTING CAVITIES

V.Balandin*, W.Decking, N.Golubeva, DESY, Hamburg, Germany

Abstract

In this paper we present the conceptual design of a mirror symmetric chicane-type beamline with two dipole-mode cavities for transverse-to-longitudinal emittance exchange.

INTRODUCTION

Optical systems for transverse-to-longitudinal emittance exchange (EEXs) were initially proposed in application to the free electron lasers for transverse emittance reduction in an electron beam with a smaller longitudinal emittance [1]. Since then EEXs involving single transverse deflecting cavity (TDC) were in great details studied theoretically and experimentally, and many interesting applications of such beamlines were suggested [2–6].

Among all EEXs chicane-type beamlines are of keen interest, because they do not alter the beam propagation direction. To our knowledge, the first design of such EEX was presented in [6] and, in minimal configuration, can be seen in Fig. 1 (beamline one). Besides TDC and four dipoles, this beamline includes fundamental (accelerating) mode cavity (FMC) to cancel the longitudinal acceleration in the TDC (the so-called thick-lens effect) and two quadrupoles (green ellipses) to reverse the dispersion at the TDC location.

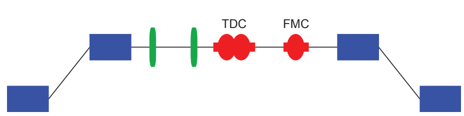

Figure 1: Schematic of non-symmetric chicane-type EEX.

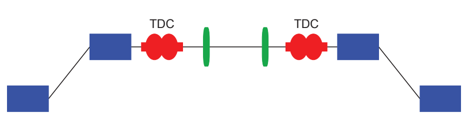

Figure 2: Schematic of symmetric chicane-type EEX.

The beamline one demonstrates two features which are common to all EEXs with a single TDC. First, such EEXs cannot be mirror symmetric with respect to the TDC center and, second, without involvement of at least one FMC the emittance exchange cannot be made exact even on the level of the linear beam dynamics. One of the ways to overcome these limitations was found in [7] where properties of EEXs utilizing two TDCs instead of one were investigated. In this paper we detail some results of [7] and present a mirror symmetric chicane-type EEX with two TDCs which does not require additional FMCs for compensation of the thick-lens effect. Schematic of this beamline (again, in minimal configuration) can be seen in Fig. 2 (beamline two), and there are the following similarities and differences in comparison with the beamline one:

- Quadrupoles in the beamline one are used for the reversion of the entrance dogleg dispersion and both are horizontally focusing. Quadrupoles in the beamline two have similar purpose and also must provide dispersion sign change, but in this case between the TDC centers. Besides that, they have an additional duty and work for suppression of the thick-lens effect, which allows to avoid usage of FMCs.
- With equal dispersions generated by the entrance dogleg, the total transverse deflection required is equal for both beamlines. It means that the strength of each TDC in the beamline two is two times smaller than the strength of the single TDC in the beamline one.
- The mirror symmetry of the beamline two automatically cancels part of nonlinear aberrations in the beamline map.

MATRICES AND SYMMETRIES

In the deriving conditions for a beamline to be an EEX, we consider the linear symplectic dynamics in the horizontal and longitudinal degrees of freedom and ignore the vertical degree of freedom, which (on the linear level) is assumed to be decoupled from the two others. Still, for convenience, we index elements of the 4×4 horizontal-longitudinal transport matrices as if these matrices were extracted from the complete three degrees of freedom 6×6 matrices, where the first degree of freedom is horizontal, the second is vertical, and the longitudinal comes as the third.

Transport Matrices

From the assumptions made it follows that the horizontal-longitudinal matrix of a magnetostatic system has the form

$$M = \begin{bmatrix} m_{11} & m_{12} & 0 & m_{16} \\ m_{21} & m_{22} & 0 & m_{26} \\ m_{51} & m_{52} & 1 & m_{56} \\ 0 & 0 & 0 & 1 \end{bmatrix}, \qquad (1)$$

and, as concerning the TDC matrix, we take it in the commonly used approximation

$$R(\kappa, l_c, q) = \begin{bmatrix} 1 & l_c & \kappa l_c/2 & 0 \\ 0 & 1 & \kappa & 0 \\ 0 & 0 & 1 & 0 \\ \kappa & \kappa l_c/2 & q\kappa^2 l_c & 1 \end{bmatrix}, \qquad (2)$$

where l_c is the cavity length, κ is the deflecting strength, and q is the energy gain factor. The particular value of q depends from the cavity design and, for example, for the n-cell pillbox resonator satisfies $1/6 < q \leq 1/4$.

Approximations made in the equations of motion in order to obtain matrix (2) include among others the neglection of the terms of the order $O(\gamma_0^{-2})$, where γ_0 is the Lorentz factor of the reference particle. To be consistent with this, we

SENSITIVITY OF LINAC OPTICS TO FOCUSING AND ENERGY ERRORS

V.Balandin*, W.Decking, N.Golubeva, DESY, Hamburg, Germany

Abstract

The ability to control beam optics in the presence of such imperfections as focusing and energy gain errors is essential for a successful operation of high brightness electron linacs providing beams for free-electron lasers. We characterize the cumulative effect of these imperfections using the value of mismatch parameter calculated at the linac exit and show how it depends on the design of the focusing lattice.

INTRODUCTION

Control of the optics matching is one of the key ingredients for a successful operation of modern high brightness electron linacs providing beams for free-electron lasers (FELs). Available operational experience indicates that in order to optimize FEL signal at different wavelengths or to fine-tune the FEL wavelength, empirical adjustment of the machine parameters is often required and, therefore, the sensitivity of the beamline optics to small changes in the beam energy and in the magnet settings becomes one of the important issues which affects both, the final performance and the reproducibility of the results after breaks in operation. This fact was quickly recognized when the FLASH facility at DESY started its regular user operation in August 2005. In a little while after that the simple criteria for comparison of the optics sensitivities was introduced, new (lower sensitivity) optics for the FLASH beamline was developed and brought in operation in spring 2006, and has shown a superior performance with respect to the previous setup of the transverse focusing [1]. Later on this criteria also has been usefully adopted as a part of the optics redesign strategy during commissioning of the FERMI@Elettra FEL facility [2].

The purpose of this paper is to give some generalizations and provide details of the derivation of the optics sensitivity criteria which were missing in [1], and practical examples and discussions of the application strategies can be found in the papers [1] and [2].

DYNAMICAL VARIABLES AND TWISS PARAMETERS

We consider the linear beam dynamics with acceleration in one degree of freedom (lets say, horizontal) and use the variables $z = (x, q)^{\top}$ for the description of the horizontal beam oscillations. We assume that evolution of these variables along the linac is described by the linear equation

$$dz \,/\, d\tau \;=\; F(\tau)\, z, \tag{1}$$

where the independent variable τ is the longitudinal position. As concerning the physical meaning of the variables z, we do not see any particular reasons to specify it at this point, because, first, there is no single commonly accepted transverse coordinates for description of the beam dynamics in the linacs and, second, the main object of our study (the mismatch parameter) is, up to some extend, independent on the coordinate system choice.

As often, we introduce the Twiss (or Courant-Snyder) parameters using the second central moments of the particle distribution and define them as follows

$$\beta = \langle x^2 \rangle \,/\, \epsilon, \quad \alpha = -\langle xq \rangle \,/\, \epsilon, \quad \gamma = \langle q^2 \rangle \,/\, \epsilon, \tag{2}$$

where

$$\epsilon \;=\; \sqrt{\langle x^2 \rangle \langle q^2 \rangle - \langle xq \rangle^2} \tag{3}$$

is the rms emittance. With this definition, the Twiss matrix

$$\Sigma \;=\; \begin{bmatrix} \beta & -\alpha \\ -\alpha & \gamma \end{bmatrix}, \quad \det(\Sigma) \;=\; 1 \tag{4}$$

satisfies the linear differential equation

$$d\Sigma \,/\, d\tau \;=\; JH\Sigma \;-\; \Sigma HJ, \tag{5}$$

where J is the 2×2 symplectic unit matrix and the 2×2 symmetric matrix H is defined by the expression

$$H(\tau) \;=\; \tfrac{1}{2}\mathrm{tr}[F(\tau)]\, J \;-\; JF(\tau). \tag{6}$$

The solution of Eq. (5) is given by the formula

$$\Sigma(\tau) = M(\tau)\, \Sigma(0)\, M^{\top}(\tau), \tag{7}$$

where the symplectic matrix M satisfies the equation

$$dM \,/\, d\tau = JHM, \quad M(0) = I, \tag{8}$$

and the rms emittance ϵ evolves according to the rule

$$\frac{\epsilon(\tau)}{\epsilon(0)} = \det\left[A(\tau)\right] = \exp\left(\int_0^{\tau} \mathrm{tr}[F(\xi)]\, d\xi\right), \tag{9}$$

where A is the fundamental matrix solution of the Eq. (1). Because the matrices M and A are connected by the relation

$$M(\tau) = \frac{1}{\sqrt{\det\left(A(\tau)\right)}} \cdot A(\tau), \tag{10}$$

and because for an arbitrary 2×2 matrix X

$$X\, J\, X^{\top} = X^{\top} J\, X = \det(X)\, J, \tag{11}$$

the transport rule (7) can also be written as follows

$$[\Sigma(\tau) J] = A(\tau)\; [\Sigma(0) J]\; A^{-1}(\tau). \tag{12}$$

Alternatively, the matrices M and A can be expressed using Σ and ϵ, if they are known, in the familiar forms

$$M(\tau) \;=\; T^{-1}(\tau)\, R[\mu(\tau)]\, T(0), \tag{13}$$

$$A(\tau) \;=\; \sqrt{\epsilon(\tau)/\epsilon(0)} \cdot T^{-1}(\tau)\, R[\mu(\tau)]\, T(0), \tag{14}$$

where

EMITTANCE REDUCTION POSSIBILITIES IN THE PETRA III MAGNET LATTICE

V. Balandin, W. Decking, N. Golubeva*, R. Wanzenberg
DESY, Hamburg, Germany

Abstract

PETRA III is a third generation light source at DESY that has been operated as a user facility since 2010 with a horizontal emittance of 1 nm · rad at a beam energy of 6 GeV. Recently an upgrade for additional photon beamlines has been carried out, and the recommissioning of PETRA III started in February 2015 [1]. Because the current optics solution for the upgraded storage ring predicts about 20% increase in the horizontal emittance, it motivates us to study a question whether or not there are optics modifications which allow the reduction of the emittance without significant changes in the present magnet arrangement. In this paper we present the results of the first look at this problem mostly limiting our consideration to the capabilities of the linear optics of the separate storage ring parts.

STORAGE RING OVERVIEW

The current layout of the PETRA III storage ring [2,3] is shown in Fig. 1, and one sees that it does not look like a conventional synchrotron light source constructed from large number of identical cells accommodating insertion devices. This is a result of a long history of the modifications of the facility. The former electron-positron collider PETRA has been turned into a pre-accelerator PETRA II for HERA, and then, after the shutdown of HERA, PETRA II has been converted into the synchrotron light source.

PETRA II has consisted of four identical quadrants, each of them mirror symmetric with respect to the center of a straight section. Therefore one octant (half of quadrant or one eight of the ring) has reflected all lattice and optics properties of the machine. For PETRA III [2] it was decided to accommodate all insertion devices in one octant. The octant extending from North-East to East was redesigned, and the FODO lattice was replaced by a sequence of the double-bend achromat (DBA) cells (in the following we will refer to this section as the "new octant"). Besides that, for the additional emittance reduction, twenty 4 m long damping wigglers were installed in the straight sections West and North. As concerning the chromaticity correction, no sextupoles were placed in the DBA lattice, and the chromaticity correction was performed globally using old sextupoles in the remaining seven octants [4].

In the recent upgrade [3] two new experimental halls were built, one in the North and one in the East, each housing 5 new photon beamlines. In order to accommodate new insertion devices, the part of the hardware of arcs in two old octants is removed and replaced by DBA-like cells (the extensions North and East), and for the rest of these arcs (shortened octant arcs) the FODO structure is kept. No new sextupoles are added but several old sextupoles are uninstalled that leads to some reduction of the dynamic aperture (∼ 20% predicted, which is acceptable).

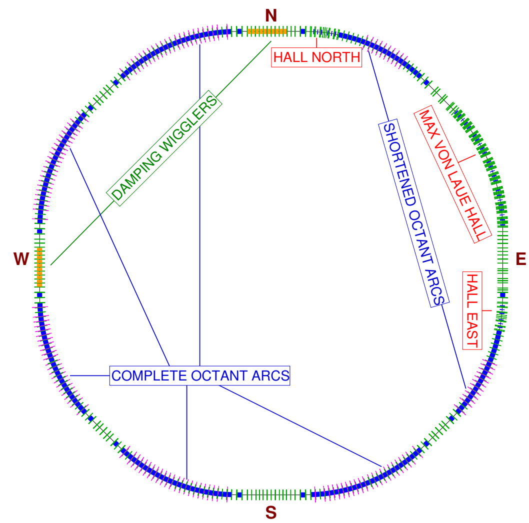

Figure 1: Layout of the PETRA III ring. Blue, green and red colors mark dipole, quadrupole and sextupole magnets, respectively. Yellow rectangles in the straight sections West and North indicate locations of the damping wigglers.

Contribution of Different Ring Sections to the Horizontal Emittance

One of the main figures of merit of the synchrotron light source quality is the value of the horizontal emittance which can be calculated as follows

$$\varepsilon_x \; [nm \cdot rad] \; = \; 1470 \left(E \; [GeV] \right)^2 \cdot \frac{I_5}{J_x \, I_2}, \qquad (1)$$

where I_2 and I_5 are the second and the fifth synchrotron radiation integrals, respectively, and J_x is the horizontal damping partition factor.

Table 1: Emittance Contributions of Ring Sections

Section	I_2	I_5
Old Octant Arcs	0.027 (9.5%)	3.29e-6 (48%)
New Octant	0.031 (11%)	1.70e-6 (25%)
Extension North	0.0057 (2.1%)	8.57e-7 (12.5%)
Extension East	0.0058 (2.1%)	8.05e-7 (11.8%)
Wigglers	0.211 (75.4%)	1.95e-7 (2.85%)
Total	0.280	6.84e-6

The contribution of different sections of the ring to the emittance is summarized in Table 1, where only the values of I_2 and I_5 are shown, because PETRA III contains no gradient dipoles and therefore $J_x \approx 1$. The value of I_2 is defined only by the reference orbit curvature and does not depend on the lattice functions. This means that the relative

VIRTUAL CAVITY PROBE GENERATION USING CALIBRATED FORWARD AND REFLECTED SIGNALS

S. Pfeiffer*, V. Ayvazyan, J. Branlard, Ł. Butkowski, H. Schlarb and C. Schmidt,
DESY, Hamburg, Germany
R. Rybaniec, ISE, Warszawa, Poland

Abstract

The European X-ray free electron laser requires a high-precision control of accelerating fields to ensure a stable photon generation. Its low level radio frequency system, based on the MicroTCA.4 standard, detects the probe, forward and reflected signals for each cavity. While the probe signal is used to control the accelerating fields, a combination of the forward and reflected signals can be used to compute a virtual probe, whose accuracy is comparable to the directly sampled probe. This requires the removal of cross-coupling effects between the forward and reflected signals. This paper presents the precise generation of a virtual probe using an extended method of least squares. The virtual probe can then be used for precise field control in case the probe signal is missing or corrupted. It can also be used to detect any deviation from the nominal probe profile.

INTRODUCTION

The Free Electron LASer (FLASH) at the *"Deutsches Elektronen Synchrotron"* in Hamburg is a facility for research with tunable laser light. It provides its users a pulsed light in the X-ray range with tunable wavelength down to 4.2 nm generated by SASE processes. Electron bunch trains of variable length and frequency with a repetition rate of 10 Hz are accelerated to about 1.2 GeV. Each pulse is enabled for about 1.4 ms, meanwhile up to 2400 bunches with a maximum repetition rate of 3 MHz are injected. In order to provide stable and reproducible photon pulses a precise acceleration field control is needed. During the last years, several control strategies for vector-sum regulation, i.e. the sum of up to 16 cavities and its RF field probes, were developed and included in the Low-Level RF (LLRF) controller. Hereby learning feedforward (LFF) minimizes repetitive amplitude and phase errors from pulse to pulse [1], whereas the multiple input multiple output (MIMO) controller acts within the pulse [2]. The necessary RF field regulation requirements are reached and below a relative amplitude error of 0.01 % and an absolute phase error of 0.01 degree. Besides the detection of the cavity probe signal, the forward and reflected signals of each cavity at the waveguide distribution is measured, as depicted in Fig. 1. In this paper, it is shown that the latter can be used to generate a virtual probe signal usable for system health detection and failure classification. If the real probe detection fails, the virtual probe can still be used to drive the system and ensure the amplitude and phase regulation requirements.

* sven.pfeiffer@desy.de

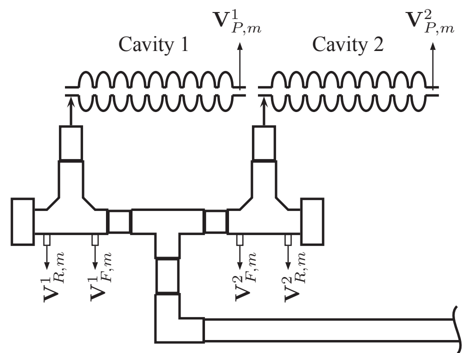

Figure 1: Waveguide distribution as example for the first accelerator module ACC1 at FLASH with depicted complex probe ($\mathbf{V}^c_{P,m}$), forward ($\mathbf{V}^c_{F,m}$) and reflected ($\mathbf{V}^c_{R,m}$) signal measurement for 2 out of 8 cavities, i.e. $c = 1, 2$.

THEORETICAL APPROACH

The main goal of this contribution is to calibrate the measured (index m) complex forward ($\mathbf{V}_{F,m} \in \mathbb{C}$) and complex reflected ($\mathbf{V}_{R,m} \in \mathbb{C}$) signals to the calibrated (index c) $\mathbf{V}_{F,c} \in \mathbb{C}$ and $\mathbf{V}_{R,c} \in \mathbb{C}$, respectively. An example for signal detection is shown in Fig. 2. As can be seen, the forward

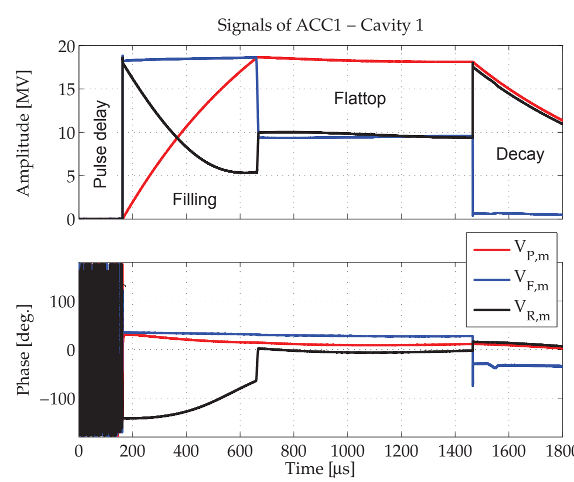

Figure 2: Measured probe, forward and reflected signals (pre-calibrated by (1)) for a standard RF pulse with $Q_L \ll Q_0$ for $\beta \gg 1$.

signal shows an amplitude value which is non-zero during decay, although the RF drive is switched off. A measurement calibration can overcome the imperfection of the signal detection, mainly caused by signal couplings at the pick-up, also visible in the reflected signal.

INVESTIGATION OF RADIATION DAMAGE OF INSERTION DEVICES AT PETRA III DUE TO PARTICLE LOSSES USING TRACKING RESULTS WITH SIXTRACK

G. K. Sahoo#, M. Bieler, J. Keil, A. Kling*, G. Kube, M. Tischer, R. Wanzenberg
Deutsches Elektronen-Synchrotron, Notkestraße 85, Hamburg, Germany

Abstract

PETRA III is a 3rd generation synchrotron light source dedicated to users at 14 beamlines with 30 instruments since 2009. The horizontal beam emittance is 1 nmrad while a coupling of 1% amounts to a vertical emittance of 10 pmrad. Some undulators and wiggler devices have accumulated total radiation doses of about 100 kGy. Doses measured regularly by Thermo Luminescent Dosimeters (TLDs) are monitored, which lead to inspect the magnetic field of all insertion devices in the PETRA tunnel. We are investigating particle losses with tracking simulation using SixTrack to gain a certain understanding of the radiation damage of the insertion devices. The goal is to develop a strategy to protect the insertion devices from further radiation damage.

INTRODUCTION

PETRA III [1, 2] is a 3rd generation synchrotron light source operating with electrons at beam energy of 6 GeV which is an upgrade of the previous machine PETRA II. The horizontal beam emittance of 1 nmrad is achieved using 20 damping wigglers each of 4 m length, while a coupling of 1% amounts to a vertical emittance of 10 pmrad. The machine is dedicated to users at 14 beamlines with 30 end-stations. Parts of PETRA III [3] have recently been rebuilt to accommodate 12 new beam lines including a super luminescence in near UV beamline providing bending magnet radiation. PETRA III operates with several filling modes, such as 40, 60, 240, 480 and 960 bunches with a beam current of 100 mA.

The insertion devices (IDs) and other accelerator components are expected to experience extreme radiation in synchrotron light sources especially where higher beam energies, beam currents and smaller gaps are in place. It is worth to mention that, permanent magnets operating under conditions of high radiation are especially susceptible to demagnetization [4] caused by direct and scattered radiation induced by electrons, positrons, high-energy photons and neutrons. Serious demagnetization has been observed in some of the operating light sources such as ESRF, where insertion devices experienced field losses of as much as 8% [5] and at the APS [6]. Here we report a partial demagnetization profiles which is not linear along the device [7, 8] in some of the IDs in PETRA III caused by radiation, similar loss patterns are also clearly seen in tracking results. To protect the IDs additional collimators have been installed at PETRA III.

gajendra.kumar.sahoo@desy.de

OBSERVATION OF RADIATION DAMAGE OF INSERTION DEVICES

Inspection of the magnetic structures and in-situ magnetic peak field measurements revealed a partial demagnetization of devices exhibiting performance losses. Some results of these measurements are summarized in Fig. 1 [7]. Devices located upstream in canted straight sections as PU02 and PU08 are damaged at the entrance end of the magnet structure while the downstream located device PU03 is damaged at the exit end (Fig. 1a). The measured decrease of the peak field is attributed to radiation damage and is most likely caused by particle losses.

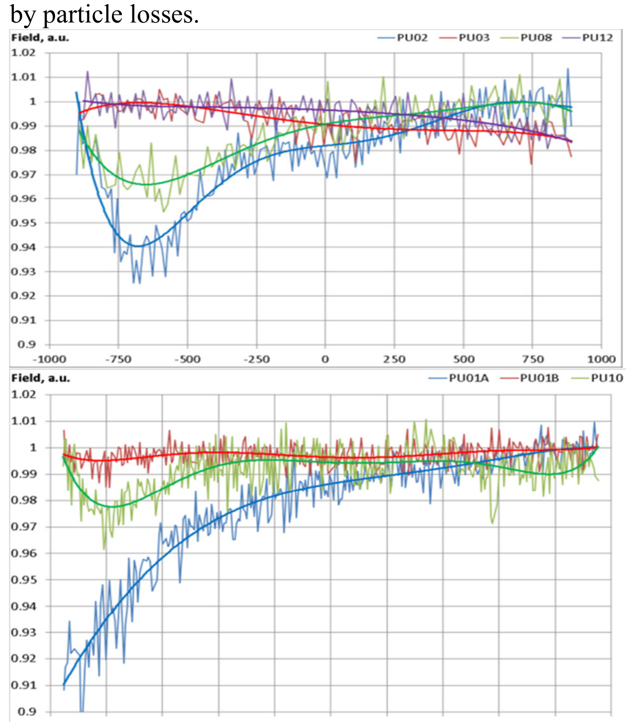

Figure 1: Recently measured longitudinal normalized peak field variation of (a) 2 m devices, (b) 5 m devices installed in PETRA III verses longitudinal position in mm.

A similar situation is observed for the 5 m long devices (Fig. 1b). In sector 1, the upstream device PU01a is strongly damaged at the upstream end. The 5 m device PU10 also confirms the damage pattern observed at the 2 m devices installed in the canted straight sections. PU10 is installed in a standard (not canted) straight section. PU10 shows signs of demagnetization at the entrance and

SUB-fs ELECTRON BUNCH GENERATION USING MAGNETIC COMPRESSOR AT SINBAD

J. Zhu[#1,2], R. Assmann[1], U. Dorda[1], J. Grebenyuk[1], B. Marchetti[1]
[1] DESY, Hamburg, Germany
[2] University of Hamburg, Hamburg, Germany

Abstract

In order to achieve high quality electron beams by laser-driven plasma acceleration with external injection, sub-fs bunches with a few fs arrival-time jitter are required. SINBAD (Short Innovative Bunches and Accelerators at DESY) is a proposed dedicated accelerator research and development facility at DESY. One of the baseline experiment at SINBAD is ARES (Accelerator Research Experiment at SINBAD), which will provide ultra-short electron bunches of 100 MeV to one or two connected beam lines. We present start-to-end simulation studies of sub-fs bunch generation at ARES using a magnetic compressor with a slit. In addition, the design of a dogleg with tunable R_{56} for the second beamline is also presented.

INTRODUCTION

Plasma-Wakefield Accelerators (PWFA) can produce acceleration gradients up to 100 GV/m [1], which makes them promising candidates for compact accelerators and novel light sources. SINBAD (Short and INnovative Bunches and Accelerators at DESY) is a proposed dedicated research facility where Laser-driven Plasma Wakefield Acceleration (LWFA) with external injection will be explored by using ultra-short electron bunches generated at ARES (Accelerator Research Experiment at SINBAD) [2]. External injection allows precise manipulation of phase-spaces of electron bunches and thereby provides possibilities to optimise the subsequent acceleration and transport inside the plasma.

ARES will consist of a compact photo-injector providing ultra-short electron bunches to one of the two connected beamlines [3]. The ~5-MeV electron bunches generated by the 1-1/2 cell S-band photocathode RF-gun are accelerated by two S-band travelling-wave RF-structures (TWS) to around 100 MeV. A third S-band TWS is foreseen in the future to boost electron bunches to higher energy, which will reduce the impact of the space-charge effects on bunch compression and final focus before the plasma cell. Downstream of the photo-injector the beamline includes quadrupole magnets and a magnetic chicane bunch compressor (BC) with a slit located in the middle of it. Ultra-short bunches at ARES can be produced by both velocity bunching and magnetic compression. In order to deliver ultra-short bunches to the second beamline, a dogleg section is also foreseen.

#jun.zhu@desy.de

MAGNETIC CHICANE WITH A SLIT

Since it is difficult to directly compress the pulse duration of an electron bunch generated at a photo-injector to sub-fs in one compression stage even with a high-harmonic cavity, the slit method is employed in our design, as shown in Fig. 1 [4]. The coherence synchrotron radiation (CSR) at the chicane can be reduced by using a weak chicane and a large initial correlated energy spread. Because the slit only allows the central slice of the whole bunch to pass, the energy spread of the compressed bunch remains small enough. Likewise, the emittance of the final bunch will not be affected by the chromatic aberration from quadrupoles upstream of the chicane. More importantly, the bunch arrival-time jitter downstream of the chicane will be reduced if the chicane is weak [5], which is vitally important for plasma acceleration with external injection [6]. On the other hand, the R_{56} should be large enough in order to compress the bunch with a reasonable chirp. As a result, R_{56}=-10 mm was chosen in the current design.

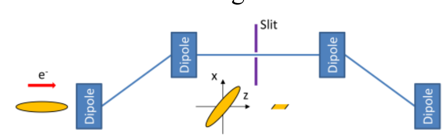

Figure 1: Schematic of the magnetic chicane with a slit.

Start-to-end Simulation

The start-to-end (S2E) simulation of the beam dynamics at ARES were performed with ASTRA [7] and IMPACT-T [8]. The electron bunch was first transported to the end of the linac by using ASTRA with 2D cylindrical-symmetric space-charge effects, and then the rest part was simulated by using IMPACT-T with 3D space-charge effects and 1D CSR effect. The photocathode laser is assumed to follow a Gaussian longitudinal distribution with rms duration of 3 ps, and a uniform transverse laser intensity distribution was taken at the photocathode. The two TWSs are operated at the same gradient and phase in order to minimize the bunch arrival-time jitter [5]. The chirp of the bunch at the linac exit is approximately -1/R_{56} in order to fully compress the bunch. The final longitudinal phase-spaces (LPS) and the current profiles 0.4 m downstream of the last dipole magnet with two different initial bunch charges are shown in Fig. 2, and the parameters of the final bunches are summarized in table 1. The results indicate that sub-fs electron bunch with charge of several pC is achievable at ARES. However, it is found that the bunch starts to

Abstract

OCELOT has been developed as a multiphysics simulation tool for FEL and synchrotron light source studies. In this work we highlight recent code developments focusing on electron tracking in linacs taking into account collective effects and on x-ray optics calculations.

INTRODUCTION

OCELOT has been developed as a multiphysics python-based simulation and on-line control framework for free electron laser (FEL) and synchrotron light source studies. Overview of its design and application areas can be found e.g. in [1]. FEL simulations comprise electron beam dynamics, FEL process proper, and interaction of radiation with optics components. OCELOT is a framework to account for all such processes, by including native physics models or interfacing to third-party codes. FEL calculations heavily rely on *Genesis 1.3* [2], while for other physics processes native models of various complexity exist. In this work we focus on recent code developments in two application areas not discussed in [1]: electron beam dynamics with space charge effects and x-ray optics. Accounting for space charge effects is necessary to extend the application area to low energy electron transport. The other major physics process which has to be taken into account for electron beam dynamics in FELs is Coherent Synchrotron radiation (CSR). A corresponding solver for OCELOT is being introduced and will be discussed elsewhere. The x-ray optics module has been largely driven by the needs of self-seeded FEL and some crystal optics simulations. This paper discusses calculations of crystal reflectivity and transmissivity in the optics module. Ray tracing and Fourier optics methods have also been introduced but are not discussed here.

SPACE CHARGE EFFECTS

OCELOT has been recently extended for particle tracking with collective effects. A three-dimensional Poisson solver to take into account the space charge forces has been included. In the near future additional modules for coherent synchrotron radiation and wakefields will be included in the code as well. The tracking of particles is done in the same way as, for example, in Elegant [3]. Quadrupoles, dipoles, sextupoles, radiofrequency (RF) cavities and so on are modelled by linear or nonlinear maps. The focusing effect of RF cavities is taken into account according to [4]. The space charge forces are calculated by solving the Poisson equation in the bunch frame. Then the Lorentz transformed electromagnetic field is applied as a kick in the laboratory frame.

* ilya.agapov@xfel.eu

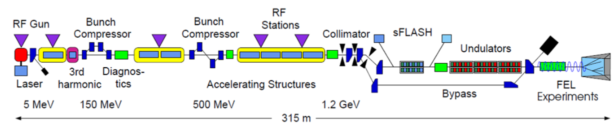

Figure 1: FLASH1 layout.

For the solution of the Poisson equation we use an integral representation of the electrostatic potential by convolution of the free-space Green's function with the charge distribution. The convolution equation is solved with the help of the Fast Fourier Transform (FFT). The same algorithm for solution of the 3D Poisson equation is used, for example, in ASTRA [5]. However, ASTRA solves equations of motion directly with a Runge-Kutta method, while in OCELOT particles are tracked using maps.

In this Section beam dynamics simulations for FLASH [6] using OCELOT are presented. FLASH is a high-gain FEL operating in the wavelength range of 4.2 - 45 nm. The layout of the facility is shown in Fig. 1. The formation of the electron bunch is carried out in two bunch compressors and seven TESLA-type 1.3 GHz superconducting accelerator modules. Each 12 m long module contains eight cavities. A special superconducting 3.9 GHz module built at FNAL has been installed in 2010 to improve the quality of the accelerated electron beam. The initial low-energetic part (14 meters from cathode of the gun) of the facility up to the third harmonic module was simulated with ASTRA since gun simulation is not presently possible in OCELOT. Then OCELOT was used to track the beam up to the entrance of the undulator section (203 meters from the cathode). The beam was tracked with and without taking space charge into account. The impact of space charge on the beam optics is shown in Fig. 2, where beta functions in the vertical plane without space charge (gray solid line) and with space charge (black points) are compared. A considerable mismatch is seen, which of course can be corrected. Such correction is not shown here since the focus is on benchmarking OCELOT with ASTRA.

The results of simulating the same setup with ASTRA is shown in Fig. 3. A slight disagreement between the two simulations is related to the fact that only first order maps were used for quadrupoles in OCELOT (higher order maps are presently used only for sextupoles and octupoles). This is also confirmed by cross-checks with Elegant. Higher order corrections to quadrupole and bending magnet maps are now being introduced in OCELOT as well. The current profile at the undulator entrance is shown in Fig. 4, where results obtained with OCELOT and ASTRA are compared.

QUASI-FROZEN SPIN METHOD FOR EDM DEUTERON SEARCH*

Abstract

To search for proton Electric Dipole Moments (EDM) using proton storage ring with purely electrostatic elements, the concept of frozen spin method has been proposed [1]. This method is based on two facts: in the equation of spin precession, the magnetic field dependence is entirely eliminated, and at the "magic" energy, the spin precession frequency coincides with the precession frequency of the particle momentum. In case of deuteron we have to use the electrical and magnetic field simultaneously as will be explained later, keeping the frozen spin direction along the momentum as in the pure electrostatic ring. In this article, we suggest the concept of the quasi-frozen spin, in which the spin oscillates around the momentum direction within the half value of the advanced spin phase in magnetic arcs, each time returning back in electrostatic arcs. Due to the low value of the anomalous magnetic moment of deuteron, an effective contribution to the expected EDM effect is reduced only by a few percent compared with frozen spin method.

INTRODUCTION

The frozen spin method [1] is based on the fact that at a certain so-called "magic" energy, the particle spin begins to rotate with the frequency of the momentum and is always directed along the momentum. Under this condition, the signal growth of presumably existing electric dipole moment is maximized. This is clearly evident from the T-BMT equations:

$$\begin{aligned}
&\frac{d\vec{S}}{dt} = \vec{S}\times\left(\vec{\omega}_G + \vec{\omega}_{edm}\right)\\
&\vec{\omega}_G = -\frac{e}{m}\left\{G\vec{B} + \left(\frac{1}{\gamma^2-1} - G\right)\frac{\vec{\beta}\times\vec{E}}{c}\right\}\\
&\vec{\omega}_{edm} = \frac{e\eta}{m}\left(\vec{\beta}\times\vec{B} + \frac{\vec{E}}{c}\right)\\
&G = \frac{g-2}{2},
\end{aligned} \tag{1}$$

where G is the anomalous magnetic moment, g is the gyromagnetic ratio, ω_G is the spin precession frequency due to the magnetic dipole moment (hereinafter called MDM precession) relative to the momentum, ω_{edm} is the spin precession frequency due to the electrical dipole moment (hereinafter called EDM precession), and η is the dimensionless coefficient defined by the relation $d = \eta e\hbar / 4mc$ in (1).

It is reasonable to implement the frozen spin method in a purely electrostatic machine with electrical deflectors holding a beam on orbit. The advantages of purely electrostatic machines are especially evident at the "magic" energy, where

$$G - \frac{1}{\gamma_{mag}^2 - 1} = 0, \tag{2}$$

and the spin oriented in the longitudinal direction rotates in horizontal plane with the same frequency as the momentum, which is $\omega_G = 0$ [2].

However, this method cannot be used for deuterons having the negative anomalous magnetic moment $G = -0.142$, which follows from condition (2). Therefore, the only possible method in this case is a storage ring with both electric and magnetic fields [3]. It was proposed to store a longitudinally polarized deuteron beam of 1 GeV/c total momentum in an electro-magnetic storage ring of 0.5 T, where they minimize ω_G. It should be small, but not zero. This can be done by applying a radial electric field of magnitude to cancel the $G \cdot B$ contribution to ω_G in Eq. (1):

$$E_r = \frac{GBc\beta\gamma^2}{1 - G\beta^2\gamma^2} \approx GBc\beta\gamma^2 \tag{3}$$

However, studying the proton spin-orbital dynamics in a purely electrostatic ring [4], we realized that the condition (2) is feasible only for the reference particle. For all other particles the spin is not frozen and changes in time. In addition, condition (3) forcibly couples the values of the electric and magnetic fields, assuming both of them exist in each element. Firstly, the latter determines the rate of EDM signal increase, and secondly, it complicates the design of the element with incorporated E and B field.

QUASI-FROZEN SPIN CONCEPT

Thus, the only requirement of the "frozen" spin condition is to maximize the EDM signal growth. However, if the spin oscillates in the horizontal plane with respect to frozen spin direction with amplitude Φ_s, then the EDM growth decreases proportionally to the

FIRST TESTS OF A BEAM TRANSPORT SYSTEM FROM A LASER WAKEFIELD ACCELERATOR TO A TRANSVERSE GRADIENT UNDULATOR*

C. Widmann[1]†, V. Afonso Rodriguez[1], S. Kuschel[3], M. Nicolai[2], R. Rossmanith[3], A. Sävert[2], M. B. Schwab[2], W. Werner[1], M. C. Kaluza[2,3], A. Bernhard[1], A.-S. Mueller[1]

Abstract

An experimental setup for the generation of monochromatic undulator radiation at the laser wakefield accelerator (LWFA) in Jena using a transverse gradient undulator (TGU) is planned. Proper matching of the betatron functions and the dispersion of the electron beam to the undulator is essential. Therefor a beam transport system with strong focusing magnets and chromatic correction of the magnets is required.

As a first step, a linear beam transport system without chromatic correction was assembled at the LWFA. With this setup the electron beam's dispersion and the beta function of one selected energy are matched to the required parameters at the TGU. This contribution presents the experimental results of these measurements.

INTRODUCTION

A challenging but essential part of any experimental setup at a laser wakefield accelerator (LWFA) is the beam transport system. One has to match the electrons of the LWFA to the parameters required by the experiment. Due to the relative energy spread of the LWFA-generated bunches of some percent a chromatic correction is necessary. At the same time the large initial divergence of some milli-radian required strong focusing with compact magnets.

For the generation of monochromatic undulator radiation at the LWFA using a transverse gradient undulator (TGU) a dogleg chicane is required for matching the beam parameters and the dispersion. In the chicane the electron bunch is dispersed in the deflection plane of the undulator, i.e. the x-z-plane, and the resulting lateral distribution of the electron energy is matched to the flux density amplitude $B_y(x)$ of the undulator with a transverse gradient dB_y/dx. So a broadening of the radiation spectra is prevented such that electrons of different energies emit radiation at the same wavelength [1, 2].

Several studies were performed to optimize the layout of a beam transport system to the TGU [3, 4]. In this measurement campaign such a beam transport system was set up to demonstrate that it is possible to transport a LWFA-generated bunch with a complex transport system and to match the beam parameters required for the undulator. As a first step a linear system was assembled consisting of six quadrupoles to focus the beam and two dipoles for generating the dispersion. The transverse beam profiles were measured with scintillating screens. For measuring the spectra an electron spectrometer was integrated in the setup.

In this contribution the results of a first experiment are presented. The parameters of the LWFA and of the magnets and the alignment procedure is described in the next section. Thereafter some magnet configurations and the measured beam profiles are presented and compared to simulations performed with *elegant* [5] and MADX [6].

EXPERIMENTAL SETUP

The experiment was performed at the JETI-40 laser system in Jena. The laser pulse with an energy of 700 mJ and a pulse duration of 27 fs was focused by a f/12 off-axis parabolic mirror to a spot size of 12 μm^2 (FWHM). This results in a peak intensity of $I_L = 9.1 \cdot 10^{18}$ W/cm^2. The target was a gas cell of 3.0 mm length. A gas mixture of 95% helium and 5% nitrogen was used.

The beam transport system consisted of six in-house built quadrupoles [7] installed inside the vacuum chamber and two commercially available dipole magnets [8], which were inside an air-box as they are not designed for in-vacuum use. A sketch of the setup is shown in Fig. 1. The yoke length of the quadrupoles is 80 mm and the gradient at the maximum current of 5 A is 35 T/m for the quadrupoles with the slightly larger size (Q2 and Q5) and 29 T/m for the quadrupoles with the more compact design (Q1, Q3, Q4 and Q6). The dipoles with rectangular pole shape and a pole length of 50 mm have a maximum field of 460 mT.

All quadrupoles are mounted on motorized vertical translation stages for alignment in x, the deflection plane. The four compact quadrupoles have an additional horizontal translation stage for alignment in y. Quadrupole four to six are inclined by the deflection angle of 24.5 mrad. The dipoles are mounted at a fixed height without inclination.

For measuring the electron beam profile a scintillating screen, which was placed under an angle of 45° to the beam axis, could be placed at three different positions along the beam line at 0.7 m, 1.8 m and 2.9 m distance from the electron source (marked as screen 1 to 3 in Fig. 1).

The electron spectrometer consists of a permanent dipole magnet, which deflects the electrons to a scintillating screen. The range corresponding to an electron energy of 3 MeV to

LATTICE AND BEAM DYNAMICS OF THE ENERGY RECOVERY MODE OF THE MAINZ ENERGY-RECOVERING SUPERCONDUCTING ACCELERATOR MESA*

D. Simon†, K. Aulenbacher, R. Heine, F. Schlander
Institut für Kernphysik, Johannes Gutenberg-Universität Mainz,
D-55128 Mainz, Germany

Abstract

The Mainz Energy-recovering Superconducting Accelerator (MESA) is a proposed multi-turn energy recovery linac for particle physics experiments [1, 2]. It will be built at the Institute for Nuclear Physics (KPH) at Mainz University. Because of the multi-turn energy recovery mode, there are particular demands on the beam dynamics. We present the current status of the lattice development.

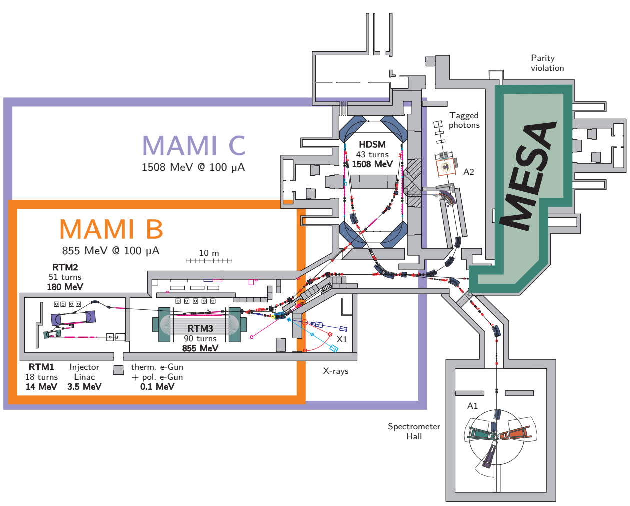

Figure 1: Floor plan of the MAMI facility. Space intended for MESA is marked in green.

INTRODUCTION

The MESA accelerator will be a CW-electron beam accelerator and will operate in two modes: an energy recovery mode (ER) with currents up to 1 mA (up to 10 mA in stage-2) and a polarized external beam mode (EB) with up to 150 μA. As presented in [3], MESA will be a double-sided recirculating linac with vertical stacking of the return arcs similar to a proposal for the LHeC ERL test facility [4]. A normal conducting linac with an extraction energy of 5 MeV will be used as injector. The linear lattice was designed with our own matrix optics program "Beam Optics" and also with Mad X [5]. To allow for space charge effects and pseudo-damping of the TESLA 9-cell cavities [6], the lattice was additionally simulated with PARMELA [7].

As shown in Fig. 3, MESA consists of:

- a 100 keV polarized photo-cathode electron gun [8],
- a normal conducting injector linac with an extraction energy of 5 MeV [2, 9],
- two superconducting linac modules with an energy gain of 25 MeV each [10],
- four spreader sections for separating and recombining the beam [3] vertically,
- five 180° arcs for beam recirculation,
- two chicanes for the injection and extraction of the 5 MeV beam,
- an 180° bypass arc for ER mode incorporating the internal experiment and a chicane to adjust the path-length (not shown in Fig. 3),
- a beam line to the external experiment.

SPACE CONSTRAINTS

MESA will be built in three existing halls formerly used for Experiments at the Mainz Microtron (MAMI) [11] (as shown in Fig. 1). These halls are located 10 m underground. Therefore alteration of the building is a challenge, due to the building statics. The main accelerator will be located in two of these halls; the third is appointed for the experiments. Due to the space restrictions, the lattice for MESA was optimized for a footprint area of circa 7.7 m × 27 m [3].

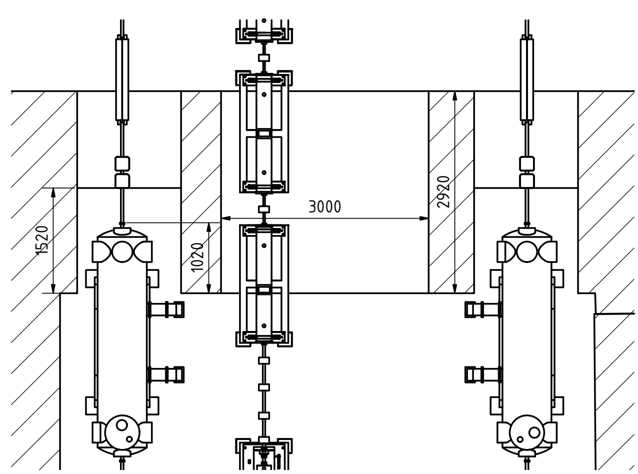

Figure 2: Sketch of the top view of the walls including the cryomodules and the injector linac (old concept).

START TO END SIMULATION OF HIGH CURRENT INJECTOR USING TRACEWIN CODE

Sarvesh Kumar, Abanimohan Mandal
Inter University Accelerator Centre, New Delhi, INDIA

Abstract

High Current Injector (HCI) is an alternate injector to superconducting linac at IUAC in addition to pelletron. It consists mainly of high temperature superconducting ECR ion source (PKDELIS), radio frequency quadrupole (RFQ) and a drift tube linac (DTL). The ions of mass to charge (A/q) ratio of 6 are analysed initially and accelerated through RFQ and DTL to a total energy of 1.8 MeV/u. The different energy regimes connecting the accelerating stages are named as low, medium and high energy beam transport section (LEBT, MEBT and HEBT). The energy spread of beam increases from 0.02% at ECR source to 0.5% at the LINAC entrance. An ion beam of normalized transverse and longitudinal emittance of 0.3 pi mm-mrad and 3 keV/u-ns has been considered at the start for the simulation of ion optics using TRACEWIN code. The whole beam transport system has been designed using GICOSY, TRANSPORT and TRACE 3D codes piecewise and TRACEWIN code is used to simulate whole ion optics from start to end including acceleration stages such as RFQ and DTL. Simulation results shows that beam can be injected through LEBT, MEBT and HEBT into LINAC without significant emittance growth and beam loss.

HIGH CURRENT INJECTOR

The ECR ion source [1,2,3] provides intense ion beams of high charge states which is the main requirement for nuclear physics experiments for better statistics and maximum energy gain from LINAC [4]. The beam optics calculations have been done piecewise [5] using different codes earlier and presently performed using TRACEWIN code [6] from start to end in envelope mode within framework of linear beam optics regime. A normalised longitudinal emittance of 3keV/u-ns and normalised transverse emittance of 0.3 pi mm-mrad has been assumed at the ECR ion source to design the whole system.

LEBT SECTION

The LEBT section consists of an electrostatic einzel lens (EL) and an electrostatic quadrupole doublet (EQD) so that all the ions follow same trajectory independent of their mass which are analysed as mass to charge ratio of 6 using a large acceptance analysing magnet [7] (AM). These ions are followed by a combination of electrostatic quadrupole triplet (EQT) and electrostatic accelerating section (AS) to transversely focus across the RF gap of a 12.125 MHz multiharmonic buncher. The input (i) and output (o) ion beam parameters for designing the individual LEBT, MEBT and HEBT section which connects the acceleration stages like high voltage DECK, RFQ [8] and DTL [9] are given in Table-1 where all twiss parmeters are in unit of mm/pi-mrad and all emittances (100%) are in unit of pi-mm-mrad.

Table 1: Ion Beam Parameters of Beam Transport Sections

Parameters	LEBT	MEBT	HEBT
α_{xi}, β_{xi}, ε_{xi}	0,1.0 0.3	0.62,0.05 0.46	-0.44,0.98 0.46
α_{xo}, β_{xo}, ε_{xo}	1.72,0.14 0.46	2.2,0.53 0.46	0.14,0.84 0.38
α_{yi}, β_{yi}, ε_{yi}	0,1.0 0.3	-0.59,0.22 0.3	-0.1,1.1 0.3
α_{yo},β_{yo}, ε_{yo}	1.73,0.14 0.3	2.2,0.45 0.3	0.02,0.97 0.3
α_{zi}, β_{zi}, ε_{zi}	0,22.5 1.31	-2.2,1.1 1.36	-9.1, 18.6 1.36
α_{zo}, β_{zo}, ε_{zo}	-0.05,0.2 1.36	-2.8,0.54 1.36	2.8,2.1 1.32
ME/q^2 (amu.MeV)	0.108	6.48	64.8
E (MeV/u)	0.003	0.180	1.8

These ions are bunched using a RF voltage of around 500V to the entrance of RFQ and transversely focussed using a set of four air cooled magnetic quadrupoles (MQS). The particles are bunched with a repetition rate of 83 ns and squeezed to a bunch width within 5 ns. The RFQ provides bunching, focusing to the injected ions from LEBT section and acceleration to an energy around 180 keV/u. The horizontal and vertical beam envelope for this section followed by RFQ section is shown in Fig. 1. The ion optical design of RFQ has been studied by TRACK code previously.

MEBT SECTION

This section matches the beam from RFQ to DTL. It consists of a set of magnetic quadrupoles and a spiral buncher for transverse and time focusing at the entrance of DTL respectively. The ion optical design of DTL has been studied using LANA code previously.

TRANSVERSE EMITTANCE MEASUREMENT FOR LOW ENERGY ION BEAMS USING QUADRUPOLE SCAN METHOD

Sarvesh Kumar, Abanimohan Mandal
Inter University Accelerator Centre, New Delhi, India

Abstract

Low energy ion beam facility (LEIBF) at IUAC consists of all permanent magnet 10 GHz electron cyclotron resonance (ECR) ion source (NANOGAN) along with 400 kV high voltage accelerating platform, a switching cum analysing magnet and electrostatic quadrupoles. Intense low energy ion beams puts tremendous challenge to transport from ion source to target with minimum emittance growth and beam losses. The normalized emittance of analysed ion beam is measured using electrostatic quadrupole scan method for various source parameters like RF power and injection pressure of gas etc. It is attributed to beam rotation induced by ECR axial magnetic field, effect of ion temperature in plasma, nonlinear electric fields and space charge etc. which play a significant role in emittance growth.

INTRODUCTION TO LEIBF

The new low energy ion beam facility (LEIBF) [1] at the Inter-University Accelerator Centre (IUAC) is a facility dedicated to provide multiply charged ion beams at a wide range of energies (a few keV to a few tens of MeV) for experiments in Atomic, Molecular and Materials Sciences. This facility consists of an all permanent magnet (NdFeB) 10 GHz electron cyclotron resonance (ECR) ion source (NANOGAN) [2] installed on a high voltage platform (400 kV) for obtaining multiply charged intense ions and the analysed beam is transported to the three beam lines along 75deg., 90deg. and 105 deg. angles using a switching cum analysing magnet. The beam tuning parameters of various ion beams are verified experimentally within first order linear beam optics analysis. The emittance is measured for various parameters of NANOGAN using quadrupole scan method in 90 deg. beam line. Standard beam dynamics and 3D field computation codes have been used to design beam transport element. The whole system has been installed and tested and facility is being used by scientific users.

ECR ION SOURCE AND LOW ENERGY BEAM TRANSPORT

The ECR ion source [3, 4] acts as prominent injector into heavy ion accelerators as they can produce the broad range of intense ions in multiple charge states for maximum energy gain in linear accelerators. Simultaneously, they are also used as a compact facility in low energy regime to perform implantation experiments on target samples. The magnetic confinement necessary to sustain the ECR plasma makes the ion density distribution across the extraction aperture inhomogeneous and charge state dependent. Thus it is necessary to characterize the extracted beam in terms of its emittance and transmission along the beam lines. The ion beam parameters from the exit of ECR ion source taken for beam optics simulations are given in Table 1.

Table 1: Ion Beam Parameters

Parameters	Values
Emittance ε (π mm-mrad)	100
Extraction Energy (E) keV/q	30
Max. ME/q^2 along 75°, 90° and 105° lines (MeV.amu)	44.68, 30.37 22.96

The beam is extracted using 30kV dc potential and focussed by a combination of electrostatic quadrupole doublet (EQD), 400kV accelerating section (AS) and an electrostatic quadrupole triplet (EQT) directly to object point of switching magnet (SW). The beam optics for the whole facility in 90 deg. line is shown in Fig. 1 using code TRANSPORT [5]. Different colour envelopes corresponds to different charge states of Ar ion beam. Based on this beam optics, the whole facility is installed and commissioned. Transverse emittance measurements of analysed beam have been performed using electrostatic quadrupole scan method.

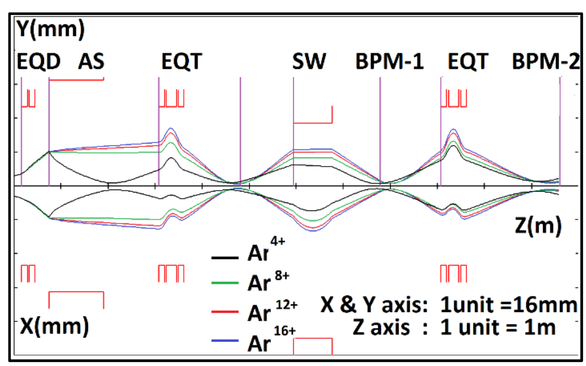

Figure 1: Beam optics of LEIBF in 90° line using TRANSPORT code for charge states of Ar ion beam at the energy of q*210 keV.

QUADRUPOLE SCAN METHOD

The two beam profile monitors before and after the EQT in 90 deg. line are used to measure the emittance using quadupole scan method [6, 7]. It is based upon linear transformations of beam phase space and

SIMULATION OF CRAB WAIST COLLISIONS IN DAΦNE WITH KLOE-2 INTERACTION REGION*

M. Zobov, A. Drago, A. Gallo, C. Milardi, INFN/LNF, Frascati, Italy
D. Shatilov, BINP, Novosibirsk, Russia
A. Valishev, FNAL, Batavia, IL, USA

Abstract

After the successful completion of the SIDDHARTA experiment run with crab waist collisions, the electron-positron collider DAΦNE has started routine operations for the KLOE-2 detector. The new interaction region also exploits the crab waist collision scheme, but features certain complications including the experimental detector solenoid, compensating anti-solenoids, and tilted quadrupole magnets. We have performed simulations of the beam-beam collisions in the collider taking into account the real DAΦNE nonlinear lattice. In particular, we have evaluated the effect of crab waist sextupoles and beam-beam interactions on the DAΦNE dynamical aperture and energy acceptance, and estimated the luminosity that can be potentially achieved with and without crab waist sextupoles in the present working conditions. A numerical analysis has been performed in order to propose possible steps for further luminosity increase in DAΦNE such as a better working point choice, crab sextupole strength optimization, correction of the phase advance between the sextupoles and the interaction region. The proposed change of the e^- ring working point was implemented and resulted in a significant performance increase.

INTRODUCTION

DAΦNE is an accelerator complex the main element of which is a double ring electron-positron collider operating at the c.m. energy of the Φ-resonance (1.02 GeV) [1].

The implementation of the Crab Waist collision scheme (CW) has led to the achievement of the record peak luminosity L=4.5×10^{32} cm^{-2}s^{-1} while working for the SIDDHARTA experiment [2]. This success has led to a decision to reinstall the upgraded KLOE detector, KLOE-2, exploiting the advantages of the CW scheme. For this purpose, the KLOE interaction region (IR) was carefully redesigned [3], and in 2013 the KLOE detector has been upgraded with new layers in the inner part of the apparatus [4]. The new KLOE-2 IR is much more complex as compared to the SIDDHARTA IR because the collisions take place inside the detector solenoid, IR has rotated quadrupoles and additional compensator solenoids.

At present, the luminosity of 1.9×10^{32} cm^{-2}s^{-1} has been achieved to be compared with 1.5×10^{32} obtained in the previous KLOE run [5]. Table 1 summarizes the most relevant machine and beam parameters. It is worth noting that the performance is mostly limited by collective effects such as electron cloud, microwave instability, feedback system noise, etc. [6]. An extensive campaign of experimental and simulation studies is in progress in order to fully exploit the CW potential and push the luminosity to higher values.

Numerical simulations of beam-beam effects with the weak-strong particle tracking code Lifetrac proved to be very efficient for the detailed understanding of the crab-waist collision scheme, and for the collider performance optimization [7,8]. The goal of the present work was to implement the complete model of DAΦNE with the KLOE-2 IR in weak-strong beam-beam simulation and apply the modeling to guide parameter optimization.

In addition to the value for the DAΦNE program, the studies represent a unique opportunity to benchmark the numerical tools against the experimental data to enable further application towards the High Luminosity upgrade of the LHC.

Table 1: DAΦNE Machine and Beam Parameters during 2015 Operation with KLOE-2 Detector (April 2015)

Parameter	Value
Number of bunches	95
Bunch spacing	2.7 ns
Full horizontal crossing angle	50 mrad
Number of electrons / bunch	2.05×10^{10}
Number of positrons / bunch	2.05×10^{10}
Electron emittance, r.m.s. (x,y)	0.28, 0.0021 μm
Positron emittance, r.m.s. (x,y)	0.28, 0.0021 μm
Momentum spread, r.m.s.	5.5×10^{-4}
Bunch length, r.m.s. (e^-, e^+) σ_z	1.55, 1.6 cm
Electron betatron tunes (ν_x,ν_y)	0.130, 0.170
Positron betatron tunes (ν_x,ν_y)	0.098, 0.130
Damping decrements (x,y,z)	(1.1, 1.1, 2.2) ×10^{-5}
Beta-function at IP (x,y)	25, 0.84 cm
Beam-beam parameter, e^+ (x,y)	0.011, 0.04

BEAM DYNAMICS STUDIES TO DEVELOP A HIGH-ENERGY LUMINOSITY MODEL FOR THE LHC

G. Campogiani, University of Rome “La Sapienza”, Rome Italy and CERN, Geneva, Switzerland
Y. Papaphilippou, CERN, Geneva, Switzerland

Abstract

Luminosity, the key figure of merit of a collider as the LHC, depends on the brightness of the colliding beams. This makes the intensity dependent beam-beam effect the dominant performance limiting factor at collision. The parasitic interactions due to the electromagnetic mutual influence of the beams in the interaction region of a collider induce a diffusive behaviour in the tails of the beam. The evolution of charge density distribution is studied to model the beam tails evolution in order to characterize beam lifetime and luminosity. To achieve this, tools are developed for tracking distributions of arbitrary number of single particles interacting with the opposing strong-beam, to analyse the halo formation processes due to the combined effect of beam-beam and machine non-linearities. This paper presents preliminary results of the simulations, both for the LHC Run I and nominal LHC parameters. The former will be used to benchmark simulations while the latter aims at supporting luminosity estimate for the Run II.

INTRODUCTION

The figure of merit of a collider is the (istantaneous) luminosity $\mathcal{L}$, defined as the proportionality factor between the cross-section σ_p and the rate of events per seconds $\frac{dR}{dt}$, and corresponds to the volume of overlap integral of the beams charge density distributions in the interaction region times the number of bunches, the revolution frequency and the product of the population in each of the opposing bunches. In the simplifying assumption of round ($\sigma_x = \sigma_y$), symmetric, equally populated beams colliding head-on and with Gaussian charge density distribution, the ideal luminosity formula is the following

$$\mathcal{L}(t) = \frac{n_b f_{rev} N^2(t)}{4\pi\sigma_x(t)\sigma_y(t)} = \mathcal{L}_0(t)$$

where N is the number of particles in each of the colliding bunches, $\sigma_{x,y} = \sqrt{\beta^*_{x,y}\epsilon_n/\gamma_{rel}}$ is the beam transverse size, $\gamma_{rel} = (1-(\frac{v}{c})^2)^{-1/2}$ is the relativistic gamma, ε_n is the normalised transverse emittance, n_b is the number of bunches per beam and f_{rev} is the revolution frequency.

In the real machine additional effects reducing luminosity are present: the presence of a crossing angle, the hour-glass effect due to the spatial modulation of the betatron function when $\sigma_s \gg \beta^*$, where σ_s is the bunch length, and an offset in the position of the beams at the interaction point. Thus, a more realistic expression for the instantaneous luminosity is [1]

$$\mathcal{L}(t) = \Lambda(t)N^2(t)$$
$$\Lambda(t) = \frac{n_b f_{rev}}{4\pi}\frac{\gamma_{rel}}{\beta^*\varepsilon_n}H(\frac{\sigma_s(t)}{\beta*})F(\theta_c,\sigma^*(t),\beta^*)$$

where $H(\sigma_s(t),\beta^*)$ is the reduction factor due to the hour-glass effect and $F(\sigma_s(t),\beta^*)$ is the geometrical reduction factor due to the presence of a crossing angle θ_c that reduces the geometrical intersecting volume of the colliding beams with respect to the head-on one. This form of the expression of luminosity is convenient to highlight its dependence on beam intensity, while the other factors are included in the $\Lambda(t)$ term.

It is evident how, for a fixed energy value, such as the collision one, the easiest way to increase the luminosity would be to increase the ratio of $\frac{N}{\varepsilon_n}$ which is proportional to the beam brightness. From injection to collision energy, several phenomena interplay to cause emittance growth, and in particular intra-beam scattering (IBS). Once the beams reach the maximum energy level and are brought into collision, the intensity dependent long-range beam-beam effect is dominant, putting a limit to performance optimization. This phenomenon is due to the non-linear lens behaviour of the electromagnetic field of one beam on the other one in the interaction region, both in the collision point (head-on) and at a distance from the design interaction point (long-range).

The parasitic encounters drive beam-halo formation. Our aim is to study the beam dynamics of the halo through numerical simulations, to characterize beam lifetime and luminosity evolution at hight energy. To reach this goal, the evolution of charge density distributions in the beam is analyzed, by tracking particles through a symplectic integrator that includes the beam-beam effect as a thin-kick in the transverse phase-space. The final goal is to find ways to better characterise the beam lifetime and be able to predict the component of luminosity evolution due to beam-beam effect through numerical simulations based on detailed beam dynamics models.

Table 1: Summary of Machine Optics and Beam Parameters Used in the Simulations

Parameter	Run I	nominal
E_{kin}[TeV]	4	7
ε_n[μm-rad]	2.5	3.75

Abstract

A formation/irradiation technique of large-area uniform ion beams based on nonlinear focusing of multipole magnets has been developed toward advanced research and efficient industrial applications at the TIARA AVF cyclotron facility of Japan Atomic Energy Agency. The formation procedure of the uniform beam has been established as follows: An ion beam extracted from the cyclotron is multiply scattered with a thin foil so that the transverse beam intensity distribution can be smoothed into a Gaussian-like one, prerequisite to the formation of a highly uniform beam. Then, the tail of the Gaussian-like distribution is folded into the inside by the nonlinear force of octupole magnets and eventually the distribution can be made uniform on a target. We have realized large-area uniform beams of ^{1}H, ^{12}C, ^{40}Ar, and ^{129}Xe typically over 100 cm^2 in area and below 10% in uniformity. Such uniform beams have enabled the suppression of local target heating and efficient low-fluence irradiation, and been applied to radiation degradation testing of space-use solar cells and a study on functional materials.

INTRODUCTION

The ion accelerator complex TIARA (Takasaki Ion Accelerators for Advanced Radiation Application) is an accelerator facility in Japan Atomic Energy Agency (JAEA), dedicatedly constructed for the advanced research and development (R&D) on material, biological and medical sciences and their applications [1]. The complex consists of four accelerators: An azimuthally-varying-field (AVF) cyclotron (*K* number of 110 MeV), a 3-MV tandem accelerator, a 3-MV single-ended accelerator and a 400-kV ion implanter.

A theoretical and experimental R&D study has been carried out on the formation of a large-area uniform beam with multipole magnets using ion beams from the AVF cyclotron for various applications [2-4]. The uniform-beam formation is based on the transformation of the transverse beam intensity distribution by means of the nonlinear focusing force produced mainly by octupole magnets [5]. It is possible to make the intensity distribution uniform by folding the tail of the Gaussian beam distribution with octupole magnets in a properly-designed beam transport line.

Recently, we have established the tuning procedure of the uniform-beam formation and then achieved the primary objective (to form a uniform region 100-cm^2 in area with a uniformity below 10%) using several species of ion beams from the cyclotron. In these proceedings, the latest R&D results and application examples of the uniform beam are reported.

BEAM TUNING PROCEDURE IN THE BEAM TRANSPORT SYSTEM

The schematic view of the cyclotron facility in TIARA is illustrated in Fig. 1. The main elements for the uniform-beam formation are a thin scattering foil for conditioning the prerequisite beam, octupole magnets for beam tail folding and a target station for beam measurement and utilization. The tuning procedure in the beam transport system for the efficient uniform-beam formation has been determined as follows through the beam optics design, tracking simulation, and repeated experiments.

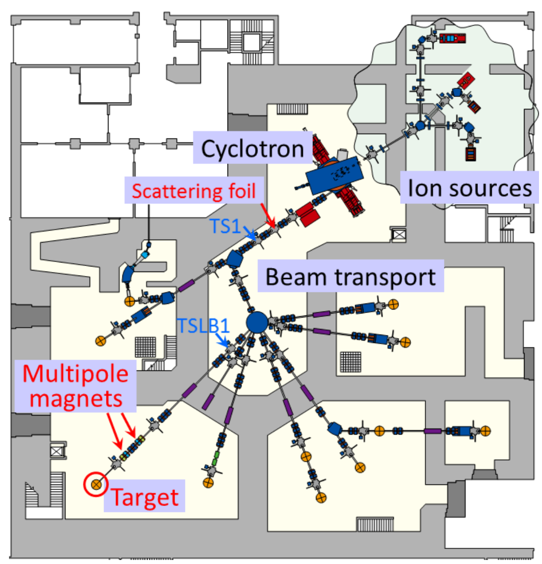

Figure 1: Schematic view of the JAEA AVF cyclotron facility. There are four ion sources, which can generate various ions from proton to osmium. A scattering foil is mounted at the first straight section after the cyclotron. The gray squares on the beam lines correspond to the beam diagnostic stations (labelled as TS1 and TSLB1) equipped with a silt, a wire profile monitor, a phosphor screen, and a Faraday cup. Multipole (sextupole and octupole) magnets have been installed in one of the beam lines for the formation of a uniform beam.

First, the transverse beam size and position are adjusted to the diameter (30 mm) of the scattering foil and the beam waist is formed at the diagnostic station TS1 using

EMITTANCE PRESERVATION IN SUPERKEKB INJECTOR

S. Kazama*, M. Satoh, H. Sugimoto, M. Yoshida, Y. Ogawa
High Energy Accelerator Research Organization (KEK), Tsukuba, Ibaraki, 305-0801, Japan

Abstract

Injector linac at KEK is now under the way to produce high current and low emittance beams for SuperKEKB. The target luminosity for SuperKEKB is 40 times higher than that of KEKB. A short-range transverse wakefield and a dispersive effect at the linac cause an emittance growth, and a longitudinal wakefield effect enlarges an energy spread of the beams. In this paper, we presented simulation studies concerning the emittance preservation and the energy spread issues. As a candidate for the mitigation of the emittance dilution originating from the transverse wakefield, a so-called "offset injection" method using steering coils is considered. It is demonstrated that the offset injection remarkably improves the emittance preservation.

INTRODUCTION

SuperKEKB is an electron-positron collider with an energy of 7 GeV and 4 GeV, respectively. The target luminosity is $8\times10^{35}\mathrm{cm}^2\mathrm{s}^{-1}$, which is 40 times higher than that of KEKB [1]. SuperKEKB main ring therefore requires a high current and low emittance beam. These parameters are summarized in Table 1. In order to meet the requirement, photo-cathode RF guns are now installed at the injector linac for the electron beam. For the production of a low emittance positron beam, a damping ring is now under construction. Since the target emittance is quite small compared to that of KEKB, much more attention should be paid to the emittance growth through the linac. The Short-range wakefield and the dispersive effect are considered to be the major sources of the emittance dilution. In this paper, we report on a design study on SuperKEKB injector for high current, low emittance, and low energy spread beams. We mainly report on simulation studies concerning the emittance preservation issues and how to suppress the increase of the energy spread. All simulation presented in this paper is performed with elegant [2].

Table 1: Required parameters for SuperKEKB

	Phase 2 (e^+/e^-)	**Phase 3** (e^+/e^-)
Bunch charge [nC]	2 / 2	4 / 5
Vertical emittance [mm mrad]	20 / 20	20 / 20
Horizontal emittance [mm mrad]	100 / 50	100 / 50
Energy spread [%]	0.1	0.1

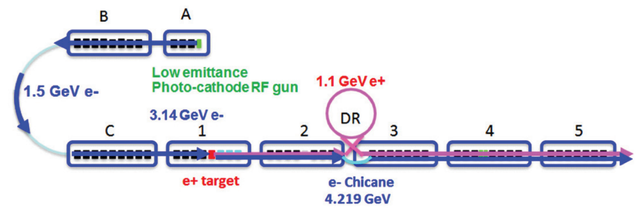

Figure 1: Schematic of SuperKEKB injector linac.

TRACKING SIMULATION

Figure 1 shows a schematic of SuperKEKB injector linac. The linac is mainly composed of 9 sections. In this paper, simulation is performed from C-sector to 5-sector for simplicity.

Condition of Simulation

The initial particle distribution in the longitudinal direction at the C-sector is a Gaussian of 10 ps bunch length (FWHM) with 2 or 5 nC charge and 1.5 GeV energy. The distributions of transverse phase space and energy spread are both assumed to be Gaussian. The initial emittance in the horizontal and vertical directions and the energy spread are set to be 10 mm mrad and 0.1 %, respectively. Longitudinal monopole and transverse dipole wakefield are incorporated in the simulation with an analytical expression of the wake functions [3]. Long-range wakefield effects are not taken into account in the simulation. The electron beam is approximated by 10^5 macro particles. For the study of the effect of misalignment on the emiitance growth, alignment errors for quadrupole magnet and acceleration tube are considered, and their distributions are assumed to be Gaussian.

EMITTANCE PRESERVATION

Short-Range Wakefield and Misalignment

When a bunch of electron beam passes through a misaligned accelerating structure, the head particles in the bunch will interact with the beam pipe and leave a wakefield to the tail particles. The induced wakefield can deflect the trailing particles further away from the axis, resulting in an increase of the projected beam emittance. A small amount of misalignment and a short bunch length can reduce the transverse wakefield strength. However, the short bunch length causes the strong longitudinal wakefield, resulting in a large energy spread. Therefore, the bunch length has to be optimized with a detailed simulation. The dependence of the bunch length on the energy spread will be discussed in the next section. To achieve the required emittance, the magnitude of the misalignment must be kept as small as possible. Figure. 2 shows a simulated vertical emittance at

EFFECT OF NUMBER OF MACRO PARTICLES ON RESOLUTION IN PHASE SPACE DISTRIBUTION

T. Miyajima*, KEK, Tsukuba, Ibaraki 305-0801, Japan

Abstract

In order to analyze charged particle beam in an accelerator, a beam model is used to reduce number of degrees of freedom, e.g. charged disk model, charged cylinder model and macro-particle model. In numerical simulation, the macro-particle model, which has same mass-to-charge ratio, is widely used, since it does not require any symmetry of beam shape. However, the estimation of proper number of macro-particles is one of the important issues. In order to study the effect of the number of macro-particles for the numerical model, we defined a simple transformation to generate reduced distribution. The transformation was applied for one dimensional and two dimensional particle distributions. The static electric fields due to the transformed distributions were calculated. As a result, we confirmed the effectiveness of the transformation.

INTRODUCTION

In an accelerator, the motion of a charged particle beam which consists of N particles can be described by a trajectory on $6N$ dimension phase space. Since an actual beam contains enormous number of particles, for example $N \sim 4.8 \times 10^8$ electrons in an Energy Recovery Linac with 77 pC operation, degree of freedom in a simulation and a theoretical analysis is reduced using an approximation. In order to analyze the charged particle beam, a beam model is used to reduce number of degrees of freedom, e.g. charged disk model, charged cylinder model and macro-particle model [1]. The macro-particle model, which does not depend on the symmetry in the beam, is versatile method to describe it.

In numerical simulation, the macro-particle model, which has same mass-to-charge ratio, is widely used, since it does not require any symmetry of beam shape. However, the estimation of proper number of macro-particles is one of the important issues, since it affects the resolution of the phase space distribution of the beam. Then, we define a transformation to reduce macro-particles, and study the relation between the number of macro-particles and the resolution in the phase space. In this paper, we report the transformation and static electric fields calculated by the transformed distribution about an electron beam for one and two dimensional distributions.

MACRO PARTICLE MODEL

The equation of motion of an electron in electro-magnetic field, $\boldsymbol{E}$ and $\boldsymbol{B}$, is

$$c\frac{m_e}{e}\frac{d(\gamma\boldsymbol{\beta})}{dt} = \boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B}, \qquad (1)$$

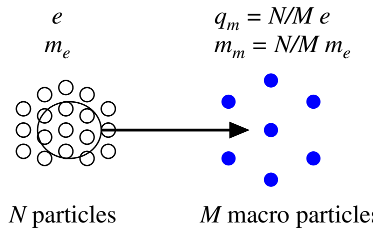

Figure 1: Description of charged particle beam by macro-particle model. The mass-to-charge ratio is a conserved quantity.

where, m_e and e are the mass and the charge of an electron, c is the speed of light, $\boldsymbol{v}$ is the speed of the electron, $\beta = v/c$ and $\gamma = 1/\sqrt{\beta^2 - 1}$. Here, the electron beam consists of N electrons. In order to describe the electron beam by the macro-particle model with$M$ macro-particles, we have to preserve the mass-to-charge ratio. As shown in Fig. 1, the macro-particle contains $a(= N/M)$ electrons, and the mass and charge are $m_m = am_e$, $q_m = ae$, respectively. The equation of motion of the single macro-particle is

$$c\frac{m_m}{q_m}\frac{d(\gamma\boldsymbol{\beta})}{dt} = \boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B}. \qquad (2)$$

It is the same equation as the single electron, Eq. (1), because $m_e/e = m_m/q_m$. Therefore, the description of the beam motion by macro-particle model corresponds to an approximation by M charged particles with the mass, am_e, and the charge, ae. However, we have to select proper number of macro-particles, which preserves the property of the original beam, because the replacement by the macro-particles causes the loss of information about the beam. In order to study this mechanism, we introduce a transformation, particle pair transformation, to describe the replacement by the macro-particle in the next section.

PARTICLE PAIR TRANSFORMATION

In this section, we define a particle pair transformation to describe the replacement of an particle distribution by macro-particles. The original distribution consists of n_0 macro-particles with the mass, m_{m0}, and the charge, q_{m0}. The procedure of the transformation has the following five steps.

1. Calculate the center of the original particle distribution.
2. Choose the most distant particle from the center, and the nearest neighbor particle from it.
3. Calculate the average position about the above two particles.
4. Replace the two particles by a new macro-particle with $m_{m1} = 2m_{m0}$ and $q_{m1} = 2q_{m0}$ on the average position.

STUDY OF EMITTANCE GROWTH CAUSED BY SPACE CHARGE AND LATTICE INDUCED RESONANCES

Kazuhito Ohmi, KEK, Tsukuba, Japan

Abstract

Emittance growth and beam loss in high intensity circular proton accelerators are one of the most serious issue which limit their performance. The emittance growth is caused by linear and nonlinear resonances of betatron/synchrotron oscillation due to lattice and space charge nonlinear force. The resonances are induced by errors in many cases. The space charge effects have been studied by computer simulations. Simulations with taking into account errors at random are consuming. We should first understand which resonances are serious. Resonance strength and resonance width induced by space charge and lattice nonlinearity is discussed with integrals along a ring like the radiation integrals. Emittance growth is evaluated by model with the resonance width to understand the mechanism.

INTRODUCTION

Particles move with experience of electro-magnetic field of lattice elements and space charge. We study slow emittance growth arising in a high intensity circular proton ring. We assume that the beam distribution is quasi-static, and each particle moves in the filed of the quasi-static distribution. Actually we concern about beam loss of 0.1-1% during a long term ($\approx$ 10,000 turns) in J-PARC MR. A halo is formed by the nonlinear force due to the electro-magnetic field. The halo, which consists of small part of whole beam, does not affect potential. Particle motion is described by a single particle Hamiltonian in the averaged field. This picture is not self-consistent for a distortion of beam distribution due to space charge force. Hamiltonian is separated by three parts for (1) linear betatron/synchrotron motion (μJ) (2) nonlinear component of the lattice magnets (U_{nl}) and (3) space charge potential (U).

$$H = \mu J + U_{nl} + U_{sc}. \tag{1}$$

where Hamiltonian is represented by action variables J and ϕ, which are Courant-Snyder invariant ($W = 2J$) and betatron phase, respectively.

Hamiltonian is expanded by Fourier series,

$$H = \mu J + U_{00(J)} + \sum_{m_x, m_y \neq 0} U_{m_x,m_y}(J)\exp(-im_x\phi_x - im_y\phi_y) \tag{2}$$

where Phase space structure near resonances are characterized by the resonance width. It is determined by their strength and tune slope for amplitude as follows [1],

$$\Delta J_x = 2\sqrt{\frac{U_{m_x,m_y}}{\Lambda}} \qquad \Lambda = \frac{\partial^2 U_{00}}{\partial J_x^2}. \tag{3}$$

EVALUATION OF RESONANCE WIDTH

Resonances Due to Space Charge Force

We first discuss the space charge potential U_{sc} [2]. Beam distribution is assumed to be Gaussian in transverse determined by emittance and Twiss parameters. U contains linear component, which gives a tune shift and Twiss parameter distortion. Twiss distortion is given by solving an envelope equation including linear space charge force self-consistently.

$$U_{sc} = \int ds' U_{sc}(s') = \frac{\lambda_p r_p}{\beta^2\gamma^3}\oint ds' \tag{4}$$
$$\int_0^\infty \frac{1 - \exp\left(-\frac{\beta_x(s')X(s,x')}{2\sigma_x^2+u} - \frac{\beta_y(s')Y(s,s')}{2\sigma_y^2+u}\right)}{\sqrt{2\sigma_x^2+u}\sqrt{2\sigma_x^2+u}} du$$

X and Y are normalized betatron coordinates at s' as

$$\begin{aligned} X(s,s') &= \sqrt{2J_x}\cos(\varphi_x(s') + \phi_x(s)) \\ Y(s,s') &= \sqrt{2J_y}\cos(\varphi_y(s') + \phi_y(s)). \end{aligned} \tag{5}$$

where $\varphi_{x,y}(s')$ is the betatron phase difference between s and s'.

The Fourier component, which correspond to resonance strength, is given by

$$U_{m_x,m_y}(J_x,J_y) = \frac{\lambda_p r_p}{\beta^2\gamma^3}\oint ds \int_0^\infty \frac{du}{\sqrt{2\sigma_x^2+u}\sqrt{2\sigma_y^2+u}}$$
$$\Big[\delta_{m_x0}\delta_{m_y0} - \exp(w_x - w_y)(-1)^{(m_x+x_y)/2}$$
$$I_{m_x/2}(w_x)I_{m_y/2}(w_y)e^{-im_x\varphi_x - im_y\varphi_y}\Big]. \tag{6}$$

The tune slope $\partial^2 U_{00}/\partial J_x^2$ in Eq.(3) induced by space charge potential is obtained as follows. The tune slope is evaluated by $U_{00}(J_x,J_y)$ in Eq.(7).

$$U_{00}(J_x,J_y) = \frac{\lambda_p r_p}{\beta^2\gamma^3}\oint ds \int_0^\infty \frac{d\eta}{\sqrt{2+\eta}\sqrt{2r_{yx}+\eta}}$$
$$(1 - e^{-w_x-w_y}I_0(w_x)I_0(w_y)). \tag{7}$$

where $r_{yx} = \sigma_y^2/\sigma_x^2$ and

$$w_x = \frac{\beta_x J_x/\sigma_x^2}{2+\eta}. \qquad w_y = \frac{\beta_y J_y/\sigma_y^2}{2+\eta/r_{yx}}. \tag{8}$$

$$\frac{\partial}{\partial J_x} = \frac{\beta_x/\sigma_x^2}{2+\eta}\frac{\partial}{\partial w_x}. \qquad \frac{\partial}{\partial J_y} = \frac{\beta_y/\sigma_x^2}{2r_{yx}+\eta}\frac{\partial}{\partial w_y}. \tag{9}$$

TRANSVERSE MULTI-PASS BEAM BREAKUP SIMULATION FOR KEK ERL LIGHT SOURCE

S.Chen*, M.Shimada, N.Nakamura, D.Zhou, KEK, Oho 1-1, Tsukuba, 305-0801, Japan
K. Liu, S. Huang, IHIP, Peking University, Beijing 100871, China

Abstract

In this paper, simulation results of the transverse multi-pass beam breakup for KEK ERL light source are presented.

INTRODUCTION

An X-ray synchrotron light source based on a multi-GeV ERL is under design in KEK, which is expect to be a successor of the existing synchrotron light sources of Photon Factory in KEK [1]. A preliminary design report of this project has been published in 2012 [2,3]. An average beam current up to 100mA is required for KEK ERL light source. It is known that the multi-pass transverse beam breakup could be a possible limitation to the average current. It is primarily contributed by a positive feedback between the recirculated bunch with transverse offset and insufficiently damped dipole HOMs in superconducting cavity. If the average current is larger than a certain value which is called threshold current, exponential growth of HOM power and transverse oscillation amplitude will occur and thus cause beam breakup. A two-dimensional analytical formula for the multi-pass BBU threshold current is [4]

$$I_{th} = -\frac{2pc}{e(\frac{\omega}{c})(\frac{R_d}{Q})Q_{ext}M_{12}^{*}\sin(\omega T_r)}, \qquad (1)$$

where (R_d/Q) is the shunt impedance of the dipole mode in the cavity, Q_{ext} is the external quality factor, ω is the HOM frequency, T_r is the bunch recirculating time, and

$$M_{12}^{*} = T_{12}\cos^2\theta + \frac{1}{2}(T_{14}+T_{23})\sin 2\theta + T_{34}\sin^2\theta,$$

where T_{ij} are the elements of the pass-to-pass transport matrix and θ is the polarization angle of the dipole HOM.

Eq. 1 shows the main determinants of multi-pass BBU instability in an ERL. This formula only valids in the case of single cavity, single HOM and $M_{12}^{*}\sin(\omega T_r) < 0$. In real cases, the situation is more complicated. It's necessary to use simulation codes to compute the BBU threshold current. In this paper, the code *bi* [5] based on particle tracking is used to simulate the multi-pass BBU effect of KEK ERL light source. Some features of the BBU of high energy ERLs are then discussed based on the simulation results.

KEK 3-GeV ERL LIGHT SOURCE

Several linac configurations have been designed for KEK ERL light source. In this paper, we are referring two of them. One configuration consists of 28 cryomodules with 8 cavities in each cryomodule. The cavity gradient is about 13.4 MV/m and the full energy is about 3.01 GeV [2]. The other configuration consists of 34 cryomodules of the same structure. The cavity gradient is about 12.5 MV/m and the full energy is about 3.41 GeV [6].

To improve the dipole HOM damping, a 9-cell KEK-ERL mode-2 cavity (shown in Fig. 1) with a larger iris diameter compared with TESLA-type cavity and two large beam pipes to provide stronger HOM damping [7]. Several major dipole HOMs in the mode-2 cavity are listed in Table 1. A previous work shows the BBU threshold current of more than 600 mA can be achieved when applying this type of cavity to a 5-GeV ERL configuration [8].

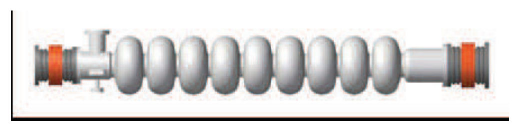

Figure 1: 1.3 GHz 9-cell KEK-ERL mode-2 cavity

Table 1: Major Dipole HOMs in KEK-ERL 9-cell Cavity

f GHz	Q_e	R/Q Ω/cm^2	$(R/Q)Q_e/f$ $\Omega/cm^2/GHz$
1.835	1.1010×10^3	8.087	4852
1.856	1.6980×10^3	7.312	6691
2.428	1.6890×10^3	6.801	4732
3.002	2.9990×10^4	0.325	3246

4.330	6.0680×10^5	0.018	2522

BBU SIMULATION RESULTS

Lattice Configuration

The focusing effect of the RF field in the superconducting cavity is considered in the simulation. The Rosenzweig's form of the transport matrix for a pure π-mode standing-wave cavity [9] is applied in the simulation, i.e.,

$$M_{cav} = \begin{pmatrix} \cos\alpha - \sqrt{2}\sin\alpha & \sqrt{8}\frac{\gamma_i}{\gamma'}\sin\alpha \\ -\frac{3}{\sqrt{8}}\frac{\gamma'}{\gamma_f}\sin\alpha & \frac{\gamma_i}{\gamma_f}\left[\cos\alpha + \sqrt{2}\sin\alpha\right] \end{pmatrix}, \qquad (2)$$

where $\alpha = \frac{1}{\sqrt{8}}\ln\frac{\gamma_f}{\gamma_i}$, $\gamma_{i(f)}$ is the initial (final) relativistic factor of the particle, $\gamma' = qE_0\cos(\Delta\phi)/m_0c^2$ where E_0 is the maximum particle energy gain from the RF cavity and $\Delta\phi$ is the phase of acceleration.

SPACE CHARGE SIMULATION AND MATCHING AT LOW ENERGY SECTION OF J-PARC LINAC

S. Artikova, Y. Kondo, T. Morishita, JAEA, Tokai-Mura, Japan

Abstract

An intensity upgrade of Japan Proton Accelerator Research Complex (J-PARC) included the installation of a new ion source (IS) and a radio-frequency quadrupole (RFQ) which to be used at first stage of acceleration. The linac is divided into two sections on the basis of operating frequencies and three sections on the basis of family of RF cavities to be used for the acceleration of 50 mA beam of H^- ions from 50 keV to 400 MeV. Low energy part of linac consists of an IS, a two-solenoid beam transport (LEBT) and the RFQ. The transition from one section to another can limit the acceptance of the linac if these are not matched properly in both longitudinal and transverse plane. Initially, we have calculated the acceptance of the RFQ at zero current in which space charge effects are not considered. In addition, a particle tracking technique is employed to study the space charge effects in LEBT of the J-PARC linac after the intensity upgrade in order to match the beam to the RFQ. Also, RFQ tank level and intervene voltage calibration factor is determined by comparing the simulation results of the beam transmission with the test measurement of tank level vs. transmission.

INTRODUCTION

J-PARC - the Japan Proton Accelerator Research Complex is a high intensity proton accelerator facility located at Tokai village in Japan [1]. A new linac front-end had been installed for intensity upgrade in 2014, July-September [2]. It consists of a 50 keV IS, a two-magnetic solenoid based LEBT and 324 MHz RFQ accelerating H^- beam to 3 MeV. To support commissioning of J-PARC linac, General Particle Tracing (GPT) code [3] is used for H^- beam dynamics simulations. The particle tracking technique using 3D field-maps is a convenient tool to study the charged particle dynamics in electromagnetic fields. The goal is to optimize beam quality and transmission through the accelerator and to prepare the beam for the next section. For high intensity, low energy ion beams the electric field created by space charge reveals defocusing effect and is non-linear as induced by the non-uniform distribution of charge density. This defocusing effect can be compensated by transporting the low energy beam in space charge neutralization regime. Here we discuss the process of creating a partially-neutralized beam and examine the effects of space charge on the beam emittance. For optimizing the beam matching to the RFQ transverse emittance measurements are also used in simulations. RFQ acceptance with zero current and taking into account the space charge is determined. RFQ tank level and intervene voltage calibration factor is found by comparing the simulation results of the beam transmission with the measurement of tank level vs. transmission.

LEBT

Low energy part of linac consists of an IS, LEBT and the RFQ. The length of LEBT is approximately 566 mm. It consists of two short solenoid magnets, a gate valve and a diagnostic chamber which has a vacuum partition plate with an orifice of 15 mm. The solenoid magnets can produce a magnetic flux of 1.1 T. Solenoid based magnetic focusing transport system has been confirmed to be superior for the injection of the RFQ used to accelerate H^- beams. In the transport of high current low energy ion beams the space charge forces are most prominent. In the LEBT, the H^- beam traverses a region containing H_2 background. The vacuum level at upstream and downstream of LEBT is 3×10^{-3} Pa and 2×10^{-5} Pa, relatively. H^- beam and H_2 interaction is possible in two channels: detachment of an electron from the beam and ionization of the H_2. The compensation of space charge effects by charge neutralization using secondary particles produced in the interaction between ion beam and residual gas can significantly reduce the required focal strength and reduce emittance degradation.

Transverse Beam Emittance Measurement from IS Test Stand

At IS test stand a slit-and-grid emittance-meter located after the first solenoid and measurements for 66 mA beam were taken. The horizontal and vertical emittances are measured by using two sets of W-slit emittance monitors, each of them is composed of a movable slit and a movable Faraday-Cup with slit (FCS) [4]. Each slit has an opening of 0.1 mm. The measured emittance is visualized by randomly plotting dots, whose number is proportional to the current detected by the FCS and is normalized to make the total number 10 000, in each mesh area defined by the moving steps (0.2 mm and 2 mrad) and the positions of the slit and the FCS. 3D raw data analysis is shown in Fig. 1. To suppress the background noise, an arbitrary threshold is applied to cut off some data. Obviously, this can effect the tail of the beam. Gray area shows where the intensity is higher than the threshold and the main part of particles are situated approximately in this area. The knowledge of beam phase space at the IS exit is essential for transverse matching of the beam into the RFQ. For this reason, an algorithm to reconstruct the beam phase space distribution from emittance measurement developed and can be used to find the optimized solenoid settings for transverse matching. 3D field maps of solenoid magnets and the RFQ are calculated by CST EM Studio Suite.

MEASUREMENT RESULTS OF THE IMPEDANCE OF THE RF-CAVITY AT THE RCS IN J-PARC

Y. Shobuda, H. Harada, H. Hotchi, J-PARC Center, Ibaraki, Japan

Abstract

The kicker impedance dominates at the RCS in J-PARC. Recently, we observe beam instabilities, which are not explained by the kicker. As a candidate causing the beam instability, the impedance of the RF-cavity is measured. The longitudinal impedance is measured by stretching a single-wire inside the cavity. On the other hand, the measurement of the transverse impedance is done by horizontally shifting the single-wire, due to the accuracy problem. The measured impedance is too low to explain the beam instability.

INTRODUCTION

The Rapid Cycling Synchrotron (RCS) in Japan Proton Accelerator Research Complex (J-PARC) [1] is a machine, where protons are accelerated from 400 MeV to 3 GeV during 20 ms. The injection beam from the LINAC is accumulated there during 500 μs in synchronization with the excitation of the injection bump magnets [2].

The role of the RCS is to deliver the proton beam to the Material and Life Science Facility (MLF)-target as well as to work as the injector to the main ring in J-PARC. Main objective of the RCS is to routinely supply one mega-watt beam (8.3×10^{13} particles per a pulse with the repetition rate 25 Hz) to the MLF-target.

Let us consider a situation that 8.3×10^{13} particles per a pulse are accelerated, where the chromaticity is corrected only at the injection energy. When the bunching factor of the beam and the tune-tracking are inadequately manipulated during the ramping process [3], we can observe beam instabilities [4]. However, the characteristic of the beam behavior can be understood by assuming that the cause of the instability mainly attributes to the kicker impedance. In this sense, the RCS is characterized by the machine where the kicker impedance dominates, from an impedance point of view [3–7].

At the high intensity proton beam, the space charge effects produce large tune spreads. Thereby, some particles cross resonance lines, which are the source of the particle losses. In order to avoid the particle loss, the typical horizontal and the vertical operation tunes of the RCS are chosen to be $\nu_x = 6.45$ and $\nu_y = 6.42$, respectively, at the injection period [8].

To make matters worse, the resonance lines severely restrict the allowable operation region near the present tunes ($\nu_x = 6.45, \nu_y = 6.42$) at the RCS. Accordingly, a trial was done to change the operation tunes to the other ones ($\nu_x = 5.86, \nu_y = 5.86$). This is because significant resonance structures cannot exist there from a viewpoint of magnetic error sources.

Contrary to our expectations, significant beam instabilities are observed under the operation tunes.

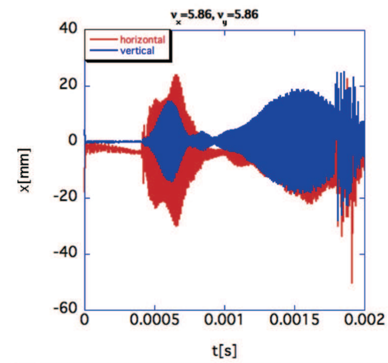

Figure 1: Beam instability observed at $\nu_x = \nu_y = 5.86$.

The measured results are shown in Fig. 1. The horizontal and the vertical axes show the acceleration period and the transverse position of the beam, respectively. The red and the blue lines show the horizontal and the vertical beam positions, respectively. The chromaticity is corrected only at the injection energy by quarter against the full chromaticity correction. The particle per a bunch is only 1.32×10^{13}, which is equivalent to 316 kW beam. Considering 1MW-equivalent beam is already achieved at the RCS [8], the impedance source is incredibly huge. To tell the truth, the beam power is weaker and the conditions (partial correction of the chromaticity) may rather stabilize the beam.

The results in Fig. 1 demonstrate that the beam becomes unstable around 1.5 ms. However, the injection bump magnets are perfectly turned off at that time. Consequently, it is hard to consider that the instability attributes to the field errors due to the injection bump magnet [9, 10]. Moreover, the beam instability is not related to x-y coupling, because the instability occurs even when one of the transverse tunes sits on $\nu_x = 5.86$ or $\nu_y = 5.86$ lines, independently.

Now, it is necessary to review the impedance source causing the unexpected beam instabilities, and to specify the impedance source along the RCS. As a first step, let us measure the impedance of RF-cavity. In the next section, let us see the measurement scheme and the results.

MEASUREMENTS

A schematic picture of RF-cavity is shown in Fig. 2. Four chambers are connected through three ceramic breaks (red). The chambers are surrounded over six Magnetic Alloy cores (blue). The inner radius of the chamber is 123.5 mm.

DYNAMIC APERTURE STUDIES FOR THE FCC-ee*

L. Medina†, Universidad de Guanajuato, Leon, Mexico
R. Martin, Humboldt-Universität zu Berlin, Germany
R. Tomas, F. Zimmermann, CERN, Geneva, Switzerland

Abstract

Dynamic aperture (DA) studies have been conducted on the latest *Future Circular Collider – ee* (FCC-ee) lattices as a function of momentum deviation. Two different schemes for the interaction region are used, which are connected to the main arcs: the crab waist approach, developed by BINP, and an update to the CERN design where the use of crab cavities is envisioned. The results presented show an improvement in the performance of both designs.

INTRODUCTION

The FCC-ee is a proposed high luminosity e^+e^- collider [1,2] with a center-of-mass energy from 90 to 350 GeV. The ring has separate beam pipes for electrons and positrons, which intersect at two or four interaction points (IPs). The FCC-ee is a potential intermediate step in a global study towards a 100 TeV hadron collider –the FCC-hh– sharing the same 100 km tunnel. A first parameter set, used as a basis for the design study, has been published [3]. One of the main constraints of the FCC-ee design is the imposed limit of 50 MW of synchrotron radiation per beam. Four operation energies have been proposed, with beam energies of 45 , 80 , 120 , and 175 GeV, corresponding to the Z pole, the WW threshold, the HZ cross-section maximum, and the top pair threshold, respectively.

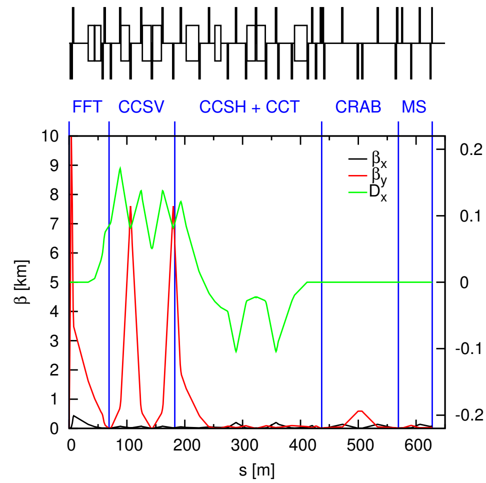
The present DA studies have been performed for the lattice at a beam energy of 175 GeV, for which the off-momentum DA is most critical.

Table 1: Lattices Under Study

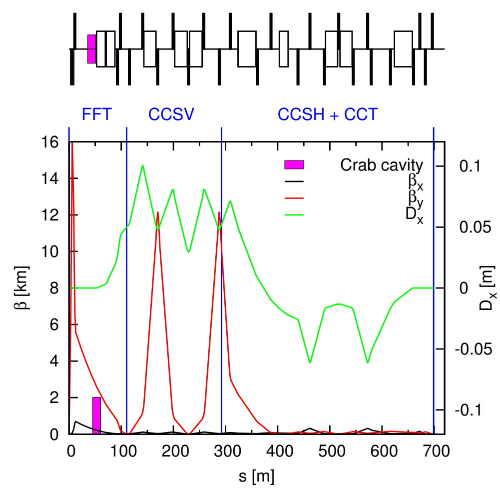
Opt.	Ring	Interaction Region	Comments
1	R-v14	CW-v13	Crab off
2	R-v14	CW-v14	Crab off, set 1
3	R-v14	CW-v14	Crab off, set 2
4	R-v14	CW-v14	Crab on, set 2
5	R-v16	CW-v14	Crab off, set 2
6	R-v16	Small crossing angle	Crab cavity

LATTICES

Six main lattices, called options 1 to 6 in Table 1, have been studied. In our model, the main arc is enclosed by the left and right sides of the interaction region (IR), with the interaction point located at their respective ends; the complete ring is a sequence of four of this structures (i.e. 4 IPs). Each of the main arcs is composed of three arcs and two RF cavity sections. Ring versions 14 (R-v14) and 16 (R-v16) differ in the structure of the basic arc cell, the number and position of the arc sextupoles, and the horizontal phase advance attained, namely 90° for R-v14, and 79.2° for R-v16 [4]. A set of quadrupole strengths for the basic arc cells of R-v16 with 90° phase advance is also available, but this configuration has not been explored.



(a) Crab waist scheme.



(b) Small crossing angle scheme.

Figure 1: General layout and optical functions of the IR.

The first design for the IR follows a crab waist (CW) scheme [5, 6]; the advantage of such approach is the higher luminosity at the lower beam energies. Its general layout and beta functions are shown in Fig. 1a, and consists of a final telescope (FFT), dedicated chromaticity correction sections for both transverse planes (CCSV and CCSH), a chromaticity correction telescope (CCT) that also provides

THE COUPLING IMPEDANCE MEASUREMENT OF THE FAST EXTRACTION KICKER IN CSNS/RCS *

Liangsheng Huang#, Yudong Liu, Sheng Wang, CSNS/IHEP, CAS, Dongguan, 523803, China

Abstract

The Rapid Cycling Synchrotron of the China Spallation Neutron Source is a high intensity proton accelerator. In order to high intensity beam operation, the beam coupling impedance of the extracted kicker must be controlled. The measurement of longitudinal and transverse coupling impedance of the fast extraction kicker is described.

INTRODUCTION

The electromagnetic interaction of a charged particle beam with its surroundings in the accelerator is conveniently described by the coupling impedances of its components. Coupling impedance and its instability budget are the important part of designing of a high intensity accelerator. Impedance measurement on the bench is a useful method to study the impedance [1] [2].

China Spallation Neutron Source (CSNS) is a high intensity proton accelerator based facility, which consists of an H- Linac, a Rapid Cycling Synchrotron (RCS) and two beam transport lines [3]. It accumulates and accelerate proton beam from 80 MeV to 1.6 GeV. The bunch length is range from 460 ns on injection to 80 ns on extraction. To achieve high beam current, the impedance must be carefully studied. The extraction kicker is the vital component devoted to the impedance. There are eight fast extraction kickers and the No. 2 kicker is measured. Figure 1 shows the kicker system. The main part of the kicker is the window-frame geometry ferrite with the material of CMD5005 [4]. The side strap connects the upper and lower busbar plates, and the busbar and the window-frame ferrite are located in a vacuum vessel, 0.58 m length. The power of the magnet comes from the PFN via the 130 m length cable. It is difficult to theoretically calculate the impedance for the complicated structure. Thus studying the impedance by measurement is a relevant method.

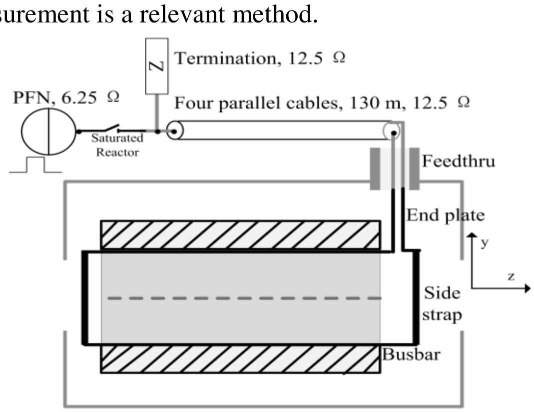

Figure 1: The extraction kicker system.

MEASUREMENT METHOD

The assign of measurement is measure longitudinal and vertical impedance of the kicker system on range from 1 MHz to 100 MHz. Figure 2 shows the schematics of longitudinal impedance measurement with coaxial transmission line and transverse impedance measurement by the twin-wire and the loop method. The copper wire with 0.5 mm diameter is stretched in the Device Under Test (DUT) with the appropriate resistor for matching to the 50 Ω cables at both ends, and the matching resistor is mounted by 35 mm sucobox [5]. The Vector Network Analyzer (VNA, Agilent E5071C) is connected to measure the S_{21} and the input impedance. Four attenuators with 6 dB between the hybrid and the DUT are applied in the transverse impedance measurement by the twin-wire. The differential-mode signal in transverse measurement can be obtained by Hybrid ZFSCJ-2-1-N [6].

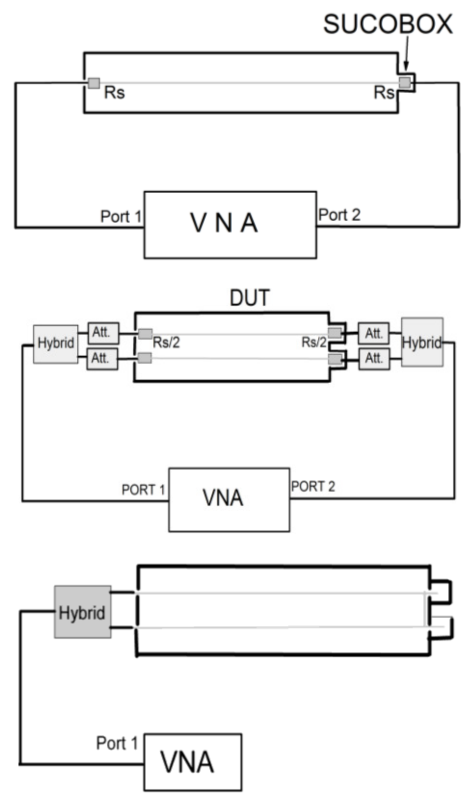

Figure 2: The schematics of longitudinal impedance measurement (coaxial transmission line, top) and transverse impedance measurement (twin-wire, middle and loop method, bottom).

The longitudinal and transverse coupling impedance in the measurement can be obtained as formulas

ADS INJECTOR I FREQUENCY CHOICE AT IHEP

Fang Yan, Shilun Pei, Huiping Geng, Cai Meng, Huafu Ouyang, Yaliang Zhao
Key Laboratory of Particle Accleration Physics and Technology, Institute of High Energy Physics (IHEP), Chinese Academy of Science, Beijing 100049, China

Abstract

The China ADS driver linac is composed of two major parts: the injector and the main linac. There are two frequency choices for the injector: 325 MHz and 162.5 MHz. The former choice is benefit for the same frequency with the front end of the main linac. For half frequency choice, to obtain the same longitudinal acceptance of the main linac comparing with 325 MHz injector, the tune depression of the beam reaches the lower design limit of 0.5, no current upgrade opportunity is reserved; contrarily to get the same space charge effect, 16 more cavities would be the cost to get the same acceptance. However the disadvantage of the 325 MHz injector choice is the bigger power density of the copper structure CW RFQ and the smaller longitudinal acceptance of the SC section. The details of the comparing for the two frequency choices are introduced and presented.

INTRODUCTION

The China ADS driver linac is proposed to accelerate the CW proton beam up to 1.5 GeV with average beam current of 10mA. It consist two major components: the injector and the main linac as shown in Fig. 1. The injector part accelerate beam up to 10 MeV. The main linac boosts the energy from 10 MeV to 1.5 GeV. The injector is composed of an ECR source, a LEBT, a four vane type copper structure RFQ, a LEBT and a Superconducting (SC) linac. The MEBT1 undertakes the matching between the RFQ and SC section. There are two design strategies for the injector. Injector I scheme is on basis of 325 MHz RFQ and β=0.12 SC spoke cavity with same frequency. Injector II scheme is on basis of 162.5 MHz RFQ and SC Half Wave Resonator (HWR) structure with same frequency. Injector I scheme is benefit for the same frequency with the front end of main linac while Injector II has a frequency jump.

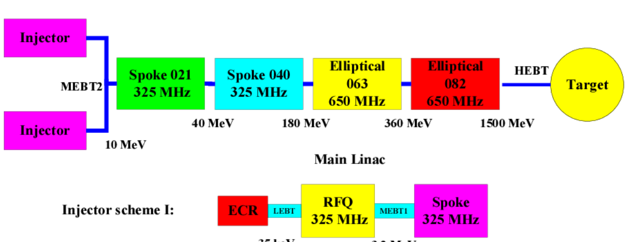

Figure 1: The general layout of the ADS linac in China.

*Work supported by Chinese Academy of Science (CAS) strategic Priority Research Program-Future Advanced Nuclear Fission Energy (Accelerator-Driven Sub-critical System).
#yanfang@ihep.ac.cn

The frequency jump has effects to the linac design on two aspects. On the one hand, 325 MHz choice is benefited for attenuated space charge effect comparing with half frequency if the longitudinal beam size out of injector kept the same for both frequency choices. The space charge effect is very crucial for the ADS applications (with final beam power of MW magnitude). Because nonrelativistic proton beam with stronger space charge effect is more sensitive to the mismatch and has bigger possibility inducing parameter/structure and coupling resonances and finally leading to halo growth and particle losses. Although space charge effect for 10 mA average current is not so strong, higher current upgrading opportunity is necessary to be kept for the future power upgrading.

On the other hand, if keeping the space charge effect to be the same, the longitudinal beam size out of the injector has to be increased for the 162.5 MHz choice. Bigger longitudinal beam size means more cavities numbers. To keep the same acceptance, the 325 MHz choice is benefit for less cavities leading to less cost at the whole downstream linac. However there are also drawbacks for the 325 MHz RFQ and SC linac of the injector. Finally 325 MHz is adopted for the ADS injector I at IHEP. The advantages and disadvantages of this choice will be introduced.

ADVANTAGES

The utmost design goal of a high intensity linac is controlling the beam loss along the linac as low as possible. The commonly acceptance of the beam loss rate is 1 W/m considering hands on maintenance. The higher the final beam power is, the more challenging to realize it. For China ADS project, the designed beam power on target is 15 MW, this means that the particle loss rate has to be controlled down to the magnitude of 1×10^{-8} /m at high energy part, this request is much higher than existing high intensity accelerators. To control the beam loss in design stage, on the one hand is keeping big enough acceptances. On the other hand is choosing a reasonable range for the tune depression of the beam.

Space Charge Effect

One important design principle for high current linac is to keep the tune depression of the beam bigger than 0.5 [1-2]. If half frequency is chosen for the China ADS injector, the particle charge in one bunch would be doubled under the condition that the longitudinal beam size keeping the same. For different average currents, the tune depressions are calculated for two different frequencies as shown in Table 1 on basis of the first SC

OPTIMIZATION OF THE MOMENTUM BANDWIDTH FOR FINAL FOCUS SYSTEM IN CEPC*

S. Bai[#], Y.W. Wang, D. Wang, H.P. Geng, J. Gao, T.J. Bian, M. Xiao, F. Su, IHEP, Beijing, China

Abstract

With the discovery of the higgs boson at around 125GeV, a circular higgs factory design with high luminosity ($L \sim 10^{34}\ cm^{-2}s^{-1}$) is becoming more popular in the accelerator world. To achieve such high luminosity, a final focus system in non-local chromaticity correction scheme with very low β functions at the interaction point is designed. The narrow momentum bandwidth is a crucial problem of this kind of design. It is shown that by introducing additional sextupoles the momentum acceptance of the CEPC final focus system can be increased by about a factor of four.

INTRODUCTION

With the discovery of a Higgs boson at about 125 GeV, the world high-energy physics community is investigating the feasibility of a Higgs Factory, a complement to the LHC for studying the Higgs [1]. There are two ideas now in the world to design a future higgs factory, a linear 125 × 125 GeV e^+e^- collider and a circular 125 GeV e^+e^- collider. From the accelerator point of view, the circular 125 GeV e^+e^- collider, due to its low budget and mature technology, is becoming the preferred choice to the accelerator group in China. In order to achieve high luminosity ($L \sim 10^{34}\ cm^{-2}s^{-1}$), the beam dimensions at the interaction point have to be extremely small, typically $\sigma_x^*\sigma_y^* \sim 10^{-11}\ cm^2$. This requires, in addition to small beam emittances, a beam-optical system which produces very low β functions at the interaction point. Unavoidably, the natural chromaticity of such a system becomes very large and its compensation difficult. On the other hand, high luminosity and overall efficiency of the collider calls for a high bunch intensity which in turn increases the momentum spread within a bunch due to the longitudinal wakefields in the linac. It is therefore clear that a large momentum acceptance of the final focus system (usually defined as the range of δp/p for which the spot size at the interaction point varies by less than a factor of two) is highly desirable.

In this paper, the limitation of the momentum bandwidth is first analyzed. An improved chromaticity correction section is achieved by adding Brinkmann sextupoles. The momentum bandwidth of the final focus system is then increased by a factor of four. The performance of the optimized system is investigated with particle tracking simulations.

-I TRANSFORMATION MATRIX BREAKDOWN

The CEPC final focus system are designed that the chromatic aberrations caused by the final focus doublet are compensated with a two-family non-interleaved sextupole distribution (Fig. 1). Each family consists of two identical sextupoles connected by a $-I$ transformer. The non-interleaved scheme of the sextupoles almost cancels the pure geometric aberrations from the sextupoles except for the aberrations produced by the finite thickness of the sextupoles.

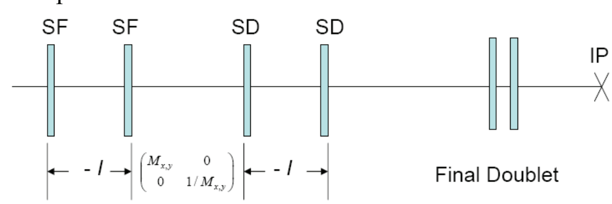

Figure 1: Sextupole families.

The increase of the vertical beam size due to the thickness l_s of the sextupole is written as [2]:

$$\Delta_y \equiv \frac{\Delta\sigma_y^{*2}}{\sigma_y^{*2}} = \frac{5}{12}\frac{k'^4\beta_y^4\varepsilon_{Ny}^2 l_s^2}{\gamma^2} \tag{1}$$

Where k', l_s and β_y are the strength, thickness of the SD sextupole and the vertical β function at the sextupole.

HIGH ORDER ANALYSIS IN CEPC FFS

Due to the breakdown of the $-I$, the non-linear kicks for off-momentum particles are no longer cancelled. The aberrations which caused by this will degrade the momentum acceptance for off-momentum particles. We analyzed the high-order aberrations of CEPC final focus system with different energy spread using a code called MAPCLASS [3] which is developed in CERN.

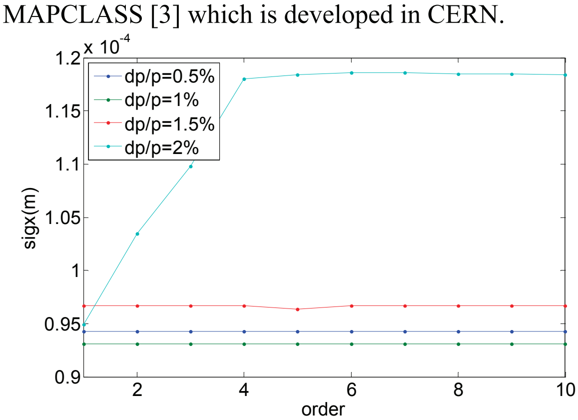

Figure 2: Order analysis of horizontal in CEPC FFS.

UNIFORMIZATION OF THE TRANSVERSE BEAM PROFILE BY A NEW TYPE NONLINEAR MAGNET*

Shengdong Gu# and Weibin Liu, Key Laboratory of Particle Acceleration Physics and Technology, Institute of High Energy Physics, Chinese Academy of Sciences, 19(B) Yuquan Road, Beijing 100049, China

Abstract

The uniform transverse profile beam is desirable in many beam applications. One method to get this type of beam distribution is using octupoles, but loss of particles in the halo will be produced by this method. To reduce the beam loss, a new type of magnet is proposed in this paper. The field in the middle region of the new type magnet is similar to the octupole magnet field, but the rate of rise decline quickly in the edge. So that the particle in the edge experience a lower magnet field compared with the octupole, and this would result in less particle loss. We also add a mechanical structure on the new type magnet to make it possible to adjust the size of middle region. So that the magnet can adapt to different transverse dimensions of the beam, and this would further reduce particle loss. Some numerical simulations have been done respectively with the octupole and the new type of magnet. The simulation results show that the new type of magnet could get the uniform distribution of particle beam with less particle loss. We are processing a magnet now, and an experiment to test the magnet will be arranged on CPHS.

INTRODUCTION

The beam with uniform spatial distributions is required in several practical applications such as irradiation of targets for isotope production, uniform irradiation of detectors for improved efficiency, irradiation of biological samples and materials. A general method to get a transverse uniform beam from a Gaussian profile beam is utilizing odd-order nonlinear focusing magnets. Many people have theoretically studied uniformization of the transverse beam profile with multipole magnets [1-4].

Yuri et al. have theoretically studied uniformization of the transverse beam profile using nonlinear-focusing forces produced by multipole magnets. They get distribution at the target is related to that at the multipole magnet position as follows [1],

$$\rho_t = \rho_0 \left(\frac{dx_t}{dx_0}\right)^{-1}$$
$$= \frac{\rho_0}{M_{11} - \frac{\alpha_0}{\beta_0} M_{12} - M_{12} \sum_{n=3}^{\infty} \frac{K_{2n}}{(n-2)!} {x_0}^{n-2}}$$
$$= \frac{\rho_0}{M_{11} - \frac{\alpha_0}{\beta_0} M_{12} - M_{12} \sum_{n=3}^{\infty} \frac{K_{2n}}{(n-2)!} {x_0}^{n-2}}$$

#gushengdong@ihep.ac.cn

Where $M_{ij} (i, j = 1,2)$ are the elements of M**.** M is the transmission matrix. Where K_{2n} is the 2n-pole integrated strength of the multipole magnet and the magnet is assumed to be a thin lens for simplicity's sake. Where ρ_0 and ρ_t are the particle density functions in the real space at the initial and at the target. Where β_0 and β_t are the beta functions at the initial and at the target. The initial particle distribution can be transformed into a different one at the target by using the nonlinear magnetic field.

Many beam distributions ρ_0 are Gaussian or can be fitting with Gaussian. After some algebraic transformation we can get all of the odd-order nonlinear fields are needed for transformation of an ideal Gaussian beam into a totally uniform beam. But the realistic case is that the multipole magnet produces only one nonlinear component. So we usually use the octupole magnet to get the uniform distribution beam. But loss of particles in the halo will be produced by this method. To reduce the beam loss, a new type of magnet is proposed in this paper.

THE NEW TYPE OF MAGNET

The new type magnet is shown in Figure 1. The top is the mode of the Opera 3D. And the bottom is the section of the central plane. To get a uniform distribution beam, the field in the middle region of the new type magnet is similar to the octupole magnet field. But the rate of rise decline quickly in the edge in the new type magnet. So that the particle in the edge experience a lower magnet field compared with the octupole, and this would result in less particle loss. We also add a mechanical structure on the new type magnet to make it possible to adjust the size of middle region.

Opera 3D is used for the new magnet design. The magnetic field of the new type magnet is compared with the magnet of the octupole for the distance between the C-type dipoles equal to 0.2m in the top of Figure 2. The magnetic field profiles are plotted at the centre plane. As we have mentioned, we would add a mechanical structure on the new type magnet to make it possible to adjust the size of middle region. The new magnet is separated for three parts (two C type dipoles and the shield block). The distance between the two dipoles can be changed with the mechanical structure. And the size of the middle region, the octupole-like region, can be changed with the distance change. The Figure 2 give the change of the magnet field with the distance from the centre. As shown in the Figure 2, the top figure is plotted while the distance is the minimum and the right figure is plotted while the distance is the maximum. While the distance is the minimum, the size of the middle region is also the minimum. The

SIMULATION ON BUILDUP OF ELECTRON CLOUD IN RAPID CYCLING SYNCHROTRON OF CHINA SPALLATION NEUTRON SOURCE *

Liu Yu-Dong#, Li Kai-Wei, Wang Sheng, Huang Liang-Sheng
IHEP, CAS，Beijing 100049, China

Abstract

Electron cloud interaction with high energy positive beam are believed responsible for various undesirable effects such as vacuum degradation, collective beam instability and even beam loss in high power proton circular accelerator. An important uncertainty in predicting electron cloud instability lies in the detail processes on the generation and accumulation of the electron cloud. The simulation on the build-up of electron cloud is necessary to further studies on beam instability caused by electron cloud. China Spallation Neutron Source (CSNS) is the largest scientific project in building, whose accelerator complex includes two main parts: an H- linac and a rapid cycling synchrotron (RCS). The RCS accumulates the 80Mev proton beam and accelerates it to 1.6GeV with a repetition rate 25Hz. During the beam injection with lower energy, the emerging electron cloud may cause a serious instability and beam loss on the vacuum pipe. A simulation code has been developed to simulate the build-up, distribution and density of electron cloud in CSNS/RCS.

INTRODUCTION

In high intensity proton circular accelerator, the electron cloud effect has been considered as one of the main sources of beam instability, which can lead to the uncontrolled beam loss [1]. This electron proton instability has been observed and confirmed in many commission proton circular accelerators, such as LANL PSR [2], KEK Booster [3], CERN PS [4] and SNS in ORNL [5]. The primary electrons produced by proton losses at the chamber surface attracted and accelerated by the body of bunch then released at the bunch tail or bunch spacing. The secondary electrons are produced and amplified when the accelerated electron hitting the chamber wall. This secondary electron multipacting attributes to the main source of electron cloud.

Table 1: The main parameters of the RCS/CSNS

Parameters	Injection	Extraction
Circumference C (m)	227.92	227.92
Energy E (GeV)	0.08	1.6
Bunch Population N_p (10^{13})	1.56	1.56
Revolution Frequency ω (MHz)	3.20	6.78
Bunch length σ_p (m)	48.931	22.285
Beam transverse size σ_x, σ_y (cm)	1.5, 1.5	1.2, 1.2
Pipe radius b (cm)	10	10

#liuyd@mail.ihep.ac.cn

A high intensity proton accelerator facility as neutron source proposed in past ten years and is being built in China, which is named China Spallation Neutron Source (CSNS) [5]. The facility is equipped with an H- linac and a rapid cycling synchrotron (RCS). A simulation code has been developed and benchmarked to ascertain detailed establishment of electron cloud in CSNS/RCS. The physical mechanism on primary electron production, its dynamics, secondary electron emission and electron accumulation is described in section II of this paper. By tracking dynamics of electrons with physical model in section II, a simulation code for obtaining distribution and density of electron cloud has been developed and benchmarked with other machines. With the beam parameters of RCS/CSNS, the process of electron cloud buildup is studied in different simulation conditions such as average beam loss rate, secondary electron yield, transverse and longitudinal beam profile, and beam intensity. Most of the simulations are performed in a field-free region mainly. The comprehensive simulation on electron cloud in RCS/CSNS gives the quantitative relation between electron density and beam parameters which is meaningful to the construction of RCS/CSNS.

PHYSICAL MODEL

The electron sources in proton circular accelerator may be classified into (1) electrons stripped at injection region; (2) electrons produced by proton loss incident the vacuum chamber; (3)secondary electron emission process; and (4) electrons produced by residual gas ionization. The stripped electrons generated near the stripping foil, which can be absorbed by installing a special collector at the injection region [7]. The yield of ionization electrons is determined by the ionization cross section and vacuum pressure in beam chamber. Because of the lower vacuum pressure about 10^{-7} Pa and ionization cross section for CO and H_2 approximately 1.3 MBar and 0.3 MBar, the ionization electrons can be neglected in simulation. In the electron dynamic tracking for RCS/CSNS, the primary electrons produced by proton losses and secondary electrons are considered.

These striking electrons may produce secondary electrons if their energy is high enough. The fraction between the emission electrons from pipe surface and the total incident electrons is defined as secondary electrons yield (SEY). If SEY is above 1, the electrons multipacting will happen. Actually, the secondary electrons include two types: elastic backscattered electrons and true secondary electrons. The yields of the true secondary electrons and elastic backscattered electrons can be expressed with formula (1) and (2) [8], respectively. In formula, δ_{max} is the

THEORY OF TRANSVERSE IONIZATION COOLING IN A LINEAR CHANNEL

Ming Xiao*, Jie Gao, Teng Yue
Key Laboratory of Particle Acceleration Physics and Technology,
Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China

Abstract

Ionization cooling is the most hopeful method to reduce the emittance of muon beams, which plays an important role in neutrino factory and muon collider. Within the moment-equation approach, we present a way to derive the formulae of emittance in transverse under linear channel. All heating and coupling terms are reserved in the deriving process. From our formulae, it is a way to achieve a small emittance by designing the cooling channel compact to make the beta function changing sharply.

INTRODUCTION

The physics potentials of neutrino factories and muon colliders have stimulated worldwide studies of the feasibility of high-energy muon accelerators. Ionization cooling of particles proposed a long time ago in [1]. Ionization cooling theory is being studied for a very long time. And this cooling channel is developed to reduce the emittance of muon beam for envisioned neutrino factory and muon collider. Basic concept of this proposal is that the friction force acting to the particle moving through the absorber, directed against instant velocity of particle. As the longitudinal component of momentum lost in absorber could be restored by the longitudinal electric field in a RF cavity, the loss of transverse component is not, so this process resulting emittance reduction. This process is similar to the one with radiation losses; in some sense excitation of betatron oscillation while emitting the quanta in a channel with nonzero dispersion is similar to the (multiple) scattering in absorber.

Ionization cooling in a quadrupole channel has been discussed extensively by many authors, especially Neuffer's cooling formulae in [2]. Neuffer's formulae of transverse cooling theory is

$$\epsilon_{xn} = \frac{\beta_\perp E_s^2}{2\beta E_\mu L_{rad}|\mathrm{dE/ds}|} \tag{1}$$

where $\beta_\perp$ stands for the betatron function, E_μ is the particle energy, L_{rad} is radiation length.

And, Wang and Kim have developed coupled cooling equations including dispersion, wedges, solenoids, and symmetric focussing [3][4][5][6].

SINGLE PARTICLE DYNAMICS

We consider an idealized uncoupled quadrupole channel with quadrupole strength $K(s)$; horizontal bending radius ρ. Using the standard Frenet-Serret coordinates $\{x, y, s\}$, the Hamiltonian can be written as

$$\begin{aligned} H =& \frac{1}{2}\{P_x^2 + [K(s) + \frac{1}{\rho^2}]x^2\} + \frac{1}{2}[P_y^2 - K(s)y^2] - \frac{\delta x}{\rho} \\ &+ \frac{1}{2}[\frac{1}{\gamma_0^2}\delta^2 + V(s)z^2] + \eta[xP_x + yP_y] + \eta_x xz \\ &- \sqrt{\chi}(\xi_x x + \xi_y y) - \sqrt{\chi_\delta}\xi_z z \end{aligned} \tag{2}$$

where $\{x, P_x\}$, $\{y, P_y\}$ are the horizontal and vertical canonical variables, and $\{z, \delta\}$ are the longitudinal canonical variables. And γ_0 is the Lorentz factor of the reference particle, $K(s)$ is the quadrupole strength, $\rho(s)$ is the horizontal bending radius, $V(s)$ is the RF focusing strength, δ is momentum deviation from the nominal momentum, η is a positive quantity characterizing the cooling force from energy loss, χ is the projected mean-square angular deviation per unit length due to multiple scattering, $\xi_{(x,y,z)}$ is uncorrelated unit stochastic quantities describing the fluctuation forces due to multiple scattering and energy straggling.

From eq.(2), one could get the equations of motion directly. Because the forces are linear, we use the Fokker-Plank equations to study the phase-space distribution.

FORMULAE OF TRANSVERSE IONIZATION COOLING IN A LINEAR CHANNEL

According to eq.(2), horizontal and vertical motions in the two transverse planes are uncoupled. It is sufficient to treat only the x phase space dynamics, so the Hamiltonian simplifies into the form:

$$H = \frac{1}{2}[P_x^2 + K_x(s)x^2] + \eta x P_x - \sqrt{\chi}\xi_x x \tag{3}$$

where $K_x(s) = K(s) + \frac{1}{\rho^2}$.

Then the single-particle equations of motion according to eq.(3) are:

$$\frac{\mathrm{d}x}{\mathrm{d}s} = \frac{\partial H}{\partial P_x} = P_x + \eta x \tag{4}$$

$$\frac{\mathrm{d}P_x}{\mathrm{d}s} = -\frac{\partial H}{\partial x} = -K_x(s)x - \eta P_x + \sqrt{\chi}\xi_x \tag{5}$$

After some algebra within eq.(4) and eq.(5), we obtained the second-order beam moments in x plane:

$$\langle x^2\rangle' = 2(\langle xP_x\rangle + \langle \eta x\rangle) \tag{6}$$

$$\langle xP_x\rangle' = \langle P_x^2\rangle - \langle K_x(s)x^2\rangle + \langle\sqrt{\chi}x\xi_x\rangle \tag{7}$$

$$\langle P_x^2\rangle' = -2(\langle K_x(s)xP_x\rangle + \langle\eta P_x^2\rangle - \langle\sqrt{\chi}P_x\xi_x\rangle) \tag{8}$$

Abstract

Scalable software package for beam dynamics simulation are playing more and more important role in precise design and optimization of the linear accelerator. In this paper, recent upgrades (version 2.0) on LOCUS3D, which is a parallel software developed for beam dynamics simulation, are introduced. The numerical methods are kept as before, but whole structure of the software has been rebuilt. These upgrades include optimized software structure, more reasonable arrangements of components, and capability of simulating several different kinds of particles with different charge states and masses. It also provides suitable structures for extension to use modern heterogeneous supercomputers. Standard accelerator devices have been tested again for this new version. The new software can run on several different platforms, such as INSPUR cluster, TIANHE-2, and BG/P at ANL. At last, some simulation results for DTL with large number of particles will be shown.

INTRODUCTION

Many beam dynamics codes [1-5] have been developed for beam dynamics simulations, but few of them were designed and developed specifically for efficiently use of the newly emerged software and hardware technologies for large supercomputers. LOCUS3D [6] was developed for meeting this purpose in 2013. It solves the Poisson's equation for the space charge effect, and the time integration algorithm uses sub-steps for effects of electric and magnetic fields separately. After several years of successful simulations, several places need improvements to meet more broad requirements.

In this paper, we explain several upgrades on the LOCUS3D. These upgrades include new data structure, software structure, and future extension for heterogeneous supercomputers. The new data structure setup new relations between different elementary classes, such as PtcSet, Bunch, Device and Solver etc. The new relation is based on natural relation between these concepts, which make them easier to be used for building applications in BDS. The new software structure separates functions based on different classes by different levels. High-level functions are built on low-level functions, and are made from them. Furthermore, new software structure provides extension, which can easy use the heterogeneous supercomputers in the future. These upgrades require new particle initialization module, time integration module, Poisson solver module, parallel model and parallel I/O module. The new version has been tested to simulate beam dynamics in the basic accelerator devices, such as multi-pole lenses, solenoid, and Drift Tube Linac (DTL). The parallel Poisson solver has been successfully redeveloped and benchmarked on the new Solver class. Besides the FFT Poisson solver, other numerical methods can easily build alternative solver under new software structure. This upgrade makes LOCUS3D more suitable to meet various demands exist in design and modelling of linear accelerators. Accelerator physicists and engineers can easily have features that satisfy their requirements. The paper will introduce the new data and software structure first, and then give benchmark and simulation results.

NUMERICAL METHOD

The numerical methods are similar, and can be divided into two parts: particle tracking and electromagnetic (EM) field computation, including external fields and space charge (SC) fields. Particle tracking is designed to have different time integration schemes for choices [7], which can be realised easily based on the new software structure. A parallel Poisson solver using Fast Fourier Transform (FFT) [8] has been developed for SC field computation. Currently LOCUS3D uses sub-steps to separates the effects of electric and magnetic fields, which is similar to the algorithm of BEAMPATH code. But it has many differences from B6EAMPATH, such as units of quantities, Poisson solver, parallel model, etc. Detail information can be found in our previous paper, which will be omitted in the following sections.

UPGRADE STRUCTURES

LOCUS3D was designed from beginning to be parallel software for complete beam dynamics simulations. It is based on MPI library, and object-oriented C++ language. It targets on modern supercomputers, such as TIANHE, BG/P, etc. After several years of successful running, we are upgrading it for many places in order to make its structure more reasonable in nature, easier for extension for simulating complex physics and for using modern supercomputers.

EMITTANCE EXCHANGE BEAMLINE DESIGN IN THU ACC LAB

Qiang Gao[1,2,#], Jiaru Shi[1,*], Huaibi Chen[1], Yingchao Du[1], Wenhui Huang[1], Wei Gai[1,2]
[1] Tsinghua University, Beijing 100084,China, [2] Argonne National Laboratory, Lemont, IL 60439, USA

Abstract

Emittance exchange (EEX) provides a novel tool to enhance the phase space manipulation techniques. This study presents a beamline design for exchanging the transverse and longitudinal emittance of an electron bunch based on the Tsinghua Thomson scattering experimental facility. This beamline consists of a 2.856 GHz half-one-half cell deflecting cavity with no axis offset and two doglegs. In this paper, by optimizing the beam envelope parameters for Tsinghua Thomson scattering source, we report the theoretical analysis and a good particle tracking simulation result about emittance exchange and longitudinal shaping.

INTRODUCTION

Since the emittance exchange (EEX) concept was firstly came up with in 2002 [1], lots of researches have been developed to optimize the exchange result for different applications. Theoretical analysis for identical dogleg-type exchanger presented an exact result contrast to chicane-type in 2006 [2]. A proof-of-principle transverse and longitudinal emittance exchange experiment conducted at Fermi Lab demonstrates the feasibility of EEX theory [3]. Although the initial motivation for EEX aims to attain an optimized transverse emittance for FEL, a significant innovation proposed in [2] and [4] which provide a novel tool for advanced phase space manipulation really extends the application of EEX and incites a new term research in bunch shaping for many kinds of accelerators. In the wakefield acceleration, a short and low energy but high current drive beam can create high gradient fields to accelerate trailing bunch. A novel shaped drive bunch to enhance the transformer ration which can extremely increase the acceleration efficiency has been proposed in Argonne AWA group based on EEX [5]. Now the experiment to achieve this specific shaped bunch is being conducted at Argonne. A similar beam shaping using emittance exchanger is presented in LANL [6].

Tsinghua University has been constructed a Thomson Scattering X-ray (TTX) beamline in 2009 [7], which aims at an ultra-fast, high flux, and tuneable X-ray source for advanced imaging applications. Based on this experimental facility, we design an EEX beamline to use RF deflecting cavity for bunch longitudinal shaping. Whether to shape electron bunch for wakefield accelerator or for tuneable subpicosecond electron bunch train generation [8], this EEX technique can be the spectacular tool in accelerator physics.

This paper is organised in three parts, firstly we report the theoretical design of EEX beamline based on TTX, and secondly we introduce the half-one-half deflecting cavity designed for EEX, finally the particle tracking simulation of emittance exchange and bunch shaping using this beamline is presented.

gao-q12@mails.tsinghua.edu.cn
* shij@tsinghua.edu.cn

ANALYTIC TRANSFER MATRIX

Generally, two identical doglegs sperated by a deflecting cavity consist the main components of EEX beamline. The transfer matrix of dogleg and deflecting cavity in first order can be written as

$$M_{DL}=\begin{bmatrix}1 & L_{DL}/2 & 0 & \eta\\ 0 & 1 & 0 & 0\\ 0 & \eta & 1 & \xi/2\\ 0 & 0 & 0 & 1\end{bmatrix}, M_C=\begin{bmatrix}1 & L_C & kL_C/2 & 0\\ 0 & 1 & k & 0\\ 0 & 0 & 1 & 0\\ k & kL_C/2 & k^2L_C/n & 1\end{bmatrix} \quad (1)$$

Where L_{DL},η,ξ,L_c,k denote respectively the whole length of two doglegs, dispersion, compression of one dogleg, and length, dimensionless strength of deflecting cavity. The factor n is related to the effective deflecting cavity length, and n equals 4 for one pill-box cavity. When particles pass through the dogleg, their horizontal and longitudinal momentum has an impact of dispersion η on their longitudinal and horizontal position respectively. Similarly, deflector relates the initial longitudinal and horizontal position to final horizontal and longitudinal momentum. On the condition that $1+k\eta=0$, this dogleg type EEX transfer matrix is

$$M_{EEX}=M_{DL}M_CM_{DL}=\begin{bmatrix}0 & \frac{L_C}{n} & m_{13} & m_{14}\\ 0 & 0 & k & \frac{k\xi}{2}\\ \frac{k\xi}{2} & m_{32} & \frac{k^2\xi L_C}{2n} & \frac{k^2\xi^2L_C}{4n}\\ k & m_{42} & \frac{k^2L_C}{n} & \frac{k^2\xi L_C}{2n}\end{bmatrix} \quad (2)$$

Where m_{ab} represents the function of parameters in expression (1). In order to achieve the exact phase space exchange (PSEX), additional quadrupoles are needed before the first dogleg so that we can shape the bunch to some specific shape. Figure 1 is the schematic of this beamline. In our design, by using four quadrupoles, we can transform the left bottom sub matrix of matrix M to an approximate identical matrix, so the final transfer matrix of our beamline can be written as

$$M_{PSEX}=\begin{bmatrix}0 & m_{12} & m_{13} & m_{14}\\ 0 & 0 & m_{23} & m_{24}\\ m_{31} & 0 & \sim 0 & \sim 0\\ 0 & 1/m_{31} & \frac{k^2L_C}{n} & \frac{k^2\xi L_C}{2n}\end{bmatrix} \quad (3)$$

Where ~0 denotes a small quantity approximating zero. Eq.3 explains that on the first order approximation, initial

EFFECT ON BEAM DYNAMICS FROM WAKEFIELDS IN TRAVELLING WAVE STRUCTURE EXCITED BY BUNCH TRAIN

Abstract

Electron bunch train technology is used to excited coherent high power RF radiation in travelling wave (TW) structures. This article concentrates on the analytical expression of wakefields excited by bunch train in TW structures and the effects of wakefields on beam dynamics. We focus on the first monopole mode and the first dipole mode wakefields. The long range wake function has a linear decrease which agrees well with the ABCi simulations. Taking example of the 11.7 GHz wakefields structure at the Argonne Wakefield Accelerator (AWA) facility, with 1.3 GHz interval drive electron bunch train, we have done the beam dynamics simulation with a point to point (P2P) code. Results shows the effects of wakefields on the energy distribution and the transverse instability for each sub-bunch.

INTRODUCTUION

Electron bunch train is used as drive beam to resonantly excited wakefields in travelling wave (TW) structure. In the two beam accelerator scheme in linear accelerators [1], driven beam is usually consists of *ps* sub-bunches, and the interval between bunches is the RF periods. The beam dynamics of the drive beam is affected by both the self-wake of each bunch and the long range wake from the head bunches. A lot of tracking codes can be applied to study the self-wake effect by means of a convolution integral or sum, based on the mesh technology, such as in ASTRA [2]. For the case of long range wake field effect caused by the head bunches, since the bunch interval is much longer than the bunch length, sub-bunches are always taken as point particles in order to reduce mesh and computation cost [3].

When concern about the motion of each particles in the drive beam, due to bunch instability such as beam break up (BBU) issue, we have to calculate the interaction between the wakefields and all the particles, thus a point to point (P2P) beam dynamics simulation code is desired. This paper starts from the analysis expression of the first monopole and the first dipole mode wake fields in TW structure. Taking the 11.7 GHz X-band TW PETS as an example, with drive bunch train of 1.3 GHz interval at the Argonne Wakefields Accelerator (AWA) facility, the P2P simulations show the longitudinal and transverse wake effects on each sub-bunch.

WAKEFIELDS IN TRAVELLING WAVE STRUCTURE

The Gradient of a Single Mode Wakefield

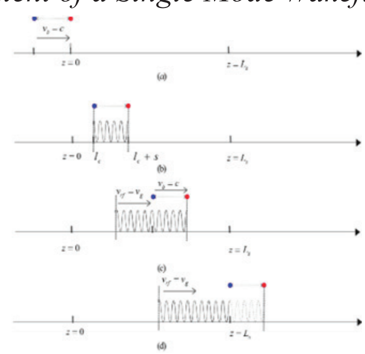

Figure 1: Single mode wakefields in TW structure.

When a drive particle with charge Q_d (red dot shown in Fig. 1) passing through a PETS of length L_s, wakefields is generated. Ignoring the attenuation, the electric field has constant gradient along Z direction for a single mode wake [4]. Once we know the parameters of the structure at certain mode, including the R over Q, relative group velocity β_g, and wake frequency ω, we can figure out the gradient. The gradient of the first monopole mode (TM_{01}) wake field is:

$$E^{//}_{w01}(s) = 2Q_d \cdot \kappa_{01} \cdot \cos\left(\frac{\omega_{01}s}{c}\right) \cdot H(s) \cdot Boolean(s \le L^{01}_w) \qquad (1)$$

Here k_{01} is the loss factor of TM_{01} mode, H(s) is the Heavenside step function and L^{01}_W is the duration of the wake field. The $Boolean(s \le L^{01}_W)$ in Eq. 1 declares the finite duration of wakefields in finite TW structure. For clarity we will omit the *Boolean* word in the following discussion. The duration of the wake is:

$$L^{01}_w(s) = L_S(1/\beta^{01}_g - 1) \qquad (2)$$

Loss factor in Eq. 1 is defined with the group velocity modification in TW structure

$$\kappa_{01} = \frac{\omega_{01}}{4}\left(\frac{R}{Q}\right)_{01}\frac{1}{(1-\beta^{01}_g)}$$

The loss factor of the structure and the drive particle charge determine the amplitude of the wakefield as a constant of $2Q_d \cdot k_{01}$.

Linear Decrease of the Wake Function

Wake function is used to describe the integrated wake field effect along the whole structure. The definition is

$$w_{//}(s) = -\frac{1}{Q_d}\int_0^L dz \cdot [E^{//}_W(s,z,t)]_{t=(z+s)/c} \qquad (3)$$

MEASURING DUKE STORAGE RING LATTICE USING TUNE BASED TECHNIQUE*

Wei Li[1,2†], Jingyi Li[1], Hao Hao[2], Stepan F. Mikhailov[2], Victor Popov[2], Ying K. Wu[2]
[1]NSRL, University of Science and Technology of China, Anhui, 230029, China
[2]DFELL/TUNL, and Department of Physics, Duke University, NC, 27708, USA

Abstract

The Duke electron storage ring is a dedicated driver for oscillator Free-Electron Lasers (FELs). A 34 m long straight section of the storage ring is used to host up to four FEL wigglers in several different configurations. A total of six wigglers, two planar OK-4 wigglers and four helical OK-5 wigglers, are available for FEL research. The storage ring magnetic lattice has to be designed with great flexibility to enable the storage ring operation with different FEL wigglers, at various wiggler settings, and for different electron beam energies. Since 2012, the storage ring has demonstrated all designed characteristics in terms of lattice flexibility and tuning. This work is aimed at gaining better understanding of the real storage ring lattice by performing a series of measurements of the beta-functions along the storage ring. Unlike the LOCO technique, the β-functions in the quadrupoles are directly measured with good accuracy using a tune measurement system. We will describe our experimental design and techniques, and measurement procedures. We will also report our preliminary results for the lattice characterization.

INTRODUCTION

The Duke electron storage ring is a dedicated driver for oscillator Free-Electron Lasers (FELs). This facility consists of three accelerators, a linac pre-injector (0.16 GeV), a booster injector (0.16 – 1.2 GeV), and an electron storage ring (0.24 – 1.2 GeV). In the south part of the storage ring, a 34 m long straight section is used to host up to four FEL wigglers in several different configurations. Two planar OK-4 wigglers and four helical OK-5 wigglers, are available for FEL research. To enable the storage ring operation with different FEL wigglers at various wiggler settings, and for different electron beam energies, the storage ring magnetic lattice has to be designed with great flexibility. The storage ring with a number of new wiggler configurations has demonstrated all designed characteristics in terms of lattice flexibility and tuning since 2012 [1]. This work is aimed at gaining better understanding of the real storage ring lattice by performing a series of measurements of the β-functions along the storage ring. This technique is different from the LOCO technique, β-functions in the quadrupoles are measured directly with good accuracy measurement using transverse feedback system [2, 3]. We will introduce β measurement method and measurement system, discuss tune changes related with beam current decay, influence of quadrupole hysteresis on β measurements, describe our experimental design and preliminary measurement results for the lattice characterization.

† weili@fel.duke.edu

MEASUREMENT METHOD AND SYSTEM

In a storage ring that quadrupole strength change can be controlled independently, β functions at the location of the quadrupole can be measured directly. A change in the quadrupole strength will cause a tune change proportional to the β-function at the quadrupole, we can measure β-functions by measuring the tune changes [4]. The relation between β-function and the changes in tune is given by:

$$\Delta\nu_{x,y} = \frac{1}{4\pi}\int_{quad}(\Delta K_1)_{x,y}\,\beta_{x,y}\,ds$$

$$\text{or } \left\langle \beta_{x,y} \right\rangle = \frac{4\pi\Delta\nu_{x,y}}{(\Delta K_1)_{x,y} L_{eff}}$$

where ν is the measured betatron tune, K_1 is the quadrupole strength, L_{eff} is the effective length of the quadrupole, and the measured $\langle\beta\rangle$ is the average β at the location of the quadrupole.

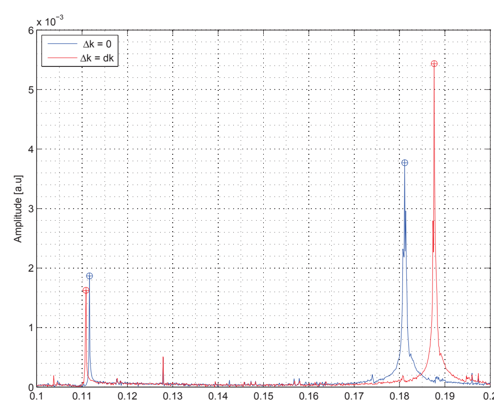

Figure 1: Tune signals measured with a network analyzer system, with a 638 MeV beam. The blue line is the nominal tune, the red line is the tune signal after a quadrupole is changed by $\triangle K_1$. The fractional nominal tune is [0.11, 0.18], the left peaks show the horizontal tune ν_x and the right peaks show the vertical tune ν_y.

This method of β-function measurement is based on tune measurements. The basic approach to measure the betatron tune of the electron beam is to excite the beam and measure its response. Two sets of tune measurement systems are

ELECTRON GUN LONGITUDINAL JITTER：SIMULATION AND ANALYSIS *

Liu Ming-shan, Pei Shi-Lun, Chi Yun-long, Sui Yan-feng, IHEP, Cas Beijing 100049, China

Abstract

Electron gun timing longitudinal jitter is fatal not only for electron beam performance but also for positron yield in routine operation of Beijing Electron Positron Collider (BEPCII) Linac, which has been observed many times practically. We simulated longitudinal jitter effect of electron gun using PARMELA during one cycle and analyzed its results about beam performance including average energy, energy spread, emittance and longitudinal phase of reference particle. It is concluded that longitudinal jitter of gun trigger time is seriously for maintaining good beam performance and stable operation, which also gives a salutary lesson to any other longitudinal jitter which can affect beam bunching in pre-injector.

INTRODUCTION

In 2006, the sub-harmonic bunching (SHB) system was installed on BEPCII linac pre-injector to obtain single bunch per beam pulse and to increase positron beam injection rate[1] from linac to storage ring, which is composed of electron gun, two sub-harmonic bunchers (SHB1 & SHB2), one 4-cell travelling wave buncher and a standard 3-m long accelerating structure[2-3] as shown in Fig. 1.

Figure 1: Schematic of the pre-injector.

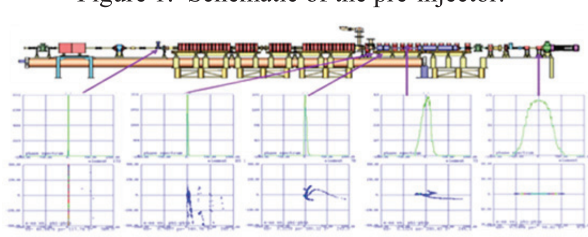

Figure 2: Schematic and simulation of bunching process.

Figure 2 is schematic of beam bunch process and simulation results at every bunch unit calculated by PARMELA when SHB system was designed[4]. The beam macro-pulse width at gun exit is 1ns FWHM with 1.6ns bottom width, after velocity modulation by SHB1 and SHB2, the beam length is ~900ps and 500ps at their exits without any real acceleration while it is ~60ps and ~10ps at buncher and A0 exit, respectively, beam energy is about 50MeV at A0 exit[3-5], which can be measured by an analysis magnet installed at A0 accelerator exit[6]. During bunch process, any variation in longitudinal sequence between pre-injector cells can be called longitudinal jitter that may deteriorate beam performance to some extent.

In order to ensure expected bunching results, physical tolerances in pre-injector were studied[7] when SHB system was designed, which are listed in Table 1. The electron gun is powered by a high voltage power supply and triggered by signal from timing system. SHBs are derived by independent power supplies with 142.8MHz and 571.2MHz microwave signals, As for buncher and A0 accelerator whose microwave comes from the 1st klystron, any perturbation of power and phase of its exporting microwave also give variation to beam performance. In other sense, timing stabilization between bunch cells in pre-injector was vital, any variation of them can cause longitudinal jitter.

Table 1: Physical Tolerance in the Pre-injector[8]

Jitter	Tolerance
Electron gun timing	±50ps
Electron gun high voltage	±0.4%
SHB phase	±1.5%
SHB power	±1.5%
Buncher phase	±2%
A0 accelerator phase	±2%

LONGITUDINAL JITTER MEASUREMENT

In electron gun trig system, electrons are emitted started by Trig On button and optimized by adjusting Delay or Fine Delay button in following operating interface as illustrated in Fig. 3. The units of them are nano-second and pico-second, respectively.

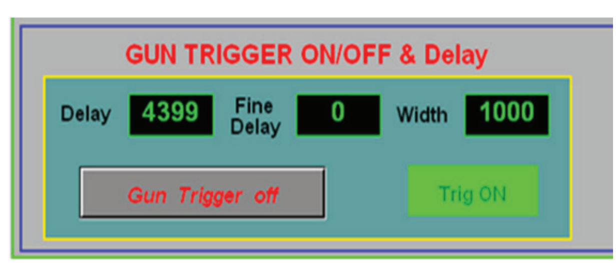

Figure 3: Operating interface of electron gun trigger.

For beam instrumentation, a beam current transformer (BCT1) is installed at gun exit, a beam current transformer(BCT2),a beam position monitor(BPM) and an Analysis Magnet are installed after A0 exit in sequence to measure beam parameters. The beam current and time

SUPPRESSION OF MICROBUNCHING INSTABILITY VIA A TRANSVERSE GRADIENT UNDULATOR

D. Huang*, C. Feng, H. Deng, D. Gu, Q. Gu, Z. Zhao
Shanghai Institute of Applied Physics, Shanghai 201800, China

Abstract

The microbunching instability in the linear accelerator (linac) of a free-electron laser facility has always been a problem that degrades the electron beam quality. In this paper, a quite simple and inexpensive technique is proposed to smooth the electron beam current profile to suppress the instability. By directly adding a short undulator with transverse gradient field right after the injector to couple the transverse spread into the longitudinal direction, additional density mixing in the electron beam is introduced to smooth the current profile, which results in the reduction of the gain of the microbunching instability. The magnitude of the density mixing can be easily controlled by turning the strength of the undulator magnet field. Theoretical analysis and numerical simulations demonstrate the capability of the proposed technique in the accelerator of an X-Ray free-electron laser.

INTRODUCTION

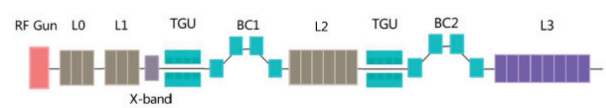
X-Ray free-electron lasers (FELs) are being developed to serve as ultra-short, tuneable, intensity radiation sources for advanced user applications. In the recent years, the successful user operation of the first FEL facilities in soft and hard x-Ray regimes announced the birth of the x-Ray laser. High intensity electron beams of sub-picosecond (sub-ps) length typically required for x-Ray FELs are usually obtained by compressing longer beams in magnetic bunch compressors at relativistic energies. The bunch compressor manipulates longitudinal phase space of the electron beam with a considerable energy chirp by introducing the dependence of particle's longitudinal position on their relative energy. The bunch length therefore can be significantly compressed by the compressor. However, in the compression process, the initial small energy and density perturbation in the electron bunch can be amplified with a large gain factor in many cases, which will increase the fragmentation of the longitudinal phase space and dilute the emittance. This process of amplification is usually known as the microbunching instability, and it will seriously degrade the FEL performance thereafter.

The microbunching instability can be suppressed by various techniques that rely on the electron beam manipulation. The idea of using a transverse gradient undulator (TGU) to mitigate the effects of electron beam energy spread in FEL oscillators has been initially described in reference [1]. Recently, this idea has been applied to laser-plasma accelerator driven high-gain FELs. It is found later that TGU is a functional device that provides an additional measure for manipulating the electron beam via transverse-to-longitudinal phase space coupling. One of the applications of this manipulation technique is to perform the phase merging effect for significantly improving the frequency up-conversion efficiency of a seeded FEL. In this paper, a quite simple and inexpensive technique based on the transverse-to-longitudinal phase space coupling is proposed and studied for suppression the microbunching instability of the electron beam. It is found that by directly adding a TGU after the injector in a linac, the gain of the microbunching instability in the electron beam can be effectively suppressed. Compared with the previous techniques, this method is quite simple and could be easily applied on all existing FEL facilities in addition to the laser heater. Moreover, the change of the chromaticity introduced by the scheme in this paper is ignorable and the transverse emittance of the beam is preserved well enough throughout the whole linac lattice after transverse matching, which is considered as another great advantage.

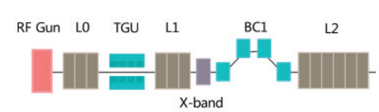
*huangdazhang@sinap.ac.cn

METHODS

The schematic layouts of the proposed technique are shown in Figure 1. In Figure 1(a), a short TGU is added after accelerating section L1 and another one is added after L2 in the linac, the linear energy chirp of the beam exists in both the locations. In Figure 1(b), one TGU is placed right after the injector where there is no energy chirp. The selections of the locations of TGUs will be discussed later on in this paper.



(a) Double TGU scheme



(b) Single TGU scheme

Figure 1: (Color) Layouts of two TGU schemes.

TGU, like what described by its own name, is an undulator with transverse gradient between magnetic poles. Such a device can be realized by canting the poles of an regular undulator and the gradient is usually made in the horizontal direction. Because electrons at different horizontal positions feel different magnetic fields, the path length of an electron traversing TGU depends on its transverse coordinate at the entrance of TGU. Because of

Abstract

Multi-Bend Achromatic (MBA) cell has been well known to significantly reduce the beam emittance of the synchrotron radiation light sources in the past two decades. With the great development of the high gradient magnets, the small-aperture vacuum chamber and the precise alignment, the ultimate-emittance ring based on MBA lattice became practical in recent years. We present a preliminary lattice design for the upgraded SSRF storage ring based on a 7BA lattice in this paper. The circumference and the number of the straight sections are preserved for the existing tunnel. The beam emittance is desired toward diffraction-limited of X-ray, as much as possible.

INTRODUCTION

SSRF has been operated for users experiments since 2009. It has 13 beamlines now, and about 40 beamlines will serve users around 2020 [1]. The storage ring of SSRF has 20 DBA cells (four folds), and the beam emittance is 3.9 nm.rad on the beam energy of 3.5 GeV. In the past several years, worldwide discussion about the diffraction-limited light source of X-ray was frequently made. The beam emittance of many synchrotron light sources is designed to reach the order of 100 pm.rad, and lots of operated machines have the same upgrade considerations or plans [2]. In order to increase the photon brightness by a factor of about 100, SSRF has a preliminary upgrade plan (SSRF-U) to reduce the beam emittance by a factor of 10, reduce the beam energy to 3.0 GeV, and appropriately increase the beam current. In the following section, the lattice design of the SSRF-U storage ring is presented.

LATTICE AND BEAM PARAMETERS

The lattice of the SSRF-U storage ring is based on 7BA, because it is a good tradeoff between the emittance reduction and the cell lengthening. There are 20 cells and four folds, the same as SSRF. The upgrade ESRF-type [3] structure with beta and dispersion bump is applied due to its very effective chromaticity correction. There are only focusing quadrupoles in the arc cells, and all the defocusing gradients are provided by the combined dipoles. Six sextupoles are installed in the sections of the two beta and dispersion bumps of each cell in order to correct the chromaticity, and four harmonic sextupoles to correct the high order geometric aberrations. The maximum gradients of the quadrupole and sextupole are 80 T/m and 4000 T/m^2, respectively.

Figure 1 plots the liner optics of the SSRF-U storage ring, and Table 1 summarizes the main lattice parameters. A triplet of quadrupole beside the long straight section increase the horizontal beta function at the injection point to 25, in order that a sufficient dynamic aperture for beam injection can be obtained. The working point is optimized to be 43.22 in the horizontal plane and 17.32 in the vertical plane, and the natural emittance reaches down to 202.5 pm.rad with the beam energy of 3 GeV. Due to the IBS effect, the horizontal emittance will increase by about 37.7%, with the coupling of 10%, the RF frequency of 500MHz and the bunch current 0.4mA/bunch. A third harmonic cavity will reduce the horizontal emittance growth to 13.4%. The energy loss per turn in bare lattice is 0.44 MeV, and a RF voltage of about 2 MV can compensates the beam. The length of 5.6m of the standard straight section is left for IDs.

COMPENSATIONS OF DEPU EFFECTS AT THE SSRF STORAGE RING

M.Z. Zhang, Q.L. Zhang, S.Q. Tian, B.C. Jiang, M. Zhang, J.H. Tan
Shanghai Institute of Applied Physics, Shanghai 201800, P. R. China

Abstract

A pair of Apple-II type EPU (DEPU) is installed in the SSRF storage ring. They introduce closed orbit distortion, tune shift, coupling, reduction of the dynamic aperture and so on. The distortions and the compensations of these effects are described in this paper. Feedforward tables of corrector coils, quadrupole and skew quadrupoles are used to correct the COD, tune shifts and coupling, respectively. Sextupole optimization is used to correct the dynamic aperture.

INTRODUCTION

Shanghai Synchrotron Radiation Facility (SSRF) [1] is a dedicated third generation synchrotron light source with nominal energy of 3.5 GeV. A beam line (named 'Dream Line') of Angle Resolved Photoemission Spectroscopy (APRES) and Photoemission Electron Microscope (PEEM) has been built and installed at SSRF [2]. In order to get very wide photon energy and reduce the heat load to optics instrument simultaneously, two Apple-II type EPUs (DEPU) are used. The lower energy photon from 20 to 200eV is produced by U58 whose period is 58mm and minimal gap is 17mm. The higher energy photon from 200 to 2000eV is produced by U148 whose period is 148mm and minimal gap is 22mm.

EPU is widely used in the synchrotron radiation sources. The effects and compensations are well studied in many labs over the world [3]. There are many effects are introduced by the EPU [4][5]: closed orbit distortion, tune shift, reduction of the dynamic aperture, coupling. The effects and compensation on the real machine are described in this paper.

CLOSED ORBIT DISTORTION

The COD results from the nonzero 1st order integral fields (dipole errors) [5]. The dipole errors vary with the gaps and block position. The integral field of U148 and U58 both are about 200Gs-cm. The peak-to-peak values of the orbit distortion between the gap of 160mm and 22mm are 150um and 80um in horizontal and vertical plane. The large distortion affect the photon position and thus flux not only the dream line but also other beam lines. The integral fields also changes when the frame and shifts changed. Figure 1 shows the orbit positions vary with the shift position. The standard deviation of orbit distortion (COD) varies from 0 um to 25 um in horizontal and vertical plane. The maximum of orbit distortion introduced by frame position is about 200um at the edge of U148. Figure 2 shows the orbit distortion before and after correction when the gap of U58 varies, it rises rapidly when the gap is less than 60mm, the maximum value is 60 and 120um in horizontal and vertical plane. It seems to be in reverse to the square of the gap and consistent with theoretical calculation.

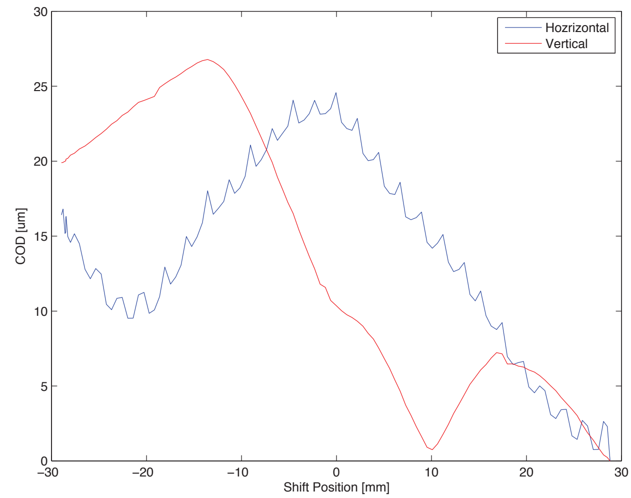

Figure 1: COD varies with the shift position.

There are 2 correction coils in each plane at the entrance exit of DEPU. In order to increase the tuning speed, one select analogy power supply. Scanning the correctors' strength with different gaps and shifts makes a feed forward table. Controller varies the power supply settings when it detects the gap change. This work takes lots of time to get the table data and tests at more and more gaps and shifts are still needed.

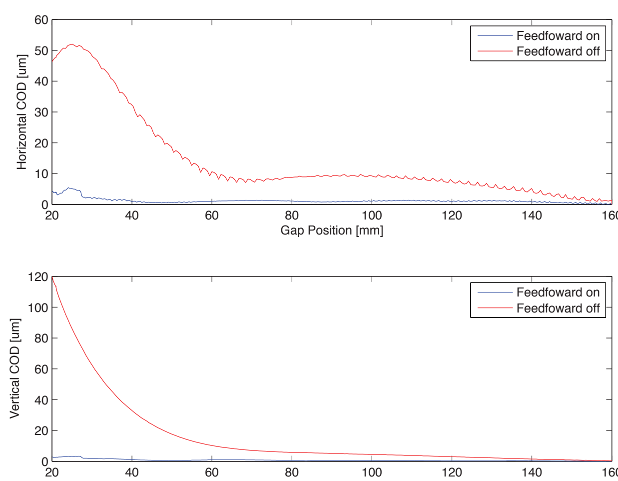

Figure 2: The CODs in both planes before and after correction during gap variation.

The feedforward reduces the COD to 5um. But it's still larger than the requirement of beam position stability. Slow and fast orbit feedbacks are needed during the daily operation to correction these distortions.

START-TO-END SIMULATION FOR RAON SUPERCONDUCTING LINAC

Hyojae Jang, Ji-Ho Jang and Hyunchang Jin, IBS, Daejeon, Korea

Abstract

An ion accelerator, RAON is going to be built in Daejeon, Korea by Rare Isotope Science Project(RISP) team in Institute of Basic Science(IBS). The linac part of RAON consists of two low energy linacs, one high energy linac and two bending section for transporting accelerated low energy ions to high energy linac. It is planned to accelerate many diverse ions like proton, carbon, calcium, uranium, etc. which have different A/q values. Consequently the lattice design for each ion and to investigate beam dynamics issues for each case are one of the important topics for this project. For enhancement of beam acceleration a study to suppress emittance growth and to maximize the longitudinal acceptance is conducted while designing the RAON lattice. In this presentation the designed linac lattices for various ions and start-to-end simulation results will be described.

INTRODUCTION

Nowadays the importance of an ion accelerator is increasing as it is an essential tool for research of medical, nuclear, material, science and many other areas. Since 2009 Rare Isotope Science Project (RISP) project has been going on in Korea to build an ion accelerator which can generate high-power ion beams and rare isotopes. [1]- [2] For acceleration of stable ions, electron cyclotron resonance ion source (ECR-IS) is going to be used while electron beam ion source (EBIS) and ECR-IS are going to be used as ion sources of isotope separation on-line (ISOL) system which will generate rare isotopes. Because the ions from these systems have various charge states they will be filtered to desired charge states in low energy beam transport (LEBT). Radio frequency quadrupole (RFQ) and medium energy transport (MEBT) will be installed after LEBT for beam acceleration and bunching. Superconducting linear accelerators start immediately after MEBT. They consist of two low superconducting energy linacs (SCL1 and SCL3), one high energy superconducting linac (SCL2), two bending section for bridging of linacs and one 120m beam transport for transporting high energy ions to high energy beam transport of IF(In-flight Fragment seperator) system. The layout of RAON superconducting linear accelerators is shown in Fig. 1. SCL1 accelerates stable ion beams while SCL3 accelerates rare isotope. Ions from low energy linacs are transported to high energy linac, SCL2. In this transport there are two charge strippers and charge selection selections between SCL1 and SCL2 and between SCL3 and SCL2. The charge state of ions become higher and it leads to the enhancement of acceleration efficiency. To provide high quality ion beams, RAON adopted superconducting cavity and normal conducting quadrupole doublet structure for linac lattice. The Bunch frequency of the linear accelerator is 81.25 MHz. There are four kinds of cavities in RAON. Quarter wave resonators (QWR) will be used at the first part of low energy linac and this section is called as SCL11 and SCL31. Half wave resonators (HWR) are going to be used for the rest of low energy linac and this section is called as SCL12 and SCL32. In high energy linacs (SCL2) two kinds of single spoke resonators (SSR) which have dfferent geometrical betas are going to be used and they are called as SCL21 and SCL22. Selected optimum betas were β_g=[0.047,0.12,0.3,0.51]. Also the accelerating voltages according to beam beta are shown in Fig. 2.

Each period in linac consists of a cryomodule containing superconducting cavities, one quadrupole doublet and a beam box which will be used for vacuum pumping, installing the diagnostics. Also recently transport line for transporting high energy is designed. In this section there are two cryomodules which are similar to the cryomodules used in SCL22 section. Summarized parameters of each linac section for stable ion acceleration are summarized in Table 1.

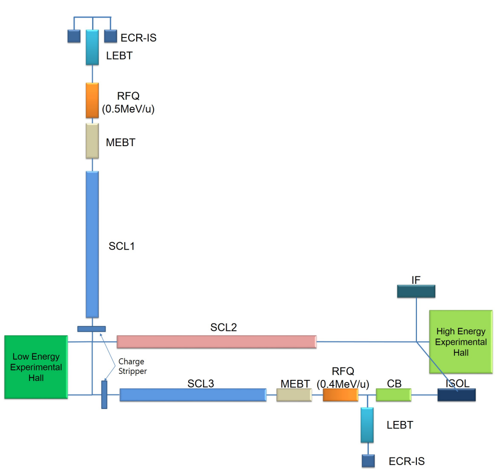

Figure 1: Layout of RAON superconducting linacs.

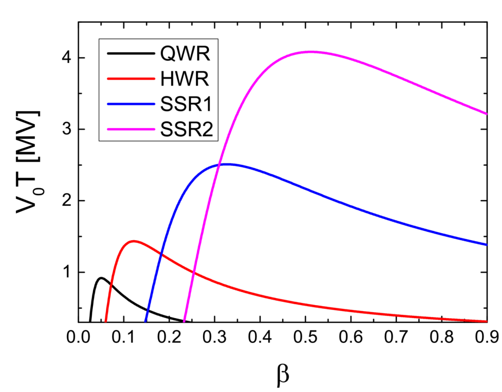

Figure 2: Effective accelerating voltage of cavities in RAON superconducting linac.

ERROR ANALYSIS AND CORRECTION AT THE MAIN LEBT OF RAON HEAVY ION ACCELERATOR

Hyunchang Jin, Ji-Ho Jang, In-Seok Hong, and Hyo-Jae Jang
Institute for Basic Science, Yuseong-daero 1689-gil, Yuseong-gu, Daejeon, Korea

Abstract

The main Low Energy Beam Transport (LEBT) section of Rare isotope Accelerator Of Newness (RAON) heavy ion accelerator is designed to transport the ion beams which are generated by Electron Cyclotron Resonance Ion Source (ECR-IS) to the Radio Frequency Quadrupole (RFQ). In the main LEBT, one or two beams are selected among a variety of ion beams to meet the beamline experiment requirements such as beam charge and current. In a uranium beam case, two charge-state, 33+ and 34+, beams are chosen and transported to the RFQ. For transportation of two charge-state beams, beams can be seriously affected by dipole kick or unexpected dispersion caused by magnet errors. These effects of magnet or cavity errors lead to beam loss at the main LEBT or RFQ. Therefore, the effect to the beam orbit and size should be identified and the research for reducing such effect should be required in the main LEBT. In this paper, we will examine the orbit distortion and beam size growth caused by magnet errors and discuss the correction of errors by using correctors and BPMs.

INTRODUCTION

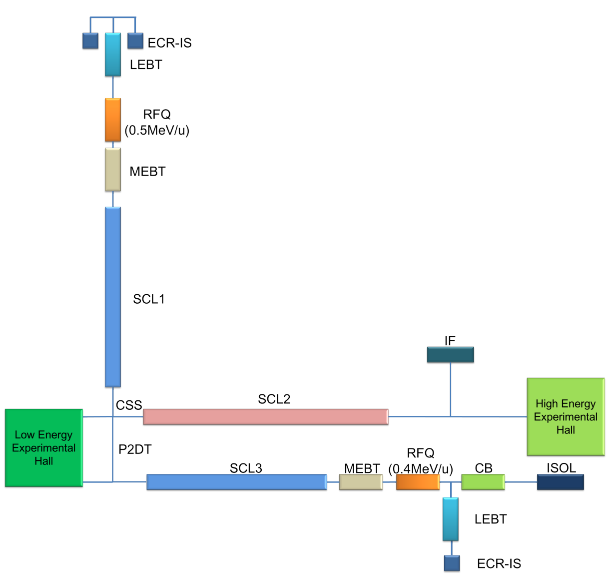

Figure 1: Schematic view of RAON heavy ion accelerator.

The RAON heavy ion accelerator [1] proposed by Rare Isotope Science Project (RISP) is in progress to become one of the world leading facilities as a rare isotope accelerator. At the RAON accelerator, the rare isotopes can be generated with two ways; one way is the isotope separation on line (ISOL) system [2] and the other is the projectile fragmentation in the in-flight fragmentation (IF) system [3]. In a wide range of science programs, we can use these rare isotopes.

For a uranium beam case, the beam generated by electron cyclotron resonance ion source (ECR-IS) with a beam energy of 10 keV/u reaches to an energy 200 MeV/u and a power 400 MW at the IF system to produce a high-intensity rare isotopes. For this process, RAON accelerator will use a low energy superconducting linac (SCL1) and a high energy superconducting linac (SCL2) [4]. The beams generated by the ECR-IS passes through the low energy beam transport (LEBT), the radio frequency quadrupole (RFQ), and the medium energy beam transport (MEBT) before entering the SCL1. The schematic layout of RAON accelerator is shown in Fig. 1.

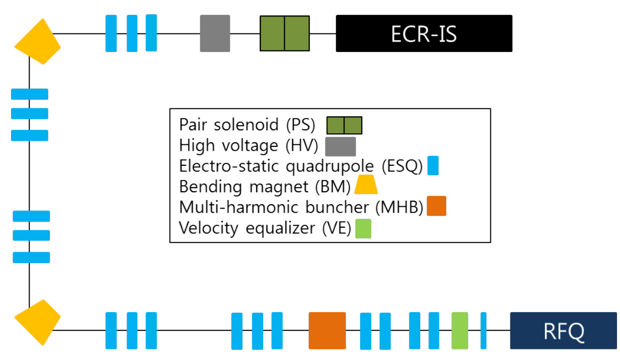

Figure 2: Layout of the main LEBT.

The main LEBT consists of many components: a pair solenoid (PS), high voltage platform (HV), 20 electro-static quadrupoles (ESQ), two 90-degree bending magnets, a multi-harmonic buncher (MHB), and a velocity equalizer (VE). All the components of it can be error sources of orbit distortion and the error of ESQs is a dominant source. The schematic layout of main LEBT is shown in Fig. 2.

We have developed the graphical user interface (GUI) for the error analysis and correction in RAON accelerator by using a multi-particle beam simulation code, DYNAC [5], and a computing language program, MATLAB [6]. In this paper, we will present the orbit distortion induced by magnet errors and correction to the errors by using correctors and beam-position monitors (BPMs) in the main LEBT.

PROCEDURE FOR ERROR ANALYSIS AND CORRECTION

With the lattice information, the orbit trajectory is calculated with and without errors by using the DYNAC code. The whole procedure of error analysis and correction with DYNAC and MATLAB programs is listed in Table 1.

CATEGORIZATION AND ESTIMATION OF POSSIBLE DEFORMATION IN EMITTANCE EXCHANGE BASED CURRENT PROFILE SHAPING

Gwanghui Ha, Moohyun Cho, Won Namkung, POSTECH, Pohang, Gyeongbuk 790-784, KOREA
Wei Gai, Kwang-Je Kim, John Gorham Power, Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

Bunches with shaped current profiles can be used to increase the transformer ratio in the beam-driven collinear wakefield acceleration. Shaped current profiles can be generated with an emittance exchange (EEX) and controlled by the incoming beam parameters as well as the EEX beam line parameters. The ideal bunch shape, predicted from first order theory in the absence of collective effects, is deformed in the real case. In this paper, we categorize the sources of deformation with a deformation parameter and observe their deformation pattern on the current profile.

CATEGORIZATION OF DEFORMATION

Perturbation theory can be used to categorize the deformations of the bunch shape that arise with the emittance exchange (EEX) based bunch shaping. We define the ideal bunch shape, $N_0(\mathrm{z})$, as that which occurs under the ideal conditions of zero emittance, thin-lens deflecting cavity, first-order beam dynamics, and the absence of collective effects [1]. In this case, there is perfect linear relationship between the initial horizontal position (x_i) and the final longitudinal position ($z_f^0 = \{k\xi - s(\eta + k\xi(L+D))\}x_i$). The actual bunch shape, $N(\mathrm{z})$, is deformed from the ideal when realistic effects are included. In this paper, we characterize the deformation patterns in order to improve the beamline design. We analyse the deformation of an ideal single triangle current profile and determine how the deformation affects the transformer ratio (TR).

Single Particle Treatment

The final bunch position (z_f) can be treated as a perturbation to the ideal bunch position (z_f^0) by adding perturbation terms.

$$z_f = z_f^0 + \sum C_m \prod X_n, \tag{1}$$

where C_m are the perturbation coefficients of the beam parameters $X_n \in \{x_i, x_i', y_i, y_i', z_i, \delta_i\}$. Based on the polynomial form of Eq. (1), there are three categories. (1) random deformation where all X_n are not correlated to x_i This deformation spreads the particle from its ideal position without any preferred direction. The thick-lens effect from the deflecting cavity ($\frac{L_c}{6}\kappa^2\xi z_i + \frac{L_c}{6}\kappa^2\xi^2\delta_i$) belongs to this category since z_i and δ_i are not correlated to x_i [1]. (2) correlated-random deformation contains at least one X_n which is and is not correlated to x_i. This deformation makes a similar effect like the random perturbation, but it changes the shape of the current profile in the different way. Since a divergence after the deflecting cavity ($x_2' = \kappa z_i + \kappa\xi\delta_i$) is not correlated to x_i, and an energy spread after the deflecting cavity ($\delta_2 = \kappa x_i + \kappa(L+L_{bc})x_i{}'$) is correlated to x_i, the second order term $\mathrm{T}_{526}x_2'\delta_2$ is the one of the correlated random deformation terms [2]. (3) correlated random deformation only has X_n which is correlated to x_i. Since all parameters are correlated to x_i, particles move to the specific position based on its original position. This collective movement makes the strongest deformation to the current profile.

EEX BASED SHAPING DEFORMATION PATTERNS

Each major deformation categories can be further separated into several minor cases depending on the sign of the coefficients and the order of beam parameter terms. By considering up to the second order for the random and the correlated-random case, and the third order for the correlated case, there are total ten minor deformation cases.

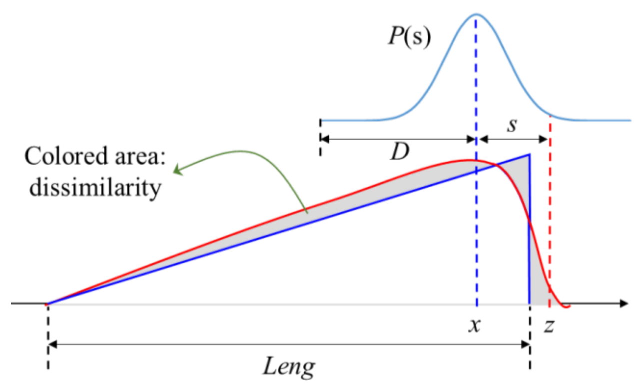

Figure 1: Definition of parameters

Deformed Density Profile

We define a perturbation function (which is similar to the probability density function) in order to analyse the cases. If s is the distance between two positions, $P(s \equiv z - x)ds$ indicates what portion of particles in position $[x, x+dx]$ moves to z (Fig. 1). This function satisfies $\int_{-\infty}^{\infty} P(s)ds = 1$. Also, the deformed profile related to the ideal profile, $N_0(x)$, can be expressed

$$N(z) = \int_{-\infty}^{\infty} N_0(x)P(z-x)dx. \tag{2}$$

HIGH RESOLUTION LONGITUDINAL PROPERTY MEASUREMENT USING EMITTANCE EXCHANGE BEAM LINE

Gwanghui Ha, Moohyun Cho, and Won Namkung, POSTECH, Pohang, Gyeongbuk 790-784, KOREA
Wei Gai, Kwang-Je Kim, and John Gorham Power, Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

Most longitudinal diagnostics intentionally introduce a transverse-longitudinal correlation since it is difficult to measure longitudinal properties directly. This correlation is introduced in order to observe longitudinal properties on a transverse screen, but the initial transverse components of the beam limit the resolution of the measurement. It is possible to overcome this resolution limit with an emittance exchange beam line in which the transverse properties after the exchanger only depend on longitudinal properties at its entrance. We present a new concept for measuring longitudinal properties with an emittance exchange beamline and preliminary simulation results.

RESOLUTION LIMIT OF THE DEFLECTING CAVITY MEASUREMENT

Since it is difficult to measure the longitudinal density profile of an electron bunch directly, the longitudinal profile is often transformed into the transverse profile. An example is a transverse deflecting cavity (TDC) followed by a screen (Fig. 1). The TDC applies a time-dependent-transverse-kick to the bunch. The particles in the bunch obtain an additional transverse momentum depending on its arrival time at the TDC. Because the strength and the direction of this momentum kick varies with arrival time, the transverse position of each particle at the measurement screen is proportional to the longitudinal position inside the bunch. Therefore, we can estimate the bunch length by measuring the transverse beam size.

The transverse beam size at the screen downstream of the TDC (Fig. 1) is not an exact representation of the initial bunch length. The bunch's finite transverse size and divergence before the TDC contributes to the transverse beam size at the screen. To minimize the contribution of the initial transverse parameters, the quadrupole is used in front of the TDC. If all beam parameters at X_1 are well-known, then the beam size at the screen can be calculated using the linear transport matrix given in Eq. (1).

$$\mathrm{R} = \begin{bmatrix} 1 & L_c + D + D' & \kappa\left(\frac{L_c}{2} + D\right) & 0 \\ 0 & 1 & k & 0 \\ 0 & 0 & 1 & 0 \\ \kappa & \frac{L_c}{2}\kappa & \frac{L_c}{4}\kappa^2 & 1 \end{bmatrix}, \quad (1)$$

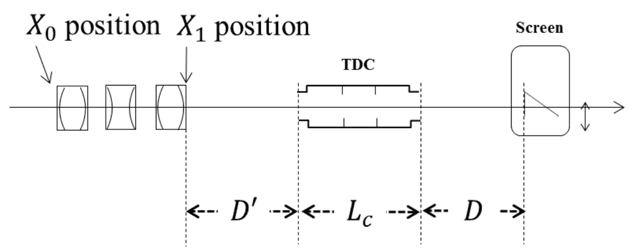

Figure 1: Typical TDC measurement configuration.

where κ is the deflecting cavity kick strength ($= \frac{\mathrm{eV}}{E}\frac{2\pi}{\lambda}$).

According to Eq. (1), the rms transverse beam size at the screen position in terms of $\mathrm{X}_1 = (x_1, x_1', z_1, \delta_1)$ is

$$\sigma^2_{\mathrm{x,screen}} = \sigma^2_{x,1} + L^2\sigma^2_{x',1} + 2L\sigma_{xx',1} + \kappa^2 L'\sigma^2_{z,1}. \quad (2)$$

where L is $L_c + D + D'$ and L' is $\frac{L_c}{2} + D$. The first three terms are due to the initial transverse parameters, while the last term is due to the bunch length. Two parameters from Eq. (2) determine the resolution. The first parameter, the scaling factor, determines the beam size at the screen due to the initial bunch length. Therefore, $\kappa L'$ in Eq. (2) is the scaling factor and a larger value improves the resolution. The second is the TDC-off transverse beam size. When the TDC is off, only the first three terms in Eq. (2) remain and the TDC-off size is the square root of those terms. The smaller the TDC-off size is the better the resolution.

To minimize the TDC-off size, the focal length of the quadrupole is adjusted to $\frac{1}{\mathrm{f}} = -\left(\frac{1}{L} + \frac{\sigma_{xx',0}}{\sigma^2_{x,0}}\right)$ (a thin-lens single quadrupole is assumed for simple calculation instead of triplet). The corresponding minimum TDC-off size become

$$\sigma_{\mathrm{x,min,screen}} = \frac{\varepsilon_{x,0}}{\sigma_{x,0}}(D + D' + L_c). \quad (3)$$

The resolution of a TDC-based measurement is the ratio of the minimum TDC-off size to the scaling factor.

$$\mathrm{Resolution} = \frac{\varepsilon_{\mathrm{x},0}(D+D'+L_c)}{\sigma_{x,0}\kappa\left(D+\frac{L_c}{2}\right)}. \quad (4)$$

Unfortunately, most of resolution related terms in Eq. (4) has a clear limit. A small emittance and large beam size enhance the resolution, but the emittance does not change

PHYSICAL MODEL OF PARTIAL RF DISCHARGE IN ISOCHRONOUS CYCLOTRONS

V.S. Dyubkov, National Research Nuclear University "MEPhI", Moscow, Russia*
S.A. Korenev, Siemens Healthcare, Knoxville, TN 37932, USA

Abstract

The physical model of partial RF discharge, based on the residual gases molecules ionization by detached electrons produced in collisions of negative hydrogen ions with residual gases, as well as electro-dissociation of H^- ions in isochronous cyclotrons, is proposed in this paper. The following problems are discussed in this article: the influence of magnetic field on the properties of partial RF discharge, the analysis of conductivity of RF plasma (partial RF discharge), the results of proposed model application for 11 MeV Eclipse cyclotrons.

INTRODUCTION

A partial electrical discharge is the first stage of forming the radiofrequency (rf) discharge in the cavities (cavity consists of dee and cooper surfaces of magnet valleys) of isochronous cyclotron which takes place before full breakdown (the so called crowbar). The main question of the discharge appearance is a question of origin of preliminary electrons that initiate rf discharge. The vacuum conditions in isochronous cyclotrons with internal ion source have large influence on loses of H^- ions. The time of processes of forming the rf partial discharge is not stable and stochastic. The analysis of existing rf discharge in charged particle accelerators [1, 2] shows that the used physical models cannot hitherto describe partial discharge appearance in low energy isochronous cyclotrons (for instance, 11 MeV Siemens Eclipse cyclotron). The partial discharge can lead to full rf discharge and consequently determines the time of irradiation. One can point, for example, that decreasing the total time of irradiation on the 15% leads to reduction of short-lived isotope activity on the 15% ultimately. A new physical model of partial discharge for isochronous cyclotrons with internal ion source is presented in this paper. Furthermore, the paper has practical aspect related to efficiency of medical radioisotopes production during target irradiation by protons.

PHYSICAL MODEL OF PARTIAL RF DISCHARGE

The main idea of proposed physical model is based on the ionization of residual gas molecules by electrons. These freed electrons appear due to stripping and electrodissociation of H^- ions. The ionization result in formation of plasma clouds between dees and trimbars with enough conductivity to decrease rf voltage (Fig. 1). This proposal makes a difference from other models of electrical discharge presented in Ref. [3]. Waveforms illustrating the partial discharge and crowbar are shown in Fig. 2. Curves in Fig. 2a are cyclotron magnet current (CH1) and a signal on RF probe (CH2) correspondingly.

3D COMPUTER SIMULATIONS OF THE ULTRARELATIVISTIC BEAM DYNAMICS IN SUPER COLLIDERS*

M.A. Boronina, V.A. Vshivkov, ICM&MG SB RAS, Novosibirsk, Russia
G.I. Dudnikova, ICT SB RAS, Novosibirsk, Russia

Abstract

The problem of numerical modeling of beam-beam interaction with high relativistic factor ($\sim 10^4$) is considered. We present a 3D self-consistent simulation model based on particle-in-cell method. The mixed Euler-Lagrangian decomposition is used in the parallel algorithm for achieving good load balancing and reducing communication costs. Stable regimes of beam dynamics, depending on the beams configuration (beta-function, emittance, energy, currents and relative offset) can be found on the base of the model. In the calculations we used grid 100×100×100 with 10^8 macro-particles, the number of processors depends highly on the beam shape.

INTRODUCTION

We present a new PIC code for mathematical modeling of the collective ultrarelativistic beam dynamics with the aim to achieve large luminosities. The high relativistic factors of the beam particles ($\gamma \sim 10^3$-10^5) lead to the luminosity restriction, the negative effects can be reduced by optimization of the beam configuration.

The standard slice approach represents the slices rearrangement, each slice of one beam impacts on the counter beam particles by two-dimensional forces. The approach is widely used for cyclic accelerators, where the beam deformations are not strong, the computations of a single interaction are fast, number of slices 5-50 and number of macro-particles in the bunch 10^5 provide sufficient accuracy [1]. The single collision of ultrarelativistic beams of high densities may lead to a strong compression and even disruption of the bunch, and in this case longitudinal resolution must be adequate to the number of pinches. The longitudinal effects cannot be simulated by a quasi-3D model, but in the case of critical beam densities such as in ILC they may play significant role, and the redistribution of energy may cause ruinous consequences. The fine resolution requires an appropriate number of macro-particles in the beam (10^8-10^{10}). A monoprocessor machine allows performing 3D simulations with maximum $2 \cdot 10^6$ macro-particles, and new efficient parallel algorithms are needed to simulate the critical regimes of the ultrarelativistic beams interaction.

In our parallel 3D algorithm we apply the particle-in-cell (PIC) method and the leap-frog scheme [2,3] to solve Vlasov-Liouville equation the three-dimensional set of Maxwell's equations. The three-dimensional nature of interaction together with the new special methods for initial and boundary conditions computations [4] allow automatically account for above difficulties and demonstrate good results.

MATHEMATICAL MODEL

We consider the motion of counter beams in a rectangular domain in Cartesian coordinates. The positron/electron beams are focused by the external focusing field and move in the self-consistent electromagnetic fields. The boundaries of the computational domain are located very close to the beams, in the near wave zone, no radiation effects are considered [5]. We use Vlasov kinetic equation for the distribution function of the particles and the three-dimensional set of Maxwell's equations to describe the beam dynamics. In dimensionless variables, which are obtained from the characteristic beam length $L = 1$ cm and the characteristic particle speed $v = c = 299792.458$ km/s, the equations may be rewritten in the following form:

$$\frac{\partial f_{+,-}}{\partial t} + \mathbf{v}_{+,-}\frac{\partial f_{+,-}}{\partial \mathbf{r}} + \mathbf{F}_{+,-}\frac{\partial f_{+,-}}{\partial \mathbf{p}} = 0$$

$$\begin{aligned} rot\mathbf{E} &= -\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t}, \\ rot\mathbf{H} &= \frac{4\pi}{c}\mathbf{j} + \frac{1}{c}\frac{\partial \mathbf{E}}{\partial t}, \\ div\mathbf{E} &= 4\pi\left(n_- e^- + n_+ e^+\right), \\ div\mathbf{H} &= 0. \end{aligned}$$

The Lorentz's force can be calculated from the following equation for each particle:

$$\mathbf{F}_{+,-} = e^{+,-}\left(\mathbf{E} + \mathbf{v}_{+,-} \times \mathbf{H} / c\right)$$

and the particle moment:

$$\mathbf{p}_{+,-} = \gamma_{+,-} m_e \mathbf{v}_{+,-}$$

$$\gamma_{+,-} = 1 \Big/ \sqrt{1 - \left|\mathbf{v}_{+,-}\right|^2 / c^2}$$

REVISION OF THE IMPEDANCE MODEL FOR THE INTERPRETATION OF THE SINGLE BUNCH MEASUREMENTS AT ALBA

T.F. Günzel and U.Iriso, ALBA Synchrotron, Cerdanyola de Vallés, Spain

Abstract

Recently [1] we were able to explain 65% of the measured vertical single bunch detuning with the developed transverse impedance model. In this note we show the improvements of the impedance model we could achieve in the meantime. We included a better bunch length parametrisation of all contributions. Moreover, the geometrical impedance of several vacuum chamber elements was recalculated with GdfidL [2] and the impedance of a couple of elements neglected so far was included in the budget. ImpedanceWake2D [3] was used for the computation of the (resistive) wall impedance.

INTRODUCTION

In the past at different accelerators significant differences between the computed and measured single bunch detuning were observed [4, 5]. However, the work [6] shows that achieving an agreement is not impossible. An accurate computation of the impedance gains importance as the construction of ultralow emittance sources pushes the instability thresholds to limits which are hardly feasible. This note describes the work carried out to carefully benchmark impedance measurements with the computated impedance at the ALBA storage ring. On one side, measurements were taken varying different machine parameters like the RF-voltage and the gap of the in-vacuum undulators. On the other hand, careful simulations using GdfidL and Impedance-Wake2D(IW2D) were carried out using an experimental bunch parametrisation.

IMPROVEMENT OF THE IMPEDANCE MODEL

The key point of this work consists in the upgrade of the underlaying vertical impedance model. The model contains two parts, the impedance of geometrical origin – also called broadband impedance – and impedance related to the resistivity of the vacuum chamber walls and that part of space charge that only depends on the chamber extension – the wall impedance. The broadband impedance (BBI) is computed by simulation of electromagnetic wake fields in corresponding vacuum chambers with the program GdfidL [2] whereas the wall impedance is computed analytically. For this work the wall impedance was computed for the first time with ImpedanceWake2D.

Wall Impedance

IW2D allows to calculate the wall impedance for a round or fully flat beam pipe consisting of n different material layers of constant thickness. Table 1 shows the list of chambers analyzed by IW2D. The code solves the Maxwell equations exactly and should be therefore best adapted to the problem (this is only partly true as no chamber wall is an assembly of layers of exactly constant thickness).

Comparing the impedance spectra of IW2D with those of the RW-models of the precedent work [1] rather good agreement was found even for multi-layer chamber walls. Actually, IW2D computes in the range $f \in [5, 50]$GHz an imaginary part slightly smaller than the one given by the traditional RW-formula for mono-layers (Fig. 1) as well as for most multi-layer chamber walls.[1] The real part was slightly higher though.

Table 1: Vacuum Chambers Analyzed by IW2D

Chamber type	**Assumed Layers**
In-vac undulator(open/closed)	Cu/Ni/CoSm
NEG-coated Al-chamber	NEG/Al/Air
Ti-coated ceramic chamber	Ti/Al_2O_3/Air/Ferrit
Wiggler chamber	Cu/Air
Cavities	Cu/Air
Different SS[2]-chambers	SS/Air

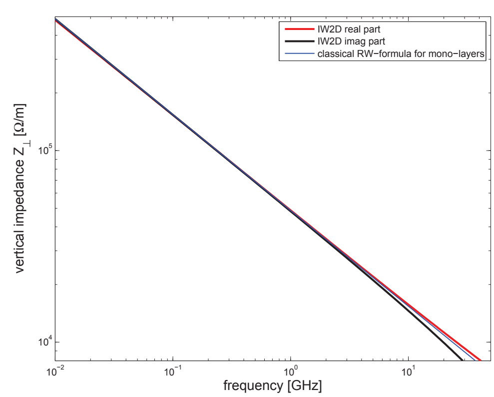

Figure 1: wall impedance of std vacuum chamber. At high frequency the imaginary part is smaller than both the real part and the one given by the classical RW-formula for mono-layers.

Geometrical Impedance

For the improvement of the geometrical impedance a revision of the geometrical models of the taper-dominated geometries and their annexes (table 2) was done. Furthermore, element geometries were equipped with the missing pump grids and their wake-fields simulated. They are all finally decomposed in monopolar, dipolar and quadrupolar

[1] formulas based on the work of [7]

BEAM-BASED IMPEDANCE CHARACTERIZATION OF THE ALBA PINGER MAGNET

U. Iriso, T.F. Günzel, ALBA-CELLS, Cerdanyola de Vallès, Spain
E. Koukovini-Platia, H. Bartosik, G. Rumolo, CERN, Geneva, Switzerland

Abstract

The ALBA pinger magnet consists on two short kickers (for horizontal and vertical planes) installed in a single Titanium coated ceramic vacuum chamber. Single bunch measurements in the vertical plane were performed in the ALBA Synchrotron Light Source before and after the pinger installation, and by comparing the Transverse Mode Coupling Instability (TMCI) thresholds for zero chromaticity, we infer the pinger impedance and compare it with the model predictions.

INTRODUCTION

Coupling impedance calculations are a key issue when designing an accelerator, in particular for electron light sources, where the presence of numerous Insertion Devices (IDs) with very small gaps can limit the circulating beam intensity in the machine. Often, these IDs are not made of a single material, but they are composed of different materials in different layers. Therefore, it is important to evaluate the reliability of the computer codes that evaluate the impedance of these devices before their installation.

At ALBA, a pinger magnet has been installed during the summer shutdown of 2014 [1]. The pinger magnet is a multilayer structure composed by a ceramic vacuum chamber of 6.5 mm thickness, with an inner Titanium (Ti) coating of only 400 nm. This vacuum chamber is surrounded with a ferrite yoke [1], and between the ceramic and the ferrite there is a gap of 1 mm width for air cooling. This structure is exactly the same as the one used for the four injection kickers installed since day-1, with the only difference in the ferrite thickness surrounding the ceramic chambers [2].

Figure 1: Vertical (left) and horizontal (right) pinger magnet installed at ALBA during summer 2014. The ceramic chamber (in white) is visible between the two structures used for the vertical (left) and horizontal (right) excitations.

Figure 1 shows a picture of the pinger magnet, where the ceramic chamber is visible in the middle. The same vacuum chamber (780 mm in length) is used for the horizontal (left) and vertical kick excitations (right). The difference for each structure consists in the position of the Copper (Cu) electrodes, which are located on left/right for the horizontal excitation, and top/bottom for the vertical.

The goal of these studies is to infer the pinger magnet impedance based on beam measurements and compare it with results using different computer simulation codes (GdfidL, CST, and IW2D [3–5]). Beam-based impedance characterization of the pinger magnet are based on Transverse Mode Coupling Instability (TMCI) studies: by analysing the machine detuning and instability thresholds before the pinger installation (Autumn 2013) and after (Autumn 2014) we can infer the contribution of the new installed element to the total machine impedance.

BEAM-BASED MEASUREMENTS

TMCI Theory

Assuming a Gaussian beam bunch with N_b particles and rms length of σ_τ, the complex frequency shift in betatron frequency for the $l = 0$ mode is expressed by [6]

$$\Omega - \omega_\beta = -iZ_{\text{eff}} \frac{N_b e c^2}{4\sqrt{\pi}(E/e)T_0\omega_\beta\sigma_\tau}, \tag{1}$$

where $\omega_\beta = Q_\beta\omega_0$ the angular betatron frequency, Q_β is the betatron tune (including the integer part), ω_0 is the angular revolution frequency, E is the beam energy, c is the speed of light, and e the electron charge. The term Z_{eff} is the effective impedance of the machine, defined as:

$$Z_{\text{eff}} = \frac{\sum \beta_i Z_i}{\langle\beta\rangle}, \tag{2}$$

where Z_i, β_i refers to the impedance and beta function of the machine element i, respectively. Equation 1 shows that the imaginary part of Z_{eff} causes a tune shift with increasing bunch current, which allows to infer the total machine impedance, as already performed in other machines [6–8].

While the vertical detuning is proportional to $\text{Im}(Z_{\text{eff}})$, the threshold at which the instability occurs decreases with increasing the impedance (approximately like $1/Z_{\text{eff}}$). In general, there is no readily available formula relating the intensity threshold and the impedance, and this has to be inferred using computer simulation codes including bunch lengthening effects.

In the following, we focus our studies on the vertical plane because the pinger transverse aperture is 80 × 24 mm (horizontal × vertical), and thus the effect is much more critical in the vertical plane.

DETAILED CHARACTERIZATION OF ALBA QUADRUPOLES FOR BETA FUNCTION DETERMINATION

Z.Martí*, J.Campmany, J. Marcos, V.Massana,
CELLS-ALBA Synchrotron, Cerdanyola del Vallès, Spain
X.Nuel, SOLEIL, Gif-sur-Yvette, France

Abstract

Beta function value at quadrupoles for a circular accelerator can be determined using the relationship between the machine tune and quadrupole strength variations. ALBA Storage Ring quadrupoles were measured during manufacturing, to be sure that their performance fitted the specifications. However, measurements were carried out at a limited number of current settings and do not allow an accurate determination of the beta function value. In fact, less than 1% error in the calibration of the hysteresis curve slope is required, and therefore new detailed measurements of the hysteresis cycle are needed. In order to make these magnetic measurements, the spare quadrupoles existing at ALBA have been used. In this paper we present the results of beta function values determination using this method for ALBA Storage Ring.

INTRODUCTION

Linear optic functions like beta functions are a common figure of merit to evaluate the performance of circular accelerators. At ALBA, the beta functions are measured using both an orbit response matrix method and Turn by Turn (TbT) data analysis [1–4]. Despite they agree at the level of $1-2\%$ rms, both methods are limited by characteristic systematic measurement errors.

On one side, the orbit response matrix method, in particular the Local Optics from Closed Orbit, known as LOCO, suffers from systematic errors as it is completely model dependent. As shown in [2] the systematic contribution to the beta beating is around 1% rms.

On the other side, the unknown gains of the BPM during the TbT acquisition can introduce considerable systematic measurement errors. Recently it has been shown that the gain issue may be solved using the phase information of the TbT data, achieving agreements with LOCO around 1% rms [5].

Given the limited accuracy of these two methods, at ALBA it has been decided to measure the beta function values also by measuring the tune changes due to quadrupole change. If the quadrupole integrated strength change $\Delta\, kL$ is small, the tune change can be expressed as follows, [6]

$$\Delta Q_{x,y} = \pm \frac{\left\langle \beta_{x,y} \right\rangle}{4\pi} \Delta kL, \tag{1}$$

where L is the length of the quadrupole and $\left\langle \beta_{x,y} \right\rangle$ the corresponding plane average beta function along the quadrupole that has been varied. This allows to measure the averaged beta function at each quadrupole. Assuming that the magnet calibration $kL(I)$ as a function of the current set point I is precisely known, Eq. (1) can be expressed as:

$$\left\langle \beta_{x,y} \right\rangle = \pm \frac{4\pi \Delta Q_{x,y}}{\Delta I \partial (kL)/\partial I}, \tag{2}$$

This well known technique encounters some difficulties:

1. It requires a very good knowledge of the calibration curves of the quadrupoles as it depends on its derivative.
2. The hysteresis effects after the quadrupole change may spoil subsequent measurements.
3. The measurement is limited by the tune jitter. The present ALBA performance is 2×10^{-4} rms. [4]
4. It is a very slow measurement.

As it is shown in this paper, the first three points can be greatly compensated. However, it is clearly a very slow measurement not suited for normal operation optics control. Nevertheless it could constitute a good bench mark method.

The paper is separated mainly in two sections. The first section describes the recent precise magnetic measurements of spare quadrupoles and the corresponding data processing. The second part describes the measurements done during this year dedicated machine time and how that agrees with LOCO beta functions at the quadrupoles position.

MAGNETIC MEASUREMENTS

The ALBA Storage Ring includes 112 quadrupoles, all of them with the same iron cross section, and which can be divided into four groups depending on the length of the iron yoke: 200, 260, 280 and 500 mm. All quadrupoles were magnetically characterized by the manufacturer (BINP) during the production process [7]. The harmonic content of each magnet was determined for 5–6 current settings between the maximum one (either 200 or 225 Amp depending on the iron length) and 50 Amp. From this data an average transfer function curve $GL(I)$ providing the integrated gradient strength for each iron yoke length as a function of the current setting was obtained.

In order to increase the accuracy of the $GL(I)$ curves, four spare quadrupoles —one for each iron yoke length— have been measured in detail at ALBA magnetic measurements laboratory. Measurements have been carried out on a rotating coil bench, using a shaft based on printed circuit coils designed and manufactured at ALBA, with a diameter

A LINEAR ACCELERATOR SIMULATION FRAMEWORK

J. Snuverink, John Adams Institute at Royal Holloway, University of London, Egham, UK
N. Fuster-Martinez, IFIC (CSIC-UV), Valencia, Spain
J. Pfingstner, CERN, Geneva, Switzerland and University of Oslo, Oslo, Norway

Abstract

Many good tracking tools are available for simulations for linear accelerators. However, several simple tasks need to be performed repeatedly, like lattice definitions, beam setup, output storage, etc. In addition, complex simulations can become unmanageable quite easily. A high level layer would therefore be beneficial. We propose LinSim, a linear accelerator framework with the codes PLACET and GUINEA-PIG. It provides a documented well-debugged high level layer of functionality. Users only need to provide the input settings and essential code and / or use some of the many implemented imperfections and algorithms. It can be especially useful for first-time users. Currently the following accelerators are implemented: ATF2, ILC, CLIC and FACET. This paper discusses the framework design and shows its strength in some condensed examples.

INTRODUCTION

When simulating linear accelerators or transport lines, one encounters repeating tasks that are basically the same for each simulation such as:

- Setting up the model of the beamline and the beam
- Specifying and saving simulation parameters
- Implementing a scripting structure to simulate typical scenarios
- Implementing of correction techniques
- Implementing imperfections such as ground motion and component imperfections
- Maintaining scripts to ease computing on a server farm
- Evaluating the results
- Performing backups and keeping track of changes

All these tasks are usually repeated for each simulation project that is started. As a result, there are a large number of implementations of very similar code in each beam physics team, which reduces the productivity significantly.

Instead of this approach, a unified simulation framework for linear accelerators based on PLACET [1, 2] and GUINEA-PIG [3], named LinSim, is described in this paper. It automates the mentioned tasks and takes a large (re)implementation burden away from the user. The user needs only to specify simulation settings and to add the minimal specific code for the given problem.

Additionally, many correction techniques (e.g. orbit feedbacks, IP feedbacks, dispersion free steering, wakefield alignment, and many other) are already implemented or need to be implemented only once, which increases productivity and leads to well debugged code.

Furthermore, LinSim includes more features than would usually be written, e.g. consistency input parameter checks, automated settings storing to be able to reproduce the results at a later stage, revision control, scripts for analysis of results and many others. This helps to increase the productivity of the user. Especially (but not only) for newcomers, LinSim is an enormous starting help, since they don't have to know all the details of the already provided simulation scripts.

FRAMEWORK STRUCTURE

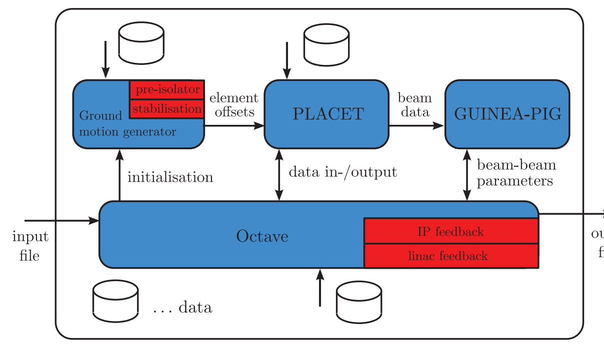

Figure 1: Internal structure of LinSim, where scripts (written in Tcl and Octave) interface the simulation codes PLACET, a ground motion generator, and GUINEA-PIG. An input file is used to control the simulations that use additional data such as lattice files and created standardised output files.

The structure of the framework is illustrated in Fig. 1. It consists of a set of scripts written in Tcl [4] and Octave [5] that interface different simulation codes: PLACET is used for the beam tracking, a ground motion simulator [6] (which has been ported to C++ and is now included in PLACET) generates realistic element misalignments, and GUINEA-PIG facilitates beam-beam simulations. Several types of imperfections are implemented and can be turned on and off. Also, many algorithms for the correction of these imperfections, e.g. beam-based alignment and orbit feedbacks, have been put in place. LinSim also provides the lattice, beam and additional information for the accelerators ATF2 [7], CLIC [8], FACET [9], and ILC [10].

SIMULATION STRUCTURE

A typical simulation consists of two components as depicted in Fig. 2. The first part is a set of provided scripts that make up LinSim itself, together with provided lattice files and additional data as, e.g. orbit response matrices. The entry point to LinSim is the script `run.tcl`, which is executed with PLACET. The second element of a simulation is the user specific test, which consists of two files: a settings file and a code file (e.g. `test_settings.tcl` and

NON-LINEAR DYNAMICS MODEL FOR THE ESS LINAC SIMULATOR

E. Laface* ESS, Lund, Sweden

Abstract

The ESS Proton Linac will run a beam with 62.5 mA of current. In the first meters of the accelerator, the non-linear space-charge force dominates the dynamics of the beam. The Drift Tube Linac, the Spoke resonators and the elliptical cavities, which are responsible for the 99.8% of the total energy gained by the beam along the accelerator, produce a significant longitudinal non-linear force on the proton beam. In this paper, we introduce a new theory to transport the probability density function of the beam under the effect of non-linear forces. A model based on this theory can be implemented in the ESS Linac Simulator for the fast simulations to be performed during the operations of the proton Linac.

INTRODUCTION

The success of the Courant-Snyder theory with particle accelerators is due to the simple connection between the dynamics of one particle and the dynamics of a beam. A single particle is fully described by the vector of its coordinates and momenta at a given time:

$$\vec{v} = (q_1 q_2 \dots q_n p_1 p_2 \dots p_n)^T . \tag{1}$$

If $\mathcal{H}$ is the Hamiltonian, the equations of motion can be expressed as

$$\frac{d}{dt}\vec{v} = S \cdot \vec{\partial}\mathcal{H} \tag{2}$$

where $\vec{\partial}$ and S are defined as

$$\vec{\partial} = (\partial/\partial q_1 \partial/\partial q_2 \dots \partial/\partial q_n \partial/\partial p_1 \partial/\partial p_2 \dots \partial/\partial p_n)^T \tag{3}$$

$$S = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}. \tag{4}$$

When the Hamiltonian is quadratic in coordinates and momenta, $\mathcal{H} = f({q_i}^2, {p_i}^2)$, it can be written as $\vec{\partial}H = A \cdot \vec{v}$, where A is a matrix. The equations of motion become

$$\frac{d}{dt}\vec{v} = S \cdot A \cdot \vec{v} \tag{5}$$

with the solution

$$\vec{v}(t) = e^{tSA} \cdot \vec{v}(0) \tag{6}$$

$$M(t) = e^{tSA} \tag{7}$$

$$\vec{v}(t) = M(t) \cdot \vec{v}(0). \tag{8}$$

In this case, $M(t)$ is the transport matrix that effects the changes of coordinates and momenta for each linear element of the accelerator.

Because of the linear nature of Eq. (8), it is possible to use the same matrix $M(t)$ to transport the r.m.s. of a bunch of particles using equation [1]:

$$\begin{pmatrix} \sigma_x^2 & \sigma_x\sigma_{x'} \\ \sigma_x\sigma_{x'} & \sigma_{x'}^2 \end{pmatrix}_t = M \begin{pmatrix} \sigma_x^2 & \sigma_x\sigma_{x'} \\ \sigma_x\sigma_{x'} & \sigma_{x'}^2 \end{pmatrix}_0 M^T \tag{9}$$

here we only consider one dimension, using the standard notation $x = q_x$ and $x' = \frac{p_x}{p_z}$, where q_x and p_x are the respective conjugate coordinate and momentum in the horizontal plane x and p_z is the momentum in the direction of motion of the particles.

When the force is non-linear, $\mathcal{H} \neq f({q_i}^2, {p_i}^2)$, Eqs. (8) and (9) are no longer valid. In the following sections, we will show how to construct a general solution for the equations of motion of a bunch of particles, starting from the solution of the equation for a single particle, generalising the Eq. (9) for the case of non-linear forces.

BEAM DENSITY

Let us assume that we were able to solve the equation of motion in (2) in the case of a non-linear force, that is, when $\mathcal{H} \neq f({q_i}^2, {p_i}^2)$. We will then have an equation of motion for a single particle in the form

$$\vec{v}(t) = f(\vec{v}(0)) \tag{10}$$

where f is

$$f : \mathbb{R}^{2n} \to \mathbb{R}^{2n} \tag{11}$$

with n coordinates and momenta; for all the practical cases $n = 3$.

In order to pass from the single-particle solution to one with many particles, we start by considering an invariant of a beam: the number of particles. This number will not change along the accelerator unless the losses are a significant fraction of the total number of particles. If ρ_{ps} is the probability density function of the beam in the phase space, the number of particles can be expressed as:

$$N = \int_{\mathbb{R}^{2n}} \rho_{ps} dq_1 dq_2 \dots dq_n dp_1 dp_2 \dots dp_n. \tag{12}$$

We know from the Liouville theorem that if the dynamics is symplectic then the volume of the phase space is preserved. Thus, any dynamics that apply it will keep the quantity $dq_1 dq_2 \dots dq_n dp_1 dp_2 \dots dp_n$ constant. On the other hand, we also know that the number of particles is preserved in the physical space and in the momentum space separately:

$$N = \int_{\mathbb{R}^n} \rho_r dq_1 dq_2 \dots dq_n \tag{13}$$

$$N = \int_{\mathbb{R}^n} \rho_m dp_1 dp_2 \dots dp_n \tag{14}$$

where ρ_r and ρ_m are the beam density in the real space and in the momentum space, respectively. These two integrals are invariant all along the machine and we can express this invariance by saying that at any time t the following

FIELD MAP MODEL FOR THE ESS LINAC SIMULATOR

E. Laface* ESS, Lund, Sweden
I. List, Cosylab, Ljubljana, Slovenia

Abstract

The proton beam driving the spallation process at the European Spallation Source, in Lund, will be accelerated and delivered onto a tungsten target by a linac. This linac is composed of four different families of accelerating structures: a drift tube linac, a section of spoke resonators and two sections of elliptical cavities for the particles' medium and high relativistic β. These structures provide 99.8% of the total energy gained by the beam along the accelerator. It is necessary, then, to have an accurate model describing the physics of the cavities in the ESS Linac Simulator (ELS), which is the online model that will simulate the accelerator during operation. Here, we present an RF-cavity model based on the field maps that we implemented in ELS, showing a maximum 10% deviation from TraceWin in the horizontal, vertical and longitudinal planes.

INTRODUCTION

In order to accurately model the accelerating components used in the ESS Proton Linac, the beam physics team is adopting a description of the electromagnetic field based on one-dimensional maps. Each spoke resonator and RF cavity is characterized by a file containing the value of the longitudinal electric field measured along the axis of symmetry (z axis). This field has a sinusoidal behaviour in the inner part of a cavity and an exponential decay on the two ends, as described in [1].

These field maps are then used to calculate the matrix representing the linear part of the equations of motion of a particle subjected to each field. The result is used to transport the beam envelope by applying the matrix of the linear elements to the covariant matrix of the beam.

To calculate the equations of motion we used two different approaches: the first evaluates the contribution of each step of the field map on the variation of the x', y' and z' momenta components for a particle, applying it as thin kicks. With this method, more precise cavity sampling improves accuracy. The second approach is to integrate the field in a certain number of cells (the NCell method), using the Transit Time Factor [2] to evaluate the proper phase and energy changes between cells. Each cell is then treated as a thin accelerating gap in the middle of a drift.

Both methods are then compared with the code used for the design of the ESS Proton Linac—TraceWin [3]—which can simulate the same kind of field maps.

* Emanuele.Laface@esss.se

FIELD MAPS

The transversal normalized momenta can be written in the paraxial approximation as

$$x' = \frac{dx}{ds} = \frac{dx/dt}{ds/dt} \approx \frac{p_x}{p_s} \tag{1}$$

$$y' = \frac{dy}{ds} = \frac{dy/dt}{ds/dt} \approx \frac{p_y}{p_s} \tag{2}$$

we will evaluate x', noting that the same treatment is valid for y'. The variation of momentum in x is given by

$$\begin{aligned}\frac{dx'}{ds} &\approx \frac{d(p_x/p_s)}{ds} = \frac{d(p_x/p_s)}{dt}\frac{dt}{ds} = \frac{\dot{p}_x p_s - p_x \dot{p}_s}{p_s^2}\frac{dt}{ds} \\ &\approx \frac{1}{\beta_s c}\frac{\dot{p}_x - x'\dot{p}_s}{p_s} = \frac{\dot{p}_x - x'\dot{p}_s}{\gamma_s \beta_s^2 mc^2}\end{aligned} \tag{3}$$

where β_s and γ_s are the relativistic parameters of the particle traveling in the s direction and the dot represents the time derivative.

The $\dot{p}_x$ and $\dot{p}_z$ components can be evaluated in terms of the Lorentz force

$$\frac{d\vec{p}}{dt} = q\left(\vec{E} + \frac{\vec{p}}{\gamma m} \times \vec{B}\right) \tag{4}$$

and, again using the paraxial approximation $p_z \approx p_s$, which is valid for the transverse plane, we have

$$\dot{p}_x = q\left(E_x + \frac{p_y B_z - p_z B_y}{\gamma m}\right) \approx q\left(E_x + p_s \frac{y' B_z - B_y}{\gamma m}\right) \tag{5}$$

and

$$\dot{p}_s = q\left(E_z + \frac{p_x B_y - p_y B_x}{\gamma m}\right) \approx q\left(E_z + p_s \frac{x' B_y - y' B_x}{\gamma m}\right) \tag{6}$$

where the quantities $x' B_y$ and $y' B_x$ are always zero because the velocity is parallel to the magnetic field, then

$$\dot{p}_s = qE_z. \tag{7}$$

Substituting Eqs. (5) and (7) into (3) we have

$$\frac{dx'}{ds} = \frac{q}{\gamma_s \beta_s^2 mc^2}\left(E_x + p_s \frac{y' B_z - B_y}{\gamma m} - x' E_z\right). \tag{8}$$

For our model, we are interested in the linear part of the fields where the following equations hold

$$E_x = \frac{\partial E_x}{\partial x} x, \quad E_y = \frac{\partial E_y}{\partial y} y \tag{9}$$

$$E_z = E_{z0}(s)\cos(\omega t + \phi) \tag{10}$$

$$B_x = \frac{\partial B_x}{\partial y} y, \quad B_y = \frac{\partial B_y}{\partial x} x \tag{11}$$

$$B_z = 0 \tag{12}$$

and where ω is the frequency of the cavity and ϕ is the phase. Substituting these equations into Eq. (8), we have

$$\frac{dx'}{ds} = \frac{q}{\gamma_s \beta_s^2 mc^2}\left(\frac{\partial E_x}{\partial x} x - \beta_s c \frac{\partial B_y}{\partial x} x - x' E_z\right). \tag{13}$$

A STEERING STUDY FOR THE ESS NORMAL CONDUCTING LINAC

R. Miyamoto*, ESS, Lund, Sweden

Abstract

Construction of the European Spallation Source is rapidly progressing in Lund, Sweden, and preparations for commissioning of its proton linac has been underway for some time now. Accurate adjustment of accelerator components to achieve ideal beam parameters is the key to maximizing performance and safe operation for any machine. This paper presents a study of beam steering for the normal conducting part of the proton linac of ESS.

INTRODUCTION

The European Spallation Source (ESS) will be a neutron source based on a 5 MW proton linac. The facility is currently under construction in Lund, Sweden and preparations for the beam commissioning are also progressing. For such a high power machine, it is the key to successful commissioning and operation to minimize beam losses and protect its components by properly adjusting the electromagnetic elements and achieving ideal beam parameters. Figure 1 shows a schematic layout of the linac of ESS and some of the high level parameters. The initial part of the linac is consist of normal conducting structures and this paper presents a study of beam steering in this part of the linac as a part of the ongoing preparations for the beam commissioning. The ion source (IS) and radio frequency quadrupole (RFQ) have nothing to adjust the beam trajectory. The low energy beam transport (LEBT) has only two dipole magnet steerers and thus the steering in the LEBT is relatively simple. Therefore, the focus of this paper is on the steering in the medium energy beam transport (MEBT) and drift tube linac (DTL).

STEERING IN MEBT

Figure 2 shows the zero current phase advances of transverse planes within the MEBT, together with a lattice schematic. This lattice is a version in 2014 [1] and has ten identical quadrupoles and an additional one surrounding the chopper. Each of ten quadrupoles is equipped with a dual-plane BPM and additional coils to produce dipole fields and steer the beam in both plane. Please note that, after evaluations in terms of beam dynamics and engineering design, it has been decided that the chopper and the quadrupole around it is separated. Hence, from the next version, the same quadrupole as other ten will be placed right after the chopper and the numbers of BPMs and steerers per plane will be increased to eleven. To identify which BPMs and steerers are essential to achieve a good steering, cases with reduced numbers of BPMs and steerers were studied and the yellow markers in Fig. 2 represent the BPM locations of one such cases with six BPMs and steerers per plane. The

* ryoichi.miyamoto@esss.se

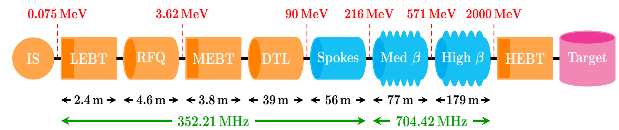

Figure 1: Schematic of the linac of ESS. Sections of superconducting cavities are in blue and those of normal conducting structures are in orange.

steerers used in this case are ones in quadrupole numbers 1, 2, 5, 7, 9, and 10.

Figure 3 shows RMS trajectories in the MEBT and the initial part of the DTL after the steering is applied to one thousand linacs with errors in the lattice elements and the parameters of the beam out of the RFQ. The layout of BPMs and steerers in the DTL used in this calculation is the new one, which is discussed in the next section. In 2014, a campaign of studies about impacts of the lattice element errors on beam quality and beam losses was conducted [2–4] and the values referred to as *tolerances* in these articles are used as the errors in this calculation. The exceptions are the dynamic errors of the cavities and inaccuracy in BPMs, to observe the effects of just the layout and the algorithm of steering. The calculations of the trajectories were done with the TraceWin code [5]. For the MEBT, the steering was done with the simplest way of minimizing the position at one BPM with one steering and performing this process one by one from the first steerer to the last (referred to as *one-to-one steering* in the following). If the layout of BPMs and steerers is adequate, this method should provide a reasonably good steering and this is indeed the case as seen in Fig. 3, even for the layout of the reduced numbers of the BPMs and steerers. The anticipated inaccuracy of the BPMs is on the order from a few hundred μm to a half mm so this will have a larger impact in the real machine. Please note that there is a small peak around ~1.2 m on the horizontal plane. This

COUPLED ORBIT RESPONSE COEFFICIENTS WITH CONSTANT REVOLUTION TIME

V. Ziemann, Uppsala University, Uppsala, Sweden

Abstract

We calculate orbit response coefficients for arbitrarily coupled lattice which keep the orbit length constant as is needed to maintain synchronicity with a radio-frequency system.

INTRODUCTION

In a circular accelerator the orbit correction system and diagnostic tools such as CALIF [1] or LOCO [2] rely on the knowledge of how steering magnets affect the beam position measured at beam position monitors (BPM). Historically the so-called response coefficients C^{ij} or response matrix elements between steering magnet labeled j and BPM i can be expressed in terms of TWISS parameters or transfer matrices by

$$C^{ij} = R^{ij}(1 - R^{jj})^{-1} \tag{1}$$

where R^{ij} is the transfer matrix from location j to location i and R^{jj} is the full-turn matrix starting at location j. Equation 1 does not constrain the revolution time, despite the fact that for example a horizontal steering magnet with kick angle θ^j lengthens the circumference by $D^j\theta^j$, where D^j is the dispersion at the steering magnet [3, 4]. This can be accommodated in the response coefficient by an additional term to Eq. 1 containing the dispersion at the location of the steering magnet and the BPM

$$C^{ij}_{12} = \left[R^{ij}\left(1 - R^{jj}\right)^{-1}\right]_{12} - \frac{D^i D^j}{\eta C} \tag{2}$$

with the ring circumference C and the the phase slip factor η.

In this note we generalize this expression to the fully coupled case.

COUPLED CASE

The six-dimensional full-turn matrix R^{jj} starting at location j maps the orbit vector $\vec{x} = (x, x', y, y', \tau, \delta)$ onto itself after one turn. If there is a perturbation vector $\vec{v}$ present at location j the requirement for a periodic solution reads

$$\vec{x} = R^{jj}\vec{x} + \vec{v}\,. \tag{3}$$

Note that the requirement to have equal entries in the arrival time and energy location, constrains the revolution time to be constant. The solution to this equation is given by $\vec{x} = (1 - R^{jj})^{-1}\vec{v}$ and the top left 4×4 part of $(1 - R^{jj})^{-1}$ is the response matrix which constrains the revolution time. This is well-known and used for example in the accelerator toolbox [5] to determine the closed orbit.

In order to find a generalized version of Eq. 2 and express the response coefficients in terms of the dispersions we need to split Eq. 3 in a transverse and longitudinal part. To achieve this we write the matrix R^{jj} in terms of its 2×2 sub-matrices

$$R^{jj} = \begin{pmatrix} A & B & C \\ D & E & F \\ G & H & I \end{pmatrix} \tag{4}$$

and split the equation into a transverse and a longitudinal part

$$\begin{aligned} |x\rangle &= \hat{R}\,|x\rangle + \begin{pmatrix} C \\ F \end{pmatrix}\begin{pmatrix} \tau \\ \delta \end{pmatrix} + |v\rangle \\ \begin{pmatrix} \tau \\ \delta \end{pmatrix} &= (G, H)\,|x\rangle + I\begin{pmatrix} \tau \\ \delta \end{pmatrix}\,. \end{aligned} \tag{5}$$

here $|x\rangle$ denotes the transverse part of the closed orbit vector $\vec{x}$. Solving the second, longitudinal equation for τ and δ, inserting in the first equation and collecting terms we arrive at

$$\left[1 - \hat{R} - \begin{pmatrix} C \\ F \end{pmatrix}(1 - I)^{-1}(G, H)\right]|x\rangle = |v\rangle \tag{6}$$

The matrix in the square brackets is the inverse of the response matrix c^{jj}. To express it in terms of the dispersion we first need to identify the dispersions in a coupled ring. It is given by the periodic orbit vector subjected to the perturbation defined by the $R_{i,6}$ matrix elements, namely

$$|D\rangle = \hat{R}\,|D\rangle + \begin{pmatrix} R_{16} \\ R_{26} \\ R_{36} \\ R_{46} \end{pmatrix}. \tag{7}$$

Consequently we introduce the dispersion-like quantities with a tilde on top

$$\begin{pmatrix} \tilde{C} \\ \tilde{F} \end{pmatrix} = (1 - R)^{-1}\begin{pmatrix} C \\ F \end{pmatrix}. \tag{8}$$

and note that the right column of $\tilde{C}$ and $\tilde{F}$ contains the dispersions. This leads to

$$\left[1 - \begin{pmatrix} \tilde{C} \\ \tilde{F} \end{pmatrix}(1 - I)^{-1}(G, H)\right]|x\rangle = (1 - R)^{-1}|v\rangle \tag{9}$$

and the special form of the matrix in the square brackets permits us to explicitly calculate its inverse with the result

$$|x\rangle = \left[1 + \begin{pmatrix} \tilde{C} \\ \tilde{F} \end{pmatrix} Q\,(1 - I)^{-1}(G, H)\right](1 - R)^{-1}|v\rangle \tag{10}$$

where Q is given by

$$Q = \left[1 - (1 - I)^{-1}\left(G\tilde{C} + H\tilde{F}\right)\right]^{-1}. \tag{11}$$

LOW EMITTANCE TUNING FOR THE CLIC DAMPING RINGS*

J. Alabau-Gonzalvo, F. Antoniou, Y. Papaphilippou, CERN, Geneva, Switzerland

Abstract

A study on the sensitivity of the CLIC Damping Ring lattice to different sources of misalignment is presented. Dipole and quadrupole rolls, quadrupole and sextupole vertical offsets are considered, as well as the impact of a finite BPM resolution. The result of this study defines a low emittance tuning procedure and establishes alignment tolerances to preserve the vertical emittance below the design value (1 pm·rad). Non-linear dynamics studies including dynamic aperture and frequency maps are shown and synchrotron radiation effects are discussed.

INTRODUCTION

The design of the Damping Ring (DR) for a future linear collider foresees unprecedent small emittances. For the CLIC DRs, the zero-current equilibrium vertical emittance is $\gamma\epsilon_y$ = 3.7 nm·rad as compared to the target of 5 nm·rad, providing enough margin for the observed growth due to IBS at the nominal current [1]. This corresponds to an ultralow vertical emittance of around 0.7 pm·rad at the DR energy of 2.86 GeV.

Alignment of the magnetic elements is crucial for reaching this ultra-low vertical emittance. The goal of this study is to define a correction procedure for a realistic machine in order to achieve the design emittance, thus identifying the target misalignment tolerances.

The CLIC DR is a racetrack lattice with Theoretical Minimum Emittance cells in the arcs and superconducting wigglers in the long straight sections. The lattice has BPMs located near the quadrupoles in the straight section FODO cells and in points of alternated high and low dispersion and beta functions in the arcs corresponding to a total of 358 monitors along the machine. Alternated horizontal and vertical orbit correctors are installed close to the straight section quadrupoles, and additional windings in the sextupoles are used for correcting both planes in the arcs, with a total of 320 vertical and 312 horizontal orbit correction knobs. Skew quadrupole correctors are installed as well as additional windings in the sextupoles. The first section of this paper explains the main differences between the previous low emittance tuning and the actual one. The results before and after applying BPM finite resolution are presented in the second section. Lastly, the non-linear behaviour of the lattice is studied with dynamic aperture (DA) and frequency maps.

* The research leading to these results has received funding from the European Commission under the FP7 Research Infrastructures project EuCARD-2, grant agreement no.312453.

LOW EMITTANCE TUNING

As introduced in previous studies [2], four kinds of misalignment are being considered:

- Quadrupole vertical offsets
- Quadrupole transverse rolls
- Dipole transverse rolls
- Sextupole vertical offsets

With respect to the previous low emittance tuning studies the coupling correction procedure has evolved in order to make it more realistic by including BPM finite resolution. Previously, the correcting method cancelled the $\langle xy\rangle$ element from the one turn transfer matrix in each BPM. This parameter was taken directly from MADX [3] and the explicit dependence with the BPM resolution is not straightforward. Now the coupling is corrected along with the dispersion and it is made directly from position measurements taken from the monitors. The response submatrix corresponding to the coupling (C) is built by measuring the change in the beam vertical position at every BPM (Δ_y) when each skew quadrupole is sequentially activated (k_{skew}), while the beam is being horizontally kicked at a fixed point:

$$\begin{pmatrix} \Delta y \\ w \cdot \Delta D_y \end{pmatrix} = \begin{pmatrix} C \\ w \cdot D \end{pmatrix} \cdot (k_{skew}) \qquad (1)$$

The algorithm foresees a weight w between dispersion and coupling correction. The optimization of this weight has been done for each kind of misalignment looking at the value that minimised the vertical emittance. The chosen optimal weight is $w = 2.1$, which corresponds to the optimal correction of the coupling due to vertical quadrupole offset since the lattice is most sensible to it.

SIMULATION RESULTS

Once the correction is applied, the four coupling elements of the one turn transfer matrix are visibly flattened and the maximum error in the dispersion is lowered by a factor 8. The beta beating is also lowered from a maximum value of 5.6% to a 0.13%. The maximum pole tip field after 200 misaligned lattices (using a set of RMS errors equal to the found tolerances, see next section) was 0.03 T for an aperture of 20 mm, which is well within the feasible limits.

Simulations have been done averaging over 200 machines for each of the four misalignment considered, which were distributed according to a 2.5σ truncated Gaussian.

Figure 1 shows the result of applying each error independently. The geometrical vertical emittance as a function of the RMS error is plotted for the uncorrected lattice in solid red line and for the corrected in solid light blue. The

AN EXTENDED SPS LONGITUDINAL IMPEDANCE MODEL

José E. Varela, T. Argyropoulos, T. Bohl, F. Caspers, J. F. Esteban Müller, J. Ghini, A. Lasheen, D. Quartullo, B. Salvant, E. Shaposhnikova, C. Zannini, CERN, Geneva, Switzerland

Abstract

Longitudinal multi-bunch instability in the CERN SPS with a very low intensity threshold is a serious limitation for the future doubling of bunch intensity required by the HL-LHC project. A complete and accurate impedance model is essential to understand the nature of this instability and to plan possible cures. This contribution describes the current longitudinal impedance model of the SPS. Electromagnetic simulations and bench measurements were used to build the model. The contribution from each element is described and compared to the total machine impedance. Together with relevant beam measurements and simulations, the analysis of the different sources of impedance is used to identify the source of the longitudinal instability limiting the SPS performance so that the responsible elements can be acted upon.

INTRODUCTION

At the end of the LHC Run 1 in 2012 the beam with 25 ns bunch spacing and with an intensity of 1.3×10^{11} p/b was successfully accelerated in the SPS. However, for the intensity of HL-LHC ($\sim 2.5 \times 10^{11}$), the SPS bunches will be too long for the LHC capture with the existing 400 MHz RF system. This limitation comes from beam loading and longitudinal beam instabilities in the SPS. As a part of the LHC Injectors Upgrade (LIU) project [1], instabilities were studied by means of beam measurements and simulations [2,3]. The simulations rely on having an accurate impedance model of the machine. This paper describes the current status of the SPS longitudinal impedance model which was recently updated with the contribution from the vacuum flanges [4]. This model is then used in macroparticle simulations and the results are compared to beam measurements.

LONGITUDINAL IMPEDANCE MODEL

The longitudinal impedance model of the SPS currently accounts for the accelerating and Landau cavities, the extraction kickers, the vacuum flanges, the Beam Position Monitors (BPM), the pumping ports, the so-called Y-chambers, the beam scrapers and resistive wall as well as space charge impedance at low energy. The main contributors are the accelerating cavities, the extraction kickers and the vacuum flanges. Recently, the focus has been put on the accurate characterization of the Higher Order Modes (HOM) of the RF cavities and on the electrostatic and magnetic septa.

Cavities

The SPS has two RF systems, four 200 MHz Traveling Wave Cavities (TWC) and two 800 MHz TWC. The existing impedance model for the fundamental pass-band of the cavities is [5]

$$Z(\omega) = R\left[\left(\frac{\sin(\tau/2)}{\tau/2}\right)^2 - 2j\frac{\tau - \sin(\tau)}{\tau^2}\right], \qquad (1)$$

with $\tau = (\omega - \omega_0)l/v_g(\omega)$, where l is the length of the cavity, $v_g(\omega)$ is the frequency dependent group velocity and R the impedance at the center frequency ω_0. This model assumes perfect main coupler matching to the traveling wave inside the cavity. It has to be highlighted that the dependence on frequency of the group velocity is specially important for the 200 MHz cavities, as it introduces a significant asymmetry in the impedance spectrum.

There are two $\sim$ 16 m and $\sim$ 20 m long 200 MHz cavities. They have $R = 875$ kΩ and $R = 1.4$ MΩ, respectively. The 800 MHz cavities are $\sim$ 3 m long and are modeled with $R = 970$ kΩ. Finally, there is one known longitudinal HOM in the 200 MHz cavities at 629 MHz. With the existing HOM damping, this HOM can be described as a resonator with $R = 108$ and 86 kΩ and $R/Q = 430$ and 346 Ω for the long and short cavities, respectively.

The black lines in Fig. 1 show the modulus of the total longitudinal impedance of the SPS in both linear and logarithmic scales. The two biggest peaks, at 200 and 800 MHz, are the contributions from the fundamental pass-bands of the cavities.

Kickers

The SPS kickers are the biggest source of longitudinal broadband impedance. A fast extraction kicker system was

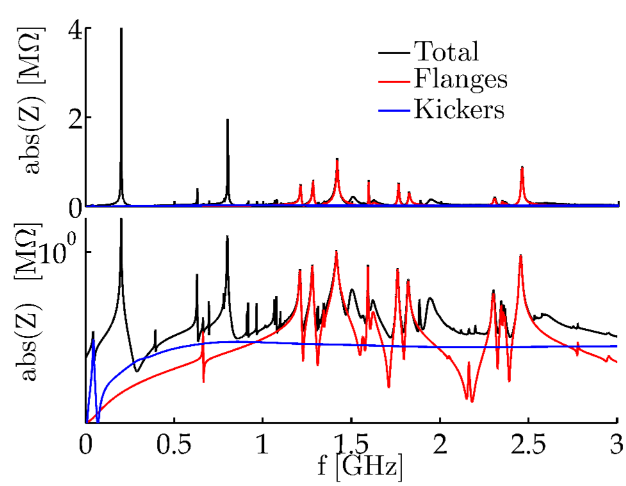

Figure 1: Modulus of the current longitudinal impedance of the SPS. The red and blue traces show the contribution of the vacuum flanges and the kickers, respectively. The top and bottom plots show the impedance in linear and logarithmic scale, respectively.

LONGITUDINAL IMPEDANCE CHARACTERIZATION OF THE CERN SPS VACUUM FLANGES

José E. Varela, CERN, Geneva, Switzerland

Abstract

This contribution describes the thorough studies carried out to characterize the longitudinal impedance of the CERN SPS vacuum flanges, which are believed to be the main source of LHC beam instability. Around 600 high-impedance flanges of 12 different types have been identified. Not only, full-wave electromagnetic field simulations, but also RF measurements have been used to evaluate the impedance of these elements. The R/Q of the relevant resonances was measured using the well-known bead-pull technique. In particular, a subset of ~ 150 flanges has been found to be the source of a high-impedance resonance at 1.4 GHz, also observed in beam measurements. Two possible ways of reducing the impedance of these elements are currently under consideration and will be briefly discussed here.

INTRODUCTION

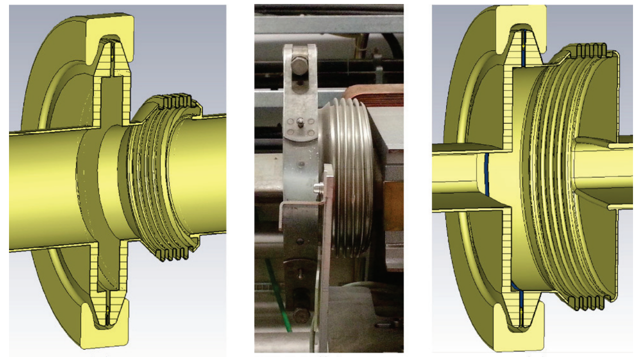
Longitudinal multi-bunch instability in the CERN SPS with a very low intensity threshold is a serious limitation for the future doubling of bunch intensity required by the HL-LHC project. During the past years, a lot of effort has been put into studying this instability by means of beam dynamics simulations [1]. Self-evidently, these simulations rely on having an accurate impedance model of the machine. This contribution describes the longitudinal coupling impedance of the elements which are believed to be the source of the instability.

The longitudinal coupling impedance of the interconnects between the different types of vacuum chambers in the SPS was already studied by G. Dôme in 1973 [2]. As a result, cylindrical resistors were placed all around the ring to damp the resonances created by the aforementioned interconnects. In 2001, around 800 pumping ports were shielded in a huge impedance reduction campaign as they were limiting the performance of the SPS [3]. Currently, the multi-bunch instability threshold is reached at $\sim 3 \times 10^{10}$ p/b. To reach the nominal intensity of 1.15×10^{11} both, the 800 MHz cavities and controlled longitudinal emittance blow up are used. The SPS bunches will be too long for the LHC to capture for the requested intensity of HL-LHC (2.5×10^{11}). As part of the LHC Injectors Upgrade (LIU) project [4], one of the potential cures for this problem is to reduce the impedance of the vacuum flanges [5].

LONGITUDINAL COUPLING IMPEDANCE CHARACTERIZATION

Classification of the Vacuum Flanges

The vacuum flanges in the SPS can be divided in two main groups depending on the vacuum chambers that they interconnect. Small (83 mm inner diameter) circular cross-section chambers are referred to as QD beam pipes. Similarly, elliptical and quasi-rectangular cross sections are named QF and MBA beam pipes. Flanges interconnecting two QD vacuum chambers, as the one shown in Fig. 1 (a), belong to group I. On the other hand, flanges interconnecting any combination of MBA and QF chambers, see Fig. 1 (b) and (c), belong to group II. Groups I and II contain approximately 400 and 240 flanges respectively. Each group is further divided into six different flange types. Finally, a number of flanges in the SPS have an enamel coating. The enamel is used to electrically isolate both sides of the flange. These flanges are part of the grounding scheme of the SPS which minimizes the effect of eddy currents.



(a) (b) (c)

Figure 1: SPS vacuum flanges. (a) Model of a QD-QD flange. (b) Photo of a QF-MBA flange in the SPS. (c) Model of an MBA-MBA flange.

Simulations

All the aforementioned types have been modeled using official SPS layouts and simulated using HFSS [6], CST [7] or both. As analogous to the method used to calculate beam-loading in the CLIC main Linac [8], an on-axis plane wave was used as a source to calculate the beam induced field inside the enameled interconnects. Non-enameled flanges were characterized using both the aforementioned method and the wake field solver of CST. The enamel coating was modeled as a 0.2 mm thick layer with relative permeability $\epsilon_r = 3$ and dielectric losses tan$\delta = 0.01$. Finally, a conductivity of $\sigma = 1.35 \times 10^6$ S/m was used for the beam pipes and bellows to model the 304L/316L stainless steel.

Flanges belonging to group II are responsible for a set of resonances around 1.4 GHz. The enameled flanges are open and inhomogeneous resonators. Radiation losses were found to be dominant in all enameled flanges of group II. On top of this, these flanges have damping resistors inside. The damping resistors are hollow alumina cylinders with

STUDY AND COMPARISON OF MODE DAMPING STRATEGIES FOR THE UA9 CHERENKOV DETECTOR TANK

A. Danisi, A. Masi, R. Losito, F. Caspers, C. Vollinger, B. Salvant, CERN, Geneva, Switzerland
T. Demma and P. Lepercq, LAL, Orsay, France

Abstract

In the framework of the UA9 experiment, the Cherenkov detector is useful to measure the amount of particles deflected by a bent crystal, proving the crystal collimation principle. The tank used to host this device is taken as a case study for an in-depth analysis of different damping strategies for electromagnetic modes which otherwise would give rise to important beam-coupling impedance contributions. Such strategies involve the use of ferrite, damping resistors and a mode-coupler, a solution which intercepts the modes inside the cavity but damps the related power outside the vacuum tank (potentially avoiding heating). Such solutions are discussed through experimental measurements and the relative quality factor is taken as a figure of merit.

INTRODUCTION

The UA9 experiment aims at the use of bent crystals instead of carbon jaws to achieve beam collimation. The UA9 experimental layout [1] includes many critical devices such as precision piezo-goniometers for crystal positioning, beam-loss monitors and Cherenkov detectors. The Cherenkov detector is installed using a special vacuum tank with four apertures.

From the beam-coupling impedance viewpoint, these apertures can give rise to resonances which could de-stabilize the beam. Many techniques are available to date [2]-[4] in order to decrease the quality factor of unwanted cavity resonances. This paper takes the UA9 Cherenkov detector (CD) as a case study for investigation on different damping techniques, based on ferrite insertions, damping ceramic resistors and mode couplers. The study is performed with experimental measurements carried out on a 1:1 scale replica of the Cherenkov vacuum tank.

THE CASE STUDY

The UA9 CD vacuum tank for use in the SPS is depicted in Fig. 1. It can be seen as a central cylindrical cavity with four smaller cylindrical cavities (ends), disposed on two perpendicular directions. Along the z direction, instead, is the beam path.

The vacuum tank is made of 316 LN steel and does not present any object in the central cavity. The detector bar is mounted on one of the four ends [5], whereas the other three ends remain available for diagnostic equipment.

A fast simulation of the UA9 CD tank using Microwave Studio has shown that two particular modes are of interest when considering the beam-coupling impedance issues of this device: the first one is at about 922 MHz and the second one is at about 1.32 GHz. Both are TM modes associated with the central cavity and are characterized by the quality factors listed in Table 1 (void cavity).

A way of decreasing or even vanishing the quality factors and shunt impedances of parasitic cavity resonances is to re-design the structure, so as to avoid the occurrence of such resonances (e.g. use of uniform-diameter sectors, RF shielding, elimination of unused empty spaces). When this step is not possible due to other design issues, i.e., when the re-design for impedance-related issues leads to unacceptable changes, passive countermeasures have to be considered.

EXPERIMENTAL RESULTS

Measurements Setup

Measurements have been carried out in transmission. The two beam pipe outputs and the four apertures of the vacuum tank have been sealed with aluminium flanges. Two small antennas mounted on coaxial assemblies, have been inserted axially and connected to a Vector Network Analyser (VNA) for the measurement of the S_{21} scattering parameter (Fig. 2).

Given the excitation scheme (axial linear antenna), mostly TM modes will be excited. The two probes are largely undercoupled so as not to perturb the configuration of the electromagnetic fields in the original uncoupled vessel. [6].

For each resonance peak measured on the S_{21} parameter, a preliminary check (through the Smith chart) has been done in order to maintain under-coupling conditions of the probes. Successively, the quality factor [4], [6] has been measured directly with the VNA.

Different damping strategies have been tested for this

IMPEDANCE STUDIES OF THE LHC INJECTION KICKER MAGNETS FOR HL-LHC

H. Day*, M.J. Barnes, L. Coralejo Feliciano, CERN, Geneva, Switzerland

Abstract

The LHC injection kicker magnets (MKIs) experienced strong heating during the first operational run, identified as being caused by power loss due to wakefields induced by circulating beam. Studies of the beam coupling impedance of the beam screen, a series of conductors embedded in a ceramic tube placed in the aperture of the ferrite yoke to screen the ferrite from the beam, resulted in new design offering improved screening: this is predicted to reduce the heating to acceptable levels for operation with 25ns beam during run 2 of the LHC. However higher beam intensities proposed for HL-LHC operation are predicted to again cause strong heating to occur. Further studies have been carried out to reduce the beam induced power loss by optimising the beam screen design, some key results and findings of which are presented here.

INTRODUCTION

The injection kicker magnets (MKIs) are fast pulsed transmission line kicker magnets, which have a ceramic tube inserted into the aperture of the ferrite yoke: this supports a number of screen conductors, designed to provide a good conducting path for the image currents of the circulating beam. One end of the screen is directly connected to the beam pipe whilst the other is capactively coupled to the beam pipe in order to preserve the fast field rise time of the magnet. Beam-induced heating, due to high circulating beam current, leads to high temperatures being observed in devices in the LHC, including the MKIs [1]. In one non-conforming MKI this lead to problems as the temperature of the ferrite yoke occassionally rose above it's Curie temperature (≈120°C) necessitating 2-3 hours waiting time between fills. Substantial work has been done to reduce the power deposited by reducing the beam coupling impedance of the device - a revised beam screen was implemented on all magnets during long shutdown 1 (LS1) which is predicted to reduce the power loss to <52W/m (see Table 1) and the temperature is <80°C [2], comfortably below the Curie temperature.

The planned high luminousity upgrade of the LHC (called HL-LHC) will involve a doubling of the beam current in the LHC under current nominal parameters [3] - this is predicted to lead again to a four fold increase in the power loss to all devices in the LHC unless counter-measures are taken. To this end further improvements to the beam screen have been studied in order to reduce the power loss into the magnet whilst continuing to ensure both good high voltage (HV) performance and good field quality during pulsing.

Building on the previous success a new design has been proposed to satisfy competing needs of low rates of electrical breakdown, during magnet pulsing, and a low beam coupling impedance to reduce the power lost into the structure by wakefields; in addition to meet strict requirements for magnet operation for field rise time and flat top ripple [4].

* hugo.day@hep.manchester.ac.uk

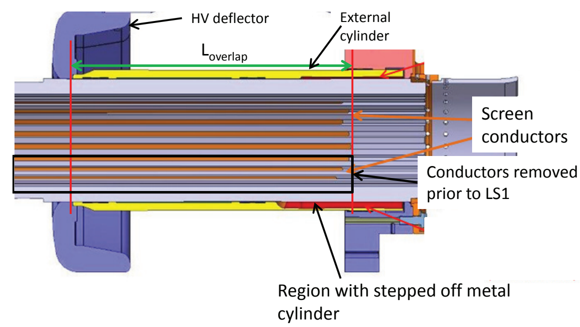

Figure 1: Cross-section of the beam screen of the MKI. Conductors circled in red weren't in place prior to long-shutdown 1.

CHANGES TO BEAM SCREEN DESIGN

Past work on the beam screen of the MKI has focused on improving the screening of the ferrite yoke from the beam by increasing the number of screen conductors in the beam screen to the full compliment of 24 - during the first run of the LHC only 15 screen conductors were in place, positioned closest to the return busbar (see Fig. 1), due to issues with surface flashover during magnet pulsing [5].

A revised beam screen was designed that reduced the electric field strength during magnet pulsing sufficiently to allow 24 conductors to be installed for post-LS1 [4], shown in Fig. 1. This is predicted to substantially reduce in the power loss in the MKIs post LS1, by a factor of more than 3 relative to the non-conforming MKI pre-LS1 (≈160W/m), even accounting for the increased beam current with the change to 25ns bunch separation. However this is not expected to be sufficient for HL-LHC operation, which will see a much higher beam current than nominal LHC operation (see Table 2) and is predicted to see power losses comparable to that which caused the non-conforming magnet to heat beyond it's Curie temperature during run 1 of the LHC [6], thus necessitating further modifications.

Previous work had showed that the beam coupling impedance of the MKI with a well shielded ferrite yoke is resonant in nature, with the frequency of the resonances, f_{res}, determined by the length of the overlap between the screen conductors on the internal face of the ceramic tube

GENERALISED TRUNCATED POWER SERIES ALGEBRA FOR FAST PARTICLE ACCELERATOR TRANSPORT MAPS

L. Deniau, C. I. Tomoiagă, CERN, Geneva, Switzerland

Abstract

A new Generalised Truncated Power Series Algebra (GTPSA) has been developed for extending, simplifying and optimising the transport maps used by particle accelerator simulation codes. TPSA are intensively used in optics code to describe transport maps of the elements constituting the particle accelerator to any order. GTPSA extend the degrees to inhomogeneous ones, where separate degrees can be specified for each variable and constrained by two total orders, one for map variables and one for ordinary variables. This allows tracking inhomogeneous planes of the 6D phase space with many extra variables. A complete set of new formulas and data structures have been derived to address the problem of memory consumption required for efficient computation of high order TPSA, including generalised indexing, multiplication and composition of inhomogeneous multivariate polynomials. The implementation has been benchmarked against well established libraries for the common subset with TPSA, and outperforms all of them for supported differential algebra operators on low and high orders, and high number of variables.

INTRODUCTION

TPSA packages are intensively used in optics code to describe transport maps of the elements constituting the particle accelerator to any order [1,2]. Most of the known fast multiplication algorithms working for univariate polynomials do not straightforwardly extend to several variables [3], and therefore the brute force approach remains the most efficient one for *truncated* power series. The performance improvements have to come from other kind of optimizations [4–7].

Notations

The TPSA are multivariate polynomials $P(\vec{z}) \in \mathbb{K}[\vec{z}]$, $\vec{z} = \{z_1, ..., z_n\}$ truncated at order d, where the commutative ring is generally $\mathbb{R}$ or $\mathbb{C}$. A multivariate polynomial is defined by the sum of all the monomials of order d or less:

$$P(\vec{z}) = \sum_{i=1}^{N} a_i \prod_{j=1}^{n} z_j^{\alpha_{ij}}, \quad \sum_{j=1}^{n} \alpha_{ij} \le d, \tag{1}$$

where the number N of coefficients a_i is given by:

$$N = C(n+d, n) = C(n+d, d) = \frac{(n+d)!}{n!d!}. \tag{2}$$

The binomial coefficient C is symmetric in variables and orders, hence a TPSA package can deal equivalently with high orders and low number of variables or low orders and high number of variables. The number N_i of monomials of order i with $0 \le\ i \le\ d$ or equivalently of monomials in the variable z_j^{d-i} with $1 \le\ j \le\ n$ can be calculated from the recurrence property of the binomial coefficient:

$$\begin{aligned} N_i &= C(n+i, n) - C(n+i-1, n) \\ &= C(n+i, n-1). \end{aligned} \tag{3}$$

Representations

The (unordered) sum of the monomials in (1) can be ordered in two practical forms:

1. By the **product of univariate polynomials** in the variables z_i, which is used by the indexing function:

$$P(\vec{z}) = \prod_{i=1}^{n} P(z_i) = \sum_{i=0}^{d} \sum_{j=1}^{N_{d-i}} a_{ij} \vec{z}_{ij}. \tag{4}$$

The monomial $\vec{z}_{ij}$ associated with the coefficient a_{ij} are generated recursively from $z_k \times \{z_{k+1}, ..., z_n\}$, e.g. the outer sum over i corresponds to the variable z_1. As an example, a multivariate polynomial of order 3 with variables $\{z_1, z_2, z_3\}$ can be represented by the series:

$$\begin{aligned} P(\vec{z}) =& a_1 z_1^0 z_2^0 z_3^0 + \\ & a_2 z_1^0 z_2^0 z_3^1 + a_3 z_1^0 z_2^0 z_3^2 + a_4 z_1^0 z_2^0 z_3^3 + \\ & a_5 z_1^0 z_2^1 z_3^0 + a_6 z_1^0 z_2^1 z_3^1 + a_7 z_1^0 z_2^1 z_3^2 + \\ & ... + a_{20} z_1^3 z_2^0 z_3^0. \end{aligned} \tag{5}$$

2. By the **sum of homogeneous multivariate polynomials** in the orders $i = \sum_{k=1}^{n} \alpha_{ik}$, , which is used by the storage of the a_{ij} and by the optimized multiplication:

$$P(\vec{z}) = \sum_{i=0}^{d} P_i(\vec{z}) = \sum_{i=0}^{d} \sum_{j=1}^{N_i} a_{ij} \vec{z}_{ij}. \tag{6}$$

The monomial $\vec{z}_{ij}$ associated with the coefficient a_{ij} are generated recursively from $P_1 \times P_{i-1}$. As an example, a multivariate polynomial of order 3 with variables $\{z_1, z_2, z_3\}$ can be represented by the series:

$$\begin{aligned} P(\vec{z}) =& a_1 z_1^0 z_2^0 z_3^0 + \\ & a_2 z_1^0 z_2^0 z_3^1 + a_3 z_1^0 z_2^1 z_3^0 + a_4 z_1^1 z_2^0 z_3^0 + \\ & a_5 z_1^0 z_2^0 z_3^2 + a_6 z_1^0 z_2^1 z_3^1 + a_7 z_1^0 z_2^2 z_3^0 + \\ & ... + a_{20} z_1^3 z_2^0 z_3^0. \end{aligned} \tag{7}$$

Generalization

The GTPSA extends the TPSA by splitting the variables in two kinds $\vec{z} = \{\vec{x}, \vec{k}\}$, where the **map variables** $\vec{x} = \{x_1, ..., x_v\}$ with $v \ge\ 1$ are present in both the map and the (G)TPSA of the map variables, and where the **knob variables** $\vec{k} = \{k_{v+1}, ..., k_n\}$ with $n - v \ge\ 0$ are only present in the GTPSA of the map variables.

LONGITUDINAL INJECTION SCHEMES FOR THE CERN PS BOOSTER AT 160 MeV INCLUDING SPACE CHARGE EFFECTS

V. Forte*, CERN, Geneva, Switzerland - Université Blaise Pascal, Clermont-Ferrand, France
E. Benedetto, A. Lombardi, CERN, Geneva, Switzerland
D. Quartullo, CERN, Geneva, Switzerland - Ministère des Affaires étrangères, France

Abstract

In the frame of the LHC Injectors Upgrade project, the CERN PS Booster will be equipped with a H- injection system at 160 MeV to tailor the initial transverse and longitudinal profiles. We are here reviewing the different multi-turn longitudinal injection schemes, from the beam dynamics point of view, taking into account the needs of the large variety of the PSB users, spanning in intensity from 5e9 to about 1.6e13 protons per bunch. The baseline of the longitudinal injection has always been the longitudinal stacking with central energy modulation: this scheme has the advantage of filling uniformly the RF bucket and mitigate transverse space charge, but it requires at least 40 turns of injection. A simpler injection protocol without energy modulation is here analyzed in detail to find the optimum initial conditions in terms of bucket filling and reduction of transverse and longitudinal space charge effects, with the advantage of minimizing the number of turns for the LHC beams. Simulations with space charge of the longitudinal injection process from different Linac4 trains are presented to fix possible longitudinal injection scenarios during the future commissioning and operation with Linac4.

INTRODUCTION

The transverse space charge in the CERN PS Booster (PSB) is one of the main bottle-necks for the machine beam dynamics. In the framework of the CERN LHC Injectors Upgrade project (LIU) project, the machine will be equipped with a new H- charge-exchange injection at 160 MeV, substituting the present 50 MeV proton multiturn injection. The Linac4 chopper will give the opportunity to tailor the longitudinal beam profiles in a way to minimize the space charge effects in terms of losses and longitudinal/transverse emittances. The PSB has to produce large variety of beams and we here consider the production of the 2 most important ones: the high intensity and large emittance beam for ISOLDE experiment and the LHC high brightness beam [1]. For ISOLDE we will inject 100 turns [2] and use the baseline scheme proposed already by C. Carli and R. Garoby [3]: in this way the energy modulation in the Linac4 requires at least 40 turns to complete this longitudinal painting scheme.

This is the reason why for the standard LHC beams (I=29.55e11 p.), 20 turns injection [4], for which it is important to minimize the number of foil hits and blow-up due to the scattering at the screen, we consider no energy modulation. The main concern of this solution is the inhomogeneities and beating of the bunch shape, leading to a dense core and less populated tails [3]. However this regulation becomes more practical in control room during the commissioning of the machine.

Several simulations have been run through the ESME [5] and PyOrbit [6] codes with Linac4 realistic bunches to evaluate the parameters of possible initial unmodulated injections in a double RF accelerating bucket for the first 10 ms after injection: it is possible, in simulation, to vary the bunch length (in reality with the chopper) and/or the energy spread ΔE (in reality with the debuncher) of the injected beams. The choice of using PyOrbit for pure longitudinal studies goes in the direction of using the code as baseline for 6D tracking including transverse-longitudinal space charge effects. Finally PyOrbit and BlonD [7] have been compared to estimate the contribution of space charge effects for the unmodulated injection scheme, after an initial benchmark between the two codes.

LONGITUDINAL PAINTING SCHEME WITH ENERGY MODULATION

A longitudinal painting scheme with energy modulation has been selected as preferred one for high intensity beams, because it makes possible a uniform population of the initial accelerating RF bucket and, therefore, a reduction of the line density [protons/m] and an increase of the bunching factor, which are favorable conditions for reduced transverse space charge effects. This scheme aims at filling the 80% of the double RF accelerating bucket through a series of small energy spread (0.1 MeV) beams which are injected at different central energy. The central energy is modulated in time in a triangular way between ±1 MeV. Figure 1 shows the bucket at the end of the filling, before the full filamentation phase. As said, this method requires at least 40 turns to be completed.

THE UNMODULATED INJECTION

The longitudinal machine settings for the simulations are shown in Table 1. Figure 2 shows the three initial tested values of energy spread from Linac4: 113 keV, 336 keV and 592 keV rms. Figure 3 shows that the solution at 336 keV (halfway) is preferable, as it minimizes the peak line density due to the rotation in the longitudinal phase space of the mismatched beam, with respect to the 113 keV case (Fig. 4). Figure 5 represents the peak line density evolution turn-by-turn for the two cases.

On the other side, at 592 keV rms, the beam has a very large energy spread (over the acceptance). In this case, to

DESIGN AND OPTIMIZATION OF ELECTROSTATIC DEFLECTORS FOR ELENA

D. Barna, University of Tokyo, Japan
W. Bartmann, M. Fraser, R. Ostojic, CERN, Switzerland

Abstract

The ELENA ring [1] will decelerate the antiprotons ejected from the Antiproton Decelerator (AD) at 5.3 MeV down to 100 keV kinetic energy. The slow antiprotons will be delivered to experiments using electrostatic beamlines, consisting of quadrupoles, correctors and deflectors. An extensive simulation study was carried out to find solutions to minimize the aberrations of the deflectors. These solutions will be presented together with the actual design of these devices.

INTRODUCTION

At low particle energies electrostatic devices have many advantages over magnetic ones, for example the absence of remanent magnetic fields, no need for cooling, cheap and simple production. Following a cost-performance analysis, electrostatic beamlines were chosen for ELENA.

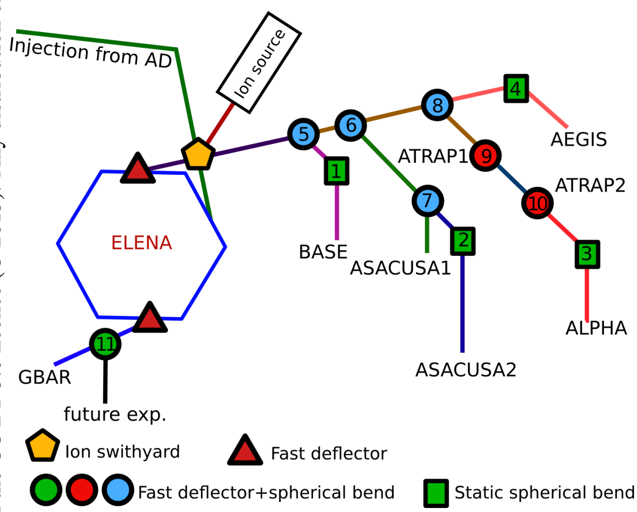

Figure 1: Layout of the ELENA transfer lines.

The schematic layout of the ELENA transfer lines is shown in Fig. 1. Due to the constraints given by the existing experiments and other equipment already present in the AD hall, the angles of the different bends could not be made equal. However, they can be arranged into groups with nearly equal angles. In order to facilitate the design, manufacturing and spare part management, identical electrode structures will be used at these positions with slightly different voltage settings to account for the different bending angles. In most cases the deflectors will have custom vacuum chambers to match the actual angle of the beamline.

The deflectors of the ELENA transfer lines can be grouped into following types (Table 1):

1. Fast switch (FS) combinations: ELENA will deliver 4 antiproton bunches with a spacing of about 1 µs in a single extraction. These bunches will be distributed among 4 experiments running simultaneously using fast switches in the beamlines. This functionality is realized by a combination of a fast electrostatic deflector [2] (the same device which is used for ejection from the ring) and a static deflector. The fast deflector has a rise time <1 µs and gives an initial kick of 220 mrad. The static deflector gives the remaining deflection. The fast switches can be further classified into two groups:
   (a) Horizontal fast switches (HFS at positions 5, 6, 7, 8 and 11 in Fig. 1) - these devices deflect the beam in the horizontal plane by a total angle between 45.7° and 48.1°.
   (b) Vertical fast switches (VFS at positions 9 and 10 in Fig. 1) - these devices deflect the beam vertically to ATRAP1 and ATRAP2.
2. Standalone static deflectors will deflect the beam by an angle between 45.77° and 50.42° at positions 1, 2, 3 and 4 in Fig. 1.

Table 1: List of Electrostatic Deflectors

Pos. in Fig. 1	Tot. defl. [deg]	Type	Electrode angle [deg]	Range [deg]
1,2 3 4	48.1 50.42 45.77	Static Static Static	48	±2.3
5,6,7 8	48.08 45.76	HFS HFS	34.3	±1.2
9,10	90	VFS	77.4	0
11	t.b.d.	HFS	t.b.d.	0

OPTIMIZATION OF ELECTRODES

The mechanical aperture (*A* in Fig. 2a) was chosen to be 65 mm - slightly larger than the value adopted for the beamlines in general (60 mm) due to the following reasons: the fringe field of the device deflects the particles already outside of the electrodes, and the central particle trajectory deviates from the nominal arc towards the bending center. Also, the same device will be used for slightly different bending angles, which gives a further excursion of the central particle trajectory from the nominal arc. A larger aperture

BEAM DYNAMICS STUDIES OF THE ELENA ELECTROSTATIC TRANSFER LINES

M.A. Fraser*, W. Bartmann, R. Ostojic, CERN, Geneva, Switzerland
D. Barna, University of Tokyo, Tokyo, Japan

Abstract

The low-energy ELENA ring at the Antiproton Decelerator (AD) facility at CERN will lower the kinetic energy of antiproton beams from 5.3 MeV to 100 keV, significantly increasing the antiproton trapping efficiency at the experiments. The antiprotons from ELENA will be distributed to two experimental areas housing several different experiments through a system of electrostatic transfer lines totalling 90 m in length. A significant optimisation of the electrostatic optical elements (deflectors, quadrupoles, and correctors) has been carried out to improve the beam quality delivered to the experiments and facilitate installation of the beam lines into the AD hall. A general overview of the beam optics is presented, including end-to-end particle tracking and error studies from the extraction point in the ELENA ring to the experiments.

INTRODUCTION

The installation of the ELENA synchrotron [1] at CERN's AD facility will lower the kinetic energy of antiproton beams to 100 keV. A network of transfer lines has been designed to distribute the low energy antiproton beam to eight different experiments. The system is presently undergoing the first stage of installation in the AD hall. The layout of the transfer lines is shown in Fig. 1 and the relevant ELENA beam parameters for discussion in this paper are collected in Table 1. The transfer lines exploit electrostatic optical elements and are built up in a modular way from a series of standardised blocks: electrostatic quadrupole doublets with integrated correctors, beam position monitors, fast electric deflectors and electrostatic deflectors. After an initial optimisation of the orientation of the ELENA ring the transfer lines have been integrated and the geometry of the lines fixed in the AD hall. The fast deflectors located at each branch permit different bunches within the same bunch train extracted from ELENA to be distributed simultaneously to up to four experiments.

DESIGN OVERVIEW

The initial beam line design [2] was carried out using electrostatic beam line elements represented as transfer matrices and implemented in MADX [3]. The transfer matrices were computed by tracking test particles in the field maps generated using the finite element electromagnetic field solver COMSOL [4, 5]. The higher-order (non-linear) field components were carefully optimised in each device as described elsewhere in these proceedings [6]. The design evolved in several iterations, evaluating each time the effects of changes in the layout, or in the design of the optical elements, on the beam quality. The final validation of the transfer line design was achieved with end-to-end particle tracking in the field maps of all elements from the ELENA ring to the experiment, in the presence of errors and imperfections.

Emit. (95%) H / V [mm mrad]	< 15 / 15	6 / 4
Momentum spread (95%)	1×10^{-3}	2.5×10^{-3}
Intensity [$\bar{\text{p}}$]	3.0×10^{7}	1.8×10^{7}
Bunch length [m]	~12.7	1.3

The basic layout of the lines is determined by a FODO focusing structure with a cell length of 3.1 m and a phase advance of 90 deg per cell. The quadrupoles are housed in the same doublet assembly in order to standardise production; in the FODO sections only one of the quadrupoles in the assembly is powered, whereas in the matching sections both are powered.

Each doublet assembly contains separated horizontal and vertical correctors between the quadrupoles, giving two correctors per plane in each cell and good control over the beam trajectory. This is particularly important in areas where stray field from experimental equipment will play a role in beam tuning.

FIXED POINTS IN PRESENCE OF SPACE CHARGE IN CIRCULAR PARTICLE ACCELERATORS

S. S. Gilardoni, M. Giovannozzi, A. Huschauer, CERN, Geneva, Switzerland
S. Machida, C. R. Prior, S. L. Sheehy, STFC/RAL, Didcot, UK

Abstract

Recent measurements performed in the framework of the multi-turn extraction (MTE) studies at the CERN Proton Synchrotron showed a dependence of the position of beamlets obtained by crossing a stable transverse resonance on the total beam intensity. This novel observation has triggered a number of studies aiming at understanding the source of the observed effect. In this paper the results of numerical simulations performed in different conditions are discussed in detail.

INTRODUCTION

The Multi-Turn Extraction (MTE) at the CERN Proton Synchrotron (PS) is a novel technique [1, 2] proposed to replace the existing extraction from the PS to the Super Proton Synchrotron (SPS) so as to allow long runs compatible with delivering good quality high intensity beams.

The MTE extraction is based on beam trapping in stable islands of the transverse phase-space: the beam is split in five beamlets by crossing a fourth-order resonance and, once sufficiently separated in the horizontal plane, each beamlet is extracted on five consecutive PS turns towards the SPS. The adiabaticity of the trapping process requires a long extraction flat top. During the splitting process, realised at 14 GeV/c for the specific CERN application, the horizontal chromaticity and the beam $\Delta p/p$ are kept both as small as possible, to assure that the largest fraction of the particles crosses the resonance all at the same moment. The beam is kept bunched during the entire capture process to precisely control the radial position, i.e., the energy, for the different reasons described in [3]. The position of the beamlets at the end of the trapping process should depend only upon the distance in tune from the resonance and the amplitude-dependent tune shift, thus from the value of the quadrupolar, sextupolar and octupolar fields introduced to create and control the islands' size and separation.

During normal operation, the total beam intensity can vary between 1×10^{13} and 3×10^{13} protons per pulse, depending on the needs of the SPS users. The intensity is usually kept constant for a certain period of time, usually days, and changed upon users requests. During the MTE commissioning period, as reported in [3], it was noticed that the position of the beamlets, i.e., the position of the stable fixed point in the horizontal phase space, changes significantly and in a measurable way with the intensity. In particular, the final position of the beamlets was found to be a linear function of the total beam intensity, whereas the four beamlets and the beam core sizes did not show any measurable change, as shown for example in Fig. 1. The observed effect suggested

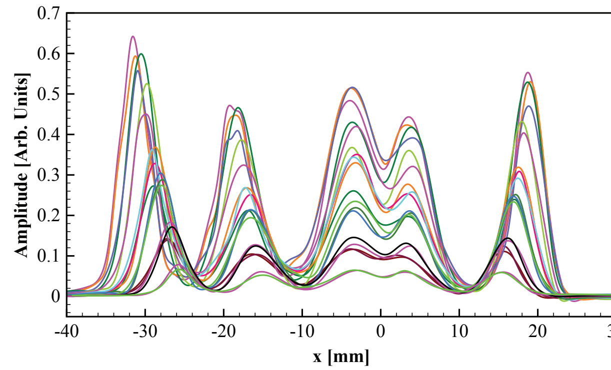

Figure 1: Example of islands profiles measured by a wire scanner and for different intensity [3]. The displacement of the islands centers with intensity is apparent.

as being generated by the superposition of two different components, i.e., the direct space charge between the beamlets and the beam core, and the beamlets interaction with the image charges on the vacuum chamber walls. Also the finite resistivity of the vacuum chamber was proposed to introduce a relevant effect.

This paper presents a first attempt to disentangle the different sources that might cause the observed change of beamlet position, and in particular space charge.

SIMPLE MODEL WITH DIRECT SPACE CHARGE

The incoherent tune shift due to the direct space charge is always negative so that the fixed points in the horizontal phase space move inward when the amplitude-dependent tune shift due to nonlinear elements has negative sign (Fig. 2). That is not the case of the experimental observation where the beamlets move outward with beam intensity [3].

SIMULATIONS WITH FROZEN SPACE CHARGE

In order to simulate the space charge effects, we consider the frozen space charge model of a coasting beam. The charge distribution and total charge of each beamlet are fixed at the beginning of the simulations and redistribution or beam loss is not considered. More specifically, the charge distribution is Gaussian in both horizontal and vertical directions and all the beamlets including that at the centre have the same charge. We calculate, however, the position of beamlets self-consistently including the space charge effects among them. When the distance among the beamlets in real space is more than the beam size of each of them, the

INFLUENCE OF THE ALIGNMENT OF THE MAIN MAGNETS ON RESONANCES IN THE CERN PROTON SYNCHROTRON

A. Huschauer, S. S. Gilardoni, R. Wasef, CERN, Geneva, Switzerland

Abstract

During the Long Shutdown 1 seven out of the one hundred combined function main magnets were removed from the tunnel to conduct maintenance. After reinstallation, the entirety of the main magnets was aligned to the reference positions and within the first week of operation of the accelerator, a beam-based alignment campaign was performed to reduce the excursions of the closed orbit. In order to further investigate and understand the source of betatronic resonances, which, already in 2011, were found to be excited by the bare machine, tune diagram measurements before and after this beam-based magnet alignment were conducted. In both cases the same resonances were found to be present; however, after the alignment, an overall increase of their strengths was observed. In this paper we present the corresponding measurement results and discuss the direct impact on the daily operation of the accelerator.

INTRODUCTION

The CERN Proton Synchrotron (PS) plays a crucial role among the accelerators in the injector chain of the Large Hadron Collider (LHC) and will provide beam to the LHC at least until 2035. Therefore, reliable performance of the accelerator components is required and extensive maintenance measures are being undertaken accordingly. This especially concerns the refurbishment of the combined-function main magnets, which are continuously subject to ionizing radiation and pulsed magnetic forces leading to degradation of these elements. In the framework of the PS main magnet consolidation program, 51 out of 100 main units (MUs) underwent maintenance between 2005 and 2009 [1] and, more recently, seven MUs were refurbished during the Long Shutdown 1 (LS1), which took place from 2013 to 2014. Before the restart of the accelerator complex after the LS1, all MUs were aligned to their reference positions. Subsequently, a beam-based realignment campaign was conducted to reduce the excursion of the closed orbit, and the effect on the betatronic resonances, which are supposedly excited by magnetic errors in the main magnets, was investigated.

The applied measurement technique, which was first proposed in [2], is based on measuring beam loss while keeping the tune constant in one plane and changing it dynamically in the other. These measurements lead to a graphical representation of the tune diagram and the underlying procedure is described in detail in [3].

In order to control the working point, two independent systems are available in the PS: the Low Energy Quadrupoles (LEQ), and the Pole Face Windings (PFW) in combination with the Figure of Eight Loop (F8L) [3, 4]. For the measurements presented in this paper, the PFW and the F8L were used, as these circuits provide larger flexibility compared to the LEQ. A single bunch with large transverse emittance and small direct space charge tune spread was required to increase the sensitivity of the measurement technique by filling the aperture at maximum. The beam parameters, which are summarized in Table 1, show that the maximum tune spreads (computed using the Laslett formula considering the variation of the optical machine parameters [5]) were basically kept constant for both cases. This is important, as it allows direct comparison of the tune scans before and after the realignment.

Furthermore, it was important to perform all measurements at injection kinetic energy of 1.4 GeV to reduce the radiological impact of the losses, as several people were required to access the machine to realign the main magnets.

MEASUREMENT RESULTS

In Fig. 1 the tune diagrams resulting from the measurements before and after the realignment are shown. In total four plots are depicted, corresponding to scans where either the horizontal or the vertical tune was kept constant.

Even though the MUs were aligned to their reference positions during the LS1, the measurements before the realignment revealed the same excited resonances as previous scans (see [3]), such as the lines $3q_y = 1$ and $2q_x + q_y = 1$. The measurements after the realignment, shown in Figs. 1c and 1d, confirm this observation, but the strengths of the various resonances appear to have increased.

Comparison of the Figs. 1a and 1c further reveals that, before the realignment, the vertical tune could be set closer to the integer resonance. In fact, the first measured line

Abstract

The current knowledge of the transverse beam coupling impedance of the CERN Proton Synchrotron (PS) has been established with beam-based measurements at different energies. The transverse coherent tune shift as a function of the beam intensity has been measured in order to evaluate the total effective imaginary part of the transverse impedance in the accelerator at the energies of 7, 13 and 25 GeV. Measurements have been performed changing the vertical chromaticity for each vertical tune scan with intensity. The data analysis revealed an increase of impedance with chromaticity for all the considered energies. The transverse impedance can be compared with the previously evaluated theoretical impedance budget taking into account the individual contribution of several machine devices.

INTRODUCTION

Coherent Transverse Tune Shift

The number of betatron oscillations per turn of the bunch center of mass is called coherent betatron tune, and it is defined as

$$Q_0 = \frac{\omega_\beta}{\omega_0}, \tag{1}$$

where ω_0 is the machine angular revolution frequency and ω_β is the angular betatron frequency. To perform tune measurements, a chirp signal is used to excite the beam, and the variation of the intensity of the bunch allows to observe a tune shift that is linear with the measured intensity. The transverse tunes can be measured in the PS with a Base Band Tune system based on diode detectors, known as the BBQ [1]. The transverse position of the bunch is acquired every turn by a beam position monitor (BPM). High amplitude short pulses measured by the BPM are then sent to a diode detector, which converts the modulation of the BPM pulses, related to beam oscillations, into a signal in the audio frequency range. This signal is then processed in order to deliver the tune content. BBQ measurements are performed here on a single circulating bunch of particles.
Measuring the tune shift with intensity gives information on the total reactive transverse impedance. For a Gaussian bunch of r.m.s. bunch length σ_z traveling with velocity $v = \beta c$, the coherent tune shift with intensity ΔQ is proportional to the imaginary part of the total (driving plus detuning) transverse effective impedance Z_t^{eff} by [2]

$$\Delta Q = -\frac{\beta e I_0}{4\sigma_z\sqrt{\pi}\omega_0^2\,\gamma\,Q_0\,m_0}\Im\left\{Z_t^{eff}\right\}, \tag{2}$$

where I_0 is the bunch current, Q_0 is the unperturbed betatron tune, γ is the relativistic factor, e the particle charge and m_0 the particle mass at rest. The effective transverse impedance is defined as the impedance weighted by the transverse bunch power spectrum centered at the chromatic frequency ω_ξ:

$$Z_t^{eff} = \frac{\sum\limits_{p=-\infty}^{\infty} Z_t(\omega')h(\omega'-\omega_\xi)}{\sum\limits_{p=-\infty}^{\infty} h(\omega'-\omega_\xi)}, \tag{3}$$

where $\omega' = \omega_0(p+Q_0)$ with p an integer, $\omega_\xi = \omega_0\,Q_0\,\xi/\eta$, with ξ the chromaticity and η the slippage factor, and the power spectrum of the Gaussian zero azimuthal bunch mode is $h(\omega) = \exp-(\omega^2\sigma_z^2/c^2)$. If the bunch length does not change with intensity, Eq. 2 predicts a tune shift linear with bunch intensity, with a slope proportional to the imaginary part of the transverse total effective impedance.

Chromaticity

The tune variation with the momentum is a machine parameter called chromaticity, defined as

$$\xi = \frac{\Delta Q/Q_0}{\Delta p/p_0}, \tag{4}$$

where p_0 is the particle momentum on the nominal closed orbit and Δp is the momentum deviation. Chromaticities in the PS can be measured by acquiring the tune shift while varying $\Delta p/p_0$. Introducing a radial offset, we generate a momentum offset that lead to a variation of the revolution frequency. The tune can be written as a Taylor series of $\frac{\Delta p}{p_0}$

$$Q\left(\frac{\Delta p}{p_0}\right) = Q_0 + Q'\frac{\Delta p}{p_0} + \frac{Q''}{2!}\left(\frac{\Delta p}{p_0}\right)^2 + \ldots + \frac{Q^n}{n!}\left(\frac{\Delta p}{p_0}\right)^n, \tag{5}$$

where

$$Q' = \frac{\Delta Q}{\Delta f/f_0} \tag{6}$$

and Q^n are the higher order terms. The chromaticity is computed applying a polynomial fit on the measured data: from the linear term we can calculate the linear chromaticity as

$$\xi = \frac{Q'}{Q_0}. \tag{7}$$

ELECTRON-CLOUD STUDIES FOR TRANSVERSELY SPLIT BEAMS

S. S. Gilardoni, M. Giovannozzi, G. Iadarola, G. Rumolo, CERN, Geneva, Switzerland
N. Pradhan, CERN, Geneva, Switzerland and University of Mississippi, MS, USA

Abstract

Recently, resonance crossing has been proposed as a means of manipulating the transverse beam distribution. This technique has application, among other topics, to injection and extraction schemes. Moreover, the transversely split beams might also be used as a mitigation measure of electron-cloud effects. The results of detailed numerical simulations are discussed in this paper, possibly opening new options for scrubbing of beam pipes in circular accelerators.

TRANSVERSE BEAM SPLITTING

In recent years, a novel beam manipulation has been proposed, which is based on beam splitting by resonance crossing in the horizontal plane [1, 2]. The process is based on the use of non-linear beam dynamics. Stable islands are created by means of sextupole and octupole magnets, which are responsible for making the beam dynamics non-linear. An adiabatic tune variation is then applied so that a given resonance is crossed. During the resonance crossing stage particles can be trapped into the islands and transported to high amplitudes. The net result is to split the beam in the horizontal phase space so that from the initial single Gaussian multiple quasi-Gaussian distributions are generated. Examples of this process for the case of the third- and fourth-order resonance are shown in Fig. 1 and 2, respectively.

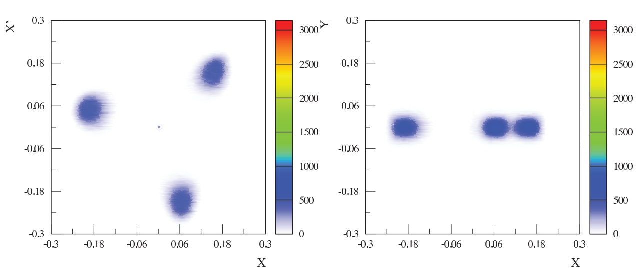

Figure 1: Phase space portraits of the final beam distribution after crossing the third-order resonance. Two of the six projections of the 4D transverse phase space are shown here, namely horizontal phase space (left), and physical space (right). The three beamlets are clearly visible in both the horizontal and physical space.

The difference between the two cases is striking and it can be summarised as follows: for an unstable resonance of order n the beam is split in n Gaussian beamlets with the centre of phase space almost completely depleted. Whereas in case of a stable resonance of order n, $n + 1$ Gaussian beamlets are created. This is a consequence of the stability of the resonance, which makes it possible for the beam at the centre of phase space to remain there, thus creating an additional beamlet. It is worth stressing the intrinsically different properties of the beamlets at non-zero amplitude with respect to the one at the origin. Indeed, while the beamlet around the origin represents a structure with periodicity equal to one machine turn, the other beamlets represent a single structure that winds up around the ring and closes up in a periodic way after n machine turns.

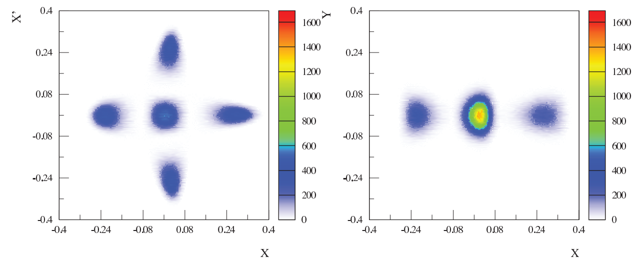

Figure 2: Phase space portraits of the final beam distribution after crossing the fourth-order resonance. Two of the six projections of the 4D phase space are shown, namely horizontal phase space (left), and physical space (right). The five beamlets are visible in the horizontal phase space, while the effect of projection is visible in the physical space.

It is also clear that properties like emittance and intensity are by definition the same for the n beamlets away from the centre as they are indeed one single structure. On the other hand, whenever it exists, the central beamlet does not need to have the same properties as the external ones. This implies that an additional degree of freedom is available (for the case of stable resonances) when defining the protocol for crossing the resonance. In fact, one can control the sharing of both emittance and intensity between the two phase space structures.

The technique of beam splitting had been originally proposed to perform multi-turn extraction from the CERN PS machine [1–6], but soon afterwards it has been realised that many more applications could be based on resonance crossing. Indeed, this technique could be time-reversed so to envisage a multi-turn injection based on beamlets' merging [7]. Such an approach would be very appealing as it allows beam shaping, which is a very interesting aspect in view of mitigating space charge effects [8]. Furthermore, the stability of the fourth-order resonance has been studied in detail proposing a method to turn it into an unstable resonance in view of generating a split beam with only four beamlets [9].

In parallel, detailed experimental studies have been performed at the PS [6] in view of an operational implementation of the novel technique to transfer beam from the PS to the SPS [10]. On a different front, intense efforts were devoted to the more theoretical aspect of the beam splitting with the goal of understanding the detail of the splitting process in a quantitative way with the help of adiabatic theory [11].

Abstract

The latest SPS transverse impedance model includes kicker magnets, wall impedance, transition pieces (e.g. flanges and vacuum chamber discontinuities), beam position monitors and RF cavities. The model has already been successfully benchmarked against coherent tune shift and transverse mode coupling instability measurements. In this paper we present measurements of the headtail growth rates for a wide range of negative chromaticities and for two different configurations of machine optics (nominal and low gamma transition). The measurement results are compared with HEADTAIL simulations using the wake fields obtained from the SPS transverse impedance model.

INTRODUCTION

In the framework of the SPS upgrade project an accurate impedance model is needed in order to determine its effect on the beam stability and assess the impact of the new devices to be installed in the machine, with both the present and future beam parameters [1]. The SPS impedance model is obtained by summing the contributions of the different devices along the machine (β-weighted for the transverse impedance). Analytical models, 3-D simulations and bench measurements are used to estimate these contributions. The SPS impedance model is dynamical because it needs to be updated to include newly identified impedance sources as well as modifications of installed elements or new elements.

THE LATEST SPS IMPEDANCE MODEL

The present version of the SPS transverse impedance model, which we present here, includes the following contributions:

- Kicker magnets. They are likely to be the most important impedance source in the SPS. In a very simple approximation a SPS ferrite loaded kicker can be modelled as two parallel plates of ferrite. For this simple geometrical model all the impedance terms (longitudinal, driving and detuning horizontal and vertical impedances) have been calculated analytically. CST 3D simulations were found to be in very good agreement with the analytical results. The excellent agreement between analytical model and numerical simulations can be read as an important benchmark for the simulation code in the correct solution of electromagnetic problems involving dispersive materials such a ferrite. In the framework of an improvement of the kicker impedance model we performed a step by step simulation study starting from the simplest model and introducing one by one the new features that make the model gradually closer to reality. This approach allows for a good understanding of the different contributions brought to the kicker impedance by the different aspects. First, the ferrite is assumed to be C-shaped and the whole finite length device is inserted in the vacuum tank and equipped with an inner conductor [2]. In order to further approach a more realistic model other aspects have to be included: the cell longitudinal structure, also called segmentation, which determines a significant increase of the beam coupling impedance for the SPS injection kickers (due to the short cell length) and the serigraphy for the SPS extraction kickers. All the details about the SPS kicker impedance model can be found in Ref. [3];
- Wall (resistive wall and indirect space charge), based on analytical calculation taking into account the different SPS vacuum chambers [3];
- Beam position monitors, based on CST 3D simulations [4];
- RF cavities, based on CST 3D simulations [5];
- Broadband impedance from step transitions, based on the information for the SPS flanges collected during the task force for the identification of the longitudinal impedance source responsible of the impedance peak at 1.4 GHz observed during beam measurements [6]. The broadband impedance of the SPS transitions has been calculated as:

$$Z_{transitions} = \sum_{i=1}^{N} Z_i \, n_i \qquad (1)$$

where N is the number of different transition types, Z_i is the β-weighted broadband impedance of the transition i and n_i is the number of occurrences of the transition type i. The broadband impedance contribution of each type of transition has been obtained by means of CST 3D EM simulations.

Figure 1 shows the full SPS impedance model including all the impedance sources analyzed weighted by the respective length and beta functions for the horizontal and vertical driving and detuning impedances [3].

BENCHMARKING THE SPS TRANSVERSE IMPEDANCE MODEL

The model has been found to reproduce with very good accuracy coherent tune shift measurements in both trans-

TRANSVERSE IMPEDANCE MODEL OF THE CERN-PSB

C. Zannini, G. Iadarola, K. Li, G. Rumolo, CERN, Geneva
B. Jones, STFC, Rutherford
T.L. Rijoff, CERN, Geneva; TU Darmstadt, Darmstadt

Abstract

In the framework of the PS-Booster upgrade project an accurate impedance model is needed in order to determine the effect on the beam stability and assess the impact of the new devices before installation in the machine. This paper describes the PSB impedance model which includes resistive wall, indirect space charge, flanges, step transitions, ejection kicker including cables, injection kickers and cavities. Each impedance contribution has been computed for different energies in the PSB cycle. Measurements of the coherent tune shifts have been performed and compared to calculations based on the impedance model.

INTRODUCTION

A first attempt to build the PSB impedance model was made in the PhD thesis of D. Quatraro [1] where the attention was focused on the model of the wall impedance, which includes resistive wall and indirect space charge, and on the estimation of the so called "broadband impedance" (i.e. the measured impedance after the removal of the wall impedance) at different energies. These studies led to the conclusion that at injection about 50% of the measured tune shift can be attributed to indirect space charge and that the broadband impedance decreases with the relativistic beta. A more detailed impedance model of the PSB could help to explain the behavior of the measured tune shift at different energies. Presently, there is an ongoing effort to build such an impedance model and continuously refine it according to the modifications in the machine or new understanding.

PSB IMPEDANCE MODEL

The latest version of the impedance model includes resistive wall, indirect space charge, vacuum pipe discontinuities, ejection kicker including cables, injection kickers and FINEMET cavities. For each accelerator element the horizontal and vertical driving and detuning impedances have been calculated [2].

Indirect Space Charge

Up to now the indirect space charge impedance was estimated assuming the PSB to have an elliptic beam pipe (half height $h = 32$ mm and half width $w = 80$ mm) for 1/3 of the circumference, and a circular one for the remaining 2/3 (radius $r = 80$ mm) [1]. However, since the indirect space charge impedance is expected to play a major role, a more accurate calculation based on the PSB aperture model has been performed. For a circular chamber the indirect space charge impedance has been analytically calculated [3]. The calculation has been extended to the different PSB vacuum chambers by using the appropriate form factors [4], which have been numerically estimated with the simulation method for non-relativistic beta described in Ref. [5] for CST Particle Studio [6]. For the dipole chambers the form factors have been found very close to the rectangular chamber case [7], while a form factor of 1.4 has been estimated for the quadrupole chambers. More details on the PSB indirect space charge impedance model can be found in Ref. [4].

Table 1: Main parameters of the resistive wall calculation for the different vacuum chambers: thickness of the wall, electrical conductivity of the wall and background material.

	Wall thick [mm]	Wall (σ_{el}) [10^6S/m]	BG
Dipoles	0.4	0.77	Iron
Quadrupoles	1.5	1.3	Iron
Straight sections	1.0	1.3	Vacuum

Resistive Wall

In Ref. [1] the resistive wall impedance was estimated approximating the PSB elliptic beam pipe with a circular pipe with radius $r = h$, and considering the circular pipe for the rest of the accelerator. For the stainless steel an electrical conductivity $\sigma_{el} = 10^6$ S/m and a relative permeability $\mu_r = 8$ were used. Here we present a more accurate calculation based on the aperture model that accounts for the different PSB vacuum chambers. The calculation has been performed with the new code TLwall based on a transmission line model [2]. In Tab. 1 the main parameters used for the calculation are summarized. As an example, Fig. 1 shows the generalized horizontal and vertical resistive wall impedance of the PSB at kinetic energy of 160 MeV. The largest contribution to the resistive wall impedance is given by the bending magnets due to the very thin wall (0.4 mm). Due to the very thin layer, assuming an electrical conductivity of 7.7 10^5 S/m, the skin depth becomes larger than the wall thickness for frequencies below 2 MHz. Therefore, below this frequency the impedance becomes strongly dependent on the background material [4]. The iron has been modeled as a silicon-steel similarly to the SPS case [2]. The dispersion model for the permeability μ has been obtained as:

$$\mu = \mu_0 \, \mu_r(\boldsymbol{B}) = \mu_0 \left(1 + \frac{\mu_i(\boldsymbol{B})}{1 + jf/f_{rel}}\right) \quad (1)$$

with $f_{rel} = 10$ kHz [8]. The relative permeability μ_r is a function of the magnetic field $\boldsymbol{B}$ and thus of the particle momentum. The behaviour of μ_i as a function of $\boldsymbol{B}$ can be found in Ref. [9]. The variation of the resistive wall impedance due to the variation of μ_r during the PSB cycle has been estimated to be lower than 5%.

EFFECT OF ELECTRON CLOUD IN QUADRUPOLES ON BEAM INSTABILITY

G. Iadarola* A. Axford, H. Bartosik, K. Li, G. Rumolo, CERN, Geneva, Switzerland

Abstract

Both simulations and machine experience at the CERN Super Proton Synchrotron (SPS) and Large Hadron Collider (LHC) have shown that the electron cloud has a lower build up threshold in quadrupoles than in dipoles and field free regions. As a consequence, while beam induced scrubbing can efficiently suppress the electron cloud in both dipoles and field free regions, a residual electron cloud can still survive in the quadrupoles and potentially degrade the beam quality. To study this effect, a PyECLOUD module for electron tracking in quadrupole fields including effects of secondary emission at the vacuum chamber has been implemented in PyHEADTAIL. With this module, the effect of the electron cloud in quadrupoles on beam stability and beam quality preservation can be assessed, as well as its impact on future LHC and HL-LHC operation.

INTRODUCTION

Electron cloud (EC) effects have been observed at the SPS throughout the years in which this machine has been prepared to become injector for the LHC, and at the LHC itself during the first three years of beam operation (Run 1, 2010–2012), becoming more and more severe while reducing the bunch spacing [1].

At the SPS, the EC has been identified as a main performance limitation since the early years of 2000. At that time a severe pressure rise was observed all around the machine together with transverse beam instabilities, significant losses and emittance blow-up on the trailing bunches of the train. Since 2002, scrubbing runs with 25 ns beams were carried out almost every year of operation in order to condition the inner surfaces of the vacuum chambers and therefore mitigate the EC. Since 2011, no important beam degradation due to EC can be observed on the cycle timescale for four batches of 72 bunches with $N \approx 1.35\times10^{11}$ p/b and normalized transverse emittances of about 3 μm (r.m.s.). However, for higher intensities, an EC driven transverse instability is observed after the injection of batches beyond the first one, leading to emittance blow up and particle losses on the trailing bunches of the injected trains. This can be due to a recrudescence of the EC both in the regions with dipole field (because of the stripes moving to out to unscrubbed regions) and in quadrupole regions, where the threshold for EC build up becomes lower due to the higher bunch intensities. Pinning down the main origin of these instabilities is crucial to decide on the future strategy of coating some parts of the SPS with low Secondary Electron Yield (SEY) material [2]. This depends not only on the multipacting thresholds in the different chambers and magnetic field configurations, but also on how much they individually contribute to render the beam unstable.

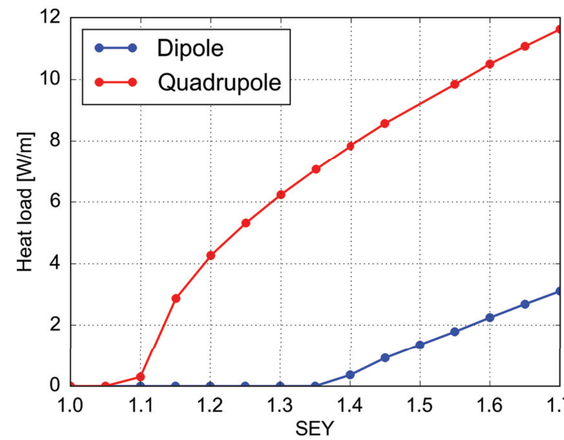

Figure 1: Heat load in the dipole and quadrupole magnets in the LHC arcs as a function of the SEY of the beam screen.

At the LHC, the EC effects could be successfully mitigated with 50 ns beams through beam induced scrubbing. This bunch spacing could be used for most of the integrated luminosity production with 7–8 TeV Center of Mass (CoM) energy in 2011–12. After the long shutdown 1 (LS1) the LHC will be able to run at 13 TeV CoM energy and the design bunch spacing of 25 ns will be used to reach the design luminosity within the pileup limits accepted by the LHC experiments. In the test runs on 2011 and 2012, the 25 ns beam, due to its significantly lower multipacting threshold, suffered from strong EC effects [1]. Thanks to the scrubbing effect, a decrease of the SEY resulted in a substantial reduction of the heat load in the cryogenic sections and of the dynamic pressure rise in the warm regions. Heat load measurements from the cryogenic system showed that up to 80% of the energy lost by the beam was deposited on the beam screens of the cryogenic arcs. Since in the LHC arcs each beam screen cooling circuit extends over a full half cell (three 15 m long dipoles and one 3 m long quadrupole plus multipoles), the individual contributions of the different magnets to the heat load cannot be disentangled. However, simulations carried out with the PyECLOUD code [1] show that the multipacting threshold in the arc quads is much lower than in the dipoles, as illustrated in Fig. 1. For SEY of 1.35, the EC can be suppressed in the arc dipoles, but not in the quadrupoles,which have a multipacting threshold of 1.1. This suggests that, even after significant scrubbing, the quadrupoles are likely to remain important contributors to the integrated EC along the LHC. Measurements from the Stand Alone Modules (SAM), which are magnets equipped with dedicated cryostats for which heat load detection is available, confirmed that the quadrupoles exhibit a much

OBSERVATIONS OF AN ANOMALOUS OCTUPOLAR RESONANCE IN THE LHC

F. Carlier, R. Tomás, E. Hamish Maclean, R. Westenberger,
J. Maria Coello de Portugal, A.S. Langner, T. Persson,
CERN, Geneva, Switzerland

Abstract

While linear LHC dynamics are mostly understood and under control, non-linear beam dynamics will play an increasingly important role in the challenging regimes of future LHC operation. In 2012, turn-by-turn measurements of large betatron excitations of LHC Beam 2 at injection energy were carried out. These measurements revealed an unexpectedly large spectral line in the horizontal motion with frequency $-Q_x - 2Q_y$. Detailed analyses and simulations are presented to unveil the nature of this spectral line.

INTRODUCTION

Linear beam dynamics in the LHC is currently well understood [1–4]. Nonlinear dynamics will play an increasingly important role in the challenging regimes of future LHC operation. Nonlinearities in circular accelerators can significantly affect the dynamic aperture [5, 6] and can lead to poor beam lifetime. Understanding these nonlinearities and their underlying sources is therefore important to improve the performance of the machine. Great progress has been made in recent years in this field in the LHC [7–12].

Spectral analysis of turn-by-turn data obtained from beam position monitors after large betatron excitations provide accurate measurements of the main tunes and secondary spectral lines related to specific resonant driving terms. Such measurements of resonant driving terms can provide insight on the presence machine nonlinearities. The theory of resonant driving terms is extensively discussed in [13–16].

In 2012, turn-by-turn measurements of large betatron excitations of LHC Beam 2 at injection energy were carried out [11]. These measurements revealed an unexpectedly large spectral line in the horizontal motion with frequency $-Q_x - 2Q_y \approx 0.1$, whose amplitude is well above model expectations. Details of these measurements can be found in [11]. This spectral line, later referred to as the (-1,-2) spectral line only appears for large diagonal excitations with nominal kick amplitudes higher than $5\sigma_{x,\text{nom}}$ and $4\sigma_{y,\text{nom}}$. This paper presents observations of the (-1,-2) spectral line and possible sources.

OBSERVATIONS

Figure 1 shows the complex spectra of turn-by-turn data for a measurement and multiparticle tracking simulation with 5000 particles for 1000 turns in the horizontal plane with measured kick amplitudes of $8.2\sigma_{x,\text{nom}}$ and $6.5\sigma_{y,\text{nom}}$. The large (-1,-2) line is observed in the measurement spectrum at $freq \approx 0.1$ corresponding to the generating term f_{2020} related to the $2Q_x + 2Q_y = p$ resonance, while its conjugate (1,2) line, corresponding to f_{1102}, is not visible. Furthermore, the amplitude of the (-1,-2) line reaches 8% of the main horizontal tune amplitude, while in tracking simulation it is not visible. Though other spectral lines are correctly reproduced from the model (0,1), (1,1), the discrepancy between model and measurement indicate a clear lack of understanding of the machine at such large betatronic excitations.

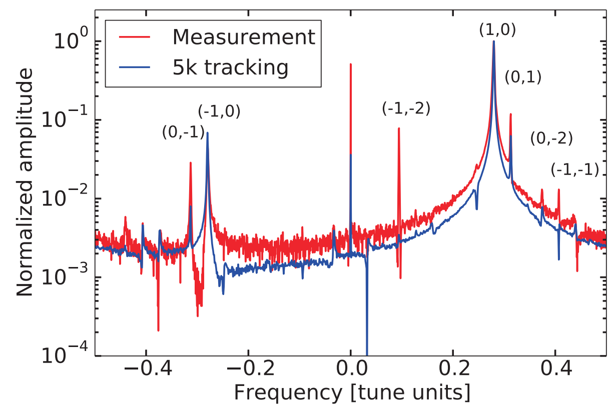

Figure 1: Complex spectra amplitude of $h_x^- = x - ip_x$ reconstructed from two BPM signals at BPM.12L1.B2 from the LHC with $8.2\sigma_{x,\text{nom}}$ and $6.5\sigma_{y,\text{nom}}$ measured kick amplitudes. A large amplitude is observed at $freq \approx 0.1$, but not at -0.1.

Further observations of the (-1,-2) line show its frequency is linear with the calculated frequency from the main tunes as it is shown in Fig. 2. This result confirms that the (-1,-2) line is not an artifact unrelated to the beam.

The decoherence of the (-1,-2) line over the number of turns is shown in Fig. 3. The measured (-1,-2) line cleary decoheres much slower than the main horizontal tune. This result motivates the study of possible surviving lines [15] as part of the cause of the large measured amplitude.

Anharmonicities for first and second order amplitude detuning have been calculated in 2012 [12]. These can be used to calculate the amplitude detuning for specific frequencies. Figure 4 shows the amplitude detuning for the (-1,-2) line for different anharmonicities than in [12], but still within the error margins of the measurements. The obtained amplitude detuning for the (-1,-2) line shows a saddle point on the diagonal of the $(2J_x, 2J_y)$-plane where the gradient is zero. A beam kicked near this critical point would have zero amplitude detuning for the (-1,-2) line and therefore a decreased

Abstract

NSLS-II is a recently constructed 3 GeV synchrotron light source with design horizontal emittance values in sub-nm range. Achieving good beam lifetime is critically important for NSLS-II as it is closely tied to such important operational aspects as top-off injection frequency, injector components wear, radiation protection and control, and others. In this paper we present lifetime-related commissioning results and describe our present understanding of beam lifetime at NSLS-II.

INTRODUCTION

At 500 mA design beam current the beam lifetime in the NSLS-II ring is expected to be Touschek-dominated [1]; contributions from gas scattering could also be significant, especially when small gap in-vacuum undulators are in operation.

Direct measurements of just the Touschek lifetime are not possible, as the combined lifetime due to all of the effects is always measured. However, contributions due to gas scattering can be separated from the Touschek effect as they generally do not depend on beam dimensions (ignoring ion trapping) and only depend on the total beam current through current-dependent outgassing rates. These rates could be measured, and, at low beam intensity their current-dependence is negligible. Touschek lifetime, on the other hand, has a strong dependence on beam dimensions and is inversely proportional to single-bunch current.

For a simplified model of constant gas pressure, gas scattering lifetime results in the exponential time dependence of the total beam current,

$$I(t) = I(0)\,\mathrm{Exp}(-t/\tau), \qquad (1)$$

where two separate processes are responsible for the decay. Elastic gas-scattering lifetime is given by [2]

$$\frac{1}{\tau_{el}} = \frac{4r_e^2 Z^2 \pi n c}{2\gamma^2}\left[\frac{\langle\beta_x\rangle}{A_x} + \frac{\langle\beta_y\rangle}{A_y}\right], \qquad (2)$$

where $A_{x,y}$ are horizontal and vertical acceptances, given by the minimum value of aperture, a(s), squared and divided by the beta function at that location, $A=\min(a(s)^2/\beta(s))$, n and Z are the concentration and the atomic number of the residual gas ions.

Lifetime due to inelastic gas-scattering, or Bremsstrahlung, is given by [2]

$$\frac{1}{\tau_{brem}} = \frac{16 r_e^2 Z^2 n c}{411}\ln\left[\frac{183}{Z^{1/3}}\right]\left[-\ln\varepsilon_{acc} - \frac{5}{8}\right], \qquad (3)$$

where ε_{acc} is the limiting momentum acceptance.

Touschek scattering process leads to the non-exponential decay of single-bunch current,

$$I_b(t) = \frac{I_b(0)}{1 + t/\tau_{tous\_1/2}}, \qquad (4)$$

where $\tau_{tous\_1/2}$ is the so-called Touschek half-life (but also called Touschek lifetime below), given by [3]

$$\frac{1}{\tau_{tous\_1/2}} = \frac{\sqrt{\pi}\, r_e^2 c N_b}{\gamma^3}\left\langle \frac{C(\zeta)}{\sigma'_x V \varepsilon_{acc}^2}\right\rangle, \qquad (5)$$

where N_b is the number of electrons per bunch, $C(\zeta) = -\frac{3}{2}e^{-\zeta} + \frac{\zeta}{2}\int_\zeta^\infty \ln(u)\frac{e^{-u}}{u}\,du + \frac{1}{2}(3\zeta - \zeta\ln\zeta + 2)\int_\zeta^\infty \frac{e^{-u}}{u}\,du$, $\zeta = \left[\varepsilon_{acc}/\gamma\sigma'_x\right]^2$, V is the beam volume, and the brackets denote averaging over the ring circumference.

For short time intervals, the current decay is relatively small, which is what is happening during top-off operations or during typical lifetime measurements. In such instances both (1) and (4) are well approximated by a linear time-dependence, so the total lifetime is given by

$$\tau_{total} = 1/(\tau_{el}^{-1} + \tau_{brem}^{-1} + \tau_{tous\_1/2}^{-1}). \qquad (6)$$

In NSLS-II ring the standard (total) beam lifetime measurements are performed by linearly fitting the decaying beam current signal, measured by DCCT, over the specified time interval (typically 5 minutes). The lifetime is simply the average current over this interval divided by the fitted slope. However, for low beam currents we found the DCCT-derived lifetime to be too noisy, especially when we could not afford long averaging times. This is why the so-called "BPM lifetime" measurement was implemented as well. Instead of the DCCT signal, it uses the average sum signal from 180 BPMs, resulting in much lower noise, even when the time averaging is performed over 30s or shorter intervals. This is the measured lifetime reported below.

MEASUREMENTS AND ANALYSIS

Phase I Commissioning

We start with the single bunch measurements from 05/08/14 as well as the 20-bunch train data from 05/11/14 (both data sets are with emittance coupling corrected to an estimated value of $\kappa=\varepsilon_y/\varepsilon_x=0.32\%$). The RF cavity voltage at the time was 1.9 MV (close to the maximum allowed) corresponding to the momentum acceptance of $\varepsilon_{RF}=2.5\%$. The measured lifetime vs. single bunch current is plotted in Fig.1 (circles). Note that the trends vs.

DEVELOPMENTS OF THE SEGMENT-BY-SEGMENT TECHNIQUE FOR OPTICS CORRECTIONS IN THE LHC

A. Langner* [1,2], J. Coello de Portugal[2], P. Skowronski[2], R. Tomás[2]
[1]University of Hamburg, Germany, [2]CERN, Geneva, Switzerland

Abstract

Optics correction algorithms will become even more critical for the operation of the LHC at 6.5 TeV. For the computation of local corrections the segment-by-segment technique is used. We present improvements to this technique and an advanced error analysis, which increase the sensitivity for finding local corrections. Furthermore, we will investigate limitations of this method for lower β* optics as they will be used in the high-luminosity LHC (HL-LHC) upgrade.

INTRODUCTION

The segment-by-segment technique (SbS) was developed at the LHC for the computation of optics corrections for local, strong error sources [1]. The concept is to run MAD-X [2] in a part of the accelerator in between two beam position monitor (BPM) locations. The optical functions which were derived from measured turn-by-turn data of the BPMs are the start parameters for this simulation. For optics corrections the simulated phase advances between BPMs are compared to the measured ones, as they are more directly observable than e.g. the β-function. Possible correction settings aim at eliminating the deviations in the phase advance. This method has been very successful at finding local optics corrections for the LHC, where it was once even able to identify a cable swap between the two beam apertures in a quadrupole which caused an unexpectedly large β-beating [3, 4]. SbS was also successfully tested at RHIC and is fully implemented there [5].

Another purpose of SbS is the propagation of optical functions from the BPM positions to other lattice elements. This allows for example to derive the β-function at the interaction points (β*). It has also been used to propagate the optical functions to beam wire scanners for an emittance study [6] and to collimators for a comparison to beam sizes as they are measured in beam-based collimator alignment [7]. These studies require very precisely measured β-functions and improvements to SbS were required to comply with these demands. Recent improvements related to SbS include an improved measurement of the β-function from BPM turn-by-turn data [8] which results in significantly more precise start parameters for the SbS simulation.

Furthermore, an automatic routine has been developed to match the measured and simulated phase advances for finding optics corrections [9, 10]. In the following sections we will show improvements in the error analysis for SbS and also present a comparison of simulated local optics corrections for LHC and HL-LHC, which shows a possible limitation of SbS for lower β* optics.

* andy.langner@cern.ch

IMPROVED ERROR ANALYSIS

Phase Advance

The β-beating propagation can be described by an oscillation with constant amplitude A which propagates with twice the betatron oscillation frequency

$$\frac{\Delta\beta}{\beta}(s) = A \cdot \sin(2 \cdot \phi(s) + \phi_0). \tag{1}$$

$\phi(s) + \phi_0$ is the phase of the betatron oscillation at the position s and ϕ_0 the initial phase for $s = 0$. Using Eq. (1) one can approximate the deviation of the phase $\Delta\phi$ due to the β-beating at the start of the segment. Error propagation on $\Delta\phi$ using the uncertainties σ_{β_0} and σ_{α_0} of the optical functions at the start of the segment leads to the uncertainty of the propagated phase

$$\begin{aligned}\sigma^2_{\phi(s)} =& \left(\frac{1}{2}(\cos(2\phi(s)) - 1)\frac{\alpha_0}{\beta_0} + \frac{1}{2}\sin(2\phi(s))\frac{1}{\beta_0}\right)^2 \sigma^2_{\beta_0} + \\ &\left(\frac{1}{2}(\cos(2\phi(s)) - 1)\right)^2 \sigma^2_{\alpha_0},\end{aligned} \tag{2}$$

where α_0 and β_0 are the initial α- and β-function at the start of the segment. The computation of uncertainties for the phase advance in the simulation, which were not regarded before, allow for a better calculation of optics corrections, since the uncertainties can be considered as weights when matching the measured and simulated phase advances. This feature is part of the automatic matching routine [10].

β- and α-function

The same approach as for the phase advance uncertainty can also be used for other optical function. The uncertainties of the propagated α- and β-function at the position s (α_s and β_s) are shown in Eqs. (3-4).

$$\begin{aligned}\sigma^2_{\beta_s} =& \left[\beta_s \sin(2\phi(s))\frac{\alpha_0}{\beta_0} + \beta_s \cos(2\phi(s))\frac{1}{\beta_0}\right]^2 \sigma^2_{\beta_0} + \\ &\left[\beta_s \sin(2\phi(s))\right]^2 \sigma^2_{\alpha_0}.\end{aligned} \tag{3}$$

$$\begin{aligned}\sigma^2_{\alpha_s} =& \left[\alpha_s \sin(2\phi(s))\frac{\alpha_0}{\beta_0} + \alpha_s \cos(2\phi(s))\frac{1}{\beta_0} - \right. \\ &\left. \cos(2\phi(s))\frac{\alpha_0}{\beta_0} + \sin(2\phi(s))\frac{1}{\beta_0}\right]^2 \sigma^2_{\beta_0} + \\ &\left[\cos(2\phi(s)) - \alpha_s \sin(2\phi)\right]^2 \sigma^2_{\alpha_0}.\end{aligned} \tag{4}$$

DESIGN OF AN INTENSE MUON SOURCE WITH A CARBON AND MERCURY TARGET

Diktys Stratakis, J. Scott Berg, BNL*, Upton, NY 11973, USA
David Neuffer, Fermilab†, Batavia, IL, USA
Xiaoping Ding, University of California, Los Angeles, CA, USA

Abstract

In high-intensity sources, muons are produced by firing high energy protons onto a target to produce pions. The pions decay to muons which are captured and accelerated. In the present study, we examine the performance of the channel for two different target scenarios: one based on liquid mercury and another one based on a solid carbon target. We produce distributions with the two different target materials and discuss differences in particle spectrum near the sources. We then propagate the distributions through our capture system and compare the full system performance for the two target types.

INTRODUCTION

In this paper we will first discuss the particle distributions created from a C target and a Hg target. We will describe our muon capture and initial cooling scenario, and then present results of simulation of that front end system.

PARTICLE DISTRIBUTIONS

We produce particle distributions from mercury and carbon targets under similar conditions. A proton bunch hits a target, with the relevant parameters described in Table 1. The target is in a field that peaks near 20 T at the center of the beam-target crossing, and tapers down to 2 T just under 5 m downstream, and continues at that field downstream from that point. The solenoids that produce this field are described in Table 2; the choice of this field profile was based on [1]. A beam pipe with an inner radius of 13 cm surrounds the target and extends downstream to 85 cm from the beam-target crossing point. Downstream from there, the beam pipe has an inner radius of 23 cm. Particle production computations were performed using MARS15(2014) [2, 3].

We found that the choice of event generator parameters for nuclear inelastic interactions had a significant impact on particle production, as shown in Fig. 1. In contrast to [4, 5], but like [6], these studies use IQGSM=1, the current MARS15(2014) default [3]. Pion production per unit of proton power in mercury is notably higher than in carbon for lower pion energies, but the production rapidly becomes

Table 1: Parameters of the target and incident proton beam. Carbon target parameters are taken from [6], without the dump, with the target radius increased to 10 mm, and a corresponding increase in the proton beam size. For mercury, the target, proton beam, and solenoid axis lie in the same plane at the crossing point, with the proton beam to the outside. The optimization process for obtaining the target geometry is described in [4].

Material	**C**	**Hg [5]**
Target Radius (mm)	10.00	4.04
RMS Beam Size (mm)	2.5	1.212
Target Tilt (mrad)	65	127
Crossing Angle (mrad)	0	20.6
Proton Energy (GeV)	6.75	8
Geometric Emittance (µm)	5	0

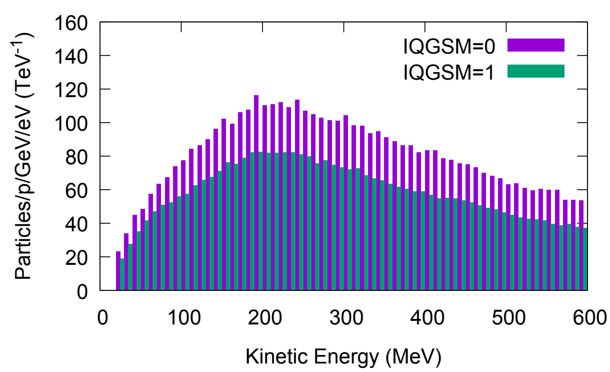

Figure 1: Spectrum of positive pions from carbon, 2 m downstream from the beam-target crossing, for different values of IQGSM in MARS15(2014) [3]: IQGSM=0 is the default value used in older MARS versions, and was used in [4, 5]; IQGSM=1 is the current default value in MARS and was used in [6] and elsewhere in this study. Values are divided by proton beam energy in GeV and histogram bin width.

closer above 250 MeV (Figs. 2 and 3). The differences are much larger for negative than for positive pions. Thus the particle capture system should be optimized differently for a mercury than for a carbon target due to the lower-energy spectrum in mercury. Furthermore, the difference in the spectral shape between positive and negative pions in mercury requires that the optimal capture parameters for positive and negative particles will be different, and some application-

OMC SOFTWARE IMPROVEMENTS IN 2014

J. Coello de Portugal, F. Carlier, A. Langner,
T. Persson, P. Skowronski, R. Tomás, CERN, Geneva, Switzerland

Abstract

We present the LHC Optics Measurement and Corrections (OMC) software developments done during 2014 on stability, performance and usability. This software is used to analyze turn-by-turn data and compute optics corrections to get the best performance of the LHC. The main developments have been an automatic local correction script to get faster and more accurate corrections in the interaction regions, a self contained test for the whole software package to avoid mistakes during the software development and the improvements in the software quality and efficiency of the Segment-by-segment technique script. We also present a study of the code quality in its current status.

DESCRIPTION OF THE SOFTWARE

The OMC software targets to measure and correct several optics parameters of the LHC. As the machine has very tight tolerances, a good control of the optics is critical for machine protection and performance.

The purpose of the software is to analyze turn-by-turn data measured during the LHC operation. Using an improved Fourier analysis [1] the spectra of the measured signal is obtained and from the spectrum the machine parameters can be computed [2–4]. This data is compared then to the nominal model of the machine and the differences are corrected so it behaves as close as possible to the designed machine.

This set of compiled programs and scripts is gathered into a GUI (*Graphical User Interface*) programmed in Java. The GUI lets the users take advantage of the software suite without having to know in depth its operating details. The chain of operations needed to analyze, compute corrections of turn-by-turn data and upload them to the machine can be done in minutes using the OMC GUI.

AUTOMATIC CORRECTIONS

During the 2012 run, the Segment-by-segment technique was used with good success to locally correct the optics at regions of importance as the interaction points [5–8]. This technique was used to identify beating in the phase advance between BPMs as phase advance is independent of BPM calibration [9]. However, these corrections were done mostly manually, fitting the phase deviation curve by varying the strength of the correctors and rerunning the scripts to watch the results. This method is slow and lacks of precision and thus, an automatic way of computing this correction has been developed.

Segment-by-segment

The Segment-by-segment technique divides the machine in a certain number of smaller segments and treats them as standalone beam lines. In absence of errors and given the measured initial conditions, the propagation of the phase advance between BPMs using the reference model should behave as that of the measured machine. The differences found in the propagations can be more easily corrected taking only these small segments into account.

Automatic Matching

To perform the automatic correction of the phase advances in a given segment, the Segment-by-segment script has to be run for both beams, as quadrupole magnets which are shared by both beams may also be used for computing corrections. Therefore, for automatic corrections, the matching script in Segment-by-segment needs to run for both beams simultaneously. After that, the MAD-X simulation software [10] is used to match the phase deviations at each measurement point:

1. A set of variables is given to MAD-X, representing the different strengths of the corrector magnets in the chosen segment.

2. The program is provided with a set of constraints, representing the deviations in the phase advance between each BPM in the region of interest:

$$\Delta\phi_{n+1} = \phi_{n+1}^{meas} - \phi_{n}^{meas} - (\phi_{n+1}^{mod} - \phi_{n}^{mod}) \qquad (1)$$

3. Then, MAD-X will try to find a configuration of the variables that satisfies the constraints as precisely as possible, using a least square minimization technique.

4. Once the phase deviation is reproduced with the desired accuracy, the resulting magnet strength corrections are flipped in sign to counteract that deviation.

If MAD-X finds a configuration of strengths that overpowers some magnet, the user can deactivate it, forcing the matching script to find another configuration. Also, if the measurement in some BPM is thought to be wrong or misleading, the algorithm can be told to ignore this matching point. Furthermore, the algorithm takes the errors in the phase measurements into account, giving less importance to those that have highest errors.

The automatic matching procedure takes around 20 seconds until it finds a solution, performing much faster and more precisely than manually. This new feature is integrated in the OMC GUI (Fig. 1).

TRACKING TEST

As 2014 has been a year of improvements not only in the performance but also in the precision and usability of the

OPTICS MEASUREMENT USING THE N-BPM METHOD FOR THE ALBA SYNCHROTRON

A. Langner* [1,2], G. Benedetti [3], M. Carlà [3], J. Coello de Portugal [2], U. Iriso [3], Z. Martí [3], R. Tomás [2]
[1] University of Hamburg, Germany, [2] CERN, Geneva, Switzerland,
[3] ALBA-CELLS Synchrotron, Cerdanyola del Vallès, Spain

Abstract

The N-BPM method which was recently developed for the LHC has significantly improved the precision of optics measurements that are based on beam position monitor (BPM) turn-by-turn data. The main improvement is owed to the consideration of correlations for statistical and systematic error sources, as well as increasing the amount of BPM combinations for one measurement. We present how this technique can be applied at light sources like ALBA, and compare the results with other methods.

INTRODUCTION

Linear optics from closed orbit (LOCO) [1] is the standard method for optics measurements and corrections at the ALBA synchrotron [2]. Turn-by-turn measurements can provide faster optics measurements than LOCO and are of great interest also for other light sources [3–5]. Recently, efforts have been put in developing optics measurements based on BPM turn-by-turn data at ALBA. However, previous measurements showed discrepancies of the measured β-beating in comparison to LOCO of 4-10 % [6]. Also at SOLEIL significant discrepancies were observed when comparing the β-beating from turn-by-turn measurements to LOCO and an optics correction study at SLS found an inferior performance of turn-by-turn measurements compared to LOCO. Studies in ESRF [7] show that the model which arises from a fit to the phase advances from turn-by-turn data is superior to their standard orbit response matrix (ORM) based model. However, this approach could not become operational for technical reasons. One method to infer the β-function uses the phase advance of the betatron oscillation between three BPMs [8, 9]. The phase advance can be derived from the BPM turn-by-turn data while an oscillation has been excited on the beam.

Previous attempts of optics measurements from turn-by-turn data at LHC and SOLEIL used only neighboring BPMs for the analysis because the effect of systematic errors for larger ranges of BPMs would quickly deteriorate the results. The N-BPM method overcomes this limitation by performing a detailed analysis of systematic and statistical errors and their correlations [10]. This allows to consider more BPM combinations for the analysis and therefore to use more information when probing the β-function at one BPM position. This is especially useful if neighboring BPMs have phase advances which are not well suited for a measurement. Optimal phase advances in between two BPMs are $45° + n_1 \cdot 90°$, and phase advances of $n_2 \cdot 180°, (n_1, n_2) \in \mathbb{N}^2$ should be avoided. The phase advances of consecutive BPMs are shown in Fig. 1 for the nominal ALBA lattice. In the vertical plane there are many consecutive BPMs with small phase advance, and considering BPMs combinations within a larger range of BPMs would allow for better phase advances for the measurement.

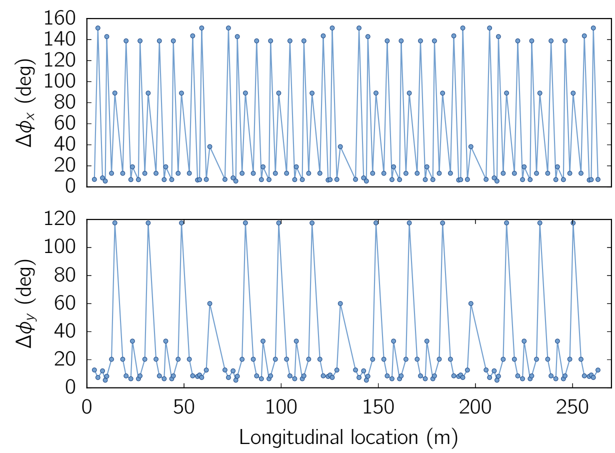

Figure 1: Phase advances of consecutive BPMs in the nominal model.

SYSTEMATIC ERRORS

For the N-BPM method it is crucial to consider model uncertainties and their correlations for the β-function measurement. They can be derived for example in a Monte-Carlo simulation where the error sources are varied within their uncertainty and the impact on the measurement is observed. The calculation of systematic errors is based on the uncertainties of magnetic measurements and alignment uncertainties, which can be found in Table 1. The Monte-Carlo simulation was performed for 1,000 iterations and the error sources were varied randomly following a Gaussian distribution.

We perform Monte-Carlo simulations separately for each contribution to study how much each error source is contributing to the total systematic error, cf. Fig 2. The dominant contribution comes from quadrupolar gradient errors (b_2), and transverse misalignment of sextupole magnets. For the horizontal plane the quadrupole b_2 errors have a larger effect than the dipole b_2, which is the opposite in the vertical plane. This is because β_y is much larger at the dipole magnets than β_x.

The systematic errors can furthermore be assessed separately for different BPM combinations. In Table 2 the aver-

FLUKA MODELING OF THE ESS ACCELERATOR

L. Lari, L.S. Esposito, ESS, Lund, Sweden and CERN, Geneva, Switzerland
M. Eshraqi, L. Tchelidze, ESS, Lund, Sweden
F. Cerutti, A. Mereghetti, CERN, Geneva, Switzerland

Abstract

In order to evaluate the energy deposition and radiation issues concerning the ESS accelerator, a FLUKA model of the machine has been created. The geometry of the superconducting beam line is built according to the machine optics, described in the TraceWin file and the CATIA drawings of the beam elements, using the LineBuilder tool developed at CERN. The objective is to create a flexible FLUKA model that is able to be adapted to the optimization of the optics, design modifications and machine integration constraints. Preliminary results are also presented.

INTRODUCTION

The European Spallation Source (ESS) is a high-energy and a high-intensity accelerator-driven facility, currently under construction at Lund, in Sweden [1]. The ESS superconducting linac is designed to accelerate protons up to 2 GeV (kinetic energy) and to provide an average beam power of 5 MW on target. Table 1 summarizes the main accelerator parameters, while the general layout of the ESS linear accelerator is shown in Fig. 1.

Table 1: Key Parameters of the ESS Proton Linac

Average Beam Power	5 MW
Peak Beam Power	125 MW
Beam on target	> 95% availability
Proton kinetic energy	2 GeV
Pulse frequency	2.86 ms
Pulse frequency	14 Hz
Peak current	62.5 mA

The proton beam from the Ion Source is transported through a Low Energy Beam Transport (LEBT) section to the Radio Frequency Quadrupole (RFQ) for bunching and acceleration. At the extraction of the RFQ, the beam is transported and matched to the normal conducting Drift Tube Linac (DTL) through a Medium Energy Beam Transport (MEBT) section. Downstream of the 5 DTL tanks, the beam enters the superconducting part of the linac, where it is accelerated via superconducting radio frequency cavities, constructed from niobium and immersed in liquid helium at a nominal temperature of 2K. The first superconducting section contains 13 cryomodules each containing a pair of double spoke cavities. The spoke section is followed by two sections of elliptical cavities, medium-β and high-β, where β is the ratio of the proton speed to the speed of the light. In this section, the cryomodules contains 4 elliptical cavities each, for a total of 9 cryomodules for the medium-β and 21 for the high-β respectively. Finally, after acceleration, the beam is transported via the High Energy Beam Transport (HEBT) to the target.

METHODOLOGY

The effect of prompt radiation and induced radioactivity are planned to be studied with Monte-Carlo simulations. For the low energy part of the ESS linac including the DTLs included, the MCNPX code is used [2], while in the more energetic part of the accelerator (at energies outside of the neutron resonance regions), the calculations are performed with MARS [3,4] and/or FLUKA codes [5,6].

In particular, FLUKA is used to address all questions for which a detailed accelerator geometry is needed, such as activation of beam line elements and it will be used to benchmark some MARS shielding results. For this reason, a detailed FLUKA model of the ESS accelerator is in progress, starting from the last DTLs until the target and including tunnel and gallery buildings as well as stubs between tunnel and gallery, and tunnel emergency exits (see Fig. 2 for a representation of the model).

The FLUKA model of the beam line follows automatically the lattice sequence described in the official TraceWin optics output file, thanks to the LineBuilder [7]. In case of future possible hardware, footprint or optics changes, the coupling between TraceWin and LineBuilder makes possible to generate a new model, if the geometry of each element is available in FLUKA.

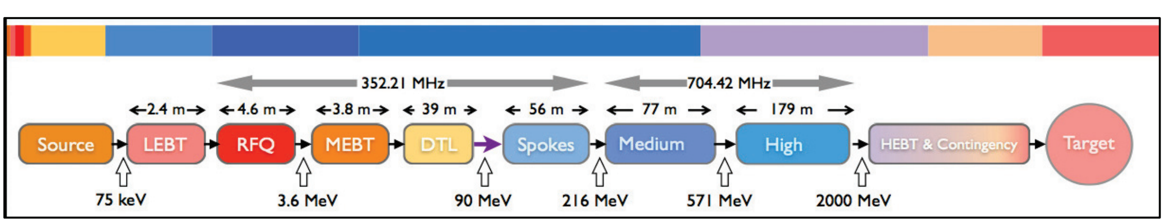

Figure 1: Schematic block diagram of the ESS accelerator lattice (bottom) and corresponding proportional length of the different sections (top). The blue items are superconducting (i.e. the spoke resonators, the medium and high β elliptical cavities), while the other items are normal conducting.

TESTS OF WAKEFIELD-FREE STEERING AT ATF2

A. Latina, J. Pfingstner, D. Schulte, CERN, Geneva, Switzerland
J. Snuverink, Royal Holloway, University of London, Egham, UK
N. Fuster, IFIC, Valencia, Spain
E. Adli, University of Oslo, Oslo, Norway

Abstract

Charge-dependent effects on the orbit and on the beam size affect the performance of the Accelerator Test Facility (ATF2) in a non-negligible way. Until now small beam sizes have only been achieved running with a beam charge significantly smaller than the nominal value. These detrimental effects on the beam have been attributed to wakefields, in the cavity BPMs, in the multi-Optical Transition Radiation (OTR) systems as well as in other components of the beamline. The successful tests of a Wakefield-free Steering (WFS) algorithm at FACET have encouraged performing tests of the same correction scheme at ATF2. The performance of the algorithm has been simulated in detail, including several realistic imperfection scenarios, including charge-dependent BPMs resolution, and incoming injection error and position jitters, which are described in this paper. Tests of Dispersion-free Steering (DFS) and of WFS have been performed at ATF2 during December 2014. The results are discussed here.

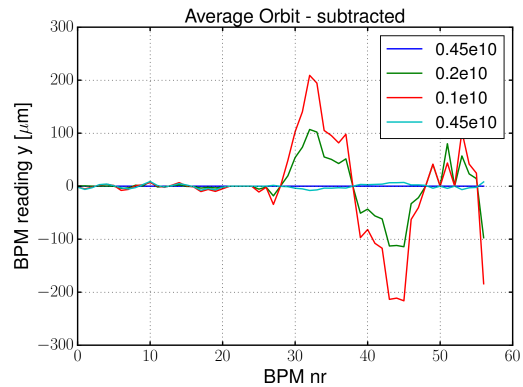

Figure 1: Example of a current-dependent beam orbit. The orbits are displayed relative to charge 4.5×10^9 particles per bunch.

INTRODUCTION

ATF2 [1] is a scaled demonstrator for the final focus system of future linear lepton colliders, the so-called local chromaticity correction scheme [2]. ATF2 is built as an extension of the ATF complex at KEK (Japan). The beam from a low emittance damping ring is extracted into the ATF2 beamline.

Effects depending on the beam current affecting the orbit and especially the beam-size, have repeatedly been reported for the ATF2, preventing it from achieving the target nominal beam-size at the focal point and from running at its fullest nominal beam current of 10^{10} electrons per bunch [3, 4]. Figure 1 shows the average beam orbit for different intensities with respect to the orbit with a bunch charge of 4.5×10^9 particles, as it was measured in April 2013. A beam orbit that changes with the bunch charge can be symptom of the presence of strong wakefields induced by some beamline components.

Techniques such as Dispersion-free steering and Wakefield-free steering have proven to be effective in reducing dispersive and wakefield effects on the orbit, and in most of the cases also managed to significantly reduce the emittance growth associated with such effects [5, 6]. These successes motivated the tests we are reporting about in this paper.

SIMULATION

The extraction line of the ATF2 was simulated using the code PLACET [7]. Wakefield effects were added at the cavity BPMs according to the calculations performed in [4]. Several static and dynamic imperfections were considered in the simulation: element misalignment, BPM resolution, and time-dependent effects such as pulse-to-pulse random variations in beam energy, position, and angle at injection. These jittering quantities were meant to assess stability and robustness of the algorithm in a realistic dynamic environment. 100 misalignment seeds were simulated with a RMS misalignment for magnets and BPMs of 100 μm. 55 BPMs were used for the steering, together with 11 correctors in both the vertical and horizontal plane. WFS was applied in 3 iterations with weights of $\beta = 5$ and $\omega = 26$. An explanation of the function of β and ω, as well as details on the implementation of WFS, can be found in [6]. The fact that the resolution of the BPMs drops with a lower charge was taken into account. Two beam charges of 8×10^9 and 5×10^9 particles per bunch were chosen as test beams for WFS, since these two values of the charge don't compromise excessively the BPM resolution, see Fig. 2, which shows the measured BPM resolution of a cavity BPM typical of the ATF2 [8].

The results of the simulations are shown in Fig. 3, where the final emittance after correction is plotted as a function of the weight parameter ω, for DFS and for WFS in combination with DFS respectively. Figure 4 shows the profile of the relative emittance growth along the beamline. Each of these results is the average of the 100 random seeds previously mentioned.

BBA AND COUPLING CORRECTION AT CLIC RTML

Yanliang Han, Lianliang Ma, Shandong University, Jinan, China
Andrea Latina, Daniel Schulte, CERN, Geneva, Switzerland

Abstract

The CLIC Ring To Main Linac (RTML) must transport the electron and the positron bunches through more than 20 km of beamlines with minimal emittance growth. The turnaround loops (TAL) are one of the most critical sections. In this paper a study of the Beam-Based Alignment (BBA) techniques in the Turnaround loop (TAL) of the CLIC RTML is presented. In order to reduce the emittance growth, the one-to-one(1:1) and dispersion-free steering (DFS) corrections have been tested. The results showed that the emittance growth budgets can be met both in the horizontal and vertical planes. The impact of coupling errors due to magnets roll on the emittance has also been studied and a coupling correction scheme has been designed. By inserting the correction scheme into the RTML dispersive region, the vertical emittance can be largely compressed. While this coupling correction result is very preliminary and more further studies are needed.

INTRODUCTION

CLIC is one of the future accelerators designed for the particle physics after LHC. The concept of two-beam acceleration can provide colliding beam energy up to 3 TeV [1]. The RTML section is the part of CLIC that connects the damping rings and the main linacs. The sketch of the RTML is shown in Fig. 1 [1]. The RTML sections for electrons and positrons are composed by the same subsystems (two bunch compressors, booster linac, central arc, vertical transfer, long transfer line, and turnaround loops), with the difference that there is no spin rotator in the positron line. In this paper we will focus on the electron RTML, and in particular the TAL. The TAL is a complex subsection featuring a lattice that must be achromatic, isochronous while minimizing ISR emittance growth.

In order to guarantee a luminosity of the order of 2×10^{34} cm^{-2}s^{-1}, CLIC accepts a very strict emittance growth budget for the RTML. The normalized emittances are respectively 500 and 5 nm·rad for horizontal and vertical plane at the entrance of RTML, and they should be smaller than 600 and 10 nm · rad at its exit [1]. Pre-alignment of dipoles and quadrupoles has been considered to be of the order of 100 μm, assuming the BPM resolution of 1 μm [1]. These values are such that BBA must be used in order to preserve the small emittances to magnets errors.

It must also be noticed that, at the entrance of the RTML, the vertical emittance is only 1% of the horizontal emittance. This implies that even very small coupling between horizontal and vertical plane will introduce large emittance growth in the vertical plane. It is known that it is hard in technique to align the rotation errors less than 100 μrad. So, a coupling correction scheme must be envisaged.

In this paper, we will use the CLIC beam tracking software PLACET, which is intended to simulate the dynamics of a beam in the presence of wakefields [2] in order to assess the performance of BBA in the TAL, and the impact of coupling errors on the beam quality.

BBA IN THE TURNAROUND LOOPS

The turnaround loops feature the most complex lattice in RTML so it is also very difficult to do the BBA. The dipoles are selected as the correctors and one dipole is added after each quadrupole. We used a gaussian distribution to misalign the lattice, with σ_{pos} denoting the standard deviation. All the quadrupoles and Beam Position Monitor (BPM) are misaligned. BPM also has a resolution $\sigma_{\text{res}} = 1$ μm. One-to-one (1:1) and DFS are used to improve the orbit. The 1:1 is a simple and faster algorithm which is often used first to correct the misalignment errors. We use the Eq. 1 to get strength of the dipole correctors for the 1:1 correction.

$$\theta = \min||\Delta\mathbf{u} - \mathbf{R}\theta||_2^2 + \beta^2||\theta||_2^2; \qquad (1)$$

Here, θ is the strength of the dipole correctors. $\Delta\mathbf{u} = \mathbf{u}-\mathbf{u}_0$ represent the beam position difference recorded by BPMs between misalignment machine and perfect machine. $\mathbf{R}$ is the response matrix between the dipole correctors and the BPMs. β is damping factor which is used to avoid the large fluctuation of corrector strength.

In the real world, BPMs always have non-zero resolution and alignment errors, we need DFS to correct this. The strength of correctors are got according to Eq. 2.

$$\theta = \min||\Delta\mathbf{u} - \mathbf{R}_1\theta||_2^2 + \omega^2||\Delta\eta - \mathbf{D}\theta||_2^2 + \beta^2||\theta||_2^2 \qquad (2)$$

Here, $\Delta\mathbf{u}$ has the same meaning as in Eq. 1 and $\mathbf{R}_1$ is same as $\mathbf{R}$. ω is weight factor. $\Delta\eta = \Delta\mathbf{u}_{\text{dis}}$ - $\Delta\mathbf{u}$ represent the dispersion recorded by BPMs, here $\Delta\mathbf{u}_{\text{dis}}$ denote beam position difference between misalignment machine and perfect machine for the beam with energy $E_0(1+\delta)$, E_0 is the nominal beam energy. In this study, we set the δ to be 0.5%. $\mathbf{D}$ is the dispersion response matrix.

Simulation Setup

The effectiveness of One-to-one correction (1:1) and DFS depends on the response matrix. In order to compute numerically the response matrix $\mathbf{R}$ and the dispersion response matrix $\mathbf{D}$, a bunch containing 100’000 particles was used. Such a large number of particles was chosen to average out the stochastic effects of the synchrotron radiation emission.

BBA was tested for different σ_{pos} misalignment levels, simulating 100 different random machines. The final observables were the average emittance, and the 90% percentile of the distribution of 100 final emittances. BBA was

[2] Collider-Accelerator Department, Brookhaven National Laboratory, Upton, NY 11973, USA
[3] Department of Applied Mathematics, Stony Brook University, Stony Brook, NY 11794, USA
[4] SLAC Accelerator Laboratory, Menlo Park, CA 94025, USA

Abstract

An advanced version of the Coherent-electron Cooling (CeC) based on the micro-bunching instability was proposed in [1]. This approach promises significant increase in the bandwidth of the CeC system and, therefore, significant shortening of cooling time in high-energy hadron colliders. In this paper we present our plans of simulating and testing the key aspects of this proposed technique using the set-up of the coherent-electron-cooling proof-of-principle experiment at BNL [2].

INTRODUCTION

In contrast to electron and positron beams, hadron beams in all present-day colliders do not have a strong natural damping mechanism to reduce their energy spreads and emittances. Cooling hadron beams transversely and longitudinally at the energy of collision may significantly increase the luminosity of high-energy hadron colliders and future electron-hadron colliders, such as RHIC, eRHIC [3] and even the LHC/LHeC. Coherent electron Cooling (CeC) [4] promises to deliver cooling of hadron beam with damping rates exceeding that of the existing cooling techniques by many orders of magnitude. The original CeC scheme is based on the amplified electrostatic interactions between electrons and hadrons using FEL as a broadband amplifier [4]. Bandwidth of FEL-based CeC is measured in THz compared with GHz for a traditional microwave stochastic cooling. It is well known that bandwidth of the amplifier determines the maximum cooling rate of the system. The bandwidth of the FEL-based CeC it determined by the duration of the FEL response – so called Green's function [5]. Typical bandwidth of FEL amplifier is a small portion (~ 0.1% to few %) of the FEL frequency. Using micro-bunching as an amplification mechanism [1] promises to extend the CeC bandwidth by additional one to two orders of magnitude. This makes this approach very interesting to explore.

Since the CeC is a novel concept, it first must be demonstrated experimentally before we rely upon it for upgrading present colliders. We are building at BNL a dedicated device, called CeC Proof-of-Principle experiment, supported by DoE Nuclear Physics office grant [2]. It is designed to demonstrate FEL-based CeC using 22 MeV electron beam.

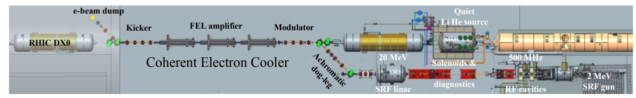

Figure 1: 3D rendering of the CeC demonstration set-up in the RHIC's IP2. It includes the following equipment: 112 MHz SRF gun; 500 MHz RF buncher/pre-accelerator; 20 MeV 704 MHz SRF module; electron beam transport magnets (dipoles, quadrupoles, solenoids, trims); helical FEL wigglers; beam dump; and RHIC DX-, D0-, and triplet-magnets. The electron beam is merged with the ion beam using an achromatic dog-leg, cools the ions in the CeC, and then is discarded into a beam dump.

We are extending this test, using NSF support, to demonstration of the key component of the micro-bunching-based CeC: specifically, demonstrating the amplification of the imprint of the hadron beam density modulation.

COHERENT ELECTRON COOLING

ORBIT CORRECTION IN THE CERN PS BOOSTER*

M. McAteer, E. Benedetto, C. Carli, G.P. Di Giovanni, B. Mikulec, R. Tomás
CERN, Geneva, Switzerland

Abstract

Prior to the Long Shutdown of 2013-2014 (LS1), control of the closed orbit in the four rings of the CERN PS Booster (PSB) was achieved by adjusting the alignment of several focusing quadrupoles. After a set of orbit corrector dipoles was installed, a major realignment campaign was undertaken to remove these intentional quadrupole offsets and any other magnet misalignments. This paper summarizes the effects of the magnet realignment on the closed orbit in the PSB and the results of closed orbit correction with corrector dipoles.

INTRODUCTION

The PSB is the first synchrotron in the LHC injector chain, accelerating proton beams from 50 MeV to 1.4 GeV in about 500 milliseconds. It is composed of four vertically stacked rings and accelerates four beams simultaneously, which are recombined before being transferred to the Proton Synchrotron. The lattice has a 16-fold periodic structure with two bending magnets and an F-D-F focusing triplet in each period. The four rings share the same bending and focusing magnets, which each have four gaps through which the four beam pipes pass. Each period also contains a multipole corrector magnet stack with an integrated beam position monitor (BPM), and a horizontal and a vertical orbit corrector dipole, but hardware limitations allow for only four orbit correctors per plane per ring to be used at any given time.

These orbit corrector dipoles were not available in the PSB until 2012, and they were not used operationally until after LS1. Prior to this, closed orbit distortion was minimized by introducing horizontal, vertical, and tilt alignment offsets to certain quadrupole magnets [1]. During LS1 an alignment survey was made and a major realignment campaign was undertaken in order to correct both random magnet alignment errors and the intentional quadrupole offsets previously used for orbit correction. In total, about ninety horizontal, vertical, or tilt magnet adjustments were made.

After the shutdown, some final magnet alignment adjustments were made in order to reduce the closed orbit distortion, and then the orbit was further corrected using corrector dipoles and the console application YASP (Yet Another Steering Program) [2].

MAGNET REALIGNMENT

At the beginning of LS1, a tunnel survey was completed to determine the alignment of the main bending magnets, the triplet quadrupoles, and elements containing both beam position monitors and multipole corrector magnets. Figure 1

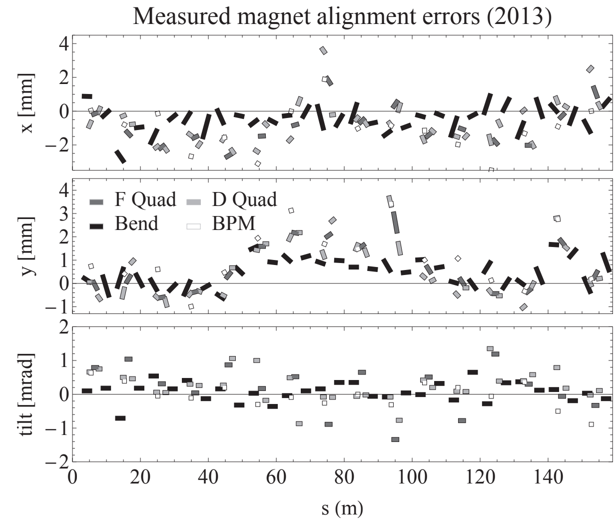

Figure 1: Initial measured alignment of bending magnets, quadrupoles, and BPM stacks, showing the transverse displacement of the ends of each element and the rotation around the longitudinal axis.

shows the measured horizontal and vertical positions of each magnet and its tilt around the longitudinal axis. To reduce aperture restrictions, a realignment strategy was formulated to minimize transverse magnet offsets and jumps between adjacent magnets, while keeping the number of hours of work in the tunnel reasonably low for radiation safety reasons.

All quadrupoles and BPMs with a radial displacement of more than 1 mm from the reference position or from the adjacent quadrupole were realigned to zero. The bending magnets have a large horizontal aperture, so they were not realigned radially. However, the bending magnets have a small vertical aperture which creates one of the main aperture restrictions in the vertical plane. Moving these magnets carries a risk of damaging them, so instead of aligning the bends and quads to the vertical reference position, the quadrupoles were aligned to a smooth curve fit to the vertical position of the bends. Quadrupole magnets and BPMs whose vertical position was more than 1 mm from this curve were moved to lie on the curve. The vertical position of bending magnets was adjusted only in a few cases where there was a jump of more than 1 mm between the position of adjacent bends.

All quadrupoles and BPMs with a tilt of more than 0.3 mrad, and all bending magnets with a tilt of more than 0.5 mrad, were corrected to zero. Note that the radial position measurements refer to the position of the magnet at beam level on Ring 3, which is the third ring up from the ground. When the magnet tilt is adjusted, the physical pivot point is at ground level. Therefore, in order to keep the ra-

BEAM IMPEDANCE OPTIMIZATION OF THE TOTEM ROMAN POTS

N. Minafra[1] on behalf of the TOTEM Collaboration
[1]INFN sez. di Bari, Italy and CERN, Geneva, Switzerland

Abstract

The TOTEM experiment has been designed to measure the total proton-proton cross section and to study elastic and diffractive scattering at the LHC energy. The measurement requires detecting protons at distances as small as 1 mm from the beam center: TOTEM uses Roman Pots (RP), special beam pipe insertions, to move silicon detectors close to the beams to detect particles very near the beam axis. In the first period of running of the LHC no problems were detected with retracted Roman Pots and during insertions in special runs; however, during close insertions to highest intensity beam, impedance heating has been observed. After the LS1 the LHC beam current will increase and the equipment that can interact with the beam needed to be optimized. A new RP, optimized to minimize the beam coupling, has been designed with the help of CST Particle Studio; a prototype has been used to test the simulation results in the laboratory with wire and probe measurements. Furthermore, in both the old and the new RPs, new ferrites have been installed. The new ferrite material has a higher Curie temperature than the one used before LS1 and a thermal treatment at 1000°C has been applied to reduce the out-gassing.

IMPEDANCE SIMULATIONS

A particle beam can induce resonances in any cavity created by the vacuum chamber. When the geometry of the vacuum chamber is too complex, analytical models can not be used to predict the impact of these resonances on the beam and on the environment. Thus, software like CST Particle Studio [1] are used to numerically simulate the evolution of the electromagnetic field inside the cavity after the passage of a particle beam.

A Roman Pot (RP) is a movable part of the beam pipe that allows the positioning of a detector up to a few millimeters from the beam without interfering with the primary vacuum. Especially for equipment that can approach the beam so closely, the impedance has to be optimized and numerical simulations were a key part of the development [2].

The interaction between the beam and the cavity can be harmful for the beam itself, introducing instabilities, but can also damage the equipment, for example due to excessive beam induced heating.

To foresee the instabilities it is useful to compute Z^{eff}, the impedance effectively felt by the beam; the imaginary part of the effective longitudinal impedance $(\Im Z_{\mathrm{long}}/n)^{\mathrm{eff}}$, where $n = f/f_{\mathrm{rev}}$ is the harmonic number, is an indication of the dispersion of the beam through the cavity.

In a similar way, it is possible to compute the power lost by the beam and transferred to the cavity [3] [4]:

$$P_{loss} = 2\,I^2 \sum_{p=1,\,\ldots,\,\infty} PS(pM' f_{\mathrm{rev}})\,\Re[Z_{\mathrm{long}}(p\,M'\,f_{\mathrm{rev}})] \quad (1)$$

where, $PS(f)$, f_{rev}, M' and I are the power spectrum, the revolution frequency and the number of buckets of the LHC;Z_{long} is the simulated longitudinal impedance.

The goal of the optimization is to reduce both heating and effective impedance.

OPTIMIZATION OF THE DESIGN

Before the Long Shutdown 1 (LS1) all Totem RP installed in the LHC were box shaped, as shown in Fig. 1. This design has several mechanical advantages; for instance, the relatively small size of the detector housing does not require the separation between the detector and the primary vacuum to be thicker than 150 μm, reducing the secondary particles shower produced inside the steel and reducing the minimum possible distance of the detector from the beam.

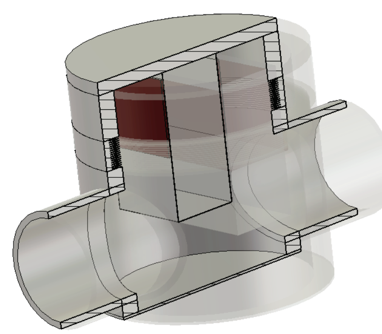

Figure 1: Before LS1 all Totem Roman Pots were box shaped. The empty space between the RP and the flange resonate at low frequency (~ 500 MHz).

However, from a RF point of view, the box RP has a considerable amount of empty space between the detector housing and the vacuum flange that resonates at low frequency (~ 500 MHz). This lead to the introduction of planes of ferrite [5].

Moreover, some of the time-of-flight detectors proposed for the the future upgrade require more longitudinal space inside the RP [6]. The new RP has been designed to increase the space available for the detector, together with reducing the impedance.

The simple solution of having a detector housing that uses all the available space would be ideal; however, the RP needs to be safely inserted and retracted and mechanical constraints and tolerances have to be considered.

CONTRIBUTION OF OPTICAL ABERRATIONS TO SPOT-SIZE INCREASE WITH BUNCH INTENSITY AT ATF2

M. Patecki*, R. Tomás, F. Zimmermann, CERN, Geneva, Switzerland
G. White, SLAC, California, USA
K. Kubo, S. Kuroda, T. Naito, T. Okugi, T. Tauchi, N. Terunuma, KEK and SOKENDAI, Ibaraki, Japan

Abstract

A primary goal of ATF2 (Accelerator Test Facility 2) at KEK is to demonstrate an unprecedentedly low vertical beam size at the interactateck ion point (IP) of about 37 nm. Measurements over the past years indicate that the ATF2 vertical beam size, achieved after tuning, strongly rises with bunch intensity. This increase could have several different origins. For example, it could be due to wake fields occurring between the ATF damping ring and the IP, and/or be due to changes in the transverse emittances and energy spread in the damping ring, which are known to increase with intensity as a result of intrabeam scattering (IBS). In this paper we address the second possibility. Past measurements and simulations of the IBS effects in the ATF damping ring and in the extraction line are used to model the intensity-dependent initial emittances and energy spread at the entrance of the final focus. Using this model, particle tracking simulations predict the IP vertical beam size growth expected from the known optical aberrations for initial beam parameters corresponding to varying bunch intensities. We consider both the nominal final-focus optics and a relaxed optics with ten times increased horizontal IP beta function, which has also been used in operation. Comparing simulation results with emittance measurements at different locations allows us to draw some conclusions about the impact of IBS in the damping ring on the IP spot size, and about possible single-bunch wakefields in the ATF2.

INTRODUCTION

Between the end of 2012 and the spring of 2014 a significant reduction of the vertical beam size was achieved [3] at ATF2 [1, 2]. This improvement coincided with two major modifications: (1) an increase of the horizontal beta function at the focal point, β_x^*, by a factor of 10 (in the following called the "$10\beta_x$ optics"), and (2) a 10-fold reduction of the bunch intensity .

The $10\beta_x$ optics decreases the horizontal beam size at almost all the quadrupole magnets of the ATF2 final-focus system, which minimizes the effect of most optical imperfections (e.g. x-y coupling, residual sextupole aberrations) on the vertical beam size at the IP [4]. In parallel, the lower bunch charge weakens single-bunch wake fields [5], and it also minimizes the emittance and momentum spread of the incoming beam, extracted from the damping ring.

In this paper we investigate the IP vertical beam size as a function of beam charge in ATF2 using MAD-X [6] simulations based on the PTC [7] tracking routines. Both the design optics and the relaxed $10\beta_x$ optics are considered. The latter optics is actually in use.

Our simulations do not include any wake fields in the extraction line or in the final focus, but they do take into account the measured dependence of the danping-ring transverse emittance and momentum spread on the bunch charge. Our simulations also incorporate the measured high-order imperfections of the final-focus magnets, i.e. their multipolar field errors. On the other hand, off-center field errors of damping-ring magnets [8] or the nonlinear components of the septum field affecting the kicked beam during extraction are not considered.

INTENSITY-DEPENDENT SPOT SIZE

In 2003 the dependence of the ATF damping-ring emittance and momentum spread on the beam intensity was measured [9, 10]. Figures 2a and b summarize the emittance measurements (grey bands). The measured growth of the momentum spread with rising bunch intensity [10], shown in Fig. 1 (upper curve), is included in all our simulations. The strong intensity dependence of the emittance, and, especially, of the momentum spread, is due to IBS [10].

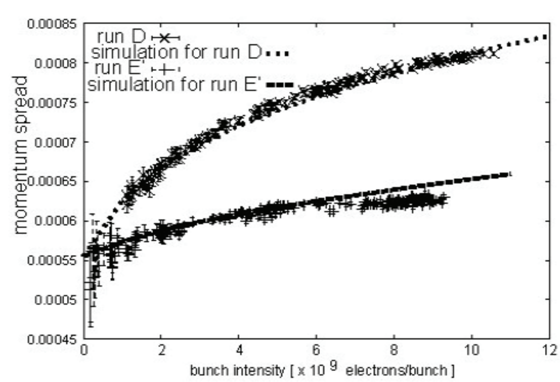

Figure 1: Measured rms momentum spread in the damping ring as a function of the bunch charge compared with IBS simulations [10]. The upper curve was obtained in standard operation, far from the coupling resonance, and it is used for our simulations.

We next examine how this beam emittance increase affects the IP vertical beam size. Three cases are considered: The first case assumes the beam emittances measured in the damping ring (DR). In the second case a constant increment is added to model the emittance of the beam extracted from

SINGLE AND MULTI-BUNCH END-TO-END TRACKING IN THE LHeC

D. Pellegrini, EPFL, Lausanne, Switzerland and CERN, Geneva, Switzerland
A. Bogacz, JLab, Newport News, VA 23606, USA
A. Latina, D. Schulte, CERN, Geneva, Switzerland

Abstract

The LHeC study aims at delivering an electron beam for collision with the LHC proton beam. The current baseline design consists of a multi-pass superconductive energy-recovery linac operating in a continuous wave mode. The high current beam (~100 mA) in the linacs excites long-range wake-fields between bunches of different turns, which induce instabilities and might cause beam losses. PLACET2, a novel version of the tracking code PLACET, capable to handle recirculation and time dependencies, has been employed to perform the first LHeC end-to-end tracking. The impact of long-range wake-fields, synchrotron radiation, and beam-beam effects has been assessed. The simulation results and recent improvements in the lattice design are presented and discussed in this paper.

INTRODUCTION

The current baseline design for the LHeC electron is sketched in Fig. 1. Each of the two 1 km long superconducting linacs provide a total acceleration of 10 GeV. The injection energy is 500 MeV. In order to reach the collision energy of 60 GeV, the electrons are recirculated three times. This is accomplished employing beam spreaders and recombiners placed at each end of the linacs. They allow to vertically separate the beams at the different energies routing them to the corresponding arcs. Arc2 and Arc4 are equipped with bypasses to avoid the interference with the detector. After the collision with the LHC proton or ion beam, the electron beam is decelerated in further three turns, allowing to increase the beam current and luminosity while limiting the power consumption [1]. The machine is operated continuously and bunches at different turns are interleaved in the linacs. An up-to-date beam parameter list can be found in [2].

The full LHeC lattice consisting of the two linacs and the six arcs has been imported into PLACET2 which allows to simulate recirculating machines [3]. A single-bunch end-to-end tracking simulation has been set up to evaluate the impact of synchrotron radiation and beam-beam effect. We verified the beam transport to the dump and we identified the lattice sections that could be improved. Moreover, since PLACET2 natively supports simultaneous multibunch tracking, it has been possible to investigate the impact of the transverse long range wakefields.

Progress has also been made with the machine design including the detector bypasses in Arc2 and Arc4. Details of the design will be presented.

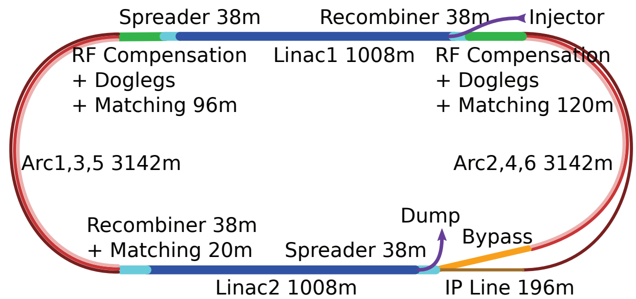

Figure 1: Scheme of the LHeC electron facility.

MACHINE MODELLING

The two linacs and the six arcs, properly connected together, have been imported in PLACET2. This code implements the recirculation in a realistic way. Each element is defined only once and its phase is computed accordingly to the beam time of flight. Although progress is being made, a complete, detailed design of the whole machine is not yet available and small footprint variations are still expected. For this reasons and for convenience the lengths of the arcs are adjusted artificially. Another simplification was applied to the IR, where the squeezing is implemented with a matrix, the beam-beam effect is then computed by GUINEA-PIG [4]. It has been found that the synchrotron radiation has a big impact in the spreader and recombiner sections and in the doglegs for path length adjustments. For the time being, in order to proceed with this study, the above effects have been ignored. The second harmonic RF, required to re-integrate the synchrotron radiation energy loss, is currently modelled as a thin element. No multipolar magnets are currently in the lattice, however higher order beam dynamics arise both from RF cavities and from the fringe fields in the dipole magnets.

APPLICATIONS OF PLACET2 TO THE CTF3 COMBINER RING

D. Pellegrini, EPFL, Lausanne, Switzerland and CERN, Geneva, Switzerland
D. Gamba, A. Latina, R. Corsini, CERN, Geneva, Switzerland

Abstract

The CTF3 Combiner Ring (CR) is an isochronous ring that employs RF-injection to combine multiple bunch trains (up to five) into a single one with higher bunch frequency. The length of the CR plays a critical role in obtaining the correct structure of the recombined train. PLACET2: the new recirculating version of the code PLACET, is particularly suited to simulate the operational scenario. In order to validate this code, two different case studies have been considered: ring-length variations due to optics scaling and vertical instabilities due to bunch-to-bunch wakefield effects. The response of the ring length to the optics scaling has been measured during the last CTF3 run. The instability has been compared with previous studies. The results are presented and discussed.

INTRODUCTION

At CTF3 the acceleration of an electron test beam is powered by an high-current electron drive beam that is decelerated in apposite power extraction units operating at 12 GHz [1]. The drive beam trains of bunches at 12 GHz are produced from longer, 1.5 GHz pulses, applying a factor 8 recombination. A first factor 2 is obtained in the delay loop [2]. The beam is then injected in the combiner ring using RF-deflectors. At every turn, new bunches are injected and interleaved with the one already turning.

The MAD-X model of the CTF3 combiner ring has been imported in PLACET2: the novel version of PLACET capable to handle recirculation [3]. A first measurement of the ring length response to the optics scaling has been performed and compared with the simulation. This has three main motivations: test the code predictions on a real machine, improve the understanding of the combiner rings optics, and demonstrate the possibility to manipulate the ring length possibly going beyond the capabilities of the wiggler magnet installed in the ring. This is particularly important to ensure a regular time structure of the combined beam that is crucial for an efficient deceleration.

The multi-bunch tracking capabilities of PLACET2 have been exploited reproducing the instability that was observed during the commissioning of the combiner ring, caused by a vertical mode trapped in the RF-deflectors.

METHODOLOGY OF THE LENGTH MEASUREMENT

The combiner ring length is measured using a button pickup or BPR: the beam-induced signal is multiplied by an external reference 3 GHz sine function. The phase slippage of the beam arrival time with respect to the 3 GHz reference becomes evident turn after turn as a modulation of the output signal. In the frequency domain the revolution frequency, f_{rev}, and its harmonics split into two sidebands whose distance, d_s, is determined by the fractional length, L_f, of the ring:

$$L_f = \pm \frac{d_s}{2 f_{rev}} \frac{c}{f_{ref}} \quad (1)$$

where c is the speed of light and f_{ref} is the 3 GHz reference frequency. The sign depends on the sidebands crossing; it can be determined empirically by varying the wiggler, whose effect on the fractional length is well understood.

The ideal machine setup for this measure consists of a 3 GHz beam from the gun, bypassing the delay loop. However, in order to not disturb other experiments, a factor 2 combined beam in the delay loop was kept. The train length was 140 ns, filling half of the ring and leaving enough time to completely switch off the RF deflector after the initial injection kick. The beam was kept circulating for approximately 100 turns.

The signal from the BPR was collected with an oscilloscope. The FFT of the signal was saved for the off-line analysis. A small dedicated C++ program has been written to clean the spectra, identify the peaks and compute the fractional length averaging over the available harmonics.

The quadrupoles and the dipoles currents where scaled independently monitoring the length variation. The data collected also comprehend a scan of the wiggler magnet.

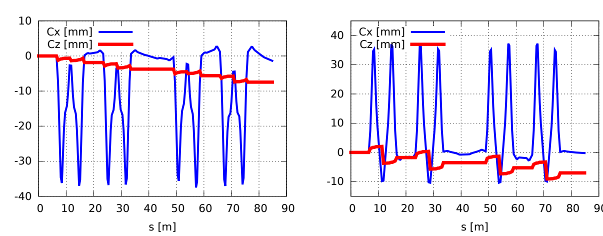

Figure 1: Horizontal and longitudinal bunch position computed for one turn in the combiner ring for two different scalings of the optics: left Q@95%, D@105%; right Q@105%, D@95%.

SIMULATION AND LOSSES

PLACET2 easily allows to track the bunch centroid in the reference frame of the ideal particle. Figure 1 shows the horizontal and longitudinal positions of a bunch for two possible scalings of the dipoles (D) and the quadrupoles (Q). Both the configurations decrease the length of the ring.

When scaling the optics by few percent, part of the beam may hit the vacuum chamber and be lost. This can affect the centroid position altering the result of the measurement.

PLACET2: A NOVEL CODE FOR BEAM DYNAMICS IN RECIRCULATING MACHINES

D. Pellegrini, EPFL, Lausanne, Switzerland and CERN, Geneva, Switzerland
A. Latina, D. Schulte, CERN, Geneva, Switzerland

Abstract

Efforts have been taken to enable the simulation of recirculating machines in PLACET. The new version, PLACET2, allows handling multiple interconnected beamlines in order to obtain a realistic model of a machine. Two new elements, injectors and dumps, have been introduced and are active components of any working machine. Trains of bunches are routed through beamlines and tracked simultaneously in a parallel manner. Tracking through time-dependent elements is possible, and care is made to preserve the correct time-structure of the beam in case of beam recombination. This allows straightforward computations of multi-bunch effects arising with high-charge and shortly spaced bunch trains, even with variable train structure. The main features of the code are presented together with its working principles and its key ideas. Two case studies are introduced: LHeC and the CTF3 combiner ring.

INTRODUCTION

The parameters of the electron beams achievable adopting recirculation techniques outperform linacs in terms of average current, but also rings in terms of the longitudinal emittance.

Today we find a flourishing number of Energy Recovery Linacs projects. Many low energy machines like ALICE in England, the cERL in Japan and the JLab FEL in the USA are already operating, but the spectrum extends to the energy frontier with studies like the LHeC and the eRHIC.

Energy recovery and multi-pass linacs are not the only kind of machines that exploits beam recirculation. CTF3 at CERN routinely applies it to fold a train of bunches on itself achieving currents up to 30 A and bunch frequency of 12 GHz. The Drive Beam Complex, a key component of the CLIC technology, will adopt the same concepts to reach a current of 100 A.

The complexity of both the topology and the operation of those machines is a big obstacle for traditional tracking codes, which describe the machines as sequences of elements and/or adopt a very rigid definition of the beam. Single-bunch start-to-end simulations with these codes requires can be pursued unrolling the lattice, however the evaluation of multi-bunch effects, that may be critical, is not feasible.

For these reasons we decided to take advantages from the experience maturated with the developing of the tracking code PLACET [1], to create a new version that allows to set up realistic simulations of the operation of recirculating machines: PLACET2. A new tracking core has been entirely written from scratch in the latest C++ standards. Efforts are being taken to implement the same physics effects handled by PLACET and more. In the next sections we will give an overview of the new-developed concepts and up-to-date code functionalities that provide to our users a powerful tool to tackle these new challenges in accelerator physics.

OVERVIEW OF THE FEATURES AND FUNCTIONALITIES

PLACET2 is developed with a wide spectrum of machines in mind, in particular ERLs like the LHeC [2], but also peculiar lattices like the CLIC Drive Beam Complex [3]. It offers a great tunability of the trade-off between speed and accuracy. On one hand the beam can be represented using multiple models, on the other hand the lattice is implemented in an innovative way that allows to split the thick element cores in order to insert the desired physical effects at the required computational precision.

PLACET2 tracks many bunches simultaneously in recirculating lattices. The bunches enter each beamline in the correct time sequence. This makes possible to compute multibunch effects.

The most common accelerator components are implemented in PLACET2. The initial global phases of time dependent elements are locked by default to the first passing bunch, this resolves any synchronization issues in an automatic manner and relieves the user from tedious initializations. Elements can be misaligned and have apertures, with the possibility to track losses. Physical effects currently include the synchrotron radiation and the multi-bunch long-range-transverse wakefields.

With a bunch-based beam structure, the beam properties can be computed and monitored in any location of the simulated machine. This allows great flexibility. Moreover it is possible to set up a bunch to collect its properties such as orbit and Twiss functions, along its path in the machine.

Although PLACET2 is entirely written in C++, a TCL scripting interface similar to the one of PLACET is provided using SWIG [4]. Recently an Octave interface have also been added following the mechanism developed for PLACET.

COMPONENTS OF PLACET2

PLACET2 adopts an intuitive way to describe a machine based on traditional concepts, but with expanded capabilities and new elements such as injectors, dumps and joints, which allows to simulate the recirculation.

Beam PLACET2 represents the beam as a collection of bunches. Bunches can be routed independently through multiple beamlines, and are recombined together where the beamlines join. PLACET2 is designed to support many

GENERAL FUNCTIONALITY FOR TURN-DEPENDENT ELEMENT PROPERTIES IN SIXTRACK*

K. Sjobak†, H. Burkhardt, R. De Maria, A. Mereghetti, A. Santamaría García
CERN, Geneva, Switzerland

Abstract

In order to facilitate studies of how dynamically changing element attributes affect the dynamics of the beam and beam losses, the functionality for dynamic kicks (DYNK) of SixTrack has been significantly extended. This functionality can be used for the simulation of dynamic scenarios, such as when crab cavities are switched on, orbit bumps are applied, optics are changed, or failures occur. The functionality has been extended with a more general and flexible implementation, such that arbitrary time-dependent functions can be defined and applied to different attributes of families or individual elements, directly from the user input files. This removes the need for source code manipulation, and it is compatible with LHC@Home which offers substantial computing resources from volunteers. In this paper, the functionality and implementation of DYNK is discussed, along with examples of application to the HL-LHC crab cavities.

INTRODUCTION

SixTrack is a 6D single particle tracking code [1,2], which is routinely used at CERN to study the dynamic aperture and collimation system in high-energy circular machines like the LHC. There are also a large number of tools built around SixTrack, both for analyzing the results and for handling very large numbers of initial conditions. For this reason, SixTrack is the natural tool to use for studying fast failure scenarios at the HL-LHC, and for other transient phenomena at other similar machines.

Functionality for applying dynamic kicks (DYNK) – i.e. time-dependent machine element parameters – was therefore added to the code [3, 4] and significantly extended. It makes it possible for the user to specify the functional form of these parameters directly in the input file, or to load them from a file. This eliminated the need for multiple private code forks, freeing up and focusing developer resources. The specification of the functions, to which elements they should be applied, and when they should be applied, is done using a simple mini-language. Some examples of this language are given below, and a full description is given on the TWIKI page [5].

DYNK currently supports setting the strength of all the standard thin elements, and also setting the voltage, phase, and frequency of crab cavities. It also supports a wide variety of functions, which may use the turn number or the output of other functions as input. It is also possible for the functions to store and retrieve data from memory, as is used for pseudo random number generating functions that stores the random seed between turns, and when loading the functions as tables from files. There is also an option to output the setting of the affected elements at every turn to a file. In order to work with LHC@Home [6], which is used for large tracking campaigns, DYNK supports checkpointing and restarting from a checkpoint. It interacts correctly with the collimation routines, including resetting the elements and generating exactly the same values for each pass of 64 particles. The ripple module is made redundant by DYNK, which can exactly reproduce its results, and is therefore removed.

* Research supported by EU FP7 HiLumi LHC – Grant Agreement 284404
† kyrre.ness.sjoebaek@cern.ch

IMPLEMENTATION

In order to make DYNK work, there are two main components: a function parser and evaluator, and a setter and getter for the element properties. Additionally, there are hooks for calling DYNK in the tracking loops, and for initialization before the start of tracking. The data storage for the functions are provided by one master table (one row per function) and a "free memory" for each of the major data types (integers, floats and strings).

This architecture is very easily extendable, making adding support for new types of functions a matter of adding a few lines to the parser and evaluator. Similarly, new elements or element attributes can be supported by adding them to the setter and getter functions – the difficulty of this is determined by the complexity of the memory structures and initialization scheme used for that element.

EXAMPLE USE CASES

Some examples for the use of DYNK are provided below. All of these are ran using the HL-LHC v1.1 lattice [7] with vertical crab cavities around the first interaction point (IP1, ATLAS). The beam was sampled at IP1 as a Gaussian distribution using the nominal HL-LHC parameters, cropped so to only include particles inside of the RF bucket.

The crab cavities closing the bump (at s=153.6, 154.6, 160.2 and 161.2 m, relative to IP1) are in this simulation called CRAB_IP1_R1$\cdots$4, while the cavities creating the bump (at s=26494.3, 26495.3, 26500.9 and 26501.9 m) are called CRAB_IP1_L1$\cdots$4. Their frequencies are set to 400.8 MHz, i.e. the same as for the accelerating cavities. The standard voltages of the closing- and opening cavities opening cavities are calculated using Eq. 4 from [8]. For the opening cavities, it is assumed that the transverse betatron β-function and phase advance is the same for all the cavities, while the voltage of each of the closing cavities are chosen such that they cancel the symmetrically positioned opening

REDUCTION OF E-CLOUD IN PARTICLE ACCELERATORS BEAM PIPES STUDIED BY RADIO-FREQUENCY MULTIPACTING

R. Leber, F. Caspers, P. Costa Pinto, M. Taborelli, CERN, Geneva, Switzerland

Abstract

For a given beam structure, chamber geometry and magnetic field configuration, the electron cloud, (EC), intensity depends on the Secondary Electron Yield, (SEY), of the inner walls of the beam pipe. The observed reduction of the EC intensity as a function of the time of exposure to the beam, often called conditioning, is attributed to the growth of a low SEY carbon film due to the bombardment of electrons from the cloud itself. The full mechanism for the growth of carbon is not yet fully understood, but it depends on the dose of electrons and their energy. As the SEY of the beam pipe surface decreases, the flux of electrons from the EC also decrease and the conditioning decelerates. In the present paper we study the time evolution of the conditioning in stainless steel and copper beam pipes. The EC is induced by Radio-Frequency, (RF), multipacting using a coaxial resonator. Strip detectors are used to monitor the intensity of the EC. After each conditioning cycle, the SEY of beam pipes is measured and the growth of carbon analysed by X-ray Photoelectron Spectroscopy. The influence of the bias voltage, the composition of the base pressure with injection of C_2H_2 and $C_{12}H_{26}$, and the resilience of the conditioning after air exposure are tackled.

EXPERIMENTAL SETUP

The RF resonator to induce electron multipacting, (MP), consists of a tungsten wire drawn along the axis of a one meter long liner with a cross section similar to a CERN-SPS Main Bending magnet of type B (MBB) beam pipe. The liner is inserted in a cylindrical vacuum chamber, which is itself enclosed in a dipole magnet. The vacuum system is unbaked and operates at ~$1x10^{-7}$ mbar. The RF signal is generated by a Vector Network Analyzer (VNA); it is amplified and injected in the resonator. The network is matched to a frequency close to 100 MHz. To maximize the MP intensity, the dipole magnetic field is set close to cyclotron resonance (~43 Gauss). The RF excitations, (shots), are applied in power ramps from -30 dBm to -10 dBm in 30s, followed by a 90s pause to avoid overheating the wire. A measurement run consists of several thousands of shots and lasts several days. A DC bias voltage can be applied to the wire and is superimposed to the RF excitation. During the runs the pressure, the reflected RF power, and the MP current can be measured. Further details on the set-up can be found in [1]. The total pressure is measured by a cold cathode gauge and the partial pressures with a Residual Gas Analyser (RGA). The MP current distribution along the axis of the beam pipe is measured using a collector with 47 transversal stripes, (8 mm width, spaced by 0.17 mm, and bundled to 16 channels). The collector is separated from the beam pipe volume by a grid with a transparency of 7% to minimize the influence of the measurements on the MP process. The current on each channel is registered for every shot and the electron dose received by the beam pipe surface is calculated by correcting with the grid transparency. A similar strip detector with longitudinal stripes is used to measure the transversal distribution of the MP. Details about the strip detectors can be found in [2] [3]. Stainless steel (316LN) and electroplated copper liners were studied. Samples for SEY measurement (10 mm x 300 mm) are made of the same material of the liners and exposed to the MP in the beam pipe. Reference samples are placed in the same vacuum system but not exposed to MP. Before each measurement run, the liner and the samples are etched and cleaned following standard CERN procedures. At the end of the run, the system is vented to the laboratory air and the samples transferred to the SEY/XPS system for measurement [4].

RESULTS AND DISCUSSION

Effect of the Bias Voltage

It was observed that positive bias voltages enhance the MP and negative bias values below -100 V, suppress it completely. For positive bias from 0 V to 1000 V the MP current increases linearly. This might be an indication that the bias voltage increases the energy of the electrons hitting the walls, so that it approaches the SEY peak value. Figure 1 (top) shows the time evolution of the average of the doses measured in all the channels of the strip detector during one RF shot for stainless steel liners at 0 V and 1000 V bias and for a copper liner at 1000 V. To allow a direct comparison between the two voltages, during the 1000 V bias conditioning some points were measured by applying 0 V. The runs lasted 11 days. The current and dose per shot with the 1000 V bias is always the highest and it induces also a faster conditioning. After 3 days conditioning at 1000 V, no more MP could be observed at 0 V bias. After 11 days at 0 V the MP still remains (with a dose per shot ~$5x10^{-8}$ C/mm^2). This is due to the fact that at higher bias voltage the cumulated dose increases faster in time. Nevertheless, Fig. 1 (bottom) shows that the conditionings obtained with the two bias voltages have the same dose dependence.

For all runs, full suppression of the MP was never achieved. The system approaches asymptotically the SEY threshold for MP. We remark that the distribution of the MP intensity along the liner changes during the conditioning process, probably due to the fact that the RF electromagnetic field is not uniform and the electron dose

NEW ELECTRON CLOUD DETECTORS FOR THE CERN PROTON SYNCHROTRON

C. Yin Vallgren, P. Chiggiato, S. Gilardoni, H. Neupert, M. Taborelli#, CERN, Geneva, Switzerland

Abstract

Electron cloud (EC) has already been observed during normal operation of the PS using classical shielded button pick-up detectors in drift sections. In the context of the LHC Injector Upgrade (LIU project), similar measurements are also needed for the combined function magnets of the machine, where the access to the vacuum chamber is strongly limited by the presence of the yoke. Two new electron cloud detectors have been studied, developed, and installed during the Long Shutdown (LS1) in one of such magnets. The first is based on current measurement by using a shielded button-type pick-up with a special geometry to reach the bottom surface of the vacuum pipe embedded in the magnet. The second one relies on a newly developed measurement method based on detection of the photons, which are emitted by cathodoluminescence from the electron cloud impinging on the vacuum chamber walls. Part of the emitted photons is collected through a quartz window by a Micro-Channel Plate Photomultiplier Tube (MCP-PMT). First results obtained during machine development runs show the feasibility of the photon detection scheme. The results are discussed and compared with pick-up measurements.

INTRODUCTION

The direct measurement of the electron cloud (e-cloud) current in an accelerator implies to collect part of the electrons arriving to the beam-pipe. The collected electrons no longer contribute to the e-cloud development and therefore the measurement slightly perturbs the electron multipacting. Such measurements are more difficult in a magnetic field, since the dedicated vacuum beam pipe must have sufficient space to host the collector electrode without aperture restrictions for the machine [1]. In order to follow the e-cloud effect in the Proton Synchrotron (PS) accelerator at CERN in the context of the LHC Injector Upgrade program, we explored the development of a device which can monitor the signal of the electrons without collecting them directly. Such a device was implemented in one of the standard combined function magnets of the PS accelerator.

PRINCIPLE OF OPERATION

The principle of operation is the detection of cathodoluminescence [2, 3] photons produced by electrons impinging on a metallic surface. The decay of the secondary electrons to lower energy states, after the excitation by the primary electrons in the solid, occurs partly by photon emission. Figure 1 illustrates the spectrum of the photons obtained with an electron beam of 300eV, 9μA (area 2 mm^2) impinging on a stainless steel 316LN as-received surface (same material as the wall of the PS vacuum pipes). The beam energy is representative of the electrons of the e-cloud impinging on the accelerator wall. The light emitted by the sample is collected by a spectrometer (Andor Shamrock 303i, CCD Andor iDus 420) in air from a quartz viewport attached to a dedicated UHV chamber hosting the sample and the electron gun. The cold BaO cathode (nominal operating T=1150 K) of the gun aims at minimizing the black body radiation in the near UV region, where the

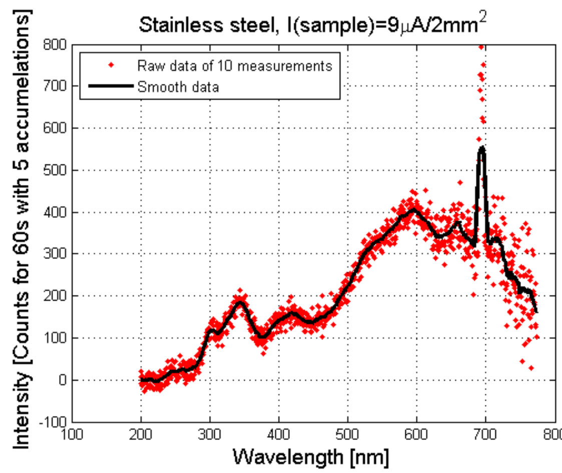

Figure 1: Typical spectrum obtained with e-gun.

cathodoluminescence is expected [2,3]. Most of the cathode radiation is indeed above 700 nm. This is proved by the fact that the signal in the range shown in figure 1 vanishes when the electron beam is deviated away from the sample. As expected the intensity is found to be proportional to the primary current impinging on the sample. A Monte Carlo simulation shows that the efficiency of collection due to the solid angle of the setup is only 0.04% (assuming isotropic emission). From this value and the measured integrated intensity between 200nm and 700nm we obtain a yield of $5x10^{-11}$ ph/e which is compatible with the literature values [2, 3].

SETUP FOR THE PS AND TESTS IN THE LABORATORY

The setup installed in the PS is shown in the scheme in Fig. 2. After the quartz viewport of the vacuum chamber the light is collected by a UV compatible optical system and brought to a PMT. The PMT (Photonis PP0365G) is robust with respect to parallel magnetic fields up to 2T and is placed in order to be parallel to the fringe field of the magnet. It has a nominal efficiency of 30% at 200-400 nm decreasing from 20% to 3% in the range 400 to 700

SIMULATIONS AND MEASUREMENTS OF LONGITUDINAL COUPLED-BUNCH INSTABILITIES IN THE CERN PS

L. Ventura, M. Migliorati, CERN, Geneva, Switzerland, Univ. Sapienza and INFN-Roma1, Rome, Italy
H. Damerau, G. Sterbini, CERN, Geneva, Switzerland

Abstract

Among various and challenging objectives of the LHC Injectors Upgrade project (LIU), one aim is to double the beam intensity of the CERN Proton Synchrotron (PS) in order to achieve the integrated luminosity target of the High-Luminosity LHC project (HL-LHC). A known limitation to reach the required high intensity is caused by the longitudinal coupled-bunch oscillations developing above the transition energy. The unwanted oscillations induce large bunch-to-bunch intensity variations not compatible with the specifications of the future LHC-type beams. A wide-band longitudinal damper has been installed in the PS to suppress these instabilities and is going to be commissioned. A measurement campaign of coupled-bunch oscillations has been launched to substantiate the extrapolations and predictions for the future High Luminosity LHC beam with the final aim to determine the maximum intensity that could be provided to the LHC. In parallel a Simulink© model of the PS is going to be implemented to predict the machine behavior in the parameter space of LIU and to be used during the beam commissioning and optimization of the feedback system.

INTRODUCTION

The Proton Synchrotron (PS) [1] is the LHC injector where the longitudinal structure of the beam train serving LHC is established. RF systems at multiple harmonics between $h = 7$ and $h = 458$ provide the flexibility required for the longitudinal bunch splitting [2]. After the beam is accelerated above transition energy [3], dipolar longitudinal coupled-bunch (CB) instabilities are observed [4, 5]. The machine longitudinal impedance changes according to the dynamic tuning of the main accelerating cavities along the magnetic cycle. During the ramp all cavities are tuned at $h = 21$ and the longitudinal impedance is maximized, thus causing a crosstalk among bunches. Presently this instability is cured by a controlled longitudinal emittance blow-up at injection energy and dedicated feedback at 15 f_{rev} and 20 f_{rev}. From the present bunch population of $1.3 \cdot 10^{11}$ p/b (72 bunches in $h = 84$), the LIU project [6] aims to reach $2.6 \cdot 10^{11}$ p/b [7]. This makes the present counter measurement (blow-up) inadequate to control the instability, producing, during the splitting at top energy, a bunch-by-bunch intensity variation not compatible with the required LHC luminosity performance.

In the following we assume as working hypothesis that the train of equidistant bunches is regularly distributed along the machine azimuth (to compare with the nominal filling pattern with 18 bunches in $h = 21$). Under this condition, the bunches are not sortable from the physical point of view (circulant symmetry). Assuming in addition that the CB oscillations can be described by a linear approximation, the circulant matrix formalism [8] becomes the ideal mathematical tool to analyze the dipolar coupled-bunch oscillations. The purpose of the study is to develop an algorithm to analyze the longitudinal profiles of the bunch train and, using the circulant matrices formalism, to perform the mode analysis of the system to study its stability. In addition a Simulink© [9] model of the PS and the new damper cavity is being implemented to take into account the non idealities of the system, i.e. the limited voltage of the damper cavity, the noise level of the longitudinal pickup (PU), the errors introduced by the quantization and sampling of the low level electronics of the feedback.

THE CIRCULANT MATRIX FORMALISM

A $2n_b \times 2n_b$ circulant matrix, $\mathbf{F}$, has the general form

$$\mathbf{F} = \begin{pmatrix} f_1 & \dots & f_2 \\ \dots & \dots & \dots \\ f_{2n_b} & \dots & f_1 \end{pmatrix}. \tag{1}$$

The evolution in the normalised longitudinal phase space of n_b bunches from turn n to turn $n+1$ can be linearly approximated by the following

$$\begin{pmatrix} x_1 \\ \Delta p_1/p \\ \dots \\ \dots \\ x_{n_b} \\ \Delta p_{n_b}/p \end{pmatrix}_{n+1} = \mathbf{M} \times \begin{pmatrix} x_1 \\ \Delta p_1/p \\ \dots \\ \dots \\ x_{n_b} \\ \Delta p_{n_b}/p \end{pmatrix}_{n}, \tag{2}$$

where $\mathbf{M}$ is a stationary block circulant matrix where each block represents a rotation matrix. This paper will discuss how to derive the $\mathbf{M}$ matrix starting from the measurement data from the longitudinal PU. Once $\mathbf{M}$ is known, the stability of the system described in Eq. 2 can be investigated by its eigenvalues if the matrix can be put in diagonal form. Since we consider a perturbative approach, it is possible to assume that all the bunches in the system have the same synchrotron tune Q_s. Therefore each bunch position x_i and each bunch momentum deviation $\Delta p_i/p$ can be written as

$$x_i = \Re\left\{a_i e^{j\phi_i} \cdot e^{j2\pi Q_s \times n}\right\} \tag{3}$$

$$\Delta p_i/p = \Im\left\{a_i e^{j\phi_i} \cdot e^{j2\pi Q_s \times n}\right\} \tag{4}$$

where $i \in \{1, \dots, n_b\}$, a_i and ϕ_i are the amplitude and the phase of the longitudinal bunch oscillation. The dynamic

THE EXTREME BEAMS INITIATIVE IN EuCARD-2*

K. Aulenbacher, JGU, Mainz, Germany; M. Biagini, INFN-LNF Italy; M. Eshraqi, ESS, Lund, Sweden; G. Franchetti, J. Struckmeier, GSI, Germany; F. Zimmermann, CERN, Switzerland

Abstract

EuCARD-2 [1] is an Integration Activity on accelerator R&D co-funded within the European Union's 7th Framework Program. The Extreme Beams (XBEAM) network of EuCARD-2 extends, and goes beyond the scope of, the previous Networking Activities of CARE-HHH and EuCARD [2] EuroLumi. XBEAM addresses, and pushes, all accelerator frontiers: luminosity, energy, beam power, beam intensity, and polarization. This is realized through five tasks, which are focusing on Coordination and Communication, Extreme Colliders (XCOLL), Extreme Performance Rings (XRING), Extreme SC Linacs (XLINAC), and Extreme Polarization (XPOL), respectively. This presentation reports the major achievements of the XBEAM activity from 2013 to 2015, and outlines the further plans through 2017.

OVERVIEW

The EuCARD-2 network on Extreme Beams ("XBEAM") aims at advancing on all accelerator frontiers, in particular luminosity, energy, beam power, beam intensity, and polarization. On the high energy and luminosity frontier it is supporting the HL-LHC crab cavity development and the studies of a Future Circular Collider, both of which became official projects thanks to activities in EuCARD, as well as plans for lepton-hadron colliders, and the preparation of SuperKEKB commissioning. At the high-intensity frontier, it is advancing projects like FAIR, the PSI cyclotron enhancement, and the ISIS upgrade, as well as preparing the ESS linac commissioning. Polarization management is improved both at high energy (LHeC, eRHIC, FCC, ILC, CLIC) and for low-energy precision experiments, such as electron storage rings for electric dipole measurements. XBEAM includes the five tasks shown in Table 1. Detailed information can be found on the XBEAM web site at http://cern.ch/xbeam.

In the first 2 years of the EuCARD-2 project, XBEAM has organised or co-organised more than fifteen workshops, as summarized in Table 2. These workshops addressed key questions for extreme colliders, extreme performance rings, extreme linacs, and extreme polarization. The XBEAM workshop achievements were complemented by a proactive outreach and dissemination effort, including numerous invited presentations at high-level conferences, workshops, or universities, several articles in the Accelerating News, the CERN Courier, and the ICFA Newsletter, plus two EuCARD-2 monographs. Some expert exchanges complete the picture.

*Work supported by European Commission under the FP7 Capacities project EuCARD-2, grant agreement 312453

Table 1: The Five Tasks of EuCARD-2 XBEAM

Task	Coordinators
1. Coordination and Communication	F. Zimmermann (CERN) and G. Franchetti (GSI)
2. Extreme Colliders (XCOLL)	M. Biagini (INFN) and F. Zimmermann (CERN)
3. Extreme Performance Rings (XRING)	G. Franchetti and J. Struckmeier (both GSI)
4. Extreme SC Linacs (XLINAC)	M. Eshraqi (ESS)
5. Extreme Polarization (XPOL)	K. Aulenbacher (JGU Mainz)

EXTREME COLLIDERS

XCOLL, together with the earlier AccNet-EuroLumi activity of EuCARD, has helped revive the idea of large high-energy circular lepton ("Higgs factory") and hadron colliders. The development and proposals started by AccNet and continued by XCOLL workshops have led to the launch, in February 2014, of an official 5-year "Future Circular Collider" (FCC) study, under a mandate from the CERN Directorate and from ECFA. The SuperKEKB B-factory soon to be commissioned in Japan will test and demonstrate the feasibility of several important features for these proposed future colliders. Impedance issues are one particular concern for both large lepton and hadron colliders, and have been investigated at a dedicated workshop co-organised by XCOLL. The scope of the LHeC study has been extended to include the integration of an electron-hadron collider option within the FCC complex. Novel compact crab cavities, earlier promoted at several workshops in the framework of CARE-HHH and EuCARD-AccNet, have now become a baseline ingredient for the LHC luminosity upgrade. Their continued development is being followed up by EuCARD-2 XBEAM XCOLL. These crab cavities may also be of interest for LHeC and FCC.

EXTREME PERFORMANCE RINGS

XRING has created discussion forums around critical areas of research for advanced storage rings. The first of these has focused on a topic relevant for FAIR, at the workshop "Beam dynamics meets Magnets" in Darmstadt. Experiences at J-PARC and LHC have provided examples for different working models with the following outcome: 1) According to LHC experience and benchmarking of the LHC dynamic aperture [1] theoretical models can correctly predict beam behaviour when the magnets parameters are well known. 2) Only for the LHC project the magnets characterization were determined by the beam-dynamics requirements, whereas in all other projects (J-PARC, RHIC) the beam dynamics calculations primarily studied the effect of given magnetic

OPTIMIZING SLS-2 NONLINEARITIES USING A MULTI-OBJECTIVE GENETIC OPTIMIZER

M. P. Ehrlichman*, M. Aiba, A. Streun, Paul Scherrer Institut, Villigen, Switzerland

Abstract

An upgrade to the SLS is currently under development. This upgrade will likely utilize the same hall and same machine circumference, 288 m, of the SLS. Achieving a sufficiently low emittance with such a small circumference requires tight focusing and low dispersion. These conditions make chromaticity correction difficult and minimization of 1st and 2nd order non-linear driving terms does not yield sufficient dynamic aperture and Touschek lifetime. In this proceeding, we discuss the multi-objective genetic optimization method implemented at SLS to aid the design of a chromaticity correction scheme for SLS-2.

INTRODUCTION

An upgrade to the `SLS`, which we will refer to as `SLS-2` in this paper, is under development [1]. The upgrade is envisioned as a complete replacement of the SLS storage ring while keeping the same hall, shielding, and booster. The beamline locations will be kept, but the beamlines themselves may be upgraded. The `SLS-2` will utilize small vacuum chambers, as pioneered by `MAX-IV`, to obtain higher field strengths, and also longitudinal gradient bends and anti-bends [2] to reduce the horizontal emittance from 5.6 nm to approximately 130 pm. The new ring will maintain the 12 cell topology of the existing SLS. 3-fold periodic lattices, like the existing SLS, and also 12-fold periodic lattices have been considered.

The new lattice uses strong quadrupole fields which induce a large chromaticity. This, in combination with small dispersion, necessitates a scheme of strong chromatic sextupoles to correct the chromaticity. These strong sextupoles generate strong nonlinearities which must in turn be compensated using harmonic sextupoles and octupoles.

Layout constraints prevent zeroing resonant driving terms (RDTs) beyond 1st order (in sextupole strength). Therefore, the optimal map has some combination driving terms and tune shift terms of 2nd order and higher. In fact, the optimal map may even have non-zero 1st order terms. Weighting 1st, 2nd, and higher order RDTs to obtain the best map, and locating the global minimum, is not straightforward. This is especially so given that RDTs are only a heuristic for the actual objectives, which are acceptance and lifetime.

An application of perturbation theory to 1st and 2nd order terms as described in [3] yields only marginally acceptable dynamic aperture (DA) and beam lifetime. We find that the direct genetic optimizer described in this proceeding consistently does better. For example, the direct optimizer finds high order corrections to the tune footprint far away from the closed orbit.

Elements of the traditional approach are maintained in our genetic optimization scheme. Chromatic and harmonic sextupoles and octupole locations are set by hand taking into consideration β-functions and phase advances. The working point is positioned considering the locations of low order resonances such that the tune footprint does not cross any dangerous resonances.

Features of the optimization scheme described here are: 1) It does not use RDTs. 2) It requires only moderate computing resources, typically about 12 hours on 64 PC cores. 3) A robust constraint system. 4) It seems to reliably converge to the global minimum. 5) Does not require seeding.

SYSTEM

The accelerator physics simulation is developed using the `Bmad` [4] subroutine library. The multi-objective genetic optimization scheme is the `aPISA` extension [5] to the PISA framework [6]. The sorting algorithm is `aspea2`, a version of the spea2 [7] sorting algorithm modified to support dominance constraints. The parallelization is implemented using Fortran COARRAYs, which are implemented as a high level layer on top of MPI. The computing resource is a Linux cluster running SGE consisting of distributed Intel Xeon compute nodes. The scheme is naturally load-balancing and works fine in heterogeneous environments.

The results from the optimizer are portable to other codes, in particular `OPA` [8], for further analysis. Effort in this project includes understanding the usage and modeling differences of different calculation codes so as to keep the development process consistent and flexible.

OPTIMIZATION PROBLEM

The goal of the optimization problem is to maximize injection acceptance and maximize the Touschek lifetime. Injection acceptance is maximized by maximizing the on-energy DA. The Touschek lifetime is maximized by maximizing the momentum aperture. However, the element-by-element momentum aperture is expensive to calculate. Therefore, instead of calculating the momentum aperture we calculate the off-momentum DA and constrain the chromatic tune footprint. As will be shown later, we find this is an effective and efficient proxy for maximizing the Touschek lifetime.

Objectives

Three objectives are used by the optimizer. The objective function, depicted for $N_{angle} = 7$ in Fig. 1, is calculated as

TRACKING THROUGH ANALYTIC QUADRUPOLE FRINGE FIELDS WITH GPT

S.B. van der Geer, M.J. de Loos, Pulsar Physics (PP), The Netherlands
B.D. Muratori, STFC Daresbury Laboratory and Cockcroft Institute, U.K.

Abstract

In the early design stages it is customary to work with a highly simplified analytic model to describe a beamline. Dipoles and quadrupoles are often based on hard-edged approximations. This is not only unrealistic, it also significantly slows down time-domain spacecharge tracking codes such as the General Particle Tracer (GPT) code. The underlying reason for the poor performance is that, despite the fact that the simple hard-edged field equations are fast to evaluate, they force the integration process to use excessively small step sizes near the field discontinuities in order to achieve the desired accuracy. In other words, the apparently simple equations turn out to be the most difficult ones to evaluate numerically. An obvious solution is to switch to field-maps, but this is not practical in the early design stages. In this contribution we show a new solution implemented in the GPT code based on analytical expressions for the fringes where the transverse size of the magnet is properly taken into account. In addition to producing more realistic results, the smooth fields increase tracking speed by over an order of magnitude for typical cases.

INTRODUCTION

Time domain simulations codes such as GPT [1, 2], PARMELA and ASTRA are essential tools for the design and understanding of high-brightness charged particle accelerators. The physics included in these codes is a particularly good match for injector / RF-photogun simulations producing pulsed, high-brightness, high-charge beams. The way the simulation codes operate is by tracking a large number of sample particles through the superposition of external fields and spacecharge fields. At each step in the simulation the codes maintain a collection of sample particles, where all particles are stored at the same time. This ensures self-consistent results for Coulomb interactions, even when the beam shape changes on relatively short time-scales. A simulation step involves the calculation of all electromagnetic fields due to external beamline components at the position of all sample particles, in addition to calculating the fields due to space charge. These fields are fed into an Ordinary Differential Equation (ODE) solver to solve the relativistic equations of motion, thereby advancing the entire population in time.

Regardless of the exact integration scheme, it is important to have the correct timestep length. On the one hand, a very small timestep gives accurate results at the costs of excessive CPU time. On the other hand, a very large timestep gives incorrect results. The best operating mode is arguably with the largest timestep possible, giving results which are 'barely good enough'. Finding the right balance is difficult, and this is further complicated by the fact that the optimal timestep varies greatly along the beamline. Very small steps must be taken during the emission process and in beamline components with large gradients, whereas very large steps can be taken in relatively constant or zero field regions.

Problems arise when part of the beamline is modelled with hard-edge approximations. It might be that the fringes capture relevant physics, and with ever brighter sources these effects become increasingly important. Furthermore, tiny integration steps need to be taken during the crossing of the interface to maintain sufficient accuracy. For just one particle this could be acceptable, but all particles have to be tracked together to get self-consistent results. Consequently, a timestep reduction for one particle crossing the interface of a hard-edged beamline component implies in a timestep reduction for all other particles as well. This significantly slows down simulation speed, especially for long bunches where there is always some particle crossing some interface. This is the problem we address in this paper, in particular for quadrupoles.

One solution to the problem of requiring small time-steps crossing a hard-edge interface is to split the trajectory in two halves at the interface: Neither half contains any discontinuities, and the simulation speed is restored. However, this solution misses relevant physics captured in the fringe fields, it requires non-trivial interpolation of the spacecharge fields to a set of intermediate timesteps, and it involves extra bookkeeping that makes misaligning beamline components in 3D prohibitively difficult. Another solution is to use realistic field maps, not containing these discontinuities. This restores the missing physics, it solves the problems arising from discontinuities, but it is often rather unpractical in the early design stages when fast parameter scans are required. Furthermore, field-maps are intrinsically based on interpolations causing a whole list of potential problems of their own.

The conceptually easiest and arguably best solution that solves all issues mentioned above is to track through a simple continuously differentiable equation for the fields, Maxwell compatible, including the fringes. Inspired by the analytical fringe fields of dipoles [3], we show in the next section how such expressions can be derived for higher order multipoles. The subsequent section presents the results of a GPT implementation of these expressions for the case of quadrupoles. Although the equations are far more complicated than the hard-edge counterparts, we will show that the overall GPT simulation speed is significantly improved.

MULTI-OBJECTIVE GENETIC OPTIMIZATION WITH THE GENERAL PARTICLE TRACER (GPT) CODE

S.B. van der Geer, M.J. de Loos, Pulsar Physics, Eindhoven, The Netherlands

Abstract

In a typical design process there are a large number of variables, external constraints, and multiple conflicting objectives. Examples of the latter are short pulse, high charge, low emittance and low price. The classical solution to handle such problems is to combine all objectives into one merit function. This however implicitly assumes that the tradeoffs between all objectives are a-priori known. Especially in the early design stages this is hardly ever the case. A popular solution to this problem is to switch to multi-objective genetic optimization algorithms. This class of algorithms solves the problem by genetically optimising an entire population of sample solutions based on selection and recombination operators. The output, the so-called Pareto front, only includes solutions that are fully optimized where no objective can be improved without degrading any other. Here we present numerical studies and practical test runs of the genetic optimizer built into the General Particle Tracer (GPT) code [1].

INTRODUCTION

GDFMGO is a new multi-objective global optimizer for the GPT code. Its internal algorithm evolves a population of candidate solutions towards the so-called Pareto-front. This front is defined as the set of points where it is impossible to improve one objective without making at least one other objective worse. The final result is a set of points equally spaced at or near the Pareto front, where each point is fully optimized in all its variables.

The Pareto front samples, for the given objectives, the optimal combination of variables. For two objectives and ten variables, the Pareto front is a line through two dimensional objective space and ten dimensional variable space. In other words, the original problem of having to choose the best combination of ten variables has been reduced to the one dimensional problem of selecting where on the line you want to be. This collapse of dimensionality makes multi-objective optimization such a powerful tool for decision making. Its power does not come from providing the 'the best' solution, but from reduction of the dimensionality of the problem and simultaneously providing insight in tradeoffs between the different objectives.

GDFMGO starts with a fixed size population of candidate solutions with variables either chosen randomly in a user specified interval or read from file. Typically this initial population is very poor in terms of the objectives, and probably in violation of a number of constraints if present. The idea is to create improved candidate solutions based on the solutions already present, while gradually removing the worst ones. This process is repeated over and over again, and slowly the population as a whole evolves in the desired direction. Global convergence properties come from the fact that the population is pushed gently towards the Pareto front instead of steepest descent into a potential local minimum. Although there are plenty of pathological cases where this does not work, in practice the algorithm finds the global optimum in a impressively large number of cases with the default parameters.

The key ingredients of the algorithm are a) creation of new candidate solutions based on the existing ones, b) ranking the solutions such that the worst can be removed and c) a stopping criterion. They are described in detail below.

New Species

New random samples are created from the existing population. The mechanism we use is known as Differential Evolution (DE) [2]. To create a new combination of variables **p**, first four random species from the population are selected. We denote them **u**, **v**, **w** and **x**. Subsequently, an intermediate point **t** is calculated from **u**, **v** and **w** using: $\mathbf{t} = \mathbf{w} + s\,(\mathbf{u} - \mathbf{v})$.

The idea is that the new point is close to the existing **w**, but offset with the direction from **v** to **u**. To enforce convergence, the direction is slightly reduced by a scale factor s that must be below 1. In practice using this intermediate point **t** as the new point already works very well. However, when the entire candidate solution lies on a hyperplane in all variables there is no escape from this plane thereby stalling the algorithm. This is where the last selected point **x** comes into play, where there is a mutation probability (1-ρ) that variables are selected from **x** instead of from **t**. To avoid duplicating **x** at least one of the variables must come from **t**. In equations:

$$cr = \text{random\_int}[1,n]$$
$$p_i = \begin{cases} t_i & \text{random}[0,1] < \rho \quad \vee \quad i = cr \\ x_i & \text{otherwise} \end{cases}$$

A lower ρ increases global convergence properties at the cost of a slower convergence rate. In practice neither the scale factor s nor the mutation rate ρ are critical parameters and the defaults of 0.6 and 0.9 respectively work fine in most cases.

New candidate solutions are added until the population size is doubled. Then the population is ranked and trimmed to the original size again. How this is done is the subject of the next section.

Y. Ishi, T. Uesugi, Y. Kuriyama, M. Sakamoto, Y. Mori, KURRI, Japan
A. Adelmann, PSI, Switzerland

Abstract

Fixed Field Alternating Gradient accelerators have been realised in recent decades thanks partly to computational power, enabling detailed design and simulation prior to construction. We review the specific challenges of these machines and the range of different codes used to model them including ZGOUBI, OPAL, SCODE and a number of in-house codes from different institutes. The current status of benchmarking between codes is presented and compared to the results of recent characterisation experiments with a 150 MeV FFAG at KURRI in Japan. Finally, we outline plans toward ever more realistic simulations including space charge, material interactions and more detailed models of various components.

INTRODUCTION

Fixed Field Alternating Gradient (FFAG) accelerators have potential to provide high intensity hadron beams for various applications. This arises from the combination of strong focusing to reach high energies with a fixed magnetic field which enables a high repetition rate and high average current. In 2013 a collaboration was formed to focus effort in the FFAG community on this topic. The collaboration aims to undertake a series of experiments to progress toward high intensity operation of the 150 MeV proton scaling FFAG accelerator at Kyoto University Research Reactor Institute (KURRI) in Japan. Relevant parameters of the accelerator can be found in Ref. [1].

At the same time a simulation campaign has been established to benchmark relevant simulation codes. This campaign aims to provide reliable tools for FFAG modelling and to help understand the results of the experiments as they progress. After short description of the codes used, we will discuss present benchmarking efforts.

SIMULATION CODES

The beam orbit in an FFAG moves radially with momentum, as in a cyclotron. Simulation codes which assume a central orbit independent of momentum are unsuitable for studying FFAGs as they do not reproduce the correct dynamics. There are a few codes which remove the constraint of the existence of the central orbit: OPAL, Zgoubi, SCODE, MAUS and EARLIETIMES, which we have selected to perform our benchmarking.

* suzie.sheehy@stfc.ac.uk

OPAL

OPAL (Object Oriented Particle Accelerator Library) [2] is an open source C++ framework for general particle accelerator simulations including 3D space charge, short range wake fields and particle-matter interaction. OPAL is based on IPPL (Independent Parallel Particle Layer) which adds parallel capabilities. The main functions inherited from IPPL are: structured rectangular grids, fields, parallel FFT and particles with the respective interpolation operators. Massive parallelism (up to 65000 processors) makes it possible to tackle the largest problems in the field.

ZGOUBI

Zgoubi is a ray-tracing code which can track particles through electric and magnetic fields introduced as field maps or as analytic elements. It has excellent flexibility in the choice of elements, and includes complex geometries with high-order multipole and combined-function magnets as analytic elements. For this reason it has been adopted as one of the main simulation codes in the FFAG community [3].

SCODE

SCODE was developed specifically for the simulation of FFAG accelerators. Some of the modules such as the space charge module and the single particle tracking module with time as the independent variable are imported from another code, Simpsons [4]. Space charge calculation in 2.5D and frozen model are available. Simple models of multiple scattering in the transverse direction and energy loss due to foil scattering are also included. Recently, tracking based on 3D magnetic field maps has been added.

MAUS

MAUS (MICE Analysis User Software [5] is a tracking and reconstruction code base on Geant4 [6]. MAUS provides a framework for accelerator raytracing using custom field map routines, the Geant4 material physics libraries and the capability to plug-in realistic diagnostic modelling.

KURRI In-house Code EARLIETIMES

EARLIETIMES [7] was developed at KURRI for the purpose of design and beam commissioning of the KURRI FFAG accelerator complex. It uses a 4th order Runge-Kutta algorithm to find the closed orbit in a 3D magnetic field calculated by external software e.g. TOSCA. EARLIETIMES treats this closed orbit as a reference orbit, which can be

BEAM DELIVERY SIMULATION - RECENT DEVELOPMENTS AND OPTIMISATION*

J. Snuverink†, S. T. Boogert, H. Garcia-Morales, S. M. Gibson, R. Kwee-Hinzmann, L. J. Nevay,
John Adams Institute at Royal Holloway, University of London, Egham, UK
L.C. Deacon, University College London, London, UK

Abstract

Beam Delivery Simulation (BDSIM) is a particle tracking code that simulates the passage of particles through both the magnetic accelerator lattice as well as their interaction with the material of the accelerator itself. The Geant4 toolkit is used to give a full range of physics processes needed to simulate both the interaction of primary particles and the production and subsequent propagation of secondaries. BDSIM has already been used to simulate linear accelerators such as the International Linear Collider (ILC) and the Compact Linear Collider (CLIC), but it has recently been adapted to simulate circular accelerators as well, producing loss maps for the Large Hadron Collider (LHC). In this paper the most recent developments, which extend BDSIM's functionality as well as improve its efficiency are presented. Improvement and refactorisation of the tracking algorithms are presented alongside improved automatic geometry construction for increased particle tracking speed.

INTRODUCTION

Many particle accelerators need to predict and minimise beam losses throughout the machine to avoid damage, radioactivation of the beamline elements and background radiation. Beam loss simulation studies often make use of several codes for different features. Typically, a fast tracking code is used to record positions where particles hit a collimator or the beam pipe, and these positions are then input into a detailed radiation transport code. Obviously, this approach is not ideal. For example, the geometry description capabilities of such codes are rarely equivalent as the fast tracking code usually has a very limited description of the geometry, the data must be transferred between the two codes, particles that scatter back into the beam pipe might not be considered, etc. For the greatest accuracy, a combined approach is required that allows both efficient transport of particles in the accelerator as well as particle interaction with surrounding material.

For this purpose BDSIM [1, 2] has been developed. BDSIM is a flexible, open source C++ particle tracking code that uses the Geant4 framework [3]. Geant4 gives access to many electromagnetic and hadronic interaction models as well as powerful geometry description and visualisation tools. For fast beam tracking inside the beam pipe efficient tracking routines are implemented.

For its input BDSIM deploys a MAD-like input syntax, which has the advantage of an easy, fast and accurate conversion from existing lattices. Additional keywords allow for a more detailed geometry and material description.

BDSIM was originally developed for the simulation of linear colliders such as the International Linear Collider (ILC) and the Compact Linear Collider (CLIC), see e.g. [4, 5]. In recent years it has been adapted to accommodate circular accelerators as well [6, 7]. BDSIM is in active development and is currently utilised for several accelerators, e.g. AWAKE [8], CLIC [9], ILC [10] and HL-LHC [11].

This paper gives an overview of the latest code developments. More information and the source code can be found on the BDSIM website [12].

GEOMETRY

For accurate background studies it is important to have the right amount of detail in the description of the geometry and material. The geometry will be of particular relevance in simulation studies for laserwire diagnostics and other Compton-photon based diagnostics, whose specification is highly dependent on their detector background environment. The geometry of poles in comparison to a generic cylinder of material for example, allows the passage of radiation between the poles significantly further along the machine.

A beamline element like a quadrupole can have many different designs and consist of various geometry components. However, it will have a beam pipe geometry (round, rectangular, ellipse, etc.), a magnet geometry (cylindrical, with poles, etc.), and possibly a supporting plinth or girder. Previously, the creation of the simulation world in BDSIM was done in a single pass in the direction of the beam, element by element. This meant that a quadrupole also needed to create beam loss monitors situated in the vicinity, a part of the tunnel, and even surrounding soil. Such a philosophy is suitable if one works with only one a few types of geometry and structures, but becomes unmanageable when one wants to add new geometry types or new structures.

To simplify the already large beamline element class `BDSAcceleratorComponent`, a more basic base class `BDSGeometryComponent` has been created. This improved geometry class hierarchy allows for a plug and play nature of components, which is normally not provided with the Geant4 toolkit where the user must take care to comprehend the geometry description and avoid geometrical overlaps.

TRACKING STUDIES IN THE LHeC LATTICE

E. Cruz-Alaniz, D. Newton, Univ. Liverpool/Cockcroft Institute, UK
R. Tomás, CERN, Switzerland

Abstract

The Large Hadron Electron Collider (LHeC) is a proposed upgrade of the LHC to provide electron-proton collisions and explore a new regime of energy and luminosity for nucleon-lepton scattering. A nominal design has previously been presented, featuring a lattice and optical configuration to focus one of the proton beams of the LHC (reaching a value of β^*=10 cm) and to collide it head-on with an electron beam to produce collisions with the desired luminosity of L=10^{33} cm^{-2}s^{-1}. The proton beam optics is achieved with the aid of a new inner triplet of quadrupoles at L^*=10 m from the interaction point and the extension of the Achromatic Telescopic Squeezing (ATS) Scheme used for the High Luminosity-LHC project. In this work, particle tracking is performed in a thin lens approximation of the LHeC proton lattice to compute the dynamic aperture and perform frequency map analysis for different types of chromatic correction schemes, in order to find the one who will provide the most beam stability and to study the effects of nonlinearities.

INTRODUCTION

The LHeC interaction region (IR), first proposed in [1] contemplates the implementation of a new set of quadrupoles closer to the interaction point (IP), called the inner triplet (IT), at a distance L^* from the interaction point 2 (IP2) to achieve head-on electron-proton collisions at a luminosity of L=10^{33} cm^{-2}s^{-1}. In order to change the trajectory of the proton beams, the polarity of the two dipoles close to the IP (D1 and D2) must be reversed, compared to the present polarity, and the strength of D2 should be 1.21 stronger and the one of D1 3.43 stronger.

A first integration of the LHeC IR into the HL-LHC lattice, was done in [2] with an extension of the Achromatic Telescopic Squeezing Scheme (ATS), successfully applied for the HL-LHC lattice in [3]. This extension was done in the arc 23 performing a telescopic squeeze to further reduce the value of β^* in IP2 while leaving the HL-LHC insertions (IP1 and IP5) with round optics undisturbed. Achieving a value of $\beta^* = 10$ cm for IP2 and β^*=15 cm in IP1 and IP5.

The flexibility of this design was studied in [4] in terms of minimising β^* to study the reach in luminosity, and in terms of increasing L^* to reduce the synchrotron radiation.

Using a thin lens version of this LHeC lattice, tracking studies can be done to study the stability of the beam for the nominal case with β^*=10 cm and L^*=10 m.

CHROMATIC CORRECTION

One of the characteristics of the ATS is the locality of the chromatic correction of the inner triplet by using one single arc of sextupoles of either side of the small β^* insertions. However, in the LHeC case, the achromaticity is broken due to the telescopic squeeze in arc 12 shared by both IP1 and IP2. In this section, three different chromatic corrections are studied using a thin lens version of the lattice to study the impact of each correction scheme on the stability of the beam.

These chromatic corrections are performed by a matching procedure in MADX. The first correction, named "LHC-like" takes as 2 variables the strengths of the focussing and defocussing families of sextupoles, to fix as constraints the global values of the horizontal and vertical chromaticity (dqx, dqy) to a value of 2. The second correction, named "LHeC-like" increases the number of variables to allow every family of sextupoles to vary independently, accounting for 32 variables (2 for every arc of the LHC), to adjust not only the global value of the chromaticities to 2 as the previous case, but also to adjust the horizontal and vertical Montague functions (Wx and Wy) below 200 in the collimation insertions interaction region 3 (IR3) and interaction region 7 (IR7). Finally the third correction, named "second order", takes the same variables and constraints as the LHeC-like correction but adds as further constraints the variation of the horizontal and vertical chromaticity with momentum below a value of 7.

Figures 1 and 2 illustrate the change of tune over momentum for the three different chromatic corrections. The presence of nonlinearities is clear, specially for the cases LHC-like and LHeC-like, with the first one having a larger variation in the tune. On the other side, the second order correction is linear for the vertical tune, although for the horizontal tune, this linearity was not achieved for the whole momentum spread.

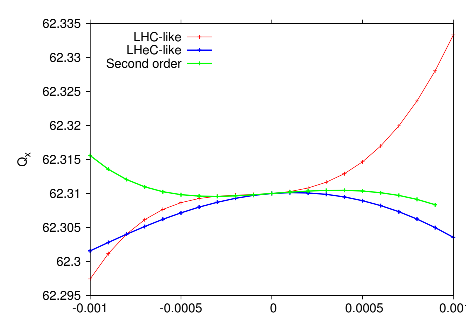

Figure 1: Q_x vs δ_p for three different chromatic corrections: LHC-like, LHeC-like and second order.

Figure 3 shows the chromatic variation over momentum

LONGITUDINAL STABILITY IN MULTI-HARMONIC ACCELERATING CAVITIES

L.R. Carver*, R.M. Jones, School of Physics and Astronomy, University of Manchester
& The Cockcroft Institute of Science and Technology, UK
Y. Jiang, J.L. Hirshfield, Yale University, New Haven, CT 06511, USA

Abstract

Accelerating cavities that excite multiple modes at integer harmonics of the fundamental frequency can potentially be used to limit the effects of rf breakdown and pulsed surface heating at high accelerating gradients. Understanding the longitudinal stability and the acceptance of such a cavity is important to their development and use. The general Hamiltonian for longitudinal stability in multi harmonic cavities is derived and the particle dynamics are explored.

INTRODUCTION

A multi-harmonic cavity that operates at high gradients could act as an alternative cavity design for CLIC. Cavities of this type have unconventional surface electric and magnetic field profiles that can potentially lower the surface field emission and/or pulsed surface heating without compromising the gradient [1]. Two particular phenomena found in multi-harmonic cavities provide the main motivation for their use: (a) the anode-cathode effect, which can be found in an asymmetric multi-harmonic cavity that relies on fields pointing into one wall (cathode-like) to be significantly smaller than fields pointing away (anode-like) from the same wall. This effect will raise the work function barrier to supress field and secondary emission, and (b) a reduction in the surface heating by lowering the average $H_{\parallel}^2$ along the surface.

For cavities of this type to be used in an accelerator, the effect of the additional mode on a bunch of traversing particles needs to be explored. To achieve this, a Hamiltonian is derived that describes the behaviour of particles with small deviations from the synchronous particle in energy and/or phase. Typical formalisms of this kind only account for a single TM_{010} mode which follow a $\cos(kz)$ longitudinal distribution [2, 3] (where k is the wave number and z is the longitudinal coordinate) and not for a combination of modes with different longitudinal field profiles.

Harmonic rf systems are often used to linearise the energy gain [4] and reduce the energy spread of the bunch [5, 6]. These typically require an additional cavity operating in a TM_{010} mode with a frequency that is an integer harmonic of the main cavities. Here however, we excite two modes simultaneously within one cavity.

The first section presents tracking results for a particle traversing a linac and this is compared with the Hamiltonian found in literature. In subsequent sections, a general Hamiltonian for multi-harmonic cavities is derived and applied to two seperate modal configurations.

* Lee.Carver@manchester.ac.uk

SINGLE MODE PARTICLE TRACKING

The electric field of a TM_{010} standing wave in a cavity with amplitude E_0 is

$$E_T = E_0 \cos(kz)\cos(\omega t + \phi). \tag{1}$$

where ϕ is the phase of the field when the particle is at $z = 0$, ω is the angular frequency and $k = 2\pi/\beta_s\lambda$. The energy gain of a charge q as it crosses a single cavity gap g is given by

$$W = qE_0 \int_{-g/2}^{g/2} \cos(kz)\cos(\omega t + \phi)dz \tag{2}$$

The energy relative to the synchronous particle is $w = W - W_s$. The relevant differential equations in terms of the Hamiltonian H are given by [2]

$$\frac{dw}{ds} = qE_1 T(\beta)(\cos(\phi) - \cos(\phi_s)) = -\frac{\partial H}{\partial \phi} \tag{3}$$

and

$$\frac{d\phi}{ds} = -2\pi \frac{w}{\gamma_s^3 \beta_s^3 mc^2 \lambda} = \frac{\partial H}{\partial w}, \tag{4}$$

where $V_0 = E_0 \int_{-g/2}^{g/2} \cos(kz)dz$. and T is the transit time factor given by

$$T(\beta) = \frac{\int_{-g/2}^{g/2} \cos(kz)\cos(\frac{\omega z}{\beta c})dz}{V_0}, \tag{5}$$

with $E_1 = V_0/g$. For the synchronous particle, T remains constant as the cavity gap increases with β_s. For negligibly small acceleration rates, the differential equations can be integrated, and the Hamiltonian is

$$H = \frac{\pi}{\beta_s^3 \gamma_s^3 mc^2 \lambda} w^2 + qE_1 T[\sin\phi - \phi\cos(\phi_s)], \tag{6}$$

where β_s and γ_s refer to the velocity and gamma factor of the synchronous particle.

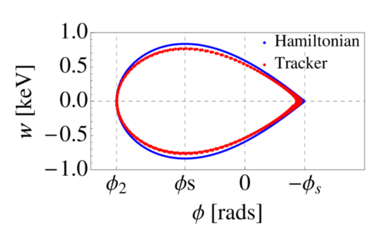

Figure 1: Comparison of Hamiltonian with particle tracked according to Eq. 2.

ANALYTICAL APPROACH TO THE BEAM-BEAM INTERACTION WITH THE HOURGLASS EFFECT

M. Crouch, University of Manchester/ The Cockcroft Institute, U.K.
B. D. Muratori, ASTeC, STFC Daresbury Laboratory, and The Cockcroft Institute, U.K.
R. B. Appleby, University of Manchester/ The Cockcroft Institute, U.K.

Abstract

The hourglass effect arises due to a coupling between the longitudinal and transverse bunch planes. This coupling will result in a charge density distribution that will vary parabolically through the Interaction Point (IP). Here a method of analytically determining the electric field a particle receives from a charge density distribution which varies parabolically when centred at the IP, is derived for a 2D transverse model of a Gaussian bunch.

INTRODUCTION.

The High Luminosity Large Hadron Collider (HL-LHC) seeks to reach even higher luminosities than previously achieved. An increased luminosity can lead to a saturation or "pile up" in the machine detectors. To avoid pile up in the detectors, luminosity levelling has been proposed which aims to hold the luminosity constant over the duration of a physics run. One proposed method of levelling the luminosity is to reduce the β-function at the IP as the bunch intensity decays due to proton burn off.

One of the benefits of levelling by this method is it is operationally easy to implement and the longitudinal vertex density remains fixed when there is no crossing angle. The flat beam option is an alternative operational scenario for the HL-LHC when there are no crab cavities installed. To reach high luminosities without crab cavities, small β^* is required to generate high luminosities. The final levelling step of the flat beam option will give a β-function at the IP of $\beta^*_{x,y} = 0.3/0.075$ m. In this scenario, the β-function in the vertical plane at the end of a physics run will be comparable to the length of the bunch. When the length of the bunch is comparable to the transverse bunch size, a coupling between the planes is introduced, which results in the bunch varying parabolically at the IP. This coupling will result in a deviation from a Gaussian distribution in the longitudinal coordinate as the bunch passes through the IP. Such a deviation will result in some particles not colliding at the minimum β^*, which will hence lead to a reduction in luminosity. This is known as the hourglass effect.

Here, a new approach is applied to the beam-beam interaction to obtain analytical solutions for the electric field of a bunch that is centred at the IP undergoing a parabolic variation due to the hourglass effect. From the electric field in the rest frame of the bunch, one can later obtain the force a test particle experiences when the counter rotating bunch is centred at the IP.

THEORY

Starting from Maxwell's equations, which when expressed in full are given by,

$$\partial_y B_z - \partial_z B_y = \mu\left(J_x + \epsilon\partial_t E_x\right), \tag{1}$$
$$\partial_x B_z - \partial_z B_x = -\mu\left(J_y + \epsilon\partial_t E_y\right), \tag{2}$$
$$\partial_x B_y - \partial_y B_x = \mu\left(J_z + \epsilon\partial_t E_z\right), \tag{3}$$
$$\partial_y E_z - \partial_z E_y = -\partial_t B_x, \tag{4}$$
$$\partial_x E_z - \partial_z E_x = \partial_t B_y, \tag{5}$$
$$\partial_x E_y - \partial_y E_x = -\partial_t B_z, \tag{6}$$
$$\partial_x B_x + \partial_y B_y + \partial_z B_z = 0, \tag{7}$$
$$\partial_x E_x + \partial_y E_y + \partial_z E_z = \frac{\rho(x,y,z)}{\epsilon_0}. \tag{8}$$

If these equations are written in the rest frame of the bunch, the problem can be treated as electrostatic, assuming that there are no external magnetic fields in the rest frame. This provides an appropriate starting point and is one that is applied in the original derivation given by Bassetti-Erskine [1]. Maxwell's equations in the transverse planes are then given by

$$\partial_x E_y - \partial_y E_x = 0, \tag{9}$$
$$\partial_x E_x + \partial_y E_y = \frac{\rho(x,y)}{\epsilon_0}, \tag{10}$$

Since the charge density distribution, ρ, is known and is given by a Gaussian distribution, one is able to solve this system of equations to obtain the transverse electric field experienced by a particle as it traverses the electric field of a counter rotating bunch. Following the method proposed by Muratori *et al*, [2], one attempts to solve these non-linear coupled partial differential equations using an expression with a number of unconstrained functions, which in turn, will reduce to the well known Bassetti-Erskine (BE) equation. This method can then be extended for a charge density distribution that has a parabolic dependence on the longitudinal coordinate.

The BE equation for radially symmetric beams with fixed transverse beam sizes is well known and is obtained through solving Poisson's equation for a Gaussian source. Poisson's equation relating the scalar potential φ to the charge density distribution is given by,

$$\nabla^2\varphi = \frac{\rho}{\epsilon_0}. \tag{11}$$

Solving this using the Green's function method as introduced by S.Kheifets [3] allows the radial electric field to be

IMPLICATIONS OF MANUFACTURING ERRORS ON HIGHER ORDER MODES AND ON BEAM DYNAMICS IN THE ESS LINAC

A. Farricker*, R. M. Jones, School of Physics and Astronomy, Univ. of Manchester, Manchester, UK
and The Cockcroft Institute of Science and Technology, Daresbury, UK
S. Molloy, ESS AB, Lund, Sweden

Abstract

The European Spallation Source (ESS) in Lund, Sweden, will be a facility for fundamental physics studies of atomic structure using a spallation source of unparalleled brightness. To achieve this end, protons will be accelerated up to 2 GeV using a suite of cavities. Here we focus on the medium beta (β=0.67) elliptical superconducting cavities and we assess the influence of potential errors in fabrication to shift eigenmode frequencies onto an harmonic of the bunch frequency. If this occurs, and countermeasures are not adopted, the beam quality will be appreciably diluted. We provide details on the geometrical parameters which are particularly sensitive to frequency errors from intensive finite element simulations of the electromagnetic fields. A circuit model is also employed to rapidly assess the shift in the eigenmodes from their anticipated design values due a variety of potential errors.

INTRODUCTION

The ESS is a material science research facility currently under construction in Lund, Sweden. It will provide an unparalleled neutron flux for neutron based experiments by colliding a 5 MW (average) proton beam with a solid Tungsten target [1]. To achieve this a superconducting (SC) linear accelerator (linac) will accelerate a 2.86 ms, 62.5 mA beam up to a final energy of 2 GeV. The beam will have a bunch frequency of 352.21 MHz and have a repetition rate of 14 Hz. The SC linac will consist of 146 SC cavities of which 26 are two-spoke resonators (β = 0.50), 36 medium-beta (β = 0.67) and 84 high-beta (β = 0.86) [2].

The introduction of a charged particle beam into an accelerating cavity results in the excitation of a wakefield. This has both longitudinal and transverse components which can be decomposed into a series of modes. Beam excited higher order modes (HOMs) can cause significant dilution in the beam quality as well as increased levels of beam loss by moving bunches outside the stable RF bucket. The affects of HOMs can be reduced by coupling out the radiation and damping them with appropriate absorbing materials. In the ESS, as the bunch charge (174 pC) is relatively small, the transverse HOMs are small enough [3] such that damping them by these means is considered unnecessary. Also the longitudinal HOMs have relatively small loss factors [4] and their impact on beam dynamics is in general quite benign. However, if the frequency of a longitudinal HOMs is close to an harmonic of the bunch frequency, it can have a detrimental impact on the beam quality and can give rise to enhanced cryogenic load.

In summary, due to the low bunch charge and frequency of the cavities the magnitude of the field excited will be small [5]. However if a monopole mode is resonantly excited due to lying on a harmonic of the bunch frequency (machine line) the induced voltage can build up significantly and have severe impact on the beam and also on the cryogenic system of the accelerator. Here we investigate this issue.

This situation can be avoided through carefully tuning the geometry of the cavity such that no mode below the cut-off frequency of the beam pipe (1.688 GHz) is within a specified frequency of a machine line, both in the design and production stages. In this case, 5 MHz is chosen as the tolerance.

This paper is arranged such that the first section considers the impact of geometrical errors in single cells. The following section assesses the change in the mode frequencies of complete cavities due to these geometric errors –both random and systematic are analysed. The last section entails a set of final remarks.

CELL FREQUENCY SENSITIVITY

The cavities in the medium-beta section of the ESS linac consist of six-cell elliptical cavities operating at a frequency of 704.42 MHz with an accelerating gradient of 15 MV/m and with a prescribed quality factor, $Q < 5 \times 10^5$. The medium beta cavities are particularly important as the transition in the accelerating frequency and also a large increase in gradient compared to the spoke cavities. These two issues will make the beam particularly sensitive to dilution effects from beam excited HOMs in these cavities.

The ESS elliptical cavities will be fabricated from high purity Niobium shaped using the deep drawing process. It is anticipated that the deviation of the internal shape will be at the 0.3 mm level. These deviations from the design will result in each cavity having HOMs at different frequencies and this shift may be large enough to move a mode to a machine line.

In the present series of simulations we use a quiet generic geometry for the medium beta cavity, driven by considerations of size, iris diameter, cell coupling, surface fields and field flatness; close, but by no means identical to the structure designed by CEA Saclay. A typical trapped HOM in this cavity is illustrated in Fig. 1.

To study, in detail, the effects of changes in geometry on the resonant frequencies of the individual cells we have simulated a cell with the code HFSS [6] in which we vary the

PARTICLE-IN-CELL SIMULATIONS OF A PLASMA LENS AT DARESBURY LABORATORY

K. Hanahoe, O. Mete, G. Xia, University of Manchester, Manchester, UK
Cockcroft Institute, Daresbury, UK
D. Angal-Kalinin, J. Jones, STFC/DL/ASTeC/Cockcroft Institute, Daresbury, UK
J. Smith, Tech-X UK Ltd, Daresbury Innovation Centre, Daresbury, UK

Abstract

Feasibility of a focusing element using the transverse fields provided by a plasma cell was studied numerically. In this paper, an experimental set up is proposed for various beam parameters available from the VELA and CLARA beam lines at Daresbury Laboratory. 2D simulation results from VSim [1], and expected results from planned measurement stations are presented. Field properties and the advantages and disadvantages of such an instrument compared to conventional focusing elements are discussed.

INTRODUCTION

Focusing of a particle beam is conventionally carried out using quadrupole magnets, either normal or superconducting, or solenoids. For final focus elements in particle colliders, the smallest possible beam size at the interaction region is desirable to achieve the highest possible luminosity. A plasma lens provides a possible means of achieving extremely large focusing gradients in both transverse directions simultaneously, but also provides a new set of challenges to overcome [2]. Study of plasma lenses using the electron beam from VELA and CLARA will provide results for comparison with previous experiments performed elsewhere and will provide a groundwork for further experiments using present and proposed accelerator test facilities at Daresbury Laboratory.

EXPECTED FOCUSING GRADIENTS

When a negatively charged particle bunch enters a plasma, the space charge force expels electrons from the path of the bunch. This leaves the bunch propagating in a region of net positive charge. If the background plasma density n_p is larger than the density of the bunch n_b (the overdense regime), the plasma left behind will completely neutralize the bunch. If n_p is lower than n_b (the underdense regime), the plasma electrons will be completely expelled leaving behind an ion channel. Applying Gauss's and Ampère's laws, the forces due to the electric and magnetic fields on a particle of charge q at a radius r within a homogenous, cylindrical bunch of charge density ρ_b and current density j, travelling at velocity v_b, can be calculated:

$$F = q\left(\frac{\rho_b r}{2\epsilon_0} + v_b \frac{\mu_0 r j}{2}\right) \tag{1}$$

In the overdense regime the net force on the particle is due to the magnetic field and is proportional to r. For comparison with magnetic quadrupoles, this can be quoted as a magnetic field gradient G:

$$G = \frac{B}{r} = \frac{\mu_0 j}{2} \tag{2}$$

Reasonable parameters for a future linear collider before final focus, with a peak beam current of 3.2 kA [3] and transverse bunch size of 100 µm, give a magnetic field gradient of 100 kT m $^{-1}$. In the underdense regime, more realistic for very high density beams, the focusing gradient will be smaller by, to a first approximation, a factor of n_p/n_b. This can still lead to very large focusing gradients compared to conventional magnets e.g. 200 T m^{-1} for quadrupoles for an LHC upgrade [4].

EFFECT OF ABERRATIONS

Compared to conventional magnets, plasma lenses have a significant disadvantage of increasing the emittance of the beam during focusing. This is caused by two main factors: the deviation of the focusing force from linearity in r, the spherical aberration, and the variation in focusing force with longitudinal position in the bunch, the longitudinal aberration. Scattering from plasma particles is not expected to be a significant source of emittance growth over the length scale of a plasma lens [5]. The emittance growth due to the spherical aberration can be calculated by considering the force on a particle at a distance from the axis of $r = 1\sigma_r$, being focused to a focal length f, in a beam of initial beta function β_0 and emittance ϵ_0 [6]. The fractional deviation in focusing strength from linearity, $\frac{\Delta K}{K}$ leads to a deviation from expected angular deflection of $\delta\theta$ given by:

$$\delta\theta = \frac{\sqrt{\beta_0\epsilon_0}}{f}\frac{\Delta K}{K} \tag{3}$$

The effective emittance ϵ_{eff} due to the spherical aberrations is given by:

$$\epsilon_{\text{eff}} = \sqrt{\epsilon_0^2 + \beta_0\epsilon_0\delta\theta^2} \tag{4}$$

The longitudinal aberration requires consideration of the phase space of the bunch as it passes through the lens. The head of the bunch enters an unperturbed plasma, and as such its space charge is not neutralized and it sees no net focusing force. Moving back along the bunch, the focusing force seen by slices of the beam will be proportional to the perturbation in plasma density. Focusing corresponds to a rotation of the phase space of the bunch, and non-uniform focusing will lead to smearing out of the phase space.

COMPARISON OF MEASUREMENTS AND SIMULATIONS OF SINGLE BUNCH INSTABILITIES AT DIAMOND

M. Atay[2], R.T. Fielder[1], I. Martin[1] and R. Bartolini[1,2]
[1]Diamond Light Source, Oxfordshire, UK
[2]John Adams Institute, University of Oxford, Oxfordshire, UK

Abstract

The single bunch dynamics in the Diamond storage ring has been analysed with a multiparticle tracking code and compared with the results of a wealth of diagnostics under development at Diamond. The interplay of various wakefield sources has been studied and it has been found that the THz spectrum can be reproduced in many cases with simple impedance models, both below and above the bursting threshold.

INTRODUCTION

The study of single bunch instabilities in modern light sources has been fostered by the user requirements to operate the storage rings with short electron bunches for the generation of short X-ray pulses or coherent THz radiation. Diamond has developed a number of low-alpha optics tailored to different users' requirements [1] attempting to optimize either the short X-ray pulse operation ($\alpha \sim 10^{-5}$) or the coherent THz radiation ($\alpha \sim 4{\cdot}10^{-6}$) [2]. This process has also stimulated the development of advanced THz diagnostics and data collection techniques described in a companion paper [3]. Numerous measurements has been carried out in the past to investigate the rich phenomenology associated to the single bunch instabilities, under different machine conditions, both below and above the instability thresholds. At the same time we have developed a macroparticle tracking code in order to gain a better insight in the mechanism driving the instabilities with the aim of reproducing the complex dynamics and guide further optimisation of the machine performance. The tracking code has been specifically tailored to replicate the data available from our diagnostics, such as THz spectrograms, streak camera images, BPM data and FTIR spectra. We present the first preliminary results of the comparisons between the measurements and tracking simulations and address the issues met.

TRACKING CODE

The beam dynamics in presence of wakefields can be described with various numerical techniques [4]. We have chosen to develop a multiparticle tracking code to study the single bunch dynamics with the influence of wakefields in 6-dimensional phase space, extending the capabilities of the code "sbtrack" [5]. While the original code was written in C, it was later translated to MATLAB to exploit its graphical capability. A number of wakefields have been implemented: most notably resistive wall (RW), coherent synchrotron radiation (CSR), shielded CSR [6] and any number of broad band resonators (BBR). The last option allows the implementation of the wakefields as computed from CST Microwave studio [7] or Gdfidl [8] by fitting a number of BBR models to the most prominent modes.

The code integrates the 6D equations of motion of the electron in the presence of the RF potential, synchrotron radiation damping and diffusion. The link to the full accelerator tracking with AT is under development, although the first tests resulted in prohibitively long computation times. The different impedance models used and the construction of the overall impedance model are described in more details below.

The output of the tracking code is the phase space evolution of the 6D macroparticle distribution on a turn by turn basis This is post-processed to extract all the relevant data that can be measured in the machine, such as tuneshifts, rise time or damping time of the instabilities, turn-by-turn and orbit data, THz emission power, spectrograms and streak camera images. All those quantities can be computed and measured as a function of the single bunch current and the various different machine parameters.

BUILDING THE IMPEDANCE MODEL

The code uses several different types of wakefields. The wake function of the broad band resonator (BBR) model is given by [4]

$$W(z) = 2\alpha R_s e^{\alpha z/c}\left(\cos\frac{\bar{\omega}z}{c} + \frac{\alpha}{\bar{\omega}}\sin\frac{\bar{\omega}z}{c}\right) \tag{1}$$

where $\alpha = \omega_R/2Q$, $\bar{\omega} = \sqrt{\omega_R^2 - \alpha^2}$, Q is a quality factor, ω_R is a resonance frequency and R_s is a shunt impedance. The CSR model is described in [6] and the shielding is taken into account as follows:

$$W(z) = -\frac{2\pi R}{4\pi\varepsilon_0} e N_e \left(\int_0^\infty \frac{2}{(3R^2)^{1/3}} \frac{d\rho(z-z')}{dz} \frac{dz'}{z'^{1/3}} - \right. \\ \left. -\frac{1}{2h^2}\int_{-\infty}^{\infty} \rho(z-z')dz' G_2\left[\frac{1}{2h}\left(\frac{R}{h}\right)^{1/2} z'\right]dz'\right) \tag{2}$$

where 2h is the gap between the shielding plates and R is the bending magnet radius. Purely resistive and purely inductive impedances have also been implemented to be able to accurately characterize the impedance of the storage ring, according to the respective wake functions:

Abstract

The Diamond storage ring will be upgraded during 2016 by replacing one of the existing double bend achromat (DBA) cells with a double-DBA (DDBA) cell [1]. One requirement of the upgrade is that following the installation of the new cell, Diamond should continue to offer dedicated user time in 'low alpha' mode [2]. In this paper we describe the particular challenges relating to this task, and present the lattice design and optimisation studies undertaken so far. The paper concludes by discussing preliminary studies of adding a second DDBA cell into the storage ring.

INTRODUCTION

An upgrade of the Diamond storage ring in 2016 will replace one of the existing DBA cells with a single DDBA cell, thereby creating space for an additional insertion device beamline. At present, the Diamond storage ring is operated for several periods each year in a dedicated 'low-alpha' optics [2], and it is the intention to continue to offer this mode following the upgrade. A comparison of the magnet layout before and after the upgrade is shown in Fig. 1.

The existing low alpha lattice has been in operation since 2010, serving both short-pulse x-ray users on the I06 'Nanoscience' ID beamline and THz users on the B22 'MIRIAM' bending magnet beamline. Part of the success of this mode of operation is down to the combination of having both low emittance and low momentum compaction, achieved by allowing the dispersion to become negative only within the bending magnets [3]. The lattice is operated with negative momentum compaction α_1, as this is found to reduce the bunch lengthening with current and causes the leading edge of the bunch profile to become sharper, enhancing the CSR gain at shorter wavelengths.

In this paper we present the adaptation of the low alpha lattice for the DDBA upgrade. This work includes optimisation of the linear and nonlinear optics, analysis of the lattice sensitivity to errors, and an assessment of the likely injection efficiency and lifetime. The paper concludes with preliminary studies of adding a second DDBA cell to the storage ring.

LATTICE OPTIMISATION

Design Constraints

The inclusion of a single DDBA cell presents a number of challenges for the optimisation. Firstly, whilst the inclusion of four gradient sector-bends helps to keep the cell

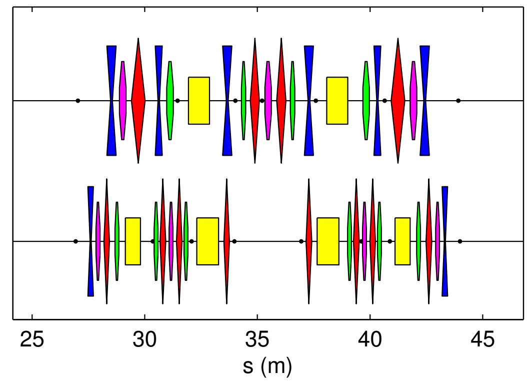

Figure 1: Existing DBA (top) and new DDBA (bottom) cell.

compact, the fixed defocussing gradient reduces the flexibility to tune it to different optics. As a result, the adjacent quadrupoles must also be powered with large gradients, increasing the natural chromaticity of the ring. The need to match the DDBA cell to the adjacent DBA cells leads to a higher dispersion than is otherwise the case with multi-bend achromat lattices designed for low emittance. However, the dispersion function within the cell is still relatively small compared with the remainder of the ring, and does not provide an obvious location to correct the added natural chromaticity locally. Similarly, the ability to correct for the second-order momentum compaction α_2 scales with $-S\eta_x^3$ [4], again requiring the sextupole strength S to increase in the remaining DBA cells.

The final, and perhaps most significant difficulty is in the loss of symmetry of the storage ring. In contrast to the nominal user optics, the low alpha lattice has so far been operated without powering the two mini-beta sections [5], thereby maintaining the 6-fold symmetry of the lattice. The inclusion of a DDBA cell clearly breaks this symmetry, with natural consequences on the sensitivity to errors.

Optimisation Techniques

Optimisation of the lattice is an iterative process, primarily carried out using the parallel version of elegant [6, 7]. Initially, the linear optics are adjusted using the 'particle swarm' option in the parallel optimisation module, having applied a number of constraints. Following this, the nonlinear optics are explored using a Multi-Objective Genetic Algorithm (MOGA) [8].

The constraints for the linear optics include fixing α_1 to the desired value, placing limits on the maximum β-functions around the ring, maximising β_x at the injection

Abstract

Above a certain threshold current, electron bunches become unstable and emit bursts of coherent synchrotron radiation (CSR). The character and periodicity of these bursts vary with bunch current, RF voltage and lattice momentum compaction. In this paper we describe recent measurements taken at Diamond of how the electron bunch longitudinal profile and energy vary during a burst, and correlate this with CSR emission at a range of wavelengths.

INTRODUCTION

The onset of microbunching instabilities in storage rings is a well known phenomenon [1, 2]. These occur when the current stored in an electron bunch exceeds a certain threshold value, at which point the interaction of the bunch with its own wakefields is sufficiently strong to cause density modulations to occur within the bunch. These in turn increase the amplitude of the wakefields, giving rise to an instability. For a given storage ring, the current threshold is found to vary both with RF voltage and momentum compaction.

In recent years the subject of CSR-driven microbunching has received considerable attention due to its detrimental effects both in rings and in linac bunch compressors [3–9]. In the case of rings, this attention has been mainly focussed on rings with positive momentum compaction, with little experimental evidence for negative momentum compaction lattices. Such data would provide a useful benchmark against which numerical simulations could be compared [10], as well be valuable for its wider academic interest. It is also of particular relevance for Diamond Light Source, as the ring is regularly operated in a negative low-alpha configuration for the generation of both coherent THz radiation and short x-ray pulses [11].

In this paper we describe recent measurements taken at Diamond Light Source in low-alpha mode that characterise the electron bunch motion during CSR bursts. These are correlated with mm-wave emissions recorded using a selection of Schottky Barrier Diodes, thus giving further insight into the underlying electron beam dynamics.

CSR BURST DETECTION

The microbunching instability primarily affects the longitudinal phase space of the electron bunch. As such, the most important observables to measure are the electron bunch length, bunch arrival time and bunch energy. Ideally one would also like to measure the internal bunch structure and energy spread during a burst; however, this is not yet possible using the diagnostics available at Diamond.

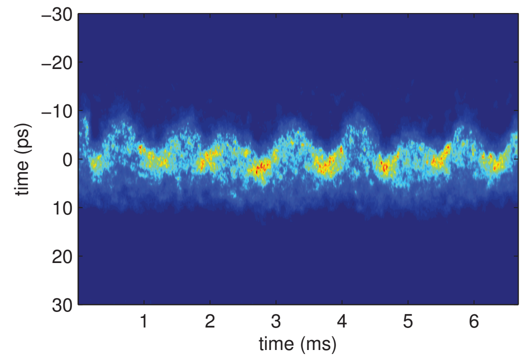

Figure 1: Streak camera image capturing CSR bursts for $\alpha_1 = -4.6 \times 10^{-6}$, $V_{RF} = 3.4$ MV, $I_{bunch} = 39.5\mu$A.

The electron bunch length and arrival time is recorded using an Optronis dual-sweep streak camera [12]. In recent years, the performance of this camera at Diamond has been optimised by the introduction of a fully reflective front-end optics and pinhole located upstream of the camera, alongside a post-processing of the recorded images by deconvolving them with the measured point-spread function [13]. An example of one such measurement is shown in Fig. 1.

The electron bunch energy is measured indirectly using the turn-by-turn BPM system. During a burst the electron bunch loses energy to the radiation field, causing it to undergo coherent synchrotron oscillations. This energy deviation can be measured from the transverse offset at positions of high dispersion, assuming the dispersion amplitude is known. The picture is slightly complicated by the presence of additional betatron oscillations. However, by averaging across BPMs of similar dispersion, and by filtering out the high-frequency betatron contributions, the mean energy deviation of the bunch can be recovered.

Whilst it is not possible to directly observe the internal structure of the electron bunches at Diamond, the detection of the accompanying CSR bursts using Schottky Barrier Diodes (SBDs) serves as a useful proxy. The detectors used during these measurements have sensitivity bandwidths of 33-50 GHz, 60-90 GHz, 90-140 GHz, 140-220 GHz, 220-330 GHz, 330-500 GHz and 500-750 GHz. These frequencies correspond to periods in the range 1.3-30 ps, and the detectors at the higher frequency end of the range in particular should be sensitive to sub-structure appearing within the electron bunch. The SBD array used during these studies is described in more detail in a companion paper [14].

NUMERICAL OPTIMIZATION OF ACCELERATORS WITHIN oPAC

C.P. Welsch#

Cockcroft Institute, Daresbury, UK and The University of Liverpool, Liverpool, UK
on behalf of the oPAC Consortium

Abstract

Powerful simulation tools are required for every accelerator and light source to study the motion of charged particles through electromagnetic fields during the accelerator design process, to optimize the performance of machine diagnostics and to assess beam stability and non-linear effects. The Optimization of Particle Accelerators (oPAC) Project is funded by the EU within the 7th Framework Program and currently supports 23 Fellows that are based at institutions across Europe. This large network carries out R&D that closely links beam physics studies with the development of diagnostics and beyond state-of-the-art simulation tools. This contribution presents selected research outcomes from oPAC, including the numerical optimization of beam loss monitor locations along the European Spallation Source's 5 MW proton linac, results from tracking studies for the LHeC lattice that allow beam stability to be assessed, and multi-objective optimization of the linear and non-linear beam dynamics of the synchrotron SOLEIL. In addition, an overview of recent and future oPAC events is given.

INTRODUCTION

oPAC – Optimization of Particle Accelerators – is a Training Network funded by the European Union [1]. With a budget of almost €6M shared between 12 beneficiary partners over a 4-year period, it brings together 34 institutions across the industry and academia to provide formation on particle accelerators to a total of 23 early stage researchers. The main objective of the oPAC network is to train the next generation of accelerator scientists and engineers for the increasingly demanding community of accelerator facilities while strengthening the bonds within this community. oPAC is also strongly engaged in raising public awareness on the importance of particle accelerators for society, through their applications in health, industry, security, energy, and fundamental knowledge.

Each of the Fellows is developing a project set in one of the following topics: research of beam dynamics, development of beam diagnostics, numerical simulation tools, and accelerator control and data acquisition systems. In addition to the research in their home institution, the Fellows undertake secondments in any of the other partner institutions, complementing their formation and fostering collaborative research. Moreover, the Fellows receive regularly specific training on complementary skills and techniques through a series of topical workshops and schools that are held at different venues across the network. The Fellows together with the central management team are also carrying out an intensive program of outreach and dissemination, through the internet and social media, but also through the organization of events and participation in conferences, trade fairs, exhibitions, etc.

*This project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement no 289485.

RESEARCH

As outlined before research within the network is carried out across four thematic work packages. The following subsections highlight progress made by three exemplar Fellows across these work packages.

Beam Loss Monitoring at ESS

The linear accelerator of ESS will produce a 5 MW proton beam. Beam of this power must be strictly monitored by a specialized Beam Loss Monitoring (BLM) system to detect any abnormal losses and to ensure that operational losses do not exceed a limit of 1 W/m. In order to optimize the detectors layout in terms of their numbers and locations a series of beam loss simulations was performed using the MARS Monte Carlo code. Different loss scenarios were considered and yielded an indication of the energy deposition along the ESS linac.

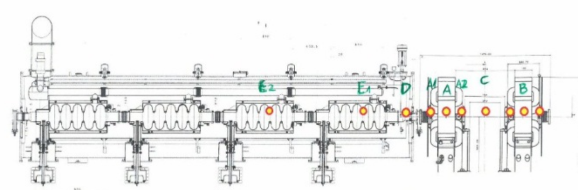

Figure 1: Loss point locations.

Different beam loss simulations were performed for four different energies in the ESS cold linac, ranging from 220-2,000 MeV [2]. For all of these energies 10 different possible locations along a cryomodule-quadrupole doublet were chosen, see Fig.1. At these locations three points on the beam pipe were considered as possible loss points. Losses were then simulated for 3 different angles: 1 mrad, 3 mrad and 1°. The power deposited in air around a loss was used as primary indicator for suitable BLM locations as it is proportional to the BLM signal within certain limits. For more accurate results, an approach using particle flux-to-generated charge converters shall be applied in the future. BLMs were placed around the cryomodule-quad assemblies in a way that optimizes three figures of merit: Distinguishability of individual losses, volume coverage and sensitivity. The aim is to avoid missing any loss (full volume coverage), ability to differentiate between individual losses, and detecting even smallest losses which are just above the noise level.

NON-INVASIVE BEAM PROFILE MONITORING

C.P. Welsch[#1], T. Cybulski[1], A. Jeff[1,3], V. Tzoganis[1,2], H. Zhang[1]
[1] Cockcroft Institute and The University of Liverpool, UK
[2] RIKEN, Nishina Center, Wako, Japan
[3] CERN, Geneva, Switzerland

Abstract

Highest energy and intensity accelerators require new approaches to transverse beam profile monitoring as many established techniques will no longer work due to the high power stored in their beam. In addition, many accelerator applications such as ion beam cancer therapy or material irradiation would benefit significantly from the availability of non-invasive beam profile monitors. Research in the QUASAR Group has focused on this area over the past 5 years. Two different approaches were successfully developed: Firstly, a supersonic gas jet-based monitor was designed and commissioned. It enables the detection of the 2-dimensional transverse beam profile of essentially any charged particle beam with negligible disturbance of the primary beam and accelerator vacuum. Secondly, a monitor based on the Silicon strip VELO detector, originally developed for the LHCb experiment, was tested as an online beam monitor at the Clatterbridge Cancer Center in the UK. The design of both monitors and results from measurements are presented in this contribution.

INTRODUCTION

Least intrusive beam profile measurement techniques that allow continuous operation of an accelerator whilst providing comprehensive information about the particle beam would be ideal for many applications, ranging from high energy/high intensity accelerators such as the LHC at CERN and its future upgrades or the high power proton driver linac at ESS where conventional diagnostics would simply not work. Various non-invasive methods have been developed for the determination of the transverse beam profile. These include Ionization Profile Monitors (IPM) [1] which are based on the collection of the ions produced by impact ionization of rest gas by the main beam and the Beam Induced Fluorescence Monitor (BIF) [2] which relies on the detection of the light produced from the excited residual gas. IPM's are truly non-invasive devices which can operate parasitically if the residual gas pressure is sufficiently high and offer very good spatial resolution down to 100 µm and time resolution in the order of 10 ms with a fast camera or a few µs with a fast readout system. However they are usually limited to high energy accelerators. BIF's are parasitical as well, but require higher residual gas pressures in excess of 10^{-6} mbar and longer signal integration times.

Gas Jet-based Beam Profile Monitor

A possible approach to overcome these limitations is to utilize a cold (< 20 K) neutral supersonic gas jet shaped into a thin curtain. The core of this monitor consists of an expansion of a room temperature high pressure gas (1-10 bars) into vacuum through a nozzle with 30 µm diameter, resulting in an adiabatic expansion and the formation of a jet with a very stable and cold inner core.

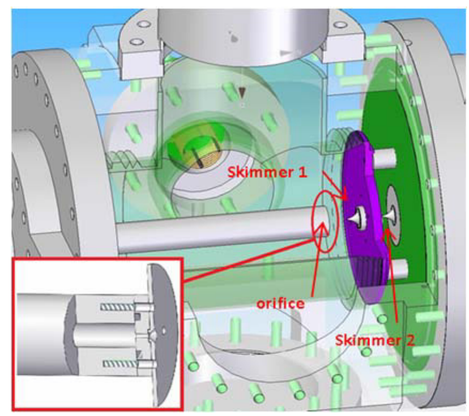

Figure 1: CAD drawing of the nozzle chamber where the first two skimmers are highlighted.

This jet is then further shaped by several skimmers. The first part of the experimental setup is illustrated in Fig. 1. Skimmers separate several differentially pumped vacuum chambers through which the jet passes until it reaches a final "reaction chamber", held at a pressure of 10^{-9}-10^{-12} mbar [3]. When entering this chamber the jet has already been shaped by a final rectangular skimmer into a curtain that crosses the primary beam to be analyzed under an angle of 45°. In this interaction impact ionization of the jet particles occurs and the resulting ions are imaged by a moderate electric field of some kV/m onto a position-sensitive double layer Micro Channel Plate (MCP) detector. The MCP provides signal amplification of up to 10^6. Finally, the resulting beam profile is observed by a Phosphor screen-camera combination that is mounted on the top of the reaction chamber, see Fig. 2.

At low energies of the primary beam the extraction electric field can lead to its displacement when passing through the reaction chamber. This is compensated by deflecting electric fields before and after the interaction region (not shown in the figure).

MODELING RF FEEDBACK IN ELEGANT FOR BUNCH-LENGTHENING STUDIES FOR THE ADVANCED PHOTON SOURCE UPGRADE *

T. Berenc, M.Borland, ANL, Argonne, IL 60439, USA

Abstract

The proposed Advanced Photon Source (APS) multi-bend achromat (MBA) lattice includes a passive bunch-lengthening cavity to alleviate lifetime and emittance concerns. Feedback in the main radio-frequency (rf) system affects the overall impedance presented to the beam in this double rf system. To aid beam stability studies, a realistic model of rf feedback has been developed and implemented in `elegant` and `Pelegant`.

INTRODUCTION

Many existing and planned storage ring light sources employ harmonic bunch-lengthening cavities [1–3]. For the required tuning in bunch-lengthening mode, the harmonic cavity contributes to Robinson mode growth which opposes the damping provided by the main rf cavities [4]. RF feedback on the main rf modifies the apparent impedance to the beam and hence influences Robinson instabilities [5]. Direct rf feedback can easily be accounted for by simply reducing the cavity shunt impedance and quality factor.

However, rf feedback systems rarely consist of, nor always include, pure direct rf feedback. They can work in either amplitude and phase (amp/phase) polar coordinates or in-phase and quadrature (I/Q) cartesian coordinates. They can also include integral feedback and other frequency shaping effects and need not be implemented symmetrically.

Including realistic rf feedback in particle tracking is essential to capture the interaction of the beam with the rf system as depicted in Fig. 1. Thus, a flexible framework for including rf feedback in `elegant` [6] and `Pelegant` [7,8] has been developed. This has allowed rf feedback to be included in APS upgrade tracking studies [9].

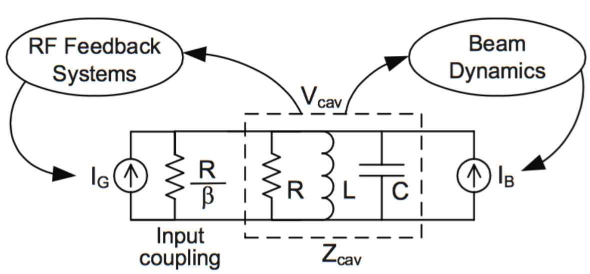

Figure 1: Interaction of beam, cavity, and rf systems.

SYSTEM MODEL

Figure 2 represents the rf feedback model added to `elegant`. The interaction between the beam current and the rf cavity is still modeled using `elegant`'s `RFMODE` element. However, instead of using a fixed generator voltage, the generator voltage is determined by amp/phase rf feedback. I/Q and combination feedback as shown are planned but not yet implemented.

The rf system signals are represented at baseband using a time-varying complex-envelope. For example, the total cavity voltage is $v_{cav}(t) = Re\left\{\mathbf{V_{cav}}(t)e^{j\omega_{rf}t}\right\}$ where $j = \sqrt{-1}$, ω_{rf} is the rf drive frequency, and $\mathbf{V_{cav}}(t) = V_I(t) + jV_Q(t)$ is the complex envelope with I/Q components $V_I(t)$ and $V_Q(t)$ respectively. The amp/phase are $|\mathbf{V_{cav}}|(t) = \sqrt{V_I^2(t) + V_Q^2(t)}$ and $\angle\mathbf{V_{cav}}(t) = \text{atan2}\left\{V_Q(t), V_I(t)\right\}$.

Filters are provided to separately process the amplitude and phase errors with respect to reference setpoints. The outputs of these filters affect the generator current which drives a cavity I/Q state-space model to obtain the generator induced voltage. To facilitate initial conditions or feed-forward, a nominal generator current $\mathbf{I_{G_o}}$ is provided.

Feedback Filters

The feedback filters are implemented as difference equations of the form

$$y[n] = \frac{1}{b_0}\sum_{i=1}^{r} b_i y[n-i] + \frac{1}{b_0}\sum_{i=0}^{m} a_i x[n-i] \quad (1)$$

where $y[n]$, $x[n]$ are respectively the filter output and input at sample n, and $y[n-i]$, $x[n-i]$ are past outputs and inputs from time $(n-i)T$ where T is the sample period equal to an integer number of rf buckets. Four parallel filter blocks, each with an unlimited number of a_i and b_i filter coefficients can be supplied to `elegant` for both the amplitude and phase feedback.

Various methods exist to transform an analog filter (like that used at APS) to a digital one [10]. The bilinear transform produces a good match for an integrator.

Generator Induced Cavity Voltage

I/Q modulation of the drive current, $I_G(t) = I_I(t)\cos\omega_{rf}t - I_Q(t)\sin\omega_{rf}t$, produces I/Q modulation of the cavity voltage. In general, the I/Q components of $\mathbf{V_{cav}}$ will each contain a response to both I/Q components of $\mathbf{I_G}$. The cavity state-space equations [11–13], when discretized using the zero-order hold method [10], become

$$\begin{bmatrix} V_I(n) \\ V_Q(n) \end{bmatrix} = \mathcal{A}\begin{bmatrix} V_I(n-1) \\ V_Q(n-1) \end{bmatrix} + \mathcal{B}\begin{bmatrix} I_I(n-1) \\ I_Q(n-1) \end{bmatrix} \quad (2)$$

The matrices $\mathcal{A}$ and $\mathcal{B}$ are given as

$$\mathcal{A} = e^{-\sigma T}\begin{bmatrix} \cos\Delta\omega T & -\sin\Delta\omega T \\ \sin\Delta\omega T & \cos\Delta\omega T \end{bmatrix} \quad (3)$$

TRACKING STUDIES OF A HIGHER-HARMONIC BUNCH-LENGTHENING CAVITY FOR THE APS UPGRADE *

M. Borland, T. Berenc, R. Lindberg, A. Xiao, ANL, Argonne, IL 60439, USA

Abstract

The Advanced Photon Source (APS) multi-bend achromat (MBA) lattice will require a bunch-lengthening cavity to decrease the effects of Touschek scattering on the beam lifetime and of intrabeam scattering on the beam emittance. Using `elegant`, we've performed tracking studies of a passive, i.e. beam-driven, fourth-harmonic cavity in the MBA lattice, including the longitudinal impedance of the ring. Studies include investigating optimal detuning, simulation of transients after loss of a bunch, simulation of effects of bunch population variation, simulation of possible non-uniform filling patterns, and simulation of filling from zero. Realistic amplitude and phase feedback of the main rf cavities is also taken into account.

INTRODUCTION

The APS MBA lattice [1] has an emittance of under 70 pm at 6 GeV. Because of the short (12.5 ps rms) zero-current bunch length, use of a higher-harmonic cavity (HHC) to lengthen the bunch is needed to reduce IBS-related emittance growth and improve the Touschek lifetime.

The HHC provides bunch lengthening by reducing the local slope of the total accelerating voltage. In the case of a passive HHC, the cavity is detuned to the positive side of harmonic n of the main rf system frequency. The voltage induced in the HHC by the beam then has a phase that reduces the slope of the time-dependent total voltage. The induced voltage and bunch shape can be computed in a self-consistent fashion as in [2].

However, such results ignore potential well distortion and the longitudinal impedance, which can best be included using a tracking code. Tracking can also include self-consistent, time-dependent interaction of the beam with the cavity mode, particularly important for a passive system, as well as higher-order beam transport effects.

SIMULATION METHODS

`Pelegant` [3, 4] was used for the tracking simulations. Although the needed features have existed in `elegant` [5] for over a decade, we took advantage of recent improvements to parallel performance [1], diagnostics, and implementation of rf feedback [6].

Eight beamline elements were used: `ILMATRIX` provides fast single-turn beam transport that incorporates longitudinal, chromatic, and transverse nonlinearities. `SREFFECTS` provides lumped simulation of synchrotron radiation. `WATCH` and `HISTOGRAM` provide bunch-by-bunch diagnostic data. `CHARGE` provides the ability via the `modulate_elements` command to achieve a quiet start by slowly ramping the beam current. `RFMODE` simulates a beam- and (optionally) generator-driven cavity mode. This is used for both the 352-MHz ($Q_L = 9.1 \times 10^3$, $R_a/Q = 208\Omega$) main cavities and the 4^{th} harmonic cavity. A feedback model is used to maintain the main cavity voltage [6]. This element implicitly includes the short-range wake resulting from the fundamental cavity modes. It can also be used for including cavity HOMs [7]. `ZLONGIT` simulates the short-range wake, using an impedance model based on the conceptual vacuum system design (an older version of that presented in [8]).

BASIC RESULTS

The passive HHC [9] has $R_a/Q = 108\Omega$ and two free parameters: the detuning $\Delta f_h > 0$ of the resonance from the harmonic condition and the loaded quality factor Q_L. Earlier studies showed that using $Q_L = 6 \times 10^5$ or greater gave improved stability in the presence of irregular fill patterns, so this value is used throughout.

Starting with $\Delta f_h \gg f_h/Q_L$ and progressively decreasing the detuning, increasing voltage is induced until the ideal bunch lengthening condition is achieved. Further reduction results in splitting of the bunch. Figure 1 shows the bunch duration and energy spread as a function of the detuning for two fill patterns. The difference between results for the two patterns stems from the microwave instability (MWI), which impacts 48-bunch mode significantly, lengthening the bunch to 35 ps rms even in the absence of the HHC. The MWI is also slightly suppressed by the lengthening of the bunch. Nominally, ideal lengthening to 50 ps rms occurs at about $\Delta f_h = 16.5$ kHz, which agrees well with the simulation results for 324 bunches.

Figure 2 shows the longitudinal profiles averaged over 2000 turns for two detuning values. For 48 bunches, Δf_h can be reduced beyond what is possible for 324 bunches without creating a strongly double-humped shape, a curious benefit of being well above the MWI threshold. Turn-by-turn longituidinal profiles can be used to compute the Touschek lifetime using the program `touschekLifetime` along with local momentum acceptance results [1], providing higher-fidelity results than would be obtained from using the rms bunch duration [10]. Since these show that $\Delta f_h = 13.50$ kHz is benefical, subsequent simulations concentrate on that value.

TRANSIENTS FOLLOWING BUNCH LOSS

The inclusion of rf feedback in the simulations allows realistic modeling of fault conditions, such as a swap-out fail-

SIMULATION OF GAS SCATTERING LIFETIME USING POSITION- AND SPECIES-DEPENDENT PRESSURE AND APERTURE PROFILES *

M. Borland, J. Carter, H. Cease, and B. Stillwell, ANL, Argonne, IL 60439, USA

Abstract

When computing gas scattering lifetime for storage rings, it is common to use the average pressure, even though it is known that the pressure varies with location in the ring and varies differently for different gas species. In addition, other simplifications are commonly made, such as assuming that the apertures in the horizontal and vertical planes are independent and assuming that the momentum acceptance can be characterized by a single value. In this paper, we describe computation of the elastic and bremsstrahlung scattering lifetimes that includes species-specific gas pressure profiles computed with Synrad+ and Molflow+. The computations make use of the detailed shape of the dynamic acceptance and the position-dependent momentum acceptance computed with `elegant`. Comparisons are made to simpler methods for the multi-bend achromat upgrade lattice for the Advanced Photon Source.

INTRODUCTION

Particles in storage rings undergo scattering from residual gas atoms, which may result in particle loss when the scattering places a particle outside the physical or dynamical acceptance of the ring. In this paper, we outline an elaboration of lifetime calculations for elastic and inelastic gas scattering that removes common assumptions. E.g., it is common to assume that the elastic gas scattering lifetime is limited in the vertical plane only, that the momentum acceptance is constant around the ring, and that the vacuum pressure is constant around the ring. The present calculations use results from Molflow+ and Synrad+ [1,2], which allow computing species-specific pressure profiles. They also use dynamic acceptance (DA) and local momentum acceptance (LMA) [3,4]. results from `elegant` [5].

A general form for the lifetime is (compare [6])

$$\frac{1}{\tau} = \frac{c}{L}\sum_{g=1}^{G}\sum_{a=1}^{C_g}\int_0^L \sigma_{g,a}(s)S_{g,a}n_g(s)ds, \tag{1}$$

where L is the length of the ring (or a periodic unit), G is the number of molecular gas constituents, C_g is the number of atomic components of gas g, $\sigma_{g,a}(s)$ is the out-scattering cross section for atomic component a of gas g at location s, $S_{g,a}$ is the number of atoms of type a in a molecule of gas g, and $n_g(s)$ is the number density of gas g at location s, which is related to the partial pressure $p_g(s)$ by $n_g(s) = \frac{p_g(s)}{k_b T}$.

* Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

The out-scattering cross section is given by

$$\sigma_{g,a}(s) = \int_{q_1(s)}^{q_2(s)} \frac{d\sigma_{g,a}}{dq}dq \tag{2}$$

where q is the scattering coordinate, q_1 is the maximum surviving value of q, and q_2 is the physically-limiting value of q. E.g., for elastic scattering, q is the change in slope of the particle trajectory, q_1 is the maximum change that will keep the particle within the acceptance, and $q_2 = \infty$. For gas bremsstrahlung, q is the change in fractional momentum deviation δ, q_1 is the momentum acceptance, and $q_2 = 1$.

ELASTIC NUCLEAR SCATTERING

Elastic scattering from atomic nuclei is described by the Rutherford cross section [7]

$$\frac{d\sigma_{g,a}}{d\Omega} = \frac{Z_{g,a}^2 r_e^2}{4\gamma^2}\frac{1}{\sin^4\frac{\theta}{2}} \equiv \frac{E_{g,a}}{\sin^4\frac{\theta}{2}}, \tag{3}$$

where $Z_{g,a}$ is the atomic number, r_e is the classical electron radius, and γ is the relativistic factor. The scattering angle θ is assumed to be large compared to the angular divergence of the particle beam. While the cross section does not depend on azimuthal angle ϕ, the out-scattering cross section may, because the maximum surviving angle $\hat{\theta}$ depends on the position in the ring, whether the scattering occurs mostly in the horizontal or vertical plane, and on the beta functions at the scattering location. The local value of the out-scattering cross section may thus be written

$$\sigma_{g,a}(s) = \int_0^{2\pi}\int_{\hat{\theta}(s,\phi)}^{\pi} \frac{d\sigma_{g,a}}{d\Omega} d\theta \sin\theta d\phi. \tag{4}$$

Performing the integral over θ gives

$$\sigma_{g,a}(s) = E_{g,a}I_e(s), \tag{5}$$

where

$$I_e(s) = \int_0^{2\pi}\frac{2}{\tan^2\frac{1}{2}\hat{\theta}(\phi,s)}d\phi. \tag{6}$$

In low emittance storage rings, the transverse aperture is determined by some combination of beam dynamics and physical aperture limits, i.e., by the "dynamic acceptance" or DA. Typically the DA is determined by tracking particles for many turns starting at $s = 0$, giving a set of (x, y) pairs at the aperture limit that trace out the DA contour. If $(x_0(\phi), y_0(\phi))$ for $\phi : [0, 2\pi]$ gives the DA contour at $s = 0$, then the beta functions β_x and β_y may be used to write

$$\hat{\theta}(s,\phi) = \left[\frac{x_0^2(\phi)}{\beta_x(s)\beta_x(0)} + \frac{y_0^2(\phi)}{\beta_y(s)\beta_y(0)}\right]^{\frac{1}{2}}, \tag{7}$$

IMPROVEMENTS IN MODELING OF COLLECTIVE EFFECTS IN ELEGANT*

M. Borland, R. Lindberg, A. Xiao, ANL, Argonne, IL 60439, USA

Abstract

elegant has long had the ability to model collective effects, including beam-driven cavity modes, short-range wakes, coherent synchrotron radiation, and intrabeam scattering. Recently, we made improvements specifically targeting simulations that require multiple bunches in storage rings. The ability to simulate long-range, non-resonant wakes was added, which can be used, for example, to study the effect of the resistive wall wake on multibunch instabilities. We also improved the implementation of short-range and resonant wakes to make them more efficient for multibunch simulations. Finally, improvements in the parallel efficiency were made that allow taking advantage of larger parallel resources.

INTRODUCTION

elegant [1] has long had the ability to simulate collective effects, starting with the addition of impedances and rf cavity modes in the early 1990s, in support of the design of the APS Positron Accumulator Ring [2]. In the late 1990s, wakefields and coherent synchrotron radiation were added, primarily in response to the needs of free-electron laser projects, e.g., [3] These features were subsequently implemented in the parallel version, Pelegant, [4, 5]. More recently, intrabeam scattering [6, 7] and Touschek scattering [8, 9] simulation were added. To confidently design a next-generation accelerator, such as the multi-bend achromat (MBA) upgrade for the Advanced Photon Source (APS) [10, 11], further improvements were needed.

The primary factor driving the recent improvements was the need for a bunch-lengthening higher-harmonic cavity (HHC) in the new ring [12] and the need for high-fidelity simulations including a multi-bunch beam and the impedance of other structures in the ring [13, 14]. Although this could be done with earlier versions of elegant and Pelegant, improved performance was needed for simulations with many bunches. Part of the issue is that inclusion of the short-range impedance necessitates the use of a large number of simulation particles in each bunch, which coupled with a desire to simulate as many as 324 bunches, makes for challenging computations.

In addition, because of the narrow beam pipe in the upgraded machine, we need to simulate multi-turn, non-resonant wakes, e.g., resistive wall wakes. This capability is new to elegant and Pelegant, which previously could only simulate single-turn wakes. Multi-turn collective effects could previously only be simulated using resonant modes.

With these improvements came the need for enhanced diagnostics, specifically the need for more convenient bunch-by-bunch diagnostics.

WAKE AND RF CAVITY SIMULATION

Bunch Mode Simulations

In order to minimize changes to the structure of the code, the bunched-mode feature was added by making use of the existing particleID property of each particle. In particular, the user may declare that different blocks of particle ID values correspond to distinct bunches. This requires use of the sdds_beam command and is documented in the manual. In brief, the user may either provide the entire multi-bunch beam as an SDDS file, or else provide a file specifying the phase space for a single bunch and request that it be duplicated n times. In the latter case, the spacing of the duplicates should also be specified. In the former case, the beam can be generated by a previous elegant run using the bunched_beam to specify the bunch properties and the bunch_frequency parameter of the run_control command to specify the interval between bunches. For more complex bunch patterns, the manual provides detailed instructions on preparing a beam file.

Given a properly prepared beam file, bunched-mode simulation is automatic for FRFMODE, FTRFMODE, IBSCATTER, LRWAKE, RFMODE, WAKE, TRFMODE, TRWAKE, ZLONGIT, ZTRANSVERSE elements. It may be turned off for any element by setting the BUNCHED_BEAM_MODE parameter to 0. Bunched mode simulation is presently not implemented for CSRCSBEND, CSRDRIFT, and LSCDRIFT.

For the diagnostic elements WATCH and HISTOGRAM, bunch-by-bunch output is obtained using the START_PID and END_PID parameters to specify the range of particle ID values to include in the output. For large numbers of bunches, one may typically select only a few bunches for output, so the setup is not too tedious. Creation of a parameter file for use with load_parameters is a convenient way to configure large numbers of diagnostic elements.

In a parallel code, a natural choice for domain decomposition is that each bunch is handled by a single core. However, this is suboptimal as it forces processors to wait in line to process bunches through elements that have effects on following bunches (e.g., rf modes or long-range wakes). In addition, this choice limits the size of computational resources that can be used. In Pelegant, these issues are avoided because bunches are shared among processors, with all processors working together on each bunch in turn. One minor

COMMISSIONING SIMULATIONS FOR THE APS UPGRADE LATTICE*

V. Sajaev, M. Borland, ANL, Argonne, IL 60439, USA

Abstract

A hybrid seven-bend-achromat lattice that features very strong focusing elements and a relatively small vacuum chamber has been proposed for the APS upgrade. Achieving design lattice parameters during commissioning will need to be accomplished quickly in order to minimize dark time for APS users. The paper will describe start-to-end simulation of the machine commissioning beginning from first-turn trajectory correction, progressing to orbit and lattice correction, and culminating in evaluation of the nonlinear performance of the corrected lattice.

INTRODUCTION

Several existing synchrotron light source facilities are considering replacing operating storage rings in order to increase the brightness of delivered photon beams. These light sources have large user communities who insist that facility "dark time" is minimized. APS, for example, is targeting 12 months for removal, installation, and commissioning. Of this 12 month period, only three months are set aside for commissioning of the new multi-bend achromat ring.

The proposed lattice [1] has natural emittance that is 40 times smaller than the present APS ring, which is achieved by much stronger focusing than in the present ring. For example, maximum quadrupole strengths increase nearly five-fold in the new lattice. Stronger focusing inevitably leads to larger natural chromaticity and thus a nearly seven-fold increase in sextupole strength is needed, resulting in rather small dynamic aperture and short lifetime even for the ideal lattice. Misalignments of the strong quadrupoles generate large orbit errors, which in the presence of very strong sextupoles leads to huge lattice and coupling errors. Add to this smaller vacuum chamber gaps that are required to achieve high gradients in the magnets, and the required rapid commissioning seems doubtful. In this paper, we address this issue using a highly realistic simulation of the commissioning.

SIMULATION PROCEDURE

While the effect of individual lattice imperfections on accelerator performance can be estimated or calculated analytically, including all errors together is beyond the realm of analytical estimations. To understand how various errors combine together and impact commissioning, a start-to-end simulation of machine commissioning was performed taking into account as many errors as possible. All simulations were done using `elegant` [2]. Table 1 gives the list of errors included in the simulations (official specification for girder alignment is 100 μm which was found to be equally workable in earlier runs).

* Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

Table 1: Rms Values for Various Errors Used for Start-to-end Commissioning Simulation

Girder misalignment	50 μm
Elements within girder	30 μm
Dipole fractional strength error	$1 \cdot 10^{-3}$
Quadrupole fractional strength error	$1 \cdot 10^{-3}$
Dipole tilt	0.4 mrad
Quadrupole tilt	0.4 mrad
Sextupole tilt	0.4 mrad
Initial BPM offset error	500 μm
BPM gain error	5%
BPM orbit measurement noise	1 μm
Corrector calibration error	5%

The simulation procedure closely follows the steps that will be performed during commissioning. We assume that before setting up the lattice, the betatron tunes are adjusted away from integer and coupling resonances (the design fractional tunes are 0.12 in both planes, they are adjusted to 0.18 and 0.24). The procedure consists of the following major steps: (1) Generate errors for all elements according to Table 1 using Gaussian distributions with 2σ cut off. (2) Correct trajectory until closed orbit is found. If needed, optimize tunes and low-order beta function harmonics. (3) Correct closed orbit down to acceptable level. (4) Correct optics and coupling.

The entire simulation procedure was automated, allowing commissioning to be simulated for 200 different error sets. The procedure was able to correct orbit and optics in 98% of all cases. The correction results were statistically analyzed for residual orbit and lattice perturbations, correctors strengths, emittances, etc. For each error set, various performance measures (e.g., rms horizontal beta error) are computed. These are then histogrammed over all error sets. Before presenting such results, we first discuss the detailed commissioning procedure.

Trajectory Correction

Simple estimations show that in order to expect a reasonable probability of the closed orbit not exceeding the vacuum chamber dimensions, magnet alignment tolerances must be three times tighter than in Table 1. Since this is considered prohibitively expensive, trajectory correction will need to be performed first in order to find a closed orbit.

Trajectory correction consists of two steps. First, `elegant`'s one-to-best method is applied, wherein steering is performed by pairing one corrector with the BPM that has the best response to this corrector. Only four correctors

EVALUATION OF POWER SUPPLY AND ALIGNMENT TOLERANCES FOR THE ADVANCED PHOTONS SOURCE UPGRADE*

V. Sajaev, ANL, Argonne, IL 60439, USA

Abstract

A hybrid seven-bend-achromat lattice that features very strong focusing elements and provides an electron beam with very low emittance has been proposed for the Advanced Photon Source upgrade [1, 2]. In order to be able to maintain stable operation, tight tolerances are required for various types of errors. Here we describe an evaluation of the effects of various errors, including magnet power supplies, alignment, and vibration.

STATIC RANDOM ERRORS

Examples of static errors are power supply calibration errors, alignment errors, etc. The effect of these errors in most cases can be measured and corrected. Two types of static errors are distinguished: initial errors (errors expected during commissioning) and reproducibility errors (errors after turning power supplies off and then back on). Table 1 gives goals for various machine parameters.

Table 1: Goals for Initial Errors and Reproducibility in High-Level Machine Parameters Driven by Static Errors

	Initial error	Reproducibility
Energy	10^{-3}	10^{-4}
Orbit	2 mm	0.1 mm
Betatron tune	0.1	0.01
Beta functions	20%	2%
Chromaticity	1 unit	0.1 unit

When a dipole power supply current changes, the energy and orbit of the electron beam change. To calculate the sensitivity of the energy offset to such errors, an `elegant` [3] simulation was used. 200 sets of dipole fractional errors with 10^{-5} rms were generated, then the orbit was calculated and corrected. Two different orbit correction configurations were tested. The results are shown in Fig. 1, left. The distribution width varies by about a factor of two, so the energy error depends little on whether orbit correction is running or not. The amplifying effect of powering dipoles in series on the energy error is significant, as Fig. 1 (right) shows. The resulting allowable initial dipole errors are $2 \cdot 10^{-3}$. Initial orbit distortion is generated by dipole errors and quadrupole misalignments, while orbit errors after a shutdown result from dipole and corrector reproducibility errors. The orbit requirements in Table 1 were chosen to ensure that the initial orbit fits inside the vacuum chamber. This leads to unrealistic requirements for individual quadrupole alignment of 10 µm. To relax this requirement, a single-turn trajectory

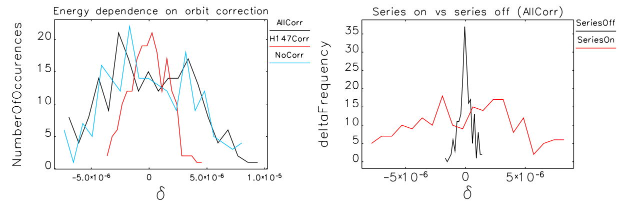

Figure 1: Left: Distribution of Energy Errors for Two Different Orbit Correction Configurations (Black and Red) and without Orbit Correction (Blue). Right: Comparison of Energy Errors for the Cases When M1 and M2 Dipoles Powered in Series or Separately.

correction will be used to obtain the first closed orbit. For orbit reproducibility after shutdowns, all of the error budget is assigned to dipoles and correctors. This gives $\Delta\alpha/\alpha = 10^{-4}$ for dipoles and $\Delta\theta/\theta = 7 \cdot 10^{-3}$ for correctors, assuming an equally split error budget.

Betatron tune errors come from quadrupole gradients, beam energy, and orbit inside sextupoles. Initial tune errors will be dominated by the orbit in sextupoles. Simple estimations show that 1-mm rms orbit errors in sextupoles will produce a tune error of 0.9. Therefore, during commissioning, after the first closed orbit has been established, the tune will need to be corrected. Despite this need for early tune correction, it is still advisable to limit tune error contributions from quadrupoles and dipoles. The effect of quadrupole errors can be estimated using a simple expression, while the effect of dipole errors is more complex and was obtained from simulations. Assuming that the tune error budget of 0.1 is distributed equally between quadrupoles and dipoles, the requirements for the initial errors are: $\Delta K_1/K_1 = 3 \cdot 10^{-3}$ and $\Delta\alpha/\alpha = 1.2 \cdot 10^{-3}$.

Initial beta function errors are expected to be dominated by the orbit errors in sextupoles. If the quadrupole contribution is limited to 20% beta beating, a simple simulation of beta function errors due to random quadrupole errors results in an initial quadrupole error requirement of $1 \cdot 10^{-3}$.

Chromaticity errors are generated by sextupole errors and by lattice errors. Simulations show that chromaticity errors after the beam is first stored have an rms of five units due to lattice errors. After orbit correction, the chromaticity error decreases to one unit rms. The contribution from sextupole strength errors is required to be one unit as well. Simple calculation results in the initial error requirement of $2.7 \cdot 10^{-2}$. Table 2 summarizes tolerances for random static errors.

VARIABLE ERRORS

Variable errors can be split in several parts according to their frequency spectrum: "slow" (slower than 100 seconds), "fast" (between 0.01 Hz and 1 kHz), and "very fast" (faster than 1 kHz). The required limits on the varying errors are

INTRA-BEAM AND TOUSCHEK SCATTERING COMPUTATIONS FOR BEAM WITH NON-GAUSSIAN LONGITUDINAL DISTRIBUTIONS*

A. Xiao†, M. Borland, ANL, Argonne, IL 60439, USA

Abstract

Both intra-beam scattering (IBS) and the Touschek effect become prominent for multi-bend-achromat- (MBA-) based ultra-low-emittance storage rings. To mitigate the transverse emittance degradation and obtain a reasonably long beam lifetime, a higher harmonic rf cavity (HHC) is often proposed to lengthen the bunch. The use of such a cavity results in a non-gaussian longitudinal distribution. However, common methods for computing IBS and Touschek scattering assume Gaussian distributions. Modifications have been made to several simulation codes that are part of the `elegant` [1] toolkit to allow these computations for arbitrary longitudinal distributions. After describing these modifications, we review the results of detailed simulations for the proposed hybrid seven-bend-achromat (H7BA) upgrade lattice [2] for the Advanced Photon Source.

INTRODUCTION

The natural emittance of next-generation storage ring light sources will be reduced by more than an order of magnitude compared to present rings. As a consequence, the Coulomb scattering rate among particles, which is inversely proportional to the bunch volume, increases rapidly. The small angle multiple scattering process (IBS effect) significantly increases beam emittance at the operating current, and limits benefits obtained from a ultra-low emittance machine. The large angle single scattering process (Touschek effect) puts more particles outside the rf acceptance, resulting in a much shorter beam lifetime.

To mitigate these problems, an HHC is often proposed to lengthen the bunch. Due to the distortion of the rf potential well, the particles are no longer Gaussian-distributed longitudinally. To accurately simulate beam scattering effects, all of our original beam scattering simulation tools—developed based on the assumption of Gaussian distributions—have been updated to allow arbitrary distributions. This paper first describes the technique used to deal with non-Gaussian distributed beam, then gives calculation results from the original and new methods for the same Gaussian distributed bunch to verify the code. The results of detailed simulations for the H7BA lattice with HHC are presented at the end.

TOUSCHEK SCATTERING

The Touschek scattering rate R is given by Eq. 28 in [3] and is an integral of the local scattering rate over all beam coordinates:

$$R = 2\beta c \int P_1 P_2 \sigma \chi dV, \tag{1}$$

where βc is the particle's velocity, σ is the Møller cross-section transformed into the laboratory system, χ is the half angle between the scattered particles' momenta vectors $\vec{p_1}$ and $\vec{p_2}$, $P_{1,2}$ is bunch density function, and dV is given by

$$dV = d\Delta s_1 dx_{\beta 1} dy_{\beta 1} d\Delta p_{s1} d\Delta p_{s2} dx'_{\beta 1} dx'_{\beta 2} dy'_{\beta 1} dy'_{\beta 2}. \tag{2}$$

The density function P is well known for a Gaussian distributed beam, giving an analytical expression for R [3]. For a non-Gaussian beam, the integral is less straightforward. One option is the Monte-Carlo integration method [4], which is already coded in `elegant`. However, this method is computationally-demanding, and we elected to also enhance the faster-running `touschekLifetime` program. The quantity $\sigma\chi$ is dependent on the momenta and thus on the transverse coordinates owing to $x-p_x$ and $y-p_y$ correlations. In general, there is less correlation between $s - p_s$ in a storage ring, thus the integral over ds can be done separately, i.e., the beam can be sliced longitudinally.

For each longitudinal slice, particles are Gaussian distributed in all dimensions except in s, which is approximately uniformly distributed. One can show that the scattering rate R_U for a uniform longitudinal distribution of length L is related to the rate R_G for a Gaussian distrubtion with $\sigma_s = L$ by

$$R_U = 2\sqrt{\pi} R_G. \tag{3}$$

Since R_G is already computed by `touschekLifetime`, relation 3 is used to calculate the scattering rate from each slice $R_{U,m}$. The total scattering rate will be the sum of $R_{U,m}$ over all slices m, giving a lifetime

$$\frac{1}{T_l} = \left\langle \frac{R}{N_0} \right\rangle = \left\langle \frac{\sum_m R_{U,m}}{\sum_m N_m} \right\rangle, \tag{4}$$

where N_m is the population of slice m.

To verify the code, the total local scattering rate of a Gaussian distributed bunch was calculated with slicing (21 slices) and without slicing. Results shown in Fig.1 agree very well with one another.

INTRA-BEAM SCATTERING

A similar slicing technique can be used for IBS calculations. Since IBS is a multiple scattering process and the beam emittance is diluted over time, the equilibrium beam emittance results from the interplay of many factors, such as synchrotron radiation damping, quantum excitation, and beam optics. The standalone `ibsEmittance` tool is

EXPERIENCE WITH ROUND BEAM OPERATION AT THE ADVANCED PHOTON SOURCE *

A. Xiao†, L. Emery, V. Sajaev, B. Yang, ANL, Argonne, IL 60439, USA

Abstract

Very short Touschek lifetime becomes a common issue for next-generation ultra-low emittance storage ring light sources. In order to reach a longer beam lifetime, such a machine often requires operating with a vertical-to-horizontal emittance ratio close to an unity, i.e. a “round beam”. In tests at the APS storage ring, we determined how a round beam can be reached experimentally. Some general issues, such as beam injection, optics measurement and corrections, and orbit correction have been tested also. To demonstrate that a round beam was achieved, the beam size ratio is calibrated using beam lifetime measurement.

INTRODUCTION

It is foreseen that the brightness from a next-generation storage ring based light source can be improved by several orders with an ultra-low emittance lattice design. One of the biggest challenges associated with an ultra-low emittance storage ring is the necessarily much shorter beam lifetime. In many cases, the lifetime is so short that the beam can only satisfy operational requirements under a “round beam” operation scenario. A good example of how the beam lifetime varies with beam size ratio can be seen from the proposed APS upgrade MBA lattice design [1], and is illustrated in Fig. 1.

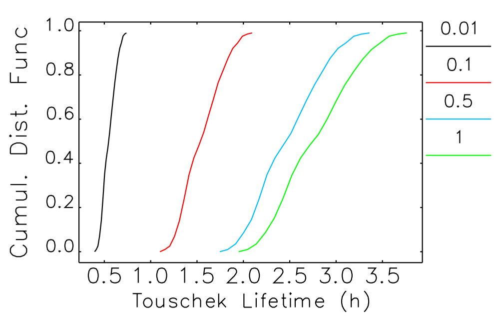

Figure 1: Cumulative distribution functions for the Touschek lifetime from the 100 error ensembles of H7BA optics at different emittance ratios (legend).

A round beam can be achieved in two ways. One is introducing strong skew quadrupoles in the lattice. This method not only couples the x and y beam motion, but also couples optical functions. This scheme could generate difficulty for routine machine operations procedures such as orbit correction, optics measurement and correction, etc. Another way to obtain a round beam is to operate machine at the difference resonance (equal fractional betatron tunes). This way, the coupling coefficient does not need to be large; real machine imperfections with weak skew elements installed in the ring could be enough. Thus the beam operation will be close to a normal decoupled regime of operation, and the x and y optical functions can still be treated separately. The x and y moments (from random process of synchrotron radiation) would simply exchange their values internally due to the resonance effect.

To test the idea of a round beam generation and related operational issues at the coupling resonance, experiments had been performed at the APS storage ring, and results are compared with simulation for the calibrated machine model [2]. We had measured beam lifetime, off-axis injection efficiency, optical response matrix, etc. at different machine coupling coefficients. Beam emittances are calculated from beam sizes measured using dipole synchrotron radiation. The existing vertical beam size measurement system is configured for measurement of only small beam sizes, and does not respond to the round beam conditions that we need to confirm. Thus we used Touschek lifetime at lowered rf voltage to estimate the vertical beam size.

SIMULATION STUDY ON COUPLING RESONANCE

A simple theory for weak betatron coupling can be found in [3]. Assuming that a particle is excited in the x plane, the presence of coupling will cause an interchange of the oscillation energy between the two planes, as shown in Fig. 2. The interchange period T and modulation factor S are given by

$$T = \frac{1}{f_{\rm rev}\sqrt{\Delta^2 + |C|^2}}, \tag{1}$$

$$S = \frac{E_T}{E_{max}} = \frac{|C|^2}{\Delta^2 + |C|^2}, \tag{2}$$

where $f_{\rm rev}$ is particle’s revolution frequency, $\Delta = (\nu_x - \nu_y)$ is separation of uncoupled tunes, and $|C|$ is the machine coupling coefficient, which indicates the strength of the x-y coupling. From Eq. 2 a full x-y energy modulation (round beam) can be reached when $\Delta = 0$. In a real machine, Δ can not be made exactly zero for many reasons, such as tune spread inside the bunch, PS noise, etc. Therefore, we need to test that the round beam can be reached when $\Delta^2 \ll |C|^2$.

Thus the allowable Δ variation range for keeping S above a certain level (for example, $S > 0.9$) depends on $|C|$. If $|C|$ is large, then machine tolerances on various errors are also large, and the oscillation energy is interchanged between x

DESIGN OF SUPERCONDUCTING CW LINAC FOR PIP-II *

A. Saini†, V. Lebedev, J.F. Ostiguy, N.Solyak, V. Yakovlev, Fermilab, IL 60510, USA

Abstract

Proton Improvement Plan (PIP) -II is a proposed roadmap to upgrade existing proton accelerator complex at Fermilab. It is primarily based on construction of superconducting (SC) linear accelerator (linac) that would be capable of operating in continuous wave (CW) mode. This paper presents reference design layout and beam optics of SC linac and discusses some of the underlying requirements and motivations.

INTRODUCTION

An ambitious program is proposed to develop a high intensity proton beam facility that would support, over the next two decades, a world-leading neutrino program and rich variety of high intensity frontier particle physics experiments at Fermilab. This program, referred to as Proton Improvement Plan -II (PIP-II), is primarily based on construction of 800 MeV SC linac that would provide flexible platform for further enhancement of the existing Fermilab accelerator complex. A schematic of PIP-II facility is shown in Fig 1. A detailed description of site layout is presented elsewhere [1].

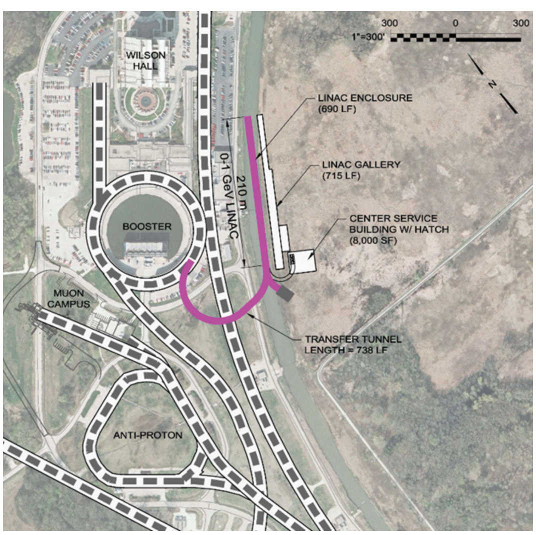

Figure 1: Schematic of PIP-II facility.

To reconcile a stringent budgetary situation and an immediate requirement for high beam power by existing operating experiments, we plan to expedite construction by leveraging the existing Fermilab infrastructure. In particular, the cryogenic infrastructure of the now decommissioned Tevatron will be re-purposed for the PIP-II SC linac. While the machine is designed to be fully compatible with continuous wave (CW) operation, limitations in the capacity of the Tevatron system will require that the linac initially operate in pulsed mode. Success of the PIP-II facility depends critically on the robustness of the SC linac design. While the reference design parameters [1] have been established, the optics is still evolving to incorporate technical constraints and to address issues that may potentially cause degradation of beam quality and result in beam losses. In this paper we discuss baseline configuration of PIP-II SC linac and present results of preliminary beam optics studies.

LINAC ARCHITECTURE

A schematic of linac baseline configuration is shown in Fig 2. It consists of room temperature front-end and SC linac. Each superconducting section in Fig 2 is represented by optimal beta of respective cavities except LB and HB section which are shown for geometrical beta of corresponding cavities. The room temperature front-end is composed of

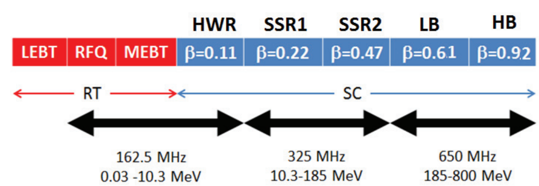

Figure 2: Technology map of PIP-II linac.

an ion source, a low energy beam transport (LEBT) section, an RFQ and a medium energy beam transport (MEBT) section. The DC ion source delivers a nominal current of 5 mA at 30 keV. The beam is transported through the LEBT and matched to the RFQ. The RFQ operates at a frequency of 162.5 MHz and accelerates the beam up to 2.1 MeV. The beam then enters the MEBT where it gets chopped to acquire the time structure required to drive different experiments.

The H^- ion is non-relativistic at kinetic energy of 2.1 MeV and its velocity changes rapidly with acceleration along linac. In order to achieve efficient acceleration SC linac employs several families of accelerating cavities optimized for specific range of velocities. On the basis of these families, SC linac is segmented into five sections. The first SC section is based on Half Wave Resonators (HWR) operating at frequency of 162.5 MHz.

The choice of this frequency was motivated by several factors, including reducing transverse RF defocusing. It can be observed from equation 1 [2] that RF kick is directly proportional to the frequency. Operation at lower frequency helps making maximum use of the available accelerating gradient in cavities. HWR section accelerates the beam from 2.1 MeV to 10.3 MeV. It is required eight HWR cavities assembled in single cryomodule to cover this energy range.

$$\Delta(\gamma\beta r') = -\frac{\pi E_0 T L sin(\phi)}{mc^2\gamma_s^2\beta_s^2\lambda} r \tag{1}$$

APPLICATIONS OF AN MPI ENHANCED SIMULATED ANNEALING ALGORITHM ON NUSTORM AND 6D MUON COOLING*

A. Liu†, Fermilab, Batavia, IL, 60510, USA

Abstract

The nuSTORM decay ring is a compact racetrack storage ring with a circumference ~480 m using large aperture (⌀ = 60 cm) magnets. The design goal of the ring is to achieve a momentum acceptance of 3.8±10% GeV/c and a phase space acceptance of 2000 μm·rad. The design has many challenges because the acceptance will be affected by many nonlinearity terms with large particle emittance and/or large momentum offset. In this paper, we present the application of a meta-heuristic optimization algorithm to the sextupole correction in the ring. The algorithm is capable of finding a balanced compromise among corrections of the nonlinearity terms, and finding the largest acceptance. This technique can be applied to the design of similar storage rings that store beams with wide transverse phase space and momentum spectra. We also present the recent study on the application of this algorithm to a part of the 6D muon cooling channel. The technique and the cooling concept will be applied to design a cooling channel for the extracted muon beam at nuSTORM in the future study.

INTRODUCTION

The nuSTORM decay ring shares the production straight and part of the arc with a pion beamline, so that the pions can be injected into the ring without fast kickers but through an Orbit Combination Section (OCS) [1–3]. The design aims at achieving a momentum acceptance of 3.8±10% GeV/c ($\delta = \Delta P/P \in \pm 0.1$) and a phase space acceptance of 2000 μm·rad (denoted as 2 mm in the rest of the paper). Because of the large δ, a large linear chromaticity can cause resonance crossings for many times. Moreover, the productivity of neutrinos in the decay ring critically rely on a large ratio of the production straight length to the circumference of the ring. Accordingly, an arc design with combined function magnets was proposed to achieve small linear chromaticities and reduce the arc length. The schematic layout of the nuSTORM facility and the linear optics of the decay ring is shown in Fig. 1 and Fig. 2.

Many nonlinearity terms in the decay ring become significant with the large particle emittance and the momentum offset, and thus need to be corrected, primarily by sextupoles. However, using sextupoles in the arcs of the ring is constrained because of the space and the maximum field limits. Octupolar fields can also be added in the design, but the two limits still apply. Also, adding more higher order nonlinear fields stimulates more nonlinear resonances. Therefore, nonlinear fields that are above sextupolar are not considered in the correction scheme.

† aoliu@fnal.gov

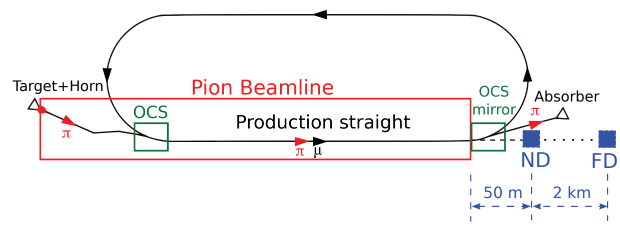

Figure 1: The layout of nuSTORM facility.

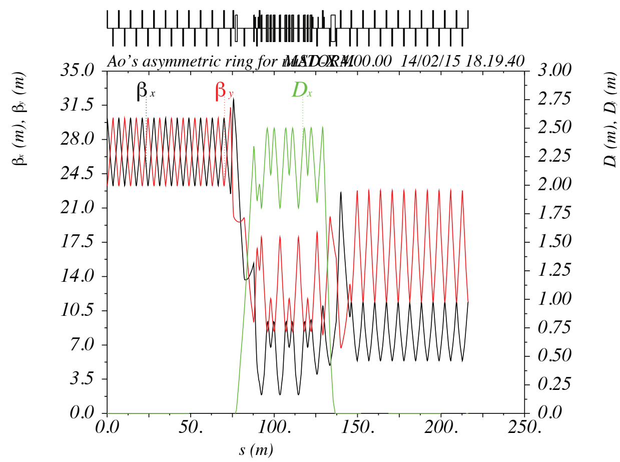

Figure 2: The linear optics of the proposed ring design with combined function magnets in the arcs.

The natural higher order nonlinearities combine with those induced by the sextupoles and play significant roles in the beam stability. Therefore, choosing and correcting the most significant terms as done conventionally in other designs does not work the most efficiently. In order to find the balance among corrections of all the nonlinearities that limit the acceptance of the beam, it is straightforward to apply a numerical algorithm to find the best configuration. This is a single objective optimization, which is to maximize the acceptance of a muon beam with a 2 mm Gaussian transverse admittance, and a uniform momentum spread within 3.8 ± 10% GeV/c. The variables are the strengths, lengths, and locations of the sextupolar fields. Since the concept of "sextupole families" does not apply in this design, namely all the variables are independent of each other, a meta-heuristic algorithm that thoroughly searches the parameter space for the global optimum can be implemented.

The Simulated Annealing (SA) algorithm is known for its efficiency in performing a satisfactory global search, especially when limited computing resources are available [4]. In the SA algorithm, each set of variables determines a "state"

COUPLER RF KICK IN THE INPUT 1.3 GHz ACCELERATING CAVITY OF THE LCLS-II LINAC

A. Lunin#, N. Solyak, A. Sukhanov, and V. Yakovlev, FNAL, Batavia, IL 60510, USA*

Abstract

Main and HOM couplers break the cavity axial symmetry, distort RF field and, thus, create a transverse kick, even for a particle moving along the cavity axes. Dependence of a kick on the RF phase causes beam emittance dilution and degrade the FEL radiation quality. The transverse kick is most dangerous for a beam passing through the first accelerating structure of a linac, where particles energy is low. In this paper we analyse the coupler RF kick in the first accelerating structure of the LCSL-II linac.

INTRODUCTION

The 1.3 GHz ILC accelerating structure is chosen as a baseline for the LCLS-II linac. The cavity contains 9 elliptical cells, a main power coupler, and two HOM couplers, upstream and downstream, see Figure 1.

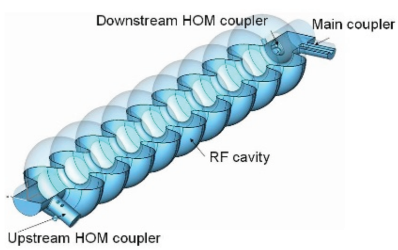

Figure 1: The 1.3 GHz ILC accelerating cavity with main and HOM couplers.

Main and HOM couplers break the cavity axial symmetry, distort electromagnetic field and, thus, create a transverse kick, even for a particle moving along the cavity axes. Dependence of the kick on the RF phase causes beam emittance dilution and may degrade the FEL radiation quality [1, 2]. Bellow we analyze a coupler RF kick in the first accelerating structure of the LCLS-II linac [3]. Beam and cavity parameters relevant to the coupler kick and emittance growth calculations are listed in the Table 1.

Table 1: Parameters for the RF Kick Simulations

Bunch transverse size, rms, σ_t	1 [mm]
Bunch length, rms, σ_z	1 [mm]
Input beam energy, E_{inp}	0.75 [MeV]
Accelerating gradient	12 [MeV/m]
Operating frequency	1.3 [GHz]

GENERAL

The longitudinal component of electric field near the cavity axis is few orders of magnitude larger than the transverse one. Therefore, any misalignment of mesh elements in respect to the axis may result in appearance of a nonzero transverse projection of the longitudinal component and, thus, produce spurious transverse components of electric field. Since a magnetic field is usually derived from the solution of an electric field we have the same problem for an accurate magnetic field representation near the cavity axis. The remedy is use a regularized mesh with the elements aligned to the cavity axis. The regular mesh pattern near the cavity axis and the vertical component of electric field are shown in Figure 2 as a result of ANSYS HFSS simulation [4].

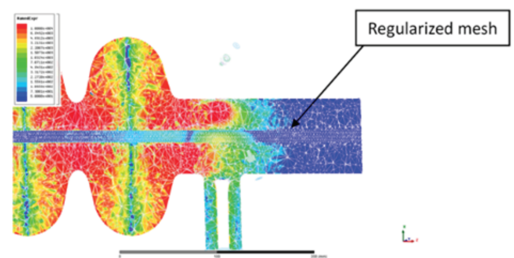

Figure 2: Map of the vertical electric field component E_y.

The transverse RF kick is the total beam transverse momentum change along the trajectory. For a low relativistic beam which is moving not along a straight line, dependence of the transverse momentum on the accelerating gradient becomes non-linear. Therefore we characterize RF kick in this case as a non-normalized transverse kick accumulated along the actual beam trajectory at a given accelerating gradient:

$$V_x = \Delta P_x \frac{c}{e_0} = \int_{t_1}^{t_2} (E_x - \beta_z Z_0 H_y) e^{i(\omega t + \varphi_s)} dt \tag{1}$$

where t_2-t_1 is the beam transit time, β_z is the longitudinal beam velocity as a fraction of speed of light, φ_s is the synchronous RF phase, e_0 is electron charge and c is the speed of light. The beam tracking in the accelerating structure is realized with MATHCAD script using the paraxial approximation for particles motion [5, 6].

CAVITY RF FOCUSING

A beam RF focusing at the entrance of first accelerating structure, where particles energy is low, is not fully compensated by defocussing forces at its exit [7]. Thus, the structure itself is producing a non-zero net

NUMERICAL SIMULATIONS OF TRANSVERSE MODES IN GAUSSIAN BUNCHES WITH SPACE CHARGE*

Alexandru Macridin, James Amundson, Eric Stern, Fermilab, Batavia, Illinois, USA

Abstract

The transverse modes and the intrinsic Landau damping in Gaussian bunched beams with space charge are numerically investigated. The evolution of the phase space density is calculated with the Synergia accelerator modeling package and analyzed with Dynamic Mode Decomposition (DMD) method. DMD is a relatively new technique used to calculate mode dynamics in both linear and nonlinear systems. The properties of the first three space charge modes, including their shape, damping rates and tune shifts are calculated over the entire range of the space charge interaction.

INTRODUCTION

Landau damping provides an important mechanism for stabilizing beam propagation. The mechanism operates via an energy exchange between the potentially unstable coherent mode and some resonant particles. A necessary condition for the Landau damping mechanism is the existence of resonant particles with a continuous frequency spectrum around the coherent frequency. In accelerators, aside from the tune spread due to nonlinear lattice elements, there is a tune spread caused by the space charge interaction which plays an important and not-well-understood role in the damping mechanism. Here we neglect the nonlinear lattice effects and focus only on the intrinsic effect of space charge on the transverse modes of a Gaussian bunch. The beam dynamics are investigated over the entire range of the interaction, from no space charge to the strong space charge limit.

The effect of space charge on the head-tail modes was first addressed by Blaskiewicz [1] who showed that space charge can improve beam stability. The strong space charge regime for bunches of arbitrary shape was addressed analytically in [2, 3]. The mode shapes, tune shifts and damping rates were calculated for Gaussian bunches. A numerical investigation of the transverse modes in longitudinal Gaussian bunches with K-V transverse distribution using particle tracking simulations was done by V. Kornilov *et al.* [4]. Our simulations for bunches with K-V charge distribution (not shown here) are in agreement with the ones in Ref [4].

ANALYTICAL RESULTS

The tune shift for a particle propagating through a lattice and experiencing a transverse space charge force $\frac{eE_x}{\gamma^2}$ is [5]

$$\Delta Q_{sc} = \frac{e}{m\gamma^3\beta^2c^2}\frac{1}{4\pi}\oint \beta(s)\frac{\partial E_x}{\partial x}(\bar{x},s)ds\ . \tag{1}$$

where $\beta(s)$ is the lattice beta function.

We define the transverse displacement density as

$$X(z,u,s) = \frac{\int dxdp_xdydp_y\, x\rho(x,p_x,y,p_y,z,u,s)}{\rho(z,u)} \tag{2}$$

where $\rho(x,p_x,y,p_y,z,u,s)$ is the density in phase space with z being the longitudinal position relative to the reference particle and $u = \frac{\delta p}{p}$ being the relative momentum spread. Following Ref [3] and defining $X(z,u)$ such as

$$X(z,u,s) = X(z,u)e^{(-i\omega_0 Qs - i\chi z)} \tag{3}$$

where ω_0 is the reference particle angular velocity and χ is the effective chromaticity one gets the equation of motion

$$(Q - Q_\beta)X(z,u) + iQ_s\frac{\partial X}{\partial\theta}(z,u) = -\Delta Q_{sc\ eff}(z)(X(z,u) - \bar{X}(z))\ , \tag{4}$$

with θ being the synchrotron oscillation phase. $\Delta Q_{sc\ eff}(z)$ is the effective space charge tune shift. For a Gaussian beam we define the space charge parameter as

$$q_{eff} = \frac{\Delta Q_{sc\ eff\ max}}{Q_s} = 0.52\frac{\Delta Q_{sc\ max}}{Q_s} \tag{5}$$

where $\Delta Q_{sc\ max}$ is the maximum tune shift (at the beam center) and Q_s is the synchrotron tune. This definition is in agreement with the one in Ref [2]. For a Gaussian beam the effective tune shift is about 0.52 smaller than the maximum tune shift [2]. In order to determine q_{eff} we numerically calculate the integral in Eq. 1 using the electric field from the simulation.

When the space charge is zero there is a simple solution to Eq. 4,

$$X(z,u) \equiv X(r,\theta) = R(r)e^{im\theta}\ , \tag{6}$$

with r and θ being the amplitude and the phase of the synchrotron oscillation. The tune shift is given by

$$Q - Q_\beta = mQ_s \tag{7}$$

for integer m. The modes are defined by the angular number m and are radially degenerate.

Large q_{eff} requires solutions which are weakly dependent on u, i.e. $X(z,u) \approx X(z)$. A detailed calculation of the modes properties is presented in [2, 3]. The strong space charge modes form an orthogonal set

$$\int X_k(z)X_m(z)\rho(z) = \delta_{km}, \tag{8}$$

where k and m represent mode numbers. For the mode k the tune shift is $\frac{\nu_k Q_s}{q_{eff}}$ (the values of ν_k are tabulated in [2]), while the Landau damping is $\lambda_k = \frac{k^4 2\pi Q_s}{q_{eff}^3}$.

SIMULATION OF MULTIPACTING IN SC LOW BETA CAVITIES AT FNAL*

Gennady Romanov#, Paolo Berrutti, Timergali N. Khabiboulline, Fermilab, Batavia, Illinois, USA

Abstract

Proton Improvement Plan-II at Fermilab is a plan for improvements to the accelerator complex aimed at providing a beam power capability of at least 1 MW on target at the initiation of LBNE (Long Base Neutrino Experiment) operations. The central element of the PIP-II is a new 800 MeV superconducting linac, injecting into the existing Booster. Multipacting affects superconducting RF cavities in the entire range from high energy elliptical cavities to coaxial resonators for low-beta applications. This work is focused on multipacting study in the low-beta 325 MHz spoke cavities; namely SSR1 and SSR2, which are especially susceptible to the phenomena. The extensive simulations of multipacting in the cavities with updated material properties and comparison of the results with experimental data helped us to improve overall reliability and accuracy of these simulations. Our practical approach to the simulations is described in details. For SSR2, which has a high multipacting barrier right at the operating power level, some changes of the cavity shape to mitigate this harmful phenomenon are proposed.

INTRODUCTION

Proton Improvement Plan-II [1] at Fermilab is a plan for improvements to the accelerator complex aimed at providing a beam power capability of at least 1 MW on target at the initiation of LBNE (Long Base Neutrino Experiment) operations. The central element of the PIP-II is a new 800 MeV superconducting linac, injecting into the existing Booster. The PIP-II 800 MeV linac is a derivative of the Project X Stage 1 design as described in the Project X Reference Design Report [2]. A room temperature (RT) section accelerates H^- ions to 2.1 MeV and creates the desired bunch structure for injection into the superconducting (SC) linac. Five superconducting cavity types operating at three different frequencies are required for acceleration to 800 MeV.

The electron multiplication on surfaces exposed to an oscillating electromagnetic field causes the phenomenon of multipacting, which is a serious obstacle to be avoided for normal operation of particle accelerator and their RF components. In worst cases this phenomena, described in many accelerators, can completely prevent normal operation of an accelerating cavity.

Multipacting affects superconducting RF cavities in the entire range from high energy elliptical cavities to coaxial resonators for low-beta applications. This work is focused on multipacting study in the low-beta structures; namely 325 MHz Single-Spoke Resonators: SSR1 (β=0.22) and SSR2 (β=0.47).

Study of MP in SSR2 was a primary goal of this work along with sharpening of simulation technique. SSR2 is currently under development for PIP-II linac [3]. The design has been finalized recently, and the preliminary simulations indicated strong MP in the cavity. It was necessary to understand at what level this resonator is affected by multipacting, what critical gradients are, where the MP develops in the cavity geometry and what can be done to mitigate this harmful phenomena.

Multipacting in the SSR1 cavity has been studied already [4], and the results have been compared with experimental data on multipacting barriers found during the vertical test of the SSR1 cavity [5]. In this work the MP simulations in the SSR1 cavity were repeated by two reasons. First, a new secondary emission yield (SEY) data for niobium became available – the previous simulations of the SSR1 used SEY for copper, that allows defining RF power levels of MP, but is not correct to evaluate intensity and exact boundaries of MP discharge. Second, 12 SSR1 cavities were manufactured and tested at high power level since then, and rich experimental data on the MP behaviour in SSR1 during RF conditioning was accumulated [6]. Comparison of the MP simulations that used updated material properties with experimental data helped us to evaluate overall reliability and accuracy of our simulation technique.

NEW IN SIMULATION SET UP

There are a number of numerical simulation codes for predicting multipactor, each with various pros and cons. Our choice is still CST Studio Suite because it smoothly combines flexible and developed modelling, electromagnetic field simulation, multi-particle tracking, adequate post-processing and advanced probabilistic emission model (Furman-Pivi model [7]), which is very important capability in multipactor simulations. In general we follow earlier established simulation procedure [4, 8] but several new features have been added.

CST Particle Studio (PS) offers two solvers for particle tracking; this time both were used in our MP simulations. One of them is the Gun Solver & Particle Tracking solver (TRK) which is used to compute trajectories of charged particles within RF fields and optionally electrostatic or/and magnetostatic fields. Other one is the Particle-In-Cell solver (PIC) that computes the charged particles motion in self-consistent transient fields. Usually the space charge effects are not taken into account in MP simulations, so just simple particle tracking in electromagnetic fields was used for both solvers.

PIC solver can use only imported field maps, while TRK solver has its own eigenmode solver, but it also can

SIMULATION OF THE FERMILAB RECYCLER FOR LOSSES AND COLLIMATION*

E. Stern, R. Ainsworth, J. Amundson, B. Brown, Fermilab, Batavia, IL 60510, USA

Abstract

Fermilab has recently completed an upgrade to the complex with the goal of delivering 700 kW of beam power as 120 GeV protons to the NuMI target. A major part of boosting beam power is to shorten the beam cycle by accumulating up to 12 bunches of 0.5×10^{11} protons in the Recycler ring through slip-stacking during the Main Injector ramp. This introduces much higher intensities into the Recycler than it has had before. Meeting radiation safety requirements with high intensity operations requires understanding the effects of space charge induced tune spreads and resulting halo formation, and aperture restrictions in the real machine to develop a collimation strategy. We report on initial simulations of slip-stacking in the Recycler performed with Synergia.

INTRODUCTION

Fermilab has recently completed an upgrade to the complex [1] with the goal of delivering 700 kW of beam power as 120 GeV protons to the NuMI target. Possible methods for increasing beam power are increasing the intensity of individual bunches and move beam bunches through the accelerator chain at a faster rate. Since we are already producing bunches close to the intensity limit that we can transport, we will be reducing the cycle time from 2.2 s to 1.33 s. Previously, the Main Injector combined one set of six booster batches each containing 80 beam bunches were combined with an additional set of six batches using the slip-stacking [2] procedure at 8 GeV. The resulting set of batches were then accelerated to 120 GeV for extraction to the NuMI target. Both the accumulation/slip-stacking and the ramping are time consuming operations. We will instead perform the accumulation and slip-stacking in the Recycler ring while the Main Injector performs its ramp.

The Recycler [3] is a permanent magnet based proton storage ring originally constructed to accumulate antiprotons during the Tevatron Run II era. As such it was not anticipated that it would have experience significant space charge problems. Injecting high intensity proton bunches now introduces space charge tune shifts causing possible resonance excitation, halo production and resulting particle loss. The slip-stacking procedure is inherently messy as it involves the transport of bunches at different mimatched momenta in the ring while at the same time the chromaticity has to be kept at large negative values to suppress a head-tail instability. To understand the dynamics of the machine and develop a plan for collimation and halo reduction we have initiated a campaign of simulation of the Recycler dynamics including the slip-stacking and true locations and sizes of machine apertures with the Fermilab developed beam dynamics code Synergia [4, 5].

SYNERGIA

Synergia is developed and maintained at Fermilab by the Accelerator Simulations group within the Scientific Computing Division to provide detailed high fidelity simulations of particle accelerators or storage rings specializing in space charge and wakefield collective effects. Synergia is a Particle-in-Cell (PIC) based code that tracks macro-particles through the lumped elements of the accelerator. Synergia simulates the usual single particle optics from produced by magnetic elements as well as RF cavities. Space charge and impedance kicks are applied at locations around the ring using the split-operator method. So that realistic particle losses can be simulated, apertures may be associated with each element. The Synergia aperture model includes rectangular and elliptical apertures of arbitrary size and transverse offset as well as arbitrary user defined polygonal apertures. To achieve statistically meaningful results in a reasonable time, Synergia has been designed from the beginning to take advantage of multiprocessing systems such as Linux clusters and supercomputers.

RECYCLER SIMULATION MACHINE MODEL

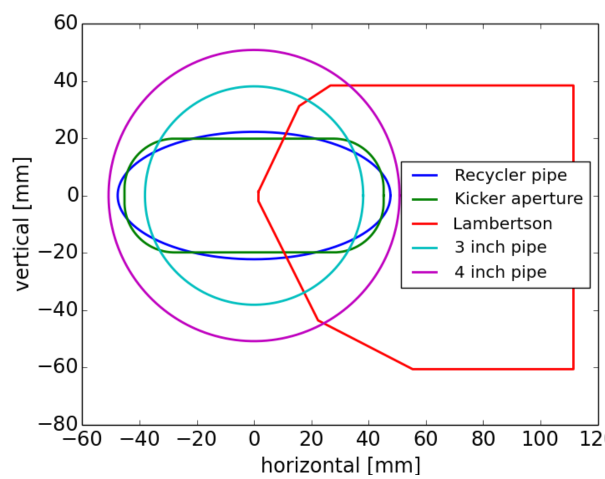

Figure 1: Apertures in the Recycler.

The Recycler machine lattice is described by a MAD file [6, 7] incorporating the measured multipoles for the magnet body and shim correctors. Synergia reads and interprets the same MAD description. The lattice functions for the Recycler calculated by Synergia are identical to those calculated by MAD. The apertures in the recycler are: 3" diameter pipe,

MEASUREMENT AND CORRECTION OF THE FERMILAB BOOSTER OPTICS WITH LOCO*

C.Y. Tan†, V. Lebedev, A.K. Triplett, Fermilab, Batavia, IL 60510, USA,
M. McAteer, CERN, Geneva, Switzerland

Abstract

The optics of the original Booster lacked the ability for full optics correction and it was not until 2009 when new optics corrector packages were installed between gradient magnets that this ability became available. The optics correction method that is chosen is called LOCO (Linear Optics from Closed Orbits) that measures the orbit response from every beam position monitor (BPM) in the ring from every kick of every dipole corrector. The large data set collected allows LOCO to not only calculate the quadrupole and skew quadrupole currents that both reduces beta beatings and corrects coupling, it also finds the dipole kicker strengths, BPM calibrations and their tilts by minimizing the difference between the measured and ideal orbit response of the beam. The corrected optics have been loaded into Booster and it is currently being tested to be eventually used in normal operations.

INTRODUCTION

The Fermilab Booster is a rapid cycling synchrotron that accelerates protons from 400 MeV to 8 GeV in 33 ms to supply beam to the rest of the complex for high energy physics. Booster has been operational since 1971 [1] but it was not until 2009 that new optics corrector packages were installed between the gradient magnets that the ability to completely correct its optics for the entire ramp became available. Fig. 1 shows an example of a corrector package that contains dipole correctors in both planes, a normal quadrupole, a skew quadrupole, normal sextupole, a skew sextupole, and beam position monitors in both planes.

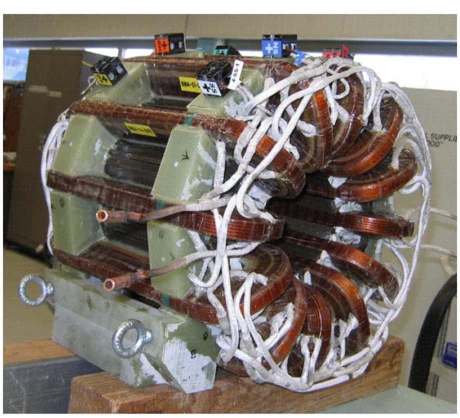

Figure 1: A Booster corrector magnet package before potting.

The method that has been chosen to correct Booster optics is called LOCO (Linear Optics from Closed Orbits) and has been adapted to the peculiarities of Booster which will be discussed below. This method has been successfully used to correct the optics of other machines, for example the NSLS (National Synchrotron Light Source) X-Ray ring from which LOCO originated. [2]

BOOSTER LOCO

The principle of LOCO is the measurement of the orbit of the beam (i.e. orbit response) at every BPM as each dipole kicker in the ring is used to consecutively 1-bump the beam up the ramp at predefined breakpoints. Mathematically, the process can be parameterized as measuring the orbit response $\Delta x_i/\Delta\theta_j$ of the beam at BPM i due to the kick from kicker j of a fully decoupled machine at each breakpoint:

$$\begin{aligned}\frac{\Delta x_i}{\Delta\theta_j} &= \frac{\sqrt{\beta_i\beta_j}}{2\sin\pi\nu_x}\cos(|\psi_i-\psi_j|-\pi\nu_x)- \\ &\frac{D_i}{D_{\mathrm{RPOS}}}\frac{\sqrt{\beta_{\mathrm{RPOS}}\beta_j}}{2\sin\pi\nu_x}\cos(|\psi_{\mathrm{RPOS}}-\psi_j|-\pi\nu_x)\end{aligned} \tag{1}$$

where $\Delta\theta_j$ is the size of the dipole kick from the jth kicker, Δx_i is the change in position at BPM i and $\beta_{i,j}$ are the beta functions at BPM i or kicker j respectively, $\psi_i-\psi_j$ is the phase advance between these two elements, and ν_x is the horizontal betatron tune. The RPOS device here is the radial feedback monitor. The beta function β_{RPOS} and dispersion D_{RPOS} (measured separately) at RPOS is required in the formula because Booster uses radial feedback and thus the dispersion function has a large efect on the response. The same formula without the dispersion term is used when the vertical plane orbit response is considered by appropriately replacing horizontal β's for vertical ones.

It is obvious that the same equation, Eq. 1, is found when the "measurement" comes from the lattice model. Clearly, both these methods will yield different values for $\Delta x_i/\Delta\theta_j$ and so a χ^2 error can be defined and it is

$$\chi^2=\sum_{i,j}\left[\left(\frac{\Delta x_i}{\Delta\theta_j}\right)_{\text{measured}}-\left(\frac{\Delta x_i}{\Delta\theta_j}\right)_{\text{model}}\right]^2\frac{1}{\sigma_{ij}^2} \tag{2}$$

where σ_{ij} is the statistical error taken at the 95% confdence interval of the slope in the linear fit of the measured orbit response at the ith BPM from a set of kicks using the jth kicker. The use of slopes as the response rather than absolute positions is one reason why LOCO is a successful method.

In principle, LOCO minimizes the χ^2 error, but in practice Eq. 2 is not directly used in the algorithm as the measure. An equivalent measure is defined instead so that a linear algebra

NUMERICAL ANALYSIS OF PARASITIC CROSSING COMPENSATION WITH WIRES IN DAΦNE*

A. Valishev, FNAL, Batavia, IL 60510, USA, D. Shatilov, BINP, Novosibirsk, Russia
C. Milardi, M. Zobov, INFN/LNF, Frascati, Italy

Abstract

Current bearing wire compensators were successfully used in the 2005-2006 run of the DAΦNE collider to mitigate the detrimental effects of parasitic beam-beam interactions. A marked improvement of the positron beam lifetime was observed in machine operation with the KLOE detector. In view of the possible application of wire beam-beam compensators for the High Luminosity LHC upgrade, we revisit the DAΦNE experiments. We use an improved model of the accelerator with the goal to validate the modern simulation tools and provide valuable input for the LHC upgrade project.

INTRODUCTION

The long-range (also referred to as the parasitic) beam-beam interactions in colliders occur when the two particle beams moving in a common vacuum chamber and separated transversely, interact via the electromagnetic field. Such interactions may be a significant factor limiting the performance of multi-bunch particle colliders: for example, they were shown to impact the luminosity lifetime and increase particle losses during the Tevatron collider Run II [1]. At the Tevatron, the beams collided head-on in two high-luminosity Interaction regions (IR), and were separated by means of electrostatic separators in the rest of the machine, where each bunch experienced 70 parasitic interactions with the separation ranging from 6 to 10 of the beam σ. It was shown that four collisions at the smallest separation of 6 σ were responsible for the dramatic degradation of lifetime of both beams [2]. At the LHC, the beams collide at an angle in the experimental IRs and move in separate vacuum chambers in the arcs. Still, the number of parasitic crossings in the common sections is up to 120 with 25 ns bunch spacing at the nominal transverse separation of 9.5 σ [3]. Experiments during the LHC Run 1 have shown that with ½ the nominal number of bunches (bunch spacing of 50 ns), the onset of high losses is at the transverse separation of ≈5 σ for nominal bunch intensity [4]. The HL-LHC upgrade demands a two-fold increase in the total beam current [5], which leads to a significant enhancement of the long-range beam-beam effects [6]. As a consequence, the transverse separation of the two beams, and hence the crossing angle, has to be increased (to 12.5 σ in the baseline scenario), which in turn leads to several undesired effects: the geometric loss of luminosity, increased pile-up density, and the demand for large-aperture final focus magnets.

Compensator devices in the form of current-bearing wires (also referred to as the Beam-Beam Long-Range Compensators, BBLRC) were proposed as a way to mitigate the long-range beam-beam effects [7], and since were extensively studied both theoretically [8-10] and experimentally [11,12]. A remarkable demonstration of the effectiveness of BBLRC for improvement of collider performance was achieved during the 2005-2006 operation of DAΦNE at INFN/LNF (Frascati, Italy). The application of BBLRC devices during the KLOE run resulted in approximately 50% improvement of the average luminosity integration rate [13].

Numerical simulations of beam-beam effects with the weak-strong particle tracking code Lifetrac [14] guided the design of DAΦNE beam-beam compensation. Over the past decade, the code functionality has been considerably expanded. The most important additions include the implementation of Frequency Map Analysis (FMA) [15] and the ability to perform tracking in detailed machine lattices. The goals of the present work are to revisit the results of DAΦNE beam-beam compensation experiment using the modern computing tools, and demonstrate the predictive power of Lifetrac simulations with BBLRC for future applications.

EXPERIMENTAL DATA

We compiled a comprehensive set of machine and beam parameters during the 2005-2006 run with the KLOE detector (see Tab. 1). The collider performance data relevant to the BBLRC experiments is presented in Figs. 1, 2 showing the time dependence of electron and positron intensities, luminosity, and the beam-beam related portion of positron losses for the cases of BBLRC turned off and on, respectively. The beam-beam related loss rate $\dot{N}_{BB}$ was derived from the total loss rate $\dot{N}$ according to the following consideration:

$$\dot{N} = \dot{N}_{Lum} + \dot{N}_T + \dot{N}_{BB}$$

where $\dot{N}_{Lum} = \sigma_{tot} L$ is the luminous loss rate (σ_{tot} = 0.048 barn), $\dot{N}_T$ is the Touschek loss rate, and the losses due to scattering on the residual gas are vanishingly small. The typical positron loss rate in the experimental runs was about 2×10^9 s^{-1} (corresponding beam intensity lifetime $\tau\approx10^3$ s), and was dominated by the Touschek and beam-beam effects with luminous losses being a relatively minor contribution at about 5×10^6 s^{-1}. The highlighted time intervals in Figs. 1, 2 are the data samples used for comparison with the beam-beam simulation as they represent stable beams in weak-strong

A PARALLEL PARTICLE-PARTICLE, PARTICLE-MESH SOLVER FOR STUDYING COULOMB COLLISIONS IN THE CODE IMPACT-T*

Chad Mitchell† and Ji Qiang
LBNL, Berkeley, CA 94720, USA

Abstract

In intense charged-particle beams, the presence of Coulomb collisions can result in growth of the beam slice energy spread and emittance that cannot be captured correctly using traditional particle-in-cell codes. Particle-particle, particle-mesh solvers take a hybrid approach, combining features of N-body and particle-in-cell solvers, to correctly capture the effect of short-range particle interactions with less computing time than direct N-body solvers. We describe the implementation and benchmarking of such a solver in the code IMPACT-T for beam dynamics applications.

INTRODUCTION

Coulomb collisions can play a significant role in the dynamics of low emittance, high-intensity beams for applications such as high-brightness photoinjectors, electron microscopy, and storage ring light sources [1, 2]. Short-range fluctuations in the fields seen by each particle can result in a growth of emittance and energy spread that is not captured by traditional accelerator particle-in-cell codes, which assume a smooth (mean-field) model of the beam space-charge seen by each particle.

These effects can be captured by N-body solvers that directly compute the Coulomb particle-particle interactions for every particle pair [3]. However, the successful use of these solvers is limited to beams with extremely low bunch charge, since computing times scale as $O(N_p^2)$, where N_p is the number of particles per bunch. In cosmology, plasma physics and molecular dynamics, such collisional many-body problems have been treated successfully [4, 5] using particle codes with improved scaling ($O(N_p \log N_p)$ or better) including tree codes [6] and particle-particle, particle-mesh (P^{3}M) solvers [7]. The application of these methods to charged-particle beams is relatively new in the context of accelerator systems. In this paper, we describe the implementation of a parallel P^{3}M solver in the photoinjector code IMPACT-T [8].

THE P^{3}M SOLVER

The solver is based on the algorithm described in Chapter 8 of [7]. In the reference frame in which the bunch centroid is at rest, the Coulomb force on a particle at location $\mathbf{x}_i$ due to a particle at location $\mathbf{x}_j$ is expressed in terms of the displacement $\mathbf{r}_{ij} = \mathbf{x}_i - \mathbf{x}_j$ as:

$$\mathbf{F}(\mathbf{r}_{ij}) = \frac{q^2 \mathbf{r}_{ij}}{4\pi\epsilon_0 |\mathbf{r}_{ij}|^3} = \mathbf{F}^S(\mathbf{r}_{ij}) + \mathbf{F}^L(\mathbf{r}_{ij}). \quad (1)$$

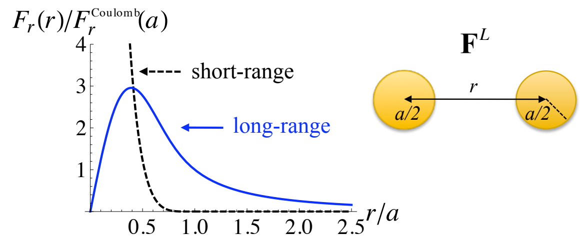

Figure 1: Short-range and long-range contributions to the Coulomb force between two particles (1) for a given cutoff radius a used by a P^{3}M solver in IMPACT-T.

Both $\mathbf{F}^S$ and $\mathbf{F}^L$ are radial forces determined by the interparticle distance $r = |\mathbf{r}_{ij}|$ and a parameter a known as the *cutoff radius*. The long-range contribution $\mathbf{F}^L$ is the smooth, nonsingular force between two spherically-symmetric distributions of charge q and radius $a/2$ whose centroids are separated by distance r, while the short-range contribution $\mathbf{F}^S$ satisfies $\mathbf{F}^S(r) = 0$ for $r > a$. See Figure 1. We use expressions for $\mathbf{F}^S$ and $\mathbf{F}^R$ corresponding to the S2 shape function described in (8-3) of [7].

The net long-range force acting on each particle is computed in the beam rest frame by solving on a mesh for the long-range contribution to the corresponding electric and magnetic fields. This is done using an FFT-based convolution procedure [7, 8]. The net short-range force acting on each particle is computed in the beam rest frame by directly summing the short-range forces due to all other particles in the beam. To reduce computing time, in addition to the potential mesh, a second *chaining cell* mesh is introduced whose cells have side $HC \geq a$. At each timestep, particles are sorted according to chaining cell location. During the short-range force computation, the solver needs to sum only over the subset of particles that lie within the current chaining cell or its nearest neighbors. The long-range and short-range force computations are each parallelized using domain decomposition [4, 5].

The cutoff radius a is typically chosen as 3-4 times the side H of a potential mesh cell. In the limit $a \to 0$ for fixed H, one has $\mathbf{F}^S \to 0$ and the P^{3}M computation is equivalent to a particle-in-cell computation (approximating a mean-field model), while in the limit $a \to \infty$ for fixed H, one has $\mathbf{F}^L \to 0$ and the P^{3}M computation is equivalent to a direct N-body simulation (all collisional effects are included).

CSR INDUCED MICROBUNCHING GAIN ESTIMATION INCLUDING TRANSIENT EFFECTS IN TRANSPORT AND RECIRCULATION ARCS*

C. -Y. Tsai#, Department of Physics, Virginia Tech, VA 24061, USA
D. Douglas, R. Li, and C. Tennant, Jefferson Lab, Newport News, VA 23606, USA

Abstract

The coherent synchrotron radiation (CSR) of a high brightness electron beam traversing a series of dipoles, such as transport or recirculation arcs, may result in the microbunching instability (μBI). To accurately quantify the direct consequence of this effect, we further extend our previously developed semi-analytical Vlasov solver [1] to include more relevant coherent radiation models than the steady-state free-space CSR impedance, such as the entrance and exit transient effects derived from upstream beam entering to and exiting from individual dipoles. The resultant microbunching gain functions and spectra for our example lattices are presented and compared with particle tracking simulation. Some underlying physics with inclusion of these effects are also discussed.

FREE-SPACE CSR IMPEDANCES

For an ultrarelativistic beam traversing an individual dipole, the steady-state CSR impedance in free space can be expressed as [2,3]

$$Z_{CSR}^{ss}\left(k(s);s\right)=\frac{-ik(s)^{1/3}A}{\left|\rho(s)\right|^{2/3}} \tag{1}$$

where $k = 2\pi/\lambda$ is the modulation wave number, ρ is the bending radius, and the constant $A \approx -0.94 + 1.63i$.

Prior to reaching steady-state interaction, the beam entering a bend from a straight section would experience the so-called entrance transient state, where the impedance can be obtained by Laplace transformation of the corresponding wakefield [4,5]

$$Z_{CSR}^{ent}\left(k(s);s\right)=\frac{-4}{s^*}e^{-4i\mu(s)}+\frac{4}{3s^*}\left(i\mu(s)\right)^{1/3}\Gamma\left(\frac{-1}{3},i\mu(s)\right) \tag{2}$$

where $\mu(s) = k(s)z_L(s)$, s^* the longitudinal coordinate measured from dipole entrance, $z_L=\left(s^*\right)^3/24\rho^2$ and Γ the upper incomplete Gamma function.

In addition, there are exit CSR transient effects as the beam exits from a dipole. For the case with fields generated from an upstream electron (at retarded time) propagating across the dipole to downstream straight section, i.e. Case C of Ref. [6], the corresponding impedance can be similarly obtained by Laplace transformation:

$$Z_{CSR}^{exit}\left(k(s);s\right)=\frac{-4}{L_b+2s^*}e^{\frac{-ik(s)L_b^2}{6|\rho(s)|^2}\left(L_b+3s^*\right)} \tag{3}$$

where s^* is the longitudinal coordinate measured from dipole exit and L_b is the dipole length.

Instead of performing Laplace transformation of the wakefield expression for the case with fields generated from an electron (at retarded time) within a dipole propagating downstream the straight section, here we use Bosch's expression [7] for the exit transient impedance:

$$Z_{CSR}^{drif}(k(s);s)\approx\begin{cases}\frac{2}{s^*},\ \text{if}\ \rho^{2/3}\lambda^{1/3}\le s^*\le\lambda\gamma^2/2\pi\\ \frac{2k(s)}{\gamma^2},\ \text{if}\ s^*\ge\lambda\gamma^2/2\pi\\ 0,\ \text{if}\ s^*<\rho^{2/3}\lambda^{1/3}\end{cases} \tag{4}$$

where s^* is the longitudinal coordinate measured from dipole exit. This expression assumes the exit impedance comes primarily from coherent edge radiation in the near-field region (i.e. $z < \lambda\gamma^2$), and in our simulation we only include such transient effects [Eq. (3) and (4)] right after a nearest upstream bend. Here we note that these CSR models are valid only when the wall shielding effect is negligible. The wall shielding effect becomes important when the distance from the beam orbit to the walls h is to satisfy $h\le\left(\rho\lambda^2\right)^{1/3}$. We further note that the above impedance models, Eqs. (1-3), assume the beam is at ultrarelativistic energy. It is interesting to examine how the above models deviate for non-ultrarelativistic beams, and this is currently under study in parallel [8].

NUMERICAL METHODS

To quantify the μBI in a single-pass system, we would estimate the microbunching amplification factor G (or, gain) by two methods. One is to solve the linearized Vlasov equation [9] using given impedance models [e.g. Eqs. (1-4)]. The other, served as a benchmarking tool, is by ELEGANT tracking [10,11]. For the former, we actually solve the general form of Volterra integral equation [9,12]

$$g_k(s)=g_k^{(0)}(s)+\int_0^s K(s,s')g_k(s')ds' \tag{5}$$

where the kernel function is particularly expressed as

$$K(s,s')=\frac{ik}{\gamma}\frac{I(s)}{I_A}C(s')R_{56}(s'\to s)Z\left(kC(s'),s'\right)\times[\text{Landau damping}] \tag{6}$$

for the [Landau damping] term

$$[\text{Landau damping}]=\exp\left\{\frac{-k^2}{2}\left[\varepsilon_{x0}\left(\beta_{x0}R_{51}^2(s,s')+\frac{R_{52}^2(s,s')}{\beta_{x0}}\right)+\sigma_\delta^2R_{56}^2(s,s')\right]\right\} \tag{7}$$

with

$R_{56}(s'\to s)=R_{56}(s)-R_{56}(s')+R_{51}(s')R_{52}(s)-R_{51}(s)R_{52}(s')$ and $R_{5i}(s,s')=C(s)R_{5i}(s)-C(s')R_{5i}(s')$. Here the kernel function $K(s,s')$ describes CSR effect, $g_k(s)$ the resultant bunching factor as a function of the longitudinal position

PROPOSED CAVITY FOR REDUCED SLIP-STACKING LOSS

J. Eldred, Department of Physics, Indiana University, Bloomington, IN 47405, USA
R. Zwaska, FNAL, Batavia, IL 60510, USA

Abstract

This paper employs a novel dynamical mechanism to improve the performance of slip-stacking. Slip-stacking in an accumulation technique used at Fermilab since 2004 which nearly double the proton intensity. During slip-stacking, the Recycler or the Main Injector stores two particles beams that spatially overlap but have different momenta. The two particle beams are longitudinally focused by two 53 MHz 100 kV RF cavities with a small frequency difference between them. We propose an additional 106 MHz 20 kV RF cavity, with a frequency at the double the average of the upper and lower main RF frequencies. In simulation, we find the proposed RF cavity significantly enhances the stable bucket area and reduces slip-stacking losses under reasonable injection scenarios. We quantify and map the stability of the parameter space for any accelerator implementing slip-stacking with the addition of a harmonic RF cavity.

INTRODUCTION

Slip-stacking is integral to high-intensity operation at Fermilab and will likely play a central role in upgrades to the accelerator complex [1–3]. Particle loss in the slip-stacking process is a limiting factor on ultimate performance [1,4]. Single-particle dynamics associated with slip-stacking contribute directly to the particle losses. Our previous work [5] has introduced new tools for characterizing the stable phase-space boundary of slip-stacking and evaluating particle loss in slip-stacking scenarios. A recommendation provided in this work, an upgrade of the Booster cycle-rate from 15-Hz to 20-Hz, has subsequently been incorporated into the Proton Improvement Plan (PIP-II) [1,6]. In this paper, we propose the addition of a new 106 MHz 20 kV RF cavity to further reduce particle losses from the single-particle longitudinal dynamics of slip-stacking.

BACKGROUND

Slip-stacking is a particle accelerator configuration that permits two high-energy particle beams of different momenta to use the same transverse space in a cyclic accelerator (see [7] and [4]). The potential beam intensity of a synchrotron is doubled through the application of this technique. The two beams are longitudinally focused by two RF cavities with a small frequency difference between them. Each beam is synchronized to one RF cavity and perturbed by the other RF cavity. The proposed harmonic RF cavity has a frequency equal to twice the average of the upper and lower frequency.

This paper follows the research program outlined in [5]. Prior work in the single-particle dynamics of slip-stacking can be found in [8–10]. Fermilab has implemented slip-stacking operationally since 2004 [4,10,11] and is currently applied to neutrino production for Neutrinos at Main Injector (NuMI) experiments [12–14].

Beam-loading effects can impact the effectiveness of slip-stacking. A summary of beam-loading research can be found in [5] and draws upon work on beam-loading conducted for the slip-stacking in the Fermilab Main Injector [15–18].

STABILITY WITH HARMONIC RF

The equations of motion for a single particle under the influence of two main RF cavities with frequencies separated by Δf and a harmonic RF cavity at twice the average frequency is given by:

$$\begin{aligned} \dot{\phi} &= 2\pi f_{rev} h\eta\delta \\ \dot{\delta} &= f_{rev} V_\delta [\sin(\phi) + \sin(\phi - \Delta f t) + \lambda \sin(2\phi - \Delta f t)]. \end{aligned} \tag{1}$$

where V_δ is the maximum change in δ during a single revolution under the action of a single cavity [19] and λ is the ratio of the harmonic RF voltage to the main RF voltage.

Broadly speaking, slip-stacking is complicated by the fact that the two RF systems will interfere and reduce the stable bucket area. To quantify this, the literature [5,8–10] has identified the importance of the slip-stacking parameter

$$\alpha_s = \frac{\Delta f}{f_s} \tag{2}$$

as the criterion for effective slip-stacking. Here f_s is the single-RF synchrotron frequency (see [20]). The further the buckets are away from each other in phase-space, the higher α_s is and the less interference there is. Our numerical simulation results show that a negative value of λ (bunch-lengthening mode) can counteract the interference effect that arises as the α_s decreases.

We create a stability map [5] for each value of the slip-stacking parameter α_s and the harmonic voltage ratio λ. We map the stability of initial particle positions by integrating the equations of motion for each initial position. Each position is mapped independently and only the single particle dynamics are considered. A particle is considered lost if its phase with respect to each of the first RF cavity, the second RF cavity, and the average of the two RF cavities, is larger than a certain cut-off (we used $3\pi/2$). Figure 1 shows an example of a stability without a harmonic RF cavity and with a harmonic RF cavity.

The bucket area is computed as the product of the total number of ultimately surviving points and the cell area. The slip-stacking area factor $F(\alpha_s, \lambda)$ is the defined to be the ratio between the slip-stacking bucket area to that of a single-

ELECTRON CLOUD MEASUREMENTS IN FERMILAB MAIN INJECTOR AND RECYCLER

J. Eldred, Department of Physics, Indiana University, Bloomington, IN 47405, USA
M. Backfish, C. Y. Tan, R. Zwaska, FNAL, Batavia, IL 60510, USA

Abstract

This conference paper presents a series of electron cloud measurements in the Fermilab Main Injector and Recycler. A new instability was observed in the Recycler in July 2014 that generates a fast transverse excitation in the first high intensity batch to be injected. Microwave measurements of electron cloud in the Recycler show a corresponding dependence on the batch injection pattern. These electron cloud measurements are compared to those made with a retarding field analyzer (RFA) installed in a field-free region of the Recycler in November. RFAs are also used in the Main Injector to evaluate the performance of beampipe coatings for the mitigation of electron cloud. Contamination from an unexpected vacuum leak revealed a potential vulnerability in the amorphous carbon beampipe coating. The diamond-like carbon coating, in contrast, reduced the electron cloud signal to 1% of that measured in uncoated stainless steel beampipe.

BACKGROUND

Electron cloud instabilities have been observed in a variety of modern proton accelerators [1–5]. Electron cloud was first observed in the Fermilab Main Injector in 2006 [6] and in the Fermilab Recycler in 2014 [7].

During the build-up of electron cloud, the particle beam causes the transverse acceleration of stray electrons which then scatter additional electrons from the beampipe. The number of electrons increase exponentially until a saturation is reached. The secondary electron yield (SEY) of a surface is the ratio of the average number of electrons scattered from the surface to the number of electron impacting the surface. The density of the electron cloud depends critically on beam intensity and SEY of the inner surface of the beampipe [8–10].

ELECTRON CLOUD MEASUREMENTS IN FERMILAB RECYCLER

Beginning in July 2014, a fast intensity-induced transverse instability was observed in the Recycler and limited operation until November. The instability has the unusual feature of selectively impacting the first high-intensity batch. A detailed description of the instability is given in [7]. The threshold of the instability is sensitive to batch intensity and bunch length, but recent studies in the Recycler demonstrated that the threshold of the instability was not sensitive to the azimuthal spacing of batches. Consequently, the prevailing theory is that the instability is caused by the electron cloud that is trapped [11, 12] in the gradient focusing dipoles of the Recycler [13]. In response to the instability, the electron cloud in the Recycler has been measured by retarding field analyzers (RFAs) and the dispersion of microwaves.

Microwave Measurements of the Recycler

The presence of electron cloud was measured in the Recycler by transmitting a microwave signal between a pair of two “split-plate” BPMs [14]. These studies follow the technique implemented in the Main Injector by Crisp et. al. in [15] and also by others elsewhere [16–18].

The first microwave measurement in the Recycler was conducted on August 20, 2014 by temporarily repurposing two Recycler BPMs (VP201 and VP203). During this measurement, the first batch was operating at an intensity of $\sim 3.6e12$ and subsequent batches at an intensity of $\sim 4.5e12$ per batch. During the pre-scheduled shutdown period from September 5 to October 23, spare Recycler BPMs (VP130 and VP202) were dedicated to the microwave experiment on a permanent basis. The second microwave measurement of the Recycler was conducted on December 18, 2014 using the new measurement location. At this time, the beampipe in the Recycler had conditioned and the instability no longer limited the operation of the Recycler. During the second measurement, the six batches each had an intensity of $\sim 4.4e12$.

A schematic of the electronic setup used for these studies is shown in Figure 1. The use of split-plate BPMs as improvised microwave antennas results in a ~ -80 dB transmission loss. Due to differences in the transmission spectrum at the two measurement locations [19], the second measurement was made at a carrier frequency of 2.060 GHz whereas the first measurement was made at 1.977 GHz.

The density of the electron cloud is modulated by the revolution harmonics of the proton beam (~90 KHz) and therefore the carrier frequency is phase-modulated (PM) in the presence of the electron cloud. Consequently, the electron cloud signal is seen as 90kHz sidebands on either side of the carrier frequency [7, 15]. The contribution that each batch makes to the sideband is $2\pi/7$ out of phase with the contribution made by the adjacent batch. This creates a possible ambiguity between changes in the density of the electron cloud and changes in the distribution of the electron cloud.

Figure 2 and Figure 3 show the first and second microwave measurement of the Recycler respectively. Each figure plots the average spectral power of the lower sideband frequency as a function of time within the Recycler cycle. The sharp feature in the beginning of each batch injection is composed of several sharp peaks, each declining in height with respect to the previous peak. The peaks are spaced at half-synchrotron period intervals and coincide with the minimums of the bunch length oscillation. The peaks in the

CHROMATICITY & DISPERSION IN NONLINEAR INTEGRABLE OPTICS*

S. D. Webb†, D. L. Bruhwiler, RadiaSoft, LLC, Boulder, CO 80304, USA
S. Nagaitsev, A. Valishev‡, Fermilab, Batavia, IL 60510, USA
V. V. Danilov, Oak Ridge National Lab, Oak Ridge, TN 37831, USA

Abstract

Proton accumulator rings and other circular hadron accelerators are susceptible to intensity- driven parametric instabilities because the zero-current charged particle dynamics are characterized by a single tune. Landau damping can suppress these instabilities, which requires energy spread in the beam or introducing nonlinear magnets such as octupoles. However, this approach reduces dynamic aperture. Nonlinear integrable optics can suppress parametric instabilities independent of energy spread in the distribution, while preserving the dynamic aperture. This novel approach promises to reduce particle losses and enable order-of-magnitude increases in beam intensity. In this paper we present results, obtained using the Lie operator formalism, on how chromaticity and dispersion affect particle orbits in integrable optics. We conclude that chromaticity in general breaks the integrability, unless the vertical and horizontal chromaticities are equal. Because of this, the chromaticity correcting magnets can be weaker and fewer correcting magnet families are required, thus minimizing the impact on dynamic aperture.

INTRODUCTION

Nonlinear integrable optics [1] is a concept for mitigating collective instabilities in intense beams using specially designed magnetic elements which introduce large tune spreads with integrable, bounded motion. The lattices which use nonlinear integrable optics are fundamentally different from conventional uses of strong focusing. In conventional strong focusing lattices, nonlinearities introduced by, for example, octupoles for Landau damping are small perturbations on the overall linear dynamics. This is to minimize their impact on the dynamic aperture. For lattices using nonlinear integrable optics, the nonlinear elliptic potential is a dominant part of the dynamics which introduces a large tune spread. This requires particular design considerations to implement properly.

The design of these lattices requires special considerations to ensure that the dynamics remains as close to integrable as possible. In the original treatment of this work, which considers transverse dynamics in the absence of collective effects and zero energy spread, the lattice required a drift section with equal vertical and horizontal beta functions. This was the first design consideration for a nonlinear integrable lattice.

In this proceeding we introduce two additional design criteria based on a study of off-momentum dynamics. Using a Lie map [2] formalism, we derive an expression for the single turn transfer map including the elliptic potential and chromatic and linear dispersive effects. As a result of this calculation, we conclude that chromaticity serves to both modify the invariants and, if not carefully managed, ruin the integrability. Similarly, dispersion through the elliptic element drift breaks the invariant potential. Because the calculations are too elaborate for this proceeding, we here simply state the key results. The detailed work may be found in [3].

BERTRAND-DARBOUX EQUATION

Because the specific conditions of the Bertrand-Darboux equation [4, 5] are critical for understanding the conclusions of this work, we summarize the results here. This is a partial differential equation for a two-dimensional potential $V(x, y)$ which has an invariant of the motion quadratic in the momenta. That is, the Hamiltonian $H = {}^1\!/_2(p_x^2 + p_y^2) + V(x, y)$ has a second invariant (aside from the Hamiltonian itself) given by the form

$$\begin{aligned} I = p_x^2 A(x, y) + p_y^2 B(x, y) + p_x p_y C(x, y) + \dots \\ \dots + p_x D(x, y) + p_y E(x, y) + F(x, y). \end{aligned} \tag{1}$$

First, and importantly, we note that H is isotropic in the momenta – the coëfficients of p_x and p_y are equal. This is not generally true; a Hamiltonian for a ring with different vertical and horizontal tunes will have differing coëfficients.

The resulting Bertrand-Darboux differential equation is given by

$$\begin{aligned} xy\left(\frac{\partial^2 V}{\partial x^2} - \frac{\partial^2 V}{\partial y^2}\right) + \dots \\ \dots + (y^2 - x^2 + c^2)\frac{\partial^2 V}{\partial x \partial y} + 3y\frac{\partial V}{\partial x} - 3x\frac{\partial V}{\partial y} = 0. \end{aligned} \tag{2}$$

Here we note two more features required of the potential: (1) that the partial differential equation is linear in V and therefore the sum of any set of potentials V_i which satisfy this will have an associated invariant and (2) that only specifically $x^2 + y^2$ satisfies the differential equation, and not x^2 or y^2 individually. Because of (1), a strong focusing lattice with a nonlinear element can form an integrable potential of this form. Because of (2), said strong focusing lattice must have equal vertical and horizontal tunes, a

EXPERIENCES SIMULATING NONLINEAR INTEGRABLE OPTICS*

S.D. Webb†, D.L. Bruhwiler, R. Kishek, RadiaSoft, LLC, Boulder, CO 80304, USA
S. Nagaitsev, A. Valishev, Fermilab, Batavia, IL 60510, USA
V.V. Danilov, Oak Ridge National Lab, Oak Ridge, TN 37831, USA

Abstract

With increasing interest in the nonlinear integrable optics, it is important that early experiences with simulating the lattices be shared to save time and point out potential difficulties in the simulations. We present here some details of simulating the nonlinear integrable lattices. We discuss correctly implementing and testing the elliptic element kicks, and the limits of the thin lens approximation. We also discuss generating a properly matched bunch in the transverse phase space, and how to analyze the resulting computational data from simulations.

INTRODUCTION

Nonlinear integrable optics [1] is a concept for mitigating collective instabilities in intense beams. It has generated considerable interest in the field, and multiple groups and institutions have begun contributing to the research. Because of the novel form of the potential, they require special considerations for beam matching, calculating the kick in a drift-kick symplectic tracking code, and analyzing the results of simulations.

At the moment, the nonlinear element is implemented and benchmarked in Synergia [2], LIFETRAC, PyORBIT [3], and MAD-X [4] by way of PTC [5]. Please contact the authors if you plan to implement the nonlinear element in your tracking code. As the collaboration grows and the number of implementations expands, it is important to keep track of updates and changes and compare computational results. By sharing post-processing scripts and source code, we hope to minimize the redundant effort required for new researchers to begin studying nonlinear integrable optics.

MATCHED DISTRIBUTIONS

The Hamiltonian described by eqns. (10) and (18) in the original paper by Danilov and Nagaitsev [1] is an invariant of the single-particle motion in a nonlinear integrable lattice. As is well-known, any distribution which is a pure function of the invariants is itself an invariant of the motion – it is a matched beam. Any computational study of a nonlinear integrable lattice must start with, at the minimum, a beam properly matched in the transverse direction including the elliptic potential. Early attempts at simple linear matching showed severe mismatch in the nonlinear lattice, leading to large excursions of single particle orbits.

The Hamiltonian in the normalized coördinates is given by

$$\mathcal{H} = \frac{\hat{p}_x^2}{2} + \frac{\hat{p}_y^2}{2} + \frac{\hat{x}^2}{2} + \frac{\hat{y}^2}{2} + t\mathcal{U}(\hat{x}, \hat{y}) \qquad (1)$$

where $\mathcal{U}$ is the normalized elliptic potential given by eqn. (18) of [1]. Here, the overhat denotes the usual Courant-Snyder normalization of the momenta and coördinates. Thus, a function of $\mathcal{H}$ will be matched to a lattice with zero collective effects and zero longitudinal-transverse coupling (i.e. the zero chromaticity limit).

The generalization of the Kapchinskij-Vladimirskij distribution [6] is a delta function in the generalized emittance $f(\varepsilon) = \delta(\varepsilon - \varepsilon_0)$ for a beam where every particle has its Hamiltonian equal to a single emittance, $\mathcal{H}_i = \varepsilon_0$. To generate this delta function distribution, it is convenient to pick a magnitude of the transverse momentum, $\hat{p}_0$, at random, limited to the range $\hat{p}_0 \in [0, \sqrt{2\varepsilon_0})$. Then, solve for $\hat{x}$ and $\hat{y}$ in the nonlinear equation

$$\frac{1}{2}\left(\hat{x}^2 + \hat{y}^2\right) + t\mathcal{U}(\hat{x}, \hat{y}) = \varepsilon_0 - \frac{\hat{p}_0^2}{2} \qquad (2)$$

One method of doing this is to pick an angle at random from $\theta \in [0, 2\pi)$ and solve for the radius using a numerical root finding algorithm. Another method, what we call the “lemming method”, is to pick random values of $\hat{x}$ and $\hat{y}$ from inside some bounding box and walk the point in $\hat{x}$ at fixed $\hat{y}$ until it solves the origin. Either method should generate a uniform distribution in the $\hat{x} - \hat{y}$ plane, filling the isoenergetic contours in Fig. (1).

To generate a general distribution in $\mathcal{H}$, generate the distribution as a Riemann sum of delta functions on the desired distribution function. Thus, $f(\varepsilon)$ is a Riemann sum of K-V distributions. Specifically, consider the unit-normalized distribution $f(\varepsilon)$, such that

$$\int_0^\infty d\varepsilon\; f(\varepsilon) = 1 \qquad (3)$$

and a total of N particles. Then on a finite interval from $\varepsilon' - \Delta\varepsilon/2$ to $\varepsilon' + \Delta\varepsilon/2$, there will be $N f(\varepsilon')\Delta\varepsilon$ total particles. If there are $N_{\text{macro.}}$ macroparticles with weight w, then there will be $N_{\text{macro.}} w f(\varepsilon')$ macroparticles with $\mathcal{H} = \varepsilon'$. Thus, a way to generate the arbitrary distribution $f(\varepsilon)$, we can approximate this with a large number of KV distributions with the proper number of macroparticles in each sub-distribution.

To invert the generated coördinates to real coördinates, generate a uniformly random angle θ for the momentum and

MULTISYMPLECTIC INTEGRATORS FOR ACCELERATOR TRACKING CODES*

S. D. Webb†, D. L. Bruhwiler, RadiaSoft, LLC, Boulder, CO 80304, USA

Abstract

It has been long understood that long time single particle tracking requires symplectic integrators to keep the simulations stable. In contrast, space charge has been added to tracking codes without much regard for this. Indeed, multisymplectic integrators are a promising new field which may lead to more stable and accurate simulations of intense beams. We present here the basic concept, through a spectral electrostatic field solve which is suitable for adapting into existing tracking codes. We also discuss the limitations of current algorithms, and suggest directions for future development for the next generations of high intensity accelerators.

INTRODUCTION

Integrating single-particle orbits in storage rings using symplectic integration has been a staple of the accelerator field for decades[1]. The fundamental idea of symplectic integrators is: if the continuous equations of motion derive from an action principle, then so too should their discretization.

Keeping in this idea, recent work in the plasma-based accelerator field [2, 3] has expanded on early work [4, 5, 6] generalizing the idea of symplectic integration to field theories such as Maxwell's equations. Conventional particle-in-cell algorithms have discretized the particle motion and field solvers individually, then used charge deposition and force interpolation to enforce energy or momentum conservation. The difficulty with this approach is that conservation laws are encoded in the action principle, and arise from Noether's Theorem. Thus, momentum or energy conservation should be a natural result of the discretization of the continuum Lagrangian, not an *ad hoc* addition to impose certain physical constraints.

These ideas have a clear application to studying beam physics with intense space charge, or other dynamical effects over the long term. One can roughly understand non-symplectic versus symplectic integrators as being similar to secular versus canonical perturbation theory. In the secular theory, the expansion over a parameter ε is only valid for small times, so that $|\varepsilon t| \ll 1$. Canonical perturbation theory is valid for all time, so long as ε is small. As applied to accelerators, this means that a non-symplectic integrator will only give reliable results over time scales short compared to the space-charge tune shift (for example). Thus, a non-symplectic space charge simulation is likely only reliable for $n \propto (\Delta Q_{\text{SC}})^{-1}$ turns, with additional scaling for the step size such that $n \to \infty$ as $h \to 0$.

We here present the basic concepts of multisymplectic integration using a Lagrangian approach. We discuss this first schematically, then using a specific example – a spectral electrostatic particle-in-cell algorithm. We conclude with a discussion of future work required to implement these ideas in accelerator tracking codes.

MULTISYMPLECTIC INTEGRATION

The current literature in the field deals primarily with Lagrangians, as the plasma physics community generally thinks in terms of the tangent space (position and velocity) rather than the cotangent space (coördinates and momenta). However, the geometric structures (symplectic 2-form, conserved momenta, etc.) have a clear translation between Lagrangian and Hamiltonian treatments, so the basic principles will be the same.

The so-called Low Lagrangian [7] can be written generally as

$$\begin{aligned} L = \int d\mathbf{x}_0 d\mathbf{v}_0 \Big[T\left(\frac{\partial \mathbf{x}}{\partial t}(\mathbf{x}_0, \mathbf{v}_0)\right) + \dots \\ \dots - q\varphi + \frac{q}{c}\frac{\partial \mathbf{x}}{\partial t}\cdot \mathbf{A}\Big] f(\mathbf{x}_0, \mathbf{v}_0) + \dots \\ \dots + \frac{1}{16\pi}\int d\mathbf{x} F_{\mu\nu}F^{\mu\nu} \end{aligned} \tag{1}$$

where T is the kinetic energy term and $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the antisymmetric electromagnetic tensor. We note that the conservation of phase space density implies that $f(\mathbf{x}_0, \mathbf{v}_0) = f(\mathbf{x}, \mathbf{v}, t)$. Variation with respect to the individual vector potential components A, and the position $\mathbf{x}$, lead to the familiar Lorentz force law and Maxwell's equations, assuming we are using the conventional coördinate systems (Cartesian, cylindrical, spherical...). The specific application for accelerator coördinates will diverge from these familiar forms.

The first step in discretizing this Lagrangian is to discretize the spatial components of the fields. Thus, each component of the 4-vector potential

$$A = \sum_\sigma \Psi_\sigma(\mathbf{x}) a_\sigma(t) \tag{2}$$

over some set of indices σ. These could be finite elements, structured finite elements (which lead to finite difference equations), Fourier decompositions, eigenmodes formulations, or a variety of other possibilities. Similarly, we dis-

SIMULATIONS OF DIAMOND DETECTORS WITH SCHOTTKY CONTACTS*

G. I. Bell†, D. Dimitrov, S. Zhou, D. Meisner, J. Cary, D. Smithe, Tech-X Corp, Boulder, CO, 80303, USA
J. Smedley, Brookhaven National Lab, Upton, NY, 11973, USA
E. Muller, M. Gaowei, Stony Brook University, Stony Brook, NY, 11794, USA

Abstract

We present simulations of semiconductor devices using the code VSim (formerly Vorpal). The 3D simulations involve the movement and scattering of electrons and holes in the semiconductor, voltages which may be applied to external contacts, and self-consistent electrostatic fields inside the device. Particles may experience a Schottky barrier when moving between the semiconductor and a metal contact. Example devices include MOSFETs as well as a diamond X-ray detector. Our code VSim includes scattering models for GaAs and diamond, and runs in parallel on thousands of processors. We compare our simulation results with experimental results from a prototype diamond X-ray detector.

INTRODUCTION

Diamond is a promising material for use in X-ray and particle detectors [1]. Figure 1 shows the experimental

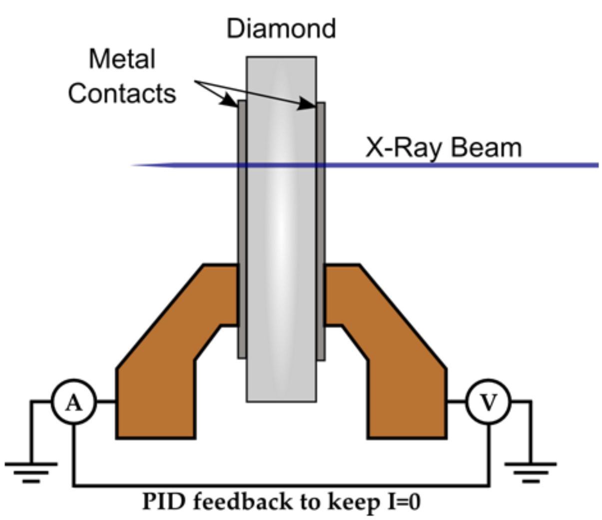

Figure 1: Schematic of an experimental X-ray detector.

setup, using a thin sheet of diamond 90 μm thick. When an X-ray photon passes through this thin diamond sheet, it may be absorbed, creating an electron-hole pair. The electron and hole scatter inelastically in diamond, creating many more secondary electrons and holes. Further relaxation of low energy charge carriers is dominated by scattering with phonons.

If a voltage bias is applied between the metal contacts, the generated electrons and holes drift in opposite directions and become separated. Diffusion also affects both charge carriers, and with the voltages applied experimentally (up to 8 V across the metal contacts) the effects of drift and diffusion are similar in magnitude. A charge carrier will drift at a constant rate due to the applied field, while the average distance traveled as a result of diffusion scales as the square root of the elapsed time. When these charge carriers reach the metal contacts, they may be absorbed, generating a net current. In order to reach the metal contacts, electrons and holes must cross a potential barrier.

Modeling this detector requires that we resolve widely disparate time scales. In order to accurately model the high-energy electrons produced in the initial X-ray absorption, we must resolve the mean time between inelastic collisions, on the order of 10^{-17} seconds. On the other hand the low energy electrons and holes interact with phonons much less frequently, about once every 10^{-14} seconds. Finally, the time needed for an electron or hole to drift or diffuse across 90 μm is around 10^{-8} seconds (10 ns). There are nine orders of magnitude between the smallest time scale of the simulation and the final time, so we can't simulate all these processes for 10 ns.

In contrast to the experiments, in these simulations we consider the delta-function response of the detector to a single photon—or, for better statistics, many photons all absorbed by the device at time $t = 0$.

SIMULATION OF A DIAMOND DETECTOR WITHOUT BARRIERS

In order to understand the role played by a Schottky barrier (which can prevent charge carriers from exiting through the metal contacts) we first simulate a diamond detector without barriers.

Our 3D simulations of the diamond detector use a domain of size $90 \times 20 \times 20$ μm, and we use periodic boundaries in y and z. The electrostatic field is calculated at each time step by doing a Poisson solve based on the current charge density, with boundary conditions in x using the applied voltage difference.

We consider 500 photons, each with an energy of 3 KeV, and absorbed by the diamond detector at $t = 0$. In diamond 3 KeV X-rays have an absorption length of 31.6 μm [2]. In order to determine the initial x position of the primary elec-

MODELING ELECTRON EMISSION AND SURFACE EFFECTS FROM DIAMOND CATHODES*

D. A. Dimitrov, J. R. Cary, D. Smithe, C. Zhou, Tech-X Corp., Boulder, CO 80303, USA
I. Ben-Zvi, T. Rao, J. Smedley, E. Wang, BNL, Upton, NY 11973, USA

Abstract

We developed modeling capabilities, within the Vorpal particle-in-cell code, for three-dimensional (3D) simulations of surface effects and electron emission from semiconductor photocathodes. They include calculation of emission probabilities using general, piece-wise continuous, space-time dependent surface potentials, effective mass and band bending field effects. We applied these models, in combination with previously implemented capabilities for modeling charge generation and transport in diamond, to investigate the emission dependence on applied electric field in the range from approximately 2 to 17 MV/m along the [100] direction. The simulation results were compared to experimental data when using different emission models, band bending effects, and surface-dependent electron affinity. Simulations using surface patches with different levels of hydrogenation lead to the closest agreement with the experimental data.

INTRODUCTION

High-average current and high-brightness electron beams are needed in advanced applications such as ultra-high Free-Electron Lasers, electron cooling of hadron accelerators, and Energy-Recovery Linac light sources. Semiconductor cathodes with negative electron affinity are known [1] to have good quantum efficiency (QE) (10% achieved experimentally) properties. To address the high brightness requirements for these applications, a new design for a photoinjector with a diamond amplifier was proposed [2] and is currently being investigated (see, e.g. [3–5] and references therein).

The operation of the diamond-amplifier cathode consists of using first a primary beam of electrons, accelerated to about 10 keV, (or photons with similar energies) to impact a diamond sample. The energetic primary electrons scatter inelastically generating secondary electrons. These electrons, and their related holes, relax their energies initially by producing more electron-hole pairs and later by scattering with phonons.

In applied electric field, the generated electrons and holes drift in opposite directions and are separated. The secondary electrons are transported towards a diamond surface with a negative electron affinity (NEA). Part of these electrons are then emitted into the accelerating cavity of an electron gun. The NEA is used to enhance the emission. Two orders of magnitude charge amplification (number of emitted electrons relative to the number of injected primary ones) has been observed in different experiments [4,5].

* We are grateful to the U.S. DoE Office of Basic Energy Sciences for supporting this work under grants DE-SC0006246 and DE-SC0007577.

Investigation of the phenomena involved in using diamond for generation of amplified electron beams via simulations requires modeling of secondary electron generation, charge transport, and electron emission. We have now implemented models for these processes in the Vorpal computational framework [6, 7].

MODELING ELECTRON EMISSION

The overall modeling approach involves three main steps shown in the simplified digram in Fig. 1. First, creation of (secondary) electrons in the conduction band and holes in the valence band is started by inelastic scattering with highly energetic primary electrons. Next, the free electrons and holes relax their energies via inelastic scattering (creating more electron-hole pairs and/or emission/absorption of phonons). Field is applied causing electrons to drift towards the band bending region (BBR) that ends with a (usually hydrogenated) negative electron affinity surface. In the final step, the electrons are emitted or reflected when they attempt to cross the diamond-vacuum interface.

For the secondary electron generation, we used our implementation of the Tanuma–Powell-Penn model. For modeling charge transport, we used a Monte Carlo approach. Detailed description of these modeling capabilities is provided in Ref. [6]. Recently, we implemented several emission mod-

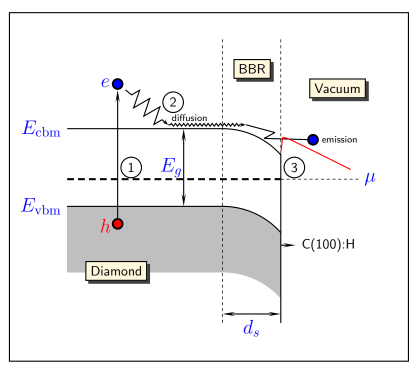

Figure 1: Three main processes are modeled: electron-hole generation, charge transport, and electron emission from surfaces with different potentials and band bending regions.

els and started using them to study electron emission from semiconductor cathodes [7] (and references therein for use of these models to investigate electron emission from GaAs). For the results presented here, we used our implementation of the transfer matrix (TM) model for calculation of emission probabilities and a surface potential energy that includes the effect of the image charge:

$$V(x) = \chi - Fx - Q/x, \tag{1}$$

CURRENT STATUS OF THE GPU-ACCELERATED ELEGANT *

J.R. King, I.V. Pogorelov†, Tech-X Corporation, Boulder, CO 80303, USA
M. Borland, R. Soliday, Argonne National Laboratory, Argonne, IL 60439, USA
K. Amyx, Sierra Nevada Corporation, Centennial, CO 80112, USA

Abstract

Efficient implementation of general-purpose particle tracking on GPUs can result in significant performance benefits to large-scale tracking simulations and direct (tracking-based) accelerator optimization techniques. This paper is an update on the current status of our work on accelerating Argonne National Lab's particle accelerator simulation code ELEGANT using CUDA-enabled GPUs. We summarize the performance of beamline elements ported to GPU, and discuss optimization techniques for some important collective effects kernels. We also present the latest results of scaling studies with realistic lattices of the GPU-accelerated version of the code.

INTRODUCTION

ELEGANT is an open-source, multi-platform code used for design, simulation, and optimization of FEL driver linacs, ERLs, and storage rings [1, 2]. The parallel version, Pelegant [3, 4], uses MPI for parallelization. Several "direct" methods of simultaneously optimizing the dynamic and momentum aperture of storage ring lattices have recently been developed at Argonne [5]. These new methods typically require various forms of tracking the distribution for over a thousand turns, and so can benefit significantly from faster tracking capabilities.

Graphics processing units (GPUs) offer unparalleled general purpose computing performance, at low cost and at high performance per watt, for large problems with high levels of parallelism. Unlike general purpose processors, which devote significant on-chip resources to command and control, pre-fetching, caching, instruction-level parallelism, and instruction cache parallelism, GPUs devote a much larger amount of silicon to maximizing memory bandwidth and raw floating point computation power.

Our main goals for this project are (1) to port a wide variety of beamline elements to GPUs so that ELEGANT users can take advantage of the high performance that GPUs can provide, (2) support CUDA-MPI hybrid parallelism to leverage existing GPU clusters, and (3) maintain 'silent support' so that GPU-accelerated elements can be used without additional input from the user.

* Work supported by the DOE Office of Science, Office of Basic Energy Sciences grant No. DE-SC0004585, and in part by Tech-X Corporation. This research used resources of the Oak Ridge Leadership Computing Facility, which is a DOE Office of Science User Facility supported under Contract DE-AC05-00OR22725.

BEAMLINE ELEMENT PERFORMANCE

In this section we present a list of the particle beamline elements fully ported to the GPU, and rough estimates of their acceleration compared to the reference CPU code, comparing an NVIDIA Tesla K20c GPU to an Intel Core i7-3770K CPU in simulations with a few million particles.

QUAD and DRIFT: Quadrupole and drift elements, implemented as a transport matrix, up to 3^{rd} and 2^{nd} order, respectively: $\sim$ 100x acceleration, achieving particle data bandwidth of 80 gb/s and over 200 GFLOPS in double precision.

CSBEND: A canonical kick sector dipole magnet with exact Hamiltonian (computationally intensive): Nearly 30x acceleration due to its high arithmetic intensity.

KQUAD, KSEXT, MULT: A canonical kick quadrupole, sextupole, and multipole elements using 4^{th} order symplectic integration: 45x acceleration.

EDRIFT: An exact drift element: Roughly 20x acceleration (purely bandwidth bound).

RCOL: Rectangular collimator: 60x acceleration if particles are removed from simulation.

LSCDRIFT: Longitudinal space charge impedance: $\sim$ 45x acceleration using optimized histogram calculation.

CSRCSBEND: A canonical kick sector dipole with coherent synchrotron radiation: Over 50x acceleration using optimized histogram calculation.

RFCW: RF cavity element, a combination of a first-order matrix RF cavity with exact phase dependence (RFCA), longitudinal wake (WAKE) and transverse wake (TRWAKE) specified as a function of time lag behind the particle, and LSCDRIFT: over 30x acceleration, convolution-based wake elements being the primary bottleneck.

SCRAPER: A one-side collimation element: a 14.5x acceleration with intensive random number generation.

MATTER: A Coulomb-scattering and energy-absorbing element simulating material in the beam path: an acceleration of 23x.

OPTIMIZATION OF COLLECTIVE-EFFECTS KERNELS

In this section we briefly summarize some of our results on optimization of the collective-effects elements. A more detailed discussion can be found in [6].

Histogram Computation

Most collective effects elements in ELEGANT require computing a histogram, which is difficult on a GPU because of the thread contention problem. Thread-safe atomic operations do not provide a practical solution to this problem

ELECTRON CLOUD BUILDUP AND DISSIPATION MODELS FOR PIP-II *

S. A. Veitzer†, Tech-X Corporation, Boulder, CO, 80303 USA
P. H. Stoltz, Tech-X Corporation, Boulder, CO, 80303 USA

Abstract

Buildup of electron plasmas in accelerator cavities can cause beam degradation and limit performance in high-intensity circular particle accelerators. This is especially important in machines such as the LHC, and PIP-II, where mitigation techniques such as beam scrubbing in order to decrease the SEY are expensive and time consuming. Modeling of electron cloud buildup and dissipation can provide understanding as to the potential negative effects of electron clouds on beam properties, as well as estimates of the mitigation required to maintain accelerator performance and beam quality as accelerators move to higher intensity configurations. We report here on simulations of electron cloud buildup and dissipation for geometry, beam and magnetic field configurations describing the Recycler at Fermilab. We perform electrostatic simulations in 3D with VSim PIC, including the effects of space charge and secondary electrons. We quantify the expected survival rate of electrons in these conditions, and argue that improvements in reducing the SEY is unlikely to mitigate the electron cloud effects.

ELECTRON CLOUD SURVIVAL RATE IN CIRCULAR ACCELERATORS

In circular accelerators, electron clouds may build up from very low densities as trains of bunches pass through the accelerator. As each bunch passes, electrons experience the potential of the beam and are accelerated through the center of the beam pipe to the opposite wall. Typically they will gain enough energy to produce secondary electrons, which are in turn accelerated by the next bunch.

This process produces a build up of an electron plasma, which saturates at a density that is some large fraction of the linear charge density of the beam [1], depending on the bunch length and the cross-sectional size of the beam pipe. At saturation, electrons near the beam pipe walls are shielded from the beam potential by other electrons, and are not significantly accelerated to produce more secondaries. Also, electrons that are accelerated by the passing beam encounter space charge due to these electrons and so impact the walls with lower energy, which can reduced overall secondary yields.

Electron clouds dissipate during the period of time when there are no bunches crossing, as they drift to beam pipe walls with energies low enough that they do not produce significant secondary electrons. The dissipation typically occurs very swiftly, with the number of electrons decreasing exponentially. However, without the influence of additional bunch crossings, some electrons will have very low energies, and will drift for long enough that they are present when the first bunch in the beam returns.

ELECTRON CLOUD BUILD UP AND DISSIPATION NUMERICAL MODELS

Electron cloud build up has previously been modeled using a variety of high-performance Particle-In-Cell (PIC) codes, including Vorpal [1–3], WARP coupled with POSINST [4–6] and others. Build up simulations have typically focussed on the saturation density, and dynamics of electron cloud evolution under different magnetic field configurations e.g. [7], and the effects of different wall materials on overall cloud densities e.g. [8]. Here, we focus on the build up and dissipation aspects of electron clouds, in order to understand the survival rate of electrons over more than a single revolution period.

We use the plasma simulation package VSim [9], which employs the Vorpal simulation engine [10] to model electron cloud build up, dynamics, and dissipation. Our models use the following physical parameters, corresponding to the Fermilab Recycler storage ring. We simulate the crossing of 504 Gaussian-shaped bunches (84 bunches per batch and 6 batches per beam) with bunch lengths of 60 cm, bunch spacing of 18.94 ns, beam radius of 3.0 mm, and 5.25×10^{10} protons/bunch. The bunches cross during the first 9.545 μs of the simulation, followed by 1.5265 μs where there is no beam, for a total revolution period of 11.0723 μs.

The beam pipe cross-section is elliptical with major radius $a = 0.047$ m and minor radius $b = 0.022$ m. We simulate $l = 0.50$ m of beam pipe in the longitudinal (beam axis) direction. We apply an external magnetic field that is primarily a dipole field with an additional quadrupole component,

$$
\begin{aligned}
B_x &= 0.0 && (1)\\
B_y &= B_0 + Gz && (2)\\
B_z &= Gy, && (3)
\end{aligned}
$$

where $B_0 = 0.1375$ T and $G = 0.3355$ T/m, x is the longitudinal direction, and y and z are the transverse directions. We seed the simulation with a low-density, randomly distributed electron cloud. We examine the dependence of build up time and saturation density with initial seed density in section below. We use the Furman-Pivi secondary electron yield model [11] for stainless steel, with max(SEY) = 2.05 at a primary energy of $E_{\text{max}} = 292.0$ eV.

SECONDARY ELECTRON YIELD MEASUREMENT AND ELECTRON CLOUD SIMULATION AT FERMILAB

Yichen Ji, Linda Spentzouris, Department of Physics, Illinois Institute of Technology, IL 60616, USA
Robert Zwaska, FNAL, Batavia, IL 60510, USA

Abstract

Fermilab Main Injector is upgrading the accelerator to double the beam intensity from 24e12 protons to 48e12 protons, which brings the accelerator into a regime where electron cloud effects may limit the accelerator performance. In fact, an instability that could be caused by electron cloud effects has already been observed in the Recycler [1, 2].

Secondary Electron Yield (SEY) is an important property of the vacuum chamber material that has great influence on the process of building up free electrons. The Main Injector of the Fermilab accelerator complex offers the opportunity to measure SEY and conditioning effects in the environment of a running accelerator, since samples of these materials are located at the beampipe wall. The SEY of stainless steel (SS316L) and TiN coated SS316L in the proximity of the proton beam were measured and compared.

A series of simulation studies of electron cloud build up were done for the Main Injector and Recycler using the code POSINST. Parametric studies were done to determine the maximum electron density vs. peak SEY at different beam intensities in the Fermilab Main Injector. Threshold simulations of electron cloud density versus SEY were extended from Main Injector to include the Recycler Ring [3]. It was found that the electron cloud density around the beam depends on bunch location within the bunch train.

SEY MEASUREMENT

The Secondary Electron Yield (SEY) measures on average how many electrons are emitted when one electron hits the beam chamber surface. SEY is generally dependent on the incident electron energy, E, and the incident angle, θ. The SEY of different materials and coatings has been studied for many years; however, the effect of the accumulated dose under actual accelerator conditions has only been studed recently [4].

SEY Test Stand

The SEY measurement stand was originally designed and built by Cornell. Modifications were made to adapt it to the Main Injector, reduce background, and improve signal level for the Main Injector tunnel conditions [4, 5].

The measurement stand has two different arms so that two samples can be exposed to the same dose for comparison. The arms are protected by faraday boxes to eliminate leakage current. Each sample is a small curved piece that sits on the vacuum chamber wall. They are retracted from the vacuum chamber on an electrically isolated arm during measurements. Two Kimball Physics ELG-02 electron guns were installed and are directed towards the sample at a 15° angle, which will increase the measured SEY by 1% compared to normal incidence, according to the Furman-Pivi probabilistic model [6]. The electron guns scan over an energy spectrum of 45 eV to 1545 eV with a 1 mm diameter spot on a 3 × 3 grid. A Keithley 6487 pico-Ammeter is used to indirectly measure the SEY of the sample. A bias voltage must be applied during measurements and the pico-Ammeter is also used to apply this bias voltage.

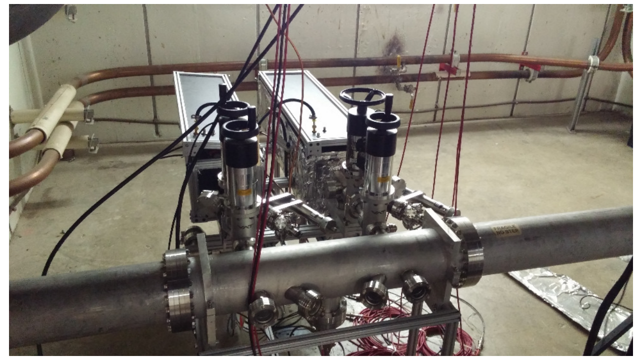

Figure 1: The SEY test stand.

A typical measurement generally takes 6 to 8 hours, which includes transportation of the DAQ-control computer, equipment set-up and warm-up and then the actual measurement. The test stand vacuum vessel is grounded during measurements. The gun was set to to deliver 0.5 to 1.0 nA beam at 300 eV. The primary current I_p is measured by applying a +150 V bias voltage that recaptures all secondary electrons. The total current I_t is measured by applying -20 V that repels all low energy secondary electrons. Then the secondary emission current is given by $I_{SEY} = I_t - I_p$. The SEY can be calculated by the following equation.

$$SEY = \frac{I_{SEY}}{I_p} = \frac{I_t - I_p}{I_p} \tag{1}$$

Leakage Current

Due to the low signal current measured, the bias voltage induced leakage current can cause a very high background during a measurement. The leakage current can reach as high as tens of nano-Amperes and must be compensated when calculating the SEY from the data. High leakage current generally occurred when the ceramic (used to isolate the vacuum vessel from the sample) got wet due to moisture from the surrounding atmosphere, or there were excessive vibrations around the testing stand, or current leakage from the wire to the faraday box. The following modifications were made to control the leakage current:

1. Implementation of a faraday box.

ANALYSIS OF BEAM TRANSVERSE INSTABILITIES AT FERMILAB

T. Zolkin*, The University of Chicago, Chicago, IL 60637, USA

Abstract

The transverse beam dynamics in Fermilab Recycler ring has been analyzed using *SCHARGEV* Vlasov solver. In the first part of paper we discuss how *SCHARGEV* analyses collective instabilities for Gaussian bunch with strong space charge in resistive impedance environment. In the second part the bunched beam dynamics is studied depending on head-tail phase and damper gain. An example for Fermilab Recycler is presented.

SSC THEORY AND BUROV EQUATION

For transverse oscillations of bunched beams, a parameter of the space charge strength is a ratio of the maximal space charge tune shift to the synchrotron tune. When this parameter is large, the transverse oscillations are described by a one-dimensional integro-differential **Burov equation**

$$\nu\, y + \frac{1}{Q_{\rm eff}}\frac{\mathrm{d}}{\mathrm{d}\,\tau}\left(u^2\frac{\mathrm{d}\,y}{\mathrm{d}\,\tau}\right) = \varkappa\, N\left(\hat{W}+\hat{D}\right), \quad \left.\frac{\mathrm{d}\,y}{\mathrm{d}\,\tau}\right|_{\tau\to\pm\infty} = 0,$$

derived in [1]. *SCHARGEV* Vlasov solver is based on numerical solution of the equation above and for more details see [2].

Below we will consider the case of Gaussian bunch which corresponds to a thermal equilibrium when the bunch length is much shorter than the rf wavelength [3]. In this case the Sturm-Liouville problem for no-wake case leads to the **Burov-Balbekov functions** [1, 4]:

$$\begin{cases} \bar{y}''(\tau) + \nu\, e^{-\tau^2/2}\,\bar{y}(\tau) = 0, \\ \bar{y}'(\pm\infty) = 0, \end{cases}$$

where the natural system of units is employed: the distance τ is measured in units of the RMS bunch length σ, and, eigenvalues ν_k is measured in units of $u^2/\sigma^2 Q_{\rm eff}(0) = Q_s^2/Q_{\rm eff}(0)$. First eight eigenfunctions, $\bar{y}_k(\tau)$, are plotted in Fig. 1.

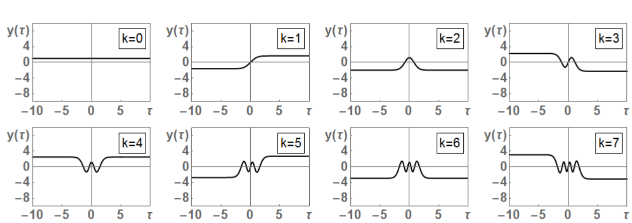

Figure 1: The first 8 eigenfunctions of the Gaussian bunch, $\bar{y}_k(\tau)$. The modes do not depend on the chromaticity, except the common head-tail phase factor $\exp(-i\zeta\tau)$.

* zolkin@uchicago.edu

DIPOLE MOMENTS AND DAMPER

For further discussion we need to introduce the bunch dipole moments defined as functions of the head-tail phase:

$$I_k(\zeta) = \int_{-\infty}^{\infty} \rho(\tau)\bar{y}_k(\tau)e^{i\zeta\tau}\,\mathrm{d}\tau : \quad I_k^*(\zeta) = (-1)^k I_k(\zeta),$$

where $\rho(\tau) = \int_{-\infty}^{\infty} f(v,\tau)\,\mathrm{d}v = (2\pi)^{-1/2}\exp(-\tau^2/2)$ is the normalized line density of the beam. First four of them are plotted in Fig. 2.

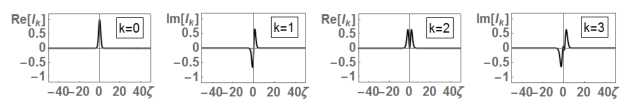

Figure 2: The first 4 bunch dipole moments for the Gaussian bunch as a function of the head-tail phase, $I_k(\zeta)$. Only real or imaginary part is plotted for even and odd ks respectively.

Matrix elements of an operator of the linear bunch by bunch damper can be constructed as a direct product of a set of dipole moment functions

$$\hat{G}_{lm}(\zeta) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \rho(\tau)\rho(\sigma)\bar{y}_l(\tau)\bar{y}_m(\sigma)e^{i\zeta(\tau-\sigma)}\,\mathrm{d}\sigma\,\mathrm{d}\tau$$
$$= I_l(\zeta)I_m^*(\zeta) = (-1)^m I_l(\zeta)I_m(\zeta),$$

(same matrix describes the couple bunch wake terms for sufficiently separated bunches).

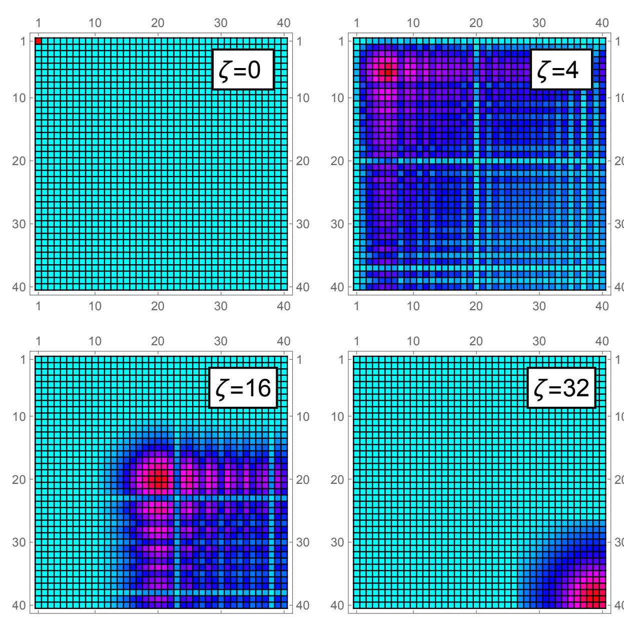

Figure 3: Absolute value of 40 by 40 dipole moments direct product matrices, $\hat{G}_{lm}$, plotted for different values of the head-tail phase ($\zeta = 0, 4, 16, 32$).

EXPERIMENTAL OBSERVATION OF HEAD-TAIL MODES FOR FERMILAB BOOSTER*

T. Zolkin†, The University of Chicago, Chicago, IL 60637, USA
A. Burov‡, V. Lebedev§, FNAL, Batavia, IL 60510, USA

Abstract

The Fermilab Booster is known to suffer from beam transverse instabilities. An experimental attempt of head-tail modes extraction from the stable beam motion by periodic excitement of betatron motion has been performed. The shapes of head-tail modes have been successfully obtained while eigenfrequencies separation from the betatron tune were too small to be resolved. The qualitative agreement between the theory and an experimental data has been demonstrated. This is an important step towards the understanding of general theory of collective instabilities for strong space charge case, which is a rather typical case for hadron machines.

INTRODUCTION

The goal of experiment was an observation and decomposition of head-tail modes. Usually head-tail modes can be observed when beam is in an unstable regime. Here we used a different approach studying the stable beam motion and exciting a betatron motion by pinging a beam every 100 turns [1]. Further analysis of collected data allowed to resolve the spatial structure of intra-bunch modes. Obtained experimental results have been interpreted according to the existing theory of collective beam motion and they do coincides with existing qualitative picture of beam motion in a Booster. This experimental activity is a very important step in order to build the bridge from theoretical expectations to real machine life; it should help with the further understanding of collective instabilities and possible ways to suppress them or move further the transverse mode coupled instability mode threshold.

FERMILAB BOOSTER

The FNAL Booster accelerator is a proton synchrotron, originally designed and constructed in the beginning of 1970's to match the beam from the linear accelerator to the Fermilab Main Ring, see Fig. (1). Since the 70's the whole accelerator complex has undergone many changes. At the present time, Booster accumulates the 400 MeV proton beam from the LINAC and then gives an intermediate boost to the beam energy. Booster was build as a fast cycling machine operating at 15 Hz which goes through repeated acceleration cycles delivering extracted 8 GeV beam pulses (referred to as a batch) to different experiments or filling the Main Injector ring which is about seven times larger. A multiple turn injection system increases the Booster intensity; it allows to stack successive turns of LINAC beam layered on top of each other. LINAC provides Booster with 400 MeV debunched H^- ion beam. The H^- ions and circulating beam passes through the stripping foil, which removes electrons of the ions and made of a thin layer of carbons. Operationally, the practical limit for maximum intensity is about 7 to 8 turns; fractional turns are not used normally.

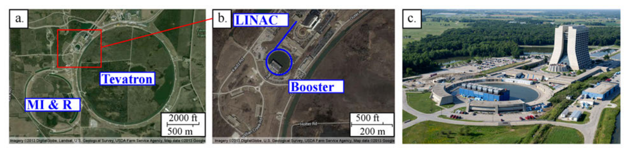

Figure 1: (a.), (b.) Satellite images of the Fermilab site showing Linear Accelerator (LINAC), Booster, Main Injector (MI), Recycler (R) and Tevatron ring. (c.) Photo of the Fermilab Willson Hall, LINAC and Booster.

Booster lattice consists of 96 combined function magnets which are arranged in 24 superperiods of the FOFDOOD-type cells; each superperiod containing two horizontally focusing magnets (F magnet) and two horizontally defocussing magnets (D magnet), along with short (O) and long (OO) straight sections, 1.2 and 6 meters respectively. All magnets are combined function magnets which bend the beam (a dipole magnet function) and focuses the beam either horizontally or vertically (a quadrupole function) and are powered by a resonant power supply with sinusoidal current waveform.

SSC THEORY FOR GAUSSIAN BUNCH

Below we will consider the case of Gaussian bunch which has a special practical importance; it corresponds to a thermal equilibrium when the bunch length is much shorter than the rf wavelength, in which case the longitudinal distribution function is

$$f(v,\tau) = \frac{N_\mathrm{b}}{2\,\pi\,\sigma\,u(\tau)}\,e^{-v^2/2\,u^2-\tau^2/2\,\sigma^2}.$$

The equation describing strong space charge no-wake head-tail modes for a bunch with Gaussian distribution [2]

$$y''(\tau) + \nu\,e^{-\tau^2/2}\,y(\tau) = 0, \qquad y'(\pm\infty) = 0,$$

leads to **Burov-Balbekov functions**, $y_k^0(\tau)$. The natural system of units is employed: the distance τ is measured in units of the RMS bunch length σ, and, eigenvalues ν_k is measured in units of $u^2/\sigma^2 Q_\mathrm{eff}(0) = Q_s^2/Q_\mathrm{eff}(0)$.

LONGITUDINAL BUNCH SHAPING AT PICOSECOND SCALES USING ALPHA-BBO CRYSTALS AT THE ADVANCED SUPERCONDUCTING TEST ACCELERATOR*

B.L. Beaudoin, Institute for Research in Electronics & Applied Physics, University of Maryland, College Park, MD 20742-3511, USA

D. Edstrom Jr., A.H. Lumpkin, J. Ruan, J. Thangaraj, Fermi National Accelerator Laboratory, Batavia, IL 60510-5011, USA

Abstract

The Integrable Optics Test Accelerator (IOTA) electron injector at Fermilab will enable a broad range of experiments at a national laboratory in order to study and develop solutions to the limitations that prevent the propagation of high intensity beams at picosecond lengths. One of the most significant complications towards increasing short-beam intensity is space-charge, especially in the vicinity of the gun. A few applications that require a longitudinally shaped electron beam at high intensities are for, the generation of THz waves and dielectric wakefields, each of which will encounter the effects of longitudinal space-charge. This paper investigates the effects of longitudinal space-charge on alpha-BBO UV laser shaped electron bunches in the vicinity of the 1½cell 1.3 GHz cylindrically symmetric RF photocathode gun.

INTRODUCTION

The IOTA electron linac is currently being built and commissioned at Fermilab. As of March 27, 2015 they commissioned the electron linac up to 20 MeV, a laboratory record for maximum electron energy achieved [1]. The work presented in this paper seeks to answer the question: *How do density perturbations evolve and affect the electron beams 6-D beam phase-space brightness in a linear accelerator under various beam and machine conditions, such as acceleration?*

The University of Maryland Charged Particle Beam Laboratory has pioneered the ability of generating controlled perturbations to understand longitudinal space-charge an intense beams [2]. These controlled perturbations have ranged from grid modulations of a thermionic gun to UV laser focused onto the dispenser cathode, in-turn extracting additional current through photoemission and thus modulating a local region of the longer beam bunch [3-9]. This work intends to extend these studies to pico-second high current bunch lengths in the MeV range.

IOTA LASER & ELECTRON LINAC

IOTA facility houses a superconducting high intensity electron linear accelerator (linac). The first stage of the facility has generate and transported a 20 MeV intense electron beam (shown in Fig. 1 below) using the accelerating cavity CAV2 [10]. Additional cavities are installed in the tunnel and conditioned that will allow the accelerator to transport up to 250 MeV electron beams.

Currently the electron linac is running with a Cs_2Te cathode for commissioning of the gun RF systems. A Cs_2Te photocathode is illuminated with an ultraviolet (263 μm) laser pulse, producing bunch trains at a repetition rate of 1-5 Hz and a frequency of 3 MHz for a 1 ms macro-pulse duration [11-12]. The number of bunches can be anywhere from 1-3000 depending on the beam charge.

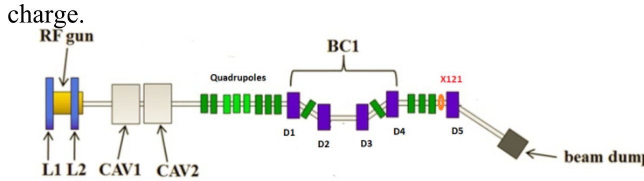

Figure 1: The 50 MeV electron beamline showing the RF gun followed by CAV1 and CAV2 that will accelerate the beam to 50 MeV. The green boxes show the quadrupoles used to focus the beam. The purple boxes are the dipoles that are used to bend the electron beam. D5 is the spectrometer dipole that is used in measuring the energy spectrum of the bunch. X121 is an Optical Transition Radiation (OTR) monitor that will be used to measure the current profile of the electron beam [11].

The photoinjector consists of a 1½ cell 1.3 GHz (L-band) cylindrical-symmetric RF gun injecting beam into the linac at nominally 5 MeV. By changing the gradient inside the RF gun, were able to generate beam energies ranging from 2-to-5 MeV.

TEMPORAL PULSE STACKING

The generation of longitudinally uniform electron beams can be achieved utilizing UV birefringent crystals by temporally stacking the incident laser pulse. The method of using birefringent crystals for temporal pulse stacking was developed at the Argonne Wakefield Accelerator (AWA) facility to generate 83-167 GHz electron bunch trains from an RF photocathode gun [13].

When a short laser pulse is incident on a birefringent crystal at a particular angle, the pulse will split into two pulses (or two rays), with different polarizations. The two pulses also separate in time as a result of the different group velocities. This separation in time can be calculated using Eqn. 1 below:

$$\Delta t = L\left(\frac{1}{v_{ge}} - \frac{1}{v_{go}}\right) \quad (1)$$

BARRIER SHOCK COMPRESSION WITH LONGITUDINAL SPACE-CHARGE*

B.L. Beaudoin, I. Haber, R.A. Kishek, Institute for Research in Electronics & Applied Physics, University of Maryland, College Park, MD 20742, USA

Abstract

Synchrotrons and storage rings routinely employ RF barrier buckets as a means of accumulating charge to increase the peak intensity and preserve longitudinal emittance while minimizing emittance growth [1-3]. This was shown in the main injector and recycler at Fermilab as well as the SIS-18 at GSI Helmholtz center for heavy ion research. The RF cavities typically used are ferrite loaded magnetic alloys with low Q to maximize bandwidth and generate single pulses, either as delta functions, triangular or half/full period sine waves.

The University of Maryland Electron Ring (UMER) group is studying a novel scheme of bunch compression in the presence of longitudinal space charge. It has been analytically shown through 1-D computations that the presence of space-charge considerably improves the efficiency of the barrier compression by taking advantage of the shock-front that launches when the barrier moves into a space-charge dominated beam. In this paper, we summarize the initial results of the study.

INTRODUCTION

The University of Maryland Electron Ring is a storage ring that accesses high intensities through the use of low momentum high-current electron beams. The machine is capable of injecting various beam currents ranging from 0.6-to-104 mA (shown in Table 1) and has since propagated a new low current beam of approximately 50 µA in Nov 2014 [4]. This beam is still undergoing full characterization.

Table 1: Beam Parameters vs Injected Current

Current (mA)	Emittance (mm-mr)	c_s (1×10^6 x m/s)
0.05	TBD	0.066
0.6	7.6	0.285
6.0	25.5	0.766
21.0	30.0	1.27
78.0	58.9	1.90
104.0	64.0	2.03

Longitudinal space-charge causes the ends of the beam to axially expand, filling the ring with charge [5-6]. In order to overcome the longitudinal space-charge forces, a barrier bucket system was developed to prevent the expansion, allowing us to store the beam for more than 1000 turns [5]. The barrier bucket system consists of two independently operated burst mode modulators, where the first modulator applies an 8 ns FWHM negative voltage pulse to the head of the bunch and the other applies the equivalent positive pulse to the tail of the bunch. Both modulators are synchronized to injection and operate at the revolution frequency of the beam. Figure 1 below illustrates the voltage pulses (red), the beam current (black) from the wall current monitor in the ring as well as the synchronization between them. Note in this figure the voltage pulses are applied every fifth turn.

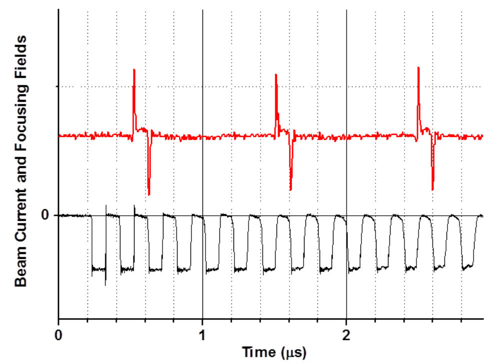

Figure 1: Synchronization between the barrier bucket fields (red) and beam current (black) from the wall-current monitor in the ring.

Once the barrier bucket fields are initiated, the beam can be stored for as long as required for a given experiment, limited by the average power that the pulse modulators can drive the low Q cavity. The modulators are capable of storing the 0.6 mA beam for more than 1000 turns. The barrier fields are not perfectly matched to the beam edges, resulting in space-charge waves induced at the edges of the beam that bounce from edge to edge during a long store of charge [5].

Various barrier bucket compression schemes have been explored in the past, to produce more intense beams for neutrino based programs demanding high intensity hadron beams [1]. A few schemes that have been explored are: barrier flip-flop, adiabatic compression and momentum stacking. Each of these schemes compresses the total charge in order to increase the peak current with little consideration for longitudinal emittance growth and especially when intense longitudinal space-charge forces are considered.

This paper summarizes both the computational and experimental progress on this novel method of compression with intense space-charge.

NOVEL METHOD OF LONGITUDINAL COMPRESSION

This method of compression utilizes longitudinal space-charge to assist with the compression of the beam,

CONCEPTUAL DIFFICULTIES OF A THERMODYNAMICS DESCRIPTION OF CHARGED-PARTICLE BEAMS *

Santiago Bernal, Institute for Research in Electronics and Applied Physics, University of Maryland, College Park, MD, 20742, USA

Abstract

We review the existing phenomenological theories of emittance growth with and without entropy terms and re-examine the condition for thermal equipartitioning in an unbunched charged-particle beam. The model incorporates linear space charge and a uniform-focusing lattice. Because of non-extensitivity of the transverse ("thermal") energy and the absence of a classical heat bath, we conclude that a rigorous classical thermodynamics treatment of charged-particle beams is not possible. In particular, the postulated relationships between the rms emittance and temperature and entropy must be qualified.

INTRODUCTION

Lapostolle suggested some 45 years ago [1] that a thermodynamic model may apply to the observed emittance exchanges between degrees of freedom in intense charged-particle beams (e.g., proton linacs at CERN). He went further to comment that heat flow may occur between degrees of freedom corresponding to different temperatures; under these circumstances, entropy would increase and emittance blow up in an irreversible manner.

Since Lapostolle's work, phenomenological theories of emittance growth have been developed by Wangler, Reiser, and others [2, 3]. Furthermore, a connection between rms emittance and entropy had been suggested by Lawson, Lapostolle and Gluckstern in 1973 [4]. Although the original work by Wangler et al does not address reversibility, an extension of the theory by O'Shea [5] predicts a connection between entropy changes and reversible and irreversible rms emittance growth. However, a thermodynamic framework for describing beam dynamics has neither been theoretically examined in detail nor tested in simulations.

Recent work by Hofmann and Boine-Frankenheim [6] emphasizes computational aspects of emittance and entropy growth. Their simulation studies focus on the role of grid resolution and numerical collisions on (6D) rms emittance and entropy growth in 3D beams confined by a periodic potential. Moreover, Hofmann and Boine-Frankenheim compare the numerical results to the predictions of a stochastic model developed by Struckmeier [7] based on temperature anisotropy and the effect of using macro-particles.

ENTROPY AND EMITTANCE GROWTH

In the phenomenological theory of Wangler et al [2, 3], the rate of change of normalized rms emittance (squared) in an unbunched beam is described by the equation

$$\frac{d\tilde{\varepsilon}_n^2}{dz} = -\frac{1}{8}\beta^2\gamma^2 \left\langle x^2 \right\rangle K \frac{d}{dz}\left[\frac{U(z)}{W_0}\right], \tag{1}$$

where z is the axial coordinate, $U(z) = W - W_u$ the difference between field energies per unit length of the actual beam distribution and the equivalent uniform distribution, i.e., the Kapchinskij-Vladimirskij (K-V) beam [3], and W_0 is the space-charge field energy per unit length inside the boundary of the equivalent K-V beam. The excess energy $U(z)$, or *free energy*, is available for the beam to thermalize. The symbol K represents the generalized beam perveance, which is proportional to current; $\left\langle x^2 \right\rangle = \left\langle y^2 \right\rangle$ is the squared rms transverse dimension at z, and the rest of the quantities have the standard meanings from special relativity.

No statement about *reversibility* is made in the original derivation of eq. (1). In O'Shea's work [5], though, eq. (1) is qualified as one *valid when the entropy change is zero* and, therefore, when the rms emittance change is in principle *reversible* by the application of *appropriate* forces. The reversibility, however, will depend on our ability to apply corrective forces with the same fine resolution that lead us to conclude that no entropy growth occurred. In many practical situations, this resolution is not possible and, hence, we must conclude that entropy in fact increased and emittance change is irreversible.

The normalized information entropy, S_n, in O'Shea's work is related to the normalized transverse rms emittance. For a 2-D beam we have [4]:

$$S_n(z) \equiv \frac{S_2(z)}{k_B N L} = \ln[\tilde{\varepsilon}_n(z)] + \ln[C(z)] - \ln[A_2], \tag{2}$$

where k_B is Boltzmann's constant, N is the number of beam particles per unit length, L, the bunch's length, is $L >>$ transverse dimension. $C(z)$ depends on the form of the phase-space particle distribution at z, and A_2 corresponds to the size of the grid cell for the computation, or the experimental resolution of the measuring device. Equation (2) tells us that it is possible to have rms emittance growth while entropy remains constant because the evolution of $C(z)$ may compensate for the growth. By the same token, it is possible for rms emittance to decrease while entropy increases. The value of $C(z)$ at $z = 0$, the start of the simulation or experiment, is denoted by C_0. For the widely used K-V distribution, for example, $C_0 = \pi$; for a thermal (Gaussian) distribution, $C_0 = \sqrt{2}\pi^{3/2}$ [4], more than twice the value for the K-V distribution.

SIMULATIONS AND EXPERIMENTS IN SUPPORT OF OCTUPOLE LATTICE STUDIES AT THE UNIVERSITY OF MARYLAND ELECTRON RING *

K. Ruisard, B. Beaudoin, I. Haber, T. Koeth
University of Maryland, College Park, MD, USA

Abstract

We present plans for a nonlinear lattice at the University of Maryland Electron Ring (UMER). Theory predicts that a strong nonlinear lattice can limit resonant behavior without reducing dynamic aperture if the nonlinear fields preserve integrability or quasi-integrability. We discuss plans for a quasi-integrable octupole lattice, based on the work of Danilov and Nagaitsev. We use Elegant and the WARP PIC code to estimate the octupole-induced tune spread. We discuss improvements to the ring in support of octupole lattice experiments, including generation and detection of emittance-dominated, negligible space charge beams.

INTRODUCTION

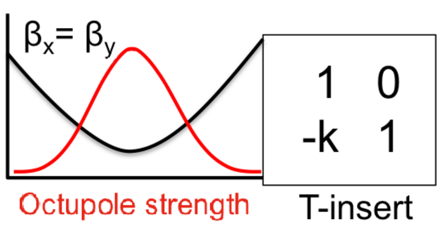

Figure 1: Toy model of quasi-integrable octupole lattice.

Conventional accelerators are based on Courant and Snyder's theory of the alternating-gradient synchrotron, developed in 1952 [1]. In an AG focusing lattice, particles oscillate transversely with a characteristic tune. Unfortunately, this system is susceptible to coherent resonances which lead to beam loss and halo growth. Thin lens octupoles for Landau damping limit coherent resonances, but introduce unbounded chaotic orbits leading to particle losses and limiting achievable beam intensity.

A novel approach by Danilov and Nagaitsev suggests an integrable but highly nonlinear lattice as an alternative to the standard AG synchrotron [2]. In a nonlinear lattice with a large amplitude-dependent tunes spread, particles that are resonantly driven to higher amplitudes will decohere from that resonance and have only limited amplitude growth. Effectively, the beam is immune to coherent resonances. This nonlinear detuning is also shown to mitigate halo growth driven by beam envelope mismatch [3].

The fully integrable elliptic potential willl be tested at Fermilab's IOTA ring [4]. Danilov and Nagaitsev also consider the case in which the nonlinear field is purely octupolar. Particles contained in an octupole potential that scales as $V(s) \propto {}^{1}/_{\beta^3(s)}$ will conserve a single invariant of transverse motion, the normalized Hamiltonian, and particle orbits will be chaotic but bounded. The nonlinear optics program at UMER will test this quasi-integrable lattice by incorporating octupole magnets into the existing ring framework.

This paper describes the progress being made towards the UMER octupole lattice design and experiments. The simulation effort is focused on identifying an operating point for the lattice that maximizes beam tune spread with acheivable octupole fields. Experimental work includes demonstration of a negligible space charge beam for future lattice studies.

NONLINEAR UMER LATTICE

The theory of quasi-integrable nonlinear optics assumes a symmetric beam is propagating in nonlinear fields that are scaled longitudinally with the inverse of the envelope function [2]. External focusing must be provided for a bounded envelope function. To achieve this in a ring, a nonlinear channel will installed over a symmetric beam waist, and the remaining linear lattice has a transfer function equivalent to a thin x-y symmetric focusing lens. This is shown schematically in Fig. 1.

UMER is a 10 keV, 11.52 meter storage ring that supports electron beams with variable tune depressions $({}^{\nu}/_{\nu_0} = 0.85 - 0.15)$ for the study of space charge dominated beam dynamics. The ring lattice is 36 FODO cells composed of printed circuit quadrupoles and dipoles. To modify UMER as a nonlinear optics test bed, we will superimpose an octupole channel onto the existing lattice, as shown in

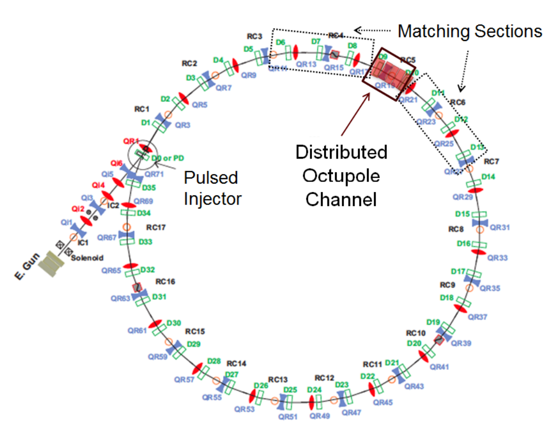

Figure 2: UMER lattice showing quadrupole and dipole elements, with overlay of future octupole channel.

NONLINEAR BEAM DYNAMICS STUDIES OF THE NEXT GENERATION STRONG FOCUSING CYCLOTRONS AS COMPACT HIGH BRIGHTNESS, LOW EMITTANCE DRIVERS*

S. Assadi#, P. McIntyre, A. Sattarov, Texas A&M University, College Station, TX 55057, USA
N. Pogue, PSI, 5234 Villigen, Switzerland

Abstract

The Strong Focusing Cyclotron development at Texas A&M University has evolved from stacks of cyclotrons to a single layer high brightness, low emittance device to produce greater than 10 mA of proton beam to a desired target at 800 MeV. The latest design has a major geometric design optimization of strong focusing quadrupoles and a modified algorithm of high gradient cavities. These optimizations address the turn separation and interaction of radially neighbouring bunches and produced a reduced the number of turns necessary to reach the desired final energy under control conditions. In this paper, we present the new design, the physics of nonlinear synchrobetatron coupling, mvh+nvv=p causing beam blow-up in other form of cyclotrons and how this work has resolved it. The cavity beam loading, and space charge effects of multi turns at low energies to reduce losses, are discussed.

INTRODUCTION

The Accelerator Research Lab at Texas A&M University is developing designs for a strong-focusing cyclotron (SFC) as a high-current (10 mA CW) proton driver for fundamental physics, ADS fission, production of medical isotopes, and as a spallation source for neutron damage studies. Challenges associated with high power, high brightness linear accelerators, such as minimizing particle losses, space charge and beam stability, are also obstacles from the SFC. Cyclotrons have additional degrees of complexity as the multi-bunches pass through the cavities and have coulomb and Wakefield interactions. We report on three studies in this paper: (1) better understanding of proposed cavity by modelling stiffened cavity after additional corrugations, (2) initial corona and multipacting studies of the new cavity, and lastly wakefield studies of uncoupled and coupled bunches traversing through SFC cavity with a realistic 6D initial bunch distribution.

BEAM DYNAMCIS

The world-record CW beam power for a proton accelerator today is the PSI isochronous cyclotron [1], which produces 2.2 mA CW at 590 MeV. Two issues pose the main limits to its beam current: succeeding orbits overlap strongly so the defocusing action of space charge is exacerbated; and it has only weak focusing so that the betatron tunes migrate throughout acceleration and cross multiple resonances. We solve both problems in the SFC, see Fig. 1, by incorporating two new elements:

- superconducting ó-wave slot-geometry cavities that provide sufficient energy gain per turn to fully separate the orbits;
- beam transport channels that provide alternating-gradient strong focusing to maintain constant betatron tunes throughout acceleration.

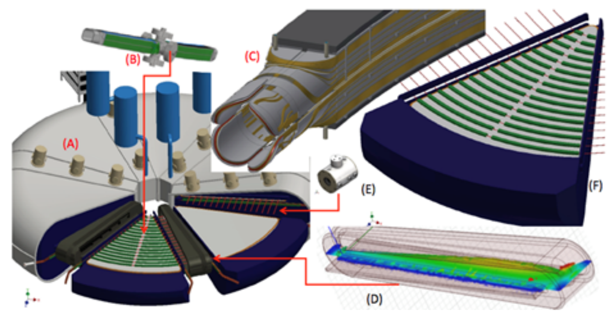

Figure 1: Strong-focusing cyclotron: a) cutaway showing the proton orbits, warm-iron flux return, (B) Beam Position Monitors between every two quad-channel. (C) quad channel composed of corrector and MgB2 4.2 cm bore magnet, (D) electric field distribution in the superconducting slot-geometry ½ wave cavity, (e) twenty five cm long 500 Watt instrumented beam dump at extraction channel, and (f) cold-iron flux plate with FD pairs of arc beam transport channels defining each equilibrium orbit.

Our initial simulations show that one such 800 MeV SFC could deliver > 10 mA continuously (cw) so that a high-current proton beam could be available for the above-mentioned purposes. In Ref. [2] we addressed the versatilities of quad focusing and added correctors allowing one to compensate for out of tolerance magnets by 100 times of other cyclotrons or 1% of main field. Additionally it has been shown the system can accept the loss of one of the ten cavities. In this paper we attempt to address the cavity and demonstrated a deep understanding of the self-field and beam coupling in the cavity.

SRF Cavity

The original straight cavity designed for SFC-800 MeV did not incorporate any corrugations in its calculations, although they were planned to be inserted based on the experience at BNL [3].

DEVELOPMENT OF A SINGLE-PASS AMPLIFIER FOR AN OPTICAL STOCHASTIC COOLING PROOF-OF-PRINCIPLE EXPERIMENT AT FERMILAB'S * IOTA FACILITY

M. B. Andorf[1], V. A. Lebedev[2], and P. Piot[1,2],
[1]Department of Physics and Northern Illinois Center for Accelerator & Detector Development, Northern Illinois University DeKalb, IL 60115, USA
[2]Accelerator Physics Center, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

Optical stochastic cooling (OSC) is a method of beam cooling which is expected to provide cooling rates orders of magnitude larger than ordinary stochastic cooling. Light from an undulator (the pickup) is amplified and fed back onto the particle beam via another undulator (the kicker). Fermilab is currently exploring a possible proof-of-principle experiment of the OSC at the integrable-optics test accelerator (IOTA) ring. To implement effective OSC a good correction of phase distortions in the entire band of the optical amplifier is required. In this contribution we present progress in experimental characterization of phase distortions associated to a Titanium Sapphire crystal laser-gain medium (a possible candidate gain medium for the OSC experiment to be performed at IOTA). We also discuss a possible option for a mid-IR amplifier.

INTRODUCTION

An Optical Stochastic Cooling experiment (OSC) is planned to take place at the Advanced Superconducting Test Accelerator (ASTA) in the Integrable Optics Test Accelerator (IOTA) ring at Fermilab [1]. OSC is a beam cooling technique capable of providing damping rates orders of magnitude larger than the conventional and widely implemented microwave stochastic cooling. In OSC a particle passes through an undulator (the pickup) and radiates; see Fig. 1. This radiation is amplified while the particle is delayed via a magnetic chicane. The particle and amplified radiation then meet in a second undulator (the kicker) with a relative phase in such a way to provide a corrective longitudinal kick [2] [3].

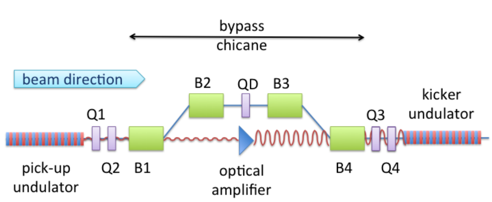

Figure 1: Schematics of the OSC insertion. The labels "Qx", "Bx" respectively correspond to quadrupole and dipole bending magnets.

* M. A. is financially supported by a Great-Journey Assistantship from Northern Illinois University. V. L and P.P are supported by the Fermi Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the US DOE.

The chicane is only capable of providing a few millimeters of delay and thus puts a serious constraint on the optical amplifier (OA) design. A single-pass OA was suggested in [4] using Titanium Sapphire (Ti:Sapph) as the gain medium with a center wavelength of 780 nm.

The Cooling rate is inversely proportional to the bandwidth of the system. Since the undulator bandwidth can be made quite large, the system bandwidth is determined by the OA and so a gain material with a large bandwidth is desirable. Ti:Sapph is a promising candidate gain material because it is capable of providing a large amount of gain for a short signal delay over a large bandwidth.

This paper discusses progress made in the development of a single pass OA using Ti:Sapph, specifically steps toward characterizing the possibility of phase distortions in the amplification process. Additionally Cr:ZnSe is suggested as an alternative gain medium.

PHASE MEASUREMENTS

Technique

If a gain material of thickness T and index of refraction n is inserted into one leg of an interferometer, the relative phase of light passing through can be written as

$$\phi = k[\Delta L + Tn(\lambda)] \tag{1}$$

with ΔL being the path length difference between the two legs, $k \equiv \frac{2\pi}{\lambda}$ and λ is the wavelength of the radiation. The path length difference can be written as $\Delta L = C - Tn(\lambda_o)$ with C being a constant and λ_o a fixed wavelength. The index of refraction can also be Taylor expanded around λ_o. Doing so up to second order and inserting the expression for the path length difference into Eq. (1) yields

$$\phi = kT\left[\frac{C}{T} + \frac{dn}{d\lambda}(\lambda - \lambda_o) + \frac{1}{2}\frac{d^2n}{d\lambda^2}(\lambda - \lambda_0)^2\right] \tag{2}$$

Dividing the above expression by kT results in a quadratic equation in $(\lambda - \lambda_o)$. The linear portion of this equation results in a net delay of the optical pulse and thus can be compensated for by the chicane. The non-linear portion results in a modification of the pulse shape and is not able to be compensated by the chicane. It is this coefficient $a = \frac{d^2n}{d\lambda^2}$ that needs to be measured during the amplification process. This is done by measuring the phase as a function of wavelength and performing a least squares fit.

SMOOTH FAST MULTIPOLE METHOD FOR SPACE CHARGE TRACKING: AN ALTERNATE TO PARTICLE-IN-CELL

A. Gee*,[1] and B. Erdelyi†,[1,2]

[1]Physics Department, Northern Illinois University, DeKalb, IL 60115, USA
[2]Physics Division, Argonne National Laboratory, Argonne, IL 60439 , USA

Abstract

The fast multipole method (FMM) algorithm was developed by Greengard and Rokhlin in 1987 [1]. As one of the top ten algorithms of the 20th century, it has been applied in a wide range of fields. The FMM complexity is $O(N)$, where N is the number of particles, allowing for large-scale simulations. However, it includes all the two-body collisional forces, in contrast to other methods such as the popular particle in-cell (PIC) methods. While collisionality can be very important, many applications require only the mean field effects. PIC is frequently used in this regime. Due to recent concerns of unphysical effects of grids, interpolation and other approximations in PIC codes, an alternative based on different underlying assumptions would prove enlightening. For these cases, a smoothed or softened FMM using a Plummer-like smoothing parameter holds much promise. Unfortunately, the original FMM algorithm based on analytic expansions of the $\frac{1}{r}$-like potentials does not allow for Plummer softening. We present our new soft-FMM employing differential algebras (DA) to obtain the modified expansions. We also compare the performance of the smoothed DA-FMM with examples from PIC simulations.

INTRODUCTION

Algorithms to solve the N-body problem have advanced greatly in recent years. With increasing interest in high intensity beams, tracking codes must efficiently simulate collective effects, particularly space charge. Particle in-cell (PIC) is the standard class of methods for the accelerator and beam community. Since all PIC methods share the basic assumptions [2], comparing PIC codes would not distinguish unphysical behavior, which are well-known to exist due to numerical noise, interpolation errors, grid heating, etc. An alternative method based on completely different assumptions would prove insightful.

Of recently developed methods, the fast multipole method (FMM) shows great promise. We present the smoothed FMM as an alternative to PIC. Previously, we implemented the FMM using a differential algebraic (DA) framework. With the DA method, we reformulated the FMM in real Cartesian space and made it kernel independent. However, while PIC estimates the mean fields, the FMM includes all collisional effects. Since close encounters lead to strong collisions, unphysical in this context, we introduced Plummer-like smoothing or softening into the FMM. This technique could not be done with the original FMM, but the kernel independence based on the DA framework allows computational cost in the smooth FMM to be near the same as the original FMM. With appropriate softening parameter, the FMM can estimate the mean fields to be used for space charge tracking. This paper illustrates the behavior of the smoothed FMM for transverse space charge and compares it to theory, the method of statistical moments (MoM) [3], and a widely-used representative PIC code.

SMOOTHED DA-FMM IN CARTESIAN FORM

The smoothed 2D Coulomb potential at (x, y) due to a source at (x_0, y_0) of unit charge with smoothing parameter λ is given by (1), or alternatively by (2). (1) and its derivative are used for particle-particle interactions.

$$\Phi(x, y, \lambda) = -\frac{1}{2}\log\left((x-x_0)^2 + (y-y_0)^2 + \lambda^2\right) \quad (1)$$

$$= -\frac{1}{2}\left\{\log\left(x^2+y^2+\lambda^2\right) + \log\left[1 + \frac{x_0^2+y_0^2}{x^2+y^2+\lambda^2} - 2\frac{xx_0+yy_0}{x^2+y^2+\lambda^2}\right]\right\} \quad (2)$$

Far multipole expansion

We can separate (2) as $\Phi(x, y, \lambda) = \Phi_T + \Phi_M$, where Φ_T only depends on the target position. We expand Φ_M in (2) from the origin. Let $r^2 \equiv x^2 + y^2 + \lambda^2$. We define DA variables, $d_x = \frac{x}{r^2}$, $d_y = \frac{y}{r^2}$, $d_\lambda = \frac{\lambda}{r^2}$, and $d_r^2 = \frac{1}{r^2} = d_x^2 + d_y^2 + d_\lambda^2$. Substituting these into the second log term of (2), we have the form for the smooth multipole expansion Φ_M, given in (3).

$$\Phi_M(x, y, d_x, d_y, \lambda, d_\lambda) = -\frac{1}{2}\log[1 + (x_0^2+y_0^2)d_r^2 - 2(x_0d_x + y_0d_y)] \quad (3)$$

The DA framework allows efficient expansion of Φ_M in terms of the DA variables. Thus, we will get a Taylor series in d_x, d_y, d_λ describing the multipole expansion, which we may evaluate using the DA variables defined earlier.

Multipole-to-multipole translation

To remap (3) to a new multipole center, (x_m, y_m), we redefine the DA variables as $d_{x_2} = \frac{x_2}{r_2^2}$, $d_{y_2} = \frac{y_2}{r_2^2}$, $d_{\lambda_2} = \frac{\lambda}{r_2^2}$,

Abstract

Density modulations on electron beams can improve machine performance of beam-driven accelerators and FELs with resonance beam-wave coupling. The beam modulation is studied with a masked chicane by the analytic model and simulations with the beam parameters of the Advanced Superconducting Test Accelerator (ASTA) in Fermilab. With the chicane design parameters (bending angle of 18°, bending radius of 0.95 m and R_{56} ~ - 0.19 m) and a nominal beam of 3 ps bunch length, the analytic model showed that a slit-mask with slit period 900 μm and aperture width 300 μm induces a modulation of bunch-to-bunch spacing ~100 μm to the bunch with 2.4% correlated energy spread. With the designed slit mask and a 3 ps bunch, particle-in-cell (PIC) simulations, including nonlinear energy distributions, space charge force, and coherent synchrotron radiation (CSR) effect, also result in beam modulation with bunch-to-bunch distance around 100 μm and a corresponding modulation frequency of 3 THz. The beam modulation has been extensively examined with three different beam conditions, 2.25 ps (0.25 nC), 3.25 ps (1 nC), and 4.75 ps (3.2 nC), by tracking code Elegant. The simulation analysis indicates that the sliced beam by the slit-mask with 3 ~ 6% correlated energy spread has modulation lengths about 187 μm (0.25 nC), 270 μm (1 nC) and 325 μm (3.2 nC). The theoretical and numerical data proved the capability of the designed masked chicane in producing modulated bunch train with micro-bunch length around 100 fs.

INTRODUCTION

We have been investigating the masked chicane technique [1 – 3] with the available beam parameters such as the 50 MeV photoinjector of the Advanced Superconducting Test Accelerator (ASTA), which is currently being constructed and commissioned in Fermilab [4]. Downstream of the ASTA 50 MeV photoinjector beamline, a magnetic bunch compressor, consisting of four rectangular dipoles, is adopted and a slit-mask is designed and inserted in the middle. Based on this slit-masked chicane, the bunching performance and the ability of sub-ps microbunch generation are studied.

In order to evaluate bunching performance with nominal beam parameters, the masked chicane has been analyzed by the linear bunching theory in terms of bunch-to-bunch distance and microbunch length. Elegant code is employed to examine the theoretical model with the ASTA nominal beam parameters (RMS bunch length $\sigma_{z,i}$ is 3 ps and energy ratio τ is around 0.1). The Particle-In-Cell (PIC) simulation (CST-PS) includes space charge and CSR effect and nonlinear energy distribution over macro-particle data. For Elegant simulations, bunch charge distribution and the beam spectra are mainly investigated with three different bunch charges, 0.25 nC, 1 nC, and 3.2 nC, under two RF-chirp conditions of minimum and maximum energy spreads. The corresponding bunch length for the maximally chirped beam is 2.25, 3.25, and 4.75 ps and the correlated energy spread is 3.1, 4.5, and 6.2 % respectively for bunch charge of 0.25 nC, 1 nC, and 3.2 nC

ANALYTIC DESIGN

The designed chicane consists of four dipoles and a slit mask with slit spacing, *W*, and aperture width, *a*, is inserted in the middle of the bunch compressor (dispersion region). Before the beam is injected into the masked chicane, a positive linear energy-phase correlation is imposed by accelerating the beam off the crest of the RF wave in the linear accelerator. The chicane disperses and re-aligns the particles with respect to their energies in phase space. The input beam is then compressed and the phase space ellipse is effectively rotated toward the vertical. In the middle of the chicane, the beam is partially blocked by the transmission mask and holes are introduced in the energy-phase ellipse. In the second half of the chicane, the beam is deliberately over-bunched and the beam ellipse is slightly rotated past the vertical. In this step, the linear energy-phase correlation is preserved by over-bunching, accompanied with a steeper phase-space slope. Consequently, the projection of the beam ellipse on the time axis generates

IMPLEMENTATION OF QUADRUPOLE-SCAN EMITTANCE MEASUREMENT AT FERMILAB'S ADVANCED SUPERCONDUCTING TEST ACCELERATOR (ASTA)

A. T. Green, Department of Physics, Northern Illinois University, Dekalb, IL 60115, USA
Y. M. Shin, Department of Physics, Northern Illinois University, Dekalb, IL 60115 and
Accelerator Physics Center (APC), FNAL, Batavia, IL 60510

Abstract

Transverse emittance measurements based on the quadrupole scan technique have been widely used to characterize the beam phase space parameters in linear accelerators. This paper discusses the implementation of the technique at the Advanced Superconducting Test Accelerator (ASTA) at Fermilab. We plan on deploying a flexible implementation that permits an operator to select a quadrupole with associated analyzing screen to measure the beam emittance. Our implementation utilizes Python scripts combined with Fermilab's control system ACNet and ELEGANT tracking code. We also discuss the applicability of the quadrupole scan method at 20.3 MeV at an operating charge of 250 pC at ASTA. Some preliminary measurements will also be presented.

INTRODUCTION

The Advanced Superconducting Test Accelerator (ASTA) has been constructed and commissioned in Fermilab and it is currently scheduled to build a high energy beamline (150 – 300 MeV) by adding a cryomodule with construction plan of the Integrable Optics Test Accelerator (IOTA) ring by 2016. Most recently, 20 MeV of electron beam energy was successfully demonstrated in the ASTA injector beamline and it is planned to increase the beam energy up to 50 MeV with the schedule to add a capture cavity downstream of the photoinjector. Along with the timeline of the construction/commissioning schedules, it is necessary to assure a beam monitoring technique for a full scale transverse and longitudinal phase-space characterization of a commissioned beam, which enables to precisely operate the machine. Instantaneous monitoring of beam parameters is highly required for preserving the beam emittance along the beamline. We have been working on the idea of developing a real-time emittance monitoring system based on a quadruple-scan technique [1,2]. Our plan is to design a Python script programmed with a quad-scan algorithm and to implement it in the ASTA beamline control system (ACNet console). We expect that successful development of a designed system will allow a beamline operator to trace temporal profiles of transverse beam parameters and also to systematically control the dynamics using quadrupoles installed in the ASTA beamline.

BEAM DYNAMICS

Emittance is an important property of charged particle beams, allowing for a description of beam quality and the comparison of beams. Generally, emittance can be described in six-dimensional phase space $[x, y, z, p_x, p_y, p_z]$ as the spread of density of particles in the beam. In many cases, the transverse emittance is of particular interest and the six-dimensional phase space is split into subspaces comprised of (x, p_x) and (y, p_y) [1].

The area occupied by the particles of interest may be considered as being bound by an ellipse and can mathematically be described by the following beam matrix:

$$\Sigma_{beam} = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}. \quad (1)$$

Figure 1 shows the beam ellipse and the physical interpretation of its physical components. In the figure, x and x' are the position and angle of the particles, respectively.

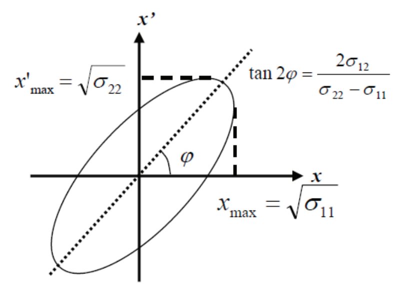

Figure 1: Beam ellipse with physical interpretation of the physical components [1].

Using the beam matrix, the geometrical emittance can then be defined as:

$$\epsilon = \pi\sqrt{\Sigma_{beam}} \quad (2)$$

The beam ellipse and matrix can also be expressed in terms of the Courant-Snyder parameters:

$$\epsilon = \gamma x^2 + 2\alpha x x' + \beta x'^2, \quad (3)$$

where $\gamma = \Sigma_{22}/\epsilon$, $\alpha = -\Sigma_{12}/\epsilon$, and $\beta = \Sigma_{11}/\epsilon$ [3].

A more complete description of the emittance may be given as the root mean square emittance (ϵ_{rms}). With this description, the moments of the particle distribution in phase space can be related to the beam matrix elements by [1]:

CHARACTERIZING BETATRON TUNE KNOBS AT DUKE STORAGE RING *

H. Hao†, S. Mikhailov, V. Popov, Y.K. Wu, TUNL, Duke University, Durham, NC 27708, USA
J. Li, University of Science and Technology of China, Hefei, Anhui 230029, China

Abstract

A good control of the electron beam betatron tune is critical for the operation of a storage ring. As the driver for Duke free-electron lasers (FELs) and the High Intensity Gamma-ray Source (HIGS), the Duke storage ring is operated in a wide energy range (0.3 GeV – 1.2 GeV), with several different electromagnetic wiggler configurations. This creates the challenge of controlling the betatron tune in a global manner. As the the first step, the feedforward tune compensation schemes were designed and implemented to the real-time computer control system to compensate the tune change caused by the wiggler field. To further increase the flexibility of the operation, a set of tune knob schemes are designed for various wiggler configurations. The β function changes caused by these knobs are constrained within the south straight section where the tune knob is located, minimizing the impact on the electron beam dynamics (i.e. injection and lifetime). The tune and β function measurements show a good agreement with the calculation. In addition, it is found that some tune knob schemes are effective for new wiggler configurations that are not originally designed for.

INTRODUCTION

In the operation of a storage ring based light source, it is necessary to have a good control of the storage ring lattice, i.e. the ability to vary the betatron tunes in a desired way. This type of control is usually realized using the tune knob, a scheme to vary a set of quadrupoles simultaneously in a way such that the global tunes can be changed as needed. As the driver for Duke free-electron lasers (FELs) and the High Intensity Gamma-ray Source (HIGS) [1] [2], the Duke storage ring is operated in a wide energy range from 0.3 GeV to 1.2 GeV, with several different electromagnetic wiggler configurations. The vasitility of the Duke storage ring opeation creates the challenge of designing a set of betatron tune knobs to work with different lattice configurations. As part of the wiggler switchyard upgrade project in 2012, a set of tune knobs were designed on top of the lattices with wiggler focusing compensations [3]. The knobs were implemented into the EPICS control system in a feedforward manner [4]. The tune knobs have been used for the HIGS γ-ray operation since 2012. In this paper, we report the quantitative investigation of effectiveness of these tune knobs and document a set of calibrations to improve the usefulness of the tune knobs.

* Work supported by US Department of Energy grant DE-FG02-97ER41033.
† haohao@fel.duke.edu

DESIGN OF THE TUNE KNOB

A tune knob is realized by changing the the strength of a set of quadrupoles in the storage ring. To minimize the impact on the beam dynamics of the Duke storage ring, e.g. the injection, the β fucntion changes introduced by the quadrupole variations are constrained within the 34-meter-long south straight section (SSS). The lattice at two ends are required to match with the arc lattice when the quadrupoles are varied. To preserve the beam dynamics, the symmetry of the lattice also should be preserved whenever possible.

For the HIGS γ-ray operation, the electron beam energy, FEL wiggler strength and configuration are varied in a wide range to produce high-flux γ-ray photon beams for a variety of nuclear physics experiments. To cover such wide range of operation, a number of tune knobs are designed for 6 commonly used wiggler configurations, with the wiggler strength varying from zero to its maximum setting. The horizontal (or vertical) tune knobs are designed to control tune only in one direction, with a minimum impact on the tunes in the other direction. The complete tune knob to change both ν_x and ν_y is realized by simply adding together the two independent knobs in the two directions. Numerical computation shows that this design could simultaneously control tunes (ν_x, ν_y) in both directions.

CALIBRATION OF THE TUNE KNOBS

The calibration of tune knobs requires a large number of tune measurements. A transverse feedback (TFB) based tune measurement technique was used to reduce the tune measurement time [5]. In the measurement, the electron beam is excited by a pseudo white noise signal with a finite bandwidth which covers the frequency range of betatron tunes. The turn-by-turn BPM signal of the transverse orbit motion is recorded by the TFB. By using the fast Fourier transform (FFT), the betatron tune can be identified. Compared to the conventional network analyzer based method that we also use, the TFB based tune measurement technique reduces the measurement time by a factor of 3, with an improved tune resolution. In the operation of Duke storage ring, the tune variation cannot reach the maximum designed tune knob values of ±0.1 due to the betatron tune resonances. One of the resonances is the horizontal integer resonance $\nu_x = 9$; another one is the difference resonance $\nu_x - \nu_y = 5$. In our measurements, the tune knob variation is limited within ±0.05, which is more than adequate to cover the tune variation for HIGS operation.

START-TO-END SIMULATION OF FREE-ELECTRON LASERS

C.C. Hall, H.P. Freund, S.G. Biedron, S.V. Milton
Colorado Sate University, Fort Collins, CO 80523, USA

Abstract

Start-to-end (S2E) modeling of free-electron lasers (FELs) normally requires the use of multiple codes to correctly capture the physics in each region of the machine. Codes such as PARMELA, IMPACT-T or MICHELLE, for instance, may be used to simulate the injector. From there the linac and transport line may be handled by codes such as DIMAD, ELEGANT or IMPACT-Z. Finally, at the FEL a wiggler interaction code such as GENESIS, GINGER, or MINERVA must be used. These codes may be optimized to work with a wide range in magnitude of macro-particle numbers (from 10^4-10^8 in different codes) and have different input formats. It is therefore necessary to have translator codes to provide a bridge between each section. It is essential that these translators be able to preserve the statistical properties of the bunch while raising or lowering the number of macro-particles used between codes. In this work we show a suite of such translators designed to facilitate S2E simulations of an FEL with a new wiggler code, MINERVA, and use these codes to provide benchmarking of MINERVA against other common wiggler simulation codes.

INTRODUCTION

The simulation of an FEL including the injector, linac, beam transport, and undulator requires modeling of the electron beam in a variety of regimes, all of which have differing dominant effects. To accurately perform these start-to-end simulations it is normally necessary to use of variety of codes, each of which is adapted to accurate simulation in a particular regime. It is therefore necessary to be able pass the beam distribution from one code onto another. Unfortunately, these codes often use a variety of conventions for representing the distribution and in the case of macro-particle based codes there is often great disparity in the number of macro-particles necessary for effective simulation. In this paper we describe a set of software tools built to provide translation between the particle tracking codes PARMELA [1], DIMAD [2], and ELEGANT [3] to the undulator simulation code MINERVA [4]. In particular we look at the use of an ELEGANT output to perform an FEL simulation in MINERVA.

MINERVA

MINERVA is a new FEL code under development capable of modeling a large range of FEL configurations, including seeded and self-amplified spontaneous emission (SASE) amplifiers and FEL oscillators (through interface with the optical propagation code OPC [5]). The formulation used in MINERVA describes the particles and fields in three spatial dimensions and includes time dependence as well. Electron trajectories are integrated using the complete Newton-Lorentz force equations. No wiggler-averaged-orbit approximation is made. The magnetostatic fields can be specified by analytical functions for a variety of analytic undulator models (such a planar or helical representations), quadrupoles, and dipoles. These magnetic field elements can be placed in arbitrary sequences to specify a variety of different transport lines. The electromagnetic field is described by a modal expansion. For free-space propagation, MINERVA uses Gaussian optical modes, while waveguide modes are used when the wavelength is comparable to the dimensions of the drift tube. As a result, MINERVA can treat both long and short wavelength FELs. A combination of the Gaussian and waveguide modes is also possible when there is partial guiding at, for example THz frequencies.

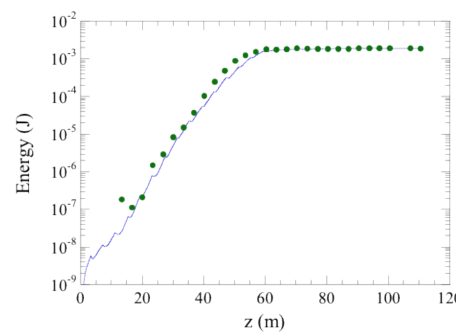

Figure 1: Comparison between experimental data for the LCLS (Green dots) and simulation in MINERVA (blue line).(LCLS data courtesy of P. Emma and H.-D. Nuhn.)

Particle loading is done in a deterministic way using Gaussian quadrature that preserves a quiet start for both the fundamental and all harmonics. Shot noise is included using the usual Poisson statistics algorithm [6] so that MINERVA is capable of simulating SASE FELs; however, provision is made for enhanced shot-noise due to various levels of micro-bunching.

Shown in Fig. 1 is a comparison between measured and simulated pulse energies for the LCLS SASE FEL. The simulation results represent an average over an ensemble of runs performed with different noise seeds

ELEGANT

The code ELEGANT, ELEctron Generation And Tracking is a macro-particle code that can track particles in 6-D phase space using matrices, canonical-kick elements, numerically integrated elements, or a combination of techniques [3]. Of particular importance to linac-based FEL design, ELEGANT includes a 1-D coherent synchrotron radiation (CSR) model [7]. This allows for modeling the impact of CSR in the

MUSIM, A GRAPHICAL USER INTERFACE FOR MULTIPLE SIMULATION PROGRAMS

Thomas J. Roberts*, Muons, Inc., Batavia, IL 60510, USA
Paul Guèye, Hampton University, Hampton, VA 23668, USA

Abstract

MuSim is a new user-friendly program designed to interface to many different particle simulation codes, regardless of their data formats or geometry descriptions. It presents the user with a compelling graphical user interface that includes a flexible 3-D view of the simulated world plus powerful editing and drag-and-drop capabilities. All aspects of the design can be parameterized so that parameter scans and optimizations are easy. It is simple to create plots and display events in the 3-D viewer (with a slider to vary the transparency of solids), allowing for an effortless comparison of different simulation codes. Simulation codes: G4beamline [1], MAD-X [2], and MCNP [3]; more will be coming. Many accelerator design tools and beam optics codes were written long ago, with primitive user interfaces by today's standards. MuSim is specifically designed to make it easy to interface to such codes, providing a common user experience for all, and permitting the construction and exploration of models with very little overhead. For today's technology-driven students, graphical interfaces meet their expectations far better than text-based tools, and education in accelerator physics is one of our primary goals.

OVERVIEW

MuSim is designed to make it easy to construct, simulate, and analyze all types of particle simulations, using any supported simulation code. As shown in Fig. 1, the user interface is 100% graphical and offers advanced user features not available in any other particle-simulation program. It has a flexible 3-D viewer that displays the system as it is constructed, and into which Library objects can be simply dragged and dropped (objects can also be placed at specific positions and orientations). The basic abstraction is based on solid objects placed into the world and/or each other, which is much more flexible and intuitive than the geometry specifications of some simulation codes like MCNP. Along with the parameterization of any aspect of the simulation, this makes simulation decks far more modifiable and maintainable. There is a comprehensive Help system that follows user navigation, and a slider for solid transparency (easily see inside them).

MEASUREMENT AND MODELING OF SINGLE BUNCH WAKE FIELD EFFECTS IN CESR*

J. Calvey, ANL, Argonne, IL 60439, USA
M. Billing, W. Hartung, J. Perrin, D. Rubin, D. Sagan, S.T. Wang, CLASSE, Ithaca, NY 14853

Abstract

Short-range wake fields have been incorporated into a Bmad-based particle tracking code to assess their contribution to current-dependent emittance growth, tune shift, and single bunch instabilities. The wakes are computed for CESR vacuum components using T3P. Simulation results are compared with measurements of bunch length, vertical beam size, and coherent tune shift. Additionally, we use movable scrapers to vary the transverse wake and measure the effect on the beam. We show that a vertical emittance increase at high current may be due to a transverse monopole wake produced by pumping slots in the beam pipe.

INTRODUCTION

The interaction of the electric field from an ultra-relativistic beam of charged particles with its environment, commonly known as its wake field, can cause a variety of problems in particle accelerators, including instabilities, distortion of the bunch's phase space, and beam loss [1]. This effect has been previously studied at the Cornell Electron Storage Ring (CESR) [2–4]. However, two recent developments at CESR have generated a renewed interest in wake field effects: the observation of a vertical emittance blowup at high single bunch current [5], and the installation of a small aperture chamber for a new undulator [6] (which is expected to have a strong transverse wake).

To investigate these effects, we have modified an existing particle tracking code designed for intra-beam scattering (IBS) studies [5] to include wakes. This paper will describe our methodology for calculating the wake fields and how their effect on the beam is simulated. It will then compare these simulations to measurements at 2.1 GeV of bunch lengthening, tune shifts, and emittance growth.

METHODOLOGY

We simulate the effect of wake fields on the beam using a particle tracking code, which makes extensive use of the Bmad software library [7]. The bunch is modeled as a distribution of macroparticles, and tracked through a realistic lattice for several radiation damping times. The single particle wake (i.e. the wake of a point charge) is added to each impedance element, and the effect on the bunch is calculated using a "pseudo-mode" formalism (described below).

Wakes for a given accelerator element are calculated using the ACE3P electromagnetic simulation suite, developed at SLAC [8]. First, the three-dimensional structure of the element is constructed using the finite element mesh toolkit CUBIT [9]. Next, the longitudinal wake for a given bunch is calculated using the time domain wake field solver T3P, which is part of ACE3P.

The primary sources of longitudinal impedance in CESR are sliding joints, horizontal separators, RF cavities, and tapers into and out of the RF sectors. Fig. 1 shows the CUBIT model of the separator. Because this element has approximate top-down and left-right symmetry, only one quarter is modeled, which saves on computation time. Fig. 2 compares the longitudinal wake calculated by T3P for each of the major CESR elements. Although the wake for a single sliding joint is small, there are approximately 100 of them in CESR, so they collectively represent the largest longitudinal impedance.

In principle, we can obtain the single particle wake by deconvolving the wake calculated by T3P from the bunch distribution. However, numerical inaccuracies will cause this calculation to diverge at high frequency, so we suppress any high frequency structure in the wake. While we verify that re-convolving our single particle wake with the bunch spectrum gives us our original wake back, the lack of high frequency information will limit the reliability of the simulation at distance scales short compared to the bunch length.

Once the single particle wake is obtained, it is decomposed as a sum of "pseudo-modes" of the form $A_i \cos(\omega_i t + \phi_i)$ where A_i, ω_i and ϕ_i are parameters of the i^{th} pseudo-mode and are chosen to best reproduce the calculated wake. During tracking, each macroparticle in the bunch adds to the amplitude of each mode, and is kicked by the wake generated by the macroparticles in front of it. By expressing the wake in terms of modes that can be added together at different phases, we avoid having to calculate the effect of each macroparticle on every other one. Thus the computation time scales linearly with the number of particles, rather than quadratically.

SPACE-CHARGE NEUTRALIZATION OF 750-keV PROTON BEAM IN LANSCE INJECTOR LINE*

Y.K. Batygin#, LANL, Los Alamos, NM 87545, USA

Abstract

The 750-keV low-energy beam transport of the Los Alamos Neutron Science Center (LANSCE) linac consists of two independent beam lines for simultaneous injection of H^+ and H^- beams into the linear accelerator. Space charge effects play an important role in the beam transport therein. A series of experiments were performed to determine the level of proton beam space charge neutralization by residual gas ionization, and time required for neutralization. Study was performed as emittance scans between pairs of emittance measurement stations. The value of compensated space charge was determined through comparison of results of measurements and simulations using macroparticle method and envelope code. Obtained results provide new setup for beam tuning in transport beamline.

750 keV H^+ LANSCE BEAM TRANSPORT

The H^+ beam injector includes a duoplasmatron proton source mounted at 750 keV Cockroft-Walton accelerating column and low-energy beam transport line (LEBT). The 750 keV LEBT (see Fig. 1) consists of a quadrupole lattice, 81° and 9° bending magnets, RF prebuncher, diagnostics and steering magnets to prepare beam for injection into the Drift Tube Linac (DTL). Slit-collector beam emittance measurements at 750 keV are performed at three locations: 1) TAEM1 (just after the Cockroft - Walton column), 2) TAEM2 after pre-buncher, and 3) TDEM1 (before the entrance to the DTL).

BEAM EMITTANCE SCANS

Ionization of residual gas by transported particles is an important factor of low-energy beam transport. Typical pressure measured by ion gauges along the transport channel is 9×10^{-7} Torr. A series of beam emittance scans along 750 keV proton beam transport were performed to determine time and level of space charge neutralization of the beam, value of effective beam current under space–charge neutralization, and the value of effective beam emittance. Measurements were done as pair measurements between each pair of emittance stations TAEM1–TAEM2, TAEM2–TDEM1. Measurements were performed with an ion source pulse length of 825 µs. The emittance was sampled within 50 μs of the ion source pulse being delayed at τ = 10 – 400 µs after beginning of beam pulse. The value of proton beam current at 750 keV was 15.2 mA.

EFFECT OF SPHERICAL ABERRATION ON BEAM EMITTANCE GROWTH*

Y.K. Batygin#, LANL, Los Alamos, NM 87545, USA

Abstract

Spherical aberration in axially symmetric magnetic focusing lenses results in an S-shape figure of beam emittance. Filamentation of beam emittance in phase space is a fundamental property of a beam affected by aberrations. An analytical expression for effective beam emittance growth due to spherical aberration is obtained. Analysis is extended for intial emittance growth in drift space and within a focusing channel, induced by beam space charge.

BEAM EMITTANCE GROWTH IN AXI-AL-SYMMETRIC LENS

Beam dynamics in an axially-symmetric field may be severely affected by spherical aberrations, which results in beam emittance growth. Magnetic field of the focusing lens can be approximated as

$$B(z) = \frac{B_o}{1+(z/d)^n} , \qquad (1)$$

where B_o is the peak field, and d is the characteristic length. Parameter $n = 2$ corresponds to the well-known Glazer model [1] for short length/diameter lenses, while in many cases the field of a solenoid is better approximated by $n = 4$, which yields a flatter distribution.

Let us estimate the emittance growth of a beam during its passage through the lens. We assume that the position of the particle is not changed while crossing the lens, and only the slope of the particle trajectory is altered. The transformation of particle variables before $(r_o,\ r_o^{'})$ to after $(r,\ r^{'})$ lens-crossing is given by [2]:

$$r = r_o , \qquad r' = r_o^{'} - \frac{r}{f}(1 + C_\alpha r^2) , \qquad (2)$$

where $f = (4/D)(mc\beta\gamma/qB_o)^2$ is the focal length of the lens, D is the effective length of the lens, and C_α is the spherical aberration coefficient. For the Glazer model $D = (\pi/2)d$, $C_\alpha = 0.25 d^{-2}$, and for $n = 4$ $D = d3\pi/4\sqrt{2}$, $C_\alpha = (5/12)d^{-2}$ [3]. In many applications, the spherical aberration coefficient can be expressed through solenoid sizes as $C_\alpha = 5/(S+2a)^2$, where $2a$ is the pole piece diameter and S is the solenoid pole gap width [4].

Suppose that the initial phase space volume of the beam with radius R is bounded by the ellipse

$$\frac{r_o^2}{R^2}\ni + \frac{r_o^{'2}}{\ni}R^2 = \ni , \qquad (3)$$

where $\ni$ is the unnormalized beam emittance. To find the deformation of the boundary of the beam phase space after passing through the lens, let us substitute the inverse transformation $r_o = r$, $r_o^{'} = r' + (r/f)(1 + C_\alpha r^2)$ into the ellipse equation, Eq. (3). The boundary of the new phase space volume, occupied by the beam after passing through the lens at phase plane $(r,\ r^{'})$ is given by:

$$\frac{r^2}{R^2}\ni + \frac{R^2}{\ni}\left(r' + \frac{r}{f} + C_\alpha\frac{r^3}{f}\right)^2 = \ni . \qquad (4)$$

Let us introduce new variables $(T,\ \psi)$ arising from the transformation:

$$\frac{r}{R} = \sqrt{T}\cos\psi , \qquad \left(r' + \frac{r}{f}\right)\frac{R}{\ni} = \sqrt{T}\sin\psi . \qquad (5)$$

In terms of the new variables, the shape of the beam emittance after lens-crossing is

$$T + 2\upsilon T^2 \sin\psi\cos^3\psi + T^3\upsilon^2\cos^6\psi = 1 , \qquad (6)$$

where the following notation is used

$$\upsilon = \frac{C_\alpha R^4}{f\ni} . \qquad (7)$$

Without nonlinear perturbations, $\upsilon = 0$, and Eq. (6) describes a circle in phase space. Conversely, if $\upsilon \neq 0$, Eq. (6) describes an S – shape distorted figure of beam emittance (see Fig. 1). Accordingly, filamentation of beam emittance in phase space is a fundamental property of a beam affected by aberrations.

Being symplectic in nature, the transformation, Eq. (2), conserves phase-space area. However, the effective area occupied by the beam, increases as a result of the encounter. Let us determine the increase in effective beam emittance as a square of the product of minimum and maximum values of T:

$$\frac{\ni_{eff}}{\ni} = \sqrt{T_{\min}T_{\max}} . \qquad (8)$$

The values T_{max}, T_{min} are determined numerically from Eq. (6). Dependence of the emittance growth on the parameter υ is shown in Fig. 2.

Qualitatively, this relationship can be approximated by the function:

LORENTZ BOOSTED FRAME SIMULATION OF LASER WAKEFIELD ACCELERATION USING HYBRID YEE-FFT SOLVER IN QUASI-3D GEOMETRY

P. Yu*, A. Davidson, A. Tableman, V. K. Decyk, F. S. Tsung, W. B. Mori, UCLA, CA 90024, USA

F. Fiuza, SLAC National Accelerator Laboratory, CA 94025, USA

Abstract

We present results from a preliminary study on modeling Laser wakefield acceleration (LWFA) with OSIRIS in a Lorentz boosted frame using a quasi-3D algorithm. In the quasi-3D algorithm, the fields and currents are expanded into azimuthal harmonics and only a limited number of harmonics are kept. Field equations in (r, z) space are solved for a desired number of harmonics in ϕ. To suppress the numerical Cerenkov instability (NCI) that inevitably arises due to the relativistic plasma drift in the simulation, we use a hybrid Yee-FFT solver in which the field equations are solved in (k_z, r) space, where $\hat{z}$ is the drifting direction. Preliminary results show that high fidelity LWFA boosted frame simulations can be carried out with no evidence of the NCI. Good agreement is found when comparing LWFA boosted frame simulations in the full 3D geometry against those in the quasi-3D geometry. In addition, we discuss how the moving window can be combined with the hybrid Yee-FFT solver to further speed up the simulation. The results indicate that unprecedented speed ups for LWFA simulations can be achieved when combining the Lorentz boosted frame technique, the quasi-3D algorithm, and a moving window.

INTRODUCTION

Laser wakefield acceleration (LWFA) [1] offers the potential to construct compact accelerators that have numerous potential applications including the building blocks for a next generation linear collider and for compact light sources. Due to the strong nonlinear effects that are present in LWFA [2], particle-in-cell (PIC) simulations play a very important role in LWFA research. The PIC algorithm follows the self-consistent interactions of particles through the forces directly calculated from solving the full set of Maxwell equations with the currents and charge densities calculated from the particle trajectories. However, using a standard PIC code to study LWFA in a nonlinear regime can be very CPU-time consuming, e.g. a 10GeV stage run takes approximately 30 million CPU hours. While computing resources now exist to do a few of such simulations, it is not possible to do parameter scans in full three-dimensions (3D).

Recently, there has been much research focused on performing simulations in a Lorentz boosted frame with a plasma drifting towards the laser with a Lorentz factor γ_b [3, 4]. So long as there is no reflected light, then the effective time and space scales to be resolved in a numerical simulation may be minimized. The increase in time step and decrease in the plasma length in this frame lead to savings of factors of γ_b^2 as compared to a lab frame simulation using the so-called moving window [5]. Another reduced model that has been recently proposed is to expand the fields in azimuthal mode numbers m and truncate the expansion [6]. This can reduce modeling a 3D problem with low azimuthal asymmetry into the similar computational cost as using a 2D $r - z$ code. The quasi-3D algorithm was implemented into OSIRIS [7] including a new charge conserving current deposit for improved accuracy [8].

It was pointed out in [9, 10] that it would be intriguing to combine the two methods. Similarly to full PIC simulations in cartesian geometry, it was found [9] that in cylindrical geometry, one of the obstacles that needs to be overcome the numerical Cerenkov instability (NCI) [11], that arises due to the inevitable numerical coupling between the Langmuir modes (main and aliasing) and electromagnetic (EM) modes in relativistically drifting plasma frame [12–14]. This makes clear that Lorentz invariance is not strictly true in a PIC code [15, 16]. However, while the multi-dimensional NCI theory in 2D/3D Cartesian coordinates has been well studied, there is currently no dispersion relation for the NCI in the quasi-3D geometry.

In cartesian geometry several ideas have been proposed to minimize and in some cases essentially eliminate the NCI [10, 13–15, 17]. For example, theory and simulations show how to eliminate the NCI through the use of FFT (spectral) solvers and additional strategies including filters [15]. Recently, it was proposed and demonstrated that a hybrid Yee-FFT solver could also be used to greatly minimize the NCI and that this scheme can be used to suppress the NCI in quasi-3D geometry [10] . In this solver, the Maxwell equation is solved in (k_z, r) space, where $\hat{z}$ is the drifting direction of the plasma for each azimuthal mode number. In this way, the fastest growing modes of the NCI at $(\mu, \nu_1) = (0, \pm 1)$ can be well suppressed by filtering the current in k_z space. Here μ and ν_1 refer the time and space aliased modes [14]. Furthermore, the highly localized $(\mu, \nu_1) = (0, 0)$ NCI modes have similar patterns to that of a 2D spectral solver in Cartesian coordinate, and can be suppressed by reducing the simulation time step, or using a local dispersion modification that accurately eliminate the $(\mu, \nu_1) = (0, 0)$ NCI modes [15].

IMPEDANCE MEASUREMENT FOR THE SPEAR3 STORAGE RING*

Xiaobiao Huang†, James J. Sebek, SLAC, Menlo Park, CA 94025, USA

Abstract

We studied the transverse impedance of the SPEAR3 storage ring with tune shift vs. beam intensity, head-tail instability and transverse mode coupling instability measurements. By taking measurements under different machine conditions, we probed the frequency dependence of the impedance, from which an impedance model was built. This model is consistent with instability measurements and previous bunch lengthening results.

INTRODUCTION

Impedance of a storage ring is an important factor that determines the performance of the machine. For an operational machine, knowledge of the machine impedance helps one to understand the machine performance and provides input for upgrade considerations.

SPEAR3 is a third generation storage ring light source. Table 1 shows a list of selected parameters relevant to this study. Great care was given to controlling the machine impedance during the design and building phases. Consequently the ring is passively stable under normal operation conditions.

Table 1: Selected Parameters of SPEAR3

Parameters	Value	Unit
Energy	3	GeV
Circumference	234.1	m
Current	500	mA
Tune $\nu_{x,y}$	14.106, 6.177	
RF gap voltage	2.85	MV
Bunch length σ_{z0}	6.3	mm
Phase slippage η	1.62×10^{-3}	
Synchrotron tune ν_s	0.0093	

During the 2014 and 2015 runs, we took various beam-based measurements in order to determine the transverse impedance of the machine. These include tune shifts vs. bunch current measurements, head-tail instability measurements and single bunch current threshold measurements. Machine conditions, such as momentum compaction factor, chromaticities, fill pattern, and RF gap voltages were changed as needed to probe the spectrum of the impedance. We tried to interpret the measured impedance with a model that includes resistive wall impedance and a broad-band resonator.

In the following we will show measurements and calculations and discuss the impedance model.

TUNE SHIFT MEASUREMENT

Vertical Plane

The betatron tune shift of a storage ring is related to the transverse impedance through [1, 2]

$$\frac{\Delta\nu_\beta}{\Delta I_b} = \frac{R}{4\sqrt{\pi}(E/e)\sigma_z}\sum_i \beta_i \mathrm{Im}\{Z^{\mathrm{eff}}_{\perp,i}\}, \qquad (1)$$

where I_b is the bunch current, R the average ring radius, E/e beam energy in eV, σ_z the bunch length, β the beta function, $Z^{\mathrm{eff}}_{\perp,i}$ the effective impedance, and $\mathrm{Im}\{\cdot\}$ represents taking the imaginary part. The summation over i is for sections of the ring whose beta functions and impedance contributions may differ. The effective impedance is defined as

$$Z^{\mathrm{eff}}_{\perp} = \frac{\sum_p Z_\perp(\omega_p)h(\omega_p-\omega_\xi)}{\sum_p h(\omega_p-\omega_\xi)}, \qquad (2)$$

where $\omega_p = (p+\nu_\beta)\omega_0$, ν_β the betatron tune, ω_0 the angular revolution frequency, $\omega_\xi = \xi\omega_0\nu_\beta/\eta$, ξ the chromaticity, η the phase slippage factor, and $h(\omega)$ the spectral power density function for the $m = 0$ azimuthal mode. For a Gaussian beam, $h(\omega) = e^{-\omega^2\sigma_t^2}$, with $\sigma_t = \sigma_z/c$, c being the speed of light.

We measured tune shifts vs. bunch current for various machine conditions. Data for the vertical plane are shown in Figure 1. The vertical chromaticity was corrected to zero for the low emittance (LE) lattice data. One of the LE data points was measured with the RF gap voltage reduced to 1.40 MV in order to increase the bunch length. The LE data points at 2.85 MV were taken with 1, 6, 10, and 12 bunches filled, respectively. The low alpha data (LA4) were taken in a lattice for which the momentum compaction factor is reduced to 2.73×10^{-4}. The vertical chromaticity was $\xi = 0.62$ for the low alpha lattice because we had exhausted our sextupole knobs for second order alpha control. The low alpha measurements were repeated on two shifts, each time with RF gap voltage settings of 3.2, 2.4, 2.1 and 1.4 MV, respectively. All data points were taken with the in-vacuum undulator BL12-2 gap open.

Using the data in Figure 1 and Eq. (1) we can calculate the total effective impedance for the ring under the smooth optics approximation,

$$\mathrm{Im}Z^{\mathrm{eff}}_{\perp} = \frac{1}{R/\nu_y}\sum_i \beta_i \mathrm{Im}\{Z^{\mathrm{eff}}_{\perp,i}\}. \qquad (3)$$

The total impedance includes the contribution of resistive wall (RW) impedance, which can be directly calculated, knowing the geometry and surface material of the vacuum chamber. For SPEAR3, the vacuum chamber height in the arcs and in straight sections without insertion devices (ID) is 34 mm. At the ID straight sections, the height ranges from

LINEAR OPTICS AND COUPLING CORRECTION WITH TURN-BY-TURN BPM DATA*

Xiaobiao Huang†, SLAC, Menlo Park, CA 94025, USA
Xi Yang, BNL, Upton, Long Island, NY 11973, USA

Abstract

We propose a method to measure and correct storage ring linear optics and coupling with turn-by-turn BPM data. The independent component analysis (ICA) is used to obtain the amplitudes and phase advances of the betatron normal modes, which are compared to their counterparts derived from the lattice model. By fitting the model to the data with quadrupole and skew quadrupole variables, the linear optics and coupling of the machine can be obtained. Simulation demonstrates that errors in the lattice and BPM parameters can be recovered with this method. Experiments on the NSLS-II storage ring show that it can find the same optics as the linear optics from closed orbit (LOCO) method.

INTRODUCTION

The linear optics of a storage ring is often distorted by various error sources such as systematic and random errors of quadrupole magnets, feed-down effect from orbit offsets in sextupole magnets, and perturbations by insertion devices. The machine with distorted optics has large beta beating and phase advance deviation, which would have a negative impact on the nonlinear beam dynamics performance, resulting in reduced dynamic aperture and/or Touschek lifetime. There is also a need to accurately implement the design optics in order to deliver certain beam properties to users or to facilitate beam diagnostics and beam protection systems. Therefore, optics correction is of crucial importance for storage ring operation. The uncorrected machine may also have a large linear coupling, which needs to be corrected in order to reduce the vertical emittance.

The LOCO method [1] is widely used for both linear optics and coupling correction for storage rings. It fits the measured orbit response matrix data to a lattice model, from which one can derive the required quadrupole and skew quadrupole adjustments for optics and coupling correction. This method is very effective if care is taken to avoid the weakly constrained directions of parameter space from having large contributions in the corrections [2]. A main disadvantage of the LOCO method is that it is time consuming to measure the orbit response matrix. Depending on the size of the ring and the ramp rate of the corrector magnets, the time for measuring the orbit response matrix may vary from 10 min to a few hours.

Similar to the orbit response matrix, turn-by-turn (TBT) BPM data taken when beam undergoes coherent betatron oscillation contain valuable information of the linear optics of the machine. Taking TBT BPM data requires only a few seconds and is nearly non-invasive to the beam. There have been previous proposals and experimental studies on the use of TBT BPM data to measure and correct optics [3–6]. There have also been studies that utilize TBT BPM data to correct linear coupling [7, 8]. These methods typically treat in-plane optics correction and coupling correction separately, despite the fact that TBT BPM data contain optics and coupling error information simultaneously, much the same as the orbit response matrix data.

In this study we propose a method to simultaneously measure and correct linear optics and coupling with TBT BPM data. Similar to LOCO, quadrupole and skew quadrupole variables in the lattice model are varied to fit the measured data, resulting in a calibrated lattice model. The independent component analysis (ICA) method is employed to retrieve the normal mode components for each BPM, which are then compared to model calculations.

In the following we will give a description of the method and present simulation and experimental results.

DESCRIPTION OF THE METHOD

With linear coupling, the beam motion observed on each plane of a BPM is a combination of two normal modes. The ICA can separate the normal modes simultaneously for all BPMs and obtain the beam motion at each BPM in a form [3]

$$\begin{aligned} x_n &= A\cos\Psi_1(n) - B\sin\Psi_1(n) + c\cos\Psi_2(n) - d\sin\Psi_2(n), \\ y_n &= a\cos\Psi_1(n) - b\sin\Psi_1(n) + C\cos\Psi_2(n) - D\sin\Psi_2(n), \end{aligned} \tag{1}$$

where x_n and y_n are observed beam positions for the x and y planes at the n'th turn, respectively, $\Psi_{1,2}(n) = 2\pi\nu_{1,2}n + \psi_{1,2}$, and $\nu_{1,2}$ and $\psi_{1,2}$ are the tunes and initial phases of the normal modes. Note that $\psi_{1,2}$ are equal for all BPMs.

On the other hand, the phase space coordinates $X = (x, x', y, y')^T$ are related to the normal mode coordinates

$$\Theta = \begin{pmatrix} \sqrt{2J_1}\cos\Phi_1 \\ -\sqrt{2J_1}\sin\Phi_1 \\ \sqrt{2J_2}\cos\Phi_2 \\ -\sqrt{2J_2}\sin\Phi_2 \end{pmatrix} \tag{2}$$

via a transformation $X = P\Theta$, where $J_{1,2}$ and $\Phi_{1,2}$ are the action and phase variables for the two normal modes, respectively [9]. Explicitly,

$$\begin{aligned} x &= p_{11}\sqrt{2J_1}\cos\Phi_1 + \sqrt{2J_2}(p_{13}\cos\Phi_2 - p_{14}\sin\Phi_2), \\ y &= \sqrt{2J_1}(p_{31}\cos\Phi_1 - p_{32}\sin\Phi_1) + p_{33}\sqrt{2J_2}\cos\Phi_2, \end{aligned} \tag{3}$$

where we have made use of the fact that $p_{12} = p_{34} = 0$ by definition of P and $\Phi_{1,2}$. The phase variables $\Phi_{1,2}$ advance

ADVANCES IN PARALLEL FINITE ELEMENT CODE SUITE ACE3P*

Lixin Ge, Kwok Ko, Oleksiy Kononenko, Zenghai Li, Cho-Kuen Ng[1], Liling Xiao,
SLAC, Menlo Park, CA 94025, USA
Ji Qiang, LBNL, Berkeley, CA 94720, USA

Abstract

New capabilities in SLAC's parallel finite element electromagnetics simulation suite ACE3P are reported. These include integrated electromagnetic (Omega3P), thermal and mechanical (TEM3P) modules for multi-physics modeling, an interface to particle-material interaction codes for calculation of radiation effects due to dark current generation (Track3P), and coupled electromagnetic (ACE3P) and beam dynamics (IMPACT) simulation. Results from these applications are presented.

INTRODUCTION

SLAC has developed the electromagnetics simulation suite **ACE3P** (**A**dvanced **C**omputational **E**lectro-magnetics **3D** **P**arallel), consisting of modules in frequency and time domains [1]. These massively parallel codes are based on the high-order finite-element method so that geometries of complex structures can be represented with high fidelity through conformal grids, and high solution accuracies can be obtained using high-order basis functions in finite elements. **ACE3P** consists of the following modules: **Omega3P**, an eigensolver for cavity mode (damping) calculations; **S3P**, a frequency-domain solver to calculate S-parameters of rf components; **T3P**, a time-domain solver for transients and wakefield computations; **Track3P**, a particle tracking code for multipacting and dark current studies; **Pic3P**, a particle-in-cell code for self-consistent particle and field interactions; **TEM3P**, a multi-physics code for integrated electromagnetic, thermal and mechanical effects. Running on DOE supercomputing facilities, these six applications modules have been applied to a wide range of modeling and simulation problems for accelerators [2].

Recent advances in the modeling capabilities of **ACE3P** have been focused on enhancing the multi-physics module **TEM3P** and the integration of **ACE3P** modules with other application codes. The major improvements include

- Benchmarking **TEM3P** thermal calculations for a realistic 3D structure against measurement;
- Development of a mechanical eigensolver in **TEM3P** to determine mechanical modes of a superconducting (SRF) cavity to facilitate the investigation of microphonics [3];
- Development of an electro-mechanical analysis tool to decompose the Lorentz force displacement into those of the mechanical modes of an SRF cavity;
- Integration of **ACE3P** with the beam dynamics code **IMPACT** for realistic calculation of beam emittance in accelerator structures and systems;
- Interface of **ACE3P** to particle-material interaction codes such as Geant4 and Fluka for evaluating radiation effects in accelerators.

In the following sections, simulation results from these applications are presented.

THERMAL CALCULATIONS FOR LCLS-II COUPLER

The LCLS-II adopts the TTF3 coaxial fundamental power coupler with modest modifications to make it suitable for CW operation. The coupler consists of a cold section and a warm section made of different kinds of materials with a thin copper coating at the warm side. The fully 3D geometry of the coupler is modeled using **TEM3P** to determine the temperature distribution along the feedthrough of the coupler [4]. The temperature distribution shown in Fig. 1 is obtained for using 6 kW power for the standing wave on resonance. The maximum temperature is found at the bellows located near the central region of the coupler, and it agrees well with the value from high power tests at Fermilab, as shown in Fig. 2 [5].

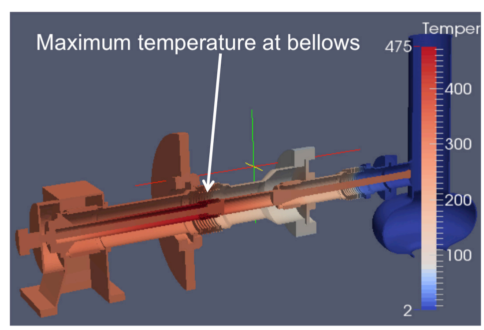

Figure 1: Temperature distribution in TTF3 coupler calculated using TEM3P.

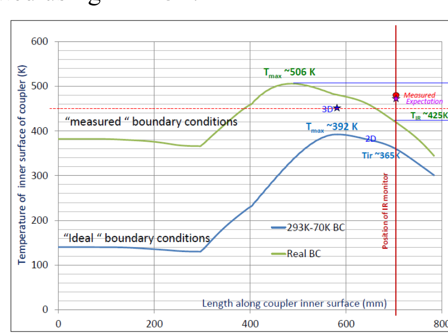

Figure 2: Temperature along the inner conductor with the red dot showing the agreement of simulation and measurement.

DYNAMIC APERTURE STUDIES FOR THE LHC HIGH LUMINOSITY LATTICE*

R. de Maria, M. Giovannozzi, E. McIntosh, CERN, Geneva, Switzerland
Y. Cai, Y. Nosochkov†, M-H. Wang, SLAC, Menlo Park, CA 94025, USA

Abstract

Since quite some time, dynamic aperture studies have been undertaken with the aim of specifying the required field quality of the new magnets that will be installed in the LHC ring in the framework of the high-luminosity upgrade. In this paper the latest results concerning the specification work will be presented, taking into account both injection and collision energies and the field quality contribution from all the magnets in the newly designed interaction regions.

INTRODUCTION

The low-β optics of the high luminosity LHC [1] demands very stringent requirements on the field quality (FQ) of the new large aperture interaction region (IR) magnets: the inner triplet (IT) quadrupoles, the D1 and D2 separation dipoles, and the Q4 and Q5 matching quadrupoles. Specifications of the FQ of these magnets have been studied based on dynamic aperture (DA) calculations with the goal of reaching an acceptable minimum DA ($\simeq 10\sigma$) while being realistically close to the expected magnet FQ. The latter is based on magnet design or scaling from existing magnets FQ. In this paper, the impact of the latest FQ estimate of the IT and Q4 quadrupoles, and the D2 dipoles on DA at collision and injection energies is analyzed, and the necessary adjustments to this FQ are proposed.

The DA study was done for the latest HLLHCV1.0 lattice [2]. Nominally, the so-called `round` beam optics at collision energy was used, where $\beta^*_{x,y}$ = 15 cm at the interaction points IP1 and IP5. In this study, we extend the simulations to other lattice options with different values of β^* which will be described in more detail later. The DA of these lattices was also studied for an extended range of machine linear chromaticity ξ from +2 (nominal) to +18.

The DA was obtained using SixTrack [3,4] with the following set-up: 10^5 turns, 11 x-y phase space angles, 30 particle pairs per $2\,\sigma$ amplitude step, 60 random error seeds, normalized emittance of 3.75 μm, $\Delta p/p = 2.7\cdot10^{-4}$ and $7.5\cdot10^{-4}$ at 7 TeV (collision) and 450 GeV (injection) beam energy, respectively. The machine errors included the arc field errors based on measured FQ of the existing magnets, and the IR magnet field errors based on the latest FQ specifications. The simulations included the correction of tune, chromaticity, coupling and orbit, the use of b_3, b_4, b_5 correctors in the arc dipoles, as well as the IT non-linear field correctors up to the 6th order [5]. Beam-beam effects were not included in this study.

LATEST FIELD QUALITY

The FQ of LHC magnets is defined by [6]

$$B_y + iB_x = 10^{-4} B_N \sum_{n=N}^{\infty} (b_n + ia_n) \left(\frac{x+iy}{r_0}\right)^{n-1}, \quad (1)$$

where the a_n, b_n coefficients are determined at a reference radius r_0, and B_N is the main field at r_0. Furthermore, each a_n and b_n is composed of the mean (a_{nm}, b_{nm}), uncertainty and random terms, where the uncertainty and random values are randomly generated based on their Gaussian sigmas a_{nu}, b_{nu} and a_{nr}, b_{nr}, respectively (see, e.g., Ref. [5]).

The FQ tables for the new IR magnets can be found at the official LHC repository [7]. The recent updates include the new FQ estimates for the IT and Q4 quadrupoles, and for the D2 dipoles.

D2 and Q4 Magnets

The new estimate of the D2 FQ is referred to as `D2_errortable_v5` and includes an update to several b_n coefficients at both the collision and injection energies [8]. The impact of the D2 FQ at collision energy was verified previously [9] and found acceptable since it improved the minimum DA to DA$_{\text{min}} = 9.85\,\sigma$. It has been designated the new D2 FQ specification. The updated D2 FQ coefficients at injection energy are shown in Table 1. The new non-zero b_2 term affects the linear optics. In machine operation the IR focusing errors are expected to be compensated. However, due to lack of such correction in the simulations, this term was set to zero to avoid its impact on the DA. With this assumption, the effect of the updated D2 FQ on DA at injection energy was found negligible and, hence, this FQ is acceptable as a new D2 specification. In this case, the DA$_{\text{min}} = 9.92\,\sigma$.

Table 1: Updated Coefficients of the D2 FQ at Injection Energy (r_0 = 35 mm). Old Values are Shown for Reference

	b_{2m}	b_{3m}	b_{4m}	b_{6m}	b_{7m}	b_{8m}	b_{9m}
Old	0	3.8	-8.0	0	0.1	0	0.02
New	5.0	-19.0	2.0	2.0	1.3	1.0	0.52

The new estimate of Q4 FQ is referred to as `Q4_errortable_v2` and it affects all the field coefficients. In this update, the high order terms (n>9) are reduced at the expense of somewhat larger low order coefficients. Also, new non-zero systematic terms are introduced: b_{6m}, b_{14m} at collision energy and b_{6m}, b_{10m}, b_{14m} at injection. On the other hand, the corresponding uncertainty and random terms b_{nu}, b_{nr} of order n=6,10,14 are cancelled. The SixTrack calculations showed negligible impact of this Q4 FQ

CSR IMPEDANCE FOR NON-ULTRARELATIVISTIC BEAMS*

R. Li#, Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA
C.-Y. Tsai, Department of Physics, Virginia Tech, VA 24061, USA

Abstract

For the analysis of the coherent synchrotron radiation (CSR) induced microbunching gain in the low energy regime, such as when a high-brightness electron beam is transported through a low-energy merger in an energy-recovery linac (ERL) design, it is necessary to extend the existing CSR impedance expression in the ultrarelativistic limit to the non-ultrarelativistic regime. This paper presents our analysis of CSR impedance for general beam energies.

INTRODUCTION

Modern accelerator designs often demand the generation and transport of high brightness electron beams. For these designs it is important to have accurate estimation of the coherent synchrotron radiation (CSR) effects on the degradation of the beam phase space quality. The analytical expressions of CSR wakefield are often utilized in time-domain particle tracking. For example, in ELEGANT, CSR effects are modelled for ultrarelativistic beams using CSR wakefield obtained for the steady-state interaction [1] or for the transient-state interaction [2]. On the other hand, the analytical expression of CSR impedance is necessary for the frequency-domain analysis, such as for the Vlasov anslysis of the microbunching gain [3,4]. For ultrarelativistic bunch in free space, the CSR impedance is given by [3,4]

$$Z(k) = -iA\, k^{1/3} R^{-2/3} \tag{1}$$

For

$$A = -2\pi[Bi'(0)/3 + iAi'(0)] = -0.94 + 1.63i \tag{2}$$

where Ai and Bi are Airy functions.

The designs of low-energy mergers in ERLs requires the knowledge of CSR interaction at low energy and also LSC interaction on a curved orbit. For time-domain particle tracking with codes such as GPT [5] or TStep [6], the study of CSR wakefields are extended from ultrarelativistic regime [1,2] to the low energy regime [7,8]. Similarly, to apply the Vlasov analysis of microbunching gain [3,4] in the frequency domain for the low energy regime, we need to extend the CSR impedance in Eq. (1) to the low energy regime. In the following we present our analysis of the steady-state CSR impedance for general beam energies. The impedance expression reduces to Eq. (1) under ultrarelativistic approximation. In addition, it is shown that the real part of the CSR impedance is consistent with the synchrotron-radiation power loss spectrum given by Schwinger [9]. Note that an existing expression of CSR impedance in free space for general beam energies was presented earlier [10], which takes different form from our expression. Relation between the two will be established in our coming-up studies.

ANALYSIS OF CSR IMPEDANCE FOR GENERAL BEAM ENERGIES

Consider a rigid line bunch, with the longitudinal density distribution $\lambda(z)$, moving at velocity v on a circular orbit with radius R. We will start with the longitudinal wakefield on the bunch as a result of steady-state CSR interaction in free space, and obtain the impedance from the Fourier transform of the CSR wakefield.

First, the electric field on a particle at (s,t), due to the CSR interaction from all other particles in the bunch, is expressed in terms of the retarded potentials

$$\vec{E} = -\nabla\Phi - \frac{\partial\vec{A}}{c\partial t},$$

$$\Phi(s,t) = \int_{-\infty}^{\infty} ds' \frac{\rho(s',t')}{|\vec{r}(s)-\vec{r}(s')|}, \quad \vec{A}(s,t) = \int_{-\infty}^{\infty} ds' \frac{\vec{\beta}(t')\rho(s',t')}{|\vec{r}(s)-\vec{r}(s')|}.$$

Here the retarded time is

$$t' = t - |\vec{r}(s)-\vec{r}(s')|/c$$

and the longitudinal charge density distribution is

$$\rho(s,t) = e\lambda(z) \quad \text{for} \quad z = s-\beta ct.$$

The energy loss rate for the particle per unit path length is

$$e\hat{\beta}\cdot\vec{E} = -e\frac{d\Phi}{vdt} + e\left(\frac{\partial\Phi}{v\partial t} - \vec{\beta}\cdot\frac{\partial\vec{A}}{v\partial t}\right).$$

For the rigid line bunch on the circular orbit, we have

$$\vec{\beta} = (\beta_r,\beta_\theta,\beta_z) = (0, v/c, 0) \quad \text{and} \quad \frac{d\Phi}{dt} = 0.$$

The longitudinal wakefield on the particle is subsequently

$$E_\theta = -\left(\frac{\partial\Phi}{\partial z} - \vec{\beta}\cdot\frac{\partial\vec{A}}{\partial z}\right),$$

in which

$$\Phi - \vec{\beta}\cdot\vec{A} = e\int_{-\infty}^{\infty} ds' \frac{(1-\beta^2)+\beta^2\left[1-\cos\left((s-s')/R\right)\right]}{|\vec{r}(s)-\vec{r}(s')|}\lambda(z')$$

for $z' = z-(s-s')+\beta|\vec{r}(s)-\vec{r}(s')|$.

Using Fourier expansion,

$$\lambda(z) = \int_{-\infty}^{\infty} dk\lambda(k)e^{ikz}, \quad E_\theta(z) = -e\int_{-\infty}^{\infty} dk\, Z(k)\lambda(k)e^{ikz}, \tag{3}$$

we obtain the CSR impedance

AN ALTERNATE RING-RING DESIGN FOR eRHIC

Yuhong Zhang, Thomas Jefferson National Accelerator Facility, Newport News, VA 23606, USA

Abstract

I present here a new ring-ring design of eRHIC. It utilizes high repetition rate colliding beams and is likely able to deliver the performance to meet the requirements of the science program with low technical risk and modest accelerator R&D. The expected performance includes high luminosities over multiple collision points and a broad CM energy range with a maximum value up to 2×10^{34} $cm^{-2}s^{-1}$ per detector, and polarization higher than 70% for the colliding electron and light ion beams. This new design calls for reuse of decommissioned facilities in the US, namely, the PEP-II high energy ring and one section of the SLAC linac as a full energy injector.

INTRODUCTION

A polarized electron-ion collider (EIC) in a CM energy range up to 100 GeV/n is envisioned as a future facility for nuclear science research in the US [1]. Presently, both BNL and JLab are engaged in design studies for this future collider [2,3,4,5]. Since the beginning in 2001, the EIC design studies have been focused on achieving superior performance. The EIC science program [1] requires high luminosity (above 10^{33} $cm^{-2}s^{-1}$ per detector) over a broad CM energy range with a wide array of fully stripped ion species up to lead or uranium, and high polarization (>70%) for both colliding electron and light ion beams. Both ring-ring and linac(ERL)-ring collider scenarios have been adopted respectively for MEIC (the JLab design [4,5]) and eRHIC (the BNL design [3]).

The MEIC design is based on a very high bunch repetition rate for both colliding beams and strong final focusing to achieve a luminosity close to 10^{34} $cm^{-2}s^{-1}$ per detector [6]. The design concept was formulated more than 10 years ago and is still considered the best approach for MEIC. Recently, the reuse of the PEP-II high energy ring for the MEIC electron collider ring has been integrated into the present baseline [5].

eRHIC started with a ring-ring collider design [2] and advanced to the present ERL-ring collider design [3] around 2007 to maximize luminosity. This design is very innovative and introduces a set of new and advanced concepts and schemes, and relies on several yet-to-be-demonstrated technologies [3]. These include a high current polarized electron source based on a multi-cathode Gatling gun; high energy high current multi-pass ERL based on FFAG-type recirculation beam lines; space charge compensation; and coherent electron cooling. While these concepts and technologies are expected to improve the eRHIC performance, they do require R&D effort for development and proto-typing, and for proof-of-principle demonstrations.

In this paper I propose an alternate eRHIC design based on a ring-ring scenario and the same luminosity concept used in the MEIC design. This design has the potential to reach high luminosities and polarization while requiring modest accelerator R&D. I also include a discussion on implementation issues and the required accelerator R&D.

* yzhang@jlab.org

DESIGN CONCEPT

Design Strategy

I choose a ring-ring collider scenario as the basis of this alternate eRHIC design since it is technically a conservative approach compared to an ERL-ring design but still able to deliver very high luminosities. The design supports simultaneous operation of multiple detectors, thus increases science productivity. This is different from an ERL-ring design where an electron bunch is allowed to collide only once (at one of the detectors) due to a large beam-beam disruption, so the detectors can only be operated alternately.

The strategy for high luminosity has been demonstrated already in the B-factories [6] and has been adopted for the MEIC design since 2002 [4]. The concept involves specific design choices of colliding beams, interaction region (IR) and beam cooling. Namely, (1) both colliding beams have a high bunch repetition rate, very small bunch lengths, bunch charges and transverse emittances; (2) the IR has very strong final focusing to attain very small beam spots at collision points; it also has an implementation of crab crossing of colliding beams to support high bunch repetition; (3) electron cooling is responsible for reduction of the proton or ion beam six-dimensional emittances.

New Design Baseline

The following key elements are proposed as the new ring-ring eRHIC baseline

- *Electron collider ring*: the PEP-II high energy ring;
- *Ion collider ring*: one of the RHIC rings;
- *Electron full energy injector*: a section of the SLAC warm linac;
- *Ion injector*: the RHIC ion complex

Reuse of the PEP-II high energy ring includes the entire magnet set and the vacuum chamber as well as the RF system. This results in a 476 MHz bunch repetition rate of the electron beam in the collider ring. Following this approach, no major new facility is required.

RHIC Upgrade

I further propose to upgrade RHIC and its injectors

- To support high bunch repetition rates;
- To support multi-phased electron cooling;
- To improve the RHIC polarized ion beam operation.

To match bunch structure of the electron beam, the RF system of RHIC (and part of AGS) should be rebuilt to support 476 MHz frequency. This provides an

SPACE CHARGE STUDIES IN FFAG USING THE TRACKING CODE ZGOUBI

M. Haj Tahar*, F. Méot, N. Tsoupas, BNL, Upton, Long Island, New York, USA

Abstract

A method is implemented in Zgoubi that allows the computation of space charge effects in 2D distributions and with some restrictions in 3D distributions. It relies on decomposing field maps or analytical elements into slices and applying a space charge kick to the particles. The aim of this study is to investigate the accuracy of this technique, its limitations/advantages by comparisons with other linear/nonlinear computation methods and codes, and to apply it to high power fixed field ring design studies.

INTRODUCTION

Accelerator Driven Systems are still in the early development stage. One of the main challenges is the average beam current required in order to achieve high transmutation rates. By choosing the effective multiplication factor as to accommodate any possible positive reactivity insertion during the operation of the reactor, it can be shown that the minimum average beam current is ~ 10 mA. So, in order to investigate the possible benefits of FFAGs for Accelerator Driven Systems, one has to develop techniques to understand and master the space charge effects.

IMPLEMENTATION

Zgoubi [1] is a ray-tracing code which can track particles through electric and magnetic fields introduced as field maps or as analytic elements. We carry out a self consistent multi-particle simulation that is based on the space charge KV model [2] : the beam is supposed to have a uniform distribution with elliptical cross section, and a constant linear charge density. In that case, the free-space self-field solution within the beam is:

$$E_x = -\frac{\partial \phi}{\partial x} = \frac{\lambda}{\pi \epsilon_0} \frac{x}{(r_x + r_y) r_x} \tag{1}$$

$$E_y = -\frac{\partial \phi}{\partial y} = \frac{\lambda}{\pi \epsilon_0} \frac{y}{(r_x + r_y) r_y} \tag{2}$$

The kick received transversly by the particles after each integration step Δs is thus given by:

$$\Delta x' = \frac{2Q}{(r_x + r_y) r_x} x \Delta s \tag{3}$$

$$\Delta y' = \frac{2Q}{(r_x + r_y) r_y} y \Delta s \tag{4}$$

where Q is the generalized pervance term defined by, $Q = \frac{q\lambda}{2\pi\epsilon_0 m_0 c^2 \beta^2 \gamma^3}$. So, in order to evaluate the space charge force, one has to evaluate the beam radii and vice-versa.

* mhajtahar@bnl.gov

Slicing

If we cut the magnet into thin slices, we may assume that the beam radii do not change much within each slice. Thus, each particle will experience a transverse space charge kick given by the formula (3) and (4) above. The main assumption here is that each particle in the beam does not see its immediate neighbors, but the smooth potential which is derived from the bunch (with uniform distribution) as a whole. Taking the statistical averages (rms quantities) is the natural way to derive analytically the evolution of such quantities as the beam emittance or the beam edge radius. Here we restrict ourselves to the KV model for which we define:

$$r_x = 2 < x^2 >^{1/2} \tag{5}$$

$$\epsilon_x = 4[< x^2 >< x'^2 > - < xx' >^2]^{1/2} \tag{6}$$

Given that the space charge forces are linear, the rms edge emittance in this model is constant and represents the maximum Courant-Snyder invariants. This was successfully checked. Also, the transverse particle equation of motion (when dispersion is neglected and only valid within the beam) is given by [3]:

$$x''(s) + \left(\kappa_x(s) - \frac{2Q}{[r_x(s) + r_y(s)] r_x(s)}\right) x(s) = 0 \tag{7}$$

If we consider a KV beam composed of N particles and with zero rms emittance, such as x_i(s=0)=x_i and x_i'(s=0)=0 $\forall i \in [\![1 \,;\, N]\!]$. Then the envelope edge radius in a drift is given by:

$$r_x(s) = x_i^{max} \cosh\left[\left(\frac{2Q}{r_{x0}(r_{x0} + r_{y0})}\right)^{1/2} \times s\right] \tag{8}$$

where r_{x0} and r_{y0} are the envelope edge radii at the entrance of the drift. Fig. 1 shows a comparison of the axial beam envelope in a drift obtained from tracking with the analyti-cal formula (8). Similar tests were performed in quadrupole element which gave agreement as well. A natural test of the convergence of this method is to vary the number of slices until the beam envelope stabilizes: Fig. 2 below illustrates the convergence in a drift element (which is easy to picture). This result can be interpreted in the following way: it shows the speed at which the space charge force evolves in a KV beam (in a drift).

SPACE CHARGE EFFECTS IN SCALING FFAG

Analytical Model of the 150 MeV KURRI FFAG

The current work is a first step to understand the space charge effects in the 150 MeV scaling FFAG at KURRI in

CROSS-PLATFORM AND CLOUD-BASED ACCESS TO MULTIPLE PARTICLE ACCELERATOR CODES VIA APPLICATION CONTAINERS*

D.L. Bruhwiler#, R. Nagler, S.D. Webb, RadiaSoft, Boulder, CO 80304, USA
G. Andonian, M.A. Harrison, S. Seung, RadiaBeam Technologies, Santa Monica, CA 90404, USA
T. Shaftan, BNL, Upton, NY 11973, USA
P. Moeller, Bivio Software, Boulder, CO 80303, USA

Abstract

Particle accelerator and radiation modeling codes focus on specific problems, rely on complicated command-line interfaces, are sometimes limited to a small number of computing platforms, and can be difficult to install. There is also a growing need to use two or more codes together for end-to-end design or for complicated sub-systems. RadTrack [1,2] is a lightweight cross-platform GUI for such codes, based on the Qt framework [3] and PyQt [4] bindings for Python. RadTrack is designed to support multiple codes, placing no burden on the corresponding development teams. Elegant [5] and the Synchrotron Radiation Workshop (SRW) [6-9] are supported now in a pre-beta stage, and support for GENESIS 1.3 [10,11] is under development. These codes are being containerized via the open source Docker platform [12] for use in the cloud. The open source Vagrant [13] and Virtual Box [14] are used for MacOS and Windows. We discuss RadTrack and our vision for cloud computing.

RADTRACK USER TESTING

In preparation for an upcoming beta test program, user testing of RadTrack was conducted at the IPAC conference in Richmond, VA on May 4 and 5, 2015. In order to ensure the entire team has access to user feedback, we are using Screenflick [15] on the Mac and BB Flashback [16] on Windows to record user actions, audio and video. These videos have been invaluable in discovering basic user interaction (UX) issues. We are now improving the workflow to be more intuitive for end-users.

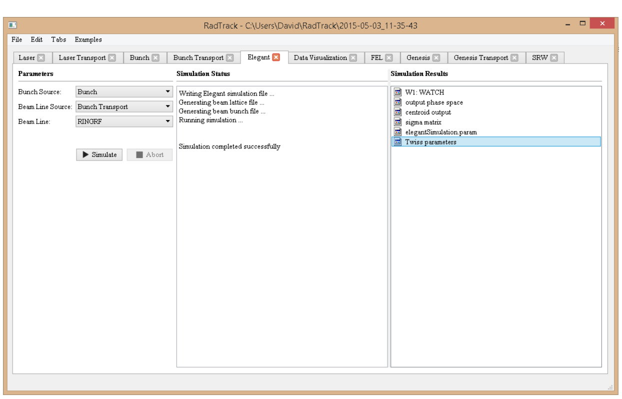

Figure 1: RadTrack Qt widget for Elegant simulations.

The use case presented to test subjects was to build a FODO accelerator lattice from scratch, beginning with a 65 MeV electron beam, and to simulate the problem with Elegant. Figure 1 shows the widget for Elegant modeling. This Tab manages the selection of an accelerator lattice and a beam description, shows runtime output, then provides easy access to the resulting output files for visualization.

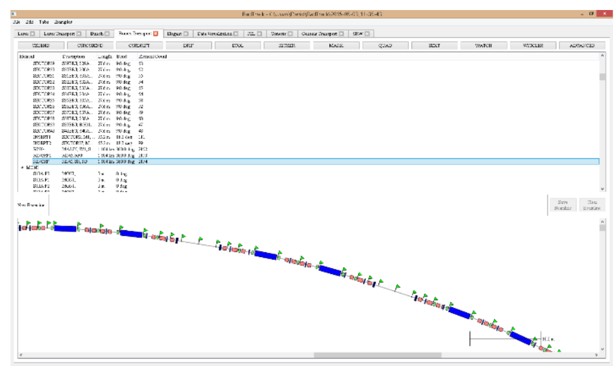

Figure 2: RadTrack Qt widget for drag-and-drop construction and visualization of particle accelerator lattices.

Figure 2 shows the bunch transport tab, which parses Elegant lattice files to present a graphical representation of the beamline. Drag-and-drop features enable interactive modification of existing lattices or rapid creation of new beamlines. The Elegant tab can use the bunch transport tab directly, or parse a specified lattice file. The user can create multiple bunch transport tabs.

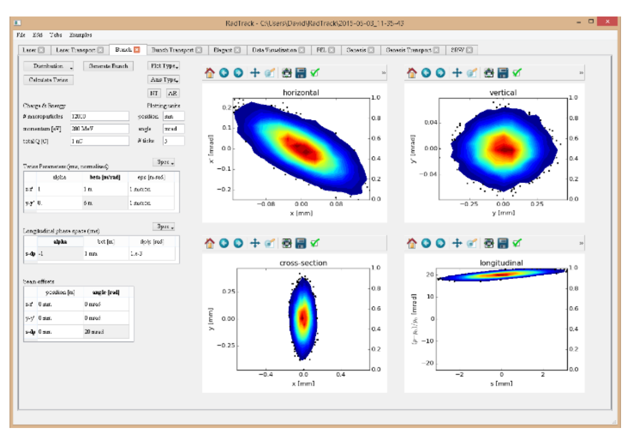

Figure 3: RadTrack Qt widget for interactive specification and visualization of particle beams.

NON-LINEAR MAGNETIC INSERTS FOR THE INTEGRABLE OPTICS TEST ACCELERATOR*

F. H. O'Shea, R. Agustsson, Y.-C. Chen and E. Spranza,
RadiaBeam Technologies, 1717 Stewart St., Santa Monica, California, USA
D. W. Martin and J. D. McNevin
RadiaBeam Systems, 1717 Stewart St., Santa Monica, California, USA

Abstract

We present here a status update of the manufacture and magnetic measurements of the non-linear inserts for the Integrable Optics Test Accelerator. RadiaBeam Technologies is designing the 2-meter structure from magnetic field specifications, including pole design, measurement systems and alignment fiducialization. Herein, we will describe the current state of the project.

STATE OF THE PROJECT

The goal of the Integrable Optics Test Accelerator (IOTA) is to serve as a proof of principle experiment of the integrable optics technique. Briefly, the technique seeks to improve accelerator intensity by deliberately violating the assumption of linear motion that has two invariants: particle emittance and energy [1, 2]. The IOTA ring will be constructed at the Advanced Superconducting Test Accelerator facility at Fermi National Lab [3]. While a great many of the components for the IOTA ring are being recommissioned from other projects, the non-linear inserts are entirely new and must be designed exclusively for the IOTA ring because the magnetic field of the insert depends on the configuration of the other optical elements in the ring.

Unlike magnets typically found in circular accelerators, both the magnetic field strength and the mechanical aperture of the non-linear insert are explicit functions of the longitudinal coordinate [1–3]. To reduce the complexity of manufacturing the magnets for this insert and allow flexibility for assembly, we have decided to segment the insert such that the magnetic field properties are constant along a fixed short length of the insert, but the magnetic properties vary between segments along the length of the insert in accordance with the requirements of the integrable optics theory. An example of a segmented prototype can be seen in Fig. 1. The constraints on the field quality are specified by tracking simulations to be:

1. The magnetic axes of all of the segments may not deviate from each other by more than 50 μm.

2. The field may not deviate from the theoretical field by more than 1% within some good field region.

3. The good field region should cover as much of the physical aperture as practicable.

* Work supported by DOE under contract DE-SC0009531.

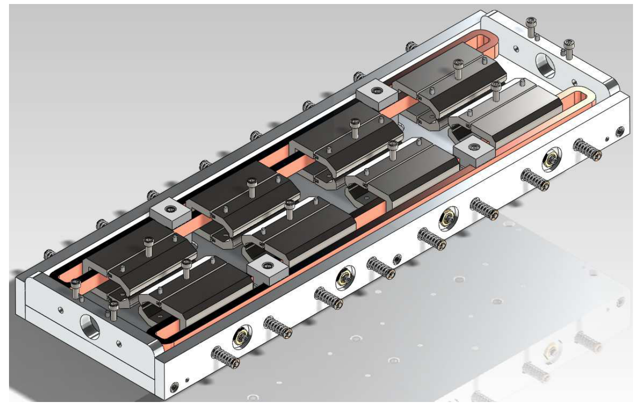

Figure 1: Isometric view of the initial IOTA insert prototype. A plate on top has been hidden to show detail below. The copper items are the excitation coils, the dark grey items are the steel poles and return yokes, and light grey items are aluminum.

In previous proceedings we reported the construction of an initial prototype to test a simple tuning mechanism to allow adjustment of the magnetic fields in the insert [4]. RadiaBeam Technologies is now moving forward with the design of a full scale prototype non-linear insert that will be installed on the IOTA ring. We have advanced the design of the full scale prototype to take advantage of the experience gained during manufacture of the initial prototype. In addition to reporting the results of the magnetic measurement of the initial prototype, we report on the design and engineering strategy for the full scale insert. Specifically, we cover the design of the vacuum system, a manufacturing strategy for the magnets, and the alignment technique we will use to align the many segments of the insert.

MEASUREMENT OF THE PREVIOUS PROTOTYPE

Previously, we had planned to measure the magnetic field of the initial prototype insert (see Fig. 1) via a custom Hall probe bench to accommodate the very small aperture of the magnets [4]. This measurement system was constructed, but it turned out to be impractical. The very small Hall probes, of total size in the mm range, required very fine wires which easily broke. In addition, the connections to the Hall effect sensor were sensitive to movement and produced spurious signals on the order of the measurement signal. As a result, we decided on a more conventional rotating

SPACE CODE FOR BEAM-PLASMA INTERACTION

K. Yu*, Stony Brook University, Stony Brook, NY 11794, USA
R. Samulyak#, Stony Brook University, Stony Brook, NY 11794 and BNL, Upton, NY 11973, USA

Abstract

A parallel particle-in-cell code SPACE has been developed for the simulation of electromagnetic fields, relativistic particle beams, and plasmas. The algorithms include atomic processes in the plasma, proper boundary conditions, an efficient method for highly-relativistic beams in non-relativistic plasma, support for simulations in relativistic moving frames, and special data transfer algorithm from the moving to the laboratory frame that collects particles and fields in the lab frame without time shift due to the Lorentz transform, enabling data analysis and visualization. Plasma chemistry algorithms implement atomic physics processes such as the generation and evolution of plasma, recombination of plasma, and electron attachment on dopants in dense neutral gas. Benchmarks and experimental validation tests are also discussed. The code has been used for the simulation of processes relevant to the eRHIC program at BNL and the high pressure RF cavity (HPRF) program at Fermilab.

INTRODUCTION

Direct numerical simulation of plasma in the presence of atomic processes such as generation and recombination of charged particles is a complex multiscale problem. Plasma number density may change by orders of magnitude during relevant time scales, creating difficulties in representing secondary plasma particles by macroparticles within the Particle-in-Cell (PIC) method. Another difficulty is in the presence of different time scale, as in the case of plasmas interacting with relativistic particle beams. Evolution of atomic physics processes may be orders of magnitude longer compared to passing times of short relativistic bunches.

Novel algorithms for the simulation of plasma undergoing atomic processes and relativistic particle beams have been developed and implemented in SPACE, a parallel electromagnetic PIC code. The code has been applied to a number of problems relevant to advanced particle cooling mechanisms.

SUMMARY OF SPACE CODE

PIC Method for Maxwell's Equations

The system of Maxwell's equations in the presence of moving charges is written as

$$\frac{\partial \boldsymbol{B}}{\partial t} = -\nabla \times \boldsymbol{E} \quad (1a)$$

$$\frac{\partial \boldsymbol{E}}{\partial t} = -\frac{1}{\epsilon_0 \mu_0}\nabla \times \boldsymbol{B} - \frac{1}{\epsilon_0}\mathbf{J} \quad (1b)$$

$$\nabla \cdot \boldsymbol{E} = \frac{\rho}{\epsilon_0} \quad (1c)$$

$$\nabla \cdot \boldsymbol{B} = 0 \quad (1d)$$

The Maxwell equations are discretized using the finite difference time domain (FDTD) [1] with second order accuracy in space and time. Electric charges are represented by discrete macroparticles coupled with electromagnetic fields by the action of Lorentz forces and electric currents.

When one solves Maxwell's equations analytically, solving Eq. (1a) and Eq. (1b) is sufficient: if Eq. (1c) and Eq. (1d) are satisfied at initial time, they remain invariants of motion at later time. Due to numerical truncation errors, this property may be violated. To resolve this problem, a special rigorous charge conservation method was developed within the PIC framework in [2]. This algorithm, implemented in the SPACE code, requires solving numerically the Poisson problem (Eq. (1c)) only once for obtaining consistent initial conditions. Then only the first two Maxwell's equations (Eq. (1a) and Eq. (1b)) and the Newton-Lorentz equation are solved numerically at each time step. A schematic of processes occurring at each time step is depicted in Fig. 1. The computational sequence is of fields and particle coordinates is shown in Fig. 2. We also implemented modifications of the Boris scheme [3] proposed in [4] for dealing with rapidly accelerating particles for which the relativistic factor is not constant.

Abstract

Understanding of the interaction of muon beams with plasma in muon cooling devices is important for the optimization of the muon cooling process. SPACE, a 3D electromagnetic particle-in-cell (EM-PIC) code, is used for the simulation support of the experimental program on the hydrogen gas filled RF cavity in the Mucool Test Area (MTA) at Fermilab. We have investigated the plasma dynamics in the RF cavity including the process of power dump by plasma (plasma loading), recombination of plasma, and plasma interaction with dopant material. By comparison with experiments in the MTA, simulations suggest several unknown properties of plasma such as the effective recombination rate, the electron attachment time on dopant molecule, and the ion – ion recombination rate in the plasma.

INTRODUCTION

When a beam passes through a dense hydrogen gas filled RF (HPRF) cavity, the beam energy ionizes the gas. The induced plasma gains energy from the RF electric field applied to cavity. This effect is called plasma loading. The induced plasma undergoes complicated recombination processes. If a small amount of dopant (molecular oxygen) is added to the hydrogen gas, plasma electrons attach to dopant molecules, creating negatively charges ions and causing ion-ion recombination processes. These processes have been studied by experiments at the MuCool Test Area at Fermilab [1,2,3]. Simulation study has been used to compare the experiment results with the mathematical model and uncover unknown or uncertain properties from the experiments. Even though the recombination rate, attachment time, and ion-ion recombination are measured in experiments, the range of measurements is restricted in narrow region. Benchmarked with experimental data, simulations suggest those rates for a large experimental range. To enable such simulations, new algorithms to resolve plasma chemistry and plasma loading have been developed and implemented in SPACE [4].

ATOMIC PHYSICS IN GAS-FILLED CAVITY

Plasma Formation

As an intense proton beam propagates in the HPRF cavity, it generates plasma by ionization due to collision of beam particles with neutral gas molecules [5,6]. When the cavity is filled with pure hydrogen gas, the plasma is formed by electrons and hydrogen ion clusters. If dopant such as oxygen is added in the gas, electrons quickly attach to dopant molecules, creating negative ions [5,7]. The formation of plasma follows the beam shape because plasma particles are generated along beam particle trajectories, and the plasma particles cannot move far away from their initial position due to collisions with the dense neutral gas. The plasma column preserves its form as time evolves (Fig. 7), even though the density of plasma changes by successive beam injections and atomic processes such as electron ion recombination, electron attachment, and ion-ion recombination in the cavity.

Plasma Loading

The energy loss by one plasma pair during one RF cycle, dw, is introduced [1,3] based on the electron or ion drift velocity (v) or mobility (μ), and the external RF field ($E_0 \sin(\omega t)$):

$$dw = \mathrm{q}\int_0^T (v_e + v_+ + v_-)\, E_0 \sin(\omega t)\, dt = \mathrm{q}\int_0^T (\mu_e + \mu_+ + \mu_-)\, E_0^{\,2} \sin^2(\omega t)\, dt \quad (1)$$

where subscripts "e", "+", and "-" denote electron, positive ion (hydrogen), negative ion (oxygen), respectively, and T and E_0 are the period and peak magnitude of the RF cycle. The external electric field E_0 in Eq. (1) has spatial distribution related to the geometry of the cavity [3]. Even though E_0 is not constant in space, we can assume it is constant for each specific plasma pair during one RF cycle since plasma charges cannot move far away from their initial positions. But different plasma pair in different position may have different E_0. Spatial distribution of E_0 is implemented in the SPACE code. Analytic computation of Eq. (1) was compared with experiments in [1,2,5]. Numerical simulation results are compared with experiments in Fig. 2.

The power delivered to gas in cavity by plasma loading is given by

$$\mathrm{P} = \frac{(V_{peak} - V)V}{R} - CV\frac{dV}{dt} \quad (2)$$

where R, C, and V_{peak} denote the shunt impedance, capacity of the cavity, and the peak RF voltage, respectively [1,3]. In simulations, the total power is computed and E_0 (V in Eq. (2)) is updated at every time step. Functions implementing the electron drift velocity

G. Wang, Brookhaven National Laboratory, Upton, New York 11973, USA

Abstract

One of the main challenges in the increase of luminosity of circular colliders is the control of the beam-beam effect. In the process of exploring beam-beam mitigation methods using plasma, we evaluated the possibility of plasma generation via ionization of neutral gas by proton beams, and performed highly resolved simulations of the beam-plasma interaction using SPACE, a 3D electromagnetic particle-in-cell code. The process of plasma generation is modelled using experimentally measured cross-section coefficients and a plasma recombination model that takes into account the presence of neutral gas and beam-induced electromagnetic fields. Numerically simulated plasma oscillations are consistent with theoretical analysis. In the beam-plasma interaction process, high-density neutral gas reduces the mean free path of plasma electrons and their acceleration. A numerical model for the drift speed as a limit of plasma electron velocity was developed. Simulations demonstrate a significant reduction of the beam electric field in the presence of plasma. Preliminary simulations using fully-ionized plasma have also been performed and compared with the case of beam-induced plasma.

PLASMA GENERATION

We study the process of plasma generation by the proton beam ionization of neutral matter, such as molecular hydrogen gas. We use the following parameters relevant to the Relativistic Heavy Ion Collider (RHIC) at the Brookhaven National Laboratory.

Table 1: Proton Beam Structure

Energy	30 GeV
Normalized emittance	2e-6 m rad
Beta function	10 m
Number of protons per bunch	2e+11
Bunch duration	5 ns
Number of bunches	110
Bunch arrival interval	110 ns

Energy loss of an incident particle in matter by ionization is described by the Bethe-Bloch formula. But since the amount of energy absorbed by excitation processes is not precisely known, we use an empirical formula and experimentally measured ionization cross-sections. The evolution of the plasma density is given as

$$\frac{dn_e}{dt} = \frac{dN_p}{dt}\sigma L n_{gas} - \beta_r n_e n_i \qquad (1)$$

where dn_e/dt is the ionization rate, dN_p/dt is the inflow of protons in the elementary volume, L is the volume length, n_{gas}, n_e, and n_i are number densities of neutral gas, plasma electrons, and plasma ions, respectively, and β_r is the recombination coefficient. The ionization cross section σ of energetic particles in molecular hydrogen was experimentally measured in [1].

The recombination of plasma is strongly affected by the presence of neutral gas with much bigger density than the plasma density, and the electric field of the proton beam. The recombination coefficient is an empirical coefficient [2, 3] evaluated as

$$\beta_r = c_1 X^{-c_2}$$

Here $X = E/P$ is the ratio of electric field and hydrogen pressure, and c_1 and c_2 are empirical numerical coefficients. We use results of measurements of plasma recombination in high-pressure hydrogen gas filled RF cavity at Fermilab [2, 3] to evaluate the recombination coefficient.

In the initial stage of plasma generation, recombination is negligible because of low plasma density, as shown in Figure 1. In this section, long-time evolution of plasma was obtained by numerically integrating equation (1). Fully resolved 3D PIC simulations are presented in the next section.

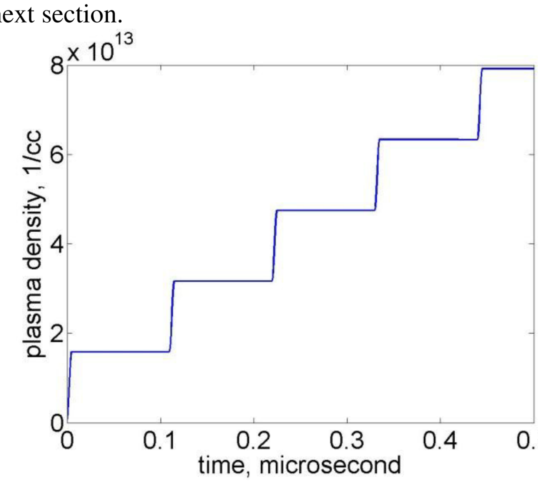

Figure 1: Plasma density evolution corresponding to first five bunches of proton beam.

DECOHERENCE DUE TO SECOND ORDER CHROMATICITY IN THE NSLS-II STORAGE RING*

G. Bassi†, A. Blednykh, J. Choi, V. Smaluk, BNL, Upton, NY 11973-5000, USA

INTRODUCTION

We study decoherence effects due to second order chromaticity for small amplitude kicks, in order to estimate the energy spread from TbT data. The measurements are taken for the bare lattice (no Damping Wigglers and Insertion devices) of the NSLS-II storage ring, since the long transverse radiation damping time $\tau_x = 54$ allows the study of decoherence effects on shorter time scales. To minimize the chromatic damping/antidamping from the slow-head tail effect, we used a short train of 50 bunches distributed over consecutive rf-buckets with an average current $I_0 = 1$mA, high enough to obtain a good BPM signal. The vertical and horizontal betatron motion have been excited independently with pinger magnets. In this contribution we limit the discussion to the horizontal case. A more detailed analysis discussing the vertical case, together with the transition to kicks of larger amplitudes to characterize decoherence with amplitude effects will be addressed in our future work. Decoherence studies have been done by independently exciting horizontal and vertical betatron oscillations with pingers, from small values of the pinger voltage for good BPM signal, to larger values in order to excite betatron oscillations of amplitude (peak to peak) 2mm. Larger betatron oscillations have been induced to clearly show the transition from decoherence due to second order chromaticity to decoherence with amplitude. Decoherence due to chromaticity and nonlinearities and beam energy spread measurements have been discussed in [1, 2].

DECOHERENCE DUE T0 LINEAR CHROMATICITY

Although in this contribution we discuss measurements for negligible linear chromaticity, in a small kick regime dominated by second order chromaticity, the decoherence due to nonzero linear chromaticity can be used as well to accurately estimate important beam parameters such as the synchrotron tune and the energy spread, based on the direct analysis of TbT data or on the analysis of their spectra. Of course, in second order chromaticity can not be made negligible, both effects (linear chromaticity and second order chromaticity) must be studied simultaneously. This case introduces little complications, for example formulae cannot eventually be put in closed form, however, as shown in the next Section, it does not prevent to estimate beam parameters. A formula for the decoherence of TbT data due to linear chromaticity is well known [3–5]. A derivation of the formula is given in Appendix. Here we discuss its use to estimate the synchrotron tune and energy spread from

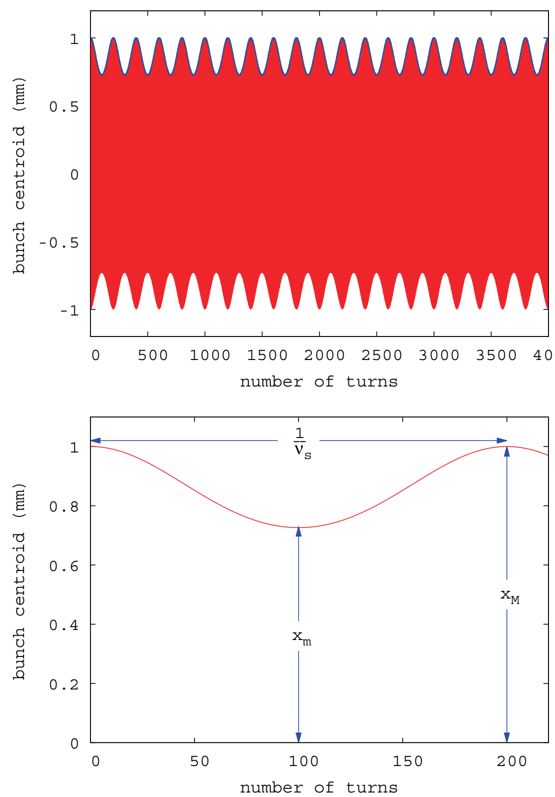

Figure 1: Top frame: evolution of the bunch centroid $\langle x(t)\rangle$. Bottom frame: enlargement of the top frame illustrating how the synchrotron tune and energy spread can be extracted from the signal of TbT data.

TbT data. Assuming for the betatron frequency ω a linear dependence on the relative energy deviation δ

$$\omega(t) = \omega_\beta + \xi\omega_0\delta(t), \tag{1}$$

where ξ is the linear chromaticity, the time evolution of the kicked (at t=0) bunch centroid $\langle x(t)\rangle$ reads (see Appendix)

$$\langle x(t)\rangle = \langle x_0\rangle e^{-2\frac{\xi^2\sigma_\delta^2}{\nu_s^2}\sin^2\frac{\omega_s t}{2}} \cos\omega_\beta t, \tag{2}$$

where η is the slippage factor, ω_s the synchrotron frequency, $\nu_s = \omega_s/\omega_0$ the synchrotron tune, σ_δ the energy spread and $\sigma_{z0} = \eta c/(\omega_s\sigma_\delta)$ the bunch length, where c is the speed of light. The top frame of Fig. 1 shows the evolution of the bunch centroid $\langle x(t)\rangle$ where its envelope shows a modulation with a characteristic wavelength and amplitude as given by Eq. 2. For illustration purposes, the linear chromaticity ξ has been chosen equal to 4. The bottom frame of Fig. 1 shows an enlargement of the top frame, and illustrates how the synchrotron tune and energy spread can be extracted from the signal of TbT data. The synchrotron tune

A GENERIC FORMULATION FOR EMITTANCE AND LATTICE FUNCTION EVOLUTION FOR NON-HAMILTONIAN SYSTEMS WITH STOCHASTIC EFFECTS

J. Scott Berg, BNL*, Upton, NY 11973, USA

Abstract

I describe a generic formulation for the evolution of emittances and lattice functions under arbitrary, possibly non-Hamiltonian, linear equations of motion. The average effect of stochastic processes, which would include ionization interactions and synchrotron radiation, is also included. I first compute the evolution of the covariance matrix, then the evolution of emittances and lattice functions from that. I examine the particular case of a cylindrically symmetric system, which is of particular interest for ionization cooling.

INTRODUCTION

I describe a general formulation for the evolution of the first and second moments of a beam distribution. Similar formulations have been presented before ([1–3] are some examples). What is of interest here is the definition of the stochastic behavior in terms of probabilities, the direct computation of the evolution of generalized lattice functions (really the symplectic normalizing transformation of the second moment matrix) and emittances, and the definition of a metric for mismatch of those lattice functions.

MATHEMATICAL FORMULATION

$\psi(z, s)$ is the distribution function for particles in the phase space coordinates z at a point s along a reference curve. We define the first and second moments of this distribution

$$\boldsymbol{a}(s) = \int z\,\psi(z, s)\,dz \tag{1}$$

$$\Sigma(s) = \int [z - \boldsymbol{a}(s)][z - \boldsymbol{a}(s)]^T \psi(z, s)\,dz \tag{2}$$

The deterministic motion of a particle is described by

$$\frac{dz}{ds} = \boldsymbol{f}(z, s) \tag{3}$$

The stochastic part of the motion is described such that $\rho(\boldsymbol{x}, z, s) d\boldsymbol{x}\, ds$ is the probability that, for a particle at z in phase space and in the interval $[s, s + ds)$, the particle is displaced in phase space by a value in the phase space volume of size $d\boldsymbol{x}$ at $\boldsymbol{x}$. Then the continuity equation is

$$\frac{\partial\psi}{\partial s} + \boldsymbol{\nabla} \cdot [\psi(z, s)\boldsymbol{f}(z, s)] = \int \psi(z - \boldsymbol{x}, s)\rho(\boldsymbol{x}, z - \boldsymbol{x}, s)\,d\boldsymbol{x} - \psi(z, s)\int \rho(\boldsymbol{x}, z, s)\,d\boldsymbol{x}. \tag{4}$$

From this one can determine the evolution of the moments. The system acts as though it were governed by a deterministic vector field $\boldsymbol{g}$ such that

$$\frac{dz}{ds} = \boldsymbol{g}(z, s) = \boldsymbol{f}(z, s) + \int \boldsymbol{x}\,\rho(\boldsymbol{x}, z, s)\,d\boldsymbol{x} \tag{5}$$

Then

$$\frac{d\boldsymbol{a}}{ds} = \int \boldsymbol{g}(z, s)\psi(z, s) \tag{6}$$

$$\begin{aligned}\frac{d\Sigma}{ds} = &\int [z - \boldsymbol{a}(s)]\boldsymbol{g}(z, s)^T \psi(z, s)\,dz \\ &+ \int \boldsymbol{g}(z, s)[z - \boldsymbol{a}(s)]^T \psi(z, s)\,dz \\ &+ \int \boldsymbol{x}\boldsymbol{x}^T \rho(\boldsymbol{x}, z, s)\psi(z, s)\,d\boldsymbol{x}\,dz\end{aligned} \tag{7}$$

If $\boldsymbol{g}(z, s) = \boldsymbol{g}_0(z) + JH(s)z$, with J the antisymmetric symplectic metric (H is symmetric only for a Hamiltonian system),

$$\frac{d\boldsymbol{a}}{ds} = \boldsymbol{g}_0(s) + JH(s)\boldsymbol{a}(s) \tag{8}$$

$$\begin{aligned}\frac{d\Sigma}{ds} = &JH(s)\Sigma(s) - \Sigma(s)H^T(s)J \\ &+ \int \boldsymbol{x}\boldsymbol{x}^T \rho(\boldsymbol{x}, z, s)\psi(z, s)\,d\boldsymbol{x}\,dz\end{aligned} \tag{9}$$

As long as Σ is positive definite (its definition insures that it is positive *semi*-definite), then one can find a symplectic A such that

$$\Sigma(s) = A(s)E(s)A^T(s) \tag{10}$$

where E is diagonal with pairs of equal diagonal elements, which are the emittances. A contains the generalized versions of the Courant-Snyder functions that describe the *distribution*. For a distribution "matched" to a lattice, A will by definition refer to the generalization of the corresponding functions for the *lattice*. If the emittances are distinct, the right hand side of A can be multiplied by any block-diagonal rotation with 2×2 blocks (there is more freedom when some emittances are equal).

UNDERSTANDING THE EFFECT OF SPACE CHARGE ON INSTABILIIES*

M. Blaskiewicz†, BNL, Upton NY 11973 USA
A. Chao, SLAC, Stanford University, Stanford CA 94309 USA
Y.H. Chin, KEK, Ibaraki, Japan

Abstract

The combined effect of space charge and wall impedance on transverse instabilities is an important consideration in the design and operation of high intensity hadron machines as well as an intrinsic academic interest. This study explores the combined effects of space charge and wall impedance using various simplified models in an attempt to produce a better understanding of their interplay.

TWO PARTICLE MODEL

The simplest nontrivial model including the space charge force requires two macroparticles [1, 2]. We consider vertical motion and use $\theta = s/R$ as the dynamical variable, it increases by 2π each turn. When particle two leads particle one during the synchrotron oscillation one has:

$$y_1'' = -\nu^2 y_1 + K(y_1 - y_2) + W y_2 \tag{1}$$
$$y_2'' = -\nu^2 y_2 + K(y_2 - y_1), \tag{2}$$

where ν is the unperturbed betatron tune, $'$ denotes $d/d\theta$, K creates the space charge tune shift and W is the wake strength. Indicies are reversed during the second half of the synchrotron oscillation. To proceed we use the single sideband approximation. Assume

$$y_i(\theta) = \hat{y}_i(\theta)\exp(-iA\theta),$$

insert these in eq (1) and(2), and neglect terms proportional $\hat{y}_i''$. Setting $A^2 = \nu^2 - K$ gives

$$\hat{y}_1' = -i\frac{K-W}{2A}\hat{y}_2 \tag{3}$$
$$\hat{y}_2' = -i\frac{K}{2A}\hat{y}_1 \tag{4}$$

Set $\kappa = \sqrt{(K-W)/K}$ and $b_0 = K\kappa/2A$ so that

$$\hat{y}_1(\theta) = \cos(b_0\theta)\hat{y}_{10} - i\kappa\sin(b_0\theta)\hat{y}_{20} \tag{5}$$
$$\hat{y}_2(\theta) = \cos(b_0\theta)\hat{y}_{20} - \frac{i}{\kappa}\sin(b_0\theta)\hat{y}_{10}, \tag{6}$$

where $\hat{y}_{10}$ and $\hat{y}_{20}$ are intial conditions.When b_0 is imaginary we use $\cos(ix) = \cosh(x)$ and $\sin(ix) = i\sinh(x)$. Setting $\theta = \pi/\nu_s$ with ν_s the synchrotron tune yields the map for the first half of the synchrotron oscillation. Reversing the roles of particle 2 and 1 yields the map for the second half. Concatenating the maps yields a two by two matrix with unit determinant. The trace of the full matrix is

$$Tr(M_0) = 2\cos^2(b_0\pi/\nu_s) - \left\{\kappa^2 + 1/\kappa^2\right\}\sin^2(b_0\pi/\nu_s). \tag{7}$$

Let λ be an eigenvalue of M. Then $Tr(M) = \lambda + 1/\lambda$ and the system is unstable if $|Tr(M)| > 2$.

AN ALTERNATE SOLUTION

By neglecting the terms proportional to $\hat{y}''$ in the previous section we introduced errors in the tunes appearing in the transport matrix. These can be avoided without sacrificing a simple closed form solution. We start off by diagonalizing equations (1) and (2). Set $z = y_1 + \alpha y_2$, where α is an unknown constant. One gets

$$z'' = -A^2 z - \alpha K\kappa y_1 - (K-W)y_2.$$

Now introduce another unknown constant β and demand $\beta z = \alpha K\kappa y_1 - (K-W)y_2$. This gives $\alpha = \pm\kappa$ and $\beta = \alpha K$.The new equations of motion are

$$z_1'' = -(A^2 + K\kappa)z_1 \qquad z_2'' = -(A^2 - K\kappa)z_2 \tag{8}$$

with $z_1 = y_1 + \kappa y_2$ and $z_2 = y_1 - \kappa y_2$. Define

$$B_1 = \sqrt{A^2 + K\kappa}, \qquad B_2 = \sqrt{A^2 - K\kappa}.$$

Now, assume κ is real and positive along with the Bs. We deal with imaginary κ later. Approximate

$$\hat{z}_m(\theta) \equiv z_m(\theta) + iz_m'(\theta)/A = \hat{z}_m(0)e^{-iB_m\theta}, \tag{9}$$

where we would divide by B_m instead of A for an exact solution. To the same level of approximation one has

$$\hat{y}_1 = (\hat{z}_1 + \hat{z}_2)/2, \qquad \hat{y}_2 = (\hat{z}_1 - \hat{z}_2)/2\kappa.$$

Now define

$$\bar{B} = (B_1 + B_2)/2, \qquad b = (B_1 - B_2)/2.$$

The map during the first half of the synchrotron oscillation is

$$\hat{y}_1(\theta) = e^{-i\bar{B}\theta}\left[\cos(b\theta)\hat{y}_{10} - i\kappa\sin(b\theta)\hat{y}_{20}\right] \tag{10}$$
$$\hat{y}_2(\theta) = e^{-i\bar{B}\theta}\left[\cos(b\theta)\hat{y}_{20} - \frac{i}{\kappa}\sin(b\theta)\hat{y}_{10}\right] \tag{11}$$

Apart from the overall phase evolution due to $\exp(-i\bar{B}\theta)$ and the small difference between b and b_0 these equations

LONGITUDINAL IMPEDANCE OF RHIC*

M. Blaskiewicz†, J.M. Brennan, K. Mernick
BNL, Upton, NY 11973, USA

Abstract

The longitudinal impedance of the two RHIC rings has been measured using the effect of potential well distortion on longitudinal Schottky measurements. For the blue RHIC ring $Im(Z/n) = 1.5 \pm 0.2\Omega$. For the yellow ring $Im(Z/n) = 5.4 \pm 1\Omega$.

INTRODUCTION

In a storage ring the net RF voltage per turn is that supplied by the RF cavities plus the voltage due to parasitic impedances. The parasitic voltage changes the incoherent spectrum [1, 2, 3]. The broad band impedance can be characterized by an inductance L. Let τ denote the arrival time of a particle with respect to the synchronous particle. The net voltage per turn is

$$V(\tau) = V_{rf}(\tau) - L dI/d\tau$$

where I is the instantaneous beam current. Consider a single RF harmonic operating above transition. Particles near the center of the bunch have the largest synchrotron frequency and the voltage there is

$$V \approx -\hat{V}_{rf}\omega_{rf}\tau - L\ddot{I}\tau$$

where $\hat{V}_{rf}$ is the amplitude of the RF voltage, ω_{rf} is the angular Rf frequency, and $\ddot{I}$ is the second derivative of the beam current with respect to time evaluated in the center of the bunch. The parasitic voltage modifies the small amplitude synchrotron frequency

$$f_s = f_{s0}\left(1 + \frac{L\ddot{I}}{\hat{V}_{rf}\omega_{rf}}\right)^{1/2} \approx f_{s0}\left(1 + \frac{L\ddot{I}}{2\hat{V}_{rf}\omega_{rf}}\right), \tag{1}$$

where f_{s0} is the small amplitude synchrotron frequency with no impedance and the approximation is excellent for our parameters. The inductance satisfies $j\omega_0 L = Z/n$ where ω_0 is the angular revolution frequency and Z/n is the impedance divided by the revolution harmonic. For space charge $Im(Z/n) < 0$ and for wall impedances $Im(Z/n) > 0$. Of course the actual value of Z/n varies with frequency and can change in sign, but for RHIC the root mean square bunch length is $\gtrsim$30 cm while the vacuum chamber radius is $\sim$ 3 cm. Therefore, all resonant wavelengths are short compared to the bunch length and only the inductive part of the parasitic impedance creates significant voltage for stable beams.

DATA ACQUISITION AND ANALYSIS

The data were obtained during an accelerator physics experiment on June 4, 2014. Figure 1 shows the blue fill pattern at the beginning of the experiment. The gold ions were accelerated to 100 GeV/nucleon and stored in the $h = 360$ (28 MHz) RF system. The spectrum analyzer was gated so that each of the 5 different batches of bunch intensity were measured individually. As time progressed intrabeam scattering and losses provided a natural spread in bunch parameters. The values of $\ddot{I}$ were obtained by averaging the bunch profiles in each group and fitting a parabolic cap to the top 30%. Wall current monitor data were acquired every 5 minutes and linear interpolation in time was used to align the wall current monitor data to the spectrum analyzer data. Some spectrum analyzer data are shown in figure 2. As is clear from the figure the peaks move, but the effect is fairly subtle. To analyze these data we fit parabolas to the top 3 points around each of the peaks and measured the difference between the location of the positive and negative synchrotron sidebands. The difference was divided by twice the order of the synchrotron mode and we obtained 12 independent estimates of synchrotron frequency for each spectrum. Data from the different synchrotron lines were analyzed independently. At this point two different techniques were employed. In the first technique we assumed a two dimentsional (2d) fitting function

$$f_s(k) = a_1 + a_2\ddot{I}(k) + \text{error}, \tag{2}$$

where a_1 and a_2 are fit parameters and index k characterizes a particular measurement. Linear least squares was used to obtain the $a_i s$ and equation(1) was used to obtain L and subsequently $Im(Z/n)$. In the second technique we assumed a three dimensional (3d) fitting function

$$f_s(k) = a_1 + a_2\ddot{I}(k) + a_3 t_{spec}(k) + \text{error}, \tag{3}$$

where $t_{spec}(k)$ was the time at which the spectra were acquired. This accounts for smooth, uncontrolled drifts in the machine parameters. Figures 4 and 5 show the least squares results for Z/n.

Figures 4 and 5 show clear discontinuities in the measured values of Z/n. We ascribe these to the presence of coherent modes and assume the low lying synchrotron modes are primarily influenced. Hence we took the average values of Z/n over the regions shown as the actual values of Z/n. Both lines fall within the one sigma errors for most of the data, so we take the average as a best estimate. For the blue RHIC ring $Im(Z/n) = 1.5\pm0.2\Omega$. For the yellow ring $Im(Z/n) = 5.4 \pm 1\Omega$. Previous results for the yellow

NSLS-II STORAGE RING BPM BUTTON DEVELOPMENT*

A. Blednykh#, B. Bacha, G. Bassi, W. Cheng, C. Hetzel, B. Kosciuk, D. Padrazo, O. Singh,
BNL, NSLS-II, Upton, NY, 11973-5000, USA

Abstract

The NSLS-II BPM Button design and its development process have been presented. Subjects discussed include BPM impedance optimization, design and construction, production, BPM selection and a first temperature measurement at 200mA average current within 1200 bunches.

IMPEDANCE OPTIMIZATION

Two types of BPM (beam position monitor) Buttons have been installed in the NSLS-II storage ring; the large aperture and the small aperture BPM Buttons. The large aperture BPM Button located on the multipole vacuum chambers of $12.5mm$ half-aperture, six BPMs per cell, 180 BPM assemblies total [1]. During the BPM Button optimization process we paid attention to: BPM Button heating due to trapped modes which are generated in the gap between the housing and the button [2]; heat transfer analysis; proper choice of the button and housing materials; dielectric materials choice from good thermal conductivity and low electrical conductivity point of views; impedance optimization process.

The large aperture BPM assemblies are located on the multipole vacuum chambers with antechamber slot of 10mm high. The standard BPM assembly consists of two BPM Flanges. Each BPM Flange, top and bottom, includes two BPM Buttons mounted into one flange as it shown in Fig. 1.

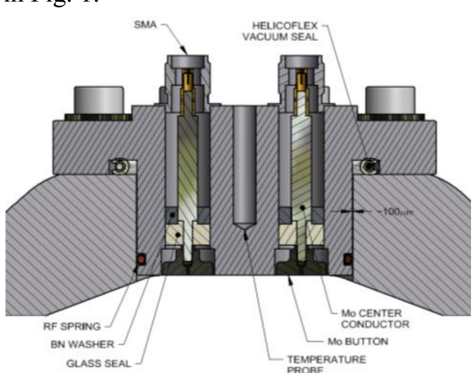

Figure 1: BPM Flange fixed to vacuum vessel. The clearance of the BPM Flange $\sim 100\mu m$ from the contact vacuum chamber surface.

The NSLS-II large aperture BPM button is chosen with a diameter of 7mm to satisfy horizontal and vertical BPM sensitivity requirements and to reduce heat load. It produces smaller geometric loss factor compared with a larger button diameter. The button thickness is chosen to be 2mm. The gap between the housing and the button is $250\mu m$. The BPM Button is made from molybdenum, which has an electrical conductivity $\sigma_{Mo} = 17 \times 10^6\ S/m$ is much larger than the conductivity of stainless steel material chosen for the BPM Flange $\sigma_{StSt} = 1.5 \times 10^6\ S/m$. Due to different material selection, trapped mode power will be predominantly dissipated in the BPM Flange rather than in well-conducted button [3]. Due to excitation of resonant modes in the buttons, the kick factor and the loss factor depend very strongly on the BPM button geometry. Several types of modes can be generated in the button geometry by a passing bunch. A coaxial TEM-mode (signal) propagates through the button and the feedthrough to the BPM electronics. If the feedthrough is matched well to 50 Ohm, there will be no TEM-modes reflected back to the chamber. Coaxial cavity type modes TE_{m1p}-mode (H_{m1p}-mode) where *m* and *p* are *1, 2, 3, k* (field variation in azimuthal and longitudinal directions). These modes then can be seen by the beam at frequencies defined by the cut-off frequency. The cut-off frequency for H_{m1}-mode like in a coaxial waveguide can be defined as

$$f_c^{H_{m1}} \approx \frac{1}{\sqrt{\varepsilon_r}} \frac{c}{\pi} \frac{m}{(r_1 + r_2)}, \qquad (1)$$

Where r_1 and r_2 are the radii of the inner and outer conductors, *m=1, 2, 3, k* and ε_r is relative permittivity (dielectric constant). As can be seen from Fig. 2, there are two types of dielectric materials present in the button geometry. It is 7070 glass (SiO2) for the vacuum seal and a Boron Nitride (BN) disc installed on the ambient side of the glass seal to improve the heat transfer from the pin to the stainless flange.

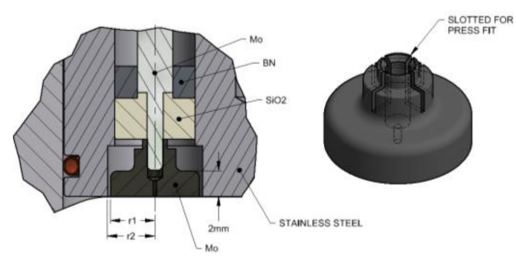

Figure 2: Internal button details with press fit connection.

The longitudinal wake potential for a 3mm Gaussian bunch and its Fast Fourier Transform are shown in Figs. 3,4. For the numerical calculation "port" boundary condition was specified at the end of the button. In this case the TEM-mode propagates out of the button without reflection. The first lowest mode is H_{11}-Mode (TE_{11}-mode). It is trapped in a gap between the housing and the button due to the button shape at frequency $f_{H11} = 13.4GHz$, which is slightly above the cut-off frequency $f_c^{H11} = 13.2GHz$ ($r_1 = 3.5mm$ and $r_2 = 3.75mm$). The peak at frequency $25.95GHz$ corresponds to the same type of mode with $m = 2$ (H_{21}-Mode). Two other peaks were identified at frequencies $15.43GHz$ and

STUDY OF NSLS-II DYNAMIC APERTURE TOLERANCES WITH RESPECT TO FIELD AND ORBIT ERRORS *

J. Choi†, G. Wang, T. Shaftan, BNL, Upton, NY 11973, USA

Abstract

As the emittance of synchrotron light sources moves towards diffraction limit, magnet tolerances for reaching dynamic aperture for high injection efficiency and long lifetime become more stringent. Once nonlinear families are designed and the machine is built, a machine operator may ask to which accuracy the linear optics and orbit should be corrected so to achieve reasonable dynamic aperture. We also studied the relations of the non-linear elements and beta-beat to the dynamic apertures by simulating NSLS-II storage ring lattice and the paper shows the results.

INTRODUCTION

As the emittance of synchrotron light sources moves towards diffraction limit, the more and more strong quadrupoles are required. The strong quadrupole field generates high linear chromaticity and to correct the chromaticity, in turn, strong sextupoles are also required. The nonlinearity from the sextupoles can create resonance excitation, and the excitation from the strong sextupoles can critically reduce the dynamic aperture (DA). The poor dynamic aperture directly impact the injection efficiency and lifetime and the normal operation will not be possible. The most traditional strategy is canceling the sextupole effects by making the lattice symmetric. Then the dynamic aperture can be recovered by lattice symmetry restoration [1]. However, as the chromatic sextupole strengths become too big to cancel each other using phase differences, geometric sextupoles are introduced in non-dispersive region to cancel out the effect of chromatic sextupoles [2]. And the symmetry becomes even more important. The usual measure of the symmetry breaking is the beta beating.

Because the dynamic aperture is so an important issue, many efforts are invested to secure it at every step of the lattice design. There are many reviews [3] and studies [4]. Many methods including analytic analysis [5] and simulations are used for the design as well as for improving the running machine. Usually, the simulation is accompanied by the frequency map analysis [6] from which we can see the quality of the DA. Also, the driving terms [7] are used to obtain the good dynamic aperture, and there are some computer tools [8] for this purpose.

Even if the dynamic aperture is good with the given sextupoles, there are many imperfections from magnets and insertion devices are added to the lattice. In general, if the linear lattice is robust, i.e. the twiss parameters are well optimized, the effect of the non-linear disturbance can be far more reduced. Therefore, we not only focus on removing the effect of the sextupoles [9] but, more importantly, we should design and maintain the robust lattice.

As the state of art synchrotron radiation source targeting sub-nanometer emittance with damping wigglers, NSLS-II storage ring is quite a robust lattice [10], as the result of the huge efforts, Still, the dynamic aperture is changing frequently from known as well as unknown reasons. To keep it big enough for the high injection efficiency and long lifetime, the machine parameters should be routinely checked and corrected. Those parameters include beta beating, tune, phase advance, dispersion and chromaticity. Among these parameters, beta beating, which is coming from the symmetry breaking, is primarily corrected for the recovery of the dynamic aperture.

The major linear errors which can break the symmetry is quadrupole field errors and sextuple alignment errors. In this paper, only by simulations, we analyzed the effects of these errors imposed on NSLS-II bare lattice. From the analysis, we want to find the relations between errors, beta beatings, and DA variations.

We'd like to mention that the error numbers in this paper have nothing to do with design specifications nor measured data. They are chosen just for convenience. The design specifications can be found in the design report [10].

QUADRUPOLE FIELD ERROR

The 792 m NSLS-II storage ring have 30 cells and 15 super periods. Each cell has 10 quadrupoles and the total number is 300 with all independent power supplies. We assigned gaussian random errors to these quadrupoles where the rms of the errors are 0.03%, 0.04%,..., 0.09%, 0.1% and, for each rms value, 10 sets of errors are generated. For each simulation, we obtained the area of the dynamic aperture and its ratio to that of the bare lattice is used as the figure of merit. To minimize the distraction, we also assume that the beta beating is corrected to at least 10% and when it is bigger than 10% the points are ignored.

Figure 1 shows the results of those precesses. The marks in Fig. 1(a) are the horizontal and vertical beta beatings of the sampled lattices. The colors of the marks represent the given rms values for the samples. Here, especially when the beta beating is bigger than 2% in the horizontal direction, the beta beating is very loosely related to the rms of the errors. That is, even though beta beating correction is necessary to reduce the field errors, it does not guarantee the reduction of the errors. Similarly, from Fig. 1(b), where the color means the relative dynamic aperture to the bare lattice, the big dynamic aperture does not necessarily mean the low beta beating and vice versa.

LOCAL IMPEDANCE ESTIMATION OF NSLS-II STORAGE RING WITH BUMPED ORBIT*

J. Choi†, Y. Hidaka, G. Bassi, A. Blednykh, BNL, Upton, NY 11973, USA

Abstract

As the newly constructed 3rd generation light source, NSLS-II is expected to provide synchrotron radiation of ultra high brightness and flux with advanced insertion devices. To minimize the beam emittance, damping wigglers are used and there is a small aperture located at the straight section with the damping wiggler and whose vacuum chamber is coated with non-evaporable getter (NEG). We used the local bump method to find the effect on the beam from the narrow aperture and this paper discusses the results.

INTRODUCTION

To reduce the electron beam emittance as well as to serve as broadband sources of very bright and high flux x-rays, 1.8T damping wigglers (DW) are installed at NSLS-II storage ring. As the first stage, 3 sets of the wigglers are installed where each set consists of 2 wigglers of 3.5 m. Most of the NSLS-II storage ring uses extruded aluminum vacuum chambers and their apertures are ±38 mm in the horizontal direction and ±12.5 mm in the vertical direction. However, the damping wiggler chambers have vertical apertures of ±5.75 mm with tapers. The narrow gap results in very limited linear conductance and, in this case, lumped pumps at the ends of the chamber will not be enough for the desired vacuum. To simplify the pumping system design, narrow-gap chambers as the DW chambers are NEG coated and the damping wiggler chambers are also included.

As the emittance of the synchrotron radiation source approaches the diffraction limit, and the vacuum chambers are becoming extremely narrow, the NEG coating is seriously considered for the solution of the vacuum system. However, there are concerns about its impact on the resistive wall impedance. Various studies have been undertaken and more are being underway, including the experience reports [1] [2], calculations and experiments [3] [4]. Also, some analytical methods to calculate the impedance of the layered structure are developed [5-9]. However, because of the uncertainties in NEG coating, the impedance from the calculation or simulation can be far from the real value. Therefore accurate impedance measurement at the NEG coated location is even more important than the measurements for the conventional cases.

The local transverse impdedance will change the transverse kick factor and the focussing effect will shift the phase at the location. If the dependence of the phase advance on the beam current is found, the local kick factor can be obtained [10] [11]. Like a quadrupole, if we make a local orbit bump, the transverse kick factor will generate closed orbit distortion, and by comparing the changes in the closed orbit between high and low beam current, the kick factor can also be obtained [12] [13]. We used the local bump methods to measure the kick factor at the NEG coated damping wiggler ID chamber. Because we are interested in the effect of the vertical narrow gap, all the measurements in this paper are regarding the vertical direction.

LOCAL ORBIT BUMP

To measure the local effect on the closed orbit using a local bump, it is very important to make a clean flat bump without any significant leak. To completely contain a local bump within a long straight where the damping wiggler is installed, only 2 upstream and 2 downstream regular correctors can be used. Given the maximum corrector strength (1 mrad) and their locations in the lattice, a phase space scan in a model found the maximum feasible height of a vertical position bump at the long straight to be 2 mm. A Python module and its frontend interactive script (as an IPython notebook) have been developed to create a local bump of an arbitrary target height/angle. This code can work both in online (actual machine) and offline (simulation using PyTracy) modes. This allows an operator to reliably and quickly create a large-amplitude bump by pre-computing corrector setpoint values for a desired bump in the offline mode, loading these values into the machine, and finally fine-tuning the bump online. With this software, a local bump with 1.8-mm vertical height was successfully created for the purpose of the impedance measurement. The leakage of the bump was minimized after multiple iterations of orbit correction using SVD. The maximum and RMS difference between the achieved orbit and the target orbit around the ring (180 regular BPMs) was 34.7 μm (~1.9 % of the target height) and 12.4 μm (0.7 %), respectively. Figure 1 shows the resulting local bump together with the generated bump with simulation. The simulated bump will be used to estimate the local impedance with fiitting.

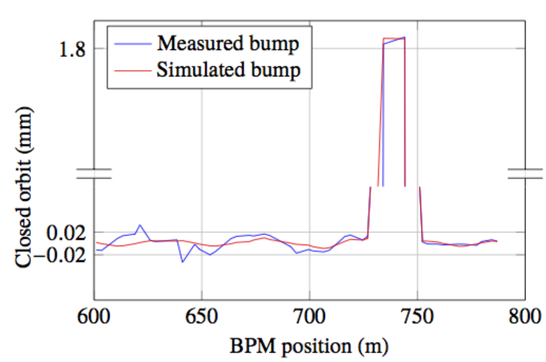

Figure 1: Local bump in the DW28.

OPTIMIZATION OF DYNAMIC APERTURE FOR HADRON LATTICES IN eRHIC

Yichao Jing*, Vladimir N. Litvinenko, Dejan Trbojevic, BNL, Upton, NY 11973, USA

Abstract

The potential upgrade of the Relativistic Heavy Ion Collider (RHIC) to an electron ion collider (eRHIC) involves numerous extensive changes to the existing collider complex. The expected very high luminosity is planned to be achieved at eRHIC with the help of squeezing the beta function of the hadron ring at the IP to a few cm, causing a large rise of the natural chromaticities and thus bringing with it challenges for the beam long term stability (Dynamic aperture). We present our effort to expand the DA by carefully tuning the nonlinear magnets thus controlling the size of the footprints in tune space and all lower order resonance driving terms. We show a reasonably large DA through particle tracking over millions of turns of beam revolution.

INTRODUCTION

The potential upgrade of the Relativistic Heavy Ion Collider (RHIC) to an electron ion collider (eRHIC) [1] involves numerous extensive changes to the existing collider complex. A high intensity electron energy recovery linac (ERL) will be added to the existing RHIC facility to collide with the strongly cooled hadron beams. The expected very high luminosity will be achieved with the help of squeezing the beta function of the hadron ring at the interaction points (IP) by at least 10-fold to a few cm, from the existing RHIC operating lattices. This will cause a large rise of the chromaticities and potentially undermines the beam's long term stability (Dynamic aperture).

It is well know that modern storage rings (both hadron rings and lepton rings) employs nonlinear magnets (sextupoles, octupoles, etc.) to correct the chromaticities from negative to small positive numbers to avoid microwave instabilities to develop. The natural chromaticities in the storage ring, i.e., the chromaticities rising from pure linear magnets (dipoles, quadrupoles), can be expressed as

$$C_x = -\frac{1}{4\pi}\int \beta_x(s)K_x(s)ds, \tag{1}$$

and

$$C_y = -\frac{1}{4\pi}\int \beta_y(s)K_y(s)ds. \tag{2}$$

Furthermore, the chromaticities rising from the IRs can be conveniently expressed as

$$C_{IR} = -\frac{2\Delta s}{4\pi\beta^*} \approx -\frac{1}{2\pi}\sqrt{\frac{\beta_{max}}{\beta^*}}, \tag{3}$$

where Δs is the distance from the IP to the first focusing magnet. Thus by squeezing the β^* 10-fold, the β_{max} increases

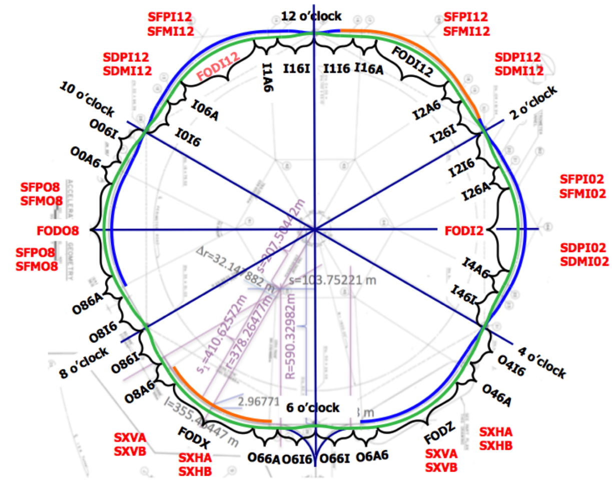

Figure 1: A schematic layout of hadron lattice for eRHIC as a rearrangements of the current operating RHIC lattice. Sextupoles families are indicated in red characters.

10 times and C_{IR} gains a 10 times of growth. This can be the dominant contribution to the total natural chromaticities in strongly focused colliders. For eRHIC, the β^* for hadron lattice is 5 cm (down from 65 cm for RHIC), which results in $C_{IR} \approx 50$, about 2 times of the chromaticities in all the ARCs. Thus the total chromaticities C_{tot} become about 70-80 for one IP and 120-140 for two IPs.

We employ strong sextupole families to correct such high chromaticities. A schematic in Fig. 1 shows the layout of eRHIC sextupole families as the rearrangements of the existing RHIC layout for higher energy and new IR designs. At the mean time, the buses of sextupole power supplies are proposed to be rewired to form more families (24 families) of independent knobs for chromatic terms corrections (detailed in following sections).

DYNAMIC APERTURE OPTIMIZATION

As mentioned above, the sextupole strengths are strong (about 2 times of the running RHIC's setup) for eRHIC due to the high chromaticities rising from strongly focused IRs. This generates strong chromatic aberration and high resonance driving terms (RDTs). Resonance driving terms, as a direct product from normal forming the one turn map of the storage ring whose schematic drawing can be found in Fig. 2, has an indirect impact on the particle's long term stability know as dynamic aperture (DA).

The direct relation between RDTs and DA is not known since the particle revolution in phase space and x-y real space in existence of nonlinear elements is highly chaotic.

DESIGN OF BUNCH COMPRESSING SYSTEM WITH SUPPRESSION OF COHERENT SYNCHROTRON RADIATION FOR ATF UPGRADE

Yichao Jing*, Mikhail Fedurin, Diktys Stratakis, BNL, Upton, NY 11973, USA

Abstract

One of the operation modes for Accelerator Test Facility (ATF) upgrade is to provide high peak current, high quality electron beam for users. Such operation requires a bunch compressing system with a very large compression ratio. The CSR originating from the strong compressors generally could greatly degrade the quality of the electron beam. In this paper, we present our design for the entire bunch compressing system that will limit the effect of CSR on the e-beam's quality. We discuss and detail the performance from the start to end simulation of such a compressor for ATF.

INTRODUCTION

Accelerator Test Facility (ATF) is ungoing an upgrade to provide users with wider spectrum of possiblities and choices. One of the most interesting applications is biology and material science which requires high charge and peak current. Such applications would make ATF become prime source for cutting edge research in photon sciences [1]. This requires a relatively higher energy (semi-GeV) electron beam with high peak current (kA) and low emittance.

The beam lines, which resembles High-gain Free electron lasers (FELs), usually are comprised of a low peak current electron beam generated at sources for acceleration and a strong bunch compressor to compress such a low peak current to a kA-level peak current for the users and other beamlines. In linac based SASE FELs, this compression usually is distributed in multiple stages along the beam transport at different energies of the beam. The linacs between two stages, in addition, could be used to accelerate the electron beam to higher energy and to prepare the electron beam for the next stages of compression. In such a way, each buncher's compression factor could be reduced (e.g. via a partial rotation in longitudinal phase space) so resulting in an overall lowering of emittance growth. Further more, the phase and strengths between different stages could be tuned for optimal performance. However, if a single stage compression can be achieved (without sacrifice of beam qualities), it benefits the layout of ATF and its upgrade. Further more, many different beam lines (for different users) can be installed downstream to such compressor to share the high quality electron beam. However, one concern of a single bunch compression scheme is CSR which could greatly degrade the quality of the e-beam [2–4].

In this paper, we present our design for a bunch compressor that will limit the effect of CSR on the e-beam's quality. We further perform the start-to-end (S2E) simulation to show our findings from a study of such a compressing scheme.

* yjing@bnl.gov

C-SHAPE CHICANE VS ZIGZAG CHICANE

A traditional approach to e-beam compression is to use a C-shape compensated chicane comprised of four dipole magnets. In such a chicane, the paths' lengths, as well as the transit time through the chicane, depend on the particles' energy. In combination with the correlated energy spread (chirp), this entails a rotation in longitudinal phase space. The emittance growth originates mostly from the third and forth magnets, where the beam is already compressed and the peak current is high. This growth in transverse emittance reflects the fact that the CSR wake depends both on longitudinal position within the bunch, as well as on the azimuth along the beamline. The head of the bunch gains energy while the tail part loses energy [5]. Furthermore, the location-dependent energy variation $\delta E(z, s)$ induced by CSR wakes engender transverse coordinate- and angular- displacements via non-zero $R_{16}(s, s_2)$ and $R_{26}(s, s_2)$ induced in the chicane. At the end of the chicane, the transverse displacement and the angle deviation will be non-zero.

The coordinate and the angular displacement that depend on longitudinal position of the particle result in a smearing in the transverse phase space, and also in the growth of the projected emittance. Figure 1 illustrates this smearing effect, comparing the plots of the transverse phase space before and after the chicane, which indicites a typical few fold of emittance growth for a C-shape chicane.

As a remedy for the above problem, i.e., the displacement in the transverse plane due to the longitudinal energy variation induced by CSR wakes, we propose to use two consequent chicanes with reversed bending directions, i.e., a Zig-Zag type compressor [6] as is shown in Fig. 2. The opposite signs of the dispersion functions should allow us to decouple the longitudinal and transverse degrees of freedom. We expect that in our scheme the transverse phase space displacement caused by CSR in the 1st chicane could be, at least, partially reversed in 2nd chicane. Thus, the resulting emittance growth due to CSR effects could be greatly reduced. Since bunch length is shorter, correspondingly CSR wake is stronger in the second chicane, and the energy change also is larger. The cancellation of the CSR effect naturally requires a weaker second chicane compared to the first one. In addition, we could better align the transverse phase-space displacements originating from two chicanes by adjusting phase advance between them.

SPIN RESONANCE STRENGTH CALCULATION THROUGH SINGLE PARTICLE TRACKING FOR RHIC*

Y. Luo, Y. Dutheil, H. Huang, F. Meot, V. Ranjbar
Brookhaven National Laboratory, Upton, NY, USA

Abstract

The strengths of spin resonances for the polarized-proton operation in the Relativistic Heavy Ion Collider are currently calculated with the code DEPOL, which numerically integrates through the ring based on an analytical approximate formula. In this article, we test a new way to calculate the spin resonance strengths by performing Fouier transformation to the actual transverse magnetic fields seen by a single particle traveling through the ring. Comparison of calculated spin resonance strengths is made between this method and DEPOL.

INTRODUCTION

The Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory is the only high energy collider in the world to collide polarized protons with the particle energy up to 255 GeV. Polarization is the average value of the projection of the spins of particles in a bunch on the average spin direction. To maintain a high polarization during the beam transfer from the injectors to RHIC and on the acceleration and at store of RHIC, we need to have a good knowledge of all the spin resonance strengths on the way.

The strengths of spin resonances are normally numerically calculated based on analytical approximate formula. For an example, DEPOL [1] numerically integrates through the ring based on known magnetic fields and linear Twiss parameters. However, DEPOL itself does not calculate the linear optics. The linear optics parameters have been imported from other codes such as MADX. To improve the accuracy of resonance strength calculation, sometime we may need to split each magnet into several slices.

SimTrack [2] is a compact c++ library for beam optics calculation and particle tracking based on symplectic integration. It has been extensively used for dynamic aperture calculation with beam-beam interaction in RHIC. Recently we implemented proton spin tracking into this code [3]. Since SimTrack tracks particles in steps through each magnet, the particle coordinates and the magnetic fields the particles feel are all transparent to the users. Therefore it is possible to calculate the spin resonance strength through particle tracking.

SPIN RESONANCES

Thomas-BMT equation describes the particle's spin motion in the presence of magnetic and electric fields,

$$\frac{d\mathbf{S}}{dt} = \mathbf{S} \times \mathbf{\Omega}, \tag{1}$$

$$\mathbf{\Omega} = \frac{e}{\gamma m}\left[(1+G\gamma)\mathbf{B}_{\perp} + (1+G)\mathbf{B}_{||}\right]. \tag{2}$$

$\mathbf{S}$ is the 3-dimensional spin vector in the particle's frame. $\mathbf{B}_{\perp}$ and $\mathbf{B}_{||}$ are the magnetic fields perpendicular and parallel to the particle velocity. It is convenient to use the path length s of the reference particle as the independent variable, then Eq. (1) turns to

$$\frac{d\mathbf{S}}{ds} = \mathbf{S} \times \mathbf{F}, \tag{3}$$

$$\mathbf{F} = \frac{\sqrt{(1+\frac{x}{\rho})^2 + x'^2 + y'^2}}{1+\delta}\frac{\mathbf{\Omega}}{(B\rho)_0}, \tag{4}$$

where $(B\rho)_0$ is the magnetic rigidity for the reference particle, ρ is the curvature for the reference particle on which the local coordinate system is built.

To study the polarization loss for a single particle when it crosses a single spin resonance, we would like to use the spinor equations where the bending angle θ is used as the independent variable. Then Eq. (3) is re-written as

$$\frac{d\mathbf{S}}{d\theta} = \mathbf{n} \times \mathbf{S}, \tag{5}$$

where $\mathbf{n} = -G\gamma\hat{y} - F_x\hat{x} - F_s\hat{s}$, $G\gamma$ is the spin tune for the reference particle. Defining $\xi = F_x - iF_s$ and expanding it in Fourier series, we have

$$\xi = \sum_K \epsilon_K e^{-iK\theta}. \tag{6}$$

Here ϵ_K is the strength of spin resonance. There are two important types of spin resonances: imperfection and intrinsic resonances. For imperfection resonances, $G\gamma = K$, K is an integer. For intrinsic resonances, $G\gamma = K \pm \mu_y$, μ_y is the fractional vertical tune.

According to Eq. (4) and Eq. (6), we have [4]

$$\epsilon_k = \frac{1}{2\pi}\oint\left[(1+G\gamma)\frac{B_x}{(B\rho)_0} - i(1+G)\frac{B_{||}}{(B\rho)_0}\right]e^{iK\theta}ds. \tag{7}$$

where B_x and $B_{||}$ are the projections of the magnetic fields seen by the particle. In Ref. [1, 4], ϵ_k can be presented with particle's coordinates as $\epsilon_k =$

$$-\frac{1}{2\pi}\oint\left[1+G\gamma)(\rho y'' + iy') - i\rho(1+G)(\frac{y}{\rho})'\right]e^{iK\theta}d\theta. \tag{8}$$

PROTON SPIN TRACKING WITH SYMPLECTIC INTEGRATION OF ORBIT MOTION*

Y. Luo, Y. Dutheil, H. Huang, F. Meot, V. Ranjbar
Brookhaven National Laboratory, Upton, NY USA

Abstract

Symplectic integration had been adopted for orbital motion tracking in code SimTrack. SimTrack has been extensively used for dynamic aperture calculation with beam-beam interaction for the Relativistic Heavy Ion Collider (RHIC). Recently proton spin tracking has been implemented on top of symplectic orbital motion in this code. In this article, we will explain the implementation of spin motion based on Thomas-BMT equation, and the benchmarking with other spin tracking codes currently used for RHIC. Examples to calculate spin closed orbit and spin tunes are presented too.

INTRODUCTION

The Relativistic Heavy Ion Collider (RHIC) is capable of colliding heavy ions and polarized protons. In the polarized proton operation, the Figure of Merit (FOM) is LP^2 and LP^4 for the single and double spin programs. Here L is luminosity and P is polarization. Polarization is the average value of the projection of the spins of particles in a bunch on the average spin direction. Spin is a 3-D vector associated with the particle's magnetic moment. To improve the FOM in the polarized proton operation, many efforts had been made to understand through numeric simulations the mechanisms of polarization loss in the RHIC's injector-Alternating Gradient Synchrotron (AGS) , and during during injection, energy acceleration, and physics store in RHIC.

Currently there are two main codes for spin simulation calculations at Brookhaven National Laboratory: one is SPINK [1] developed by A. Luccio, and the other is Zgoubi [2] developed by F. Meot. Since the spin motion is linked to the magnetic fields the particles feel on their orbits, therefore we need an accurate modeling of orbit motion. SPINK does not have its own orbit motion tracker. It uses the first and second order matrices generated with MADX. Zgoubi is a ray-searching code, which tracks particle's orbit motion directly based on Lorentz equation. The particles position, velocity, and the magnetic fields are all expanded to 5th and higher order. Orbit motion tracking in both codes is not symplectical. For a long term tracking, especially for proton accelerators like RHIC, symplecticity is crucial to avoid the unphysical results from numeric simulations.

SimTrack [3] is a compact c++ library for linear optics calculation and particle tracking for circular accelerators. It adopts the 4th order symplectic integration to transfer particles through magnets. Its optics transport in magnets had been benchmarked with Tracy-II. Its 6-D symplectic beam-beam interaction was benchmarked with SixTrack. Since 2009, SimTrack had been extensively used for particle tracking with beam-beam interaction for RHIC. For an example, simulation results from SimTrack showed that the non-luminous particle loss in the gold-gold ion collision is due to limited off-momentum dynamic aperture. SimTrack is also used to simulate head-on beam-beam compensation with electron lenses in RHIC.

In this article we first introduce symplectic integration of orbit motion and its application in SimTrack. Then we implement proton spin tracking based on Thomas-BMT equation. Examples of benchmarking of spin tracking with Zgoubi are presented. In the end, we show some examples to calculate the spin closed orbit, spin tune, and to simulate a single spin resonance crossing.

SYMPLETIC ORBIT TRACKING

Symplectic integration is one kind of numeric integrations to solve differential equations. Different from other methods, symplectic integration will preserve the symplectic condition of particle motion governed by a Hamiltian. R. Ruth invented the forth order symplectic integrator for a splitable Hamitonian [4],

$$H(p,q) = H_1(p) + H_2(q). \tag{1}$$

Here p, q are the canonical positions and momenta. In each step of integration, the solution of particle orbit motions is given by

$$\begin{aligned} e^{-:H:} = {} & e^{:-c_1 L H_1/2:} e^{:-d_1 L H_2:} e^{:-c_2 L H_1/2:} e^{:-d_2 L H_2:} \\ & e^{:-c_2 L H_1/2:} e^{:-d_1 L H_2:} e^{:-c_1 L H_1/2:} + O(L^5), \end{aligned} \tag{2}$$

where $c_{1,2}$ and $d_{1,2}$ are coefficients given in Ref. [4].

Symplectic integration has been used with an expanded Hamiltonian in many codes, where H_1 represents a drift and H_2 a thin magnetic kick. The expanded Hamiltonian is a good approximation for high energy accelerators where the particle's velocity is very close to the speed of light. Eq. (2) also can be used for solvable Hamiltonians H_1 and H_2, where H_1 normally represents an ideal bending maget and H_2 a thin magnetic kick.

In SimTrack, both expanded and exact Hamiltonians are implemented. With the expanded Hamiltonian, the computing time will be shorter than that with the exact Hamiltonian. Expanded Hamiltonian is normally used for particle tracking in RHIC at store energies. However, for a low

TRANSVERSE BUNCH BY BUNCH FEEDBACK OPERATIONS AT THE AUSTRALIAN SYNCHROTRON LIGHT SOURCE

R. Dowd, M. Atkinson, M. J. Boland, G. S. LeBlanc,
Y-R. E. Tan, K. Zingre, Australian Synchrotron, Clayton, Australia

Abstract

The Australian Synchrotron light source has recently put in operation its transverse bunch-by-bunch feedback system during user beam mode. Getting to the stage of stable operation has been a long road and this paper will outline the many difficulties that were encountered. Chief among these are the apparent strong, high frequency, vertical resonances that appear when the storage ring's three in-vacuum undulators are closed to specific gaps. The behaviour of these resonances and their effects on achieving stable feedback operation will be explored in detail.

INSTABILITY SOURCES

The vacuum chamber of the Australian Synchrotron storage ring is stainless steel and therefore a major source of resistive wall impedance. The impedance effects have been measured previously [1] with the strongest effect in the vertical plane due to the aspect ratio of the vacuum chamber. The main instability sources have been the in-vacuum undulators (IVUs). The storage ring contains two 3-metre long IVUs (IVU03 and IVU13) that close down to a 6.6 mm pole gap and one 2 metre undulator (IVU05) that closes to 6 mm. While these devices have copper wakefield shields with flexible transitions at either end, they have been the source of very strong, high frequency resonances at particular gap positions that cause primarily vertical instabilities. The high frequency nature of these instabilities poses a much stronger challenge to the successful operation of the transverse feedback system than the resistive wall effects.

IVU Resonance Mapping

Attempts to map out these resonances in order to understand their source have been conducted. These resonance maps are difficult to obtain without the beam becoming so unstable that we experience beam loss and so may be incomplete, however they do show a strong pattern of instability mode number vs. IVU gap, with the instability mode increasing by 1 for every 0.3 mm of gap change. Table 1 and Figure 1 show one such mapping, performed at low chromaticity. Later measurements performed at lower chromaticity indicate this pattern of instabilities continues into the 8-9 mm gap range.

The regular repetition of the instability at gaps of every 0.3 mm suggests a trapped mode resonance in the IVU chamber. On a simple analysis of a vertical resonance between the two pole faces however, a change in IVU gap of 0.3 mm does not correspond to a frequency change of 1 revolution harmonic (1.38 MHz), which is implied by the unit

Table 1: IVU gap setting vs peak resonance mode number. The relative spacing of the resonance modes is also shown

IVU05 Pole Gap (mm)	Peak Instability Mode	Δ (mm)
7.59 - 7.62	220	
7.28 - 7.32	221	0.30
6.98 - 7.04	222	0.28
6.68 - 6.74	223	0.30
6.40 - 6.47	224	0.27
6.12 - 6.15	225	0.32

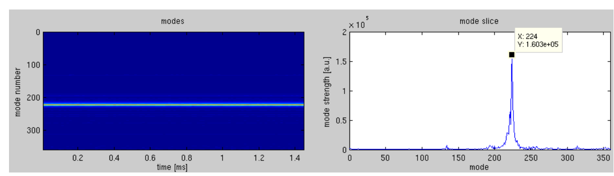

Figure 1: Instability Mode analysis of IVU05 at 6.4mm gap. Mode 224 is the strongest mode, but the neighbouring modes are also excited, indicating a resonance with width of multiple revolution harmonics.

change in instability mode number. The type of resonance is still not clear to us, although there are some possibilities, including a fast ion instability, or a situation similar to a klystron instability [6] (due to the similar geometry of the IVU device to a klystron tube).

FEEDBACK SYSTEM

Overview

While the transverse feedback system used at the Australian synchrotron has been described in detail previously [2],[3], and only a brief overview will be presented for clarity. Signals from a BPM block are sent through a hybrid mixing unit to produce X and Y signals which are sent to a mixing front-end unit, where the signal is mixed with a 1.5 GHz clock down to base band.

The mixing unit then sends the baseband signal to a pair of feedback processing units. The feedback units and frontend were supplied from Instrumentation Technologies [4].

The output waveforms are then fed through 100 W broadband amplifiers and sent to the storage ring stripline kickers. A programmable delay line before the amplifiers allows for timing of the output pulses in 20 ps steps in order coincide the peaks of the correction pulses with the arrival of the electron bunches. The overall system architecture is shown in Figure 2.

OPERATIONAL APPLICATIONS - A SOFTWARE FRAMEWORK USED FOR THE COMMISSIONING OF THE MedAustron ACCELERATOR

A. Wastl*, M. Hager, M. Regodic, EBG MedAustron, Wiener Neustadt, Austria

Abstract

MedAustron is a synchrotron-based cancer therapy and non-clinical research center located in Austria. Its accelerator is currently being commissioned prior to first medical treatment. During the tuning of the machine, many iterations of measurements involving several parameter changes are performed in order to optimize the accelerator's performance. An operation and measurement software framework called 'Operational Application Framework' (OpApp) has been developed for this purpose. It follows a modular approach and provides basic methods like 'write to file' or 'measure beam position monitor'. By appropriately combining modules, *OpApps* performing automatized measurements and complex procedures can be created. A detailed description of the setup as well as examples of use are provided here.

INTRODUCTION

The MedAustron accelerator complex includes up to four ion sources, a linear accelerator, a synchrotron and beam transfer lines guiding the beam to four irradiation rooms. Currently the accelerator commissioning is focusing on proton beams for two clinical horizontal irradiation rooms (energy range : 60 -250 MeV). For patient treatment clinical cycles of protons and carbon ion beams of 255 different energies have to be provided to three irradition rooms.

OPERATING ENVIRONMENT

Accelerator commissioning, hardware installation and software development are processes performed in parallel leading to a very dynamic working environment. Commissioning requires repetitive measurements based on complex measurement procedures to be performed in order to verify several beam and accelerator parameters. To automatize this work the MedAustron Accelerator Control System (MACS) has constantly being extended with dedicated software tools. These tools interact with the Accelerator Control System and its sub-systems like the timing system, power converter controllers, RF systems or beams diagnostic devices.

MedAustron and CERN have developed a software infrastructure that communicates with the different systems. However, even with this infrastructure the development of commissioning tools face very specific challenges: the tools have to be flexible enough to adapt to new operation modalities of the accelerator components. Furthermore, in the course of commissioning the quantity of tools provided in different programming language increase causing the duplication of code and additional effort of maintenance.

A NEW FRAMEWORK

During the commissioning phase, flexible software applications are required that can quickly be adjusted to the changing environment, new features requested by users or to work around problems. To address these requirements an own software architecture, called 'Operational Applications' (OpApps) has been developed at MedAustron. The OpApp architecture enforces the use of small re-usable modules like setting of a control values or acquiring a beam diagnostic measurement. The basic modules can be combined to bigger modules and eventually to powerful applications.

The main domain of OpApps is the provision of configuration data and the measurement of the resulting beam. The according functionality is:

- Generate cycle dependent settings like current setpoints and waveforms from optical settings such as the magnet strength
- Deploy settings to accelerator devices
- Request the generation of beam
- Acquire beam diagnostic measurements
- Store data as files or a database entry

Optical computations and advanced analysis functionality are currently not part of the OpApps. In order to close the beam commissioning cycle (Fig. 1) a thought-through concept for the storage of measurement data has been developed. The concept defines a schema for file names, folder structures and the meta-data to be included. Sophisticated analysis modules such as the CERN ALOHA [1] program or in-house Python tools access the stored data and process it. The outcome of analysis and optical computations is fed back into Operational Applications via input files.

Abstract

The efforts during the second half of 2014 towards nanometric beam position measurement and stabilization at the Interaction Point (IP) section of the Accelerator Test Facility (ATF) at KEK are presented. Recent improvements to the beam position monitor (BPM) data analysis and processing electronics, as well as the installation of a new set of C-Band BPMs, are reviewed.

INTRODUCTION

The main objective of the Accelerator Test Facility (ATF) at the High Energy Accelerator Research Organization (KEK) in Tsukuba, Japan, is to serve as an R&D platform for the technology required for linear accelerators, in particular the International Linear Collider (ILC). The ATF has already achieved a record minimum vertical beam emittance [1, 2], and so attention moves to the next step: reduction in the vertical beam size at the IP. Beam size reduction using local chromaticity correction is explored at the ATF in an extension of the original beam line known as ATF2 [3, 4]. The ATF2 lattice is the final focus system (FFS) of the ILC scaled down to 100 m and exists to demonstrate two goals: (**goal 1**) a vertical beamsize at the IP of 37 nm (**goal 2**) stabilization of the beam position at the IP to the level of a few nanometres.

In 2014 a vertical beam size of about 55 nm was measured at ATF2 [5]. Subsequently, a smaller beam size, of down to 44 nm, has been achieved [6] through systematic tuning. This demonstrates the local chromaticity correction method, though only at charges below 0.1×10^{10} particles per bunch.

The identified issue of intensity dependence is currently being explored by the ATF2 collaboration. However, even at low intensities the beam size remains above the designed 37 nm. Possible causes are: (1) increase of the incoming beam emittance throughout the ATF2 line, (2) systematic errors and resolution limitations on the beam size monitor (IPBSM), (3) beam drift beyond the tolerable margin and (4) undetected optics mismatch.

The last two issues can be addressed by measuring the beam trajectory in the IP region after the final doublet. In addition, looking forward to **goal 2**, high resolution beam position measurement is a requirement for beam stabilization.

BPM SYSTEM DESCRIPTION

A set of three cavities, two upstream and one downstream of the nominal IP, are used to measure the beam trajectory in the IP region and thus provide enough information to reconstruct the bunch position and angle at the IP.

The three cavities (IPA, IPB and IPC) are rectangular and resonate in the TM_{210} mode at 5.7 GHz in the horizontal plane and TM_{120} at 6.4 GHz in the vertical plane. They have a design decay time of 20 ns and sensitivities to bunch position of 2.2 μV/nm/nC (horizontal) and 3.7 μV/nm/nC (vertical). Two additional cylindrical cavities, one per resonant frequency, are placed downstream of the IP to measure the bunch charge and to downmix the C-Band frequency signals; these are the reference cavities.

Each position measurement cavity has two output ports in antiphase per plane connected to independent processing electronics to downmix the signals, separate them into two orthogonal components called I and Q, and set the gain according to beam charge conditions. A set of remotely-controllable attenuators, variable between 0-70 dB in steps of 10 dB, is used to increase the linear range of electronics at the expense of resolution.

The acquisition system samples the two downmixed orthogonal waveforms per cavity per plane over the decay time. This amounts to 14 simultaneous channels: I and Q waveforms for both x and y for each of the three position measurement cavities plus the charge signal from each reference cavity.

A local beam-based feedback system has been installed at the IP in order to stabilise the beam position. This system comprises a stripline kicker just upstream of the IP chamber, a fast kicker amplifier and a digital feedback controller. The feedback can be driven by any of the three IPBPM raw output signals or a linear combination of the signals from any two BPMs. The system is designed for operation on a bunch train of two or more bunches, separated by greater than 150–200 ns, where the measurement of the first bunch provides the input to the feedback system and the correction is applied to subsequent bunches.

OIDE LIMIT MITIGATION STUDIES

O. R. Blanco*, CERN, Geneva, Switzerland and LAL, U-PSUD, CNRS/IN2P3, Orsay, France
P. Bambade, LAL, U-PSUD, CNRS/IN2P3, Orsay, France
R. Tomas, CERN, Geneva., Switzerland

Abstract

Particle radiation when traversing a focusing quadrupole limits the minimum achievable beam size, known as the Oide limit. This effect may be compensated by a pair of multipoles which reduce the impact of the energy loss in the vertical beam size. Simulations in PLACET using the CLIC 3 TeV QD0 and L^* show a reduction of $(4.3 \pm 0.2)\%$ in the vertical beam size.

INTRODUCTION

In order to achieve higher luminosity, it is necessary to reduce the beam size to compensate the lower frequency collisions in linear accelerators compared with collider rings [1], radiation effects plays an important role in the presence of strong focusing required for the IP small beam size. This document addresses the radiation phenomenon called Oide effect [2].

The Oide effect is caused by the interaction of charged particles with the magnetic field from quadrupoles. Radiation in a focusing magnet, schematically represented as QD0 in Fig. 1, changes the energy of the particle and modifies the focusing effect. This results in a limit on the minimum beam size specially relevant in the vertical plane.

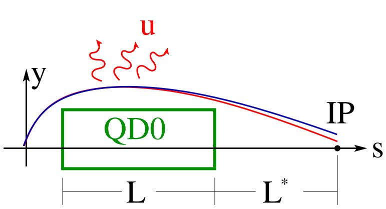

Figure 1: Designed particle trajectory in blue and the trajectory of a particle due to radiation in the quadrupole in red.

The beam size growth due to radiation is added quadratically to the linear beam size $\sigma_0^2 = \epsilon\beta$ where β represents the optical beta function and ϵ is the emittance. Therefore, $\sigma^2 = \sigma_0^2 + \sigma_{oide}^2$. The beam size contribution is [2],

$$\sigma_{oide}^2 = \frac{110}{3\sqrt{6\pi}} r_e \frac{\lambda_e}{2\pi} \gamma^5 F(\sqrt{k}L, \sqrt{k}L^*) \left(\frac{\epsilon}{\beta^*}\right)^{5/2} \tag{1}$$

where $F(\sqrt{k}L, \sqrt{k}L^*)$ is a double integral solved in [3], λ_e is the Compton wavelength of the electron, r_e is the electron radius, γ is the relativistic factor, β^* is the twiss parameter function at the observation point, in this case the IP; and, k, L, and L^* are the quadrupole gradient, the quadrupole length and the distance to the IP.

* blanco@lal.in2p3.fr

Although the total contribution to beam size depends on lattice and beam parameters, the minimum achievable beam size is given by [2],

$$\sigma_{y\ \min} = \left(\frac{7}{5}\right)^{\frac{1}{2}} \left[\frac{275}{3\sqrt{6\pi}} r_e \frac{\lambda_e}{2\pi} F(\sqrt{K}L, \sqrt{K}L^*)\right]^{\frac{1}{7}} (\epsilon_{Ny})^{\frac{5}{7}} \tag{2}$$

where $\epsilon_N = \gamma\epsilon$ is the normalized emittance, showing the independence from beam energy.

The only possibility to reduce the beam size is by changing the value of F, by modifying the magnet parameters, or to minimize the beam emittance. However, using the ILC 500 GeV [4], CLIC 500 GeV and CLIC 3 TeV [5] parameters, it is possible to conclude from Table 1 that the contribution to beam size is significant for CLIC 3 TeV.

Δy DUE TO RADIATION

Particle tracking from the imput of QD0 to the IP for CLIC 3 TeV with and without radiation, using PLACET [6], allows one to compute the effects of radiation on the six dimentional phase space. Figure 2 shows the current transverse distribution of particles at the IP. To compensate the adverse effects a compensation system would ideally remove the position change due to radiation $\Delta y = y_{\text{rad}} - y_0$.

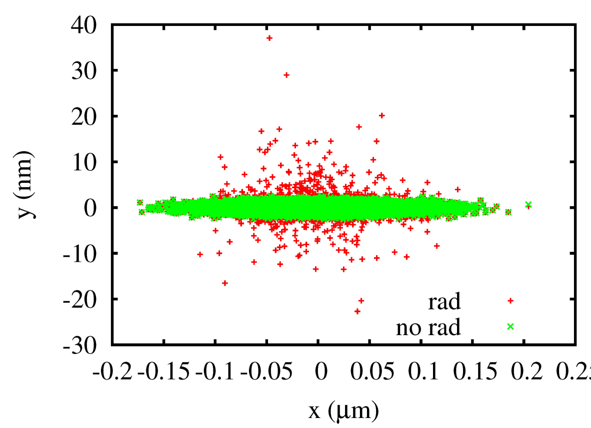

Figure 2: CLIC 3 TeV beam at the IP after tracking QD0 with and without radiation.

Although the average radiation effect is zero, $\langle\Delta y\rangle = 0$ because of the cubic term $(y_0')^3$ as stated by Oide [2], the correlation between $\Delta y, y'$ is not zero. The correlation expression is shown in Eq. (3).

$$\langle\Delta y, y_0'\rangle = \frac{2}{3} r_e \gamma^3 G(\sqrt{K}L, \sqrt{K}L^*)(y_0')^3 \tag{3}$$

A SLOW RF-LASER FEEDBACK FOR PHIL PHOTOINJECTOR

N. Elkamchi, V. Chaumat, V. Soskov, LAL, Orsay, France

Abstract

PHIL [1] is a low energy (E<5 MeV) and high current (1nC/bunch) electron beam accelerator at LAL. It uses a laser beam to extract electron bunch from a copper cathode at a repetition frequency of 5Hz.

The stability of the beam charge at PHIL is a key issue for the successful operation of the physic experiences that use the machine. It is also one of the most important specifications of a laser driven high current RF gun.

Two Integrated Current Transformers (ICT) and back-end electronics are used to monitor the stability of the beam charge at PHIL, with an accuracy of about 1pC [2].

At PHIL, the electron beam charge is quite stable, but we often note a slow charge drift on long duration experiences.

Several types of jitter can impact the stability of the beam charge. The fluctuations of the RF power or the RF to laser relative phase drift could have significant influence on the machine stability, due to temperature variations and electronic components overheating.

To correct the phase drift, we describe, in this work, a method based on slow analog-digital feedback loop between the RF wave in the gun (3GHz) and the synchronization signal of the laser (75MHz).

It allows maintaining the jitter between the laser pulse and the RF wave stable at a very low value (1° of 3GHz). As a result, the electron beam charge will be maintained at a stable level, to meet the requirements of users.

ACCELERATOR DESCRIPTION

Photoinjector

PHIL is a test facility at the Laboratoire de l'accélérateur linéaire (LAL), Orsay. The main goal of the accelerator is testing photoinjection as part of research and development of advanced RF gun.

The principal beam line of the machine is devoted to beam characterization (bunch length, transverse emittance) and standard instrumentation testing. A second beam line is used to analyze the energy distribution using a dipole (figure1).

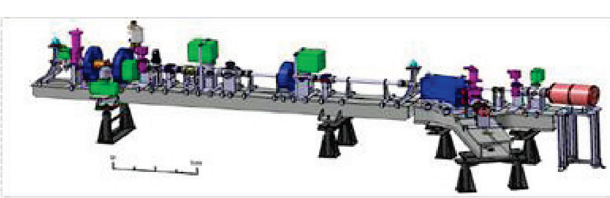

Figure 1: Drawing of PHIL beamlines. Blue boxes are magnetic elements; orange is the RF gun, green boxes stand for vacuum pumps.

Table 1: Specifications of PHIL [3]

Energy, Mev	Energy spread %	Charge , single pulse, nC	Frequency, GHz	Repetition rate, Hz	Pulse duration, ps	Emittance πmmmrad
5	< 1	0.01-2	3	5	5-10	< 5

In addition to research and development activities, PHIL is open to physics experiences that need low energy and well-defined electron beams for detector calibration.

RF Chain

The primary goal of the RF chain at PHIL is to generate and amplify the 3GHz signal destined to electron beam acceleration. It has also the role of synchronizing the laser oscillator and diagnostic facilities (figure 2).

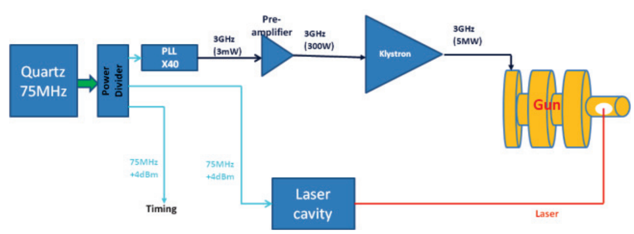

Figure 2: Drawing of PHIL RF chain and synchronization system.

It consists essentially of a quartz oscillator generating a reference signal at 75MHz turned into 3GHz via a PLL. A pre-amplifier and a klystron amplify the RF signal to reach 5MW in the gun.

The reference signal is also used to lock the laser oscillator and to generate 5Hz pulse frames for synchronizing diagnostic systems.

PHASE DRIFT AT PHIL

In photoinjector based accelerator, an accurate synchronization between the RF wave and the laser beam is highly required. This allows having an uniform electron beam with a stable charge value [4].

The RF gun of PHIL is a 2,5 cells [5].It is designed to get a maximum axial electromagnetic field at the cathode level (z=0) (figure 3) when it is hit by the laser pulse. The electromagnetic field can be adjusted using a phase shifter in low level RF electronics, to change the characteristics of the beam (charge, energy, dark current).

MODELING / MEASUREMENT COMPARISON OF SIGNAL COLLECTION IN DIAMOND SENSORS IN EXTREME CONDITIONS

V. Kubytskyi*, S. Liu, P. Bambade, LAL, Université Paris-Sud, CNRS/IN2P3, Orsay, France

Abstract

Such unique properties like radiation hardness, low dark current, good signal to noise ratio make single crystal Diamond Sensors (DS) excellent devices for measurements of beams in a wide range of conditions. Here we present a study of charge collection dynamics in a DS subjected to intensities from 1 to 10^9 Minimum Ionizing Particles (MIP). We developed a model based on the numerical solution of the 1D drift-diffusion equations, using the Scharfetter-Gummel discretization scheme. Inhomogeneity of the space-charge distribution together with the externally applied electric field are taken into account by analytically solving the Poisson equation at each discrete time step. We identified two regimes of charge collection. The first corresponds to $1 - 10^6$ MIPs, in this case the externally applied electric field is negligibly perturbed by space-charge effects during the separation of the electron/hole clouds. The second corresponds to intensities larger than 10^7 MIPs, where the space-charge effects significantly slow down the charge collection due to large concentrations of electron/hole pairs in the DS volume. The results of our modeling are in qualitative agreement with the experimental data acquired at the PHIL photo-injector electron beam facility at LAL. Our model allows optimising DS parameters to achieve desired charge collection times for different beam intensities.

INTRODUCTION

When charged particles pass trough the material it ionises the material along the track which results in the creation of electron hole pairs. In the case of diamond, 1 MIP creates on average 36 electron-hole pairs per micrometer. Applying external electric field to the diamond force the electrons and holes to move in opposite directions, this process is usually called charge collection. According to Shockley-Ramo theorem [1] the motion of these charges creates an electric current on the electrodes which can be amplified if it is necessary and measured with an oscilloscope.

However when the diamond sensor is subjected to the beam where the number of electrons (MIPs) can be as large as 10^8 electrons or more, the charge collection becomes nonlinear and it can be strongly slowed down (see [2]) for the following reasons: First, is the space charge effect that becomes important when the clouds of electron and holes are separated in the external electric field, which creates an opposite electric field to the applied one inside the sensor. Second, is the voltage drop due to the strong current which passes trough the resistive load in the readout channel.

In this paper we construct a Diamond Sensor model which includes these effects in a consecutive manner. Modeling of charge collection in diamond sensors subjected to extreme conditions is of great importance for the device parameter specification during the design and for calibration during operation.

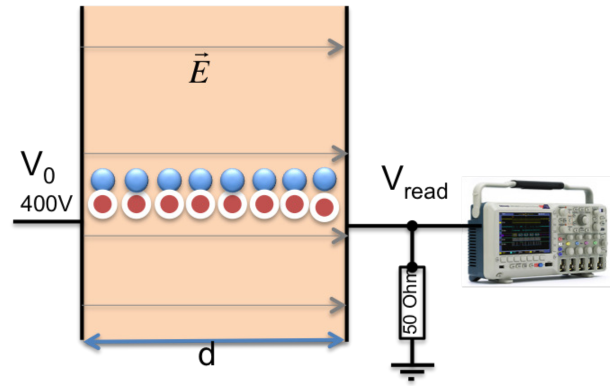

Figure 1: Schematic representation of diamond detector with electronics for data acquisition. Electrons (blue circles) and holes (red circles) pairs are created along the track of the incident MIP.

MODELLING OF CHARGE COLLECTION

Let us consider the 1D case where the detector has a finite thickness and is infinite in the lateral directions. In this case the Poisson equation can be solved analytically, giving the electric field inside the material:

$$E(x,t) = -\frac{V}{d} - \frac{q}{\varepsilon_0 d}\int_0^d\int_0^x (p-n)dx'dx + \frac{q}{\varepsilon_0}\int_0^x (p-n)dx', \tag{1}$$

where

$$V = V_0 - V_{read} \tag{2}$$

is the difference of potentials applied to the diamond due polarising potential V_0 and voltage drop on the reading electrode V_{read}; n and p are electrons and holes densities, d is the thickness of the diamond; q is the elementary charge and ε_0 is dielectric constant.

In order to obtain temporal evolution of charge densities in the volume of the diamond we are solving the drift-diffusion equations [3]:

$$\frac{\partial J_n}{\partial x} - q\frac{\partial n}{\partial t} = \frac{n}{\tau_n} \quad \text{with } J_n = qn\mu_n E + qD_n\frac{\partial n}{\partial x}, \tag{3}$$

$$\frac{\partial J_p}{\partial x} + q\frac{\partial p}{\partial t} = -\frac{p}{\tau_p} \quad \text{with } J_p = qp\mu_p E + qD_p\frac{\partial p}{\partial x}, \tag{4}$$

where, correspondingly for electrons and holes, J_n and J_p are electric current densities; μ_n and μ_p are the mobilities; D_n , D_p diffusion constants and τ_n , τ_p lifetimes.

INVESTIGATION OF BEAM HALO USING IN VACUUM DIAMOND SENSOR AT ATF2*

S. Liu, P. Bambade, F. Bogard, P. Cornebise, V. Kubytskyi, C. Sylvia, LAL, Université Paris-Sud, CNRS/IN2P3, Orsay, France

Abstract

Beam halo transverse distribution measurements are of great importance for the understanding of background sources of the nano-meter beam size monitor at the interaction point (IPBSM) of ATF2 [1,2]. One of the most critical issues for the beam halo measurement is to reach high dynamic range. Two *in vacuum* diamond sensor beam halo scanners (DSv) with four strips each have been developed for the investigation of beam halo transverse distributions at ATF2. The first DSv was installed for horizontal beam halo scanning after the interaction point (IP) of ATF2, in Nov. 2014. It aims to measure the beam halo distribution with large dynamic range ($\sim 10^6$), and investigate the possibility of probing the Compton recoil electrons produced in the interaction with the IPBSM laser beams. Studies to characterize the DS performance and measurements of horizontal beam halo performed in Nov.-Dec. 2014 are presented.

INTRODUCTION

The investigation of beam halo transverse distribution is an important issue for beam loss and background control in ATF2 and in Future Linear Colliders (FLC). A DSv was installed downstream of the IP, 1.35 m from the BDUMP bending magnet exit at ATF2, to study the beam halo transverse distribution and the spectrum of the Compton recoil electrons produced in the interaction with the IPBSM laser beams at ATF2. In order to measure the beam core, beam halo and Compton recoil electrons simultaneously, a large dynamic range of $> 10^6$ is needed [3]. Previous beam halo measurements using wire scanners have only reached a dynamic range of $\sim 10^4$ [1,4,5]. However, a single crystalline CVD (sCVD) diamond sensor is not only sensitive to single electron but also tested to have a linear response up to 10^7 electrons [6]. Therefore, two sCVD DSv have been developed for our measurements.

Since the signal strength is proportional to the metallised effective surface on diamond, DSv with four strips was designed to help cover this large dynamic range [6]. The two strips for beam halo scanning are on the outer sides, with a dimension of 1.5 mm× 4 mm and the other two in the center are for beam core scanning with a dimension of 0.1 mm×4 mm. After characterising the DSv, beam core and halo transverse horizontal distributions were measured in Nov.-Dec. 2014. Beam core measurements were used for the normalisation of the beam halo distribution.

EXPERIMENTAL SETUP

For the *in vacuum* application a ceramic PCB is used. The ceramic PCB uses silver-platinum conductor produced in thick-film technology. The PCB with the diamond sensor in the center is shown in Fig.1 (left), a low pass filter together with charging capacitors are mounted on the backside of the PCB [6].

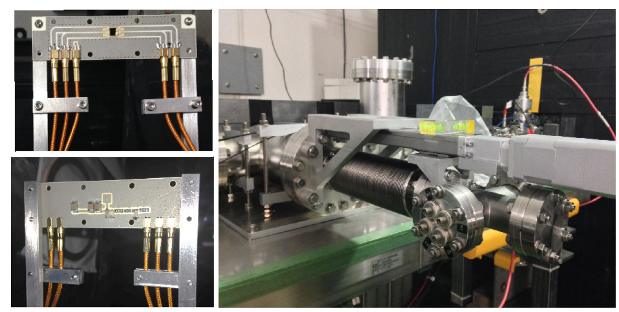

Figure 1: Layout of the DSv with the frontside (upper left) and backside (lower left) of the PCB and the motor used for the scan (right).

The DSv were fabricated by the CIVIDEC company [7] and the first set of it was installed in vacuum horizontally with a holder to scan beam and beam halo in the horizontal plane. The mechanical design was done and fabricated at LAL as shown in Fig 1 (right). The whole setup is 744mm long and it can be oriented either horizontally or vertically to scan in different axes.

Data Acquisition System

In order to transfer the signal from the DSv installed in the post-IP region to the IP laser room, where the oscilloscope is located, we have chosen a high quality LDF1-50 1/4 inch thick Heliax low density foam coaxial cable (more than 20m). For the bias voltage supply we used the Keithley 2410 sourcemeter, which can supply a bias voltage of ±1000 V. The whole data acquisition system is connected via Ethernet cables to the PC located in the control room. On the PC, Matlab is installed and used for system control and data taking. The oscilloscope we used is an Agilent oscilloscope with a sampling rate of 4 GS/s and an analogue bandwidth of 1 GHz. The motor we used for the DSv scan control is a stepper motor EMMS-ST-42-S-SEB-G2. The resolution of the steps is 10 μm and the reproducibility accuracy is 3μm. The mover precision was set as 50 μm for our experiment and the maximum scan range is 110 mm.

Abstract

Single-shot recording of pulses is possible with high repetition rates (more than 80 MHz), as was demonstrated in the framework of a PhLAM-SOLEIL collaboration [1]. This can be achieved by a relatively simple upgrade of existing setups based on spectral encoding. The strategy consists to encode the sub-picosecond information into the time domain, but at a slower scale (nanoseconds), using dispersion in a long optical fiber. Then the information is recorded by a photodiode connected to an oscilloscope. Here, we present guidelines for the practical realization of the electro-optical setup, as well as a performance analysis. In particular, we analyze the temporal resolution and compare it to the classical electro-optical sampling setup.

INTRODUCTION

The past decade has seen the rapid development of CSR studies in many storage rings. Despite the large amount of experimental observations, e.g. the recordings of coherent THz bursts, lack of direct observation of the electron bunch and its microstructures is a main issue to the test and the development of the theoretical models. Even though first real time measurements of CSR pulses using a YBCO superconductor-based detector at UVSOR-III have been successfully achieved [2, 3], a majority of storage rings emits coherent synchrotron radiation at higher frequencies than the state-of-the-art oscilloscope bandwidth (currently 65 GHz), e.g. ≈ 300 GHz at SOLEIL [4], ≈ 250 GHz at ANKA [5], ≈ 500 GHz at ELETTRA [6].

The electro-optic sampling (EOS) technique offers the possibility to measure THz electric fields with a sub-picosecond resolution. This technique has already been applied in storage rings [7–9]. However, to date, used methods based on electro-optic detection do not fulfill the requirements for a single-shot detection of CSR pulses at high-repetition rate, i.e. in the tens of megahertz (typical order of magnitude of electron bunch revolution frequency).

At first, we recall the principle of the spectrally-encoded electro-optic (EO) technique for the single-shot detection of THz CSR pulses. Then, we show the potential interest of photonic time-stretch [10, 11], well-known in optics and photonics, for the EO techniques to overcome the limitation of acquisition rate needed in storage rings, in particular we compare the performance with the classical spectral-encoding Finally, we present experimental data obtained at SOLEIL using the time-stretch EO strategy.

SPECTRALLY ENCODED ELECTRO-OPTIC DETECTION

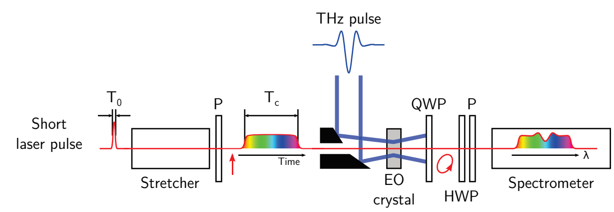

Figure 1: Schematic drawing of spectrally encoded electro-optic detection.

The spectrally-encoded electro-optic detection technique (EOSD) allows single-shot measurements of THz pulses (Fig. 1). In this technique, a probe laser pulse is stretched in a dispersive material or using a grating stretcher to a duration similar to the THz pulse duration before co-propagating in the EO crystal. In these conditions, the instantaneous frequency in the laser pulse varies with time. Thus, a modulation in time of the laser pulse induces the same modulation in the optical spectrum. The THz pulse induces a time dependent birefringence in the EO crystal through the Pockels effect and this anisotropy modulates the polarization state of the probe laser pulse which is converted into an amplitude modulation by a series of quarter-wave plate (QWP), half-wave plate (HWP) and a polarizer (P). The temporal modulation of the laser pulse is retrieved by measuring the spectrum of the laser pulse using a spectrometer and a photodiode array detector. The temporal resolution T_{min} of the EOSD is limited and is given by [12] $T_{min} = \sqrt{T_0 T_C}$, with T_0 the bandwidth-limited pulse duration (i.e. the pulse duration before the stretcher) and T_C the chirped probe laser pulse duration.

Even though the spectrally encoded EOSD allows single-shot measurements, the acquisition rate is limited by the speed of the current camera of at best around hundred kilohertz.

PHOTONIC TIME-STRETCH

Principle

The principle of time-stretch process is simple and consists in slowing down a signal before the detection. A practi-

RF FEEDBACK AND DETUNING STUDIES FOR THE BESSY VARIABLE PULSE LENGTH STORAGE RING HIGHER HARMONIC SC CAVITIES*

A. Neumann†, P. Echevarria, P. Goslawski, M. Ries, M. Ruprecht, A. Vélez , G. Wüstefeld
Helmholtz-Zentrum Berlin, 12489 Berlin, Germany

Abstract

For the feasibility of the BESSY VSR upgrade project of BESSY II two higher harmonic systems at a factor of 3 and 3.5 of the ring's RF fundamental of 500 MHz will be installed in the ring. Operating in continuous wave at high average accelerating field of 20 MV/m and phased at zero-crossing, the superconducting cavities have to be detuned within tight margins to ensure stable operation and low power consumption at a loaded Q of 5×10^7. The field variation of the cavities is mainly driven by the repetitive transient beam-loading of the envisaged complex bunch fill pattern in the ring. Within this work combined LLRF-cavity and longitudinal beam dynamics simulation will demonstrate the limits for stable operation, especially the coupling between synchrotron oscillation and RF feedback settings. Further impact by beam current decay and top-up injection shots are being simulated.

CHALLENGES FOR VSR SRF CW CAVITY OPERATION

To simultaneously create RF buckets for long and short pulses two higher harmonic RF systems have to be operated in zero-crossing at 1.5 and 1.75 GHz respectively [1, 2]. With respect to both bucket types the 1.5 GHz cavities will work in the focusing regime, whereas the 1.75 GHz cavities will be defocusing for the long buckets where the latter carry the majority of the average beam current. Table 1 shows the required RF parameters for an continuous fill pattern of the storage ring. In order to achieve the desired bunch shortening the average accelerating field will be E_{acc} 20 MV/m. This scheme implies several challenges for the stable operation of the higher harmonic system. The required power for a given cavity voltage V_{cav}, normalized shunt impedance $R/Q = V_{cav}^2/(\omega U)$, average beam current I_{b0} and accelerating phase ϕ_{acc} is [3]:

Table 1: RF system parameters for an even beam pattern without clearance gaps in the storage ring and two 5 cell cavities per higher harmonic.

Parameter per cavity	1.5 GHz	1.75 GHz
Voltage (MV)	10	8.7
E_{acc} (MV/m)	20.0	20.0
Q_L	5×10^7	4.3×10^7
R/Q TM$_{010}$-$\pi(\Omega)$	500	500
ϕ_{acc} (degree)	90	-90
Δf for beam-loading (kHz)	-11.25	15.3
Average P_f (kW)	1.49	1.0
Voltage 0.5 GHz	1.5 MV	

$$P_f \approx \frac{V_{cav}^2}{\frac{R}{Q}Q_L}\frac{1}{4}\times \tag{1}$$

$$\left\{\underbrace{\left(1+\frac{\frac{R}{Q}Q_L I_{b0}}{V_{cav}}\cos\phi_{acc}\right)^2}_{\text{resistive}}+\underbrace{\left(\frac{\Delta f}{f_{1/2}}+\frac{\frac{R}{Q}Q_L I_{b0}}{V_{cav}}\sin\phi_{acc}\right)^2}_{\text{reactive}}\right\},$$

where $\Delta f/f_{1/2}$ is the ratio of expected peak detuning to cavity half-bandwidth $f_{1/2} = f_{rf}/(2Q_L)$. Assuming the reactive beam loading can be compensated and controlled as

$$\Delta f = -\frac{R}{Q}\frac{f_{rf}I_{b0}}{2V_{cav}}\sin\phi_{acc}, \tag{2}$$

the cavity can be treated as a zero-beam CW SRF cavity operated at potentially high loaded Q to allow for low average forward power level at the coupler. This would reduce the problem to control any unwanted detuning by microphonics and coupled Lorentz-force detuning. Operation at comparable cavity voltages of a TESLA cavity at loaded Q up to 2×10^8 with low residual phase errors below 0.02 deg has been already demonstrated [4]. The optimum Q_L is then given by $\frac{1}{2} f_{rf}/\Delta f$, here about 5×10^7.

Tuning and Ramping the Cavities

In order to inject from the current booster synchrotron into the short bunches, the higher harmonic cavities (HHC) need to be ramped down to about ≤ 0.1MV [5]. As shown in Figure 1 that would require hundreds of kHz, only achievable by slow coarse tuners and such lead to a too long dark time for short pulse users. Also by the shorter lifetime of the short buckets that tuning would be performed with a high duty cycle posing the danger of mechanical stress, tuner failure or even vacuum leakage. For fast piezo tuners the typical range is far below the one needed for the field ramp. Thus an upgrade of the injection is currently discussed at HZB. At the VSR working point a power of about one kW is required to maintain the cavity voltage. The RF power overhead up to a level of 13 kW will allow one effect of the following at a time:

- A factor of three of the expected peak detuning of 20 Hz, thus $4 \times f_{1/2}$
- A not well synchronized top-up injection with a current jump of 1.5 mA

A NEW FPGA BASED TIMING SYSTEM AT ELSA

D. Proft* and W. Hillert, ELSA, Bonn, Germany

Abstract

At the electron stretcher facility ELSA a beam intensity upgrade from 20 mA to 200 mA is in progress. Investigations showed, that the maximum beam current is currently limited by excitation of beam instabilities. For separated characterization of single bunch instabilities from multi-bunch ones, a high beam current stored in a single revolving bunch is required. These high beam currents can only be achieved by accumulation of many shots from the injector.

The existing timing system is not capable of single bunch injection and accumulation in the main stretcher ring. Therefore a new FPGA based timing system, synchronized to the RF system of the accelerator, has been developed which will completely supersede the existing one. Simultaneously the "slow" timing system, providing trigger signals for the typically 6 s long accelerator cycle, is also modernized using a similar FPGA based solution to achieve a much better duty cycle during standard operation.

In this contribution the FPGA designs laying the focus on the single bunch accumulation will be presented.

ELSA

The electron stretcher facility ELSA (see Fig. 1) is a three stage accelerator consisting of two linear accelerators and a fast ramping booster synchrotron which are utilized as injector for the main storage ring. In the storage ring electrons can be accumulated by multiple injections of the booster, post-accelerated to a maximum energy of 3.2 GeV and then be extracted to one of the hadron physics experiments *Crystal Barrel* or *BGO-OD*. The typical cycle length is 6 s consisting of 400 ms injection time and 2×300 ms acceleration/deceleration time. The extraction takes place during the remaining 5 s, where the electrons are extracted using a third integer resonance, resulting in a constant electron current of typically up to 2 nA at the experiments.

Motivation

The ELSA stretcher ring is currently operated with a maximum current of 20 mA. That allows for an extraction of currents of about 2 nA during an extraction time of typically 5 s. The experiments desire an increase of this current by a factor of 10. In order to preserve the duty factor of $> 80\,\%$ the intensity of the beam accumulated in the storage ring has to be increased by one order of magnitude to 200 mA.

The maximum beam current that can be stored is limited by emerging beam instabilities. These can be classified in single- and multi bunch instabilities. The latter ones are damped by the installed three dimensional bunch-by-bunch feedback system [1] whereas the investigation of single bunch instabilities requires the accumulation of a single bunch in the accelerator.

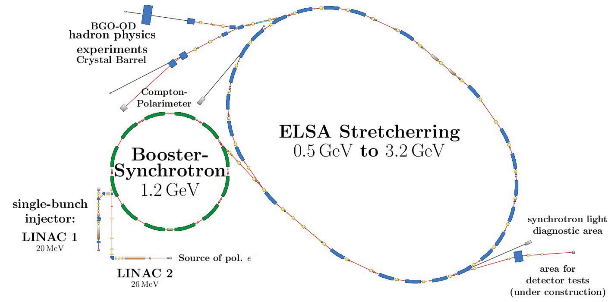

Figure 1: Sketch of the electron stretcher facility ELSA.

At the moment this can only be achieved by excitation and subsequently removing all unwanted bunches of a homogeneously filled accelerator ring. Unfortunately the attainable current per single bunch is then limited to approximately 800 µA/bunch by multi bunch instabilities occurring during injection.

To workaround these limitations a new high current single bunch injector, LINAC1 [2], is currently under construction. In the *short pulse mode* only a single bucket in the booster synchrotron can be filled whereas in *long pulse mode* it is capable of filling the whole synchrotron with a high intensity beam.

Besides the ability to accumulate electrons into a single bunch in the stretcher ring it will also be possible to produce any arbitrary filling pattern in the stretcher ring by successive injection into different buckets. This is in particular very helpful for investigations of instabilities caused by trapped ions [3].

CURRENT TIMING SYSTEM

The timing system can be separated into two different branches. The so-called *fast timing* system is operated at 50 Hz line frequency generating trigger signals for timing the injector (gun and linear accelerator) and accumulation in the stretcher ring. Due to the fluctuating line frequency the acceleration cycle in the booster synchrotron is not static. The trigger for the injector (gun and LINAC) is generated by a premagnetized peaking strip[1] placed in the magnet gap of the booster's dipole.

With the current setup there is no synchronization to the revolution clock, therefore the filled bucket in the booster synchrotron is unknown. In addition the transfer to the stretcher ring is not synchronized as well, making it impossible to accumulate electrons in a single bucket or even produce a requested filling pattern.

SUPERCONDUCTING RADIO FREQUENCY CAVITY DEGRADATION DUE TO ERRANT BEAM*

C. Peters, A. Aleksandrov, W. Blokland, M. Crofford, D. Curry, C. Deibele, G. Dodson, J. Galambos, G. Johns, A. Justice, S. Kim, T. Pelaia, M. Plum, and A. Shishlo, Spallation Neutron Source, Oak Ridge National Laboratory, Oak Ridge, TN, 37831, USA

Abstract

In 2009, the Superconducting Radio Frequency (SRF) cavities at the Spallation Neutron Source (SNS) began to experience significant operational degradation [1]. The source of the degradation was found to be repeated striking of cavity surfaces with errant beam pulses. The Machine Protection System (MPS) was designed to turn the beam off during a fault condition in less than 20 μseconds [2] as these errant beam pulses were not unexpected. Unfortunately an improperly operating MPS was not turning off the beam within the designed 20 μseconds, and the SRF cavities were being damaged. The MPS issues were corrected, and the SRF performance was restored with cavity thermal cycling and RF processing. However, the SRF cavity performance has continued to degrade, though at a reduced rate compared to 2009. This paper will detail further study of errant beam frequency, amount lost per event, causes, and the corrective actions imposed since the initial event.

INTRODUCTION

The SNS Linac consists of an ion source, Low Energy Beam Transport (LEBT), Radio Frequency Quadrupole (RFQ), Medium Energy Beam Transport (MEBT), Drift Tube Linac (DTL), Coupled Cavity Linac (CCL), and Superconducting Linac (SCL). This paper will focus on the ion source, LEBT, RFQ, DTL, CCL, and SCL. The DTL and CCL will be referred to as the Normal-conducting Linac (NCL).

ERRANT BEAM

An errant beam is a beam pulse that is not normal. The beam current may be higher or lower than expected, or the beam pulse may be shorter or longer than expected. Errant beam produces beam loss. The beam loss can be abrupt from a fast shift in beam parameters or slow with small amounts of beam loss over an extended period of time. The beam may hit cavity surfaces causing gas or particulate desorption. The gas or particle desorption can create an environment for arcing, multipacting, or field emission.

MACHINE PROTECTION SYSTEM

The major task of the MPS is to turn off the beam. Individual equipment detects fault conditions and send a signal to the MPS to interrupt beam operation. The MPS does this function by turning off the ion source RF timing gate (the ion source decays in about 20 μseconds) and the RFQ timing gate (the RFQ decays in about 1 μsecond), and the entire beam is deflected outside the entrance aperture of the RFQ for 20 μseconds (the response for beam deflection is about 1 μsecond). The design maximum turn off time for the MPS is 20 μseconds [2]. This does not include the time for fault detection by individual equipment.

INITIAL EVENT

In 2009 the SCL began experiencing increased amounts of downtime [1]. Multiple cavities required running with reduced gradients, and some had to be turned off completely. This reduction in gradient significantly impacted the overall beam availability as well as the peak beam energy. The initial investigation determined that there were significant amounts of beam loss in the SCL near the cavities that experienced operational issues. Experts suspected the MPS was not working properly.

Measurements were done to verify the proper turn off time of the MPS. It was found that it was not working properly, and in some cases entire beam pulses were transported during fault conditions. The issue was found quickly and repaired, and SCL operation was restored with thermal cycling and RF processing.

CONTINUED DEGRADATION

Though the problems with the MPS in 2009 were corrected the SCL cavity performance continued to degrade due to errant beams, although gradients could be restored to their original values by thermal cycling and RF processing during maintenance periods. Figure 1 shows the short beam trip rate and beam energy from October 2010 to October 2012. It shows that there were typically 40 short trips per day, but in some cases up to 80 trips per day. Much of these trips were errant beam trips. It also shows that the beam energy decreased during the same time. Twice during 2012 the beam energy had to be reduced due to issues with SCL cavity performance. Some cavities had to be removed from the Linac to be repaired.

MAGNETIC FIELD PARAMETRIZATION FOR EFFICIENT SPIN TRACKING WITH POLE*

J. F. Schmidt†, W. Hillert, ELSA, Bonn, Germany

Abstract

The new spin dynamics simulation suite POLE is designed to perform systematic studies of beam depolarization in circular accelerators with short storage times or fast energy ramps. It is based on spin tracking using a Runge-Kutta algorithm with adaptive step width. POLE can approximate the magnetic fields of the accelerator with a Fourier series to reduce computing time. Therefore, the magnetic field distribution is simplified with frequency filters by a C++ library before the spin tracking. The versatile library deals with import and export of lattices and particle trajectories from MAD-X and ELEGANT . The derived magnetic field distributions can be interpolated, Fourier transformed and accessed easily by applications. This contribution discusses advantages and disadvantages of the frquency filtering concept.

INTRODUCTION

The new spin dynamics simulation suite POLE is designed to perform systematic studies of beam depolarization in circular accelerators with short storage times or fast energy ramps. This includes the crossing of depolarizing resonances and the impact of synchrotron radiation on short time scales (up to seconds). The intention is to develop open source tools that are also usable for other facilities.

Spin motion in an accelerator is described by the Thomas-BMT equation [1]. So, its numerical integration is an obvious approach for spin tracking. Neglecting electric fields perpendicular to the beam axis, the Thomas-BMT equation for an electron spin $\vec{S}(t)$ can be written as

$$\frac{\mathrm{d}}{\mathrm{d}t}\vec{S} \approx c \cdot \vec{S} \times \left[(1+\gamma a)\vec{\tilde{B}}_{\perp} + (1+a)\vec{\tilde{B}}_{\parallel}\right] \qquad (1)$$

with the gyromagnetic anomaly $a = (g_s - 2)/2$, the Lorentz factor $\gamma(t)$ and the energy normalized magnetic field

$$\vec{\tilde{B}}(t) := \frac{e}{p(t)} \cdot \vec{B}(t) \qquad (2)$$

parametrized by the time t. All the information about the accelerator lattice, beam optics settings and also beam dynamics are contained in the magnetic field $\vec{\tilde{B}}(t)$ experienced by the particles. Hence, the major task for efficient spin tracking is to implement a suitable magnetic field parametrization and an according integration algorithm.

The basis for POLE is a C++ accelerator lattice library developed at ELSA. It allows to work with lattice information and particle tracking results from MAD-X and ELEGANT within any C++ code. Building on this, magnetic field parametrizations can be tested and compared. The first approach realized for POLE was a frequency filtering of the magnetic fields to balance spin tracking accuracy against computing time [2]. Advantages and disadvantages of this approach are discussed in this contribution.

C++ LATTICE LIBRARY

The C++ accelerator lattice library developed at ELSA basically provides two data structures. One represents a lattice consisting of individual elements of different types (e.g. dipole, cavity, quadrupole or kicker) stored by their position in the accelerator. The second structure implements arbitrary physical quantities, which are defined as a function of the position in the accelerator. They can have integer or floating point data type, including two or three dimensional quantities. Common examples are Twiss parameters or the closed orbit. A schematic of the library is shown in Figure 1. Lattice information can be accessed at an arbitrary position. Interpolation and Fourier transformation of the physical quantities are included using the GNU scientific library.

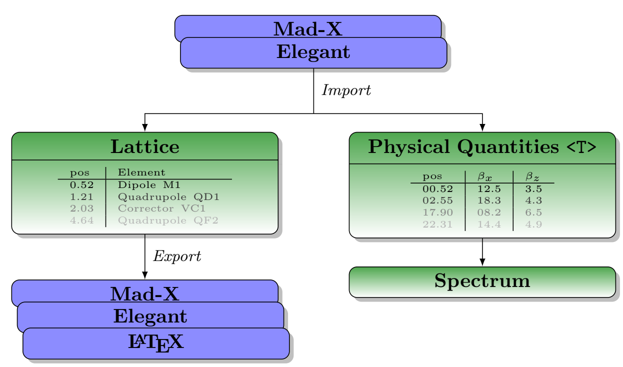

Figure 1: Schematic of the C++ accelerator lattice library.

Both data structures can be imported from the established simulation tools MAD-X and ELEGANT . Lattice definitions for these widespread tools exist for many accelerators and can be made available in any C++ program with about two lines of code. Of course, a lattice can also be constructed and modified within C++ . Additionally, the library provides a lattice export, which also facilitates the automatic lattice conversion between MAD-X and ELEGANT . Automated drawings of an accelerator can be made with a LaTeXexport using the tikz-palattice package [3]. A shared library version will be published as open source software soon.

MEASUREMENT OF MOMENTUM COMPACTION FACTOR VIA DEPOLARIZING RESONANCES AT ELSA*

J. F. Schmidt†, W. Hillert, M. Schedler, J.-P. Thiry, ELSA, Bonn, Germany

Abstract

Measuring beam depolarization at energies in close proximity to a depolarizing integer resonance is an established method to determine the beam energy of a circular accelerator. This technique offers high accuracy due to the small resonance widths. Thus, also other accelerator parameters related to beam energy can be measured based on this method. This contribution presents a measurement of the momentum compaction factor with a high precision of 10^{-4}. It was performed at the 164 m stretcher ring of the Electron Stretcher Facility ELSA at Bonn University, which provides a polarized electron beam of up to 3.2 GeV.

MEASUREMENT PRINCIPLE

Precise knowledge of key accelerator parameters is important for the analysis of numerous beam dynamics measurements and user experiments as well as to adjust the accelerator model.

One essential parameter is the beam energy. An established method to precisely determine the beam energy in a storage ring is based on spin polarization measurements. If both a polarized beam and polarimetry are available, a decrease of polarization at certain, theoretically well known beam energies can be observed. The characteristic energy of such a depolarizing resonance can be determined experimentally by measuring polarization at various storage energies around the expected resonance. The small energy width of these resonances allows for an energy measurement with a precision of $\Delta E/E \lesssim 10^{-4}$.

Building on this procedure, other accelerator parameters can be measured with likewise precision, if they are related to beam energy. One example is the momentum compaction factor. Recently, it was measured at the ELSA stretcher ring at Bonn University using a polarized electron beam.

DEPOLARIZING RESONANCES

In a flat circular accelerator (without solenoids) the stable spin axis, also known as invariant spin axis, usually points in vertical direction due to the strong vertical guiding fields of the bending magnets. The spins of revolving electrons precess around this axis γa times per turn according to the Thomas-BMT equation [1]. The spin tune $Q_{\text{spin}} = \gamma a$ is given by the gyromagnetic anomaly $a = (g_s - 2)/2$ of the electron and the Lorentz factor γ and thus depends linearly on beam energy. Only the projection of the polarization on the invariant spin axis can be preserved, since the finite energy width of the beam implies a spin tune spread, that leads to a spin spreading in the precession plane.

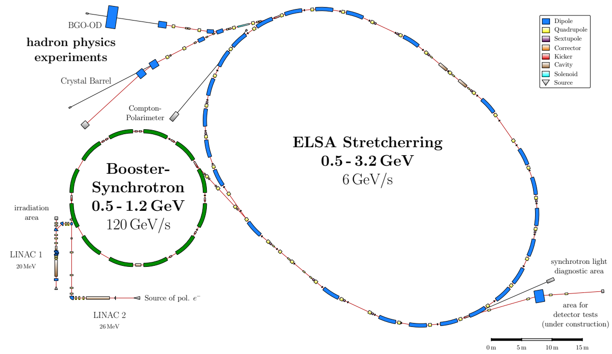

Figure 1: The Electron Stretcher Facility ELSA in Bonn.

The electrons experience horizontal magnetic fields along their trajectories occurring with specific spatial frequencies, which are related to the accelerator lattice and beam dynamics. On the one hand, magnet misalignments and vertical closed orbit distortions cause revolution harmonic contributions, which are not present in an ideal accelerator. On the other hand, betatron motion causes contributions of the quadrupole magnets depending on the betatron tunes.

Usually, spin precession around these horizontal magnetic fields averages out due to the changing phase relationship between these fields and the precession around the vertical axis. However, for certain beam energies the spin tune is in phase with one of the horizontal field contributions and the spin motion results in an additional precession around the horizontal fields. On such a depolarizing resonance, the stable spin axis is aligned completely within the horizontal plane and a beam stored at this energy has zero vertical polarization.

Though, the resonance energy can be determined experimentally by measuring vertical polarization at several energies in close proximity to the resonance. The measurements presented below use one of the so called integer resonances, which occur every 440 MeV at spin tunes

$$\gamma a = n \in \mathbb{N}\,. \qquad (1)$$

In this case, the theoretically expected resonance energy is known precisely, because it only depends on the gyromagnetic anomaly a of the electron. For that reason, the corresponding beam energy can be precisely determined by this method. Integer resonances are driven by revolution harmonic horizontal field distributions. They are mostly generated by vertical closed orbit displacements in the quadrupole magnets and rotations of the bending dipole magnets around the beam axis.

When crossing a depolarizing resonance on an energy ramp, the preserved vertical polarization decreases with the strength of the resonance driving fields and increases

IMPLEMENTATION OF A HIGH LEVEL PHASE CONTROLLER FOR THE SUPERCONDUCTING INJECTOR OF THE S-DALINAC*

T. Bahlo†, C. Burandt, F. Hug, N. Pietralla
Institut für Kernphysik, TU Darmstadt, Darmstadt, Germany

Abstract

The S-DALINAC is a recirculating electron accelerator with a design energy of 130 MeV. Before entering the 40 MeV main accelerator the electron beam passes both, a normal-conducting injector beamline for beam preparation and a superconducting 10 MeV injector beamline for preacceleration. The phase of the beam which is injected into the main accelerator is crucial for the efficiency of the acceleration process and the minimization of the energy spread. Due to thermal drifts of the normal-conducting injector cavities this injection phase varies by about 0.2 degree over a timescale of an hour. In order to compensate for these drifts, a high level phase controller has been implemented. It adjusts the phase measured at an rf-monitor at the exit of the superconducting injector by changing the phase of a prebuncher in the normal-conducting injector beamline. We will present the used hardware, the control algorithm as well as measurements showing the phase stabilization achieved by this controller.

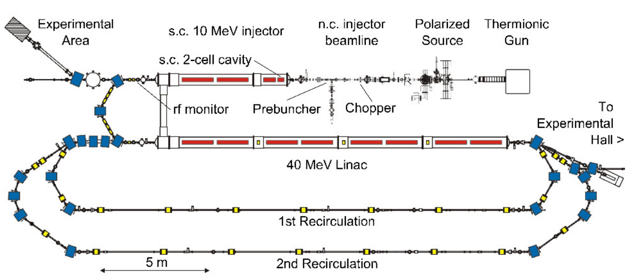

Figure 1: Floor plan of the S-DALINAC.

MOTIVATION

The Superconducting DArmstadt LINear ACcelerator S-DALINAC (see Fig. 1) is a recirculating electron accelerator with a design energy of 130 MeV that delivers electron beams with beam currents between several nA and 60 μA in cw-mode for nuclear and astrophysical experiments since 1987 [1]. The beam can be provided either thermionically and therefore unpolarized or by the photo effect from the Spin Polarized INjector SPIN [2] with a polarization of up to 86%. After beam preparation in the normal-conducting part of the injector including chopper and prebuncher cavities the electrons enter the superconducting 10 MeV injector beamline where they get preaccelerated by niobium cavities working at a resonance frequency of 3 GHz. The preaccelerated electron beam can then either be used to produce bremsstahlung for nuclear resonance fluorescence experiments at the Darmstadt High Intensity Photon Setup DHIPS [3] or be injected into the 40 MeV main accellerator. By recirculating the beam up to two times the maximum energy of 130 MeV can be reached.

It has been shown that the energy spread of the beam can be reduced significantly by using a non-isochronous recirculating mode [4]. In this case the remaining energy spread heavily depends on the correct injection phase into the main accelerator. A phase mismatch of 2° can increase the relative energy spread from $8 \cdot 10^{-5}$ to $3 \cdot 10^{-4}$. Experience shows that the beam phase behind the superconducting injector drifts and oscillates over several hours. An example measurement of the unadjusted beam phase can be seen in Fig. 2. This dynamic might either be caused by instabilities of the high voltage supply of the source or could come from thermal drifts of the normal-conducting beam preparation cavities. To compensate for these drifts a high-level phase controller has been developed.

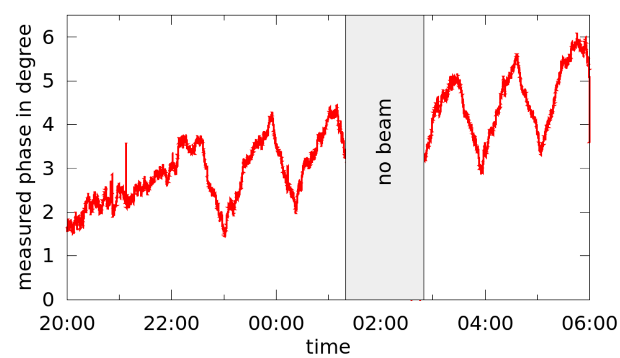

Figure 2: Measured beam phase behind the s.c.-injector with visible phase drift and oscillation.

PHASE ADJUSTMENT DEVICES

To adjust the beam phase behind the s.c. injector three devices have been tested:

Chopper

The chopper cavity converts continuous beams into bunched beams by forcing the electrons on a cone shaped trajectory and slipping them over an aperture. In this manner the chopper defines the reference phase of the beam and therefore of every adjacent rf device.

Prebuncher

The prebuncher decelerates the early electrons inside a bunch and accelerates the later ones in order to longitudi-

AUTOMATED TRANSVERSE BEAM EMITTANCE MEASUREMENT USING A SLOW WIRE SCANNER AT THE S-DALINAC*

P. Dijkstal#, M. Arnold, C. Burandt, F. Hug, N. Pietralla,
Institut für Kernphysik, TU Darmstadt, 64289 Darmstadt, Germany

Abstract

The superconducting linear accelerator S-DALINAC of the Institute for Nuclear Physics (IKP) from TU Darmstadt provides electron beams of up to 130 MeV in cw mode [1]. In order to improve beam simulations, it is planned to observe the transverse beam emittance at different locations along the beam line. A system of slow wire scanners in combination with quadrupole variation is foreseen to accomplish this task. For a first test a wire scanner was installed in the 250 keV section behind the thermionic electron gun of the S-DALINAC. A procedure to automatize measurements was developed and integrated in the EPICS-based control system [2]. We will show the status of the work on the automatized control and the results of first emittance measurements. A report on future plans will be given.

INTRODUCTION

The S-DALINAC consists of a 10 MeV injector and a 40 MeV main linac, both equipped with elliptical cavities operating in liquid helium at 2 K on a frequency of 3 GHz. Both, a thermionic and a polarized source [3] for electrons are available. The final energy is reached by using up to two recirculation paths. The current layout of the S-DALINAC is shown in Fig. 1.

Several locations are interesting for emittance measurements. It is desired to observe the emittance in between the accelerating sections and also in the extraction beam line. Additionally, two scraper systems will be in use in the near future [4, 5] and will certainly affect the emittance as well. To calculate the emittance with the method of quadrupole variation, one has to repeatedly measure the beam profile for different quadrupole currents. A wire scanner was available for this purpose from previous measurements at the polarized source [6]. The main task was to develop an automatized procedure to obtain the emittance. It should be easy to use and applicable for other locations at the S-DALINAC as well.

QUADRUPOLE VARIATION

The idea of emittance measurement with quadrupole variation is briefly recapitulated here. Detailed information can be found in many standard works on beam dynamics (e.g. [7]). In one transverse direction, a beam is commonly described with the two-dimensional σ matrix. The square root of the determinant of this matrix yields the emittance.

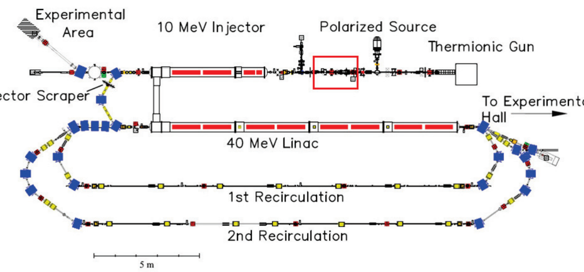

Figure 1: The section where the first emittance measurements took place is indicated with the red rectangle in this floor plan of the S-DALINAC.

$$\sigma = \begin{pmatrix} \langle x^2 \rangle & \langle xx' \rangle \\ \langle xx' \rangle & \langle x'^2 \rangle \end{pmatrix} \quad (1)$$

$$\epsilon = \sqrt{\det \sigma} \quad (2)$$

For sections that only consist of drift spaces, quadrupoles and dipoles, a transport matrix R can be defined which allows to transform the σ matrix from location a to b.

$$\sigma_b = R\,\sigma_a\,R^T \quad (3)$$

The matrix entry σ_{11} at the location of the wire scanner is easily accessible experimentally as it is the square of the beam width. In this work, a Gaussian distribution is assumed and the beam size is defined as one standard deviation. After several measurements of the profile for different quadrupole currents, a set of linear equations can be formed as the measured beam widths and the transport matrices R change. All entries of the σ matrix at the position of the quadrupole can then be determined numerically.

MEASUREMENT SETUP

The devices used for the first emittance measurements are shown in Fig. 2. The wire scanner consists of two perpendicular tungsten wires within a frame and is moved through the beam under an angle of 45° by a linear actuator. Therefore the profile in both transverse dimensions is recorded by the same device (see Fig. 3). The resulting current on the wires is picked up directly. Additionally, a linear potentiometer is attached which measures the current position of the wire scanner. Both these quantities are necessary to calculate the beam profile and have been available as EPICS process variables. A power supply for the linear actuator was developed and integrated in EPICS as well.

The quadrupole is part of a triplet in the low energy section following the electron gun. The field distribution was

BUNCH-BY-BUNCH LONGITUDINAL RF FEEDBACK FOR BEAM STABILIZATION AT FAIR*

K. Groß†, TEMF, TU Darmstadt, Germany
U. Hartel, U. Laier, D. Lens, K.-P. Ningel, S. Schäfer, B. Zipfel, GSI, Darmstadt, Germany
H. Klingbeil, GSI, Darmstadt, Germany; TEMF, TU Darmstadt, Germany

Abstract

To damp undesired longitudinal oscillations of bunched beams, the main synchrotron SIS100 of FAIR (Facility for Antiproton and Ion Research) will be equipped with a bunch-by-bunch feedback system. This helps to stabilize the beam, to keep longitudinal emittance blow-up low and to minimize beam losses. The proposed LLRF (low level radio frequency) topology of the closed loop feedback system is described. In some aspects, it is similar to the beam phase control system [1] developed at GSI Helmholtzzentrum für Schwerionenforschung GmbH. The differences and challenges are pointed out, which are mainly the bunch-by-bunch signal processing followed by the generation of a correction voltage in dedicated feedback cavities. The adapted topology was verified at SIS18 during beam time in 2014 using LLRF prototype subsystems and the two existing ferrite-loaded acceleration cavities. The experimental setup to damp coherent longitudinal dipole oscillations is presented and evaluated with focus on the realized modifications, including ongoing and pending investigations. Finally, the current status of the longitudinal feedback system for FAIR is summarized.

LLRF TOPOLOGY

Overview

Longitudinal coherent bunched beam modes can be classified by two numbers [2], the phase plane periodicity of individual bunches $m = 1$ (dipole), 2 (quadrupole), 3 (sextupole), ...with the oscillation frequencies $m\omega_{\mathrm{syn}}$, where ω_{syn} is the synchrotron frequency, and the coupled bunch mode number $n = 0, 1, 2, \ldots, M-1$ quantifying the phase shift $2\pi n/M$ between oscillations of adjacent bunches for M equidistant identical bunches. In order to damp rigid bunch oscillations with $m = 1$ and $n = 0$ the beam phase control system acts on the phase of the standard acceleration cavities. Within the scope of the longitudinal feedback (LFB) system higher order inner bunch modes, in particular quadrupole oscillations ($m = 2$), will be included using multiple filters with different settings based on the mode frequency $m\omega_{\mathrm{syn}}$. Arbitrary phase advances (mode number n) are covered by means of bunch-by-bunch signal processing and dedicated broadband kicker cavities.

Figure 1 gives a module-based overview of LLRF for the LFB system.

† gross@temf.tu-darmstadt.de

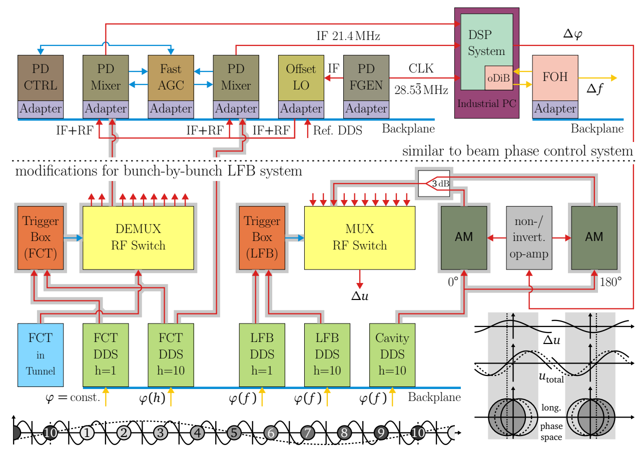

Figure 1: Sketch of LLRF of beam phase control system (top) with modifications for the LFB system (center) and principles of operation (bottom).[1]

Bunch-by-Bunch Operation

The bunch-by-bunch signal processing is based on trigger units and fast RF switches for de-multiplexing (DEMUX) of the beam current as well as multiplexing (MUX) of the correction signal for the kicker cavities. The working principle of the trigger unit is illustrated in Fig. 1 (bottom left) for operation below transition energy. It relies on an RF harmonic[2] to change over to the next bunch and the revolution harmonic as reset. This allows unambiguous assignment of the bunches for the variety of ion species and energies at GSI as well as an arbitrary choice of harmonic numbers[3]. Copies of the setup are used to determine the excitation and the required correction voltage for each bunch. Thus, the multiplexed LLRF correction signal Δu comprises the calculated control outputs from all DSP (digital signal processor) systems, i.e. for all of the bunches.

In contrast to electron machines and storage rings, where bunch-by-bunch LFB systems are well-established, special attention has to be paid to the synchronization due to fast ramp rates and a considerable frequency span. Therefore, the gray-shaded paths are cut to length to reach all interaction points with the same time delay. The phase $\varphi(f)$ of the DDS

Abstract

Coherent ultrashort THz pulses induced by a laser-electron interaction are routinely produced and observed at DELTA, a 1.5-GeV synchrotron light source operated by the TU Dortmund University. The turn-by-turn evolution of the radiation spectrum is known to shift to the sub-THz regime after the initial laser-electron interaction. Recently, an ultrafast YBCO-based THz detector has been permanently installed and a Schottky diode has been tested at the THz beamline. Measurements with these detectors showing the temporal evolution of the coherent signals after several revolutions are presented. Furthermore, the concept of a recently designed Fourier-transform spectrometer optimized for the sub-THz region is shown.

INTRODUCTION

The 1.5-GeV electron storage ring DELTA operated by the TU Dortmund University is a light source with a circumference of 115.2 m and a revolution frequency of 2.6 MHz. Since 2011, a source for ultrashort VUV and THz pulses based on the coherent harmonic generation (CHG) principle [1, 2] was commissioned. At this source, 40-fs Ti:sapphire laser pulses interact with a short slice of an electron bunch in the first section of the electromagnetic undulator U250, causing an energy modulation of the electrons. The energy modulation is converted into a density modulation forming microbunches by a dispersive section (center of the U250). In the last part of the U250, the microbunches emit coherent VUV radiation at harmonics of the laser wavelength. Energy-dependant path-length differences in the subsequent bending magnets lead to the formation of a sub-picosecond dip in the longitudinal electron density which gives rise to coherent THz radiation. The filling pattern of the storage ring during the operation of the short-pulse facility is a single bunch or a hybrid pattern in which a single bunch is injected in addition to a multi-bunch train.

A dedicated THz beamline (BL5a) for the extraction of the pulses is part of the DELTA short-pulse facility [3]. The beamline uses telescopes consisting of toroidal aluminium mirrors to transfer the THz radiation over the radiation shielding wall to an optical table. The THz laboratory is equipped with an indium-antimonide hot-electron bolometer, an ultrafast detector (<17 ps FWHM response time) [4, 5] based on the high-temperature superconductor $YBa_2Cu_3O_7$ (YBCO) and a Fourier-transform spectrometer with an Si composite bolometer.

Optimization of the laser-electron interaction relies on THz radiation as a diagnostics tool to improve the spatial and temporal laser-electron overlap. In addition, the THz radiation allows for the investigation of the turn-by-turn evolution of the density modulation induced by the ultrashort laser pulse [6, 7]. Particle-tracking simulations based on *elegant* [8] showed that the electron density modulation is present for at least 10 revolutions after the initial laser electron interaction [6, 9]. Recently, coherent THz pulses were observed for even more revolutions by means of an ultrafast oscilloscope. Furthermore, in cooperation with the Karlsruhe Institute of Technology (KIT), a Schottky diode sensitive in the sub-THz range was used to detect the laser-induced radiation at DELTA.

DETECTION OF MULTI-REVOLUTION RADIATION PULSES

As a first device for the detection of coherent pulses at the THz beamline, a liquid-helium cooled InSb hot-electron bolometer has been used [3, 10]. Because the signal repetition time is 384 ns when DELTA is operated in single-bunch mode, the InSb detector with a rise time of 350 ns is not fast enough for the investigation of the temporal evolution of the laser-induced density modulation. After first test measurements with an NbN hot-electron bolometer (<160 ps response time) and a YBCO detector (see above) [6, 7], an ultrafast YBCO detector was permanently installed at DELTA.

Figure 1 shows the response of the YBCO detector to coherent THz radiation at BL5a at DELTA acquired with an ultrafast Keysight Z-Series DSA-Z 634A real-time oscilloscope providing a bandwidth of 63 GHz at a sampling rate of 160 GS/s. Due to the high bandwidth, weak signals after several revolutions are not broadened by the readout. Hence, the coherent signals were acquired for up to 20 turns after the laser-electron interaction. Previous simulations of the evolution of the electron density distribution and spectral measurements showed that only the first turn has a significant spectral content above 1 THz [6, 7, 9]. Accordingly, the in-

A NOVEL TRANSVERSE DEFLECTING CAVITY FOR SLICE DIAGNOSTICS AT BERLINPRO*

A. Ferrarotto, B. Riemann, T. Weis, DELTA Dortmund Germany,
T. Kamps, H.-W. Glock, J. Völker, HZB Berlin Germany

Abstract

BERLinPro [1], [2] is an energy-recovery linac project to be realized at the Helmholtz-Zentrum Berlin (HZB) for an electron beam with 1 mm mrad normalized emittance and 100 mA average current. The initial beam parameters are determined by the performance of the electron source, an SRF photo-electron injector. The development of this SRF photon-electron injector is a main task of BERLinPro. Especially the beam emittance is basically defined by the SRF photogun. For beam diagnostics time dependent effects from the RF curvature and space charge must be taken into account and a sophisticated slice diagnostics is required [3]. To perform this type of diagnostics a transverse deflecting cavity has been designed, characterized and is presently under construction. This single cell cavity operates in a TM_{110}-like mode at 1.3 GHz optimized for high transverse shuntimpedance of appr. 3.2 MΩ by a concentration of fields near the beam axis. The cavity has a novel geometry that allows for an operation with both polarizations of the TM_{110}-mode. The layout of the deflecting cavity will be presented together with the results of the low RF characterization.

INTRODUCTION

The Energy Recovery Linac (ERL) project BERLinPro should provide an electron beam with an average current of 100 mA and a normalized emittance of 1 mmmrad. The electron beam should be produced in a SRF photogun operating at 1.3 GHz repetition rate in CW mode. The beam emittance is basically defined by the SRF photogun.
A SRF gun with 100 mA average current and an emittance of 1 mm mrad has never been demonstrated. As part of the development process of such a SRF gun GunLab was designed as a test facility to characterize beam parameters of SRF photoinjectors. The main challenge of GunLab is to characterize the full six-dimensional phase space as a function of drive laser and RF parameters [4]. For usage in GunLab a novel type of transversal deflecting cavity (TCAV) for slice emittance measurements [5] in horizontal and vertical direction was designed. The development process of this novel TCAV is described in this paper.

TRANSVERSE DEFLECTING CAVITIES

Typically deflecting cavities make use of a TM_{110}-like mode in a modified cylinder geometry to apply transverse momentum to particle beams. This transverse momentum

$$\Delta p_\perp = e\left|\int_{-\infty}^{\infty} B_\perp(z)\, e^{i\frac{k}{\beta}z} dz - \frac{i}{\beta c} E_\perp(z)\, e^{i\frac{k}{\beta}z} dz\right| \quad (1)$$

$$= e\left|\frac{1}{\omega}\int_{-\infty}^{\infty} \vec{\nabla}_\perp E_z(z)\, e^{ikz} dz\right| \quad (2)$$

depends on the transverse components of the electric and magnetic fields on the cavity axis acting on the particle beam. z represents the coordinate along the cylinder axis, $k = \omega/c$ represents the wave number, e the electric charge of the particles, c the speed of light and ω represents the RF angular frequency. The transverse momentum is related to the transverse deflection voltage

$$V_\perp = \frac{\Delta p_\perp c}{e} \quad (3)$$

and to the transverse shunt impedance

$$Z_\perp = \frac{V_\perp^2}{2P} = \frac{V_\perp^2 Q}{2\omega U} \quad (4)$$

with the quality factor Q of the transverse deflecting mode and the electromagnetic energy U stored in this mode.

TWO POLARIZATIONS

The theory of cylinder resonators shows that the TM_{110}-mode has two polarizations, rotated by 90 degrees. In a perfectly symmetric resonator, there are both polarizations degenerated with arbitrary spatial orientation. Usually the symmetry of the resonator is broken by inserting protrusions. This asymmetry splits the resonance frequencies and fixes the orientation of the two polarizations. The orientation of the polarization determinates the plane of transverse deflection. Depending on their actual shape, the protrusions also increase the electric and magnetic fields on the cavity axis. For use in GunLab we need a transversal deflection in both transversal planes to reconstruct the full six dimensional phase space as a function of drive laser and RF parameters. Thus we designed a novel type of transverse deflecting cavity which is able to make use of both polarizations of the TM_{110}-Mode at the same resonance frequency. To select the actual polarization we use two plungers as shown in Figure 1. The plunger which protrudes deeper inside the resonator determines the polarizations and by that the planes of transverse deflection.

CONTROL SYSTEM FOR THE FRANZ FACILITY

Suha Alzubaidi#, O. Meusel, U. Ratzinger, C. Wagner, IAP, Frankfurt am Main, Germany

Abstract

The Frankfurt Neutron Source at the Stern- Gerlach Zentrum (FRANZ) will use the reaction of ^{7}Li(p,n)^{7}Be to produce an intense neutron beam. The neutron energy will be between 10 and 500 keV depending on the primary proton beam, which is variable between 1.8 and 2.2 MeV. A volume type ion source will be used to deliver a 120 keV proton beam with currents up to 200 mA. Like any other facility, FRANZ will need a powerful and reliable control system that also allows monitoring the whole accelerator target areas and experiments. Also interlock and safety systems have to be included to protect personnel from radiation hazards associated with accelerator operations and accompanying experiments. The FRANZ control system is still under development. The ion source will be the first element to be controlled, and to gain experience. A test ion source will be used for testing and examining the performance of this control system. The plasma properties, filament ageing and an internal control loop for stable beam production with respect to controlling issues will be discussed.

INTRODUCTION

In this paper, the control system of the FRANZ facility and of all its components will be discussed. On the one hand it controls the operation status of each component permanently, on the other hand it delivers data relevant for service and personal security maintenance. This system deals with all "slow" tasks of FRANZ while there will be rf control systems and fast control loops on the ns to µs scale separately.

The FRANZ proton driver consists of a volume type ion source delivering a 200 mA d.c proton beam at an energy of 120 keV. The proton beam will be transported to the low energy beam transport (LEBT) which consists of four solenoids and a chopper system for producing beam pulses of 100 ns with a repetition rate around 250 kHz.The main acceleration of the proton beam will be provided by a radio-frequency quadrupole (RFQ) working at 175 MHz with an output energy of about 700 keV followed by an IH-DTL for achieving 2.0 MeV beam energy which may be varied by ±0.2 MeV in the following 5 gap rebuncher of the CH-type. In a next project step, a Mobley- type bunch compressor will be realized where 9 rf linac bunches will pass in individual paths and will be focused on the neutron production target within 1 ns. The neutron production target is a solid Li target. Figure 2 shows a scheme of the FRANZ facility [1-2].

FRANZ CONTROL SYSTEM

In the FRANZ facility a "Mesh Networked Data Acquisition and Control System (MNDACS)" is used as a control System [3-4]. It is a Java based control system which is developed in house by C. Wagner. It consists of a kernel that manages all device drivers, graphical user interface (GUI) and driver abstraction layer (DAL) and provides the access to devices with local drivers or drivers loaded at different computers (see Fig. 1). The project approach is to build a mesh system to tolerate control unit breakdowns with a load balancing between units.

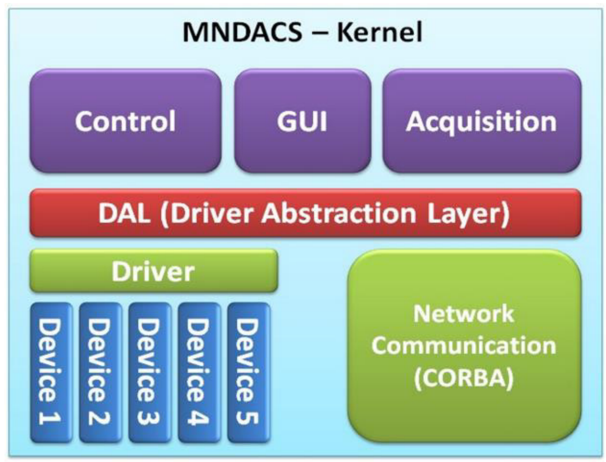

Figure 1: Program architecture of MANDACS.

The FRANZ control system consists of two basic layouts; the high level control and the data acquisition through the Ethernet layout, and the low level layout for the interlock and security system like emergency shutdown (see Fig. 3). All the devices will be connected to the TCP/IP Ethernet, which will be used as a physical communication backbone. To prevent software induced device outage, the number of computers will be as low as possible.

The network topology for FRANZ is shown in Fig. 4, where 1 Gbe links are used between devices and computers. At the FRANZ control system, three types of communications are used:

- Devices directly connected to the network (if possible).
- Connected through a converter in case of having a common interface like RS232.
- Connected through a computer in case of using an interface like USB.

Abstract

Relativistic Electron Gun for Atomic Explorations (REGAE) is a Radio Frequency (RF) driven linear accelerator. It uses frequency tripled short photon pulses (~ 35 fs) from the Titanium Sapphire (Ti:Sa.) Laser system in order to generate electron bunches from a photo-cathode. The electron bunches are accelerated up to ~ 5 MeV kinetic energy and compressed down to sub-10 fs using the so called ballistic bunching technique. REGAE currently is used for electron diffraction experiments (by Prof. R.J.D. Miller's Group). In near future within the collaboration of Laboratory for Laser- and beam-driven plasma Acceleration (LAOLA), REGAE will also be employed to externally inject electron bunches into laser driven linear plasma waves. Both experiments require very precise synchronization (sub-50 fs) of the photo-injector laser and RF reference. In this paper we present experimental results of the current and new optical to microwave synchronization systems in comparison. We also address some of the issues related to the current system and give an upper limit in terms of its long-term performance.

INTRODUCTION

Ultrafast Electron Diffraction (UED) as well as planned external laser plasma wave injection experiments at REGAE require stable (sub-picosecond) electron beam arrival at the target chamber [1–3]. Mainly, two sub-systems of the accelerator - Low-Level RF (LLRF) system and injector laser - play a significant role to deliver low jitter electron bunches. Since REGAE is a normal conducting S-band accelerator, it uses a 2.997 GHz radio frequency (RF) signal for electron beam acceleration and bunching. This 2.997 GHz reference signal from a RF Master Oscillator (MO) is distributed to the LLRF system and injector laser synchronization system. The LLRF system controls the amplitude and phase of the RF reference signal while the laser synchronization system ensures the stability of the laser beam arrival on a photocathode. Figure 1 shows the layout of the REGAE facility including its sub-systems.

Different schemes can be employed to synchronize optical lasers to a microwave reference [4–8]. Currently, REGAE is using a so called down conversion (DWC) based setup to synchronize a 83.25 MHz repetition rate Ti:Sa. laser to the 2.997 GHz reference signal from the MO [9]. Later, this DWC based scheme will be replaced by a new balanced Mach-Zehnder Modulator (MZM) based synchronization setup which is currently under development [3]. It has been shown that the short term locking performance of the DWC based setup is in the order of ~ 20 fs RMS [9]. In this paper we show that the long term locking performance of the DWC based scheme is limited by AM/PM effects and environmental dependencies of the RF reference and optical components. We also present for the first time the long term detector stability of the new single output MZM based setup and its potential for synchronizing the Ti:Sa. lasers to microwave signals or vice versa.

LONG TERM PERFORMANCE OF DWC BASED SETUP

Description of the DWC Locking Setup

Long term out-of-loop (OOL) measurements have been carried out while the Ti:Sa. laser oscillator was locked to the RF reference using the DWC setup.

Some part of the light from the Ti:Sa. laser oscillator has been coupled into the pigtailed fiber collimator connected to a fast 10 GHz bandwidth photodiode (EOT4000F). This photodiode converts laser pulses to electric signals producing an RF frequency comb, containing a fundamental frequency of 83.25 MHz and its corresponding harmonics. The 36th harmonic of the repetition rate is filtered out using a 3.0 GHz RF bandpass filter and is further amplified. This filtered signal is used to downconvert the reference frequency of 3.025 GHz derived from the Local Oscillator (LO) generation box, which receives the reference 2.997 GHz signal from the MO. The downconversion and digitalization is done by employing a commercially available MicroTCA standard boards from Struck GmbH. The DWC board provides an intermediate frequency (IF) of ~ 25 MHz which is sampled by the 125 MS/s SIS 8300 ADC board. After digitalization, the digital IF signal is further processed by the controller firmware, where amplitude and phase information is extracted using a so called digital IQ demodulation technique. The obtained phase error information is fed to a piezo driver acting on a piezo mirror inside the laser cavity to match the frequency and phase of the reference signal. More details about controller firmware and the FPGA signal processing chain can be found [9].

TRANSVERSE EMITTANCE MEASUREMENT AT REGAE

M. Hachmann, K. Floettmann, DESY, Hamburg, Germany

Abstract

The linear accelerator REGAE at DESY produces short and low charged electron bunches, on the one hand to resolve the excitation transitions of atoms temporally by pump probe electron diffraction experiments and on the other hand to investigate principal mechanisms of laser plasma acceleration. For both cases a high quality electron beam is required which can be identified with a small beam emittance. A standard magnet scan is used for the emittance measurement which is in case of a low charged bunch most sensitive to the beam size determination (2$^{\text{nd}}$ central moment of a distribution). Therefore the diagnostic and a routine to calculate proper central moments of an arbitrary distribution will be introduced and discussed.

INTRODUCTION

The Relativistic Electron Gun for Atomic Exploration (REGAE, Fig. 1) at DESY is a small 5 MeV linear accelerator with a bunch charge range of a few to some hundreds fC. The beam energy is delivered by an S-band photo-injector cavity. In addition to the gun a 4-cell buncher cavity is installed. It is designed for velocity bunching down to 10 fs. Due to the low energy a beam optics consisting of solenoids is sufficient. They are compact and focusing in both directions simultaneously.

The machine is built for two types of experiments: first a time-resolved electron diffraction experiment in order to make atomic transitions 'visible' [1] and secondly investigations of new plasma-wakefield acceleration schemes [2]. Both experiments require a low transverse beam emittance down to 10 nm (normalized emittance). Hence, there are two challenges: generate such a high quality electron bunch and measure this quality for a low-charge bunch with high precision which is discussed below.

Due to the small energy spread as well as in first approximation negligible space charge effects a phase advance method can be utilized for the emittance measurement. For this purpose a charge sensitive detector system was developed which has the required spatial resolution to measure the beam profile despite the unavoidable noise and background signals.

EMITTANCE MEASUREMENT VIA A SOLENOID SCAN

Phase Advance Method

A commonly used method to determine the transverse emittance of an electron bunch is a magnet scan. Here the phase advance between a magnet and a downstream screen is changed by varying the magnet current. Analyzing the RMS beam size as function of the focusing strength yields the emittance. Alternatively, it is possible to measure the beam size at different positions without any additional change of the optics. At REGAE the first method is used.

Assuming a small energy spread the *trace space emittance* is determined as

$$\epsilon_x = \sqrt{\langle x^2\rangle \langle x'^2\rangle - \langle x\, x'\rangle^2}$$

and is related in the following way to the *normalized emittance*: $\epsilon_x = \frac{1}{\beta\gamma}\epsilon_{n,x}$ with $\beta = v/c$, the Lorentz factor γ and the velocity v. Furthermore, $\langle\rangle$ denotes the central moment of a distribution, in this case the 2$^{\text{nd}}$ central moment where the square root is normally called RMS: $\langle x^2\rangle = x_{rms}^2$.

In order to measure the transverse beam emittance the envelope equation can be used [3]:

$$x_{rms}{}^2 = \begin{pmatrix} R_{11}{}^2 & 2\,R_{11}\,R_{12} & R_{12}{}^2 \end{pmatrix}^{\top} \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix} \qquad (1)$$

$$\text{with}\quad a_1 = x_{0,rms}{}^2$$
$$a_2 = x_{0,rms}(x_{0,rms})'$$
$$a_3 = \frac{\epsilon_x{}^2}{x_{0,rms}{}^2} + (x_{0,rms})'^2.$$

x_{rms} denotes the RMS beam size at the screen, $x_{0,rms}$ the beam size and $(x_{0,rms})'$ the envelope slope at the position of the solenoid. In order to calculate the RMS beam size a Gaussian fit is often used. But the width of the normal distribution is only equal to the RMS if the beam profile is really normal distributed. In any other case this assumption doesn't hold which causes false results. It is important to emphasize that Eq. 1 only holds for RMS quantities. But the calculation of the RMS is difficult because the whole signal has to be taken into account which means the beam signal as well as background and noise. A post-processing routine for images will be introduced in the next section.

Taking Eq. 1 as a model describing the beam size development at a certain position in dependence of varying phase advances, the emittance can be found with the method of least squares.

Detector System at REGAE

For the diffraction experiment at REGAE a highly sensitive detector system is installed which is able to detect single electrons. This detector combined with the solenoids Sol45 or Sol67 (Fig. 1) can be used for the emittance measurements. The detector contains a CsI-crystal-screen which is evaporated onto light guides, called FOS (Fiber Optics Scintillator), and a charge sensitive Electron Multiplying CCD (EMCCD). The overall spatial resolution of this detector system is ∼ 20 µm/pixel. A schematic layout is shown in Fig. 2. The FOS is orientated perpendicular to the beam propagation. To avoid high energy photons or electrons hitting the EMCCD camera a mirror reflects the visible light

OPERATION OF NORMAL CONDUCTING RF GUNS WITH MicroTCA.4

M. Hoffmann*, V. Ayvazyan, J. Branlard, Ł. Butkowski, M. Grecki, U. Mavrič, M. Omet, S. Pfeiffer, H. Schlarb, C. Schmidt, DESY, Hamburg, Germany
A. Piotrowski, FastLogic, Łódź, Poland; W. Fornal, R. Rybaniek, WUT-ISE, Warszawa, Poland

Abstract

During the last half year, the MicroTCA.4 based single cavity LLRF control system was installed and commissioned at several normal conducting facilities at DESY (FLASH RF gun, REGAE, PITZ RF gun and Booster, and XFEL RF gun). First tests during the last year show promising results in optimizing the system for high speed digital LLRF feedbacks, i.e. reducing system latency, increasing the internal controller processing speed, testing new control schemes, and optimizing controller parameters. In this contribution we will present results and gained experience from the commissioning phase and the first time period of real operation.

INTRODUCTION

The well known problem with normal conducting cavities is the temperature dependency of the resonance frequency, which introduces the main source for RF field fluctuations. The stability of the temperature defines the stability of the cavity field. For the RF gun cavities used at FLASH, XFEL and PITZ, the temperature coefficient is about 20 kHz/K. The required RF field stability is 0.01 % in amplitude and 0.01° in phase. The stabilization of the temperature for the RF guns at FLASH, XFEL and PITZ is quite challenging, because of the long RF pulses of typically 500 to 800 μs, which represents a massive heat load of typical 20 kW to the cooling system. In case of an interlock, the heat load has to be absorbed by the cooling system in a short time, while during normal operation the system has to be very accurate and keep the temperature of the gun constant below 0.03 K peak-to-peak. A further disturbance source comes from the the driving chain primary the klystron. Its stability is mainly defined by the stability of the modulator high voltage. The task of the RF controller is to suppress these disturbances. Temperature fluctuations are a slow effect, which degrades the pulse-to-pulse stability, while the klystron high voltage stability can be seen even within the RF pulse. During the commissioning phase of the new MicroTCA.4 based LLRF system at the FLASH, XFEL and PITZ gun, the main source of disturbances turned out to be quite different from facility to facility.

CONTROLLER DESIGN FOR RF GUNS

Due to the high bandwidth of normal conducting cavities of about 60 kHz (compared to superconducting cavities with about 200 Hz), the latency in the control loop of a normal conducting system is critical for the feedback controller design. It introduces a phase roll-off over the frequency, which makes the proportional feedback unstable at high feedback gains. One method to compensate this effect is the integration of a lead-lag element. The lead-lag element increases the phase margin of the closed loop transfer function in a certain frequency range, which allows to shift the area of instability to slightly higher controller gain. Additionally, it introduces an integrative part to the controller, which increases the feedback gain at lower frequencies and therefore to higher disturbance rejection. In our standard controller

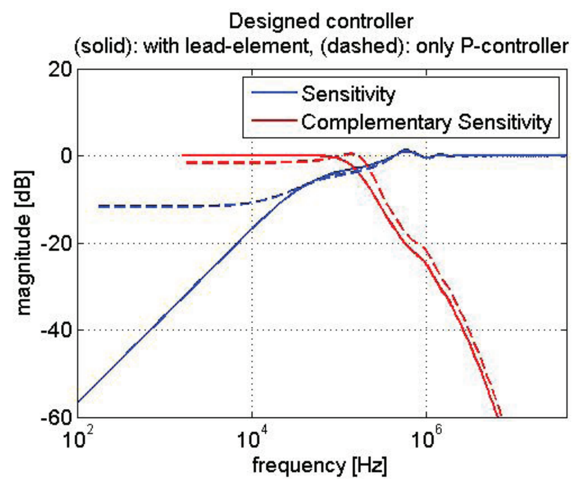

Figure 1: Sensitivity (S) and complementary sensitivity (T) function of the designed controller for the FLASH gun with lead-lag element (solid) and P-controller (dashed).

firmware, a two dimensional multiple input multiple output (MIMO) controller with second order transfer functions for each path is implemented [1]. This MIMO structure allows to compensate coupling between the real and imaginary part of the cavity field. Nevertheless, for the RF guns the main diagonal transfer functions are configured as a lead-lag element with an additional low pass filter. The low pass filter simply helps to reduce the loop back of the measurement noise, since the cavity bandwidth is just a few tens of kHz, while the detection bandwidth is several MHz. Fig. 1 shows an implementation example of the sensitivity function (S) and the complementary sensitivity function (T) of this controller. S describes the suppression of the disturbances. The S and T of a simple proportional feedback controller are shown in Fig. 1, for comparison purposes. In the low frequency regime the effect of the integrative part of the lead-lag element is clearly visible.

FLASH RF GUN

The FLASH gun is running since January 2015 with the new MicroTCA.4 based LLRF system. The system was running in parallel, already commissioned and tested during the

Abstract

The Free–Electron Laser in Hamburg (FLASH) at Deutsches Elektronen–Synchrotron (DESY), Hamburg Germany is a user facility providing ultra–short, femtosecond laser pulses down to the soft X–ray wavelength range. For the precise regulation of the radio frequency (RF) fields within the 60 superconducting cavities, which are organized in 5 RF stations, digital low level RF (LLRF) control systems based on the novel MicroTCA.4 standard were implemented in 2013. With the newly installed system, an outstanding LLRF performance was achieved so far, positively impacting the FLASH stability and operation capabilities. Also valuable experiences with failures potentially due to radiation, overheating, and ageing as well as with the general operation of the control system could be gained. These have a direct impact on the operation and on the performance of FLASH and will allow future improvements. The lessons learned are not only important for FLASH but also in the scope of European X–ray Free–Electron Laser (XFEL), which will be operated with the same LLRF control system.

INTRODUCTION

The Deutsches Elektronen–Synchrotron (DESY) in Hamburg is currently building the European X–ray Free Electron Laser (E-XFEL) [1,2]. This hard X-ray light source will generate up to 27000 coherent laser pulses per second with a duration of less than 100 fs and a wavelength down to 0.05 nm. For this, electrons have to be accelerated to 17.5 GeV using a 2 km particle accelerator based on superconducting radio frequency technology. Precision regulation of the RF fields inside the accelerating cavities is essential to provide a highly reproducible and stable electron beam. RF field regulation is done by measuring the stored electromagnetic field inside the cavities. This information is further processed by the feedback controller to modulate the driving RF source, using a low level RF system. Detection and real-time processing are performed using most recent FPGA techniques. Special calibration and fast processing techniques of the RF signals inside the system are required. Performance increase demands a powerful and fast digital system, which was found with the Micro Telecommunications Computing Architecture (MicroTCA.4) [3], offering the following advantages. It combines a high precision of measurements and with a low latency processing. It is designed for the parallel processing of a huge number of RF signals. The system standard is very compact. High reliability and availability is assured with redundancy and radiation resistance due to shielding. A further feature is the capability of remote software upgrades and maintenance. Modularity and scalability permit easy hardware system upgrades.

DESY currently is operating the free electron laser (FLASH) [4], which is a user facility of the same type as XFEL but at a significantly lower maximum electron energy of 1.2 GeV. The LLRF system for FLASH is equal to the one of XFEL, which allows testing, developments and performance benchmarks in advance of the XFEL commissioning [5].

This fact is highly beneficial in preparation for the XFEL commissioning and operation. The FLASH LLRF system is successfully operated for about 2 years in the MicroTCA.4 framework demonstrating its capability of running a highly performing field regulation. They key question to be answered are:

1. What lessons have been learned for setup and commissioning of the LLRF system?
2. What problems have to be considered for operating the XFEL LLRF with MicroTCA.4 LLRF?
3. What efforts have to be addressed to further improve the system?

In the following these questions are to be discussed with the experience gained at FLASH. Due to the long operation at this facility, a large number of bug fixes could be achieved which is already beneficial since directly applicable to XFEL. Furthermore, vice versa FLASH benefits to a large extent, since requirements of the XFEL LLRF system are directly transferred to FLASH improving its performance.

SETUP AND COMMISSIONING OF THE LLRF SYSTEM

The LLRF system as well as all other subcomponents for the European XFEL main linac are installed within the accelerator tunnel which has a major impact of the system

COMMISSIONING OF THE LOW-NOISE MTCA.4-BASED LOCAL OSCILLATOR AND CLOCK GENERATION MODULE*

U. Mavrič, J. Branlard, M. Hoffmann, F. Ludwig, H. Schlarb, DESY, Hamburg, Germany
A. Rohlev, TSR Engineering, Triest, Italy
D. R. Makowski, A. Mielczarek, P. Perek, TUL-DMCS, Łodz, Poland

Abstract

Within the Helmholtz Validation Fund Project "MicroTCA.4 for Industry", DESY together with collaboration partners from industry and research developed a compact fully MicroTCA chassis-integrated local RF oscillator module. The local oscillator and clock generation module generates a low noise local oscillator out of the global reference that is distributed over the accelerator. The module includes a splitting section which provides 9 local oscillator signals which are distributed over the RF-Backplane to the rear-transition modules. Similarly, the clock signal is also generated out of a single reference input by means of low-noise dividers. The clock is then fan-out to 22 differential lines that are routed over the RF backplane to the rear-transition modules. The functional block is implemented such that it fits in the rear slots 15 and 14 of a standard MTCA.4 crate. In the paper the commissioning results measured on the L3 low-level RF stations of the European XFEL will be presented.

SYSTEM ARCHITECTURE

The basic RF field detection scheme for the XFEL imposes specific requirements on the local oscillator (LO) and clock (CLK) generation circuits. The main design parameters are large number of tap-points and performance in terms of phase and amplitude stability. The decision was taken that each crate will have its own LO and CLK generation module. If one LO/CLK generation circuit would be serving multiple crates, this would cause issues with cable-drifts and reliability. On the other hand, having one LO/CLK generation circuits per one down-converter unit (8 field detectors) would increase the performance that could be achieved by vector-sum processing gain. The last option will be investigated in the future.

The LO/CLK module presented in this paper is located in the rear side of a standard MTCA.4 crate in slot 15. It uses a dedicated RF backplane [1] for distributing the LO and CLK signals. This reduces the amount of cables needed. The crate environment provides also the power, hardware management and data communication to the module.

One of the main functions of the LO/CLK generation module for the XFEL is to provide the local oscillator (LO) frequency at 1354 MHz. The LO frequency is generated by means of splitters and dividers as shown in Fig. 1.

* This work has partly been funded by the Helmholtz Validation Fund Project MTCA.4 for Industry.

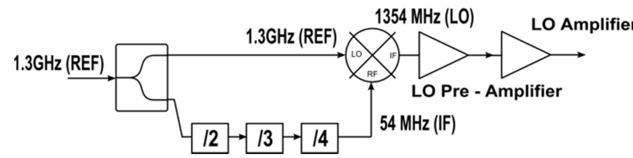

Figure 1: Generation of the local oscillator frequency.

Even if other architectures such as PLL-based circuits cover a wider frequency range of possible LO frequencies the method using dividers-only can practically achieve a lower residual phase noise while keeping the circuit simple. Because of the high number of tap-points the RF power before the splitting has to be in the order of 1 W which represents also a challenge in terms of shielding and DC power dissipation.

The generation of the CLK signals is implemented via simple clock dividers. The reasons for such architecture are similar to the ones for the LO generation.

HARDWARE OVERVIEW

The module is composed of several subsystems. The carrier hosts the RF splitting section, the CLK signal generation, the digital management section, the application processing unit and the low-noise linear regulators. Other functionalities such as DC/DC converters, the temperature controllers and the local oscillator generation are moved off the carrier board on daughter cards and connected to the main board through multi-pin connectors.

Carrier Board

The carrier board's primary function is frequency and clock distribution to the RF back plane (see Fig. 2). The 25 PECL differential clocks can be activated individually. The LO (1.354 GHz), CAL (1.3 GHz), and REF (1.3 GHz) signals are distributed via small 'RF-Mezzanine' cards that are directly soldered to the Carrier. Each RF-Mezzanine card provides a 1:9 signal fan-out as well as individual fixed attenuators and an absorptive RF switch for each signal. By swapping RF-Mezzanine cards frequency distribution up to 6 GHz can be achieved without altering the supporting carrier hardware.

The carrier also provides DC power generation for the system via a shielded 'DC/DC-Mezzanine' card that hosts two 8 A switch-mode convertors. One convertor provides a 5.9 V output used by the numerous LDO's on both RF and carrier card, the other convertor provides a 5.0 V output used exclusively for temperature control via thermoelectric controllers (TEC's) and Peltier elements.

IMPLEMENTATION OF A DIAGNOSTIC PULSE FOR BEAM OPTICS STABILITY MEASUREMENTS AT FLASH

F. Mayet, R. Assmann, S. Schreiber, M. Vogt, DESY, Hamburg, Germany

Abstract

In order to monitor long-term stability of beam optics, simple and at the same time minimally invasive procedures are desirable. Using selectively kicked bunches, betatron phase advance, as well as potential growth of the betatron oscillation amplitude and the Twiss parameters alpha and beta can be extracted from BPM data. If done periodically, this data can be compiled into a long-term history that is accessible via the control system. This way it is possible to identify potential sources of beam optics errors. At FLASH the procedure could be implemented as a server/client tool. Since the whole procedure takes less than five seconds, operation is not disturbed significantly. In this work the possible implementation of the procedure is presented. It is also shown how the history data can be evaluated in order to infer possible beam optics error sources.

INTRODUCTION

The high-gain free-electron laser FLASH at DESY, Germany produces ultra-short X-ray pulses with a duration less than 30 fs FWHH. These pulses are generated by the SASE process using a high brightness electron beam, which can be tuned to energies between 350 MeV and 1.25 GeV. This corresponds to a photon wavelength range between roughly 52 nm and 4 nm. Electron bunches are created by a laser-driven photoinjector and then accelerated by seven 1.3 GHz superconducting accelerator modules (*TESLA-type*). X-ray pulses are then generated inside the 27 m long undulator section. [1–3]

Since FLASH is a user facility, the long-term stability of the beam optics is crucial for all connected user experiments and the operation of the new second beamline FLASH2. In addition to that the seeding experiment sFLASH also demands for high beam optics stability. In [4] a simple procedure to monitor the beam optics routinely and at the same time minimally invasive was proposed. This work presents the actual implementation of the procedure at FLASH, as it is planned to be deployed during beamtime in the second half of 2015.

METHOD

The diagnostic pulse method is based on the idea of extracting beam optics stability information by measuring kicker magnet induced betatron oscillations of selected pulses periodically. These oscillations are measured by all available beam position monitors downstream the location of the kick. An online tool then analyzes the data. This way a long-term history of beam optics stability can be compiled.

The aim of the method is to reveal the cause of beam optics errors by correlating the long-term beam optics stability history with recorded machine parameters, or other events. A detailed description of the method can be found in [4].

IMPLEMENTATION

For the implementation of the method two schemes are possible. Table 1 shows the two possible scenarios at FLASH.

Fast Kicker

The first scheme is based on fast single bunch kickers. The main advantage of this scheme is the fact that it is minimally invasive and can potentially be run in the backround without disturbing any user experiments. At FLASH an appropriate fast kicker would be a dark current kicker at the beginning of the linac ($s = 0.45$ m). This device would then act as the only betatron oscillation inducing device (*DC-Kicker Scheme*). Being a sinusoidal kicker running resonantely at 1 MHz, the kicker can only be used in *single bunch mode*. Due to space constraints the installation of a second kicker is currently not possible. Since the DC-kicker only acts on the y-plane, information about the x-plane cannot be recorded. Because of the missing second kicker data analysis must rely on the *zero-crossing method*, as described in [4].

Slow Steerers

The second scheme (*Steerer Scheme*) relies on the use of two slow steerer magnets. By choosing a suitable set of steerers ($\approx \pi/2$ phase advance distance), it is possible to perform a complete trajectory fit. This then enables the extraction of beam optics parameters (like Twiss parameters β and α - see [4] for details). If two suitable sets of steerers are chosen, both the x and y plane data can be taken. First test measurements showed that in this scheme the whole procedure takes roughly 5 seconds. Therefore this scheme must be considered invasive, which is the main disadvantage. Two implementations of the *Steerer Scheme* are possible. The first one is an easy to use control panel and the other one is the integration of the diagnostic pulse measurement into the routinely performed shift documentation. This documentation already involves running several diagnostics and documentation related scripts. The diagnostic pulse measurement would then be added as another plug-in script to be run. Because of the invasive nature of the *Steerer Scheme*, currently the control panel is the favored approach.

Software

Independent of the choice of scheme, the implemenation of the diagnostic pulse measurement and beam optics stability history is based on a server/client concept. At FLASH many of the machine components are controlled via the DOOCS control system [5]. Therefore the diagnostic pulse

ALL-OPTICAL SYNCHRONIZATION OF PULSED LASER SYSTEMS AT FLASH AND XFEL

J. Müller*, C. Sydlo, M. Schäfer, M. Felber, F. Zummack, M. K. Czwalinna, S. Schulz, H. Schlarb, B. Schmidt, DESY, Hamburg, Germany

Abstract

The all-optical laser synchronization at FLASH and XFEL provides femtosecond-stable timing of the FEL X-ray photon pulses and associated optical laser pulses (photo-injector laser, seed laser, pump-probe laser, etc.). Based on a two-color balanced optical cross-correlation scheme a high-precision measure of the laser pulse arrival time is delivered, which is used for diagnostic purposes as well as for the active stabilization of the laser systems. In this paper, we present the latest installations of our all-optical synchronization systems at FLASH and the recent developments for the upcoming European XFEL that will ensure a reliable femtosecond-stable timing of FEL and related pulsed laser systems.

INTRODUCTION

The free-electron laser in Hamburg (FLASH) and the upcoming European XFEL as fourth-generation linac-based light sources are capable of producing X-ray pulses with a duration of a few femtoseconds. Particulary for time-resolved pump-probe experiments and the externally seeded operation mode it is mandatory to achieve a synchronization of the external laser systems with an accuracy on the same timescale. One possibility to fullfill the requirements of a femtosecond-precise synchronization is a laser-based infrastructure [1]. Already in operation at FLASH and currently in the installation phase at XFEL the transmission of a highly stable periodic train of laser pulses to the critical subsystems over actively stabilized optical fibers is used and provides a time-stable reference signal to the corresponding end-stations [2]. This laser pulse train can be utilized directly for diagnostic purposes like in the bunch arrival time monitors [3]. Another application is the high-precision synchronization of external pulsed laser systems using a two-color balanced optical cross-correlation scheme [4]. The first prototypes for the actual system at FLASH were installed in 2007. Meanwhile, this optical synchronization system has grown to a key part of the facility. Further improvements of the system, particulary with regard to the European XFEL, focus on reliability and maintainablity of the subsystems. As one result we show here the first version of a new engineered design for laser-to-laser synchronization that is based on the well-proven all-optical laser synchronization setup currently running at several locations at FLASH.

* jost.mueller@desy.de

LASER-TO-LASER SYNCHRONIZATION

One essential key feature of the optical synchronization systems at FLASH and XFEL is the laser-to-laser (L2L) synchronization of external pulsed laser systems. This is based on a two-color balanced optical cross correlation scheme [4] that delivers a high-precision measure of the timing error between the reference and the laser pulse. Here, a twofold sum-frequency generation process in a nonlinear crystal provides a pure timing-sensitive error signal that is not affected by amplitude fluctuations of the two input signals. The principle of the balanced optical cross-correlation is shown in Fig. 1. To lock the laser repetition rate to the reference the error signal can be fed back within an electronic control loop that tunes the laser cavity length. The initialization of the synchronization process requires an additional RF-based pre-locking with a locking stability in the order of the used pulse widths.

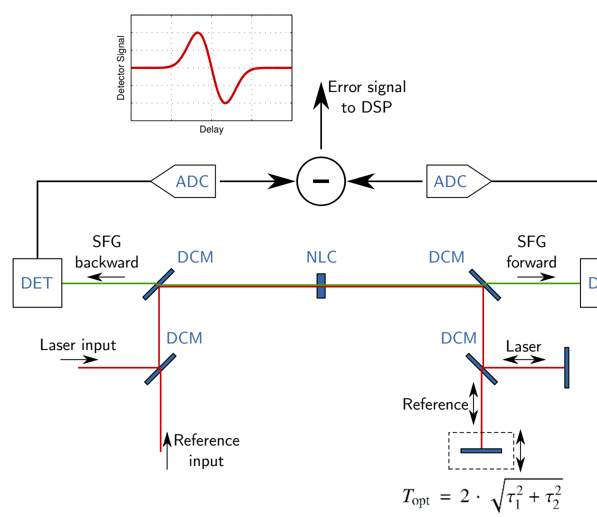

Figure 1: Principle of the balanced optical cross-correlator.

Current & Future Installations

So far we are operating three L2L-based synchronization setups at FLASH. The all-optical synchronization of the pump-probe laser system has brought great improvement regarding the jitter performance between pump-probe and FEL pulses [5]. A facility-wide timing jitter between pump-probe and FEL pulses could be shown to be below 30 fs (rms) [5]. Beside this, the injector laser system at FLASH is also equipped with an optical cross-correlator whereat no fast synchronization but a slow drift feedback is used to lock the laser to the optical reference. And meanwhile we also upgraded the synchronization system of the Ti:Sapphire

PHYSICAL PARAMETER IDENTIFICATION OF CROSS-COUPLED GUN AND BUNCHER CAVITY AT REGAE

Ayla S. Nawaz*, Herbert Werner, TUHH, Hamburg, Germany
Matthias Hoffmann, Sven Pfeiffer, Holger Schlarb, DESY, Hamburg, Germany

Abstract

A reasonable description of the system dynamics is one of the key elements to achieve high performance control for accelerating modules. This paper depicts the system identification of a cross-coupled pair of cavities for the Relativistic Electron Gun for Atomic Exploration - REGAE. Two normal conducting copper cavities driven by a single RF source accelerate and compress a low charge electron bunch with sub 10 fs length at a repetition rate up to 50 Hz. It is shown how the model parameters of the cavities and the attached radio frequency subsystem are identified from data generated at the REGAE facility.

INTRODUCTION

High field stability in phase and amplitude is the primary concern for the control of gun and buncher cavities at REGAE [1], a collaboration of the Center for Free-Electron Laser Science CFEL, the Max Planck Society, the University of Hamburg and DESY. Both the gun - a 1.5 cell cavity and the buncher - a 4 cell cavity are powered by the same klystron, Fig. (1).

The input to the klystron is modified through the feed forward tables. The required complex signal is implemented for the real and for the imaginary part separately. Power division after the klystron is obtained with the help of a T-shunt. It supplies the gun with 2/3 of the total power and the buncher with the remaining 1/3. It can be reasonably assumed, that the usage of one klystron for both the gun and the buncher cavity leads to cross-couplings between the two systems.

Signal detection, which is based on a MicroTCA.4 system standard [2], takes place in the gun and buncher respectively. For this the electromagnetic fields are measured by pick up antennas. The produced complex signal is then down converted to the intermediate frequency of 25 MHz and sampled with a frequency of 125 MHz. Results are then stored for the real and imaginary parts separately. The behaviour of the real and imaginary parts of the signals in the system can therefore be identified separately, though not independently, resulting in a two by two MIMO system for the gun as well as for the buncher. The frequency difference between the operating mode in each cavity, i.e. the π-mode, and the higher order modes lies between 2 MHz and 9.5 MHz. This difference is not enough to assume no influence of the higher order modes on the total field. The resulting electromagnetic field in the cavities is therefore a superposition of all the excited modes. This means that in the case of the gun one extra mode will be excited. In the case of the buncher there will be three extra modes. This behaviour is taken into consideration in the following system identification.

* ayla.nawaz@tu-harburg.de

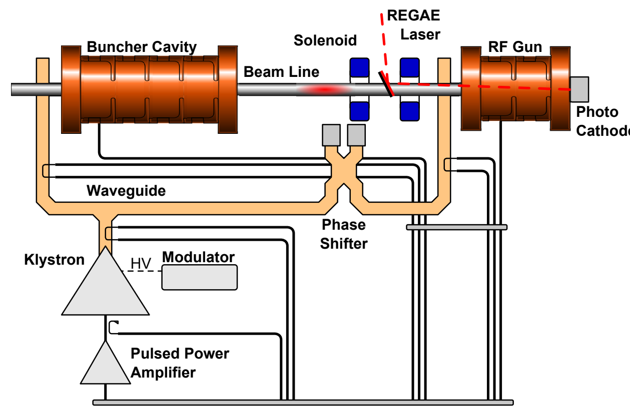

Figure 1: General cavity system set-up.

The system identification is obtained with the assumption that the cross-couplings between the gun and the buncher are negligible - case A and have to be taken into account - case B. It is shown that a consideration of the cross-couplings results in a higher accuracy of the acquired system model.

In the following the procedure of the system identification for the REGAE cavity system is explained. The used excitation signals, assumed model orders and time delays for the system are explained. Finally the results of a cross validation with the identified system model is discussed.

IDENTIFICATION

For the excitation of the system a pseudo random binary signal (PRBS) is used. This assures persistent excitation for the relevant frequency range. Two uncorrelated PRB-signals are used to excite the I and the Q channel of the input signal. The values for that are stored in the discrete time domain vector $u_I(k)$ and $u_Q(k)$ respectively. Accordingly in the frequency domain as $U_I(z)$ and $U_Q(z)$. The measured outputs are collected in the discrete time vector of $y_I(k)$ and $y_Q(k)$ and accordingly in the frequency domain as $Y_I(z)$ and $Y_Q(z)$. The general structure of the MIMO system is given by

$$\begin{bmatrix} Y_I(z) \\ Y_Q(z) \end{bmatrix} = \begin{bmatrix} G_{II}(z) & G_{IQ}(z) \\ G_{QI}(z) & G_{QQ}(z) \end{bmatrix} \begin{bmatrix} U_I(z) \\ U_Q(z) \end{bmatrix}, \quad (1)$$

representing the dependencies between the two inputs $U_I(z), U_Q(z)$ and the resulting outputs $Y_I(z), Y_Q(z)$ of the system. The z specifies the system as discrete. The parameters in the transfer functions $G_{II}(z), G_{IQ}(z), G_{QI}(z)$ and $G_{QQ}(z)$ are the unknowns. They are determined by the system identification.

HIGH VOLTAGE RTM PIEZO DRIVER FOR XFEL SPECIAL DIAGNOSTICS*

K. Przygoda#, M. Felber, C. Gerth, M. Heuer, E. Janas, U. Mavric, P. Peier, H. Schlarb, B. Steffen, C. Sydlo, DESY, Hamburg, Germany
T. Kozak, P. Predki, DMCS, Lodz, Poland

Abstract

High voltage RTM Piezo Driver (PZD) has been developed to support special diagnostic (SD) applications foreseen for XFEL facility. The RTM Piezo Driver is capable of driving 4 piezo actuators with voltages up to ±80 V [1]. The solid state power amplifiers are driven using 18-bit DACs and sampling rates of 1 MSPS. The bandwidth of the driver is remotely tuneable using programmable low pass filters. The 4-channel Piezo Driver unit provides the information of piezo output voltage and current. Three independent test setups have been built to test 4-channel Piezo Driver performance. In the paper we are presenting EOD laser lock to 1.3 GHz FLASH master oscillator using bipolar piezo stretcher (fine tuning). The piezo motor based course tuning has been applied for the long term laser stability measurements. The unipolar piezo actuator operation has been demonstrated for the Origami Onefive laser locked to 1.3 GHz LAB MO. The preliminary results of active stabilization of 3.6 km fibre link laboratory setup are shown.

INTRODUCTION

In accelerator facilities, especially free-electron lasers (FEL), the use of mode locked lasers is most common approach, e.g. for electro-optical diagnostics (EOD), as photo-cathode lasers, seeding, Beam Arrival and Beam Position Monitors (BAM, BPM) or pump-probe experiments [2].

The repetition rate of the laser train pulses is typically a sub-harmonic of the main RF synchronization signal. At European XFEL the main reference signal is at 1.3 GHz while the lasers run in a range between 54 MHz and 216 MHz. In order to synchronize the laser to the accelerator reference a piezo element within a laser cavity is applied. The main approach is to use a loop filter (digital or analog) driving a high output voltage and current power amplifier in order to minimize a phase difference between reference and the laser.

The accelerator reference signal needs to be also distributed over different places of the machine. The main idea is to encode the reference timing information in the precise rate of an optical pulse trains using master laser oscillator (MLO). The MLO optical signal is next transmitted to different accelerator locations (e.g. RF Gun, main linac or undulator sections) using fibre laser connections. The fibre lasers needs to be actively stabilized using stretcher in a fibre due to temperature drifts and microphonics. The typical active fibre link stabilization is done using balanced optical cross-correlator (OXC) that compares the optical signal of the transmitter (e.g. MLO) and receiver (e.g. Probe Laser) and minimize its phase difference using analog or digital feedback loop. The block diagram of the laser synchronization and special diagnostic applications foreseen for XFEL machine are shown in Fig. 1.

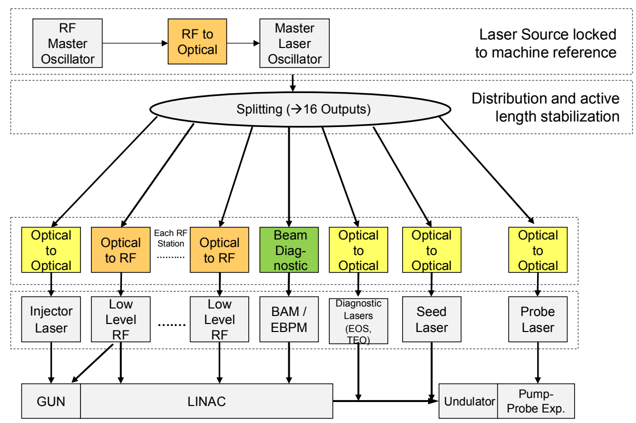

Figure 1: The block diagram of XFEL laser synchronization and special diagnostics.

The 2 laser sources locked to machine reference are foreseen for XFEL facility installation. The both MLO applications based on unipolar piezo actuator will occupy two 4-channel RTM Piezo Drivers (one channel per RTM). When considering optical signal distribution over XFEL accelerator a total of 24 fibre link connections with a length between 20 m and 3 km will be established. The bipolar piezo based fibre stretcher applications will consume 6 RTM Piezo Drivers (4 channels per RTM). The 4 electro-optical bunch length diagnostic (EOD) setups will use both bipolar (fine tuning) and unipolar (coarse tuning) piezo elements. The EOD lasers will occupy 4 Piezo Driver units. The 2 channels per module will be driven.

HIGH VOLTAGE PIEZO DRIVER APPLICATIONS

The 3 test stands have been established to check piezo driver performance for precise synchronization of optical lasers and special diagnostic applications [3].

MLO Synchronization

The Master laser oscillator application is based on Origami-15 onefive ultra-low noise femtosecond laser

BEAM OPTICS MEASUREMENTS AT FLASH2

M. Scholz, J. Zemella, M. Vogt, DESY, Hamburg, Germany

Abstract

FLASH2 is a newly build second beamline at FLASH, a soft X-ray FEL at DESY, Hamburg. Unlike the existing beamline FLASH1, it is equipped with variable gap undulators. This beamline is currently being commissioned. Both undulator beamlines of FLASH are driven by a common linear accelerator. Fast kickers and a septum are installed at the end of the linac to distribute the electron bunches of every train between FLASH1 and FLASH2. A specific beam optics in the extraction arc with horizontal beam waists in the bending magnets is mandatory in order to mitigate effects from coherent synchrotron radiation (CSR). We performed various beam optics measurements to ensure that the conditions for FEL operation at FLASH2 are fulfilled. Here we will show results of measurements.

INTRODUCTION

The existing superconducting single-pass high-gain SASE FEL FLASH (Free-electron LASer in Hamburg) at DESY, Hamburg [1] delivers photons in the wavelength range from 4.2 nm to 52 nm. The photons generated in the fixed gap SASE undulators can be delivered to five experimental stations one at a time. A second undulator beamline was attached to the linac during the last three years and is now under commissioning [1, 2]. The FEL will continue to be referred as FLASH and the two beamlines are named FLASH1 and FLASH2. Fast kickers and a DC Lambertson-Septum, installed behind the FLASH linac, allow to distribute the beam either to FLASH1 or to the extraction arc leading to FLASH2. The final angle between FLASH1 and FLASH2 is 12°. Strong bending magnets in the extraction arc require specific Twiss functions in order to mitigate emittance growth due to CSR [2, 3]. The FLASH2 undulator beamline is equipped with variable gab undulators [4] for SASE and reserves space for future seeding options. The extraction to a proposed third beamline hosting a plasma wake field experiment is considered in the beamline layout at the end of the FLASH2 arc.

DISPERSION MEASUREMENT AND MATCHING

The linear dispersion describes the derivative of the transverse beam position w.r.t. the relative momentum offset:

$$\eta_{x,y} = \frac{\Delta(x, y)}{\Delta p/p_0} \tag{1}$$

where $\eta_{x,y}$ describes the dispersion in horizontal or vertical plane, $\Delta(x, y)$ is the horizontal respectively the vertical beam offset caused by the dispersion and $\Delta p/p_0$ is the relative momentum offset.

In the extraction arc leading to the FLASH2 undulator beamline the beam is deflected in horizontal plane. However, due to the use of a Lambertson septum that requires a vertical offset – realized with two vertical kickers and additional kicks applied by quadrupole magnets – the vertical dispersion in the FLASH2 extraction arc is not zero. The extraction was designed such that the dispersion in each plane is closed after the last bending magnet deflecting in that plane. The FLASH2 design dispersion functions are shown in the lower plot in Fig. 1.

Two methods for closing the dispersion were quickly identified: First, one can adjust the strength of the dipoles in the extraction arc or, secondly, one can change the focusing strength of the quadrupole magnets in the dispersive section. However, both methods come along with a large number of possible optimization variables. It would be preferable to have a solution with a small number of parameters that can then be scanned until the (horizontal) dispersion is closed.

The results from different beam energy models in FLASH (the vector sum of the accelerating modules and two different models employing dispersive measurements) are not fully consistent. Thus a potential energy scaling error is an obvious candidate for causing the major part of the residual dispersion leaking out of the extraction arc. A wrong scaling of the main magnets plus steerer corrections to hit the reference trajectory can lead to spurious dispersion from the arc.

The approach is to correct the energy scaling of the extraction arc which will automatically close the dispersion of the arc. The only optimization parameter in this procedure is the design beam energy. We setup the arc for different beam energies within a range of ± 10 MeV and measured the horizontal dispersion (which is large than the vertical). This was repeated until the dispersion was closed. Since this method is convenient and since it worked, it is now the default procedure to close the horizontal dispersion in the FLASH2 extraction arc.

The plots in Fig. 2 show the results of the dispersion measurement after the optimization procedure was completed. As one can see the vertical dispersion is not perfectly closed but the remaining dispersion is small. It is planned to correct this in future measurements with the two vertical dipoles installed downstream the last horizontal bends or with quads located at positions were the horizontal dispersion is already closed.

BEAM OPTICS MEASUREMENT AND MATCHING

The design beta functions of the FLASH2 beamline including the injector, the linac, the extraction arc, the matching section as well as the undulator section are shown in the upper plot in Fig. 1.

VISIBLE LIGHT DIAGNOSTICS AT THE ANKA STORAGE RING

B. Kehrer*, A. Borysenko, E. Hertle, N. Hiller, M. Holz, A.-S. Müller, P. Schönfeldt, P. Schütze
Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

Abstract

Synchrotron radiation in the visible light range is a versatile diagnostics tool for accelerator studies. At the ANKA storage ring of the Karlsruhe Institute of Technology (KIT), we have a dedicated visible light diagnostics beamline and two additional beam ports close to the radiation's source point. The visible light diagnostics beamline hosts a time-correlated single photon counting unit to measure the bunch filling pattern and a streak camera for longitudinal diagnostics. Recently, the beamline has been extended with a fast gated intensified camera to study transverse instabilities. The synchrotron light monitor ports were previously used for direct source imaging. Due to the diffraction limit the vertical beam size could not be resolved. One of the two ports has recently been equipped with a double-slit to allow for interferometric measurements of the vertical beam size.

In this paper we give an overview of the different setup modifications and present first results.

MOTIVATION

ANKA, the synchrotron light source at KIT can be operated in two different modes. In the normal user operation mode the machine is operated with an energy of 2.5 GeV and a filling pattern consisting of a sequence of bunches ('train') followed by a gap. In the short bunch mode with an energy of 1.3 GeV the lattice is changed to lower the momentum compaction factor α_c. By tuning the bunch length down (to the order of picoseconds), coherent synchrotron radiation (CSR) is emitted. Depending on the beam current, this radiation is either emitted constantly or in the so called bursts with a strong temporal fluctuation of the intensity. This latter mode requires a dedicated set of measurement tools for tracking the relevant parameters to gain further insight into accelerator physics. The charge distribution plays a vital role for these processes, either as the charge distributed over the bunches (filling pattern) or as the temporal and spatial profile of the different bunches. Incoherent synchrotron radiation can be used as diagnostics tool as its intensity is proportional to the bunch charge and thus the light pulse directly represents the charge distribution. Using the visible range simplifies the handling of the required components. At ANKA we have a dedicated visible light diagnostics beamline housing a set of experimental setups, additionally two dedicated beam ports for source point imaging are in use.

VISIBLE LIGHT DIAGNOSTICS BEAMLINE

The beamline is located at a 5° port front end at a dipole magnet. Two off-axis paraboloid and two planar mirrors transport the light onto the optical table where they form an intermediate image that is rotated by 90 degrees relative to the beam. To allow parallel measurements for the different setups the light is split into spectral regions by using two consecutive short pass filters (see Fig. 1). Using those filters allows the realization of a dispersion-free beam path for the streak camera as this would deform the temporal shape of the light pulses otherwise.

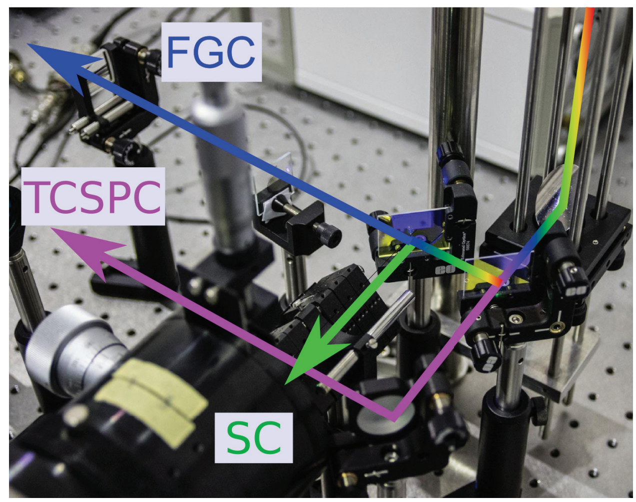

Figure 1: Picture of the of the setup for distributing the incoming light to the three different experiments (TCPSC: Time-correlated single photon counting, SC: Streak camera, FGC: Fast gated intensified camera) by using a sequence of two short pass filters (λ = 400 nm and λ = 500 nm).

Time-Correlated Single Photon Counting

For precise measurements of the filling pattern we use the time-correlated counting of single photons. The setup consists of a single photon avalanche diode (id100-20 from IDquantique [1]) and a histogramming device (PicoHarp 300 from PicoQuant [2]). The timing resolution of the setup is defined by the detector with a typical resolution of 40 ps, whilst the PicoHarp300 is operated with a channel width of 8 ps. To avoid deformations of the histogram due to too much events falling into the dead time we operate with count rates below $5\cdot10^5$ 1/s. The combination of the small sensitive area of the detector (20 μm diameter) and an iris lens mounted on the detector's C-mount leads to a good suppression of background light and thus we can operate the setup without any additional background light shielding. As the absorption depth of the photons in the solid state detector becomes smaller with decreasing wavelengths [3] we use a narrow bandpass filter (center wavelength 400 nm) to suppress the resulting diffusion tail in the histogram (see Fig. 2). This

STUDIES FOR A WAKEFIELD-OPTIMIZED NEAR-FIELD EO SETUP AT THE ANKA STORAGE RING

P. Schönfeldt*, A. Borysenko, N. Hiller, B. Kehrer, A.-S. Müller,
Karlsruhe Institute of Technology, Karlsruhe, Germany

Abstract

ANKA, the synchrotron light source of the Karlsruhe Institute of Technology (KIT), is the first storage ring with a near-field single-shot electro-optical (EO) bunch profile monitor inside its vacuum chamber. Using the method of electro-optical spectral decoding, the current setup made it possible to study longitudinal beam dynamics (e.g. microbunching) occurring during ANKA's low-alpha-operation with sub-ps resolution (granularity). However, the setup induces strong wake-fields spanning the distance between consecutive bunches which cause heat load to the in-vacuum setup for high beam currents. This heat load in turn leads to a laser misalignment thus preventing measurements during multi-bunch operation. Fortunately, the EO setup also allows us to directly study these wake-fields so simulation results can be compared to measurement data. This paper reviews a possible redesign of the setup, aiming to reduce the effects of the wakefield.

INTRODUCTION

An in-vacuum setup for for electro-optical bunch profile measurements is in regular operation at the ANKA storage ring since its installation in 2013 [1]. The measurement is based on the Pockels effect – a crystal becomes birefringent when it is exposed to an electric field. When a laser pulse is sent through the crystal, this birefringence then turns the linear polarization of a laser pulse into an elliptical one. At ANKA, a 5 mm thick Gallium Phosphide (GaP) crystal and a near-infrared laser (central wavelength 1030 nm) are used.

There are two possible measurement options: Electro optical sampling can be used to span time ranges of multiple nanoseconds. Here a short laser pulse is delayed with respect to the bunch arrival time and samples the electric field inside the electro optical crystal over many revolutions. Electro optical spectral decoding on the other hand allows to measure the bunch profile in a single shot. Here a long, chirped laser pulse is used. Afterwards one can reconstruct the time information by using a single shot spectrometer [2]. Using this mode it is possible to resolve substructures on the electron bunch, that only persist for a small number of revolutions [3].

Until now, the usage is limited to single-bunch operation. During the first measurements that were performed during multi-bunch operation, a decrease of the signal intensity was observed. The reason is that the laser has to be coupled into an optical fiber after passing the free space part inside the vacuum chamber. This step is very sensitive already to small misalignments, but the setup itself generates long ranging wakefields which cause the setup to heat up and makes misalignments unavoidable [4]. To overcome this limitation, a wakefield-optimized near-field EO setup is designed from scratch. A second design goal is a fast decrease of the wakefields' amplitude, to minimize biases when measuring electron bunches with a spacing of 2 ns.

For simulation and design, *CST Particle Studio* [5] is used. Its wakefield solver assumes a gaussian bunch shape (RMS bunch length σ_z) and can derive time dependent electromagnetic fields at defined points in space. Furthermore it computes the impedance and the integral over the longitudinal wake potential [6]

$$k_l = \frac{1}{\sqrt{2\pi}\sigma_z} \int_{-\infty}^{\infty} W_{\parallel} \exp\left(-\frac{s^2}{2\sigma_z^2}\right) \mathrm{d}s, \tag{1}$$

which is called the wake loss factor. To calculate the power an electron bunch looses by traveling through the structure, the correlation $P = k_l \times Q_b^2 \times f$ can be used, where Q_b is the bunch charge, and f the frequency bunches are passing by.

THE INSTALLED SETUP

The setup currently in operation has been designed by PSI and DESY for electro-optical bunch length measurements at SwissFEL and the European X-FEL [2]. The in vacuum part consists of a holder for the electro optical GaP crystal and a prism with a silver coated surface, which serves as a mirror.

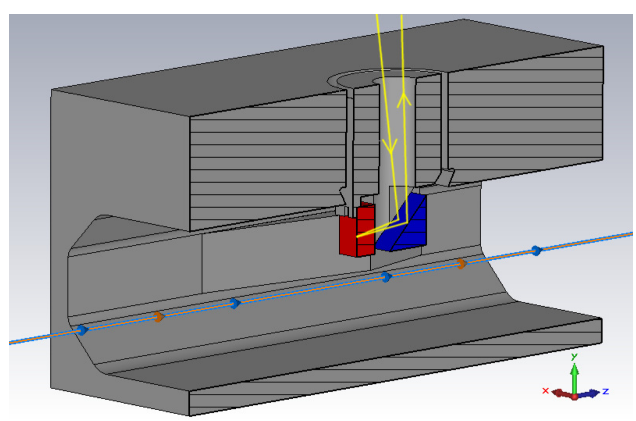

Figure 1: Cut through the beam pipe and the installed EO setup. The electron beam travels from the left to the right, the laser (yellow) enters from the top, is reflected at the mirror (blue), transverses the GaP crystal (red), is reflected at its back side and then travels back the same way.

A FAST GATED INTENSIFIED CAMERA SETUP FOR TRANSVERSAL BEAM DIAGNOSTICS AT THE ANKA STORAGE RING

P. Schütze*, A. Borysenko, E. Hertle, N. Hiller, B. Kehrer, A.-S. Müller, P. Schönfeldt
Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

Abstract

ANKA, the synchrotron light source at Karlsruhe Institute of Technology (KIT), can be operated in different modes including the short bunch operation with bunch lengths compressed to a few picoseconds. In this mode, coherent synchrotron radiation (CSR) is emitted leading to beam instabilities. For gaining further insight into those processes, a setup based on a fast gated intensified camera was installed recently at the visible light diagnostics beamline of the ANKA storage ring. The experimental layout consists of an optical setup, which magnifies the image of the beam in the horizontal and demagnifies it in the vertical plane to obtain a projection of the horizontal beam shape, the camera itself and a fast scanning galvanometric mirror that sweeps this image across the sensor. This allows the tracking of the horizontal bunch size and position over many turns.

In this paper we present the setup and show first measurement results.

INTRODUCTION

The synchrotron light source ANKA, located at the Karlsruhe Institute of Technology (KIT), can be operated at energies from 0.5 GeV up to 2.5 GeV. In addition to normal operation at 2.5 GeV, a short bunch operation at 1.3 GeV is regularly offered [1]. By lowering the momentum compaction factor α_c, bunch lengths of a few picoseconds are reached, leading to the emission of coherent synchrotron radiation (CSR) in the high GHz and THz range. Furthermore in short bunch operation micro-bunching instabilities and thus strong bursts of THz radiation occur. Their periodicity and power strongly depend on the bunch current. Various investigations of micro-bunching instabilities were performed at the ANKA storage ring, characterizing the coherent radiation bursts [2] and the corresponding longitudinal bunch profile [3].

The measurement setup presented in this paper, based on an idea of J. Corbett [4], will allow the observation of the horizontal bunch profile on a single turn base. It can be used for the observation of transverse bunch profile fluctuations, e.g. during micro-bunching instabilities.

EXPERIMENTAL SETUP

Optical Setup

The experiment is under commissioning at ANKA's visible light diagnostics beamline, which is located at a 5° port front end at a dipole magnet. There are various experiments located at the beamline, such as Time-Correlated Single Photon Counting (TCSPC) and a streak camera. The optical beam path from the source point to the fast gated intensified camera is shown in Fig. 1. A cooled planar mirror is used to filter the visible range from the synchrotron radiation spectrum. After passing through an optical chicane, the visible spectrum is split into three wavelength regions for the different experiments by using dichroic mirrors. This separation is performed directly after the second off-axis paraboloid mirror and is not shown in the drawing. For the fast gated intensified camera blue light in the range from 400 nm to 500 nm is used. More information on the other experiments carried out at this beamline can be found in [5].

The optical chicane contains two off-axis paraboloid mirrors of different focal lengths, creating a real image of the incoherent synchrotron radiation, directly representing the bunch's transverse charge distribution. It is shown in the upper part of Fig. 2.

Being the smallest aperture in this setup, the diaphragm leads to a diffraction limit of about 150 μm in the vertical plane, compared to a vertical beam size of less than 100 μm [6]. Thus, this experiment is exclusively designed for monitoring the horizontal bunch profile. To gain sensitivity in the horizontal plane, the image is stretched by two cylindrical lenses of different focal lengths. The resulting image can be seen in Fig. 2.

The last planar mirror in front of the camera will be a fast rotating, galvanometric mirror. To track the horizontal bunch profiles over many turns, this mirror sweeps the stretched images over the camera sensor, fast enough (> 500 deg/s) to place the images of consecutive turns clearly separate next to each other. A schematic scheme is shown in Fig. 3.

Fast Gated Intensified Camera

The existing transverse beam profile monitors at ANKA have a slow acquisition rate (> 50 Hz) and a relatively long exposure time (typically hundreds of μs to 1 s). Thus they are integrating over many bunches and bunch revolutions due to the minimum bunch spacing of 2 ns and a bunch revolution frequency of 2.7 MHz.

In order to observe the horizontal beam profile of a single bunch for a single turn, a fast gated intensified camera (Andor iStar 340T [7]) was installed. The optical gate with a width of less than 2 ns allows the imaging of single synchrotron radiation pulses even in a multibunch environment, since the bunch spacing at ANKA is 2 ns. A maximum gate repetition rate of 500 kHz enables the imaging of the synchrotron radiation pulse of a certain bunch at every 6th turn for the tracking of the bunch profile on fast timescales.

FIRST RESULTS OF ENERGY MEASUREMENTS WITH A COMPACT COMPTON BACKSCATTERING SETUP AT ANKA*

C. Chang, E. Bründermann, E. Hertle, N. Hiller, E. Huttel, A.-S. Müller, M. J. Nasse, M. Schuh, J. L. Steinmann, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany, H.-W. Hübers, H. Richter, Deutsches Zentrum für Luft- und Raumfahrt (DLR), Berlin, Germany

Abstract

An electron energy measurement setup based on the detection of Compton backscattered photons, generated by laser light scattered off the relativistic electron beam, has been proposed and developed for operation at the ANKA storage ring of the Karlsruhe Institute of Technology (KIT). In contrast to conventional methods based on head-on collisions, the setup at ANKA is, for the first time, realized in a transverse configuration where the laser beam hits the electron beam at an angle of ~90°. This makes it possible to achieve a relatively low-cost and very compact setup since it only requires a small side-port instead of a straight section. This development could benefit storage rings with restricted space or where no straight sections are available, for example due to interferences with existing beamlines. The setup and the first measurement results are presented in the paper.

MOTIVATION

The ANKA storage ring [1] is operated from 0.5 GeV to 2.5 GeV. In the short bunch operation mode, typically at 1.3 and 1.6 GeV, coherent THz synchrotron radiation is generated [2]. Previously, precise energy calibration at 2.5 GeV was successfully achieved by resonant spin depolarization [3]. For lower energies, however, this technique requires very long measurement times. Here Compton Back-Scattering (CBS) is more suitable as it does not require a polarized electron beam. So far, several facilities have reported energy measurements based on CBS using a head-on collision geometry ($\varphi=\pi$) with relative accuracies reaching 10^{-4} to a few 10^{-5} [4-9]. Compared to the traditional CBS method, we have for the first time developed and measured with a transverse configuration ($\varphi=\pi/2$). This setup has several advantages: It is very compact and can therefore also be used at rings with restricted space. Furthermore, the transverse setup reduces the energy of Compton edge photons by a factor of two, which either makes measurements and detector calibration much easier, or enlarges the measurable range of a specific setup considerably. The transverse configuration can in principle also be converted easily into a versatile laser wire diagnostics tool.

*Work supported by the European Union under contract PITN-GA-2011-289191

METHOD PRINCIPLE

If monochromatic (laser) photons (energy E_L) scatter off of relativistic electrons (energy E_e), the scattered photons with energy E_s follow the kinematics illustrated in Eq. 1 and Fig. 1, where φ is the collision angle between the incoming laser and the electrons and θ is the scattering angle between the scattered photons and the initial electrons. The electron velocity divided by the speed of light is denoted by β:

$$E_s = \frac{E_L(1-\beta\cos\varphi)}{1-\beta\cos\theta+E_L/E_e[1-\cos(\theta-\varphi)]}. \quad (1)$$

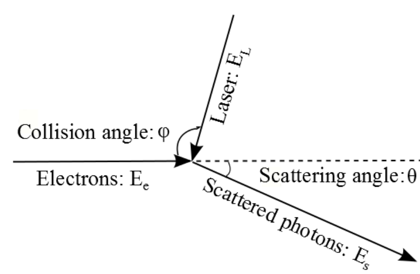

Figure 1: Scheme of CBS.

For θ=0, the energy of the scattered photons reaches its maximum E_{max} and forms a sharp cut-off edge (Compton edge) in the energy spectrum.

For typical CBS measurements at storage rings we have $E_e \gg mc^2 \gg E_L$ (mc^2 is the electron rest energy) and φ>0. The electron beam energy E_e can then be determined from the known values of mc^2 and E_L, and the measured φ and E_{max} using

$$E_e \approx \frac{mc^2}{2\sin\frac{\phi}{2}}\sqrt{\frac{E_{max}}{E_L}}. \quad (2)$$

Its relative uncertainty can be calculated as

$$\frac{\sigma_{E_e}}{E_e} = \sqrt{[\frac{\sigma_{E_L}}{2E_L}]^2+[\frac{\sigma_\phi}{2\tan(\phi/2)}]^2+[\frac{\sigma_{E\max}}{2E_{\max}}]^2}. \quad (3)$$

Here σ_{E_L}/E_L is the relative uncertainty of the average laser photon energy.

LASER WIRE BASED TRANSVERSE EMITTANCE MEASUREMENT OF H$^-$ BEAM AT SPALLATION NEUTRON SOURCE*

Y. Liu#, A. Aleksandrov, C. Long, A. Menshov, A. Zhukov
Spallation Neutron Source, Oak Ridge National Laboratory, Oak Ridge, TN 37831, USA

Abstract

A laser wire based transverse emittance measurement system has been developed at the Spallation Neutron Source (SNS). The system enables a nonintrusive measurement of the transverse emittance in both directions on a 925 MeV/1 MW hydrogen ion (H$^-$) beam at the high energy beam transport (HEBT) beam line.

INTRODUCTION

Conventional particle beam emittance measurement techniques such as the slit-and-collector or pepper-pot methods are generally intrusive and cannot be applied to full spec high-brightness particle beams [1, 2]. At the Spallation Neutron Source (SNS), we have developed a laser based, nonintrusive emittance measurement system at the high energy beam transport (HEBT) beam line [3].

The SNS laser emittance measurement setup consists of a laser wire scanner in the HEBT beam line and a metallic wire scanner in the linac dump beam line. The laser light slices out a narrow neutralized hydrogen beam (H^0) through the photodetachment process. The H^0 beam is transmitted through a downstream dipole and separated from the rest of the beam. The titanium wires measure the distribution of the H^0 beam released from the laser slit. The system has been applied to the emittance measurement of a 925 MeV/1 MW neutron production H$^-$ beam.

SYSTEM DESCRIPTION

A schematic of the laser based emittance measurement system is shown in Fig. 1. The emittance measurement setup is located about 40 meters away from the beginning of the SNS HEBT beam line. The expected beam emittance at this location is about 0.5 mm·mrad. The setup consists of two parts: a laser wire scanner (laser slit) and a conventional metallic wire scanner. The laser wire scanner is installed right before the first of eight 11.25° C-type dipoles which turn the H$^-$ beam to the accumulator ring. These dipoles also separate the neutralized hydrogen beam (H^0) from the main beam trajectory and direct the H^0 beam to the linac dump beam line. A metallic wire scanner is installed in the linac dump beam line, about 11.6 meters downstream of the laser wire station. The wire scanner measures the distribution of the H^0 beam released from the laser slit. Since the laser wire only interacts with a very tiny portion (~10^{-7}) of the ion beam and the wire scanner is interacting with an off-line H^0 beam, the entire measurement is effectively nonintrusive and can be conducted parasitically on a neutron production H$^-$ beam.

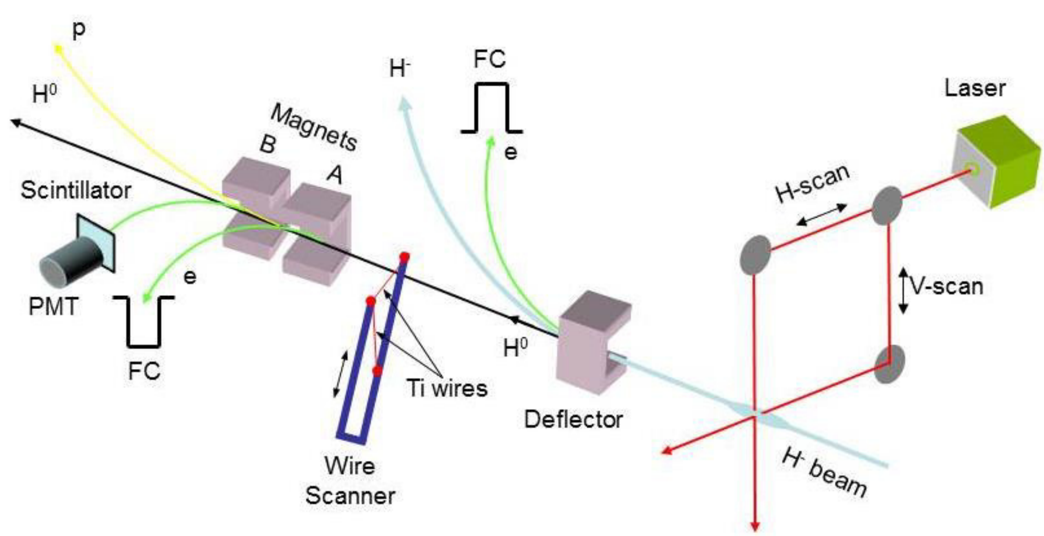

Figure 1: Schematic of laser wire based H$^-$ beam emittance measurement system. FC: Faraday cup, PMT: photomultiplier tube, Magnets A and B deflects electrons for FC and scintillator detection schemes, respectively.

ONLINE STUDIES OF THz-RADIATION IN THE BURSTING REGIME AT ANKA

M. Brosi*, M. Caselle, E. Hertle, N. Hiller, A. Kopmann, A.-S. Müller, P. Schönfeldt, M. Schwarz, J. L. Steinmann, M. Weber, KIT, Karlsruhe, Germany

Abstract

The ANKA storage ring of the Karlsruhe Institute of Technology (KIT) operates in the energy range from 0.5 to 2.5 GeV and generates brilliant coherent synchrotron radiation in the THz range with a dedicated bunch length reducing optic. The producing of radiation in the so-called THz-gap is challenging, but this intense THz radiation is very attractive for certain user experiments. The high degree of compression in this so-called low-alpha optics leads to a complex longitudinal dynamics of the electron bunches. The resulting micro-bunching instability leads to time dependent fluctuations and strong bursts in the radiated THz power. The study of these fluctuations in the emitted THz radiation provides insight into the longitudinal beam dynamics. Fast THz detectors combined with KAPTURE, the dedicated KArlsruhe Pulse Taking and Ultrafast Readout Electronics system developed at KIT, allow the simultaneous measurement of the radiated THz intensity for each bunch individually in a multi-bunch environment. This contribution gives an overview of the first experience gained using this setup as an online diagnostics tool.

INTRODUCTION

ANKA is a synchrotron radiation source located in Karlsruhe, Germany, and is operated by the Karlsruhe Institute of Technology. It consists of a 110.4 m long electron storage ring, which can operate at energies ranging from 0.5 GeV up to 2.5 GeV. Beside the standard user operation a special operation mode is provided to the research community. This so called low-alpha mode allows the reduction of the bunch length down to a few picoseconds by making use of an adaptable magnet optics. Additionally, the pattern in which the RF-buckets are filled can be chosen ranging from a single electron bunch up to custom filing patterns provided by the Bunch-by-Bunch feedback system [1].

The short bunch length of a few picoseconds in the low-alpha operation mode leads to an increase in the emitted power in the lower THz band due to the coherent emission of synchrotron radiation for wavelengths in the order of or longer than the emitting structure. Partially, coherent synchrotron radiation (CSR) is also emitted for (slightly) shorter wavelength than expected by the bunch length. This happens above a certain bunch current when a modulation of the longitudinal phase space is induced by the CSR impedance. This effect in the longitudinal particle distribution is called micro-bunching instability [2]. Due to the temporally changing/evolving nature of these substructures the emitted power in the THz regime fluctuates strongly with characteristic frequencies. The frequency of the fluctuations depends on the bunch current as well as on the parameters of the longitudinal beam dynamics, such as the RF-voltage, the synchrotron frequency and the momentum compaction factor [3]. The fluctuations of the radiated power in the THz regime are often referred to as bursts, while the whole effect is called bursting. For user experiments relying on stable intensity, it is necessary to know for each machine setting above which bunch current the micro-bunching instability occurs and bursting starts.

To detect and monitor bursting, the peak-intensity of the emitted THz pulse of each bunch at each turn is recorded using a fast THz detector combined with a dedicated data acquisition system. The peak-intensity of each bunch, recorded in one measurement, for approximately 2.7 million consecutive turns, is called the bunch's THz signal in the following. For the measurements described below, a zero-biased quasi-optical broadband Schottky diode detector from ACST [4] was combined with the KArlsruhe Pulse Taking and Ultrafast Readout Electronics system (KAPTURE) [5], which was developed for this purpose. This combination opens up the possibility to simultaneously measure the THz signal of each individual bunch in a multi-bunch fill, over an almost unlimited number of turns (see Fig. 1).

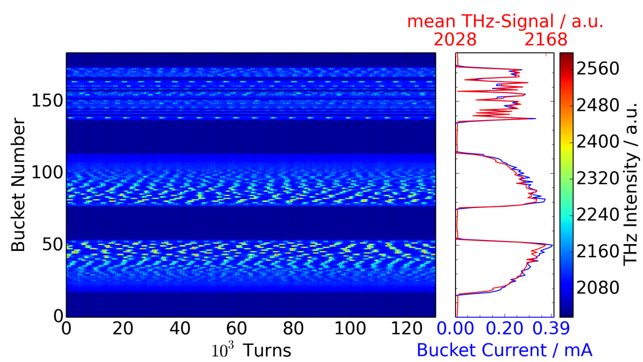

Figure 1: The peak-intensity of the THz pulses of all 184 RF-buckets is displayed over 130 thousand consecutive turns and shows strong fluctuations caused by bursting. A typical measurement takes one second and contains 2.7 million turns. The graph to the right shows the filling pattern.

This setup allows us to study the potential influence of a multi-bunch environment on the bursting behavior of each bunch. Furthermore, if these multi-bunch influences are known, then the information from all bunches with different currents in a multi-bunch fill can be used to speed up measurements like a characterization of different machine set-

PROPERTIES OF TRANSITION- AND SYNCHROTRON RADIATION AT FLUTE

M. Schwarz*, A.-S. Müller, KIT, Karlsruhe, Germany
M. Schmelling, MPIK, Heidelberg, Germany

Abstract

FLUTE (Ferninfrarot Linac Und Test Experiment) is a 41 MeV linear accelerator currently under construction at KIT. It is aimed at accelerator physics and THz radiation research. For this reason the machine will cover a wide range of bunch charges (1 pC up to 3 nC) and lengths (1 fs to 300 fs). One aim of FLUTE is the study of different mechanisms for the generation of intense THz pulses, such as transition- (TR) or synchrotron radiation (SR). In this contribution, we calculate and compare various pulse properties, such as spectra, and electric fields, for both TR and SR.

MOTIVATION

Coherent radiation is emitted by electron bunches whenever the wavelength in question is larger than the bunch length. The test facility FLUTE [1] aims to produce bunches with charges 1 pC and bunch lengths 1 fs. In this paper, we compare our own semi-analytic methods for calculating the electric field of a coherent THz pulse [2] with analytic results and standard numerical methods. Next, we apply it to compute the electric field pulse of a simulated bunch profile for synchrotron- (SR) and transition radiation (TR).

RADIATION FROM ULTRA-SHORT BUNCHES

A bunch consists of N particles at positions t_i. Assuming that each particle emits a pulse with electric field $E_0(t)$ the field of the entire bunch is given by the superposition of the individual pulses

$$E(t) = \sum_{i=0}^{N-1} E_0(t - t_i)\,.$$

Here, we are only interested in the coherent field, and thus, ignoring the transverse bunch size, approximate the bunch by a continuous normalized longitudinal density $\rho(t)$. The field of the pulse is then a convolution of the single particle pulse $E_0(t)$ and the bunch profile $\rho(t)$

$$E(t) = \int_{-\infty}^{\infty} E_0(t-\tau)\rho(\tau)\,\mathrm{d}\tau\,.$$

It is more convenient to solve the convolution in the frequency domain

$$\varepsilon(t) \equiv \int_0^{\infty} \tilde{E}_0(\omega)\,\tilde{\rho}(\omega)\,\mathrm{e}^{-\mathrm{i}\omega t}\mathrm{d}\omega\,, \tag{1a}$$

$$E(t) = N\,\mathrm{Re}\left[\mathrm{e}^{-\mathrm{i}\phi}\varepsilon(t)\right]\,. \tag{1b}$$

* markus.schwarz@kit.edu

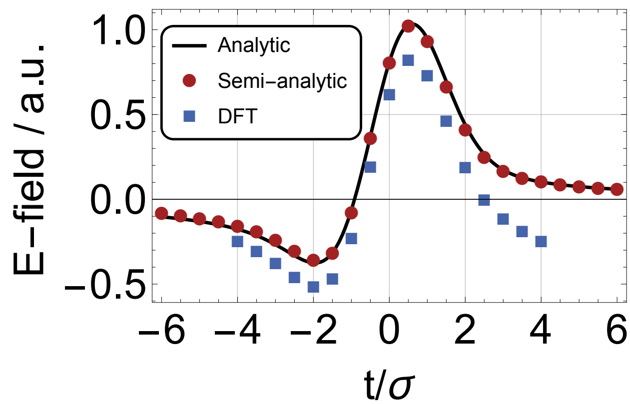

Figure 1: Electric field of a synchrotron radiation pulse emitted by a Gaussian bunch, calculated according to Eq. (1). Eq. (1) was solved analytically (continuous curve) [3], employing the discrete Fourier transform (DFT, boxes), and our own semi-analytic code (circles) [2]. Compared to the analytic result, the DFT method yields both a wrong peak field and pulse shape.

Here and in the following, a ~ above a symbol denotes its representation in the frequency domain. The phase ϕ is a property of the emission process, and determines whether the pulse is single or "half" cycle. Setting $\phi = 0, 180°$ yields a "half" cycle pulse whereas $\phi = \pm 45$ or $\pm 135°$ leads to a single cycle pulse.

The main problem is to solve Eq. (1a) for different spectra $\tilde{E}_0$ and general bunch profiles ρ. A standard way of computing the convolution would be to sample the bunch profile at reasonably many points, and use the discrete Fourier transform (DFT) to both obtain $\tilde{\rho}$ and subsequently compute Eq. (1a). That this procedure only asymptotically, i.e. for many sampling points and a large time interval, yields the correct result is demonstrated in Fig. 1 for a Gaussian bunch emitting low-frequency synchrotron radiation, $\tilde{E}_0(\omega) \sim \omega^{1/6}$. To apply the DFT, the profile was sampled by 17 equidistant data points in the interval $[-4\sigma, 4\sigma]$, containing more than 99.9% of the bunch. The boxes in Fig. 1 depict the result obtained by using the DFT. Notice that it is limited to times given by the sampling interval. The continuous curve shows the analytic result [3]. Here, the DFT gives a peak field that is about 22% too low, and the wrong shape at large (positive) times[1].

One reason for the discrepancy is that the integral $\int_{-\infty}^{\infty} E(t)\,\mathrm{d}t$ needs to vanish [4]. Thus, a positive peak needs to be balanced by a negative tail. The analytic calculation is

[1] An agreement better than 1% requires a sampling interval $\pm 50\sigma$ and ten times as many data points.

TESTING A DIGITAL BEAM POSITION STABILIZATION FOR THE P2-EXPERIMENT AT MESA*

M. Dehn, K. Aulenbacher, J. Diefenbach, F. Fichtner, R. Herbertz, W. Klag
Institut für Kernphysik, Universität Mainz, Germany

Abstract

The Mainz Energy-recovering Superconducting Accelerator (MESA) will be built at the institute for nuclear physics at Mainz University. Besides the multi-turn energy recovery mode an external beam mode is foreseen to provide 155 MeV electrons of 85% polarization at 150 μA for parity violating experiments. To achieve the required stability of the main beam parameters a dedicated digital position stabilization is currently developed and tested at the Mainz Microtron (MAMI).

INTRODUCTION

MESA as illustrated in Fig. 1 will provide the opportunity to study precision physics at lower energies but higher beam currents than the accelerator cascade of the Mainz Microtron (MAMI) [1, 2]. The main parameters of the new accelerator are listed in Table 1.

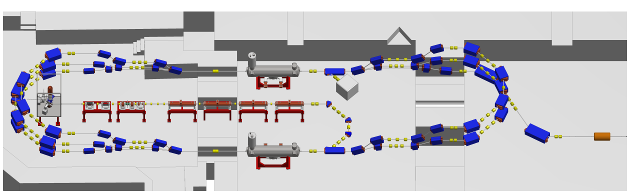

Figure 1: Illustration of MESA.

Table 1: MESA Operation Modes

Parameter stage 1 (2)	EB	ER
Energy [MeV]	155	105
Beam current	150 μA	1 mA (10 mA)
Bunch charge [pC]	0.12	0.77 (7,7)
max. Beam power [kW]	22.5	105 (1050)

Since the very beginning of MAMI (see Fig. 2) RF cavity monitors are used to acquire beam positions and relative phase as well as the intensity of the electron beam [3].

While running the machine for experiments the monitor system delivers CW signals. To optimize the position and phase of the electron beam through the microtrons pulsed beam of high intensity is used to increase sensitivity while reducing the amount of beam losses [4].

* Work supported by the German Federal Ministry of Education and Research (BMBF) and German Research Foundation (DFG) under the Collaborative Research Center 1044 and the Cluster of Excellence "PRISMA"

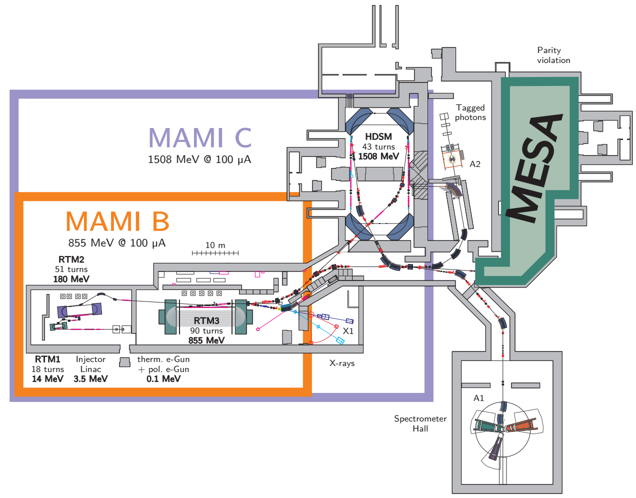

Figure 2: Floor plan of the MAMI accelerator. The space for MESA currently available is marked in green. The test setup at MAMI is installed next to the RTM3 where the beam has an energy of 180 MeV – similar to the external mode with 155 MeV of MESA.

HIGH PRECISION PHYSICS

For high precision parity violating experiments the electron beam has a certain polarization $\vec{P}$. The parity violating asymmetry $A_{LR} = \frac{n_L - n_R}{n_L + n_R}$ with the two counting rates n_L and n_R is determined by switching the helicity of the electron beam (usually $\vec{P}_L \rightarrow \vec{P}_R$). Modern experiments like the MOLLER experiment at Jefferson Lab or the P2-Experiment at MESA test asymmetries in the order of 10^{-8} with a precision of a few percent [5, 6]. If for any reason there are smallest inaccuracies while the helicity is switched there is an unwanted helicity dependend modification of the counting rates. This leads to a systematic error called "false asymmetry". To actively minimize this effect different stabilization systems are required, in our case the most important parameters to stabilize are beam intensity, position, angle and relative energy.

Parity Violating Experiments at MAMI

The A4 experiment at MAMI was performed using four RF beam position monitors (horizontal and vertical) together with four fast steerer magnets (both planes also) to achieve a sufficient suppression of helicity correlated position fluctuations of the beam. Another RF monitor is used to measure and stabilize the beam intensity very close to the electron source, another one right upstream of the target monitors the beam intensity for the experimental run control. For a single experiment at 315 MeV at 20 μA and approximately

DEVELOPMENTS AND PERFORMANCE OF THE LLRF SYSTEM OF THE S-BAND FERMI LINAC

A. Fabris[#], F. Gelmetti, M. Milloch, M. Predonzani, Elettra, Trieste, Italy

Abstract

The requirements on beam quality of the FERMI Free Electron Laser (FEL) linac impose challenging specifications on the stability of the RF fields that can only be met using reliable and high performance state of the art LLRF systems. The system installed in FERMI has met these requirements and is routinely operational for the machine on a 24/7 basis. The completion of the deployment of the LLRF units in 2015 increases the capabilities of the system, adding further measurements channels and monitoring, and allowing new functionalities. This paper provides an overview of the results achieved with the LLRF system of FERMI and an outlook of the further developments that are being implemented or planned.

INTRODUCTION

FERMI, the Italian seeded FEL located in Trieste, consists of two FEL lines, FEL-1 and FEL-2, covering the wavelength range between 20 and 100 nm and between 4 and 20 nm. Both the two FEL lines are now open to external users [1]. The accelerator is based on a 1.5 GeV S-band linac [2]. FEL generation requires very high beam stability and for the S-band RF system this translates in a specification of a stability in RF phase and amplitude within 0.1° rms and 0.1% rms respectively [3]. In addition to a careful design of all the parts of the system, from modulators supplies to cables and waveguides temperature stabilization, meeting these targets requires a high performing LLRF system. The LLRF system measures the RF signals and, according to the requirements and taking into account the beam feedbacks, controls the RF drive to the klystron. The system implemented in FERMI is an all-digital system specifically designed in collaboration with Lawrence Berkeley National Laboratory [4].

SYSTEM DESCRIPTION

Fourteen 3 GHz 45 MW peak RF plants are installed to power sixteen accelerating sections, the RF gun and the three RF deflectors. Two more accelerating sections will be added at beginning of 2016. An additional power plant is installed to provide a hot-spare backup solution for the first two. The basic hardware unit is the LLRF chassis. The layout foresees one of them for each RF powered component of the machine, whether it is an accelerating section or gun or deflector. In case of plants which power more than one section, one chassis will act as the master, controlling the RF drive to the klystron, besides monitoring the corresponding section parameters, while the second one will act as a slave chassis primarily providing information to the master, for example the RF measurements of the second section.

Hardware

The LLRF chassis basically includes the RF front end (RFFE), the processing board (AD board), the OCXO and all power supplies (see Fig. 1) [5]. The RFFE performs the conversion between RF (3 GHz) an IF (99 MHz) signals and hosts all the frequency dependent components. The AD board, which implements a Virtex5 FPGA, performs all controls, diagnostics and system communication. The chassis has five RF inputs and two RF outputs. The inputs signals are the reference, the klystron output, the cavity input forward, the cavity input reflected and the cavity load signals. The outputs channels are used for the driving signal to the klystron and to generate a calibration signal. Each LLRF unit is designed to be beam feedback ready.

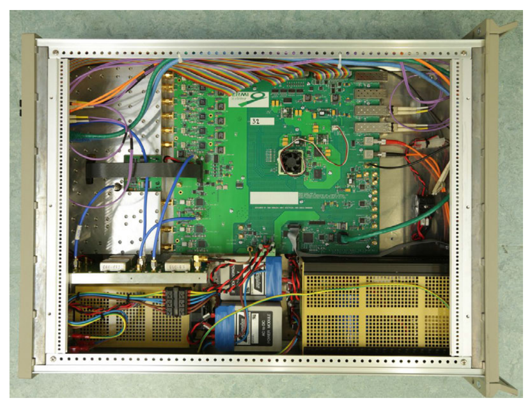

Figure 1: LLRF chassis.

A block diagram of a complete LLRF for a one klystron/two sections plant is shown in Fig. 2. The scheme shows as well the interconnections of the LLRF units with the other systems of the machine. All the components of the LLRF for each plant are installed in a temperature controlled EMC shielded IP65 rack. The temperature is kept stable better than ± 0.2 °K by means of an air/water heat exchanger. Also all the cables between racks and accelerating structures are installed in an insulated environment.

Firmware

The firmware presently in operation [6] implements all the basic loops needed: amplitude, phase, cable calibration, local oscillator phase drift and phase reference locking loops. All these are feed-forward loops. In addition, the control of the SLED phase reversal and phase modulation is also implemented through the LLRF firmware.

!CHAOS STATUS AND EVOLUTION

C. Bisegni, S. Caschera, G. Di Pirro, L. G. Foggetta, R. Gargana, E. Gioscio, D. Maselli, G. Mazzitelli, A. Michelotti, R. Orrù, S. Pioli, F. Spagnoli, A. Stecchi, M. Tota, INFN-LNF, Frascati (RM), Italy, and C. Di Giulio, INFN-ROMA2, Rome, Italy

Abstract

A synthesis of the "!CHAOS: a cloud of controls" project and its application to accelerators and large experiments will be presented. We will describe here how the !CHAOS project has evolved from a candidate for the SuperB accelerator control system to a facility for IT distributed infrastructures. !CHAOS is currently, not only suitable for accelerators and large High Energy Physics (HEP) experiments, but is also applicable to other contexts, such as social and industrial applications. Preliminary results achieved on an accelerator use case are discussed.

INTRODUCTION

!CHAOS project started as candidate of Distributed Control Systems (DCS) and Slow Control of the SuperB accelerator and detector [1], with the ambition to be a prototype of innovative DCS standards. Today, the project is supported by the MIUR (Italian Ministry of University and Research) and INFN to develop a national infrastructure prototype of high performing services devoted to devices and polyfunctional sensors distributed on LAN and WAN [2,3].

!CHAOS exploits the new high performance web technologies by strongly increasing control system performances and services, preserving scalability, redundancy and reliability, as well as the abstraction of processes at any level obtained by:

- key/value database (KVDB) implemented as distributed memory object caching systems (DOC).
- using non-relational databases, in a specific document database.
- optimizing and embedding high performance e/o standard inter process communication and handling (RPC/direct I-O/Events).
- abstracting data structure through binary data serialization (BSON)
- embedding COTS and, in general, open hardware, in order to minimize costs and integration time
- making "Controls as a services" to be responsive to new trends of IT technologies and the request of industries and society.

Moreover, the !CHAOS DCS architecture embeds by design the Data Acquisition (DAQ) topology and object data concepts which make the project able to handle Big Analog Data and their Variety, Volume, Velocity, Value and Visibility. The scope of the project is therefore to study and realize a prototype of a dynamic, on-demand Cloud-based infrastructure able to handle the "five V" for data collected from analog devices.

Finally, the project foresees applications on different use cases: accelerator DCS, building automation and environmental controls, integration in embedded devices like CRIO National Instruments, BPM Libera, Beagle Bone, etc… In March 2015 a second test [4] of !CHAOS accelerator DCS has been performed at the Frascati Beam Test Facility (BTF) [5], successfully replacing the original DCS for the monitoring and control of the beam transport magnets by integrating at the same time BTF DAQ functionalities.

ACCELERATOR USE CASE @ BTF

The BTF is a beam transfer line, part of the DAFNE complex, optimized for the production of single electron/positron in the rage 25-700 MeV mainly used for HEP detectors testing and calibration [6]. The high intensity LINAC beam, intercepted by a pulsed magnet, is attenuated by Cu target and a set of scrapers. Six quadrupoles, two 45^0 bending magnets and horizontal/vertical slits permits to select beam quality, the proper momentum and multiplicity down to single particle (Fig. 1).

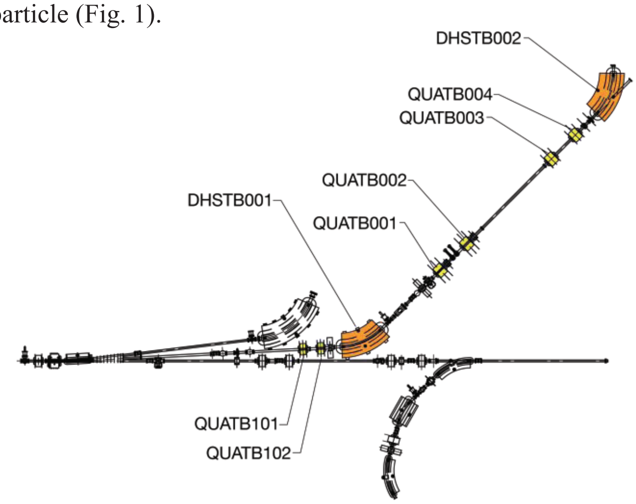

Figure 1: Beam Test Facility layout.

The test consisted in monitoring and controlling the transfer-line magnets and the facility DAQ devoted to acquire the x-y scintillating fiber system profile detector [7] and the glass lead calorimeters monitoring and acquiring single particle position and energy.

The scope of the test was to exploit the !CHAOS framework in a real operating condition, test the IT infrastructure and the Graphical User Interface (GUI), verify the stability and capability of the information service – Meta Data Service (MDS) and storing – the !CHAOS Data Service (CDS).

RF SYSTEM DESIGN FOR THE TOP-IMPLART ACCELERATOR

V. Surrenti, G. Bazzano, P. Nenzi, L. Picardi,C. Ronsivalle, ENEA,Frascati, Italy
F. Ambrosini, La Sapienza University, Roma, Italy

Abstract

In the ENEA-Frascati research center a linear accelerator for proton therapy is under development in the framework of TOP-IMPLART Project carried out by ENEA in collaboration with ISS and IRE-IFO. The machine is based on a 7 MeV injector operating at a frequency of 425 MHz followed by a sequence of 2997.92 MHz accelerating modules. Five 10 MW klystrons will be used to power all high frequency structures up to a beam energy of 150 MeV. The maximum repetition frequency is 100 Hz and the pulse duration is 4 µs. The RF amplitude and phase stability requirements of the accelerating field are within ±2% and ±2 degrees respectively. For therapeutic use the beam energy will be varied between 85 and 150 MeV by switching off the last modules and varying the electric field amplitude in the last module switched on. Fast control of the RF power supplied to the individual structures allows an energy variation on a pulse by pulse basis; furthermore the system must be able to control the RF phase between accelerating structures. This work describes the RF power distribution scheme and the RF phase and amplitude monitoring system implemented into an embedded control system.

THE TOP-IMPLART ACCELERATOR

A RF proton linear accelerator is under realization in the framework of the TOP-IMPLART (Intensity Modulated Proton Linear Accelerator for RadioTherapy) Project leaded by ENEA in collaboration with the Italian Institute of Health (ISS) and Regina Elena National Cancer Institute IFO-Rome [1].The project is devoted to the realization of a protontherapy centre to be sited at IFO based on a 230 MeV accelerator. The first segment up to 150 MeV has been funded by Regione Lazio and is under realization and test at ENEA-Frascati [2]. It is composed (fig.1) by a low frequency (425 MHz) injector (ACCSYS-HITACHI PL7 model, RFQ+DTL) and a high frequency (2997.92 MHz) booster (SCDTL up to 35 MeV and CCL up to the final energy).

A LINAC-based proton therapy facility can provide, like synchrotron-based facility, both energy and intensity active modulation. However synchrotron accelerators typically vary the beam energy in no less than 1-2 seconds (the time it takes to complete a whole acceleration cycle), while LINAC can in principle vary the energy on a pulse by pulse basis, i.e. within a few milliseconds, without the need to dump the accelerated beam.

To guarantee patient safety through the correct actuation of the desired machine settings, some subsystems are identified as "critical", namely those systems actively responsible for the energy, intensity and spot size of the beam. To this end, the critical subsystems will provide the dose delivery system with an acknowledgment of their status on successful completion of the new settings, thus allowing beam acceleration in the next pulse.

THE RF SYSTEM

The block scheme of the TOP IMPLART RF system up to 150 MeV is shown in figure 1. The high power part foresees the use of a number of identical RF plants each based on a 10 MW klystron (TH2157) and its power supply (modulator). The power is split in 4 or 2 parts depending on the needs of the fed structures. Tight controls are used to stabilize the phase among the several klystron outputs. The energy is varied by changing the power of the klystrons supplying the accelerator structure. The TOP-IMPLART aims at changing the beam energy as quickly as possible, although, as in other protontherapy plants the limiting factor is the velocity of changing the beam transport line magnetic elements, that limits the repetition frequency to 100 Hz.

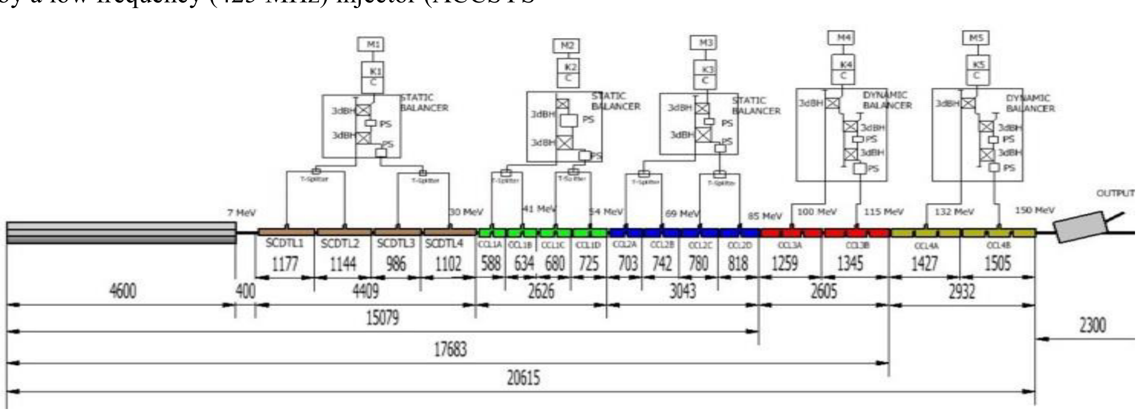

Figure 1: Block scheme of TOP-IMPLART RF system.

BEAM OPTIMIZATION OF THE DAΦNE BEAM TEST FACILITY*

L. Foggetta and B. Buonomo INFN/LNF, Frascati, Rome, Italy
P. Valente INFN, Roma, Rome, Italy

Abstract

The DAΦNE Beam Test Facility delivers electron and positron beam with a wide spread of parameters in charge, energy, transverse dimensions and time width. Thanks to the recent improvements of the diagnostics, all the beam parameters have been measured and optimized. In particular we report here some results on beam transverse size, divergence, and position stability for different energy and intensity configurations. After the upgrade of the electronic gun of the DAΦNE LINAC, the pulse time width and charge distribution have been also characterized.

DAΦNE BEAM TEST FACILITY (BTF)

The BTF (Beam Test Facility) is part of the DAΦNE accelerator complex: it is composed of a transfer line driven by a pulsed magnet allowing the diversion of electrons or positrons, usually injected into to the DAΦNE damping ring, from the high intensity LINAC [1] towards a 100 m^2 experimental hall. The facility can provide runtime tuneable electrons and positrons beams in a defined range of different parameters: energy (up to 750 MeV for e^- and 540 MeV for e^+), charge (up to 10^{10} e^-/bunch) and pulse length (1.4–40 ns). The bunch delivery rate is depending on the DAΦNE injection frequency (25 or 50 Hz) with a duty cycle also according to the DAΦNE injection requirements.

Two major modes of operations are possible, depending on the user needs. The high intensity mode is operated when the LINAC beam is directly steered in the BTF hall with a fixed energy (i.e. the LINAC one) and with a reduced capability in multiplicity selection (typically from 10^{10} down to 10^4 particles/bunch). In the low intensity mode of operation, a step copper target, allowing the selection of three different radiation lengths (1.7, 2 or 2.3 X_0), is inserted in the initial portion of the BTF line for intercepting the beam. This produces a secondary beam with a continuous full-span energy (from LINAC energy down to 50 MeV) and multiplicity (down to single particle/bunch) selection range. In the single particle mode, the multiplicity per bunch delivered to the users follows a Poisson distribution (Figure 1). A pulsed dipole magnet at the end of the LINAC allows alternating the beam between the DAΦNE damping ring and the test beam area, thus keeping a pretty high BTF duty cycle, assuring at least about 20 bunches per second during the positron injection in DAΦNE accumulator when BTF operates in low intensity regime, 28 on average for a complete e^+/e^- injection cycle.

GENERAL DAQ AND STANDALONE DIAGNOSTICS OVERVIEW

BTF DAQ

BTF DAQ is composed mainly of one data producer and two data consumers: one for online diagnostics and one for data storing. The DAQ hardware configuration is NIM/VME based and controlled by VMIC VMIVME 7750 (Intel PIII, 1,3Ghz, 0.5Gb RAM). The acquisition software, hosted in DAΦNE data control system environment (DAΦNE DCS), is written in LabVIEW® LV7.0 and a shared memory is provided for the system, based on MemCached protocol[2], in order to handle the new standalone USB/ETH/Serial based diagnostics elements. The BTF-DAQ is a dynamic composition of different modules, that can be switched on and off at run-time according to the user beam monitoring needs. A standard BTF configuration includes:

- Delay Programmable Unit
- Scaler, Peak sensing ADC, QDC, TDC
- BTF custom detectors electronics
- Digital I/O

The mostly used detectors, stably readout by the BTF DAQ front-end, are the fiber transverse beam profile hodoscope and a lead glass calorimeter[3]. The consumer software is also hosted in the DAΦNE DCS and it is normally used for online monitoring of the BTF beam and data storage.

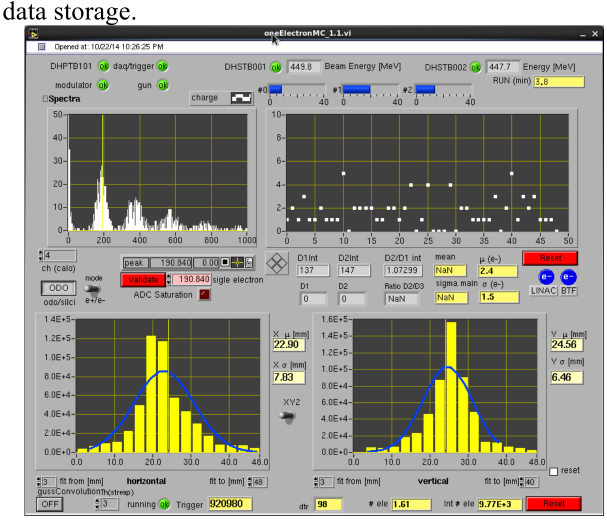

Figure 1: BTF DAQ data (Calorimeter on top and Hodoscope on the bottom) displayed in the BTF DCS diagnostics display software.

MEMCACHED

MemCached (MC) is an Ethernet based in-memory key-value store for arbitrary data (strings, objects). In the

EVOLUTION OF DIAGNOSTICS AND SERVICES OF THE DAΦNE BEAM TEST FACILITY

L. Foggetta and B. Buonomo INFN/LNF, Frascati, Rome, Italy
P. Valente INFN Roma, Rome, Italy

Abstract

The DAΦNE Beam Test Facility (BTF) is operational in Frascati since 2003. In the last years the beam diagnostics tools have been completely renewed and the services for users have been largely improved. We describe here the new transverse beam diagnostics based on new GEM TPC detectors and MEDIPIX, the new BTF network layout, the renewed DAQ system including the BCM detectors, the data caching system based on MEMCACHED and the integration of the new sub-systems in the new data-logging. All other services, such as the environmental monitoring system, vacuum system, payload remote handling, and gas distribution have been also improved.

THE DAΦNE BEAM TEST FACILITY (BTF)

The BTF (Beam Test Facility) is part of the DAΦNE accelerator complex: it is composed of a transfer line driven by a pulsed magnet allowing the diversion of electrons or positrons, usually injected into to the DAΦNE damping ring, from the high intensity LINAC [1] towards a 100 m^2 experimental hall. The facility can provide runtime tuneable electrons and positrons beams in a defined range of different parameters: energy (up to 750 MeV for e^- and 540 MeV for e^+), charge (up to 10^{10} e^-/bunch) and pulse length (1.4–40 ns) [2]. The bunch delivery rate is depending on the DAΦNE injection frequency (25 or 50 Hz) with a duty cycle also according to the DAΦNE injection requirements. Two major modes of operations are possible, depending on the user needs. The high intensity mode is operated when the LINAC beam is directly steered in the BTF hall with a fixed energy (i.e. the LINAC one) and with a reduced capability in multiplicity selection (typically from 10^{10} down to 10^4 particles/bunch). In the low intensity mode of operation, a step copper target, allowing the selection of three different radiation lengths (1.7, 2 or 2.3 X_0), is inserted in the initial portion of the BTF line for intercepting the beam. This produces a secondary beam with a continuous full-span energy (from LINAC energy down to 50 MeV) and multiplicity (down to single particle/bunch) selection range. A pulsed dipole magnet at the end of the LINAC allows alternating the beam between the DAΦNE damping ring and the test beam area, thus keeping a pretty high BTF duty cycle, assuring at least about 20 bunches per second during the injection in DAΦNE accumulator when BTF operates in low intensity regime. A large fraction of the tests required electron or positron beam, with a 10% of allocation for the tagged-photon beam and a few shifts dedicated to neutron production.

BTF TOWARD USERS' NEEDS

Some Classes of Users

Such a kind of versatility is very interesting for a wide community of experimental HEP groups: at least one half of the users have used the facility for detector-testing purposes, covering almost all the possible detection techniques:

- Calorimeters: homogenous (NaI, CsI, PbWO, LYSO, YAP: Belle-II, CMS, KLOE-2, Linear collider, Mu2e, BGO-OD); sampling (KLOE, AMS, LUMI, Linear collider, NA62, MICE, etc.);
- Gas detectors: GEM/Micromegas (LHCb, ATLAS, UA9, Siddharta, KLOE-2), drift chamber/tubes (Super-B, MEG, TPS), RPC (Linear collider);
- Silicon detectors: micro-strip (AGILE, Insulab), pixel (ALICE, MIMOSA, Linear collider);
- Scintillating/Fluorescence detectors: MEG, neutron detection, fiber-trackers (MEG, BES-III, Plasmon-X), AIRFLY (Auger);
- Cerenkov detectors: RICH (LHCb, JLAB12), threshold (UA9)
- Nuclear emulsion: OPERA.

In addition, experiments looking at specific beam-induced effects were carried on:

- Beam diagnostics: fluorescence flag, WCM diagnostics calibration, emittance measurement
- Thermo-acoustic effect: RAP (gravitational wave detection)
- Beam-induced radiation: C-SPEED, AMY
- Crystal channelling and parametric radiation emission.

In the last 10 years of operation, the DAΦNE Beam-Test Facility has delivered an average of 220 beam-days/year. The facility usually allocates slots of 1 week, Monday to Monday, and operates 24/7. More complex experimental setups of course required much longer beam-periods (i.e. up to five months of total allocation for the AGILE satellite pay-load in 2005; the beam was not delivered 100% of this period, however). Occasionally, two teams were present together, profiting of the possibility of parasitizing each other.

ONLINE SPILL INTENSITY MONITORING FOR IMPROVING EXTRACTION QUALITY AT CNAO

M. Caldara, Department of Engineering and Applied Sciences, University of Bergamo, Italy
E. Rojatti, Department of Physics, University of Pavia, Italy
J. Bosser, G. M. A. Calvi, L. Lanzavecchia, A. Parravicini, C.Viviani, CNAO Foundation, Pavia, Italy

Abstract

The CNAO Foundation is the first Italian center for deep hadrontherapy with Protons and Carbon Ions, performing treatments since September 2011. The extracted beam energy and intensity can vary over a wide range (60-250 MeV for Protons and 120-400 MeV/u for Carbon Ions, 4e6÷1e10 pps); the beam intensity uniformity during the slow extraction process is a fundamental requirement for achieving accurate and fast treatments. CNAO developed an online Fast Intensity Monitor (FIM), not perturbing the extracted beam, capable of measuring beam intensity with a bandwidth of 50kHz and a resolution of 1%. It consists of a thin (0.8 μm) metallic foil that emits secondary electrons when traversed by the beam. The electrons are multiplied by a Channeltron device, polarized at high voltage versus ground. The Channeltron output current is amplified and converted in a Pulse Width Modulated (PWM) signal, which is then decoupled and transmitted to the equipment room, where an FPGA implements a servo-spill. The work presents the detector, the floating electronics, the preliminary measurements with beam and the integration in a closed loop on the synchrotron air-core quadrupole obtaining promising results.

INTRODUCTION

CNAO is one of the four accelerators worldwide capable to perform hadrontherapy with both Protons and Carbon Ions; nowadays more than 400 patients completed the treatments, two third of them with carbon ions [1]. The active dose delivery treatment by rasterscan technique, presently used at CNAO, is the most advanced method in hadrontherapy machines for achieving accurate treatments of target volumes. The beam is directed to each tumor voxel by controlling fast magnets deflectors and the beam energy for transversal position and longitudinal penetration respectively. A uniform beam extracted intensity is favourable because it gives a higher intensity without risk of beam aborts, leading to faster treatments and thus more patients. In order to minimize the spill intensity ripple during the slow extraction, a feedback loop acting on the synchrotron fast quadrupoles [2] or on the RF Knock-Out exciter are the most diffused techniques [3-4]. A fast, accurate, high resolution and not-interceptive beam intensity measurement is essential in each servo-spill system.

MATERIALS AND METHOD

FIM Detector

In order not to perturb the beam, an ultra-thin metallic foil is the only material that can be traversed by the accelerated particles [5]; a secondary emission electrons principle is the signal origin, followed by electrons collection into a Channeltron (CEM) device [6], a single channel electron multiplier. The mechanical arrangement of the foil with respect to the beam path (Fig.1) is a compromise between secondaries yield maximization and beam perturbation minimization (α=45deg). By raising the angle between the foil and the beam trajectory, the foil thickness crossed by the beam and thus beam perturbation increases. Secondary emitted electrons angular distribution follows Lambert Law, namely it is proportional to cos(θ) (Fig.1). In consequence, if the CEM is installed on the foil perpendicular axis the number of collected electrons will be maximized. To be conservative, a foil input/output pneumatic actuator has been foreseen on the FIM instrument. The FIM monitor will be installed in the CNAO common extraction line; to get the results presented in this paper, the FIM has been installed at beam isocenter, in the treatment room.

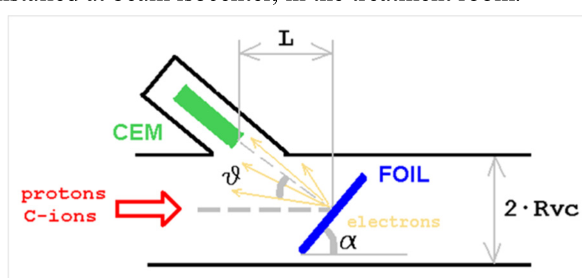

Figure 1: FIM detector mechanical layout; R_{vc} (33 mm) is vacuum chamber radius, L is 42mm.

Electronics and Processing

The CEM output electrons are attracted to an output collector, polarized to a higher voltage than the CEM output; being the beam-generated signal quasi-dc, the readout electronics cannot be AC coupled to the output collector, thus it needs to work at floating high potential with respect to ground. The system block diagram is depicted in Fig. 2. The electronics input signal is a current, thus the conversion into a voltage is implemented

SCINTILLATING FIBERS USED AS PROFILE MONITORS FOR THE CNAO HEBT LINES

E. Rojatti*, Department of Physics, University of Pavia, Pavia, Italy
J. Bosser, CERN, Geneva, Switzerland and CNAO, Pavia, Italy
G. Calvi, L. Lanzavecchia, A. Parravicini, M. Pullia, C. Viviani, CNAO, Pavia, Italy

M. Caldara, Department of Engineering and Applied Sciences, University of Bergamo, Bergamo, Italy

Abstract

The CNAO (Centro Nazionale di Adroterapia Oncologica, Pavia, Italy) is the first Italian center using Proton and Carbon ion beams for radioresistant tumors therapy. Scintillating fibers detectors are used in the HEBT (High Energy Beam Transfer) lines of the CNAO accelerator in order to monitor the therapeutic beam parameters. Twenty SFHs (Scintillating Fibers Harp) and one QPM (Qualification Profile Monitor) have been already installed for the beam transverse profiles measurement. One SFP (Scintillating Fibers plus Photodiodes) prototype, that is a SFH upgrade project, has been assembled and tested on beam. One WD (Watch Dog) detector, not already installed, has been assembled and tested to check the beam position at the HEBT end through the intensity of the beam tails. The present work describes the beam detectors, their achieved performances and the most recent beam measurements.

HEBT LINES LAYOUT

The HEBT [1] (High Energy Beam Transfer) is the extraction line of the CNAO [2] accelerator. It consists of three horizontal and one vertical transfer lines, coming from one first common sector (called H sector) and reaching three different treatment rooms.

The energy range of particles running in the HEBT line is 60 to 250 MeV/u for Protons, and 120 to 400 MeV/u for Carbon ions. The beam is slowly extracted from the synchrotron so that the spill length is settable from 1 to 10 seconds. The nominal intensities per spill are 1×10^{10} for Protons and 4×10^{8} for Carbon ions.

SFH AND QPM: DETECTORS OVERVIEW

The SFH (Scintillating Fibers Harp) and the QPM [3] (Qualification Profile Monitor) are detectors based on grids of adjacent scintillating fibers, installed in the HEBT lines for the beam profiles measurement (position and width). They have been both designed and built by the *LLR (Louis Leprince Ringuet) laboratory*, belonging to the French *CNRS*, according to the specification provided by CNAO. The CNAO Beam Diagnostic group provided the detector actuators, the installation on the beam line, and their implementation in the control system.

* elisa.rojatti01@universitadipavia.it

The SFHs are usually placed out of the nominal beam trajectory not to perturb the therapeutic beam. They are moved onto the beam path through a pneumatic actuator only during the daily beam quality controls. The QPM can be used during patient treatments, since it is installed in front of the "dump", namely a tungsten block placed in the H sector along the extracted beam trajectory. The dump is needed to stop the beam at each machine cycle, during few milliseconds after the extraction, until an orbit bump is created by four fast magnets in order to send the beam towards the selected treatment room.

Detectors Description

The SFH and the QPM active area (Fig. 1) is made up of two orthogonal planes of Polystyrene scintillating fibers, 0.5 mm thick and 0.5 mm wide (*Kuraray SCF-78 type*), each other adjacent and aluminized all around their surface and at one end to avoid any light cross-talk.

Figure 1: SFH (left) and QPM (right) active area.

Both SFH planes are made up of 128 fibers ($64 \times 64\, mm^2$). The QPM horizontal and vertical planes are respectively made up of 34 and 90 fibers ($17 \times 45\, mm^2$). Fibers are installed under vacuum at a pressure of $10^{-6} - 10^{-8}\, mbar$: the detector outgassing is mainly due to the glue that fixes the fibers.

When crossing fibers, the beam particles release energy and produce an amount of photons proportional to particles number and energy. The generated light is guided and focused, through a viewport, onto a CCD chip (1344 × 1024 pixels) of a digital camera (*Hamamatsu-C8484-03G, Peltier cooled,12 bits*) which acquires and processes the signals. The maximum camera acquisition rate is 50 Hz.

OPTIMIZATION OF ILC CRYOMODULE DESIGN USING EXPLOSION WELDING TECHNOLOGY

A.Basti, F.Bedeschi, P.Fabbricatore, INFN, Pisa/Genova, Italy
B.Sabirov, J.Budagov, G.Shirkov, Yu.Taran, JINR, Dubna, Russia
A.Bryzgalin, L.Dobrushin, S.Illarionov, E.Pekar, EWI, Kiev, Ukraine

Abstract

In the current ILC TDR design both the helium vessel shell and the connected pipes are made of expensive titanium (Ti), one of the few metals that can be welded to niobium (Nb) by the electron beam technique (EBW).

We describe work done by JINR/INFN collaboration on the construction and evaluation of transition elements, obtained by explosion welding, which could couple the niobium cavity to a stainless steel (SS) helium vessel. Several designs for these transitions have been produced and studied showing varying levels of reliability.

Based on this experience a new design, including a minimal titanium intermediate layer, has been built. Tests of resistance of the bond to extreme temperature shocks like EBW and exposure to cryogenic temperature are presented.

INTRODUCTION

Initial work on this subject was the development of a bimetallic transition element Ti+SS from the He-supply pipe to the He-vessel to be able to build this pipe and all other ancillary parts connect to it in SS (see Fig.1).

Explosion welding of two different metals is a well-known technique, but it is normally used only to weld flat surfaces, making the construction of cylindrical transitions rather cumbersome.

A key development was obtained in collaboration with the Russian Federal Nuclear Center Institute of Experimental Physics (RFNC-VNIIEF in Sarov) where a unique method for welding coaxial tubes [1] was demonstrated: two coaxial tubes of the same diameter and thickness, with an internal removable steel core, were connected by means of an external explosion around a SS collar (see Fig.2).

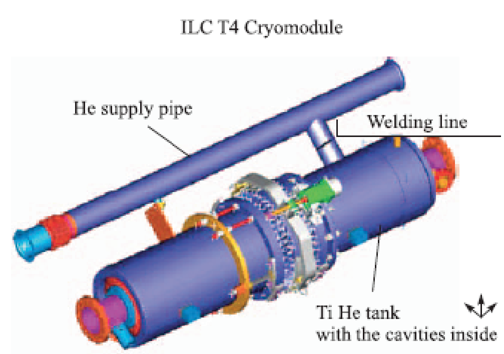

Figure 1: He-vessel connect to He-supply pipe.

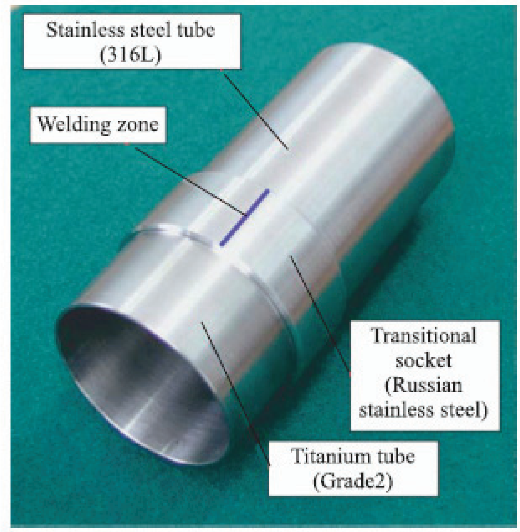

Figure 2: Ti+SS transition element.

Several samples were produced with this technique using various materials and dimensions. Finally ten samples matching the ILC cryomodule design were built and tested. The Ti+SS samples were subjected to a primary metallographic investigations of the welded joint including: macroanalysis, microanalysis, and measurement of microhardness [1]. The shear strength of the welded joint was also measured [1], the result turned out to be quite impressive: τ_{sh} about 250 MPa.

These samples were carefully leak-checked after several thermal cycles between room and liquid nitrogen temperature (77 K); no leaks were found [2,3,4,5]. They were also filled with helium at 6.5 atm and cooled to about 6 K in a cryo-cooler. The resistance of the joint after TIG welding close to it was also tested [6].

Finally the Ti+SS transitions were tested at Fermilab at the 2K temperature and under real Cryomodule conditions in the Fermilab's Horizontal Test System (HTS) and the A0 Vertical Test Dewar (A0VTD). No leaks were found also in this case [7,8,9,10].

The success obtained in explosion welding of bimetallic Ti+SS tubes led the collaboration to try a similar technique directly on Nb+SS tubes. This would allow the construction of a SS helium vessel using this transition element to connect to the cavity.

This new design would considerably facilitate the construction of the Cryomodule and, most of all, would substantially reduce the total cost of the accelerator.

Two schemes of making a transition element between the niobium cavity and the steel shell were studied: in the first the niobium tube is welded directly to the SS flange

Abstract

Dose measurements of a Medical Linear Accelerator (LINAC's) performed through a passive resonant cavity are shown in this paper. The cavity is coupled through a magnetic loop with a coaxial transmission line loaded on a microwave envelope detector. Output signal has been documented while receiving electron currents ranging from several values. This paper shows the complete equivalency, in terms of global performance, of the current revelation performed by exploiting the cavity-beam interaction principle with the classical technology, based on ionization chambers, without need of high voltage. The most important point is that the resonant cavity system, by measuring the beam current, gives a direct measurement of a physical observable quantity directly related with the dose deposed by the beam.

INTRODUCTION

Real time radiation measurement represents a fundamental aspect of medical Linear Accelerator (LINAC) development. This study was leaden by the need of a beam monitoring device for which several innovations have been proposed. In the medical LINAC field, strict regulations are imposed, mostly regarding the control of the emitted radiations delivered to the target [1], [2]. In this study the investigation have involved a medical mobile electron LINAC dedicated to intra operative radiation therapy (IORT). Actual dose monitoring systems are typically based ionization chambers and require high voltage biases [3], [4].

This study investigates on the possibility of measure dose emission through the power exchange of the beam current with a passive resonant cavity [5] placed at the output interface of the accelerator. Experimental evidence is presented showing the complete equivalency of the proposed system with the traditional technology, based on ionization chambers, however without need of high voltage. The major strength of the proposed system is represented by the direct relation between the deposed dose and beam current as physical observed quantity.

OPERATION OF MEASURING SYSTEM

The proposed radiation detector is based on the power exchange of the beam current with a passive resonant cavity [5] placed at the output interface of the accelerator.

LINAC beam current have a bunched time behavior and, as the bunches follow each other periodically in time, the spectral content of the current beam is a line at the accelerating frequency f and whole-number harmonics [4]. A simplified approach can be adopted by treating the bunched current as a square wave with an amplitude I_{beam} and duty cycle δ. The first harmonic would have an amplitude $I_1=2I_{beam}sin(\pi\delta)/\pi$. The LINAC considered in this study, operating at f =2998 MHz, can provide I_{beam}=1.11 mA, with I_1=0.66 mA. This harmonic content has been employed to induce oscillations in an opportune resonant cylindrical cavity operating in the TM_{010} mode at the accelerator normal mode frequency f.

Since the minimum energy of the beam is greater than 4 MeV, an opportune aluminum window (transparent to these energetic charges) is employed for allowing the beam crossing and entering the cavity. The window thickness is chosen to limit the surface scattering.

The beam current, exiting the LINAC, crosses the window and, centered on the axis, enters the cavity where image charges are induced on the walls exhibiting azimuthal symmetry [6]. While moving, they induce a wall current I_0 leading the cavity in resonance. An azimuthal magnetic induction field B_ϕ is generated in the cavity. A magnetic loop is placed inside the cavity volume and this field fluxes through the surface encircled by the loop, inducing a voltage V_p between the loop terminals. In order to maximize this flux, the surface enclosed by the loop is normal to the azimuthal direction.

In resonance, the cavity behaves as though its shunt impedance [6] while the loop is connected to a 50 Ω load through a coaxial line. In order to have the maximum transfer of available power, the loop shape and its distance from the axis of the cavity are chosen to have the right impedance transformation, matching the system.

For this reason it's of vital importance that the cavity shows a critical coupling, identifiable by a coupling factor k=1. This condition can be applied by employing the "detuned short position" technique [7].

The 50 Ω load closing the loop is the input port of a RF detector diode, at whose output port the envelope of V_p is

INTERACTION POINT ORBIT FEEDBACK SYSTEM AT SuperKEKB

Y. Funakoshi, H. Fukuma, T. Kawamoto, M. Masuzawa, T. Oki, S. Uehara, H. Yamaoka

Abstract

In order to maintain an optimum beam collision condition in a double ring collider such as SuperKEKB it is essential to have an orbit feedback system at the interaction point (IP). We have designed such a system based on experiences at KEKB and PEP-II. For the vertical offset and crossing angle, we will rely on the system based on the beam orbit measurement similar to that used at KEKB. For the horizontal offset, however, we will utilize the dithering system which was successfully used at PEP-II. Some hardware devices have been already fabricated and others are in preparation. The present status of the development is reported.

INTRODUCTION

The design of the system has been done based on the experiences at KEKB [1]. In the following, we summarize differences between KEKB and SuperKEKB from the view point of the IP orbit feedback. Table 1 shows a comparison of the parameters related to the feedback. The symbols for the parameters in the table are those used commonly. A remarkable point with the parameters is that the horizontal beam-beam parameters of SuperKEKB are much smaller than those of KEKB. In SuperKEKB, we will adopt so-called "nano-beam scheme", where the horizontal beam sizes at IP are very small and the crossing angle is rather large to reduce the interaction region of the two beams drastically. In this scheme, we have to use the effective horizontal beam size shown in the table rather than the actual horizontal beam sizes in the calculation of the beam-beam parameters and the luminosity. With those small horizontal beam-beam parameters, we can not rely on the beam-beam deflection method for the orbit feedback at IP in the horizontal direction. Instead, we will adopt the dithering system for the horizontal orbit feedback which was used at PEP-II [2]. Another feature of the SuperKEKB parameters is much smaller vertical emittances (ε_y) than KEKB. Roughly speaking, the vertical orbit drift at the IP will be 3 or 4 times larger in units of the vertical beam sizes than the KEKB case. The vertical beta functions at the IP (β_y^*) are also small. With smaller IP beta functions, the orbit drift in units of the vertical beam sizes will be unchanged, since both beam sizes and the sizes of the drift are proportional to the square root of β_y^* assuming that the beta functions at source points of the orbit drifts are the same. However, the vertical beta functions at the final focus quadrupoles (QC1s) get larger with the smaller IP beta functions. Also considering a higher field gradient of QC1s, the sizes of the orbit vibrations due to the vibrations of QC1s are about the same as those at KEKB. Considering this situation and the smaller vertical emittances, the orbit changes due to the mechanical vibrations of the QC1s will be by more than one order of magnitude larger in units of the vertical beam sizes than those at KEKB. We have been carefully investigating the mechanical vibrations of the final doublets and making efforts to reduce the vibration amplitudes. In the following, we summarize those efforts and their expected effects to the luminosity.

Based on the KEKB data of the vibration magnitude of the final focus quadrupoles, the orbit motion at the IP could be 4 or 5 times larger than the vertical beam sizes in SuperKEKB. To overcome this problem, four countermeasures have been considered, *i.e.* using the coherency of vibrations of quadrupoles for electrons and positrons, modified magnet supports, additional damping for magnet vibrations and finally the orbit feedback. A modal analysis has been performed with the ANSYS code. Vertical oscillation frequencies due to the vibrations of the QC1s on the right side of IP (QC1RP and QC1LP) appear at around 25, 38 , 69 and 100 Hz. If we assume the coherency of the two magnets, the orbit differences of the two beams at the IP at the frequencies will be 18.6, 1.7, 8.3 and 3.1 nm in rms, respectively. The corresponding luminosity degradations are 4.6, 0.2, 0.3, 0.3 %, respectively. The luminosity loss due to the 25Hz oscillation is expected to be recovered by the orbit feedback. The luminosity loss due to the vibrations of QC1s on the left side is similar. In the calculation, the coherency of the two magnets for the electrons and positrons is very important. If there is no coherency, the orbit differences amount to a few times of the vertical beam sizes at the IP.

VERTICAL FEEDBACK

The orbit feedback in the vertical direction will be done with the same method as that for KEKB. Changes of closed orbits give the orbit offset at the IP and the crossing angle. The changes of the orbits are detected by using four BPMs at around the IP. A difference from KEKB is that a much faster feedback will be needed at SuperKEKB. As shown above, we need to suppress the orbit change at around 25Hz. The feedback system is composed of BPMs, a special wideband detector for the BPMs, a digital signal processor unit whose outputs are kicks of corrector magnets, a power supply controller, power supplies of the correctors and the corrector magnets.

Four BPMs for the feedback are installed on the IP side of the final focus quardupoles (QC1RE, QC1RP, QC1LE and

Mitsubishi Electric TOKKI System Corporation, Amagasaki, Hyogo, Japan

Abstract

Beam commissioning of the SuperKEKB will be started in JFY2015. A new LLRF control system, which is an FPGA-based digital RF feedback control system on the MicroTCA platform, has been developed for high current beam operation of the SuperKEKB. The mass production and installation of the new systems has been completed as scheduled. The new LLRF control systems are applied to nine RF stations (klystron driving units) among existing thirty stations.

As a new function, klystron phase lock loop was digitally implemented within the cavity FB control loop in the FPGA, and in the high power test it worked successfully to compensate for the klystron phase change. Beam loading was also simulated in the high power test by using an ARES cavity simulator, and then good performance in the cavity-voltage feedback control and the cavity tuning control was demonstrated to compensate the large beam loading for the SuperKEKB parameters.

INTRODUCTION

SuperKEKB is a new upgrade project, which is aiming at 40-times higher luminosity than the KEKB [1], accordingly it requires much lower-emittance and higher-current beam storage. The first commissioning of SuperKEKB (Phase-1) will start in JFY2015.

Accuracy and flexibility in accelerating field control are very essential for storage of high-current and high-quality beam without instability. Therefore, new low level RF (LLRF) control system, which is based on recent digital architecture, was developed for the SuperKEKB, and the good performance of the prototype was demonstrated in the high power test as reported in Ref. [2]. The existing analogue LLRF systems used for KEKB operation will be replaced by new ones, step by step. In the first commissioning of SuperKEKB, the new LLRF control systems are applied to nine LLRF stations among about thirty stations.

The accelerating frequency of the storage ring is about 508.9 MHz (CW operation). The regulation stability of 0.02% and 0.02º (rms) in the cavity amplitude and phase, respectively, were obtained in the high power test of the LLRF control system [2]; that sufficiently satisfies the requirements.

For the beam acceleration of the main ring (MR), both normal conducting cavities (NCC) and superconducting cavities (SCC) are used. The NCC, which is called ARES

#tetsuya.kobayashi@kek.jp

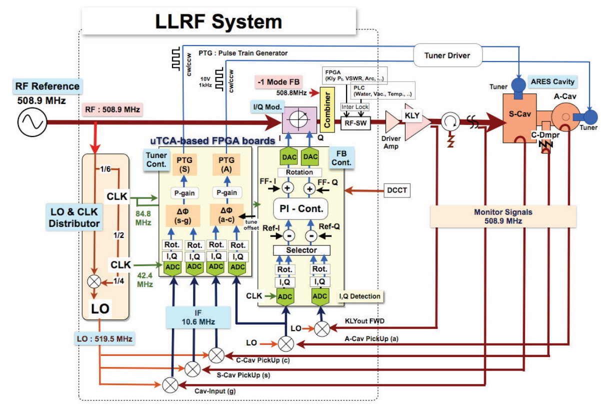

Figure 1: Block diagram for ARES cavity control.

[3], has a unique structure for the KEKB in order to avoid the coupled-bunch instability caused by the accelerating mod [4]. ARES is a three-cavity system: the accelerating (A-) cavity is coupled with a storage (S-) cavity via a coupling cavity.

A damping ring (DR) is newly being constructed at the injection linac for the positron emittance reduction. In the DR, the RF-frequency is the same as that of the main ring (MR), and three cavities, each of which is a HOM-damped single cell cavity (not an ARES type), are driven by one klystron for the acceleration. Thus another LLRF control system for the DR was also designed. It is almost the same as that of the MR, except the three-cavity vector sum control is required.

NEW LLRF SYSTEM FOR SUPERKEKB

Figure 1 shows a block diagram of cavity-voltage (Vc) feedback (FB) control and auto tuner control for the ARES cavity driving for the SuperKEKB. One klystron drives one cavity unit, so one LLRF control system corresponds to one cavity-unit control. The principal functions of this system are performed by five FPGA boards which work on MicroTCA platform as advanced

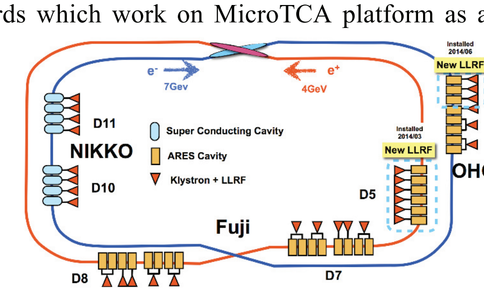

Figure 2: RF system layout for the Phase-1. Nine LLRF stations were replaced with the new ones.

BEAM BASED GAIN CALIBRATION FOR BEAM POSITION MONITOR AT J-PARC MAIN RING

H. Kuboki, T. Toyama, J. Takano, and M. Tejima, KEK/J-PARC, Tsukuba, Ibaraki, Japan
S. Hatakeyama, Mitsubishi Electric System & Service Co., Ltd., Tsukuba, Ibaraki, Japan

Abstract

A new beam-based method to calibrate the gains of Beam Position Monitor (BPM) at J-PARC Main Ring has been developed using Total Least Square fitting (TLS). The usefulness of TLS method is evaluated by the simulation. The gains are analyzed from the data obtained with the beam mapping for low and high beam intensities, and are determined with the accuracy within ±0.8% for right electrode and ±0.6% for up and down electrode.

BEAM POSITION MONITOR AT J-PARC MAIN RING

Beam Position Monitor (BPM) is one of the essential elements in a synchrotron facility. Beam positions measured with the BPMs are used to correct the closed orbit distortion (COD).

We define the "gain" such as the proportionality coefficient between the signal detected at the ADC and the ideal signal with no error as shown in Eqs. (1) and (2). The signal strength from a BPM electrode varies depending on 1) transmission characteristics of a long cable, 2) processing circuit, and 3) contact resistance at the connected parts. These are the origin of the gain fluctuation to be corrected by Beam Based Gain Calibration (BBGC) [1]. A conventional BBGC method was applied to the BPMs installed at J-PARC Main Ring (MR), however, the gains have not been corrected adequately because of the difference of the electrode shape. Therefore, a new BBGC method should be established.

Figure 1 shows the schematic of a BPM used at MR. The BPM has four electrodes of left (L), right (R), up (U), and down (D). The signal from each electrode is transmitted to the processing circuit BPMC and converted to the digitized signals shown as V_L, V_R, V_U, and V_D. Signal strength from each electrode of the BPM is represented as following.

$$V_L = \lambda\left(1+\frac{x}{a}\right),\ V_R = \lambda g_R\left(1-\frac{x}{a}\right), \quad (1)$$

$$V_U = \lambda g_U\left(1+\frac{y}{a}\right),\ V_D = \lambda g_D\left(1-\frac{y}{a}\right), \quad (2)$$

where g_R, g_U, and g_D are defined as relative gains of R, U, D electrodes divided by the gain of L electrode ($g_L = 1.0$), x and y denote horizontal and vertical position of the beam, respectively, λ denotes the line density of the beam charge with the unit C/mm^2, and a represents the effective radius of the inner surface of the electrode from the BPM center. Removing x/a, y/a, and λ from Eqs (1) and (2), we can obtain the relation

$$-\frac{R}{g_R}+\frac{U}{g_U}+\frac{D}{g_D}=L, \quad (3)$$

where V_L, V_R, V_U, and V_D are replaced by L, R, U, and D, respectively, for simplification. If we have n-data sets of (L_i,R_i,U_i,D_i) $(i = 1,\cdots,n)$, n relations of Eq. (3) can be expressed using matrix form as

$$\underbrace{\begin{pmatrix} -R_1 & U_1 & D_1 \\ \vdots & \vdots & \vdots \\ -R_i & U_i & D_i \\ \vdots & \vdots & \vdots \\ -R_n & U_n & D_n \end{pmatrix}}_{\boldsymbol{X}} \underbrace{\begin{pmatrix} G_R \\ G_U \\ G_D \end{pmatrix}}_{\boldsymbol{G}} = \underbrace{\begin{pmatrix} L_1 \\ \vdots \\ L_i \\ \vdots \\ L_n \end{pmatrix}}_{\boldsymbol{L}}, \quad (4)$$

where $\boldsymbol{G} = (G_R, G_U, G_D)$ are defined as the inverse of the gains $(1/g_R,\ 1/g_U,\ 1/g_D)$. Equation (4) can be represented as $\boldsymbol{X}\cdot\boldsymbol{G} = \boldsymbol{L}$, where $\boldsymbol{X}$ and $\boldsymbol{L}$ denote $n\times 3$ matrix and n data of L_i $(i = 1,\cdots,n)$, respectively. Firstly, we calculate the solution $\boldsymbol{G}$ from Eq. (4). Then the gains (g_R,g_U,g_D) are obtained as the inverse of each element in $\boldsymbol{G}$.

The gains are changed by a different configuration of the circuit even with the same BPM. For example, the gain changes depending on a beam intensity because the circuit configurations have to be changed to accept various signal strengths generated by different beam intensities. Here, we show the results of BBGC for two different beam intensities in **RESULTS**.

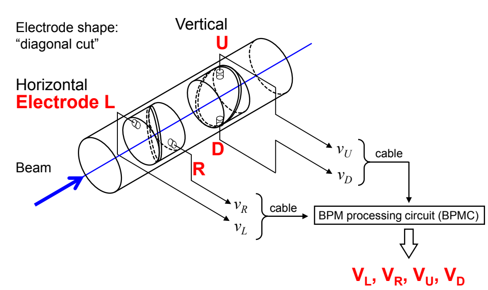

Figure 1: Diagonal-cut-type BPM at J-PARC MR.

SIMULATION

To solve Eq. (4), we have tested two methods: standard least squares fitting (LS) and total least squares fitting (TLS) [2]. We evaluated LS and TLS methods by a simulation as follows [1].

1. Gains are determined to be (g_L, g_R, g_U, g_D) = $(1.00, 1.01, 1.005, 0.975)$, which are defined as "True gain".

Abstract

The KEKB project has successfully completed its decade operation in the June of 2010. SuperKEKB main ring is currently being constructed for aiming at the peak luminosity of 8 x 10^{35} $cm^{-2}s^{-1}$. The electron/positron injector linac upgrade is also going on for increasing the intensity of bunched charge with keeping the small emittance. The key upgrade issues are the construction of positron damping ring, a new positron capture system, and a low emittance photo-cathode rf electron source. The injector linac beam commissioning started in the October of 2013. The whole control system performance determines the beam operation efficiency of injector linac, and it eventually has a strong impact on the experimental results of physics. In this decade, the linac control system has gradually transferred from the in-house system to the Experimental Physics and Industrial Control System based one for increasing the availability of beam operation. In this paper, we present the detail of SuperKEKB injector linac control system.

INTRODUCTION

The linac beam control system is based on a standard client/server model with three levels. The original linac control system has been developed by using the in-house software libraries based on the remote procedure call (RPC). The client user interfaces have been designed by a command line interface and Tcl/Tk scripting language. Around a decade ago, the middle phase of KEKB operation, the linac control system has been upgraded to a new framework based-on the Experimental Physics and Industrial Control System (EPICS) [1] to improve the affinity between the linac and ring control systems. These improvements make it easy to analyze the correlations between the linac and ring parameters. Such analysis can help finding a source of injection rate deterioration. The new client user interfaces have been implemented by Python scripting language for the rapid software development. For the simultaneous top-up injection of KEB and PF rings, an event based timing system has been implemented to enable the pulse-to-pulse beam modulation [2].

CONTROL SYSTEM OVERVIEW

Server and Client Computer Environment

The linac control system is based on the server/client model. It is useful framework to integrate the different kinds of local controllers. In the beginning of KEB project, we used the six Compaq Alpha servers with the Tru64 UNIX operating system as the server computers. Two of them were connected to the RAID disk via SCSI bus interface, and they can work as the active/standby redundant NFS servers for the high availability operation. Since the Tru64 UNIX was obsoleted, they have been gradually replaced by the Linux-based machines. After some different types of high availability cluster system based on Linux were evaluated, eventually we made decision to use the Linux base system without cluster functionality. Instead of redundant system, the blade based server system was employed as the high reliability server systems. Currently, eleven Linux based blade servers are utilized as the server computers. Both of server and client side control software are running on the server machines. Currently, Linux distribution of CentOS 5.11 x86_64 are mainly used for the daily operation. CentOS 6.6 and 7 are also under test for the future utilization. The Tektronix X terminals and touch panel displays based on PC9801/DOS machines have been originally utilized as the operator terminals. These terminals were replaced by the Linux PC and Windows PC with the X server application software of ASTEC-X and Reflection X.

Network Environment

The network system is one of the most important infrastructures for the reliable accelerator control system. During the KEKB operation, Cisco Catalyst 4506 and 3750 were utilized as the core switches. Each of them were independently connected to 45 edge switches of Catalyst 2950 via optical fiber with 100 Mbps bandwidth. The two core switches worked as the active/standby redundant system. For the network connection between the edge switches and local controllers like programmable logic controllers (PLCs), the optical fiber is used for avoiding the noise generated by the klystron modulators.

Toward SuperKEKB, the core switch system was replaced by 6 of Cisco Catalyst 3750X. Each of them can work as the active/active redundant system based on the virtual switching system technology. We replaced also the edge switch by Catalyst 2960S, and the network connection between them was improved up to 1 Gbps bandwidth.

Local Controllers

For the injector linac control system, many kinds of different local controllers are utilized for the injector linac component control as listed in Table 1. The ladder PLCs control the magnet power supplies, vacuum pumps,

FEASIBILITY STUDY ON MEASUREMENT AND CONTROL OF RELATIVE POSITIONING FOR NANO-BEAM COLLISION

H. Matsunaga#, H. Yoshioka, Takenaka Corp., Otsuka, Inzai 270-1395, Japan
Y. Ohsawa, R. Sugahara, M. Masuzawa, H. Yamaoka, KEK, Oho, Tsukuba 305-0801, Japan

Abstract

A key requirement of the SuperKEKB and future International Linear Collider projects is to measure and control the offset of very small beams with a precision of several nanometers at the interaction point. Using a relative positioning control introduces several technical problems because it is necessary to measure and control short-term vibration and long-term drift between the two distant points. In this paper, we offer a feasibility study for measuring and controlling nano-order relative position by using a laser interferometer and a piezoelectric stage.

INTRODUCTION

The SuperKEKB [1,2] is designed to improve peak luminosity to forty times that of KEKB luminosity and reduce the beam diameter to 60 nm. The beam diameter in the International Linear Collider will be 5 nm. To achieve these nano-beam collisions, it is essential to measure and control a relative offset between the electron and positron beams with a precision of several nanometers.

The electron and positron beam diameters are reduced by superconducting magnets located on both sides of the interaction point. Therefore, the most effective way is to measure and control the relative vertical beam offset at the installation points of superconducting magnets.

Many attempts have been performed to measure the microtremor at accelerator installation sites [3-6], however, those attempts have not been intended to measure relative offsets between two distant points. Kimura [7] proposed a method to measure a relative vertical offset via a water tube tiltmeter, but the method is not appropriate for measurement in the vibration region.

Yamashita [8,9] developed a mover system by using piezoelectric device. The mover can control the vibrations on a table with a precision of approximately 20 nm, however the mover is not designed to measure and control a relative offset between two distant points.

In this paper, we offer a feasibility study for measuring and controlling a nano-order relative position by using a laser interferometer and a piezoelectric stage.

MEASUREMENT ACCURACY OF THE LASER INTERFEROMETER

Experimental Systems

We adopted a laser interferometer (the laser system) of Keysight Technologies, Inc. The optical instruments are summarized in Table 1. The laser system can measure the relative displacement between a linear interferometer and a reflector with nano-order precision. We tested the measurement accuracy of the laser system in the frequency range 1‑100 Hz by using two shaking devices. Our experimental systems are shown in Figs. 1A and 1B.

DEVELOPMENT OF WIDEBAND BPM FOR PRECISE MEASUREMENT OF INTERNAL BUNCH MOTION

K. G. Nakamura, Kyoto University, Kyoto, Japan
T. Toyama, M. Okada, M. Tobiyama, Y.H. Chin, T. Obina, T. Koseki, KEK, Ibaraki, Japan
Y. Shobuda, JAEA, Ibaraki, Japan

Abstract

To suppress intra-bunch oscillations and to reduce particle losses, the intra-bunch feedback (IBFB) system has been developed in 2014 for the J-PARC Main Ring (MR). A new BPM was also installed to the MR for the IBFB system. This BPM has a sufficient frequency response and position sensitivity. (up to 1.5GHz within 15% fluctuation.) However, the performance needs to be further improved, particularly at high frequency, for more precise analysis of internal motions (e.g. due to electron clouds). We report the development of the BPM and precise measurement results of the BPM characteristics. We also show simulation studies of the digital equalizer which helps to reconstruct the beam shape from beam signals.

INTRODUCTION

The J-PARC is composed of three proton accelerators: the 400MeV linear accelerator (LINAC), the 3GeV Rapid Cycling Synchrotron (RCS), and the 30GeV Main Ring (MR) Synchrotron. At the J-PARC MR, transverse instabilities have been observed at the injection and during the acceleration. To suppress these instabilities, intra-bunch feedback system (IBFB) (Fig. 1) has been developed since 2014. It performs well in supressing instabilities and reducing beam losses [1].

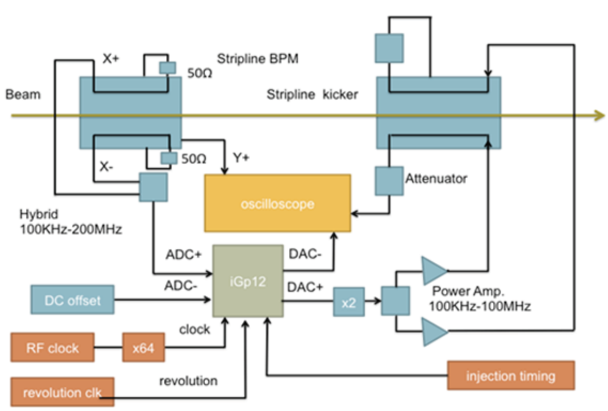

Figure 1: Schematic of the intra-bunch feedback system.

EXPONENTIAL TAPERED COUPLER

Exponential tapered couplers (ETC) [2] have been used for IBFB. They have a wider frequency response than a normal rectangular coupler. The details are described in Ref [1]. The ETC transfer function can be written as Eqs. (1) and (2). Measurement results agree with Eq. (1) within

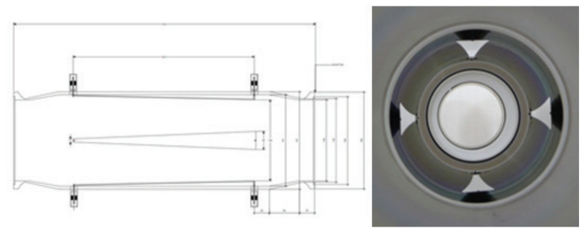

Figure 2: Side (left) and front (right) views of BPM.

15% fluctuation up to 1.5GHz (the blue line in Fig. 7). But a wider and flatter frequency response will be needed in future for more precise analysis of internal motions. In this paper, we report the development of the BPM to match measurement with theoretically designed response accurately.

$$|F(\omega)| = \frac{\frac{K\omega l}{c}}{\sqrt{a^2+\frac{4\omega^2 l^2}{c^2}}}\left(1+e^{-2a}-2e^{-a}\cos\frac{2\omega l}{c}\right)^{\frac{1}{2}} \tag{1}$$

$$Arg(F(\omega)) = \arctan\left(\frac{\frac{2\omega l}{c}\sin\frac{2\omega l}{c}+a(e^a-\cos\frac{2\omega l}{c})}{\frac{2\omega l}{c}(e^a-\cos\frac{2\omega l}{c})-a\sin\frac{2\omega l}{c}}\right) \tag{2}$$

NEW DESIGN OF BPM STRIPLINE

Impedance Matching

The fluctuation in the frequency response seems to be caused by the impedance mismatching in the BPM electrodes and some problems in the measurement method. The black line in Fig. 4 shows the impedance of electrodes measured by Time Domain Reflectometry (TDR). The two large peaks appear at the feed-through positions, and the fluctuation between them corresponds to impedance of the electrodes. The characteristic impedance of BPM is determined by the width and thickness of electrodes and their position. As the width is changed exponentially, the thickness or the distance from the chamber wall should be changed proportionally to the change in the width.

BUNCH LENGTH MEASUREMENT OF FEMTOSECOND ELECTRON BEAM BY MONITORING COHERENT TRANSITION RADIATION

Itta Nozawa[#], Masao Gohdo, Koichi Kan, Takafumi Kondoh, Astushi Ogata, Jinfeng Yang and Yoichi Yoshida
The Institute of Scientific and Industrial Research, Osaka University, Osaka, Japan

Abstract

Ultrashort electron bunches with durations of femtoseconds and attoseconds are essential for time-resolved measurements, including pulse radiolysis and ultrafast electron microscopy. However, generation of the ultrashort electron bunches is commonly difficult because of bunch length growth due to space charge effect, nonlinear momentum dispersion and so on. Several bunch length measurement methods for the ultrashort electron beams have also been considered so far, which have not been established yet. In this study, the femtosecond electron beams were generated using a laser photocathode radio-frequency gun linac and a magnetic bunch compressor. The bunch length measurement was carried out using a Michelson interferometer based on monitoring coherent transition radiation (CTR), which is characterized by square modulus of the Fourier transform of the longitudinal bunch distribution. Analyzing the experimentally obtained interferograms of CTR, the electron beams with the average duration of 5 fs were generated and measured successfully at the condition of bunch charge of 1 pC. Consideration of the longitudinal bunch shapes was also carried out using the Kramers-Kronig relation.

INTRODUCTION

Ultrashort electron bunches with pulse durations of femtoseconds and attoseconds are a key for applications of accelerator physics, for example, free electron lasers[1] and intense terahertz (THz) light sources[2]. Additionally, ultrashort electron bunches play an important role in time-resolved measurements such as pulse radiolysis[3] and ultrafast electron diffraction[4] because the time resolution of the measurements strongly depends on the bunch lengths of electron beams. On the other hand, much effort has been devoted to developing bunch length measurements of <100 fs electron bunches because of lack of time resolution of conventional longitudinal beam diagnostic methods including femtosecond streak cameras. Now, many researches of alternative measurement methods using coherent radiation (CR), electro-optic (EO) crystals, deflecting cavities have proceeded in order to evaluate bunch length of femtosecond electron bunches[5,6]. In this study, a bunch length measurement technique of the femtosecond electron bunches were investigated by monitoring coherent transition radiation (CTR) using a Michelson interferometer. The femtosecond electron bunches were generated by a photocathode-based linac with an arc-type magnetic bunch compressor[3,7]. As for the bunch length measurement monitoring CR, it is very important to detect broadband electromagnetic (EM) waves because the frequency range characterizes the time resolution of the bunch length measurement. Therefore, frequency range of the measurement system has been expanded by optimizing a beam splitter and a detector in the Michelson interferometer.

EXPERIMENTAL SETUP

Linac System for Generation of Ultrashort Electron Bunches

In this study, a laser photocathode radio frequency (RF) gun linac and an arc-type magnetic bunch compressor at the Institute of Scientific and Industrial Research (ISIR) in Osaka University were used for the generation of ultrashort electron bunches. Figure 1 shows the schematic diagram of the linac system[3,7].

This system is composed of a 1.6-cell S-band (2856 MHz) RF gun with a copper cathode, a 2-m-long S-band linear accelerating tube and a magnetic bunch compressor. In order to obtain electron beams with low emittances and short initial bunch lengths at the gun, a third harmonics of a Ti:Sapphire femtosecond laser (266 nm) was used for irradiating the copper cathode. Additionally, the charges of the electron bunches were suppressed to the picocoulomb-order to reduce bunch length growth due to the space charge effect. The electron bunches were accelerated to 4 MeV at the exit of the gun and 32 MeV at the exit of the accelerating tube. In the linear accelerating tube, an energy-phase correlation optimal for compression was also carried out for the magnetic compression. Finally, the electron bunches were

MEASUREMENT OF MOMENTUM SPREAD OF THE INJECTION BEAM WITH LONGITUDINAL TOMOGRAPHY METHOD IN THE J-PARC RCS

Masahiro Yoshimoto#, Hiroyuki Harada, Hideaki Hotchi, Pranab Kumar Saha, Fumihiko Tamura, Masanobu Yamamoto, Michikazu Kinsho
JAEA/J-PARC, Tokai-Mura, Naka-Gun, Ibaraki-Ken, JAPAN

Abstract

In the J-PARC RCS, the beam tuning toward the design output beam power of 1MW were started after the completing of the beam energy and beam current upgrades in the LINAC. One of the important issues to achieve the 1MW beam operation is the optimization of the injection beam. Due to the longitudinal beam tuning in the LINAC, we adopted the Longitudinal Tomography algorism to measure the momentum spread after the beam injection into the RCS. At first we confirmed the validity of our measurement tool developed with the Longitudinal Tomography algorism. And then longitudinal beam tuning with this tool were carried out.

INTRODUCTION

In order to observe two-dimensional (2D) beam distributions in the longitudinal phase space, the simple reconstruction tool had been developed with the Longitudinal Tomography (LT) algorithm for the 3-GeV rapid cycling synchrotron (RCS) at Japan Proton Accelerator Research Complex (J-PARC) [1]. Our reconstruction tool is adopted the Convolution Back-Projection (CBP) method [2] for the LT algorithms. This tool has some limitations to apply the beam measurement. However it is very simple enough to accelerate processing speed and achieve the on-line analysis. The reconstructed longitudinal 2D distribution has much useful information. It can diagnose not only the longitudinal beam dynamics in the RCS but also the longitudinal beam parameters from the LINAC.

In the J-PARC RCS, the beam tuning toward the design output beam power of 1MW were started after the completing of the beam energy and beam current upgrades in the LINAC. One of the important issues to achieve the 1MW beam operation is the optimization of the injection beam from the LINAC [3]. Due to the longitudinal tuning of the LINAC beam, the momentum spread (Δp/p) was measured with this reconstruction tool after the beam injection into the RCS.

MOMENTUM SPREAD MEASUREMENT WITH LONGITUDINAL TOMOGRAPHY

In order to apply the reconstruction tool with the simple LT algorism to the Δp/p measurement of the LINAC beam, there are some issues that we have to confirm, namely the reproducibility of the 2D distribution, the accuracy of the measurement quantity, and the expansion to the Acceleration mode. Thus our reconstruction tool has to be evaluated before the high power beam tuning.

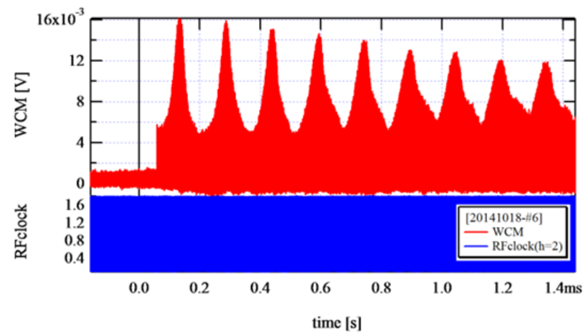

Figure 1: The typical beam bunch shape acquired by the WCM and the RF-clock generated by the LLRF.

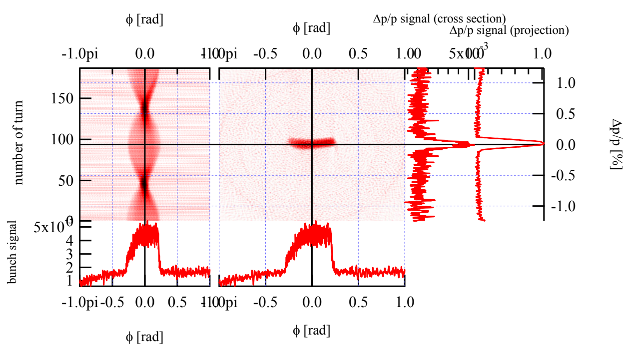

Figure 2: The reconstructed beam distribution in the longitudinal phase space with the CBP method.

Reconstruction Two-Dimensional Distribution in the Longitudinal Phase Space

The RCS adopted the multi-turn H^- charge-exchange injection scheme [4]. After the all bunched beams were injected, the longitudinal information of the LINAC beam was smeared out. Thus single intermediate bunched beam had to be injected and rotated in synchrotron phase-space. Figure 1 shows the typical measurement results of the circulating bunch signal by the WCM and the RF-clock signal generated by the low level RF (LLRF) system after the single intermediated bunched beam injection. A set of projected histograms for the Longitudinal Tomography can be obtained by cutting out from the WCM signal at the every rise timing of the RF clock. Figure 2 shows the results of the reconstruction. Left figures show the mountain plot during one synchrotron oscillation period and the first projected histogram. Right figure shows the reconstructed 2D distribution in the longitudinal phase

Abstract

The accelerating structures for CLIC must be aligned with a precision of a few µm with respect to the beam trajectory in order to mitigate emittance growth due to transverse wake fields. We report on first results from wake field monitor tests in an X-band structure, with a probe beam at the CLIC Test Facility. The monitors are currently installed in the CLIC Two-Beam Module. In order to fully demonstrate the feasibility of using wakefield monitors for CLIC, the precision of the monitors must be verified using a probe beam while simultaneously filling the structure with high power rf used to drive the accelerating mode. We outline plans to perform such a demonstration in the CLIC Test Facility.

INTRODUCTION

In the Compact Linear Collider [1] (CLIC), wakefield monitors (WFMs) are indispensable for preserving the emittance in the main linac. Even with the tight mechanical alignment tolerances of 14 µm for the accelerating structures, the corresponding vertical emittance growth $\Delta\epsilon_y$ would be in the order of 200 %, which is clearly unacceptable. Therefore, the accelerating structures will be aligned to the beam with the help of wakefield monitors. To keep $\Delta\epsilon_y$ around 5 %, the alignment tolerance is 3.5 µm including systematic and random effects.

Wakefield monitors (WFMs) are used to measure the beam position based on transverse wakes from the passing bunches. In CLIC, it is foreseen to use TD26 accelerating structures in the main linac [1], which are tapered, damped travelling wave structures with a fundamental mode at 12 GHz. Each structure consists of 26 tapered cells, as well as two coupling cells. Four waveguides are connected to each cell and damp higher-order modes. For some of the accelerating structures, the waveguides of the first normal cells are extended for the WFMs. The internal geometry of such an accelerating structure is shown in Figure 1.

On the wide sides of each of these waveguides, an antenna is used to pick up a TM-like mode at 16.9 GHz [2]. In a similar way, an antenna at the short side of the waveguide picks up a TE-like mode at 27.3 GHz. Both these modes are dipole modes, where the amplitude has a linear dependency on the beam offset from the center of the structure. Since four waveguides are used around the cell, the beam offset in both transverse dimensions can be found.

* reidar.lunde.lillestol@cern.ch

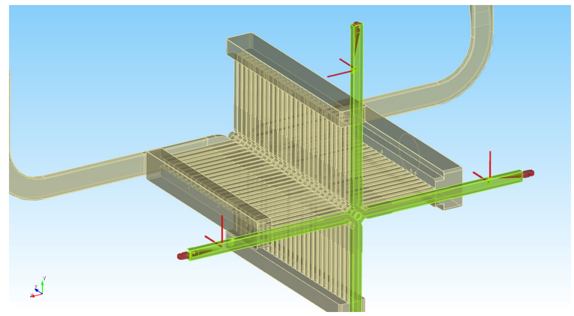

Figure 1: The internal geometry of a TD26 structure except for the first coupling cell. The WFM waveguides are shown in green and the pickup antennas in red.

The CLIC WFMs were first tested in the Two-Beam Test Stand [3, 4], which was formerly located in the same beam line as the present setup. By comparing two accelerating structures, these tests indicated a resolution of < 5µm for beam offsets of < 0.4mm.

WAKE FIELD TESTS AT THE CTF3

In the CLIC Test Facility 3 (CTF3) at CERN [5], a CLIC two-beam module (TBM) is presently installed in the Califes beamline. The CTF3 was built to demonstrate concepts and feasibilities related to CLIC, and Califes uses a probe beam representing the CLIC main beam. The TBM includes four accelerating structures, divided into two superstructures. For each superstructure, the second accelerating structure is equipped with WFMs, resulting in 8 signals for each of the two modes. The TBM also includes 2 Power Extraction and Transfer Structures (PETS), which provide about 90 MW of rf power at 12 GHz and feed the accelerating structures through a waveguide distribution network.

For each WFM signal, a bandpass filter is used to filter out unwanted modes. The signal is then read by a logarithmic detector and a digitizer. Since the time of the TBTS experiments, the mode frequencies are now different, since we now measure wakefields in the first normal cell instead of in the central cell. However, the readout electronics are still looking at the old mode frequencies, since the new bandpass filters have not yet been installed. Therefore, we measure signals at 18 ± 0.25 GHz and 24 ± 0.25 GHz instead of directly at the modes of 16.9 GHz and 27.3 GHz. Because of the low Q factors of the dipole modes, we still believe we pick up a part of the correct modes, but the signals are much weaker than they should be.

STUDY ON THE INJECTION BEAM COMMISSIONING SOFTWARE FOR CSNS/RCS*

M.Y. Huang#, S. Wang, W.B. Liu, J. Qiu, L.S. Huang
[1] China Spallation Neutron Source, Institute of High Energy Physics, Chinese Academy of Sciences, Dongguan, China
[2] Dongguan Institute of Neutron Science, Dongguan, China

Abstract

The China Spallation Neutron Source (CSNS) accelerator uses H^- stripping and phase space painting method of filling large ring acceptance with the linac beam of small emittance. The beam commissioning software system is the key part of CSNS accelerator. The injection beam commissioning software for CSNS contains three parts currently: painting curve control, injection beam control and injection orbit correction. The injection beam control contains two subsections: single bunch beam calculation and LRBT beam control at the foil. The injection orbit correction also contains two subsections: injection orbit correction by the calculation and injection trim power control.

INTRODUCTION

CSNS is a high power proton accelerator-based facility [1]. The accelerator consists of an 80MeV H^- linac and a 1.6GeV Rapid Cycling Synchrotron (RCS) which accumulates an 80MeV injection beam, accelerates the beam to the designed energy of 1.6GeV and extracts the high energy beam to the target. Its beam power is 100kW and capable of upgrading to 500kW. The design goal of CSNS is to obtain the high intensity, high energy proton beam with a repetition rate of 25Hz for various scientific fields [2].

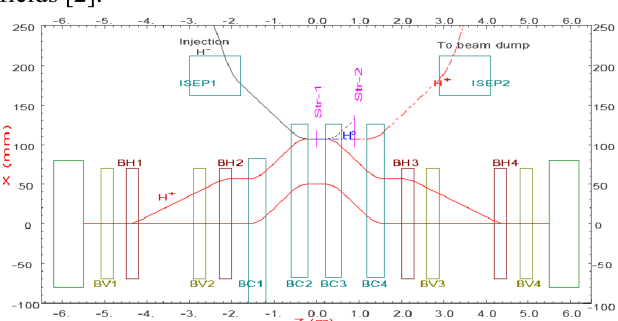

Figure 1: Layout of the RCS injection system.

For CSNS/RCS, a combination of the H^- stripping and the phase space painting method is used to accumulate a high intensity beam. Figure 1 shows the layout of the RCS injection system [3]. For the injection system, three kinds of orbit-bumps are prepared: a horizontal bump (BH1-BH4) for painting in x-x′ plane; a vertical bump (BV1-BV4) for painting in y-y′ plane; a horizontal bump (BC1-BC4) in the middle for an additional closed-orbit shift of 60mm [4].

The beam commissioning software which was programmed with the Java language plays a very important role in CSNS project, and it bases on the XAL application development environment which was developed initially by SNS laboratory [5]. The main application of this beam commissioning software system contains: device control, monitoring, online modeling and data analysis functions [6].

PAINTING CURVE CONTROL

In order to control the strong space charge effects which are the main causes of the beam losses in CSNS/RCS, the phase space painting method is used for injecting the beam of small emittance from the linac into the large ring acceptance. In general, there are two painting methods: correlated painting and anti-correlated painting. From our simulation results by using the code ORBIT [7], it can be found that the anti-correlated painting method may be more suitable for CSNS/RCS.

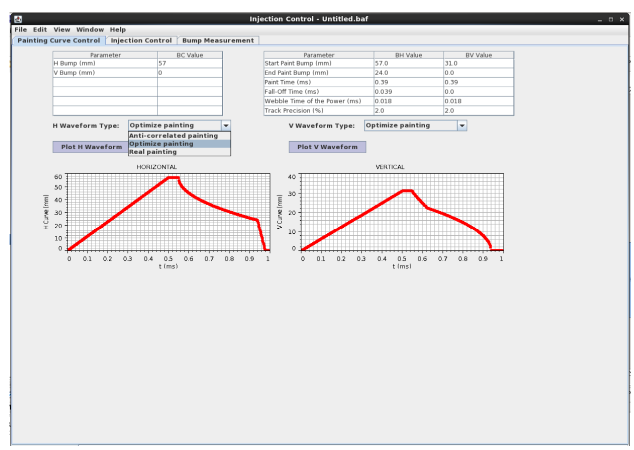

Figure 2: Injection painting curves control.

For the injection beam commissioning software of CSNS/RCS, there are three kinds of painting curves: ideal anti-correlated painting curve, optimize painting curve, and real painting curve. The optimized painting curve is obtained by the simulation and optimization of injection process. The real painting curve will be given by the accelerate operation and test. Figure 2 shows the control interface of the injection painting curves. It can be found that the painting curves can be called, displayed and saved.

PRELIMINARY HARDWARE IMPLEMENTATION OF COMPENSATION MECHANISM OF SUPERCONDUCTING CAVITY FAILURE IN C-ADS LINAC

Z. Xue#, J. P. Dai, IHEP, Beijing,China
Y. Yang, L. X. Cheng, SINANO, Suzhou, China

Abstract

For the proton linear accelerators used in applications such as C-ADS, due to the nature of the operation, it is essential to have beam failures at the rate several orders of magnitude lower than usual performance of similar accelerators. In order to achieve this extremely high performance reliability requirement, in addition to hardware improvement, a failure tolerant design is mandatory. A compensation mechanism to cope with hardware failure, mainly RF failures of superconducting cavities, will be in place in order to maintain the high uptime, short recovery time and extremely low frequency of beam loss. The hardware implementation of the mechanism poses high challenges due to the extremely tight timing constraints, high logic complexity, and mostly important, high flexibility and short turnaround time due to varying operation contexts. We will explore the hardware implementation of the scheme using fast electronic devices and Field Programmable Gate Array (FPGA). In order to achieve the goals of short recovery time and flexibility in compensation algorithms, an advanced hardware design methodology including high-level synthesis will be used.

INTRODUCTION

The Chinese ADS (C-ADS) project is aimed to solve the nuclear waste problem and the resource problem for nuclear power plants in China. To C-ADS linac, which is a high power proton accelerator, unexpected beam trips may lead to the serious change of temperature and thermal stress in the reactor core, and eventually result in the permanent damage of facilities. Therefore, the extremely high reliability and availability for C-ADS linac was proposed [1, 2], as shown in Table 1.To reach such an ambitious goal, it is clear that reliability-oriented design practices need to be followed from the early design stage [3]. In particular: (1) a high degree of redundancy needs to be planned in critical areas. (2) “Strong design” is needed. (3) fault-tolerance capabilities have to be considered. This paper will focus on the concept of fault-tolerance, and present the preliminary hardware implementation of the compensation mechanism of the superconducting cavity failures in C-ADS linac.

Table 1: Specifications of C-ADS Proton Linac

Parameters	Design	
Particle	proton	
Energy	1.5	GeV
Current	10	mA
Beam Power	15	MW
RF Frequency	(162.5)/325/650	MHz
Duty Factor	100	%
Beam Loss	<1	%
Beam Trips/Year	<25000	1s<t≤10
	<2500	10s<t≤5min
	<25	t>5min

THE COMPENSATION MECHANISM

The compensation methods of superconducting cavity failures can be divided into global compensation method and local compensation one [3]. The global compensation means that all the cavities downstream of fault cavity attend the compensation, while the local compensation is related to the elements neighbouring the failing cavity. The global compensation has lower demand of the performance of each cavity, but it needs all cavities act at the same time, which means the RF control should be extremely accurate. By contrast, the local compensation has the advantage of involving a small number of elements, yet the performance margin of the elements must be larger.

The representative compensation work may be found on SNS, which adopts the global compensation. When the cavities fail, the machine will look up the database to find the data of compensation and then readjust the parameters of the working cavities. The whole process may take a few minutes, which is too long for C-ADS linac. In this paper, we tried another way to achieve the compensation by the hardware implementation of the scheme using fast electronic devices and Field Programmable Gate Array (FPGA). The preliminary compensation diagram of the injector I of C-ADS, which is a 10MeV proton linac, is shown in Fig.1.

OPERATION EXPERIENCE OF P-CARBON POLARIMETER IN RHIC*

H. Huang†, E.C. Aschenauer, G. Atoian, A. Bazilevsky, O. Eyser, D. Kalinkin, J. Kewisch, Y. Makdisi, S. Nemesure, A. Poblaguev, W.B. Schmidke, D. Steski G. Webb, K. Yip, A. Zelenski, BNL, Upton, New York, USA, I.G. Alekseev, D. Svirida, ITEP, Moscow, Russia

Abstract

The spin physics program in Relativistic Heavy Ion Collider (RHIC) requires fast polarimeter to monitor the polarization evolution on the ramp and during stores. Over past decade, the polarimeter has evolved greatly to improve its performance. These include dual chamber design, monitoring camera, Si detector selection (and orientation), target quality control, and target frame modification. The preamp boards have been modified to deal with the high rate problem, too. The ultra thin carbon target lifetime is a concern. Simulations have been carried out on the target interaction with beam. Modification has also been done on the frame design. Extra caution has been put on RF shielding to deal with the pickup noises from the nearby stochastic cooling kickers. This paper summarizes the recent operation performance of this delicate device.

INTRODUCTION

RHIC is the first and only polarized collider in the world. During the acceleration, there are possible polarization loss due to snake resonances. In addition, there are also gradual polarization loss during the typical 8 hours physics store. Therefore, fast polarization measurements are essential for the machine setup and physics programs [1]. The absolute polarization of RHIC beams are determined from polarized hydrogen jet [2]. However, the jet can only provide polarization with statistical error bars of 2-3% for a whole store. It is used to provide absolute beam polarization information for physics stores and to calibrate the p-Carbon polarimeter. The p-Carbon polarimeter provides the polarization decay during a store, the polarization profile information for experiments to use, and for possible polarization loss during acceleration.

The p-Carbon polarimeters in RHIC are based on elastic proton scattering with low momentum transfer and measurement of asymmetry in recoil carbon nuclei production [3]. This process has a large cross-section and sizable analyzing power of a few percents which has weak energy dependence in the 24-255 GeV energy range. A very thin (10 μg/cm^2, 5-10 μm wide) carbon ribbon target in the high intensity circulating beam produces high collision rate and a highly efficient DAQ system acquires up to 7×10^6 carbon events /sec. The details of the design and construction are described in Ref. [4]. A schematic of the chamber is shown in Fig. 1.

† huanghai@bnl.gov

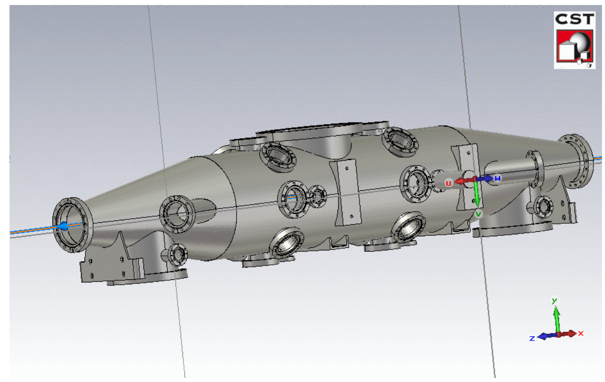

Figure 1: The 3D drawing of the polarimeter chamber. The taper structure (5:1) is to reduce the impedance impact on the overall RHIC ring impedance budget. The two view ports on both taper structure are used to monitor the target operation with remotely accessible cameras. The big view port on the top is for target installation and target motion monitor. Three cameras are mounted on these view ports to monitor the polarimeter target operation. There are two sets of six Si detectors ports surrounding the chamber on both sides of the big view port. There are six targets in both vertical and horizontal directions for each set.

TARGETS AND VACUUM CHAMBER

The use of thin target in polarimeter is essential to reduce multiple scattering for recoil carbon ions and also keep the event rate within the detectors and DAQ capabilities. Manufacturing of the ultra-thin carbon (amorphous graphite) targets requires high skill and is a time-consuming process [5]. To increase the yield of target production, the target thickness for last a few runs was at 10 μg/cm^2, instead of 5 μg/cm^2. The higher rate can be compensated by smaller Si detector strip size. As intensity increases over years, the target loss rate is higher. Cameras were installed before 2013 run. Camera videos show that the targets tails are glowing when crossing beam or even at park position, if it is near beam. About 2/3 of broken targets were broken at the tails instead of center where beam hits. This leads to hypothesis that the heat generated by the induced current on the target is the culprit [6]. The RF voltage is reduced during polarization measurement to prolong the target lifetime, as induced fields are weaker with longer bunch. Round shape fins are added this year based on the experiment test last year. The preliminary results show that the target lifetime is prolonged, even though the glowing light is not completely eliminated.

DESIGN AND TEST OF PROTOTYPE OF LLRF SYSTEM FOR KIPT NEUTRON SOURCE LINAC

X. Ma#, R. Liu, Y. Chi, G. Shu, IHEP, Beijing, China

Abstract

A 100 MeV/100 kW electron LINAC is being constructed by IHEP, China for the NSC KIPT Neutron Source project in Ukraine [1]. A LLRF system is required to produce the driver RF input of the klystron and maintain the accelerating phase and amplitude stability of the machine. The LLRF system consists of an RF reference distribution system, six identical control units, and the fast RF interlock module. The main part of control unit is the PXI-bus crate implemented with PXI9846 - 4 ADC digitizer board and ICS572 - high speed 2 ADC/2 DAC signal process board. An EPICS IOC based on WinDriver as the PCI device driver is developed and tested. Preliminary results show phase detect resolution of 0.03 degree (rms) of 2856MHz signal has been achieved.

INTRODUCTION

The 100MeV electron LINAC includes a triode-type gun, a 2856 MHz pre-buncher (PB), a 2856 MHz travelling wave buncher (B) and ten 2856 MHz travelling wave accelerating tubes (A0-A9). The layout of the LINAC is shown in Fig. 1. The pre-buncher, the buncher and the first accelerating tube are powered by one klystron. The second accelerating tube is powered by one single klystron to obtain a higher accelerating gradient. For the following accelerating tubes, each two are powered by one klystron. The Low-Level RF (LLRF) system is needed to control the phase and amplitude of each accelerating sections. The reference signal from master oscillator (MO) is distributed to each LLRF module by phase-stabilized coaxial cables.

REQUIREMENT ANALYSIS

In order to maintain the stability of the LINAC, the LLRF system must include the following requirements:

- The phase and amplitude stability of the accelerating field are ±2° and ±2% according the beam dynamic analysis [2]. The phase reference signal of each LLRF station must be stabilized.
- The LLRF system should generate drive waveform for the klystron and compensate the beam loading effect.
- The LLRF system should provide signal monitoring and some fast interlock functions such as loss of power protection and reverse power over-limit protection, etc.
- The LLRF system should provide the access point with the control system and the graphic user interface to the operators.

#maxp@ihep.ac.cn

SYSTEM DESIGN AND TEST

One typical control unit of the LLRF system is shown in Fig. 2. The hardware can be divided into two parts: the RF front-end module and the data acquisition (DAQ) module. The front-end module includes a frequency generator which provides the LO signal for the down-converters and up-converters as well as the Clock for the DAQ module. The DAQ module consists of three boards: ICS572F, PXI9846 and PXI3950, which are inserted in the same chassis with the PXI-bus connection.

The PXI9846 board from ADLINK has four 16-bit 40MSPS ADCs. It is used to digitize the down-converted IF signals of the forward/reverse signals of the klystrons and the accelerating tubes.

The ICS572F board from GE has two 14-bit 105 MSPS ADCs and two 14-bit 250 MSPS DACs. It is used to generate the drive signal of the klystron, detect the phase and amplitude of the pickup signal and implement PI and feed-forward control algorism in order to maintain the stability of the accelerating field.

The PXI3950 board from ADLINK is an embedded controller with an Intel x86 CPU and runs on the Windows XP 32-bit version operation system. The EPICS IOC which includes the device support of PXI9846 and ICS572F is built on this controller. The records that hold the waveforms of the signals and the control registers of the LLRF system are supported by these devices. So these records can be accessed by any Channel Access tools in EPICS through the Ethernet.

The version of EPICS base is R3.14.12.3 and the EPICS_HOST_ARCH is chose to be cygwin-x86.

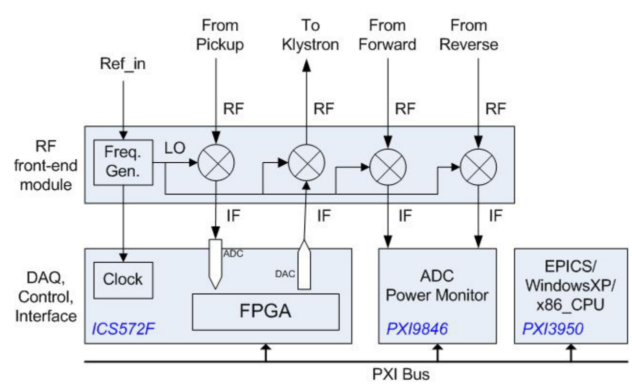

Figure 2: Structure of one LLRF control unit.

Data acquisition of PXI9846

There are two ways getting the samples through PXI9846 board: using task-oriented DAQPilot library or

CONTROL SYSTEM FOR DC-SRF PHOTO-INJECTOR AT PEKING UNIVERSITY *

L. Feng†, L. Lin, F. Wang, J. Hao, S. Huang S. Quan, K. Liu, B. Zhang
Institute of Heavy Ion Physics, Peking University, Beijing 100871, China

Abstract

A control system has been designed and constructed to full-fill the operation requirement of the DC-SRF photo injector developed at Peking University. The system includes an analog laser phase lock system, FPGA based low level radio frequency (LLRF) control system, PLC based machine protection system, VME based magnet power control, and PC based EPICS IOC. All these systems were integrated to support the stable operation of the DC-SRF photo injector and has shown their robustness. The LLRF system was optimized and tuned for 2K CW/Pulse operation and the stability of amplitude and phase achieves 0.1% and 0.1° respectively.

INTRODUCTION

The DC-SRF [1] photo injector developed at Peking University was designed to generate high repetition rate electron beam in 3-5 MeV range. This injector combines a DC pierce gun and a 3.5-cell superconductor cavity which is capable to operate in both CW and pulse mode. Recently, we've completed the commissioning of the injector [2] and had conducted experiments such as THz coherent wiggler radiation [3] on the platform. The schematic layout of the platform is shown in Fig. 1 and the photo of beamline is shown in Fig. 2.

To make it easier to operate the injector, control of the driver laser, superconductor cavity, beam transport line and other auxiliary systems has to apply. And high level control application such as user interface, data archiver, system-wide interlock was also required.

An EPICS based control system was introduced for this purpose. The remote control of each subsystem was implemented by difference kinds of EPICS IOCs. Control System Studio (CSS) was chose as the OPI tool for its flexibility.

Along with the works on integrating the system, great efforts were also spent on dealing with various of instabilities observed during the experiments. These instabilities were mainly attributed to the phase jitter of laser and RF system. To reduce those instabilities, we've developed a digital Low Level Radio Frequency (LLRF) control system [4] and the laser phase lock system were improved to reduce the relative phase jitter.

SYSTEM DESIGN

The whole system can be divided into five subsystems: injector cryomodule, magnet power supply system, driver

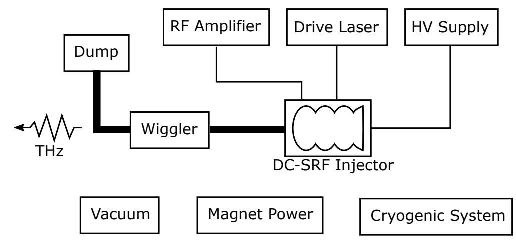

Figure 1: DC-SRF injector THz wiggler radiation experiment layout.

Figure 2: The DC-SRF injector and beamline.

laser system, RF control system, and other auxiliary systems such as cooling and vacuum system.

Injector Cryomodule Control

The DC-SRF injector cryomodule is one the main parts of the platform. Its primary function is to maintain 2 K conduction for the super conducting cavity. The cryogenic system that supplies LHe/LN for the cryomodule was constructed by Linde Inc. and Technical Institute of Physics and Chemistry, CAS. The cryogenic system was shipped with a standalone control system and operates independently. Other parts of the injector, however, need controls to ensure the proper operation of it. 16 temperature sensors were installed in the cryomodule. Two Cryocon Model-18 temperature monitors were used to measure those sensors. The measured values can then be transfered to a soft IOC through Ethernet. Because the Model-18 temperature monitor uses just plain text in their communication protocol, it is quite handy to interface them with Asyn/Stream Device module in the IOC.

Besides for the cryogenic system, a high voltage DC power supply is connected to the DC gun of the injector. The high voltage power supply has voltage control input, voltage read

AN EXPERIMENTAL STUDY OF HIGHER-ORDER MODES EXCITED BY HIGH REPETITION RATE ELECTRON BEAM IN AN SRF CAVITY*

Yongfeng Gao, Liwen Feng, Jiankui Hao, Senlin Huang, Lin Lin, Xing Luo, Shengwen Quan, Fang Wang, Zhiwen Wang, Kexin Liu, Jia-er Chen
Institute of Heavy Ion Physics, School of Physics, Peking University, Beijing 100871, China

Abstract

Higher-order modes (HOMs) excited by electron beam traversing a superconducting rf (SRF) cavity contain lots of information and can be used for intra-cavity electron beam diagnostics. Unlike single bunch, multiple bunches would excite HOMs with a much complicated spectrum. In this paper, we present our recent research on HOMs excited by a high repetition rate electron beam in an SRF cavity. Especially, we focus on the integer multiple frequency peaks in the HOM spectrum, which are determined by the nearest eigen HOM peaks. The experiments were carried out on the DC-SRF photoinjector, which was operated at MHz repetition rate. The results agree well with theoretic analysis.

INTRODUCTION

Higher-order modes (HOMs) excited by electron beam travelling through a superconducting rf (SRF) cavity contain abundant information of the electron beam [1,2]. Lots of studies have been carried out for single electron bunch excited HOMs and the applications [2,3,4]. There are also some research on HOMs excited by multiple electron bunches [5,6], in which case, however, the characteristics of HOMs have not been well studied.

We recently studied HOMs excited by high repetition rate electron bunches, with the focus on HOM characteristics. Some preliminary experiments have been conducted on the DC-SRF photoinjector [7] at Peking University. In the following sections, we will first discuss the characteristics of HOMs excited by high repetition rate electron bunches. The HOM experiments on the DC-SRF photoinjector will then be introduced. Some preliminary test results with electron beam offset in the SRF cavity will also be presented.

HOM EXCITED BY HIGH REPETITION RATE ELECTRON BEAM

When high repetition rate electron bunches go through an SRF cavity, the excited HOMs may accumulate in the cavity, depending on the time interval between the bunches and the decay time of the modes. Considering a long train of electron bunches with the bunch charge of q, equally separated by T in time domain, the HOM voltage at the time t when the Nth bunch has passed through the cavity can be obtained using the superposition principle as [8]

$$\mathrm{V_N}(t) = \sum_{n=0}^{\mathrm{N}} V_q \cos[\omega_0(t-nT)]\, e^{-\frac{t-nT}{T_d}}, \qquad (1)$$

where V_q is the HOM voltage excited by a single bunch, ω_0 and $\mathrm{T_d}$ are the frequency and decay time of the mode, respectively.

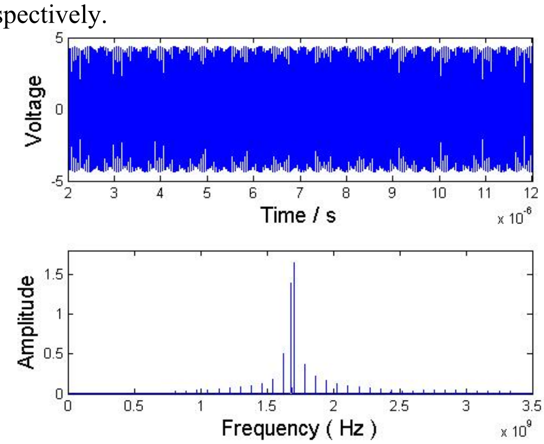

Figure 1: A typical waveform of HOM mode excited by a high repetition rate electron beam (upper) and its spectrum (lower). In the calculation, the repetition rate is assumed to be 81.25 MHz and the HOM frequency is assumed to be 1.685GHz.

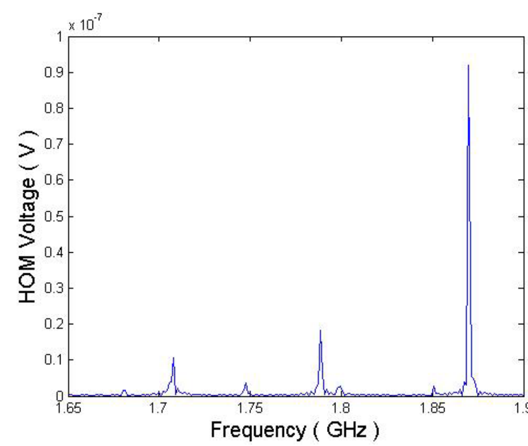

Figure 2: Simulated HOM spectrum, which is excited by a train of bunches at the repetition rate of 81.25MHz.

Figure 1 shows a typical waveform of HOM excited by a high repetition rate electron beam, calculated using Eq. (1), and its spectrum. It can be seen from the figure that the HOM spectrum is rather different to single bunch case [6]. Besides the peak at the HOM eigen frequency (referred to as eigen HOM peaks hereon), many other peaks can be observed at integer multiples of the bunch repetition frequency (referred to as IF peaks hereon).

BEAM COMPRESSION DYNAMICS AND ASSOCIATED MEASUREMENT METHODS IN SUPERCONDUCTING THz SOURCE

ZHOU Zheng, DU Yingchao, HUANG Wenhui
Department of Engineering Physics, Tsinghua University, Beijing 100084, PR China

Abstract

To ensure the quality of high brightness electron beams needed by the terahertz FEL facility at China academy of engineering physics(CAEP),which aims to obtain 100 to 300 terahertz light, a feed-back control system is required to monitor the amplitude and phase jittering by measuring beam arrival time as well as bunch length at the site of the beam position monitor(BPM).

In this paper, we make an idealized model of injector section and deduce analytic expressions of bunch arrival time and bunch length. In consideration of the space charge effect on bunch lengthening, bunch arrival time and bunch length as a function of DC gun voltage, buncher field amplitude and buncher phase is carefully calibrated by means of particle in cell (PIC) simulation. With the time and space resolution of the BPM, the control accuracy of phase is estimated to be 0.01 degree, while the amplitude is 0.04%.

INTRODUCTION

Owing to the challenge of advanced accelerator applications, the control accuracy of amplitude and phase is becoming stricter for control systems, under which circumstance emerges methods of beam-based feed-back control. Two representative examples are the fast feedback installed in Stanford Linear Collider(SLC) using BPM readings and fitted beams parameters to stabilize beams [1]; while a combination of RF and beam based feedback loops used at The Free Electron LASer at Hamburg(FLASH) has achieved regulation of ~10fs rms bunch arrival time jitter [2].

For the THz-FEL facility at CAEP [3], the main goal for the accelerator control systems is to achieve highly precise regulation of relative amplitude and absolute phase jitter below 0.01 % (rms) and 0.01 degrees (rms).

KINEMATIC MODEL WITHOUT SPACE CHARGE

In THz-FEL, the electron bunch has a length of ~30ps at the exit of the DC gun, and needs a bunching process through the downstream buncher to reach ~10ps length before entering the superconducting accelerating cavity. The BPM located close to the entrance of the accelerating cavity is used for beam position measurement. Here an ideal kinematic model without space charge is utilized to deduce analytical expressions of bunch arrival time and bunch length (compression ratio) at the site of BPM.

Arrival Time Jitter

In the FEL facility, the arrival time of electron bunch at the site of downstream BPM is effected by several factors, such as the voltage of the photocathode DC electron gun, the electric field amplitude of the buncher and working phase of the bucnher. When DC voltage, buncher amplitude and phase have a small perturbation, the consequent arrival time jitter can be decided by means of perturbation. As the perturbation of above mentioned factors is quite small compared to the set value, means of perturbation is used to find the linear relation between the arrival time and perturbation. Given parameters of the FEL facility, the linear relation between arrival time jitter and above-mentioned factors in shown by Equ. (1) to Equ. (3).

$$\Delta t\,(\mathrm{ps}) = -0.78\Delta V_0(kV)\ . \tag{1}$$

$$\Delta t\,(\mathrm{ps}) = -3.6\Delta\phi(\mathrm{deg})\ . \tag{2}$$

$$\Delta t\,(\mathrm{ps}) = 0\cdot\Delta V_b(kV)\ . \tag{3}$$

Here, V_0 is DC gun voltage, φ is the phase of the buncher, V_b is the gap voltage of buncher.

A Space Charge Tracking Algorithm (ASTRA) code is used to simulate the arrival time jitter versus DC gun voltage and phase of the buncher to check validity of the kinematic model. The result is shown in Fig. 1 ,Fig. 2 and Table 1.

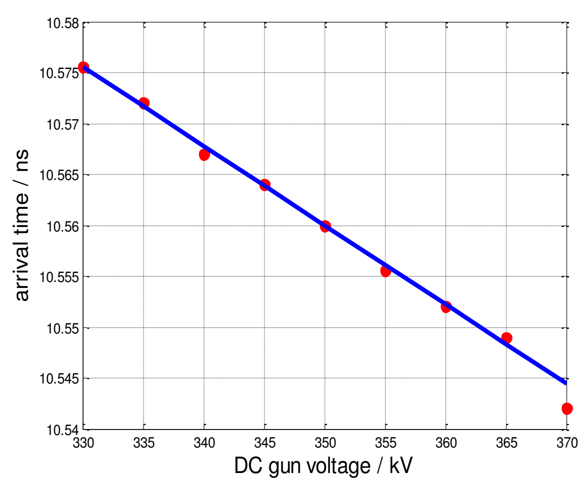

Figure 1: arrival time vs DC gun voltage.

Here, the red dot is the result of ASTRA simulation, while the blue line is theoretical result obtained from Equ. (1), and the same setting is used in following figures.

STUDY OF DIAMOND DETECTOR APPLICATION AT THE FRONT END OF A HIGH INTENSITY HADRON ACCELERATOR*

Guangyi Ren, Yuxiong Li, Weimin Li#, Duohui He, National Synchrotron Radiation Laboratory, University of Science and Technology of China, HeFei, AnHui 230029 China
Ming Zeng, Department of Engineering Physics, Tsinghua University, Beijing, 100084, China

Abstract

Diamond detectors function as beam loss or luminosity monitors for high energy accelerators, such as LHC, Babar, etc. Because of regular detectors insufficient protection of the front end, diamond detectors owning significant characteristics, like time resolution in the nanosecond range, radiation hardness and negligible temperature dependence. Thus, diamond detectors have been becoming promising candidates for detecting BLMs of fully super-conducting hadron accelerator, such as C-ADS, FRIB. In this paper, the sensitivity of diamond detectors was simulated by Monte Carlo program FLUKA and GEAN4. Meanwhile, we tested the performance of a new prototype of CVD diamond detector, and compared it with Si-PIN and Bergoz detectors at the storage ring of the HLS II. The results of the diamond detector were consistent with other two detectors well. More evaluation of diamond detectors in low energy radiation field are ongoing.

INTRODUCTION

Beam loss monitors (BLMs) are common devices usedin hadron and lepton accelerators. Depending on accelerator specifies, BLMs could be just diagnostics or could play an essential role in the machine protection system (MPS). Beam loss control is one of the bottlenecks for beam power increasing for high intensity machine. Some new hadron accelerators, like the Chinese Accelerator-Driven System (C-ADS) and the Facility for Rare Isotope Beams (FRIB), are full superconducting accelerator[1][2]. The sc cavity is more sensitive to beam loss than roomtem perature accelerating section. Thus, it's necessary to provide a high level beam loss monitor system. A widely accepted rule of thumb is to limit the beam loss to 1 W/m to keep the radioactivation levels low enough for hands-on maintenance. As beam powers grow ever higher, the corresponding fraction of the allowable beam loss necessarily becomes smaller and thus more challenging.

There are some ordinary BLM detectors such as Bergoz in NSRL and ionization chamber in SNS[3]. The Bergoz detector is based on Si-PIN sensor, in many similar applications, the Si-PIN BLM detector encountered the radiation damage problem and had limited lifetime[4]. That's why the Si-PIN sensor is not enough for a high intensity accelerator. In SNS, The ionization chamber (IC) is the main detector type in the BLM system due to its simple design and immunity to radiation damage. The biggest problem is significant background from the X-ray radiation produced by the RF cavities. And it's not sensitive enough at lower energy. Thus, it's necessary to design new type BLM detector to meet the high intensity hadron accelerator at the low energy section.

RADIATION FIELD SIMULATION

High Intensity Hadron Accelerator

Different from the room temperature accelerating section at the front-end of SNS or J-PARC, C-ADS or FRIB will accelerate the heavy ion by sc section from RFQ. In this paper, radiation field caused by beam loss of C-ADS injector will be fully discussed as a representative of new type accelerator.

Injector II, as a possible front-end of C-ADS linear accelerator, consisting of an ECR ion source, a 2.1 MeV room temperature RFQ and superconducting half wave resonator (HWR) cavities[5]. The sc accelerating section will stimulate the proton from 2.1MeV to 10 MeV. Figure 1 depicts the sc HWR cavity and the FLUKA simulation model. In the sc HWR cavity, the white structure is niobium cavity and the green one is titanium as insulation and support. Liquid helium fill the gap between niobium and titanium to keep low temperature.

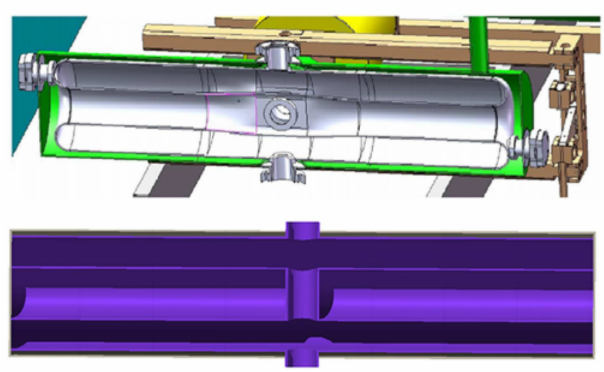

Figure 1: The upper one is the left view of HWR cavity and the lower one is the top view of FLUKA model.

Analyze of the Simulation

The secondary particles that hit the BLM detector may be electron, photon and neutron. Thay come from three mechanisms: prime proton loss, field emission and delayed process by activated materials. The sc accelerator

PRECISE POSITION MEASUREMENT BY ANALYZING THE CORRELATION BETWEEN ELECTRODES OF A SINGLE BPM*

Zhichu Chen†, Longwei Lai, Yongbin Leng‡, Yingbing Yan
Shanghai Synchrotron Radiation Facility, Chinese Academy of Sciences, China
Shanghai Institute of Applied Physics, Chinese Academy of Sciences, China

Abstract

Beam position is one of the most important parameters in a particle accelerator. The more accurate and precise the measurement system is, the more features of the beam dynamics could be revealed. A method called model-independent analysis (MIA) takes advantage of multiple beam position monitors (BPM) on the storage ring to obtain the actual beam positions by removing the random noise of each BPM. Inspired by MIA, the original voltage waveforms obtained from the electrodes of a single BPM can also be decomposed to get the beam position information. This article discusses the results of the experiments and the evaluation of the performance of the BPM at the Shanghai Institute of Applied Physics.

INTRODUCTION

BPMs are commonly used in modern light sources. The calculations and the simulations of the electrodes have already been studied. Although the fabrications are mature, the individual differences in frequency response are inevitable. Nevertheless, the impedance matchings along the cables are difficult. Thus, the original signals from different electrodes are slight different, and these signals have been mixed with parts of their reflected ones. If we still use the traditional signal processing procedures, systematic errors will be introduced in the measurements.

The induced signal from the ith electrode can be written as:

$$V_i(t) = p_i(x) \cdot Q(t) * U_i(t), \tag{1}$$

where $p_i(x)$ is the position factor, $Q(t)$ is the bunch charge distribution factor and $U_i(t)$ is the impulse voltage response. Ideally, the responses $U_i(s)$'s are identical, so the linear approximation of a two-pickup BPM is

$$V_1 \simeq (1 + K_x \cdot x) \cdot K_q \cdot q \cdot U_0, \tag{2}$$
$$V_2 \simeq (1 - K_x \cdot x) \cdot K_q \cdot q \cdot U_0. \tag{3}$$

Thus, the position of the bunch is

$$x \simeq \frac{1}{K_x} \frac{V_1 - V_2}{V_1 + V_2}. \tag{4}$$

Including the response deviations and the random noises, the final signals are

$$V_1 \simeq (1 + K_x \cdot x) \cdot K_q \cdot q \cdot (U_0 + \Delta_1) + N_1, \tag{5}$$
$$V_2 \simeq (1 - K_x \cdot x) \cdot K_q \cdot q \cdot (U_0 + \Delta_2) + N_2. \tag{6}$$

The best linear approximation for the calculated position (higher order terms like $N_1 \cdot N_2$ or $\Delta_1 \cdot N_1$ have also been omitted after the Taylor expansion) will be

$$\begin{aligned}
&\frac{V_1 - V_2}{V_1 + V_2} \\
=&\frac{K_x x K_q q(2U_0 + \Delta_1 + \Delta_2) + K_q q(\Delta_1 - \Delta_2) + N_1 - N_2}{K_q q(2U_0 + \Delta_1 + \Delta_2) + K_x x K_q q(\Delta_1 - \Delta_2) + N_1 + N_2} \\
\simeq& K_x \cdot x \\
&- \frac{K_x^2 x^2 - 1}{2U_0 + \Delta_1 + \Delta_2} \cdot (\Delta_1 - \Delta_2) \\
&+ \frac{K_x \cdot x - 1}{K_q \cdot q \cdot (2U_0 + \Delta_1 + \Delta_2)} \cdot N_1 \\
&+ \frac{K_x \cdot x + 1}{K_q \cdot q \cdot (2U_0 + \Delta_1 + \Delta_2)} \cdot N_2.
\end{aligned} \tag{7}$$

The system resolution can only be improved by removing the last three terms of the r.h.s. of the above equation.

MODE SEPARATION

The area of the envelope of the signal is used in Equation (4) to minimize the influences of the random noise and the lag differences between cables. This method will improve the accuracy of the measurement, but the response differences between electrodes and the reflection in the cable are still there. Since these response deviations, signal reflections and random noises are linearly mixed into the final signal in Equations (5) and (6), a singular value decomposition (SVD) can potentially separate them as different modes. [1,2]

Rather than calculating the integrals of the envelopes of the raw ADC waveforms, We will create a waveform matrix and the SVD of the matrix will give several—as many as the number of electrodes—modes, some of which are, hopefully, unrelated to Δ_1, Δ_2, N_1 or N_2. The spatial vectors of the U_0-related mode(s) will be used to calculate the bunch position.

Since the signals are narrow-banded sine waves, there will be two principal components we're interested in: a $\sin \omega t$ mode and a $\cos \omega t$ mode. The rest modes can all be regarded

AN INTELLIGIENT TRIGGER ABNORMAL BEAM OPERATION MONITORING PROCESSOR AT THE SSRF*

L.W.Lai, Y.B.Leng#, Y.B.Yan, Z.C.Chen
SSRF, SINAP, Shanghai, China

Abstract

An intelligent trigger abnormal beam operation monitoring processor has been designed at the SSRF. By applying digital signal processing algorithms in FPGA, the processor keeps monitoring the beam operation status. It will output a trigger signal and store the turn-by-turn beam position data when abnormal events detected. The abnormal events include injection, beam loss, and abnormal disturbance. This ability makes the processor a powerful tool for abnormal operation causes analysing and machine study.

INTRODUCTION

SSRF beam current was increased from 220mA to 240mA at the end of 2013. Occasionally partial beam loss happened during the current upgrade period. BPM turn-by-turn data around the abnormal operation event is very useful to analyse the possible causes. SSRF has more than 140 Libera DBPM processors distributed around the 20 cells storage ring. Only when external interlock signal is received the DBPM to lock TBT data for analysis. Interlock signal is given only when beam lost completely or the beam orbit out of the preset range, partial beam loss is not included. This character makes Libera DBPM helpless for analysing the possible causes when partial beam loss happened. SSRF plans to increase the current to a higher level, final aim is 300mA. There is a very necessary to have an efficient tool for future current increasing.

SSRF storage ring runs at top-up mode since December 2012. To maintain the current at 240±2 mA, electrons are injected every 10 minutes. The injection disturbance introduced transverse oscillation gives opportunity to monitor the real-time tune value. Tune value is a very important indicator to evaluate the machine status. By applying FFT method on sampled BPM turn-by-turn data during injection, we can get tune value every 10 minutes.

Above applications require a specific DBPM with functions monitoring the ring status, when partial beam loss and injection are detected, it can intelligent triggered to store BPM turn-by-turn data automatically.

DBPM PROCESSOR

SSRF have developed a DBPM processor since 2007 [1, 2], the processor consists of two boards: a mezzanine board with four channels RF conditioning modules and ADCs, a carrier board with an ARM and a FPGA. Signals from four channel BPM pickups are fed into RF conditioning modules on the mezzanine board firstly. Then signals are filtered with band pass filter (Surface Acoustic Wave filter) to centralize in 500MHz with band width of 20MHz. Then the signals are maintained at an appropriate level with attenuators and amplifiers. After the conditioning, signals are sampled with ADCs (16bits, 117MHz) by means of undersampling theory. The digitized signal is processed with FPGA (Xilinx xc5vfx70t) on the carrier board. The implanted distributed control system (EPICS) on the ARM(s3c6410) made it an all-in-one instrument. Figure 1 is the architecture of DBPM processor, Figure 2 is the picture of the processor.

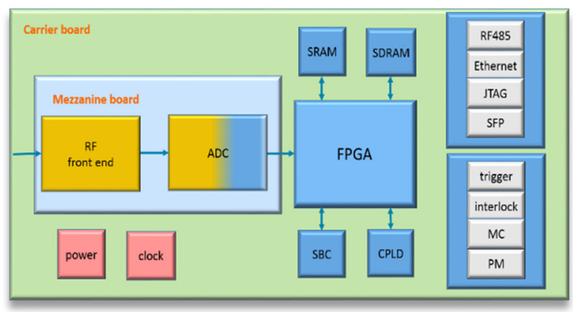

Figure 1: DBPM processor architecture.

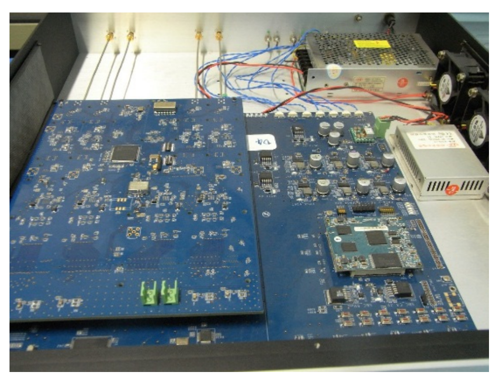

Figure 2: DBPM processor.

By applying FPGA, the DBPM provides different rate beam position data, including 694 kHz turn-by-turn (TBT) data, 50 kHz data, 10 kHz fast application (FA) data and 10 Hz slow acquisition (SA) data. The spatial resolution of TBT data is about one µm. The FPGA's powerful programmable ability enables us implement the abnormal beam operation monitoring function on the DBPM.

MEASUREMENT OF CLOCK JITTER IN BEAM DIAGNOSTIC SYSTEM*

Yong Yang, Yongbin Leng#, Yingbing Yan
Shanghai Institute of Applied Physics (SINAP), CAS, Shanghai 201204, P. R. China

Abstract

Low clock jitter can improve the performance of beam diagnostic system. This paper presents a procedure for the direct measurement of low-level clock jitter. High resolution spectrum analyzer or broadband high sampling rate oscilloscope is not demanded by using this method. Simulation will be introduced.

INTRODUCTION

As the demand for high fidelity sampling of clock frequency in excess of 100MHz continues to increase in beam diagnostic system, the aperture uncertainty (jitter) of the system sampling clock itself is becoming the limiting factor of the achievable SNR of the whole signal-conditioning chain [1]. Numerous methodologies have been proposed and discussed, since jitter performance still is one of the most challenging issues in state-of-the-art sampled systems [2].

The most directed method is using broadband high sampling rate oscilloscope. However, to measure clock jitter less than 20ps, the sampling rate of oscillator must be more than 50Gsps where the effective number bits of the ADC in oscilloscope is more enough. Integrating the phase noise near the central frequency can also obtain the clock jitter if we have a high resolution spectrum analyzer. To measure low-level clock jitter, the dynamic range of spectrum analyzer will be not enough.

Another strategy to measure the clock jitter is through the SNR of the sampling system itself. The simplest and most widely adopted one infers the jitter value from the SNR measurements at high input frequency, where the random deviation σ_T of the occurrence of the sampling edge translates into a random voltage error $\sigma_{Vjitter}$ that dominates the noise deviation σ_V. The retro-fitting is usually accomplished according to the formula:

$$SNR = \frac{P_{in}}{\sigma_V^2} \approx \frac{P_{in}}{\sigma_{Vjitter}^2} = \frac{A_{IN}^2/2}{\sigma_T^2 \frac{(A_{IN}\omega_{IN})^2}{2}} \qquad (1)$$

as applied to a sinusoidal input of amplitude A_{IN} and angular frequency ω_{IN} ($= 2\pi f_{IN}$):

$$V_{IN}(t) = A_{IN}\sin(\omega_{IN} t) \qquad (2)$$

Previous methods of estimating the jitter from the ADC's SNR were hampered by the imperfect knowledge of the real values of thermal noise, random non-linearity contributions, and any additional noise effects entering Eq. (1). Determining a f_{IN} high enough for the formula to be applied was somewhat of an arbitrary process. At very high input frequencies lots of dynamic effects such as substrate noise, signal leakage, complex device behavior, and many more, affect the noise term of the equation thus making the jitter estimation harder.

This paper describes a precise yet easy method of measuring the jitter of a clock. The description of an innovative technique for the determination of the jitter in sampled-input systems is provided. The extraction of the period jitter from the SNR data collected on a 14b 105MSps ADC is then simulated.

CALCULATING JITTER THROUGH INPUT COHERENT SAMPLING

Coherent sampling (or locked-histogram) techniques have been successfully employed in the past in order to estimate clock jitter. However, this paper presents a parametric analysis of the correlation between the jitter and the phase of the input at which noise is measured. The main advantage of the proposed technique is that the measurements obtained from the clock under test are parametrically fitted to the true profile of the jitter in such a system, thus providing for a true numerical solution to the problem. In addition, since the results are fitted to the expected shape of the jitter vs. phase theoretical dependence, the clock jitter can be measured down to levels lower than the ones allowed by the noise floor of the converter.

Jitter Formula Derivation

The theoretical RMS voltage error $\sigma_{Vjitter}$ induced by the clock cycle jitter (defined as the standard deviation of the Gaussian distribution of the periods, σ_T) is calculated through the input slope via the formula:

$$\begin{aligned}\sigma_{Vjitter} &= \sigma_T \cdot \left|\frac{\partial V_{IN}(t)}{\partial t}\right| \\ &= \sigma_T \cdot A_{IN}\omega_{IN} \cdot \left|\cos(\omega_{IN} t)\right| \qquad (3)\end{aligned}$$

Equation (3) quantifies the well-known concept that when an ADC is sampling a sinusoidal input, the contribution of clock jitter is much more pronounced when the sampling instant coincides with the zero crossing of the input, and has very little impact on the output noise when the sampling instant coincides with the top or bottom of the input sinewave.

Figure.1 illustrates this concept: the Gaussian distributions shown on the right represent the histogram of the captured output samples of the ADC, in the two cases described.

BUNCH BY BUNCH DBPM PROCESSOR DEVELOPMENT AND PRELIMINARY EXPERIMENT IN SSRF*

Yongbin Leng#, Zhichu Chen, Longwei Lai, Yingbing Yan, Yong Yang, SSRF, Shanghai, China

Abstract

Digital BPM processor with turn-by-turn capability has been widely used in synchrotron radiation facilities over the world, which is proved to be very useful and powerful for daily operation and linear optics study but not good enough in the case of individual bunch information required. In order to sufficient individual bunch diagnostics requirements a development plan of the next generation DBPM processor with bunch-by-bunch capability has been initiated in SINAP since 2012. The whole development was divided into three steps: a concept processor based on digital oscilloscope IOC, an algorithm prototype processor based on commercial high speed ADC board, and a custom designed dedicated processor. The progress of this work and several preliminary beam experiments will be discussed in this paper.

INTRODUCTION

In order to improve the efficiency and quality of the light, the top-up mode was adopted at the SSRF since the end of 2012, which results more frequent beam injections (about one injection in ten minutes).[1] Since injection process involves a variety of equipments, parameters of all the equipments can not match perfectly with each other during the transient injection process. Any parameter mismatching will lead to a closed orbit distortion, which will leave a residual betatron oscillation after injection. For light source users, this disturbance must be as little as possible. An appropriate analysis and diagnosis tool is needed to provide basis for optimizing the parameters of related equipments.

The turn by turn position data and slow acquisition data acquired by normal DBPM processor can be used to observe the average effect of bunch train disturbance. The excitation current waveform mismatch between kickers and the alignment error of kickers can be studied by using these data. But the disturbance introduced by refilled bunch is hardly analysed using turn by turn data. In this case a new DBPM processor with bunch by bunch capability is required.

On the other hand realizing the measurements of the bunch by bunch position will also help study the beam impedance, coupling instability and nonlinear dynamics quantitatively, and can provide the accelerator physicists with an incredibly powerful machine study tool.

DEVELOPMENT OF BUNCH BY BUNCH DBPM PROCESSOR

The development was divided into three steps: a concept processor based on digital oscilloscope IOC, an algorithm prototype processor based on commercial high speed ADC board, and a custom designed dedicated processor.

Concept Prototype Based on Oscilloscope

A digital oscilloscope embedded EPICS IOC was developed in SSRF to do transverse position measurement at bunch-by-bunch rate.[2] The hardware setup si shown in Fig. 1. Broad band beam signals coupled from four button electrodes, passing through a BPF (central frequency 500MHz, BW 300MHz), are feed into four channels of scope directly. To satisfy bunch-by-bunch analyse requirement an high performance digital oscilloscope, practically Agilent DSO9064A (analogue BW 600MHz, real-time sampling rate 5GHz for 4 channels, and 100M samples per channel on-board buffer), is adopted. Beam signal will be recorded simultaneous at 5GHz sampling rate.

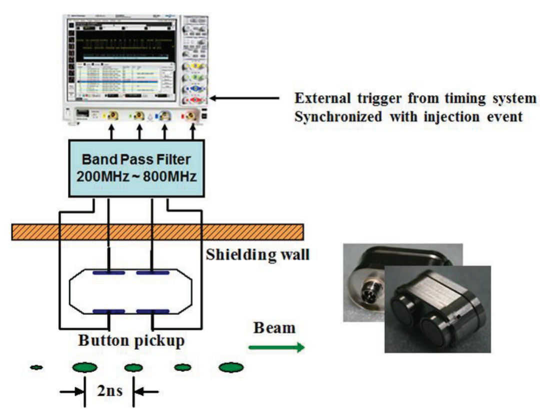

Figure 1: Hardware setup of the concept prototype of bunch-by-bunch processor.

If the sampling rate or its fraction is equal to machine RF frequency (synchronized sampling) the peak value of raw data can be used to calculate bunch charge and bunch position using Δ over Σ method directly. But for SSRF, RF frequency is usually varying between 499.654MHz and 499.674MHz depending on ground temperature. In this case using raw data will introduce a large sampling phase noise due to difference of RF and sampling frequency. A specific data processing method we called "virtual re-sampling" technique is employed to solve this problem. With correct sampling frequency and initial

BEAM DIAGNOSTIC OF THE LINAC FOR THE COMPACT HIGH-PERFORMANCE THz-FEL

T.N. Hu, B. Qin, P. Tan, K.F. Liu, Y.Q. Xiong, J. Yang, Q.S. Chen, W. Chen,
State Key Lab. of AEET, HUST, Wuhan 430074, China
Y.J. Pei#, Z.X. Tang, J. Liu, NSRL, USTC, Hefei 230029, China
Z.M. Wang, Chinagray, Hefei 230088, China

Abstract

With the aim to obtain short-pulse bunches with high peak current for a terahertz radiation source, an FEL-based LINAC is employed in HUST THz-FEL, and the LINAC consists of an EC-ITC RF gun, a disk-loaed waveguide structure with a constant gradient and collinear absorbing loads with focusing coils surrounded and so on. To achieve a balance between compactness and high performance, beam diagnostic system should be simple and high-precision. So that a cost-effective measurement scheme for the high-brightness beam extracted by the LINAC is needed. This paper will describe the beam line and beam diagnostic system of the LINAC in the HUST THz-FEL in detail and give corresponding assembly scheme. In addition, online monitor system is introduced.

BEAM LINE OF THE FEL-BASED LINAC

To achieve a balance of high performance and compact layout for a THz-FEL facility, HUST and USTC are cooperating to construct such a machine and perform corresponding experiment researches. And the facility is under commissioning right now. This facility is mainly composed of a novel EC-ITC RF gun, constant gradient travelling wave structure with a collinear absorbing load and an input coupler which makes the electric field be symmetry, and its focusing coil, beam diagnostics system, microwave power system, vacuum system, control system and so on[1]. The layout and main parameters of the LINAC are given by Fig. 1 and Table 1 respectively, and beam diagnostic equipments are sketched by Fig. 1 either.

Table 1: Main Specifications

Parameter	Unit	Value
Energy	MeV	4-15
Current	A	0.571(Macro pulse)
Width	us	1-5(Macro pulse)
	ps	1-10(Micro pulse)
Energy spread	%	0.2-0.5
Nor. emittance	mm mrad	<15
RF frequency	MHz	2856
Input power	MW	20

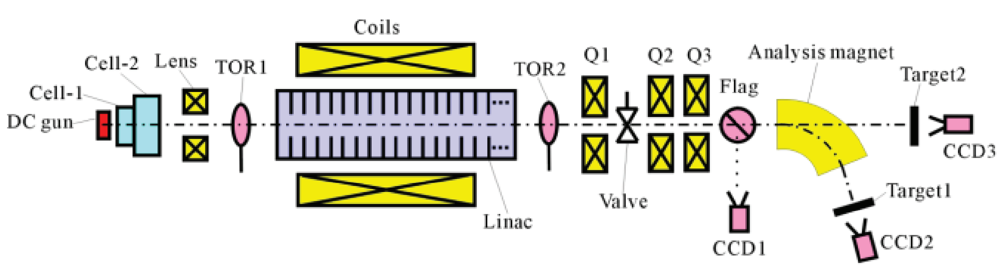

Figure 1: Layout of the HUST THz-FEL LINAC.

As the most important element, the EC-ITC RF gun plays a role of transfer DC beam to short bunches, and determines beam properties of the LINAC such as energy spread, transverse emittance, bunch length. In addition, by using velocity bunching of the standing-wave cavity, this type of gun can realize energy spread self-compensation, so that it helps to achieve the purpose of compressing the facility sizes.

Previous researches shown that, high quality bunches with ~0.3% energy spread, ~10mm mrad emittance, 201pC charge and ~2ps length can be generated by the EC-ITC RF gun[2,3]. However, in the process of dynamic calculations, a 5A DC beam are adopted as the input beam of the EC-ITC RF gun by means of parallel injection. In the actual situation, the DC electron gun has been designed to generate 4A DC beam, and it would be injected to the EC-ITC RF gun by negative angle. To press close to the actual situation, a 4A beam with negative angle is imitated, which can be shown by Fig. 2.

By adjusting power and phase parameters of two cells of the ITC cavities, the optimal results can be obtained. Dynamic results calculated by Parmela are shown in Fig. 3, meanwhile, detailed specifications of the bunches generated by EC-ITC RF gun with negative angle injection are listed in Table 2.

HIGH-CURRENT RFQ DESIGN STUDY ON RAON

Jungbae Bahng, Eun-San Kim#, Kyungpook National University, Daegu 702-701, Korea
Bonghyuk Choi, IBS-RISP, Daejeon 305-811, Korea

Abstract

The Rare isotope Accelerator Of Newness (RAON) heavy ion accelerator has been designed for the Rare Isotope Science Project (RISP). RAON will produce 400 kW continuous wave (CW) heavy-ion beams, from proton beams to uranium beams, to support research in various scientific fields. The RAON system consists of an electron cyclotron resonance (ECR) ion source, low-energy beam transport systems (LEBTs), CW radio frequency quadrupole (RFQ) accelerators, a medium-energy beam transport (MEBT) system, and a superconducting linear accelerator (LINAC). We present the design study of the RFQ accelerator for deuteron beams with energies of 30 keV/u to 1.5 MeV/u and currents meeting the requirement of at least 15 mA at the target. We optimized the normal conducting CW RFQ accelerator, which has a high transmission and low longitudinal emittance. In this paper, we will present the design results of RFQ beam dynamics studies and their 2D and 3D EM analyses.

INTRODUCTION

The Rare isotope Accelerator Of Newness (RAON) heavy ion accelerator has been designed as a facility for the Rare Isotope Science Project (RISP). RAON will produce 400 kW continuous wave (CW) rare-isotope beams, from proton beams to uranium beams, using both the In-Flight Fragment (IF) and Isotope Separation On-Line (ISOL) systems, as shown in Fig. 1. For RISP to accomplish its objective, a high-intensity light-ion beam injector is required. An injector for a relatively light heavy-ion beam consists of a short low-energy beam transport (LEBT) system with two solenoids, radio frequency quadrupole (RFQ) accelerators, and a medium-energy beam transport (MEBT) system. The generated and accelerated ion beam from the high-intensity injector is then transferred to the main MEBT and accelerated by the main linear accelerator (LINAC). For use in the high-intensity injector system of RISP, we studied RFQ accelerators that are designed to accelerate high-intensity deuteron beams from 30 keV/u to 1.5 MeV/u. RFQ accelerators [1] are among the main components that can provide high-intensity beams by strong focusing, adiabatic bunching, and efficient acceleration. Since the main LINAC base frequency was chosen to be 81.25 MHz, we considered RFQ frequencies that are harmonics of this base frequency. To meet the requirement of at least a 15 mA current and achieve an economical structure, the RFQ frequency was chosen to be twice the base frequency, and the beam intensity was chosen to be 40 mA. In this paper, we focus on the beam dynamics and EM structure design of the RFQ.

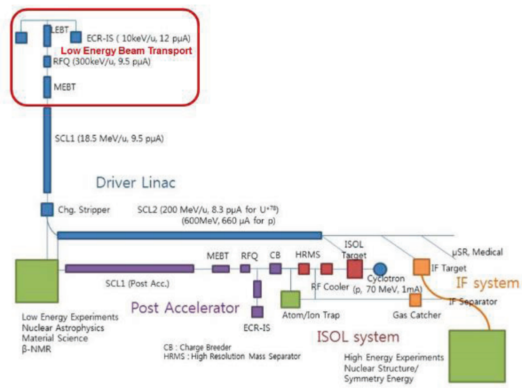

Figure 1: The layout of the RISP.

BEAM DYNAMICS DESIGN

The main RFQ design parameters are shown in Table 1.

Table 1: RAON RFQ Design Parameters

Particle (q/A)	D+ (1/2)
Frequency	162.5 MHz
I/O beam energy	30 keV/u → 1.5 MeV/u
Beam current	40 mA
Vane voltage	65~100 kV
Length	496 cm
Transmission rate	96.44 %
Tr. emittance	0.25 n.r. π mm-mrad
Max Surface Field	20.64MV/m (1.52 kilp.)

The goals of RISP high-intensity RFQ beam dynamics studies are to minimize the RFQ length, beam loss, and emittance growth. The basic objective regarding RFQs is to design beams with acceptable longitudinal bunching at the entrance of the LINAC. PARMTEQM [2] code, which was developed at Los Alamos National Laboratory, is used to generate RFQ parameters. In this study, we considered an RFQ operated at 162.5 MHz and a deuteron beam accelerated to 40 mA. We assumed that the RFQ had a low longitudinal emittance, thus avoiding transverse emittance growth, as well as a high transmission rate and short length. To optimize the RFQ design, we adopted a ramped vane voltage, slowly increased the modulation factor in the radial matching section, simultaneously

INTRODUCTION TO BINP HLS TO MEASURE VERTICAL CHANGES ON PAL-XFEL BUILDINGS AND GROUND*

Hyojin Choi†, Kwang Won Seo, Kyehwan Gil, Seung Hwan Kim, Heung-Sik Kang
Department of Accelerator, PAL-XFEL, Pohang, Korea

Abstract

PAL-XFEL is being installed and will be completed by December of 2015 so that users can be supported beginning in 2016. PAL-XFEL equipment should continuously maintain the bunch beam parameter. To this end, PAL-XFEL equipment has to be kept precisely aligned. As a part of the process for installing PAL-XFEL, a surface geodetic network and the installation of a tunnel measurement network inside buildings is in preparation; additionally, the fiducialization of major equipment is underway. After PAL-XFEL equipment is optimized and aligned, if the ground and buildings go through vertical changes during operation, misalignment of equipment's will cause errors in the electron beam trajectory, which will lead to changes to the beam parameter. For continuous and systemic measurement of vertical changes in buildings and to monitor ground subsidence (sinks) and uplift, the BINP Ultrasonic-type Hydrostatic Levelling System (HLS) is to be installed and operated in all sections of PAL-XFEL for linear accelerator, undulator and beam line. This study will introduce the operation principle, design concept and advantages (self-calibration) of BINP ULS Sensor, and will outline its installation plan and operation plan.

INTRODUCTION

During the construction of the Egypt Pyramids between 2600 and 2480 B.C., water was poured into an animal's gut in order to measure the hydrostatic level and strings were used to measure the wire position in the survey and alignment process. The Hydrostatic Levelling System (HLS) and Wire Position System (WPS) are still in use to format the horizontal axis in construction. The position of an object was measured by the human eye in the past, but these days it is measured by an electrical sensor and the data are analysed by computer - thanks to the advances in electronic equipment [1]. Recent advances in laser technology have made surveying an area of several tens of μm possible by using laser tracker [2]. But in cases where changes of the horizontal axis are measured continuously long-time, HLS and WPS, which are more precision (<1μm) then laser tracker, should be used.

HISTORY OF HLS USED ON THE ACCELERATOR

The HLS was developed by the Alignment and Geodesy (ALGE) group at the European Synchrotron Radiation Facility (ESRF) for long term monitoring and control of rapid realignment of the Storage Ring machine. The concept of the non-contact capacitive sensor developed at the ESRF for the monitoring of level differences in the ESRF storage ring has been considerably improved upon by the company FOGALE-Nanotech. ESRF announced the results of twelve years of experience in HLS operation and measurement [3]. Various types of HLS Sensors, including capacitive and ultrasonic sensors, have been developed and used. European Council for Nuclear Research (CERN) announced the results of the comprehensive testing of HLS Sensor and WPS Sensor in many forms [4]. The status and useful information about HLS and WPS used by many research institutes around the world is available at CLIC Pre-Alignment Workshop and International Workshop on Accelerator Alignment (IWAA).

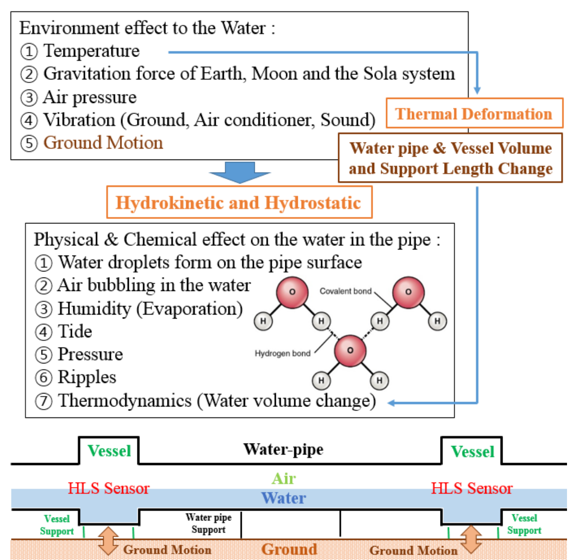

Figure 1: The surrounding environment influencing HLS.

HLS REFERENCE: WATER PIPE

The most important thing about HLS is the water pipe which provides the measurement reference. As shown in Figure 1, water within the water pipe should have good fluidity even with changes in the surrounding environment such as changes in temperature and pressure in order to maintain the constant level of water in the water pipe. It's the only way to calculate the floor deformation accurately using the measurement of all HLS Vessel floors. In terms of the fluid behaviour, after investigating studies about the way of calculating the water pipe diameter which is most appropriate for the length of full-filled and half-filled water pipes and the consequential stabilization time of water oscillation, the

CAPACITIVE LINEAR-CUT BEAM POSITION MONITOR DESIGN FOR ION SYNCHROTRON AT KHIMA PROJECT

Ji-Gwang Hwang *, Tae-Keun Yang, Seon Yeong Noh, Ga Ram Hahn, Won Taek Hwang, Chang Hyeuk Kim, Sang Hoon Nam
Korea Institute of Radiological and Medical Sciences, Seoul, Korea
Eun-San Kim
Kyungpook National University, Daegu, Korea

Abstract

The high precision beam position monitor is required to match and control the beam trajectory for the beam injection and closed orbit in synchrotron. It was also used for measuring the beta function, tune, and chromaticity. Since the bunch length at heavy ion synchrotron is relatively long, a few meters, a boxlike device with long plates of typically 20 cm is used to enhance the signal strength and to get a precise linear dependence with respect to the beam displacement. In this paper, we show the electromagnetic design of the electrode and surroundings to satisfy the resolution of 100 um, the criteria for mechanical aspect to satisfy the position accuracy of 200 um, and the measurement results of linearity by using the wire test bench.

INTRODUCTION

The the Korea Heavy Ion Medical Accelerator(KHIMA) project, a pproton and carbon therapy accelerator based on synchrotron, is currently under construction in Korea [1]. It can provide a low intensity proton and carbon beams with an energy in the range of 110 to 430 MeV/u for carbon beam and in the range of 60 to 230 MeV for proton which corresponds to the water equilibrium beam range of 3.0 to 27.0 g/cm^2 [2].

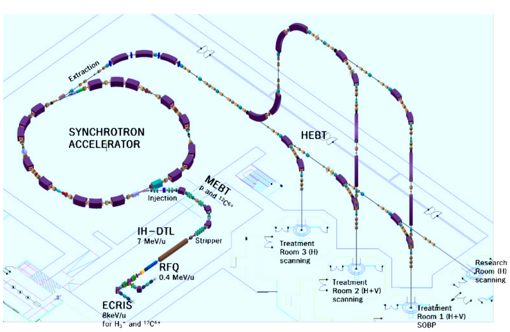

Figure 1: The layout of KHIMA accelerator.

The accelerator consists of the injector with RFQ and IH-DTL linacs, medium beam transport line, synchrotron, and high energy beam transport line. The high precision beam position monitor, which has a position resolution of $\sim$ 100 um, is required to match and control the beam trajectory for the closed orbit in synchrotron.

* hwang@kirams.re.kr

ELECTROMAGNETIC DESIGN

Since the beam intensity after the injection and capturing process in the synchrotron is low, $\sim 7.4^8$ particles for the carbon beams and $\sim 2.07 \times 10^{10}$ for the proton beams [3], the design of the beam position monitor which has the position resolution of 100 um and accuracy of 200 um is critical. The linear-cut beam position monitor was chosen to satisfy this requirements and it has the large linearity range [4]. The linear-cut beam position monitor consists of the two metal electrodes, the body for maintain the structure of the electrode, holders for combining the body with the vacuum chamber, and the vacuum chamber. The transverse and longitudinal dimension of the beam position monitor is limited because it would be installed inside the steering magnet. In order to increase the signal strength, the transverse dimension of the electrode was kept as large as possible within a limited chamber size. The 3D drawing of the designed beam position monitor is shown in Fig. 2.

Figure 2: 3D drawing of the beam position monitor.

Since the cross-talk between two electrodes determines mainly the position resolution of the beam position monitor, the distance between two electrodes is investigated to achieve lower cross-talk value that is shown in Fig. 3.

As shown in Fig. 3, the cross-talk is almost saturated when the distance between the electrodes is larger than 5 mm. Then the distance between the electrodes is determined to be 6 mm to achieve the cross-talk of less than -40 dB within an operation frequency of the beam position monitor from 0.48 MHz to 3 MHz.

The linearity of the beam position monitor is also calcu-

FAST KICKER

V. Gambaryan, A. Starostenko, BINP SB RAS, Novosibirsk, Russia

Abstract

Pulsed deflecting magnet (kicker) project was worked out in BINP (Budker Institute of Nuclear Physics). The kicker design task is: impulsive force value is 1 mT*m, pulse edge is 5 ns, and impulse duration is about 200 ns. The unconventional approach to kicker design was offered. The possibility for set of cylinders using instead of plates using is considered. This approach allows us to reduce the effective plate surface. In this case, we can decrease effects related to induced charges and currents. In the result of modelling optimal construction was developed. It includes 6 cylinders (two sets in threes). Cylinders are 2 mm in cross-section. The magnet aperture is about 5 cm. Integral magnet length is about 1 meter. This length can be obtained by single magnet or by multiplied length of magnets array. Calculated field rise time (about 1.5 ns) satisfies the conditions. Induced current effect reducing idea was confirmed. For configuration with 3 cylinders pair (with cross section of 2 mm) induced current in one cylinder is about 10% and in the wall is about 40%. However for design with plates current is about 40% and 20% respectively. Obtained magnet construction allows controlling of high field homogeneity by changing currents magnitudes in cylinders. In general, we demonstrated the method of field optimization. On the basis of this work has been developed magnet design documentation. The magnet was made in BINP. At present is preparing the stand for magnetic measurements, launched works for the numerical simulation of beam dynamics in CST Studio. *Summary.* Optimal kicker design was obtained. Cylinders using idea was substantiated. Magnet was made.

THE KICKER CONCEPT DESIGN

The kicker design should accept several requirements. The first one is vacuum chamber and kicker symmetry axis coincidences. The second one is that central angel should be about 90˚. The optimisation parameter is magnetic field homogeneity in centrally located square area (2 cm x 2 cm).

GEOMETRY OPTIMIZATION

Computer simulation was carried out for kicker's parameters optimization. Calculations were realised in FEMM and Maxwell. The central angle, the cylinders number and diameter was optimized.

The Number of Cylinders

The initial geometry is shown in Fig. 1a. The cylinders with fixed diameters were placed in the vacuum chamber (with the radius of 7.5 cm) at a distance of 6 cm from its centre. The cylinders number arranges from 4 to 20. For comparison, geometry with plates was simulated (Fig. 1b). For simulating magnetic fields, the task formulated in harmonic analysis was solved on a frequency of 200 MHz. In this task cylinders are parallel connected to a current source. The impressed current in three left cylinders is +1kA, and in three right cylinders is –1kA.

Simulation results allow us to obtain the follow geometry characteristic: field homogeneity, mean value of magnetic field in the centre of the magnet, and magnet impedance.

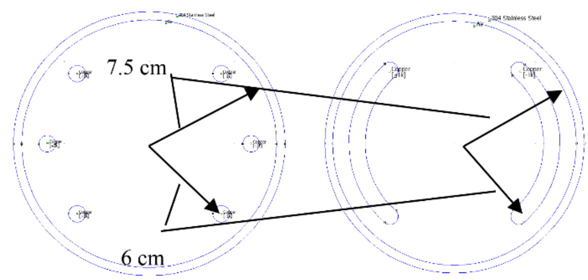

Figure 1: a). Geometry concept, b). Geometry with plates.

Field homogeneity is calculated according to Formula (1):

$$\delta B = \frac{B_{\max} - B_{\min}}{B_{\min}} \cdot 100\% , \quad (1)$$

where B_{max}, B_{min} – magnetic field maximum and minimum values, respectively, determined in centrally located square area (2 cm x 2 cm).

The field homogeneity dependence on the cylinders number is shown in Fig. 2. Here we can see that homogeneity with using 6 cylinders is equal 1%, and it does not dramatically change with the cylinders number increase. However, the increasing number of cylinders leads to a lot of technical problems associated with the vacuum feedthroughs. Thus, we should strive for the minimum number of cylinders.

The mean value of magnetic field is calculated under the same conditions as the field homogeneity. Calculation results are shown in Fig. 3. In this figure we can see that field mean value does not depend on the cylinders number.

Cylinder impedance is calculated according to energy method. To use this method two tasks were solved for the different number of cylinders. The first problem is harmonic magnetic problem. The second problem is electrostatic problem. Energies of magnetic and electric fields can be calculated according to formulas (2) and (3):

$$W_m = \frac{1}{2}\sum I_k \Psi_k , \quad (2)$$

$$W_e = U^2 C , \quad (3)$$

DISTRIBUTED BEAM LOSS MONITOR BASED ON THE CHERENKOV EFFECT IN OPTICAL FIBER

Yu.I. Maltseva*, V.G. Prisekin, BINP SB RAS, Novosibirsk, Russia
F.A. Emanov, BINP SB RAS and NSU, Novosibirsk, Russia
A.V. Petrenko, BINP SB RAS, Novosibirsk, Russia; CERN, Geneva, Switzerland

Abstract

A distributed beam loss monitor based on the Cherenkov effect in optical fiber has been implemented for the VEPP-5 electron and positron linacs and the 510 MeV damping ring at the Budker INP. The monitor operation is based on detection of the Cherenkov radiation generated in optical fiber by means of relativistic particles created in electromagnetic shower after highly relativistic beam particles (electrons or positrons) hit the vacuum pipe. The main advantage of the distributed monitor compared to local ones is that a long optical fiber section can be used instead of a large number of local beam loss monitors. In our experiments the Cherenkov light was detected by photomultiplier tube (PMT). Timing of PMT signal gives the location of the beam loss. In the experiment with 20 m long optical fiber we achieved 3 m spatial resolution. To improve spatial resolution optimization and selection process of optical fiber and PMT are needed and according to our theoretical estimations 0.5 m spatial resolution can be achieved. We also suggest similar techniques for detection of electron (or positron) losses due to Touschek effect in storage rings.

INTRODUCTION

VEPP-5 Injection Complex [1] now is under commission and will supply BINP RAS colliders with electron and positron beams. The VEPP-5 Injection Complex consists of 270 MeV driving electron linac, 510 MeV positron linac and dumping ring. In order to control beam losses along beamline during the Complex commissioning and operation we proposed to use a distributed beam loss monitor based on the Cherenkov effect in optical fiber.

This type of beam loss monitor has been developed at several facilities such as FLASH (DESY), SPring-8 (RIKEN/JASRI), CLIC Test Facility (CERN) [2–4]. The monitor overview is given by T. Obina [5].

Compared with other distributed beam loss monitors such as long ionization chamber and scintillating fiber, optical fiber beam loss monitor (OFBLM) has the following advantages: fast response time (< 1 ns) which allows to detect multi-turn beam losses in a storage ring, near zero sensitivity to background signal (mainly gamma radiation) and synchrotron radiation, unlike scintillating fiber. Moreover, optical fiber is insensitive to magnetic field, but it is susceptible to radiation damage (except quartz fiber), which limits fiber lifetime. Another disadvantage of the OFBLM is an issue with its calibration.

* Yu.I.Maltseva@inp.nsk.su

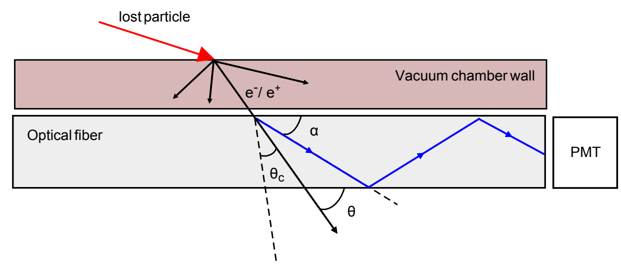

Figure 1: Scheme of beam loss monitor.

PRINCIPLE OF BEAM LOSS MONITOR

The basic idea behind the OFBLM is to detect a burst of the Cherenkov radiation (CR) generated in optical fiber by means of relativistic particles created in electromagnetic shower after highly relativistic beam particles (electrons or positrons) hit the vacuum pipe. Some of the Cherenkov photons propagate through the fiber and can be detected by PMT (Fig. 1). The following physical processes determine the beam loss detection principle of the OFBLM.

Cherenkov Radiation

The Cherenkov radiation is an electromagnetic radiation emitted in a cone around the moving charged particle with cone semi-angle θ_c:

$$\cos\theta_c(\lambda) = \frac{1}{\beta n(\lambda)} \tag{1}$$

where λ – radiation wavelength, β – particle velocity ($\beta = v/c$), n – medium refractive index. Neglecting refractive index dispersion, the number of the Cherenkov photons from a single electron or positron per unit photon energy per unit path length of the particle in a medium is given by:

$$\frac{dN}{d\lambda dx} = \frac{2\pi\alpha \sin^2\theta_c}{\lambda^2} \tag{2}$$

where α is the fine structure constant. According to eq. (2), the greater part of the Cherenkov photons is emitted in the UV range of the spectrum. For relativistic electron passing through plastic optical fiber (n = 1.492) the CR in visible spectrum (400 nm < λ < 700 nm) is generated with 30 photons per mm and emission semi-angle θ_c is about 48°.

Besides the CR, optical transition radiation can be detected by PMT. However, the number of optical transition radiation photons was estimated to be 10^4 times less than the number of the CR photons and thus can be neglected.

RADIATION OF A BUNCH MOVING IN THE PRESENCE OF A BOUNDED PLANAR WIRE STRUCTURE*

Viktor V. Vorobev†, Andrey V. Tyukhtin‡, Sergey N. Galyamin, Aleksandra A. Grigoreva
St. Petersburg State University, St. Petersburg, 198504, Russia

Abstract

Three-dimensional [1, 2] and planar [3] periodic structures can be used for non-destructive diagnostics of charged particle bunches. Here we consider a semi-infinite planar structure comprised of thin conducting parallel wires. If the period of the structure is much less than the typical wavelength of the electromagnetic field, then the structure's influence can be described with help of the averaged boundary conditions [4]. We study radiation of a charged particle bunch with small transversal size and arbitrary longitudinal one in two cases: (i) the bunch moves orthogonally to the grid at some distance from the edge (Fig. 1) and (ii) it moves along the edge of the grid (Fig. 2). The problems are solved analytically. In both cases the bunch generates a surface wave which contains the information about the size of the bunch. The shape of the surface waves is similar to the radiation generated in the presence of 3D periodical wire structures [1], however planar structure is simpler for use in accelerating system. Some typical numerical results for bunches of various shapes are given.

PASSING BY THE GRID

Firstly we consider a bunch moving orthogonally to the semi-infinite wire grid at some distance from the edge (Fig. 1). It is assumed that the bunch has an infinitesimal transverse size and an arbitrary constant longitudinal charge distribution profile $\eta(\zeta)$. Current density has form

$$\rho_q(\vec{r}, t) = \delta(x + a_0)\,\delta(y)\,\eta(z - vt). \qquad (1)$$

We solve the problem in a long-wave approximation (i.e. $\lambda \gg a$). Such approximation allows us using averaged boundary condition (ABC) technique [4], which was applied for consideration of analogous problems earlier [3, 5]. The ABC are used to set electromagnetic boundary conditions in semi-plane $z = 0$, $x > 0$ (i.e. occupied by wires).

Thus, we get the problem of diffraction of the incident field of the bunch on the semi-infinite screen with specific boundary conditions. Then we use Wiener-Hopf technique [6] in order to acquire a strict analytical solution. The field of radiation has two parts: volume radiation and the surface wave. The spectral angular density of volume radiation in spherical coordinates system has the following form

$$w^v_\omega = \left(1 - \sin^2\theta\cos^2\varphi\right) cR^2 k_0^2 |A^v_{x\omega}|^2, \qquad (2)$$

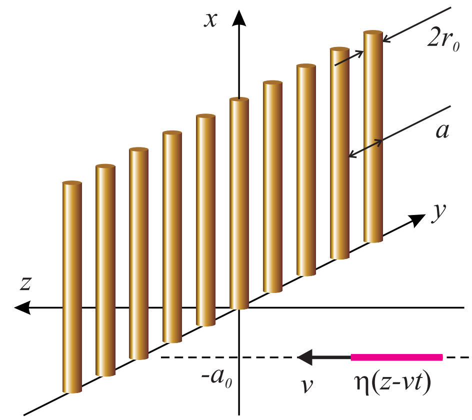

Figure 1: Bunch passing by the edge of a a grid structure.

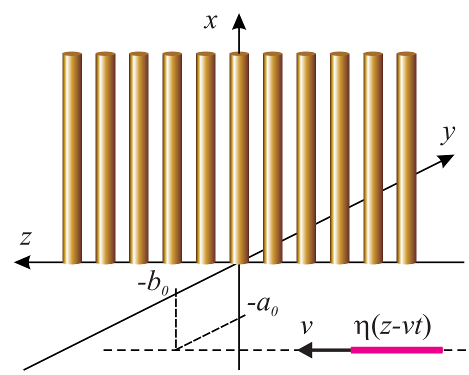

Figure 2: Bunch moving along the edge of a grid structure.

$$A^v_{x\omega} = \frac{\tilde{\eta}(\omega/v)}{\tilde{\kappa} c\beta} \frac{e^{ik_0R}}{R} \frac{\left(k_0 + \hat{k}_{x0}\right)^{-1}}{\tilde{G}_+\left(\hat{k}_{x0}, k_0\sin\theta\sin\varphi\right)} \times$$
$$\times \frac{\left(k_0\sin\theta\cos\varphi - \hat{k}_{x0}\right)^{-1}(1 - \sin\theta\cos\varphi)^{-1}}{\tilde{G}_-\left(k_0\sin\theta\cos\varphi, k_0\sin\theta\sin\varphi\right)}, \qquad (3)$$

$$\{x = R\sin\theta\cos\varphi,\ y = R\sin\theta\sin\varphi,\ z = R\cos\theta\},$$

where $k_0 = \omega/c$, $\hat{k}_{x0} = ik_0/\beta\sqrt{1 - \beta^2 + \beta^2\sin^2\theta\sin^2\varphi}$, $\tilde{\eta}(\xi)$ is a Fourier transform of bunch profile,

$$\tilde{G}_\pm\left(k_x, k_y\right) = \exp\left\{\ln\sqrt{\frac{\sin\sigma \pm \sin\tau}{1 \pm \sin\tau}} \pm \frac{1}{2\pi}\int_{\tau\pm\sigma\mp\pi}^{\tau\mp\sigma} \frac{t\,dt}{\sin t}\right\},$$

$$\tau = \arcsin\left(k_x / w_0(k_y)\right),\quad \sigma = \arccos\left(i / \left(\tilde{\kappa} w_0(k_y)\right)\right).$$

Here $-\pi < \operatorname{Re}\tau < \pi$, $\operatorname{sgn}\operatorname{Im}\tau = -\operatorname{sgn}\operatorname{Re}\tau$, $0 < \operatorname{Re}\sigma < \pi$, $w_0(k_y) = \sqrt{k_0^2 - k_y^2}$, $\tilde{\kappa} = \kappa/k_0 = \frac{a}{\pi}\ln\frac{a}{2\pi r_0}$.

NSLS-II DIGITAL RF CONTROLLER LOGIC AND APPLICATIONS*

B. Holub†, F. Gao, J. Kulpin, C. Marques, J. Oliva, J. Rose, N. Towne
NSLS-II, BNL, Upton, NY 11973 U.S.A.

Abstract

The National Synchrotron Light Source II (NSLS-II) accelerator consists of the Storage Ring, the Booster Ring and Linac along with their associated cavities. Given the number, types and variety of functions of these cavities, we sought to limit the logic development effort by reuse of parameterized code on one hardware platform. Currently there are six controllers installed in the NSLS-II system. There are two in the Storage ring, two in the Booster ring, one in the Linac and one in the Master Oscillator Distribution system.

INTRODUCTION

The NSLS-II accelerator consists of the Storage ring, the Booster ring and Linac along with their associated cavities. NSLS-II is committed to the use of digital RF controllers for controlling these cavities. The first generation of the digital RF controller was designed and built at Brookhaven National Laboratory (BNL) and successfully tested at the Canadian Light Source (CLS) [1]. Since that time a second generation controller was built that takes the original hardware, firmware and software and expands on their previous capabilities to make the controller versatile enough to be fielded into multiple NSLS-II subsystems (i.e., Storage ring, Booster ring, etc.). Some of the modifications made in the newest revision of the controller will be briefly described along with examples of its different uses and functions.

HARDWARE MODIFICATIONS

Figure 1 is the block diagram of the latest version of the controller showing its functionality. An explanation of the theory of operation will not be given in this paper as it has been written about in earlier publications [1], [2]. The main attributes of the hardware from the initial design are largely unchanged in this version but there are significant differences in terms of I/O and diagnostic capabilities. See Table 1 for a comparison of I/O capabilities between the original controller and the latest revision. As can be seen in Table 1 there is an increase in the number of opto-isolated and TTL inputs. The increase in inputs gives us the ability to handle more interlock triggers as well as more timing triggers going forward. Additionally, there is a small increase in the number of diagnostic LED indicators. In the latest version, the indicator LEDs are much more flexible because each is driven by a Field Programmable Gate Array (FPGA) pin instead of fixed signals external to the FPGA. Figure 2 illustrates the layout of the I/O on both the front and rear panels of the controller. The added extra I/O flexibility came at a cost, however, in that a second DAC output channel was eliminated, which was available in the original design. This channel was underutilized and was not imperative to the design. The seven channel slow ADC input circuit was scaled down to six channels. The slow DAC output circuit was removed to make room for an RS-232 channel that is used to control a tuner PLC.

Tuner Logic Addition

Tuner logic was developed in this latest revision to control the Storage ring cavity tuners. Located inside the FPGA, the tuner logic takes as its inputs the cavity field phase, the forward channel phase and a user supplied Phase Offset variable and computes an error signal for each tuner to act upon. This error signal is serialized, averaged and sent via the RS232 channel from the controller to the tuner PLC that then controls the tuner motors and moves them to drive that error signal to zero.

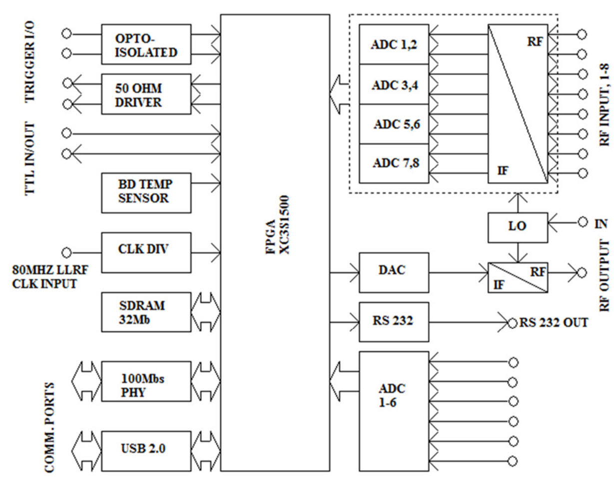

Figure 1: Functional diagram of the revised cavity field controller.

Table 1: Comparison of I/O

I/O Type	Original Rev	Latest Rev

COMPACT SINGLE PASS BPM

M. Znidarcic, E. Janezic, M. Cargnelutti, Instrumentation Technologies, Solkan, Slovenia

Abstract

Monitoring and subsequent optimization of linacs and beam transfers requires specific instrumentation for beam position data acquisition and processing. Spark single pass BPM is the newly developed prototype intended for position and charge monitoring in classical single-multi bunch operation linacs and transfer lines. Flexibility of the instrument enables the installation on electron and proton single pass machines. The motivation, processing principles and first results are presented.

INTRODUCTION

In this paper we introduce a compact platform that aims to host a wide range of applications. First instruments built on this platform will be Spark EL and Spark HL (see Fig. 1). The instruments will be designed for processing of electron beams (Spark EL) and proton beams (Spark HL) in linear accelerators and beam transfers.

Figure 1: Libera Spark front/back panel.

A NEW PLATFORM

Looking at the beam instrumentation used to monitor and stabilize an accelerator, every device suits a specific role, but it is possible to identify some key components that are always present:

- RF front-end and analogue signal processing chains
- Internal communication buses
- Power supply unit
- Cooling system

In this new development, we take advantage of the latest advances in SoC technology to introduce a compact platform that combines a high level of hardware integration with our knowledge regarding reconfigurable analogue signal processing.

HW and SW Integration

Hardware and software are designed taking in account the balance between generality and optimization. It will be always possible to add specific features to customize it, opening at the same time the way for developing different applications, as shown in Fig. 2.

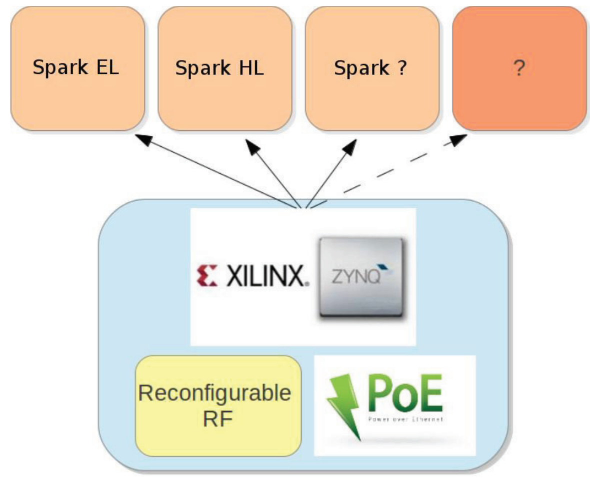

Figure 2: Platform concept based on SoC.

The core part is the SoC Xilinix Zynq 7020 [1] which combines the high-speed processing of the FPGA together with the flexibility of a CPU, all within the same chip. The inner communication between the two entities and the chance to share the same memory removes at the same time two of the biggest bottle-necks that still characterize separate-chip solutions:

- No communication protocols needed
- No data copy between FPGA and CPU.

The specifics of the analogue front-end will cover the user requirements. Integrations with specific band-pass filters, phase-locked-loop (PLL) and variable attenuators are possible if the application requires them. Fig. 2 shows an example of the HW architecture of a BPM application.

Low Power Instrument

SoC requires less power than a multiple-board solution. Furthermore proper selection of the RF components (amplifiers, analog-to-digital converters, etc.) reduces the amount of heat that the cooling system has to treat. This enables the way towards passive cooling with the integration of the heat sink in the crate. Consequently fans are no longer needed, and from the system point of view, the main advantages are:

- No moving parts means no maintenance required
- Fans-induced noise is no longer present on the signals
- Less space and less power required from the system.

With the low power requirement, precisely less than 15 Watt, the system can be powered over Ethernet according to the PoE standard IEEE802.3af. In the case of accelerator applications, if the unit is powered over Ethernet, it is possible to put it closer to the machine (e.g.

HADRON BPM FOR THE FAIR PROJECT

M. Znidarcic, E. Janezic, P. Leban, Instrumentation Technologies, Solkan, Slovenia, K. Lang, GSI, Darmstadt, Germany

Abstract

The accelerators of the Facility for Anti-proton and Ion Research are designed to deliver stable and rare isotope beams covering a huge range of intensities and beam energies. FAIR will employ heavy ion synchrotrons for highest intensities, anti-proton and rare isotope production stations, high resolution separators and several storage rings where beam cooling can be applied. Instrumentation Technologies will develop and deliver a beam diagnostic system for SIS-100, HESR and CR rings. Furthermore the beam transfers will be equipped with the beam position diagnostics. The project is on schedule and the first instrument prototypes are already being under evaluation. This article discusses the new BPM electronics concept, the tests performed in the laboratory and the performance obtained.

INTRODUCTION

Almost ten years ago, twelve Libera BPMs were delivered to GSI. At that time the purpose was building the full diagnostic system for existing SIS-18 accelerator; Instrumentation Technologies provided the hardware with data storage while GSI built advanced Digital Signal Processing.

The UNILAC and the SIS 18-ring of the existing facility (blue) [1] will serve as injectors for the new facilities of the FAIR complex (red), such as the SIS-100 accelerator ring, the HESR storage ring and the various experimental areas (see Fig. 1).

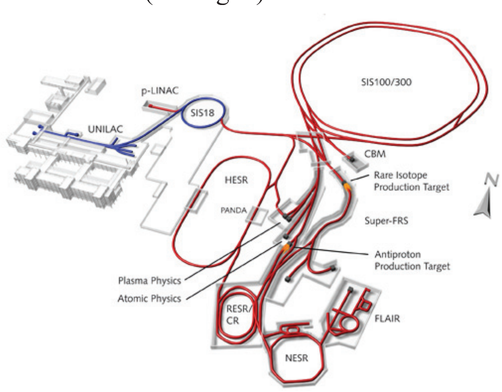

Figure 1: FAIR complex.

With FAIR project a new collaboration between GSI - FAIR and Instrumentation Technologies started. The driver for the new Hadron BPM is large SIS-100 synchrotron machine. Below are listed just some of starting points for building the new BPM system for FAIR project. A high accuracy in the order of 100 µm rms of beam position reading is required for the determination of the closed orbit, fast position readout in bunch-by-bunch manner is mandatory especially in cases when bunch manipulations will be performed, beam position data path has to be available for the closed-orbit feedback system etc.

Successful collaboration between GSI - FAIR and Instrumentation Technologies leaded to a detailed high level design. Excellent specifications and effective Instrumentation Technologies team, made it possible that in less than one year of hard work the first fully functional prototype of Libera Hadron instrument is available.

LIBERA HADRON

Libera Hadron system (see Fig. 2) is based on uTCA modular technologies with IPMI platform management. The system is therefore developed on multiple AMC modules, with each module covering different functionalities.

Figure 2: Libera Hadron.

The user can access the functions implemented in the Libera Hadron unit through a control system interface, called the Measurement and Control Interface (MCI). This interface was developed to facilitate the integration of Libera Hadron into the accelerator's control system software.

DATA PROCESSING

Libera Hadron has a capability of processing signals from shoe-box sensors or capacitive pickups, with various signal intensities, bunch repetition rates and bunch lengths [3]. Three stand alone algorithms are implemented for this purpose:

- Narrow Band analysis: Superheterodyne SDR receiver for processing bunch signals at extremely low bunch charges.
- Bunch-by-bunch for Shoe-box sensors: Bunch detection algorithm with baseline restorer for processing of unipolar signals.
- Bunch-by-bunch for capacitive sensors: Bunch detection algorithm for processing of bipolar pulses.

Libera Hadron provides four main data paths presented on Fig. 3 (raw ADC data, Bunch-by-bunch, Fast Acquisition and Slow Acquisition). Fast Acquisition data is available over SFP connector on the GDX module (optional).

PROTOTYPE RESULTS WITH A COMPLETE BEAM LOSS MONITOR SYSTEM OPTIMIZED FOR SYNCHROTRON LIGHT SOURCES

Kees Bertus Scheidt, ESRF, Grenoble, France
Peter Leban, Instrumentation Technologies, Solkan, Slovenia

Abstract

Beam loss monitors in synchrotron light sources are finding an increasing utility in particular with the trend of numerous light sources pushing to lower emittances and thus higher intra-beam scattering, while operating in top-up injection modes and employing in-vacuum undulators in their rings. The development of an optimized electron BeamLoss Monitor aims at fulfilling, in one single system, all possible functionalities and applications like both the measurement of fast-time-resolved losses at injection and the possibility of ultra-sensitive detection of low & slow electron loss level variations. This optimized beam loss monitor system comprises both the acquisition electronics and up to four sensor head per unit. The sensor heads themselves, that can be configured for different sizes or volumes, are based on the detection of the electromagnetic shower resulting from an electron loss through the use of either Cherenkov radiator or gamma scintillator and a photomultiplier tube, all assembled in a single compact housing ready for installation.

DETECTION PRINCIPLE

The loss of a high energetic electron (i.e. its irreversible departure from the core of the beam) means that initially it will hit the vacuum chamber wall which then starts the creation of a so-called electro-magnetic shower: the initially created particles (electrons & positrons and γ-particles) will themselves create more particles but over a decreasing value of energy. The exact characteristics of this shower like the shape, length, number & type of particles, energy contents etc. depends much on the other obstacles (most often metallic) that the (developing) shower will encounter on its path: in a typical accelerator environment this series of obstacles comprises the vacuum chamber wall, vacuum flanges & pumps, magnet bodies, pipes, cables trays, girders, all kinds of supports and installed systems (valves, insertion devices, cavities) etc. This electro-magnetic shower is generally directed in a forward direction, i.e. in the same direction as that of the initially lost electron. However, each individual electron loss creates its own particular shower which can also have side or even back-scattered effects. Typical beam losses (in a unit of time) imply a significant number of electrons lost at the same location, and it is the sum of all these resulting showers that allows today to simulate and calculate a typical geometric distribution of that electro-magnetic shower (Figure 1).

This shower contains essentially two different types of particles that can be detected: particles with mass (electrons, positrons) and the γ-particles. Both types can be detected by the use of a suitable scintillator or radiator that converts the passage of such high energetic particle into a visible light photon. The detection of a mass-particle can be done with a specific radiator that converts its passage into so-called Cherenkov light, while for the detection of the γ-particles various optimized and highly efficient scintillator materials are available. The choice of the type of detector material depends on various considerations. In both cases, a visible photon is created that now needs itself to be detected, i.e. converted into an electrical signal and then to be recorded.

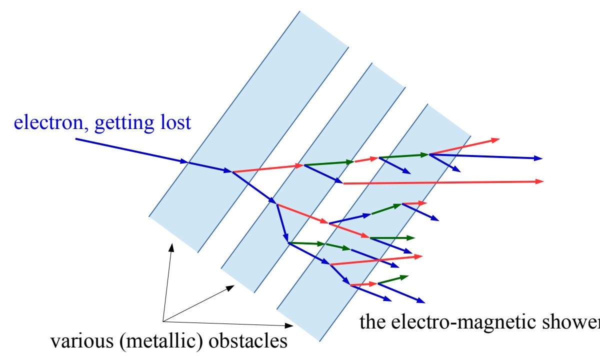

Figure 1: The electro magnetic shower.

The Photo-Multiplier Tube (PMT) will detect the visible light photon at its photo-cathode, and the emitted electron will be amplified inside this PMT and an electric current impulse will be created at its anode. And this anode's output signal will be transported over a cable to the electronics signal acquisition system. The PMT's photo-cathode is optically coupled to the scintillator (or radiator) via its input window. The size (area) of the photo-cathode and that of the scintillator (typically a cylindrical rod) are to be roughly matched so that a large part of the light generated inside this rod is effectively getting to the area of the photo-cathode. Typically diameters of 10 to 25 mm are of practical use.

ALBA LLRF UPGRADES TO IMPROVE BEAM AVAILABILITY

A. Salom, F. Perez, B. Bravo, J. Marcos, CELLS, Barcelona, Spain

Abstract

ALBA is a 3GeV synchrotron light source located in Barcelona and operating with users since May 2012. The RF system of the SR is composed of six cavities, each one powered by combining the power of two 80 kW IOTs through a Cavity Combiner (CaCo). At present, there are several RF interlocks per week. The redundancy given by the six cavities makes possible the survival of the beam after one of these trips. In these cases, the cavity has to be recovered with the circulating beam. An auto-recovery process has been implemented in the digital LLRF system in order to recover the faulty RF plant with circulating beam. But these trips also create perturbations to the beam stability. In order to minimize the beam perturbations induced by these RF interlocks, an additional feed-forward loop has been implemented. The functionally, main parameters and test results of these new algorithms will be presented.

INTRODUCTION

The RF System of the ALBA SR has been designed to provide up to 3.6MV of accelerating voltage and to restore up to 540kW of power to the electron beam [1]. The main parameters of this system are summarized in Table 1.

Table 1: RF/LLRF Specifications of ALBA SR

Frequency	499.654	MHz
No of cavities	6	NC - HOM
RF Power (per cavity)	150	kW
RF Voltage (per cavity)	600	kV
Maximum Beam Current	400	mA
Nominal Beam Current	250	mA
Beam Losses per turn (U_0)	1.1	MeV
Synchrotron Frequency	5 - 9	kHz
Amplifiers type	IOT	
Main DSP of Digital LLRF	IQ mod/demodulation	
LLRF Amplitude stability	0.1	% rms
LLRF Phase stability	0.1	º rms

At present, there are several RF interlocks per week mainly due to internal arcs in the RF amplifiers. The redundancy of the RF system and the present operation of the SR at relatively low current (100mA) make possible the survival of the beam after one of these trips. An auto-recovery process has been implemented in the digital LLRF system in order to recover the faulty RF plant with circulating beam. However, when increasing the beam current in the SR, we have observed that the disturbances induced in the beam due to these RF trips can produce a partial or total beam dump. A feed-forward loop has been also implemented to compensate these perturbations and to increase the reliability of the RF systems

CAVITY AUTORECOVERY WITH BEAM

When there is a RF trip, the stopped cavity absorbs power to the circulating beam, since instants before the interlock that cavity was properly tuned. To avoid this situation, the LLRF detunes the cavity around 500kHz immediately after the interlock is detected. Besides this, the main feedback loops, amplitude and phase, get disabled and the LLRF Drive is set to a minimum level.

After clearing the interlock source, the operator sets the RF plant back into operation while the electron beam is still circulating in the SR. Then, the LLRF moves the plunger back to the position previous to the interlock detection, while keeping the LLRF drive to the minimum level and keeping the feed-back loops disabled. When the original position of the plunger is reached, the tuning loop gets enabled. In order to let the tuning loop adjust the resonance frequency of the cavity, the RF power provided by the amplifier should be high enough to overcome the beam loading effect of the circulating beam, but at the same time, it should be low enough to avoid triggering a reflected power interlock, since the cavity is completely detuned when the plant is set into operation.

After tuning the cavity, the amplitude and phase feed-back loops get enabled and the power is increased smoothly up to the nominal value set by the operator. It is important to notice that when the RF plant is set back to operation, there are no feed-back loops to adjust the phase of the cavity voltage with respect to the beam. In order to ensure the right synchronization between the LLRF drive in open loop and the phase of the beam, a digital phase shifter has been implemented at the output of the LLRF, which compensates any phase delay between the LLRF control output and the measured cavity voltage.

All the parameters for a proper cavity recovery are accessible via the LLRF control system: minimum power, detune frequency, phase delay, so that can be easily adjusted in case of changing the RF or beam conditions.

FEED-FORWARD LOOPS FOR RF TRIP COMPENSATION

Depending on the overvoltage factor of the RF and on the circulating beam current, the voltage disturbance caused by a cavity RF trip can be transparent or may cause a partial or total beam dump. The first step to compensate the perturbations caused by a RF trip is to proper characterize these disturbances.

UPDATE ON THE DEVELOPMENT OF THE NEW ELECTRONIC INSTRUMENTATION FOR THE LIPAc/IFMIF BEAM POSITION MONITORS*

Angel Guirao†, David Jimenez-Rey, Luis Miguel Martinez Fresno, Eduardo Molina Marinas, Joaquin Molla, Ivan Podadera, CIEMAT, Madrid, Spain
Ignacio Rivera, UCM/CIEMAT, Madrid, Spain

Abstract

Among all the LIPAc/IFMIF accelerator diagnostics instrumentation, the Beam Position Monitors (BPM's) are a cornerstone for its operation. An electronics system centered on self-calibration and extraction of beam phase information for Time-Of-Flight measurement is proposed for the twenty BPM stations distributed along the accelerator. The system under development is a fully digital instrumentation which incorporates automatic calibration of the monitors' signals and allows monitoring of both fundamental and second signal harmonics. The current state of the development and first experimental results of the system on the test bench will be presented.

INTRODUCTION

The team of the International Fusion Materials Irradiation Facility (IFMIF) prepares the installation and operation of the Linear Prototype Accelerator (LIPAc), which is currently under commissioning in Rokkasho, Japan [1]. An important non-interceptive beam instrumentation for the machine operation is provided by the BPMs diagnostic array system or stations, for beam commissioning and accelerator tuning and operation. It provides to the Central Control System (CCS) the variation of the beam centroid in the transverse plane (position) and the longitudinal plane (phase). A total of 20 BPM stations are distributed on the two transport lines –Medium Energy Beam Transport line (MEBT) and High Energy Beam Transport line (HEBT)-, plus the superconducting accelerating sections (SRF linac) and the essential locations defined by beam dynamic requirements in order to obtain an exhaustive feedback for steering and transporting the beam from the RFQ to the Beam Dump.

However the BPM stations located at the Diagnostics Plate will be committed to carrying out energy measurements inside HEBT as well, and not only beam position, as such information is crucial for the tuning of the cavities and a proper validation and characterization of the output beam in each beam commissioning stage. The energy is measured through phase measurement in order to extract the Time-Of-Flight (TOF) estimation for beam dynamics. In the previous years a series of evaluation on commercial options and a prototype for the electronics based on analog processing were evaluated [2] and the decision to undertake a custom design was promoted.

BEAM POSITION MONITOR ELECTRONICS

The current prototype for the electronic system is based on the CompactPCI (cPCI) architecture. The BPM system is integrated into the EPICS control system of the accelerator facility via Ethernet and the EPICS Channel Access, and the position and phase information is sent to the CCS updated at a rate of 2 Hz approximately. Likewise, it is required to make a database system based on EPICS Channel Access in order to save the most recent position and phase information at a rate of 0.5 Hz [3].

The BPMs requirements during the accelerator operation are summarized in Table 1.

Table 1: Main LIPAc BPM Parameters

Parameter	Value
Beam Parameters	
Beam energy	5 MeV..9 MeV
Beam current	90 mA..126 mA
RF pulse width	200 μs..CW
Duty cycle	0.1 %..100 %
Resolution and precision requirements	
Position resolution	10 μm
Position accuracy (ABS)	100 μm
Phase resolution	0.3 deg
Phase precision (ABS)	2 deg
Signal levels at the Front-End electronics input	
Max. input power	22 dBm
Required Input dynamic range	50 dB

General Layout

The full system is estimated to comprise of two cPCI racks [4], mounting a variety of boards as depicted in Fig. 1.

The current prototype, designed to demonstrate operation and provide service to the Medium Energy transport line (MEBT), sports the following hardware:

- A Central Processing Unit (CPU) running linux flavour CentOS as Operating System (OS) with kernel 2.6, integrated into the IFMIF control system via EPICS.
- Two Nutaq RF Digitizers [5] with 16 ADC channels of 14-bit with a sampling rate of 100 MHz with an

MACHINE PROTECTION SYSTEMS AND THEIR IMPACT ON BEAM AVAILABILITY AND ACCELERATOR RELIABILITY

R. Andersson, A. Nordt, E. Bargalló, European Spallation Source, Lund, Sweden
E. Adli, University of Oslo, Norway

Abstract

Over the last decades, the complexity and performance levels of machine protection have developed. The level of reliability and availability analysis prior to operation differs between facilities, just as the pragmatic changes of the machine protection during operation. This paper studies the experience and development of machine protection for some of the state of the art proton and ion accelerators, and how it relates to reducing damage to and downtime of the machine. The findings are discussed and categorized, with emphasis on proton accelerators. The paper is concluded with some recommendations for a future high power linear proton accelerator.

INTRODUCTION

As the users of previous generations of research accelerators were mainly the actual developers, only the accelerator physicists themselves were concerned by the lack of protection. However, as the concept of user facilities was incorporated in the 70s, research in other fields became dependent on the accelerators performing as designed [1,2]. With this came higher demands on the machines to be more reliable and available [3]. However, even up to today, though the concepts of reliability and availability are targeted at an early stage, the main goal is still to push the beam parameters beyond existing limits. Once this goal is fulfilled, the machine reliability and beam availability receive more attention.

Because of the very high beam powers and energies in current and future accelerators [3–7], the risk of beam-induced damage is significant. In as little as a few microseconds, the energy from a deposited beam could lead to permanent damage or melting of the equipment [8]. For dealing with this, efficient protection systems need to be implemented together with appropriate monitoring. The beam interlock systems (BIS), receiving beam permit signals from the monitors, play a central role in these protection systems. The BIS creates an overall beam permit signal, which defines if beam operation will be continued or inhibited. For hazards not directly related to beam-induced damage, more sophisticated and flexible local protection systems could be implemented, which act between the monitors or sensors and the beam interlock system.

This paper looks into current state of the art proton and ion accelerator facilities and discusses their machine protection (MP) based on analysis prior to operation, pragmatic changes of the MP, and other measures of improvement.

RELIABILITY AND AVAILABILITY

Two figures to measure the performance of a system are reliability and availability, and this paper uses the following definitions [9].

Reliability is the probability of fulfilling the major design function (MDF) of the system, continuously and without interruptions, for a predefined period of time – for example one hour or one day. Mathematically, reliability is defined as $R(t) = e^{-\lambda t}$, where λ is the failure rate and t the predefined time period.

Availability is the probability to find the machine fulfilling its MDF, when it is claimed to be in operation. Mathematically, and after an extended period of operation (years), the availability can be calculated as $A(t) = 1 - MTBF/(MTBF + MDT)$, where $MTBF$ is mean time between failures and MDT is the mean downtime.

For user facilities especially, where the users are dependent on the accelerator operating as it should, those two figures of merit account to a large extent for the user satisfaction of the facility, and the aim for MP should be to have those numbers optimized.

STORAGE RINGS AND LINACS

The typical solution for MP to avoid beam-induced damage is to stop beam operation. Synchrotrons, such as the Large Hadron Collider (LHC), have the entire beam stored in its storage ring. The only option for protection in case of a hazardous fault is to extract and dump the beam, and then restart the injection and acceleration process [10]. This generally leads to low availability numbers, as much of the operational time is needed to inject and accelerate the beam up to nominal energy [11]. Therefore, the MP reliability has to be very high in order to avoid false dumping procedures.

Linacs, such as the superconducting linac at the Spallation Neutron Source (SNS), tend to aim for high average power, meaning a constant delivery of beam pulses without major interruptions. The advantage of such pulsed machines is, if an error occurs, the ability to 'skip' individual or groups of pulses or run in a degraded mode, e.g. at lower beam current or lower repetition rates. When the problem has been resolved, operation can continue as before. For this reason, high-power linacs tend to achieve higher beam availabilities than high-energy proton and ion storage rings. However, putting this simple idea into practice needs an advanced strategy for MP.

Comparing the two types of machines gives that storage rings tend to have a stronger connection between accelerator reliability and beam availability, due to the inevitable downtime associated with each beam dump.

ESS RELIABILITY AND AVAILABILITY APPROACH

E. Bargalló, R. Andersson, A. Nordt, A. De Isusi, E. Pitcher, K.H. Andersen, ESS, Lund, Sweden

Abstract

Reliability and availability are key metrics for achieving the scientific vision of the European Spallation Source, ESS in Lund/Sweden. The approach taken to define the requirements and to analyze and improve these metrics is described in this contribution.

This paper describes the basis for ESS reliability and availability requirements. It describes where the requirements come from and how they are allocated among the subsystems. It puts the operation, users and the different subsystems' behavior in context, in order to provide a coherent framework to develop the RAMI* analyses for each ESS subsystem. The requirements shown here are not yet finalized and may change in the future; however, they are considered to be the base for the RAMI studies.

INTRODUCTION

ESS is a neutron source facility that will serve the scientific community by delivering spallation neutrons to a suite of scientific instruments where scientific users will be able to perform neutron scattering experiments. ESS will consist of a 5MW accelerator that accelerates protons to 2GeV, a rotating tungsten target where the spallation process takes place and the instruments where the users perform the experiments [1]. From a user perspective, the reliability and availability of the neutron beam and the neutron scattering instruments are key performance aspects of the ESS facility. High reliability and availability will ensure the execution of scientific experiments.

The methodology used to obtain the requirements considers not only the availability and reliability figures but also the specific needs extracted from user expectations of the neutron source in order to successfully perform their experiments. A top-down requirements allocation is being developed at the same time that bottom-up analyses are being undertaken. The experiments expected at ESS and their needs in terms of neutron beam performance (reliability, availability and quality) are described, as well as the tools used to analyze them. This contribution is the first step for these studies at ESS.

ESS RELIABILITY AND AVAILABILITY REQUIREMENTS

ESS requirements have been divided into Neutron Source and NSS (Neutron Scattering Systems) requirements. The Neutron Source includes all systems that contribute to the neutron beam production: Accelerator, Target, Integrated Controls System (ICS) and Site Infrastructure (SI) (only the conventional subsystems that could affect the neutron beam production). NSS include the Instrument Systems (including Guide Bunker & Monolith Shroud), Science Support Systems (SSS) and the part of SI that supplies to the NSS subsystems.

The work presented here is related to the neutron beam requirements.

Neutron Beam Needs for the Users

It was decided that the main goal for ESS is that "*At least 90% of the users should receive a neutron beam that will allow them to execute the full scope of their experiments*". Following this goal, the different kinds of experiments and their needs in order to execute their full scope were studied.

There will be two kinds of experiments: the kinetic and the integrated-flux experiments [2]. The kinetic experiments are expected to constitute about 10% of the total number of experiments that will be performed at ESS. For these experiments it is important to have a continuous beam for the duration of the measurement (an experiment is usually composed of several measurements). The duration is typically between a few seconds and several minutes. On the other hand, integrated-flux experiments (90% of the total number of experiments) are not affected by short beam interruptions; however, it is important for them to receive a high integrated neutron flux for the time allocated to them. The integrated neutron flux received by the experiments is directly related to the beam availability and the proton beam power. The duration of these experiments typically goes from one to seven days.

Neutron Beam Requirements to Satisfy the Users

Taking into account the specific needs for the experiments as well as the best practices and the operational flexibility, the following neutron beam requirements were extracted [3]:

Kinetic experiments: *"A reliability of at least 90% should be provided for the duration of the measurement. The measurement will be considered failed when the beam power is reduced to less than 50% of the scheduled power for more than 1/10th of the measurement length".*

Integrated-flux experiments: *"For the duration of the experiment at least 90% of the experiments should have at least 85% of beam availability and on average more than 80% of the scheduled beam power. The beam will be considered unavailable when its power is less than 50% of its scheduled power for more than one minute".*

These requirements were treated in order to obtain useful, traceable and consistent requirements that will be

PERSONNEL SAFETY SYSTEMS FOR THE EUROPEAN SPALLATION SOURCE

S. L. Birch, A. Nordt, D. Paulic
European Spallation Source, ESS, Lund, Sweden

Abstract

Providing and assuring safe conditions for personnel is a key parameter required to operate the European Spallation Source (ESS).

The ESS will be responsible for developing all of the facility personnel safety related systems. All of these systems will be developed by the Integrated Control Systems Division (ICS) and all will be designed, manufactured, commissioned and operated in accordance with the IEC61508 standard, with regard to functional safety for Electrical/Electronic and Programmable Electronic (E/E/PE) safety related systems. This paper describes the ESS Personnel safety system's scope, strategy, initial design requirements, and methodology but also provides an update of the system design progress so far.

INTRODUCTION

In fall 2014 construction of the European Spallation Source (ESS) in Lund, Sweden started. The facility will comprise of a 2 GeV, 5 MW proton accelerator, a heavy metal tungsten target and 22 state of the art neutron instruments. The Integrated Control Systems (ICS) division will be responsible for the design, procurement, installation, commissioning and validation of all personnel safety systems at ESS.

PERSONNEL SAFETY SYSTEMS SCOPE

In late 2014 the overall scope of the ESS personnel safety systems was defined and 10 main systems were identified that are required to be commissioned, validated and operational for first beam of the European Spallation Source (ESS) facility in 2019. These systems are:

- The PSS for the on-site Cryogenic module test stand,
- The Accelerator Personnel Safety System,
- The Accelerator Radiation Monitoring System,
- The Accelerator Oxygen Depletion System,
- The Target Personnel Safety System,
- The Target Radiation Monitoring System,
- The Target Hot/Maintenance Cell Personnel Safety System,
- The Neutron Instrument LOKI Personnel Safety System,
- The Neutron Instrument NMX Personnel Safety System,
- The Neutron Instrument ODIN Personnel Safety System.

STANDARDS

IEC61508

As with many facilities within the accelerator research field, consensus has been that the international standard IEC61508-2010 [1] forms best practice for personnel safety systems. This has resulted in the wide adoption of this standard throughout many research facilities in the world. For it's personnel safety systems, ESS will implement the design, manufacture, commissioning, validation and operation in accordance with this standard. The IEC61508 lifecycle that ESS will follow is shown in Figure 1.

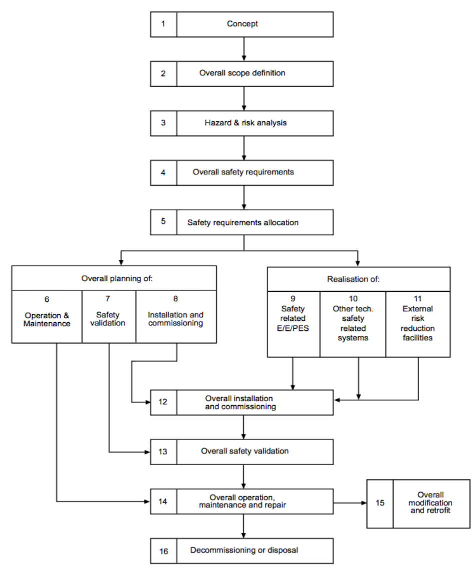

Figure 1: IEC61508 safety lifecycle.

Strålsäkerhetsmyndigheten (SSM) Swedish Radiation Authority

As part of the license application the SSM (the Swedish Radiation Authority) has requested that the ESS Personnel Safety Systems meet:

- SSM2014-127-1 [2]: "Review of application for licence for activity involving ionizing radiation" chapter 10 "review of control systems",
- SSMFS 2008-27 [3]: The Swedish Radiation Authority's "regulations concerning operations at accelerators and with sealed radiation sources".

It is important to point out that the ESS personnel safety systems primarily prevent both the public and workers

ESS COLD LINAC BLM LOCATIONS DETERMINATION

M. Jarosz, A. Jansson, J.C. Kazantzidis, T. Shea, L.Tchelidze, European Spallation Source ESS, Lund, Sweden

Abstract

The linear accelerator of ESS will produce a 5 MW proton beam. Beam of this power must be strictly monitored by a specialized Beam Loss Monitoring (BLM) System to detect any abnormal losses and to ensure that operational losses do not lead to excessive activation. A long series of beam loss simulations was performed using MARS Monte Carlo code system in order to optimize the number and setting mounting locations of the detectors for best coverage, distinguishability and sensitivity. Simulations anticipated multiple possible beam loss scenarios resulting in different loss patterns. The results of energy deposition in air in the linac tunnel in multiple locations were analysed in several different ways. Incorporated methods varied from simple brute force approach to more sophisticated singular value decomposition based algorithms, all resulting in detector layout proposals. Locations selected for BLMs were evaluated for all methods.

INTRODUCTION

The linear accelerator of ESS will produce a 5 MW proton beam. Beam of this power must be strictly monitored by a specialized Beam Loss Monitoring (BLM) System to detect any abnormal losses and to ensure that operational losses do not exceed a limit of 1W/m [1]. CERN-type ionization chamber was chosen as the primary detector for the system [2]. The arrangements of the detectors along the whole machine still need to be fixed. This paper discusses the determination of the locations only in the cold linac.

SIMULATIONS

Different beam loss simulations were performed for four energies from ESS cold linac range, ranging from 220-2000MeV. For all of these energies 10 different possible locations along a pair cryomodule-quadrupole doublet were chosen (Fig. 1). At these locations three points on the beam pipe were treated as possible loss points. Losses were then simulated in MARS Monte Carlo code system [3] for 3 different angles relative to beam pipe wall: 1 mrad, 3 mrad and 1°.

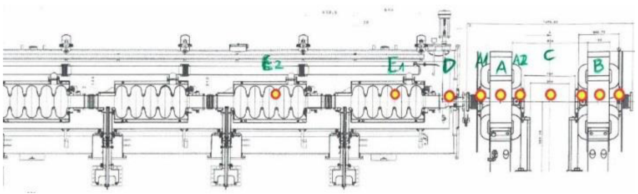

Figure 1: Loss point locations.

At the moment, the power deposited in air around a loss is used as primary indicator for suitable BLM locations as it is proportional to the BLM signal within certain limits. It can be therefore used as a good approximation for ionisation chamber response. For more accurate results, fluxes of various particles will be scored and converted into charge generated by the ionization chamber using the STRAM [4] tool described further in this paper.

MATRIX DESCRIPTION OF THE OPTIMIZATION PROBLEM

BLM's must be placed around the cryomodule-quad assemblies in the way that maximizes or at least optimizes three figures of merit: coverage, sensitivity and distinguishability of various losses. Evaluation in terms of distinguishability determines the number of beam loss scenarios possible to differentiate from each other judging by detector readings. Full coverage means reducing the number of cases which leave no traces in any of the detectors to zero and also equalising the sensitivity of the system to all loss points as much as possible. Maximizing sensitivity allows the detection of the smallest possible loss above noise level. Finally increasing resilience means minimising the loss of coverage due to failure of one or more detectors. This paper mostly focuses on maximization of coverage and distinguishability.

Let matrix M contain data on detector readings in all feasible locations. To make the situation realistic, one must select the number of monitors from the full list having in mind the optimization of coverage, sensitivity and distinguishability of losses. The problem could be described as:

$$d = M * l \tag{1}$$

where d is the vector (of length N_i – number of possible detectors) of detected losses in all possible detectors locations and l is the vector (of length N_j – number of simulated loss points) of losses at considered loss points. The set of loss point cases must be complete in order for the method to work. Excluding relevant loss points will lead to a bias in the result of monitor location selection. M therefore consists of N_j columns (different loss scenarios simulated) and N_i rows (different feasible detectors). At start the problem of finding l knowing d presented in eq. 1 is overdetermined with having more detectors then loss points, thus N_j is much smaller than N_i. By selecting a few monitor locations to place real detectors (reducing N_i to $n_i < N_j$) we introduce the underdetermination of the equation.

Decomposition of the matrix M produces the vector of its singular values. By checking its length one can judge what is the maximum number of loss scenarios that could be distinguished at all, using all feasible detectors. Using more detectors than this number doesn't increase the

MACHINE PROTECTION STRATEGY FOR THE ESS

A. Nordt, T. Korhonen, T. Friedrich, C. Hilbes*, European Spallation Source ESS, Lund, Sweden
*ZHAW, Zurich University of Applied Sciences, Winterthur, Switzerland

Abstract

The ESS proton beam power of 125MW per pulse (5MW average) will be unprecedented and its uncontrolled release could lead to serious damage of equipment within a few microseconds only. To optimize the operational efficiency of the ESS facility allowing for very high beam availability with high reliability towards the end-users, accidents should be avoided and interruptions of beam operation have to be rare and limited to a short time.

Finding the right balance between efficient protection of equipment from damage and high beam availability is the key idea on which the ESS Machine Protection Strategy is being based on. Implementing and realizing the measures needed to provide the correct level of machine protection in case of a complex facility like the ESS, requires a systematic approach, which will be discussed in this paper. A method of how to derive machine protection relevant requirements and how to assure completeness of these will be outlined as well.

THE ROLE OF MACHINE PROTECTION AT THE ESS

ESS is facing high beam availability requirements and is largely relying on custom made, specialized, and expensive equipment for its operation. Damage to this equipment could cause long shutdown periods, inducing high financial losses and, as a main point, interfering with international scientific research programs relying on ESS operation and related beam production. Implementing a fit-for-purpose machine protection concept is one of the key challenges in order to mitigate these risks.

As a user facility for neutron science, overall availability of the ESS needs to be defined from a user point of view. Hence, it should be characterized by the average neutron production during a certain time period. Availability is interpreted as the average proportion of beam production time achieved during scheduled ESS research infrastructure operation time. In general, the availability characteristics of a system are determined by its reliability, maintainability and inspect-ability. The expected operational time between two consecutive corrective or preventive maintenance actions is defined as *mean time between maintenance* (MTBM). The time for diagnostics, corrective and preventive maintenance, logistics, cool down and restart times is defined as *mean down time* (MDT). Then, the operational availability can be described as:

$$\frac{MTBM}{MTBM + MDT}$$

High operational availability is thus achieved by increasing the mean time between maintenance while avoiding large mean down times. A detailed discussion in regard to varying user experiments is presented in [1].

The Machine or the Equipment Under Control (EUC)

In the context of ESS Machine Protection, the term “machine” or *equipment under control* (EUC) encompasses all elements in the Accelerator, Target Station and Neutron Science system segments - all being necessary for neutron beam production and its further use by the neutron science experiments. Figure 1 shows a simplified architectural view of the equipment under control (EUC) and the beam states.

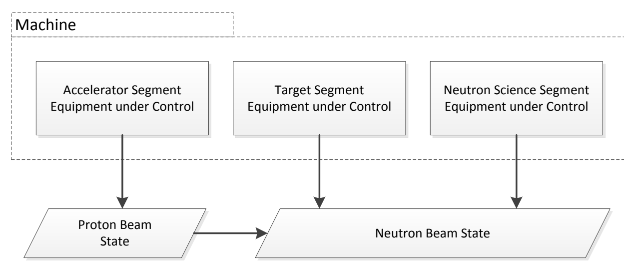

Figure 1: Simplified representation of the “machine”. Equipment under control from the accelerator segment controls the proton beam state. The neutron beam state is controlled by the Target and Neutron Science Segment EUC and is influenced by the proton beam.

Machine Protection Goals

The EUC is exposed to potential damage sources related to proton and neutron beam properties, related radiation, electrical power, vacuum, cooling, RF, etc. The severity of damage is defined with respect to neutron beam quality losses, quality loss duration and resource costs for the recovery of operational capabilities.

The goals for machine protection are defined as follows:

1. Machine protection shall, in that order, prevent and mitigate damage to the machine, be it beam induced or from any other source, in any operating condition and lifecycle phase, in accordance with beam and facility related availability requirements.
2. Machine protection shall protect the machine from unnecessary beam-induced activation having a potential to cause long-term damage to the machine or increase maintenance times, in accordance with beam and facility related availability requirements.

Machine protection is concerned with operational goals of the ESS, that means, enabling neutron science

DESIGN, DEVELOPMENT AND IMPLEMENTATION OF A HIGHLY DEPENDABLE MAGNET POWERING INTERLOCK SYSTEM FOR ESS

M. Zaera-Sanz, A. Nordt, S. Birch, A. Monera, ESS, Lund, Sweden

Abstract

Approximately 350 resistive magnets and 350 power supplies (PS) will be installed in the 600 m long linear accelerator (LINAC) at the European Spallation Source, ESS, transporting the proton beam from the source to the target station. In order to protect this equipment from damage (e.g. due to overheating) and to take the appropriate actions required to minimise recovery time, a dedicated magnet powering interlock system is being designed. The magnet powering interlock system will safely switch off a PS upon the detection of an internal magnet or PS failure and inform the beam interlock system to inhibit further beam operation. The different failure modes and related mitigation techniques of magnets and their PS will be presented. Failures of the magnet cooling system can be detected for example by interlocking the opening of a thermo-switch or a flow-switch. To achieve the required level of dependability, an interlock system based on safety Programmable Logic Controller (PLC) technology, distributed safety PLC software programming tools, PROFINET fieldbus networking, and current loops for hardwired interlock signal exchanges, has been prototyped and will be discussed.

INTRODUCTION AND REQUIREMENTS

The scope of the magnet powering interlock system is to protect the magnet system from damage in case of a failure in the cooling or powering systems, and to take the appropriate action(s) to minimize time for recovery.

Due to the complexity and requirements of flexibility (not all the powering failures require a stop of beam operation), the magnet powering interlock provides local protection to the magnets and interfaces with the beam interlock system.

To protect the magnets from overheating, a set of normally closed thermoswitches are installed in the magnets and they open as soon as the temperature reaches the threshold level (typically 65ºC). A set of normally closed flow switches are also installed in the cooling system and they open when the threshold flow level is reached. Another possibility is the use of flow meters which involves measuring the actual cooling flow (typically water) and acting when this flow is below a threshold limit.

Following the reception of an overheating (notified by the thermoswitches or the flow sensors), the magnet powering interlock performs two actions: inform to the beam interlock system to stop beam operation, and switch off the corresponding power supply(ies) with a maximum delay of 1 second.

To avoid beam deflections, the above actions must follow a sequence, i.e., first stopping the beam and later switching off the power supply.

In case of a powering fault notified by the power supply to the magnet powering interlock system, the system must inform the beam interlock system in order to stop the beam operation. The power supply will be in this case automatically switched off by itself.

Figure 1 illustrates the systems involved in the execution of the protection functions and their dependencies upon each other.

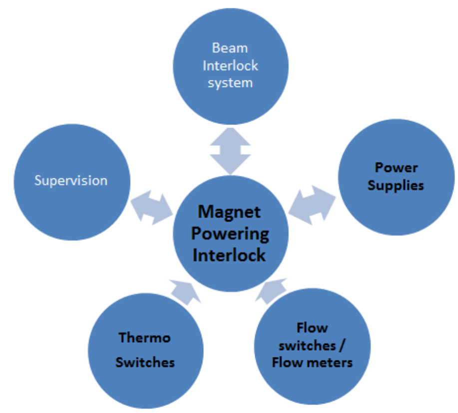

Figure 1: Relationship between the Magnet Powering Interlock system and other systems.

The magnet powering interlock system has to fulfil the following main requirements:

- Protect the magnets in the electrical circuits: in case of overheating, the necessary steps have to be taken to switch off power and stop beam operation.
- Protect the beam: the system should not generate beam stops if this is not strictly necessary. Faulty trigger signals leading to a stop of beam operation must be kept to a strict minimum in order to meet high beam availability requirements for ESS.
- Provide the evidence: in case of an overheating or a powering failure, the operator shall be notified about the root cause. The system must support the identification/diagnosis ability of the initial failure, also in case of multiple alarms (one initial failure that causes subsequent failures).
- Assist improving the operation: the diagnostics for failures should be easy. The status of the system must be clearly presented in the control room and should be transparent to the operator.

To fulfil the above requirements, the implementation of the magnet powering interlock prototype is based on PLC technology which makes use of hardwired current loops,

EXPERIMENTAL AND SIMULATION STUDIES OF HYDRODYNAMIC TUNNELING OF ULTRA-RELATIVISTIC PROTONS*

F. Burkart#, R. Schmidt, D. Wollmann, M. Zerlauth, CERN, Geneva, Switzerland
N. Tahir, GSI, Darmstadt, Germany
A. Shutov, IPCP, Chernogolovka, Russia
A. Piriz, Universidad de Castilla - La Mancha, Ciudad Real, Spain

Abstract

The expected damage due to the release of the full LHC beam energy at a single aperture bottleneck has been studied. These studies have shown that the range of the 7 TeV LHC proton beam is significantly extended compared to that of a single proton due to hydrodynamic tunneling effect. For instance, it was evaluated that the protons and their showers will penetrate up to a length of 25 m in solid carbon compared to a static range of around 3 m. To check the validity of these simulations, beam-target heating experiments using the 440 GeV proton beam generated by the SPS were performed at the HiRadMat test facility at CERN [1]. Solid copper targets were facially irradiated by the beam and measurements confirmed hydrodynamic tunneling of the protons and their showers. Simulations have been done by running the energy deposition code FLUKA and the 2D hydrodynamic code, BIG2, iteratively. Very good agreement has been found between the simulations and the experimental results [2] providing confidence in the validity of the studies for the LHC. This paper presents the simulation studies, the results of a benchmarking experiment, and the detailed target investigations.

HYDRODYNAMIC TUNNELING

The theoretical investigations of the beam–target heating problem at LHC showed that the energy deposited by few ten proton bunches leads to strong heating that produces very high pressure in the beam heated region. This high pressure generates a radially outgoing shock wave that leads to a continuous density reduction at the target center. As a consequence, the protons of the subsequent bunches, and their hadronic showers, penetrate deeper into the target. Continuation of this process leads to a substantial increase in the range of the projectile particles and their hadronic shower. This phenomenon is called *hydrodynamic tunneling* of ultra-relativistic protons in solid targets. [2] It has a important implications on the machine protection design of every high stored beam energy accelerator.

EXPERIMENTAL SET-UP

Figure 1 shows the three targets used in the experiments before their installation in the HiRadMat facility. Each target comprises fifteen copper cylinders with a spacing of 1 cm in-between that allows for visual inspection of the target after the irradiation. Each cylinder has a radius of 4 cm and a length of 10 cm. The three assemblies of cylinders are enclosed in an aluminum housing that provides rigidity to the set-up and should prevent contamination of the facility. The front face of the first cylinder and the rear face of the last cylinder in the three target assemblies are covered with cylindrical aluminum caps. The experimental beam parameters were 440 GeV, a bunch intensity of 1.5E11 protons per bunch, bunch length of 0.5 ns and a bunch separation of 50 ns. Target 1 was irradiated with 144 bunches with a beam focal spot characterized by σ = 2 mm. Targets 2 and 3 were irradiated with 108 bunches and 144 bunches respectively, in both cases with a beam focal spot size characterized by σ = 0.2 mm.

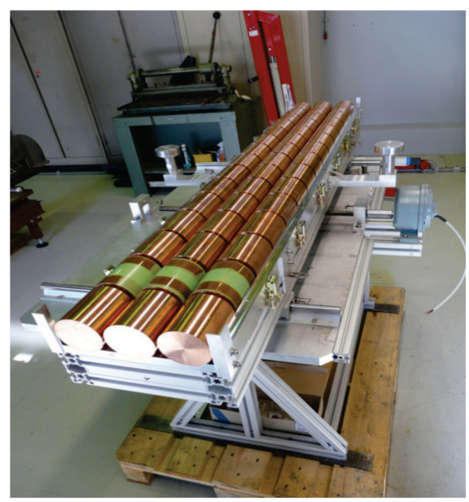

Figure 1: Target assembly.

EXPERIMENTAL RESULTS AND COMPARISON TO SIMULATIONS

The experiments were done in July 2012 and the target was opened after a cool-down period of about 10 months for a first visual inspection and the observations made at that time were published in [3,4] together with the theoretical interpretation [5]. This paper focus on the results for target 3. The results of the simulations are shown in Fig. 2. The temperature and the density along the target axis after the irradiation with 144 bunches are shown. It indicates a molten region for z = 0 - 2 cm, a

ELECTROMAGNETIC DESIGN AND OPTIMIZATION OF DIRECTIVITY OF STRIPLINE BEAM POSITION MONITORS FOR THE HIGH LUMINOSITY LARGE HADRON COLLIDER

D. Draskovic, T. Lefevre, C. Boccard, R. Jones, M. Wendt, CERN, Geneva, Switzerland

Abstract

This paper presents the preliminary electromagnetic design of a stripline Beam Position Monitor (BPM) for the High Luminosity program of the Large Hadron Collider (HL-LHC) at CERN. The design is fitted into a new octagonal shielded Beam Screen for the low-beta triplets and is optimized for high directivity. It also includes internal Tungsten absorbers, required to reduce the energy deposition in the superconducting magnets. The achieved broadband directivity in wakefield solver simulations presents significant improvement over the directivity of the current stripline BPMs installed in the LHC.

INTRODUCTION

The High Luminosity upgrade for the Large Hadron Collider (HL-LHC) is scheduled to take place during the third long shutdown (LS3), when about 1.2 km of the present LHC ring will be modified. The upgrade aims at maximizing the integrated luminosity seen by the LHC experiments, with the aim of delivering 3000fb^{-1} by mid 2030 [1]. The main change will be the installation of completely new magnets for the focussing triplet in the two high luminosity collision points (ATLAS and CMS).

Seven stripline BPMs on each side of the interaction region in points 1 and 5 are currently foreseen to be installed, located in the magnet interconnect from quadrupoles Q1 to Q5. They should provide the means to control the orbit of the two beams at the interaction point (IP) with a high resolution and stability.

As the two counter-rotating LHC beams are in the same vacuum pipe throughout this whole region the BPMs need to be able to distinguish one beam from the other. The degree to which the measurement of one beam can be decoupled from the other in a common BPM is known as the directivity and its optimisation is the subject of this paper.

STRIPLINE BPM

A transmission line (stripline) couples to the transverse electromagnetic (TEM) field of the beam. Stripline BPMs can measure two beams travelling in opposite directions and ideally their upstream and downstream ports should only be sensitive to incoming particles from a given direction. The directivity of a stripline is defined as the ratio of signal power at the upstream port to that at the downstream port in response to a bunched beam particle distribution. The directional stripline BPMs currently installed in the LHC achieve a typical broadband directivity of ~20 dB [2].

To illustrate how directivity affects the accuracy of a stripline BPM, the positioning error of beam 1 in the presence of beam 2 was calculated for different beam positions and different beam intensities for the current LHC stripline BPM (BPMSX) and a BPM with improved directivity (27dB). The results are shown in Table 1. When the two beams have equal intensity and position, the error is null. However, in the LHC the beams are physically separated before the IP up to 20 mm and the error in this case can reach more than 3% of the scale factor (~half radius) assuming the current LHC stripline, but which can be three times better if the directivity is improved by a factor of 2.

Table 1: Positioning Error of Beam 1 as a Function of the Position of Beam 2 (in mm) for the New and Current LHC BPM

Error [%]	***x*=0 new**	***x*=10 new**	***x*=0 current**	***x*=10 current**	**Intensity Ratio I_2/I_1**
***y* = 0**	0	1.22	0	3.55	1
***y* = 5**	0.66	0.6	1.92	1.87	1
***y* = 10**	1.34	0	3.99	0	1
***y* = -10**	1.34	2.56	3.99	7.51	1
***y* = -10**	0.6	1.31	2.09	3.93	0.5
***y* = -10**	2.57	4.92	7.2	13.79	2

The errors are more dramatic when the beam intensities are unequal. A factor of 2 difference in intensities leads to an error of nearly 14% for the current design, which can be reduced down to 4% with improved directivity.

These errors only apply of course if the two beams actually cross in the BPM. Both for the current LHC and HL-LHC layouts the BPM locations are chosen so as to maximise the arrival time difference between the two beams to minimise the impact of this imperfect directivity. Nevertheless the influence of one beam on the other is still observed, in particular for BPMs which could not be ideally located.

This work is therefore focused on the design of a new stripline BPM, optimizing the directivity to provide the best possible accuracy.

FIBRE MONITORING SYSTEM FOR THE BEAM PERMIT LOOPS AT THE LHC AND FUTURE EVOLUTION OF THE BEAM INTERLOCK SYSTEM

C. García-Argos, R. Denz, S. Gabourin, C. Martin,
B. Puccio, A. Siemko, CERN, Geneva, Switzerland

Abstract

The optical fibres that transmit the beam permit loop signals at the CERN accelerator complex are deployed along radiation areas. This may result in increased attenuation of the fibres, which reduces the power margin of the links. In addition, other events may cause the links not functioning properly and result in false dumps, reducing the availability of the accelerator chain and affecting physics data taking. In order to evaluate the state of the fibres, an out-of-band fibre monitoring system is proposed, working in parallel to the actual beam permit loops. The future beam interlock system to be deployed during LHC long shutdown 2 will implement online, real-time monitoring of the fibres, a feature the current system lacks. Commercial off-the-shelf components to implement the optical transceivers are proposed whenever possible instead of ad-hoc designs.

INTRODUCTION

The Beam Interlock System (BIS) [1] of the CERN accelerator chain is responsible for transmitting the beam permit along the Large Hadron Collider (LHC), the Super Proton Synchrotron (SPS), the transfer lines and the PS Booster.

The beam permit loop signals are two different square signals with frequencies 9.375 (loop A) and 8.375 MHz (loop B), sent in opposite directions. These beam permit loop signals are transmitted over single-mode optic fibre.

Figure 1 shows the topology of the beam permit loops at the LHC. There are two signals for each of the two beams, one transmitted clockwise and the other anti-clockwise.

There are seventeen Beam Interlock Controllers (BIC) in the LHC, two at each LHC point, named with the point number and side (left or right), and one at the CERN Control Centre (CCC), named CCR. The two generators of the beam permit signal, named CIBG, are installed in point 6, where the dump system is located.

In the SPS, there is a similar architecture, with one BIC per point, and two loops for one beam. Injection and extraction lines also have their own beam permit loops.

The controllers receive the users inputs, coming from the user systems. These inputs are connected with a logical AND inside the controller, resulting in the local permit at the BIC. If the local permit is true, then the BIC re-transmits the beam permit signal to the next BIC.

A total of 12 fibres are deployed at each controller: one for each incoming signal and one for each outgoing signal, for a total of eight active fibres. There are wo spare fibres to each of the neighbour controllers. The distance between controllers is varied, as short as a metre and as long as 6 kilometres.

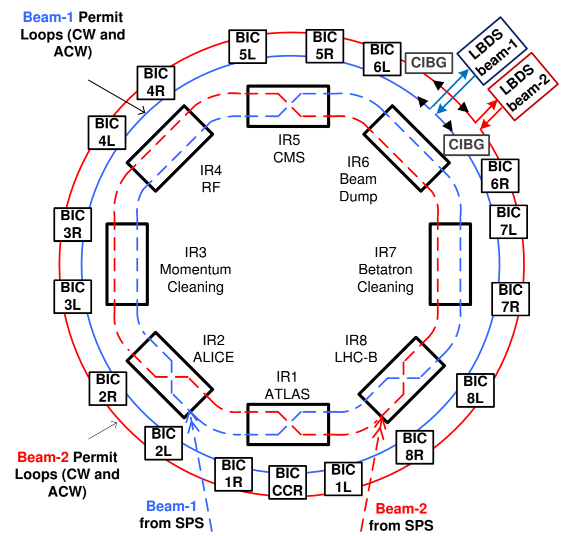

Figure 1: LHC beam permit loops.

OUT-OF-BAND FIBRE MONITORING

Motivation

The beam permit loops and the implementation of the optical links are described in [2]. The Controls Interlocks Beam Optical (CIBO) board designed at CERN uses an ELED single-mode transmitter and a PIN diode receiver to implement the optical transceiver for the beam permit signals.

The working wavelength of the loops is 1310 nm, and the receiver has a sensitive response in the range $(900, 1700)$ nm. The output power of the transmitter is typically between -25 and -15 dBm and the CIBO board is designed to deliver around -19 dBm.

The G.652 [3] type optical fibres have a maximum length of 6 km, with an initial worst case attenuation of 0.5 dB/km at 1310 nm. A number of false dumps have occurred that may have been caused by increased attenuation in the fibres, what drives the need for a monitoring system to evaluate their performance during operation.

Radiation can both create point defects in the silica and activate already existing defects, causing radiation induced

BEAM LOSS MONITORING FOR RUN 2 OF THE LHC

M. Kalliokoski, B. Auchmann, B. Dehning, E. Effinger, J. Emery, V. Grishin, E.B. Holzer, S. Jackson, B. Kolad, E. Nebot Del Busto, O. Picha, C. Roderick, M. Sapinski, M. Sobieszek, F.S. Domingues Sousa, C. Zamantzas, CERN, Geneva, Switzerland

Abstract

The Beam Loss Monitoring (BLM) system of the LHC consists of over 3600 ionization chambers. The main task of the system is to prevent the superconducting magnets from quenching and protect the machine components from damage, as a result of critical beam losses. The BLM system therefore requests a beam abort when the measured dose in the chambers exceeds a threshold value. During Long Shutdown 1 (LS1) a series of modifications were made to the system. Based on the experience from Run 1 and from improved simulation models, all the threshold settings were revised, and modified where required. This was done to improve the machine safety at 7 TeV, and to reduce beam abort requests when neither a magnet quench nor damage to machine components is expected. In addition to the updates of the threshold values, about 800 monitors were relocated. This improves the response to unforeseen beam losses in the millisecond time scale due to micron size dust particles present in the vacuum chamber. This contribution will discuss all the changes made to the BLM system, with the reasoning behind them.

BEAM LOSS MONITORING SYSTEM

Energy deposition from beam losses can cause a quench of the superconducting LHC magnets or even lead to damage. The main protection against this is provided by the Beam Loss Monitoring (BLM) system. The BLM system consists of almost 4000 detectors spread around the LHC ring. The main detector type is an Ionization Chamber (IC), which are 50 cm long with an active volume of 1.5 l, filled with N_2 at 100 mbar overpressure. The detectors are parallel plate chambers with 61 circular aluminium electrodes of diameter of 7.5 cm, separated by a drift gap of 0.5 cm [1].

To cover the full dynamic range in locations with high losses, the ICs are installed in parallel to other less sensitive monitor types: Secondary Emission Monitors (SEM) or Little Ionization Chambers (LIC). Both are based on the same geometry as the ICs, but consist of only of three electrodes. The LICs have the same properties as the ICs but due to the reduced volume are 60 times less sensitive, while the SEMs operate in a 10^{-7} mbar vacuum and are 70,000 times less sensitive than the ICs.

For the start of Run 2, only the ICs are connected to the Beam Interlock System (BIS) [2] and able to give beam abort requests. The two other detector types are installed for monitoring purposes only.

NEW INSTALLATIONS

Relocation of Monitors

The operation of the LHC during Run 1 was affected by losses on the millisecond time scale. These losses are suspected to be provoked by dust particles falling into the beams, so-called Unidentified Falling Objects (UFOs) [3-4]. UFO events are seen as the most likely loss scenario in the LHC arcs during Run 2. Based on measurements performed with secondary particles generated by the beam wire scanner, it is calculated that the resulting signal of a UFO event at 7 TeV will be about 3 times higher than at 3.5 TeV [5].

To improve the response and the protection of the magnets against UFO losses, 816 ionization chambers were relocated from the quadrupole magnets (MQ) onto the intersection of the bending magnets (MB) in the arcs and dispersion suppressors (DS) of the LHC. Figure 1 shows how the existing BLMs were relocated. Figure 2 shows a monitor at the new location on top of a dipole-dipole interconnection. In this new location, the detectors monitor the losses from both beams.

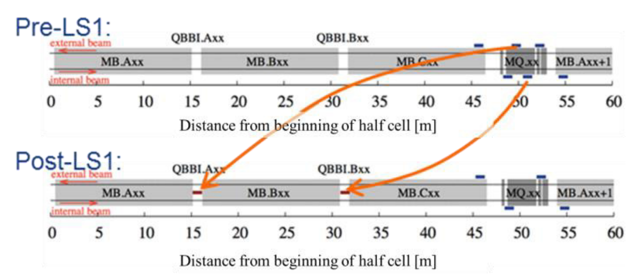

Figure 1: Relocation of beam loss monitors in the LHC arcs.

New Installations and Replacement of SEMs with LICs

SEMs are installed in parallel with the ICs to extend the dynamic range of the system towards higher dose rates to avoid saturation of the detector or electronics [6]. During Run 1 it was seen that in the events which surpassed the dynamic range of the ICs, the signal from the SEMs was still dominated by noise and no proper measurements could be made. Thus the SEMs were replaced with LICs in several locations. To further increase the dynamic range of the LICs, they are installed with RC filters connected. These filters reduce the peak amplitude for short losses, stretching the length of the signal by a factor depending on the values of the RC circuit.

ELENA ORBIT AND SCHOTTKY MEASUREMENT SYSTEM

L. Søby, M. E. Angoletta, R. Marco-Hernandez, J. Molendijk, F. Pedersen, J. S. Quesada, CERN, Geneva, Switzerland; M. Bau, M. Ferrari, V. Ferrari, Brescia University, Italy

Abstract

A new Extra Low ENergy Antiproton ring (ELENA) is under construction at CERN to further decelerate the antiprotons from the existing Antiproton Decelerator (AD) to an energy of just 100 keV. This contribution will describe the beam position system foreseen for ELENA and how it can be adapted for Schottky measurements. The orbit system being developed is based on electrostatic shoebox beam position monitors fitted with Digital Down Converters (DDC). The main requirement is to measure complete orbits every 20ms with a resolution of 0.1mm for intensities in the range of 1-3E7 charges. The pick-up signals will, after amplification with a low noise charge amplifier, be down-mixed to baseband for position computation. In order to provide the longitudinal Schottky diagnostics of un-bunched beams, the 20 BPM sum signals will, after time of flight corrections, be added digitally to give an expected S/N increase of 13dB compared to using a single electrostatic pick-up.

INTRODUCTION

The Extra Low ENergy Antiproton ELENA ring [1] is a new synchrotron with a circumference of 30.4 m that will be commissioned at CERN in 2016. Table 1 provides a summary of ELENA's main parameters, while Fig. 1 gives a schematic view of the ELENA deceleration cycle which is expected to last some 20 seconds.

Table 1: ELENA Ring Main Parameters

Parameter	Injection	Extraction
Momentum, MeV/c	100	13.7
Kinetic Energy, MeV	5.3	0.1
Revolution frequency, MHz	1.06	0.145
Expected number of particles	$3\cdot 10^7$	$1.0\cdot 10^7$
Number of extracted bunches	4 (operationally)	
Extracted bunches length, m/ns	1.3/300	

The ELENA orbit measurement system will be based on 20 circular, electrostatic Beam Position Monitors (BPMs) made out of stainless steel and mounted inside quadrupoles and dipoles. After amplification of the signals by low noise amplifiers located very near to the BPMs, the difference and sum signals will be transported by ~50m cables to the rack where they will be digitized and processed.

In a second phase it is foreseen to use the same BPM sum signals for longitudinal Schottky measurements of un-bunched beams and intensity measurements for bunched beams.

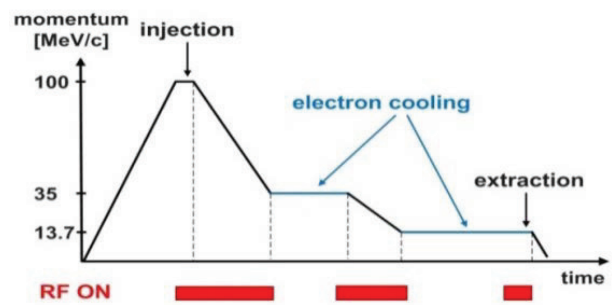

Figure 1: Schematic view of the ELENA cycle.

PICK-UP DESIGN

The proposed design is based on a stainless steel, 100 mm diameter vacuum tank containing two pairs of diagonally cut stainless steel electrodes, one for horizontal and one for vertical measurement. As can be seen in Fig. 2, no separate sum electrode is foreseen, with the sum signal generated by the addition of the electrode signals in the front-end amplifiers. Table 2 summarises the main parameters for the BPM system.

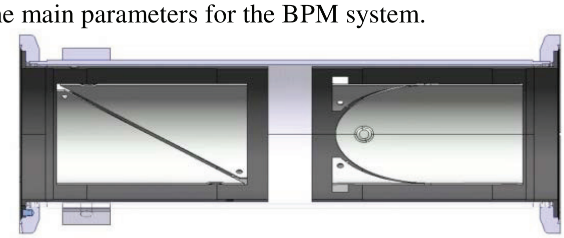

Figure 2: Cross section view of the ELENA Pick-up.

Table 2: Pick-up and Orbit Parameters

FEASIBILITY STUDY OF MONITORING THE POPULATION OF THE CERN-LHC ABORT GAP WITH DIAMOND BASED PARTICLE DETECTORS*

O. Stein, CERN, Geneva, Switzerland and University of Hamburg, Germany†
F. Burkart, B. Dehning, R. Schmidt, C. Buhl Sørensen, D. Wollmann, CERN, Geneva, Switzerland

Abstract

At the end of a physics fill and in case of a failure, the LHC beams must be extracted and transferred through a 750 m long line to the beam dump block. During the rise of the extraction kickers to their full strength a particle-free abort gap, with a length of 3 μs in the LHC filling pattern, is required to prevent beam losses that could lead to substantial quenching of magnets, with a risk of damage. Therefore the particle population in this abort gap, which is mainly due to un-bunched beam, is monitored. Above a certain threshold an active cleaning by excitation of betatron oscillations with the transverse feedback system is initiated. This paper describes a novel method of monitoring the abort gap population using diamond particle detectors for detecting the interactions of beam in the abort gap with neon gas, injected in the beam pipe. Two different layouts of the system and the expected interaction and detection rates are discussed.

IMPORTANCE OF THE ABORT GAP FOR THE LHC MACHINE PROTECTION

Due to the high stored energy in the LHC beams (362 MJ per beam at nominal energy) an uncontrolled, complete beam loss will cause serious damage in the accelerator components along the beamline. Therefore, in case of beam instabilities, machine failures or end-of-physics runs, the circulating beams have to be extracted and dumped in a controlled manner. For this purpose the dumping system, consisting of deflection magnets, the dump-line and the dump-block at the end, is installed separately for the two beams in point 6 of the LHC. This system is capable of dumping the beam safely without harming the machine.

In case of a beam abort the 15 kicker magnets (MKD) will be triggered to deflect the beam into the dump-line. The kicker magnets have a rise time of maximum 3 μs, the nominal bunch spacing in the LHC is 25 ns (50 ns). Bunches passing the kicker magnets whose fields are rising will experience a deflection smaller than it is needed for a proper extraction. These diverted bunches continue traveling on a wrong trajectory. This can result in beam losses which lead possibly to damage or quenches in the downstream magnets.

The LHC filling pattern contains a 3 μs long (ideally) particle-free gap, the so-called Abort Gap (AG), to ensure safe beam aborts. The extraction kicker magnets are synchronised to the abort gap to minimise the particle losses during the rise of these magnets.

Due to unbunched beam particles can accumulate in the abort gap. Therefore it is necessary to monitor the abort gap population continuously and if necessary induce countermeasures. One method to reduce the AG population is to excite the betatron oscillation of the particles in the gap with the LHC transverse damper system which are then lost on the collimators in point 7. This Abort gap Cleaning (AGC) method was used for abort gap cleaning, during Run 1.

Monitoring the Abort Gap Population

The main instrument to monitor the abort gap population at the LHC is the synchrotron radiation monitor (BSRA). This monitor detects the synchrotron light which is emitted when the particles pass the super conducting (sc) D3 magnet and the adjacent sc-undulator close to point 4. Due to mechanical problems in the BSRA setup the system was not always operational and no other redundant system existed to allow a continuous monitoring of the AG.

In case of a BSRA failure the AGC was switched on regularly which lead to shorter beam life time of the LHC beams.

Therefore, an additional system for monitoring the AG beside the BSRA would add a layer of redundancy.

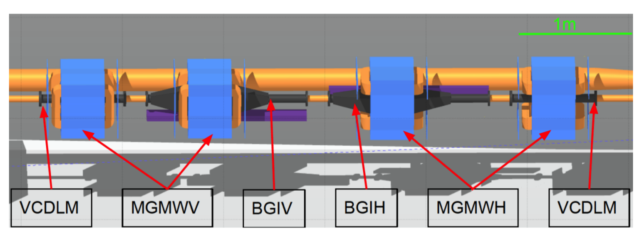

Figure 1: 3D-model of the BGI main components used for FLUKA simulations. VCDLM, 80 mm 316L drift tube. MGMW H/V, dipole. BGI H/V, vacuum chamber with BGI assembly. The second beam pipe can be seen in the background.

MONITORING THE ABORT GAP POPULATION WITH BEAM GAS INTERACTIONS

The beam gas ionisation monitors (BGI), one for each beams, are installed close to point 4 in the LHC. The original purpose of this device is to measure the transverse beam size [1].

RESPONSE OF POLYCRYSTALLINE DIAMOND PARTICLE DETECTORS MEASURED WITH A HIGH INTENSITY ELECTRON BEAM *,†

O. Stein, CERN, Geneva, Switzerland and University of Hamburg, Germany ‡
F. Burkart, B. Dehning, R. Schmidt, C. Buhl Sørensen, D.Wollmann, CERN, Geneva, Switzerland
E. Griesmayer, CIVIDEC Instrumentation, Vienna, Austria

Abstract

Comprehensive understanding of beam losses in the CERN-LHC is required to ensure full machine protection and efficient operation. The existing BLM system using ionisation chambers is not adequate to resolve losses with a time resolution below some 10 μs. Ionisation chambers are also not adequate to measure very large transient losses, e.g. beam impacting on collimators. Diamond particle detectors with bunch-by-bunch resolution have therefore been used in LHC to measure fast particle losses with a time resolution down to a level of single bunches. Diamond detectors have also successfully been used for material damage studies in other facilities, e.g. HiRadMat at the CERN-SPS. To fully understand their potential, such detectors were characterised with an electron beam at the beam test facility in Frascati with bunch intensities from 10^3 to 10^9 electrons. The detector response and efficiency has been measured with a 50 Ω and a 1 Ω read-out system. This paper describes the experimental setup and the results of the experiment. In particular, the responses of three samples of 100 μm polycrystalline diamond detectors and two samples of 500 μm polycrystalline diamond detectors are presented.

DIAMOND BASED PARTICLE DETECTORS

During the experiments at the Beam Test Facility (BTF) in Frascati, Italy, the response function and the efficiencies of two diamond detectors (dBLM) types were measured. The first type (H-type) is a special detector which was developed for high intensity ranges. This detector type was used in the damage experiment in the HiRadMat facility at CERN in 2012 [2]. The second type (L-type) is used at the LHC for monitoring fast beam losses [3]. These two detectors types consist of polycrystalline diamond (pCVD) which differs in the size and quality of the active material, see tab.1.

During the experiments at the BTF, three H-type dBLMs (H1, H2, H3) and two L-type detectors (L1 and L2) were measured.

BEAM PARAMETERS AND MEASUREMENT SETUP

The Beam Test Facility

The BTF is a beam line at the Daphne accelerator complex. In the used mode, a bunch of the primary electron beam of 500 MeV and an intensity of $\approx 10^9\ e^-$ was delivered into the experimental hall with a repetition rate of 1 – 2 Hz. The bunch length was in the order of 10 ns. The beam intensity was reduced by using scrapers in the beam line [1].

Experimental Setup

In the setup the dBLM detector was place in front of a reference detector. Both detectors were aligned on the beam axis. A collimator was placed between the two detectors to ensure that only electrons that passed through the dBLM are detected in the reference detector, see Fig.1.
The collimator consists of a 20 cm long hollow copper cylinder with an opening of the size of the active diamond crystal in the dBLM. The copper cylinder was followed by a lead cylinder for shielding Bremsstrahlung. The whole setup was shielded with lead to minimise the radiation levels in the experimental hall.
The signals of the dBLM and the icBLM were fed through 30 m long BNC-cables into a 50 Ω read-out system (scope, Agilent DSO 9254A).

The Reference Detector

For the measurements a standard LHC type ionisation chamber beam loss monitor (icBLM) was used as a reference detector. During the experiments the electron peak of the icBLM was measured which contains about 50 % of the whole charge. By applying a conversion factor to the

FIRST OPERATIONAL EXPERIENCE OF DSL BASED ANALYSIS MODULES FOR LHC HARDWARE COMMISSIONING

C.Aguilera, M.Audrain, S.Boychenko, Z.Charifouilline, M.Dragu, R.Heil, M.Koza, K.Krol, J.C. Garnier, R.Orlandi, T.Ribeiro, S.Rowan, K.Stamos, M. Zerlauth, CERN, Geneva, Switzerland

Abstract

The superconducting magnet system of the Large Hadron Collider (LHC) has been fully re-commissioned ahead of the second run of physics production in 2015. More than 20,000 tests had to be performed and analysed to qualify around 1600 electrical circuits for operation at 6.5TeV. Automated analysis modules, defined directly by the various system experts in an English-like domain specific language (DSL), have been used successfully within the Accelerator Testing framework (AccTesting) during the latest re-commissioning campaign. For this, the experts define pass criteria for the powering tests, which are automatically verified, via assertion modules, in order for the test to pass. These modules currently analyse 4 test types executed for more than 1000 systems and even allowed experts to identify issues, which were missed by manual analysis during previous campaigns. This paper describes the first operational experience with such kind of analysis modules, as well as a follow-up analysis of the results compared with previous commissioning campaigns. The analysis looks at potential shortcomings of the framework and attempts to improve the dependability of automated analysis with regards to high current (>1kA) circuits of the LHC are outlined.

INTRODUCTION

The AccTesting framework has been developed at CERN with the aim of providing dependable tracking and execution of the more than 20,000 tests that have to be performed on the magnet powering circuits of the Large Hadron Collider (LHC) to qualify it for operation after long technical stops or maintenance interventions. The need for orchestration tools was already identified during the first commissioning phase of the LHC in 2007/2008. For this first commissioning phase, over 5000 tests were completed, using a set of rather heterogeneous tools for the definition, execution, tracking and analysis of the various powering tests [1].

In subsequent (re-)commissioning campaigns the number of tests to be executed steadily increased due to the increase in individual system tests in the commissioning program. The experience gained, however, allowed for considerable improvements in both, the automation of execution of powering cycles on the electrical circuits as well as the automation of analysis for transient data recordings produced during these different validation steps. In 2010, the tracking and execution of tests has been amalgamated into a single Java based framework, which has been used successfully during multiple campaigns ever since.

In an effort to further progress towards a coherent set of tools for the operation and expert crews of the LHC, the most recent campaign has seen the inclusion of a new analysis layer within the AccTesting framework, based on the use of a DSL.

DOMAIN SPECIFIC LANGUAGE FOR AUTOMATED ANALYSIS

The use of a domain specific language for data analysis bears many advantages that are outlined in [2] [3]. When investigating first operational experience with DSL based analysis modules, emphasis is given to assess the experience relative to the main design goals of the DSL, namely:

- Facilitating analysis tasks for equipment experts and automation crews
- Increasing system reliability through dependable automated analysis
- Increased performance and test efficiency due to the removal of manual analysis

Analysis Abstraction

With the introduction of the domain specific language, a considerable abstraction and decoupling of the analysis task from software and coding knowledge can be achieved. Specific knowledge about the analysis framework is not required. Software specialists provide access to the available data sources, configuration data as well as the implementation of analysis functionality by providing a set of assertions that can be executed on the recorded data. Equipment experts can focus on the implementation of the analysis modules by constructing algorithms to satisfy specific pass criteria out of the set of assertions. Figure 1 depicts two analysis modules, each consisting of 6-9 individual assertions that validate absolute values of measurements, exponential decays or second derivatives against well-defined thresholds.

PULSE COMPRESSOR PHASE AND AMPLITUDE MODULATION BASED ON ITERATIVE LEARNING CONTROL*

Amin Rezaeizadeh†, Roger Kalt, Thomas Schilcher
Paul Scherrer Institut, Villigen, Switzerland
Roy S. Smith, Automatic Control Laboratory, ETH, Zürich, Switzerland

Abstract

This paper presents an alternative way to produce flat-topped RF pulses at the pulse compressor output. Flat-topped RF pulses are suitable for multi-bunch operation where it is often required that beams experience the same accelerating gradient. Moreover, the energy gain, in this case, is less sensitive to timing jitters. The proposed approach is based on Iterative Learning Control technique, which iteratively updates the input waveforms, in order to generate the desired output waveforms.

INTRODUCTION

The SwissFEL machine, currently being constructed at Paul Scherrer Institut, will provide a source of very bright and short X-ray pulses. The SwissFEL C-band (5.712 GHz) Linac consists of 26 Radio Frequency (RF) stations. Each station is composed of a single klystron feeding an RF pulse compressor and four accelerating structures. The pulse compressor designed for the SwissFEL is based on a single Barrel Open Cavity (BOC) which inherently has a high quality factor resulting in a significant energy storage capacity and a relatively long filling time [1]. In the original form of pulse compression, which is commonly referred to as the "phase jump" regime, the input phase flips by 180°, generating a reflected wave transient into the acceleration structure. This high power transient decays relatively slowly giving the RF structure time to build up an accelerating gradient higher than possible from the klystron alone. However, this RF pulse shape is not suitable for multi electron-bunch operation where it is often required that all electron bunches see the same amplitude and phase in the accelerating structure. More complicated operation modes are also possible by reversing the phase very slowly which is referred to as the "phase modulation". With a continuously modulated phase, the BOC output peak amplitude is lowered and flattened [2]. The SwissFEL RF drives operate in a pulsed mode at the rate of 100Hz, using normal conducting accelerating structures. The RF pulse length is of the order of 1-3μs and no digital RF feedback loop is run within a pulse. Iterative learning control (ILC) is a control technique for systems that operate in a repetitive manner [3]. In this method, the measured waveform or trajectory is compared to the desired one to give an error estimate, which is then used to update the inputs for the next run. Therefore, for our problem, i.e. controlling the pulse shape, an iterative approach is a good candidate. Previously in [4], a model-free ILC algorithm was employed

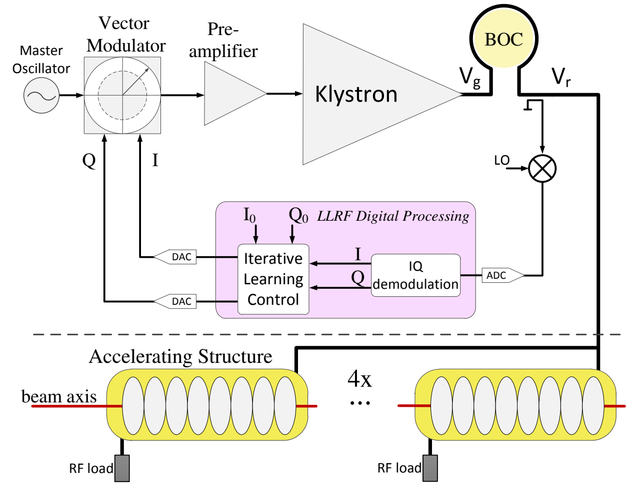

Figure 1: The simplified RF layout of a C-band RF station in the SwissFEL beamline.

to flatten the klystron RF pulse. In this paper, an ILC-based approach for producing flat-topped RF pulse is introduced, which modulates both input phase and amplitude waveforms. This method has been successfully applied on the RF pulse compressor at the SwissFEL Linac test facility.

SYSTEM DESCRIPTION

The layout of a C-band RF station is illustrated in Fig. 1. The RF signal source (5.7 GHz) is generated by a master oscillator. The discrete sequences of the in-phase, I, and quadrature, Q, components of the RF signal are fed into the vector modulator to be up-converted. Each sequence contains 2048 samples with sampling time of $T_s = 2.4$ ns. The RF signal drives the klystron and finally, the high power RF signal is split over four accelerating structures. The measured I and Q waveforms are used in the ILC controller to produce the next I and Q inputs to the Digital-to-Analog Converters (DAC). The control objective is to make flat amplitude and phase pulses at the output of the pulse compressor.

The Pulse Compressor Model

The relation between klystron and pulse compressor voltage is given by [2]

$$\alpha V_g = V_c + \tau \dot{V}_c, \tag{1}$$

where V_g and V_c are respectively the klystron and pulse compressor voltage phasors.

BEAM-BASED POWER DISTRIBUTION OVER MULTIPLE KLYSTRONS IN A LINEAR ACCELERATOR*

Amin Rezaeizadeh†, Roger Kalt, Thomas Schilcher
Paul Scherrer Institut, Villigen, Switzerland
Roy S. Smith, Automatic Control Laboratory, ETH, Zürich, Switzerland

Abstract

A linear accelerator including several klystron driver RF stations can be viewed as a single virtual RF station [1] with a certain accelerating RF voltage (in amplitude and phase). This paper develops an optimization scheme that, for a specified beam energy gain, determines the klystrons output powers and the modulators high voltages optimally. The algorithm employs the klystron nonlinear static characteristics curves to calculate the input RF amplitude of the drive chain.

INTRODUCTION

A linear accelerator (Linac) is composed of multiple Radio Frequency (RF) stations, delivering high power RF to feed the accelerating structures. If the high power is generated by klystrons, finding the appropriate operating points of the klystrons is a topic to be considered. In order to increase the RF stability as well as the efficiency, it is preferable to operate the klystron very close to its saturation limit. The saturating power depends on the high voltage of the klystron. Nonlinear characteristic curves of the klystron, make it not so straightforward to determine the high voltage and the input amplitude from a specified klystron output power. Figure 1 depicts the klystron output power versus the RF input amplitude and the voltage of the high voltage power supply (HVPS). Two contours of constant power are plotted to illustrate the problem. This issue has been previously addressed in [3] by introducing the concept of operating point determination (OPD). In this paper, we consider multiple klystrons, in which the operating points are determined according to the specified total energy gain. This leads us to the concept of beam-based multiple operating point determination (BM-OPD). In this scheme, an optimization procedure is developed which minimizes the high voltages of the klystrons, while keeping the total beam energy gain constant. Since the breakdown rate of the klystron is directly related to the high voltage level, the proposed optimization tends to reduce the probability of breakdowns. The approach is based on a convex optimization which uses the models of klystron characteristics and the energy gain of the RF stations. This method has been successfully tested at the SwissFEL injector test facility using three full-scale RF stations to simulate a Linac. The SwissFEL is currently being constructed at Paul Scherrer Institut [2]. The SwissFEL injector and the Linac RF drives operate in a pulsed mode at the rate of 100 Hz. There are 26 RF stations in the SwissFEL Linac. The proposed algorithm facilitates the RF setting with an automatic procedure for the specified energy gain of a Linac.

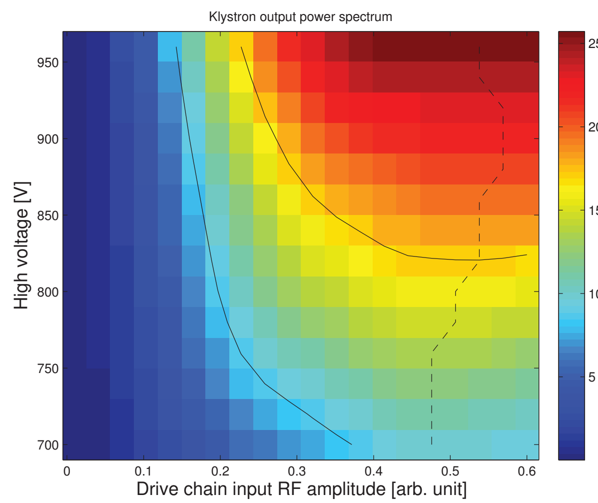

Figure 1: The klystron output power versus the RF input amplitude and the high voltage power supply setting. The curves (in black) denote the contours of constant output power. The dashed line indicates the saturating power. The klystron operating point should fall in the left side of the dashed line to avoid over-saturation.

OPTIMIZATION SCHEME

A Linac with multiple klystrons is often viewed as a single RF station with a certain energy gain. The energy gain can be tuned via each individual klystron RF amplitude as well as the high voltage. The way that the klystrons contribute to generate the desired total energy gain, is the main focus of this section. The distribution of the individual energy gain of the RF stations is done through an optimization problem. As a result, the RF power of each individual klystron is determined, which is then used as an input to the OPD, along with the predefined headroom to the saturation, to provide the assigned energy gain.

The optimization is meant to minimize the overall probability of breakdowns in klystrons, which usually occurs at higher high voltages. Throughout this study, we assume that the RF phases are set to zero, i.e. the “on-crest phase”.

We consider a Linac with M klystrons. The energy gain of each RF station, ΔE_i, is related linearly to the klystron output RF amplitude. That is,

$$\Delta E_i = \alpha_i y_i + \beta_i, \tag{1}$$

where y_i denotes the output amplitude of i-th klystron , and where β_i and α_i are constants. On the other hand, according

THE ENERGY SAVING PROCESSES FOR UTILITY SYSTEM IN TPS

Chih-Sheng Chen, Wen-Shuo Chan, Yung-Chiang Chang, Yen-Ching Chung, Ching-Wei Hsu
Ching-Yuarn Liu, Zong-Da Tsai, Jui-Chi Chang
NSRRC, 101Hsin-Ann Road, Hsinchu Science Park, Hsinchu 30076, Taiwan

Abstract

There are more and more non-linear electronic equipments such as inverters using in facility nowadays. These non-linear electronic equipments let us achieve energy saving, but induce other electrical pollution to the whole power grid in contrast. How to take the advantages from these energy-saving equipments without electric pollutions should be well considered at the first step of the utility operation in TPS (Taiwan Photon Source). Meanwhile, for there will be lots of chance that TLS (Taiwan Light Source) and TPS will be operated at the same time, the electrical power consumption will increase with no doubt. Under the circumstances of limited budget, some energy saving processes for utility must be applied. According to the historical data, the utility consumes the majority of power consumption. Even a small portion of usage saved will be a respectable amount. Thanks to the connection pipe between two utility buildings, the realization of the energy saving processes at the first phase of TPS project becomes much easier.

INTRODUCTION

The accelerator is a sophisticated facility and sensitive to environmental changes. According to the research by J. C. Chang et al., the supplied air temperature and cooling water temperature are the critical factors to affect the beam orbit [1]. Once the temperature fluctuations of cooling water and air exceed 1 °C and 0.2 °C respectively, the stability of beam orbit will become worse. For this reason, a lot of efforts had been made to realize precise temperature control. On the other hand, precise temperature control prevents unnecessary energy lost. The later reason is getting more and more important when it comes to energy conservation. For air conditions, Z. D. Tsai et al. have made experiments applying the Run-Around Heat Recovery process to air handling unit [2]. From the results, the temperature fluctuation of outlet air could be minimized to ±0.05 °C, and the energy saving runs up to 30%. In this article, the benefit of connection pipe between chillers in TLS and TLS will be introduced. The TLS and TPS chilled water systems hence support to each other, and the reduction of power consumption is the additional profit while new chillers operating. The coefficient of performance (COP) of overall chilled water system goes up too.

After four years of engineering constructions, the first light of TPS shines on December 31, 2014. It encouraged every member in NSRRC, at the same time, it also means more and more energy is required to operate both TLS and TPS. Electrical power consumption is highly increased after the completion of civil construction of TPS. The number of contract power capacity has been increased from 3.5 MW in 2000 to 5.5 MW in 2015. The power bill in 2014 was also nearly three times more than in 2008. Figure 1 shows the monthly average fee in NSRRC from 2008 to 2014 [3]. Due to the rising bill and the limited budget, it is an urgent object to develop energy saving processes for utility group.

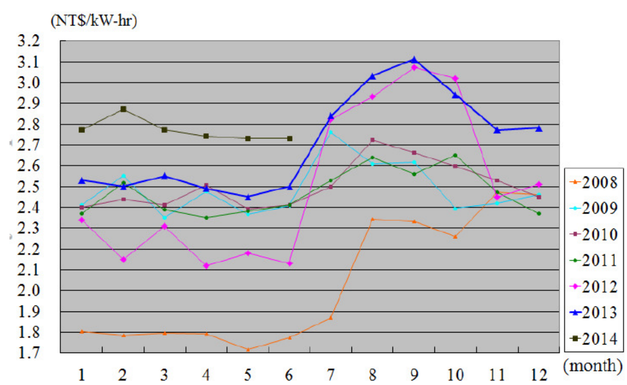

Figure 1: Monthly average fee from 2008 to 2014 in NSRRC.

RUN-AROUND HEAT RECOVERY PROCESS

Run-around heat recovery system is composed of ordinary air handling unit and two additional heat exchange coils. As shown in figure 2, these two additional heat exchange coils are used as pre-heating and pre-cooling coils separately.

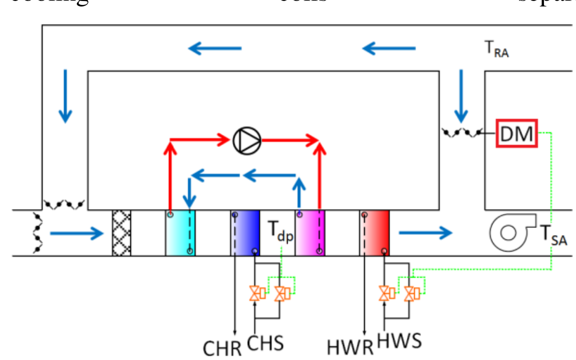

Figure 2: Control Diagram of High Precision Temperature Control System.

Counting from right side, the first coil is pre-cooling coil; the second one is cooling coil; the third and the

THE FLEXIBLE CUSTOMIZED SUPERVISOR AND CONTROL SYSTEM FOR UTILITY IN TPS

Chih-Sheng Chen, Wen-Shuo Chan, Yung-Chiang Chang, Yen-Ching Chung, Ching-Wei Hsu, Ching-Yuarn Liu, Zong-Da Tsai, Jui-Chi Chang
NSRRC, 101Hsin-Ann Road, Hsinchu Science Park, Hsinchu 30076, Taiwan

Abstract

In order to maintain and operate a synchrotron radiation light source well requires quite a few efforts. All parts of the big machine, including vacuum system, all kinds of magnets, RF facility, cryogenic equipments, radiation security, optic devices and utility equipment must cooperate in harmony to provide high quality light. Any one of the above system contains lots of analog or digital signal transmission, not to mention the vast range of utility. Numbers of programmable automation controllers (PACs) are applied in utility system in TPS to ensure the utility operates normally. In addition to the high reliability and distribution, the flexible programmability of PAC is the most critical feature in this project. A well-designed program, Archive Viewer, provides a platform for showing these big data from all distributed systems. The architecture of the server system for utility is described in this paper as well.

INTRODUCTION

There are mainly three kinds of resources provided by the utility group in NSRRC. First, the de-ionized water (DIW) system offers cooling water to carry out waste heat generated by accelerator operation. The DIW system is composed of four subsystems in TLS and TPS respectively. The copper (Cu) DIW subsystem provides with cooling de-ionized water to take out exhaust heat while the magnet system and power supplies operate. The vacuum chambers in NSRRC are mostly made of aluminium; therefore, the aluminium (Al) subsystem is in charge of waste heat from the equipments of the vacuum group. The RF subsystem is for RF transmitters and cavities, and the Bl (beam line) and Bo (booster) subsystem is for the usage of all beam line devices. Second, the air system including air-condition system and compressed air system offers an environment with stable temperature and sufficient air pressure for pneumatic equipments running. The last part is the most critical, the reliable electric system ensures all electronics are working. All the three elements seem fundamental, however, an advanced facility like particle accelerator need a stably-operated and well-controlled utility system to realize. Referring to former studies of utility group in NSRRC, it is strongly proven that the stability of utility affects the operation of accelerator [1]. This article will focus on the water system and air system of TPS utility.

The temperature of DIW system is globally controlled within ± 0.1℃ in TLS due to former efforts [2]. With the experiences from TLS, the precise temperature control could be achieved by many local controllers. The specifications of TPS water subsystem are listed in Table 1. The capacities of cooling water, chilled water and hot water are larger than normal consumption. The over design capacity avoids unexpected heat load shock and ensures all systems work under the most suitable conditions.

Table 1: Specifications of Water Subsystems of TPS

	Temperature	Pressure	Capacity
Cu DIW	25 ± 0.1 °C	7.5 ± 0.1 kg	1659 GPM
Al DIW	25 ± 0.1 °C	7.5 ± 0.1 kg	380 GPM
RF DIW	25 ± 0.01 °C	7.5 ± 0.1 kg	1284 GPM
Booster DIW	25 ± 0.1 °C	7.5 ± 0.1 kg	1238 GPM
Cooling Tower	32 ± 0.5 °C	2.5 ± 0.1 kg	12000 RT
Chilled Water	7.0 ± 0.2 °C	2.5 ± 0.1 kg	8400 RT
Hot Water	50 ± 0.3 °C	2.5 ± 0.1 kg	1600 kW

CONTROL SYSTEMS OF TPS UTILITY

There are three typical controllers used in the utility system of TPS. They are Programmable Automation Controller (PAC), Direct Digital Control system (DDC) and Programmable Logic Controller. Direct digital control is an automated control by a computer, which is broadly used on HVAC (Heating, Ventilation and Air Conditioning) control systems based upon PLC technology. In the TPS project, DDC controllers are widely used in every AHU (Air Handling Unit) to achieve precise temperature control. Local controllers are responsible for the temperature steadiness of local area. Due to the diversity of air condition demands, there are quite a few typical models to satisfy all kinds of requirements.

The mathematical model had been established to find out the relationships between the beam orbit and the supplied air temperature [3]. The beam orbit stability will become worse once the fluctuation of environmental temperature exceeds 0.2℃. Based on this thesis, lots of efforts had been made to increase temperature steadiness during TLS. With the endeavours of TPS project, the fluctuation of supply air temperature is greatly reduced within ± 0.1℃. By means of PAC, the fluctuation could be minimized within ± 0.01℃ in laboratory. Owing to much more accurate sensors and high performance

COMPENSATION STRATEGIES FOR RAMPING WAVEFORM OF TPS BOOSTER SYNCHROTRON MAIN POWER SUPPLIES

P. C. Chiu, C. Y. Wu, Jenny Chen, Y. S. Cheng, Demi Lee, B. S. Wang, K. B. Liu, K. H. Hu, K. T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

Booster synchrotron for the Taiwan photon source project which is a 3 GeV synchrotron light source constructed at NSRRC had been commissioning successfully when the electron beam was accelerated to 3 GeV on December 16 2014. The booster is designed to ramp electron beams from 150 MeV to 3 GeV in 3 Hz therefore the large main power supplies have features of waveform play with trigger functionalities. However, due to the limited bandwidth of power supplies, different magnet loading will result in quite different phase lag for dipoles and four quadrupoles families and the relative err of input and output of dipole and quadrupoles would be quite different. To improve the relative error between the output readings and reference, several strategies are developed and will be summarized in this report.

INTRODUCTION

The TPS is a state-of-the-art synchrotron radiation facility featuring ultra-high photon brightness with extremely low emittance [1]. The 3 GeV stored electron beam with 5 mA was achieved and the first synchrotron light was observed in December 31. It consists of a 150 MeV electron Linac, a 3 GeV booster synchrotron, and a 3 GeV storage ring. The EPICS (Experimental Physics and Industrial Control System) was chosen for the TPS accelerator control.

The booster main power supplies are composed of one dipole power supply with maximum current 1200 Ampere and four family quadrupole power supplies with maximum current of 120/150 Ampere. At first, these power supplies supported external trigger and internal waveform generator for booster power supply ramping. However, the reproducibility of power supply itself was unsatisfactory at injection due to non-synchronize and asynchronous internal clock of power supply regulator and external trigger. Therefore, the original digital regulation loop was modified to analogue and control interface was also revised so that all of power supplies could be driven by synchronized current waveform reference with common clock source and trigger. It effectively improved the reproducibility more than 1/5 [2, 3].

Figure 1 shows the overall booster ring power supplies control interface. One dedicated EPICS IOC equipped with one CPU blade, one EVR fanout and ADC/DAC modules is built to serve synchronous control and monitor of main booster power supply. Serial to Ethernet adapter are used to interface with On/Off control and status monitor. Moreover, the DT8837 which has 24 bits ADC provide extra high more precision monitoring than ADC modules and also support the external clock for synchronization.

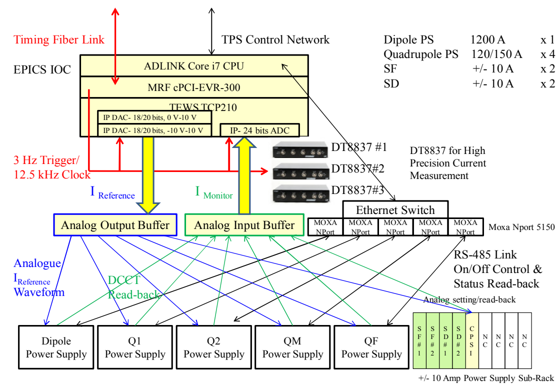

Figure 1: Control infrastructure of TPS booster ring power supplies.

POWER SUPPLY CHARACTERIZATION

Power supply for booster dipole and quadrupoles were contracted and delivered by Eaton. Figure 2 shows the step response of dipole and four quadrupole power supplies at first arrival. It exhibited quite different frequency response which would result in unacceptable tracking error difference between dipole and quadrupole power supplies at injection during ramping as Fig. 3. Adjusting loop gain of power supply analogue regulator by changing resistors could improve the difference but ineffective, imprecise and time-consuming. When one of power supply fails and the spared is necessary, the characterization of the spared would be required re-calibrated, this will cost much man-power and time. It will be quite a burden from maintenance points of view.

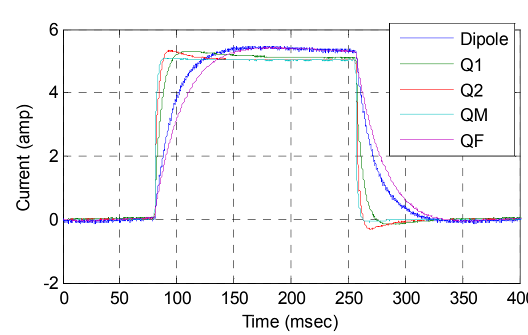

Figure 2: Step response of dipole and four quadrupole power supplies. Dipole and QF had slower response due to larger magnet loading.

BEAM STABILITY OF THE TAIWAN LIGHT SOURCE STORAGE RING

Hung-Chiao Chen*, Hsin-Hui Chen, Szu-Jung Huang, Jar-An Li, Yao-Kwang Lin, Chang-Hor Kuo, Yung-Sen Cheng
National Synchrotron Radiation Research Center, 101 Hsin-Ann Road, Hsinchu Science Park, Hsinchu 30076, Taiwan, R.O.C.

Abstract

The Taiwan Light Source Storage Ring (SR) has been in operation since many years ago. Maintaining best stability of the electron beam is becoming the main challenge. This study endeavored to improve the electron beam stability and injection efficiency of The Taiwan Light Source Storage Ring (SR). Employing the artificial neural network (ANN)-constructed experiment design to analyze and optimize the storage ring betatron tunes .This report outlines the details of the beam stability and injection efficiency process experiment.

INTRODUCTION

Using the basic theory of response surface methodology (RSM), this study aimed to improve the electron beam stability and injection efficiency of the National Synchrotron Radiation Research Center (NSRRC) storage ring. Artificial neural network (ANN) design software, known as computer-aided formula engineering (CAFE) [1], was used to analyze and optimize the betatron tunes of the storage ring. We aimed to identify the main influential the betatron tunes of the storage ring and, through optimization, develop the betatron tunes of the storage ring adjustment program that best stability and maximizes injection efficiency of the electron beam.

DATA ANALYSIS

Artificial Neural Network

ANNs are construction methods for nonlinear models. Among which, back-propagation networks (BPNs) are currently the most representative and commonly applied of the ANN learning models [2, 3].

Beam Stability Analysis

After calculating the ANN model construction, we obtained the "train- and -test" error convergence curve, as shown in Fig. 1. The representative model construction was ideal because they appear to converge after approximately 1,500 computations.

chiao@nsrrc.org.tw

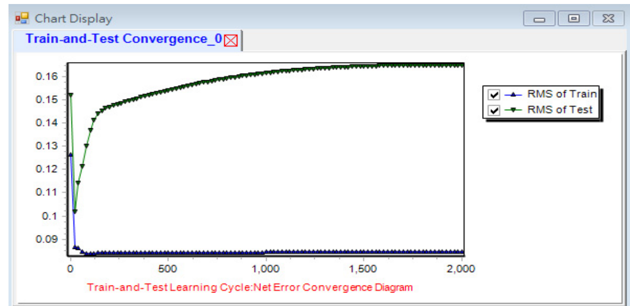

Figure 1: The "train- and -test " error convergence curve.

The "train- and -test" scatter plots for the training sample is shown in Fig. 2 respectively. The predictive ability of the representative model was also ideal [4].

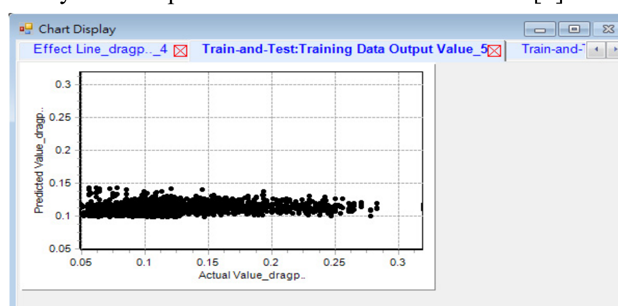

Figure 2: The "train- and -test " scatter plot of the training samples.

Analysis of the experimental results included sensitivity analysis and influence line analysis. Sensitivity analysis was conducted using weight value analysis graphs, and influence line analysis was conducted using a main effect diagram with status. The sensitivity analysis results revealed the significance of quality factors, as shown in Fig. 3. We found the betatron tune fy quality factor had the highest significance.

- The weight of the betatron tune fx was 0.015.
- The weight of the betatron tune fy was 0.061.

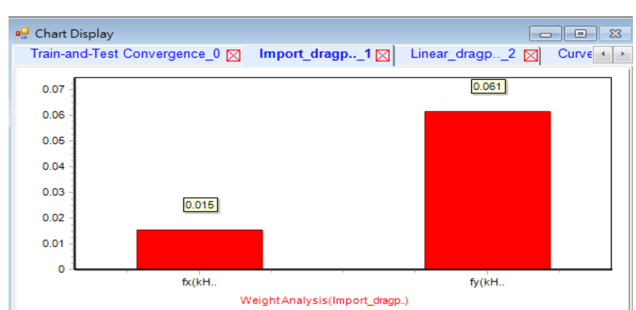

Figure 3: A bar graph of Y significance.

CONTROL INTERFACE AND FUNCTIONALITY OF TPS BOOSTER POWER SUPPLY

C. Y. Wu, P. C. Chiu, Y. S. Cheng, C. Y. Liao, Jenny Chen, Demi Lee, C. H. Huang, K. H. Hu, K. T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

The TPS booster is a synchrotron with injection energy at 150 MeV and extraction energy at 3 GeV in 3 Hz. Booster main power supplies consist of one dipole power supply with maximum current 1200 Ampere and four quadrupole family power supplies with maximum current of 120/150 Ampere. The small power supply for booster corrector and sextupole is a low noise switching power supply with +/- 10 Ampere current range. The TPS booster control environment is based on EPICS framework to support rich functionalities including power supply control, waveform management, operation supports, and so on. All power supplies support DC mode and 3 Hz ramping mode operation for TPS booster commissioning and operation. Efforts on control interface and functionality for TPS booster power supply will be summarizes.

INTRODUCTION

The TPS [1] is a latest generation of high brightness synchrotron light source which had completed phase I commissioning in March, 2015 [2-3]. It consists of a 150 MeV electron Linac, a 3 GeV booster synchrotron, and a 3 GeV storage ring. The EPICS (Experimental Physics and Industrial Control System) was chosen for the TPS accelerator control.

The control interfaces of TPS booster power supplies have two major categories: one is for the large main power supply which could provide current up to 1200 and 120/150 amperes and used for dipole magnets and quadrupole magnets respectively; the other is small power supply which supports +/- 10 Amperes current output and used for sextupole magnets and correctors. Table 1 summarizes the specifications of booster ring power supplies [4-5].

Table 1: TPS Booster Ring Power Supply Summary

Magnet	Type	Max Current	Number of PS	PS Vendor	Control Interface
Dipole	Unipolar	1200 A	1	Eaton[4]	RS485 & Analog interface
Quadrupole	Unipolar	120/150 A	4~5	Eaton	RS485 & Analog interface
Sextupole	Bipolar	± 10 A	4	ITRI [5]	Analog interface
Corrector	Bipolar	± 10 A	HC: 60 VC: 36	ITRI	CPSC (Ethernet)

All of these power supplies should have features of waveform play with external trigger functionalities to enable electron beams ramp from 150 MeV to 3 GeV in 3 Hz. The large power supply provides RS-485 control interface for ON/OFF and status reading and analog input for current setting. One dedicated EPICS IOC is used to serve its control and monitor. The small power supplies have 12 special designed corrector power supply controllers (CPSC) with embedded EPICS IOCs allocated at power supply rack for its control. The control environment of these power supplies will be summarized in this report. Fig. 1 shows the pictures of dipole and quadrupole power supply for booster synchrotron which had been installed in the site.

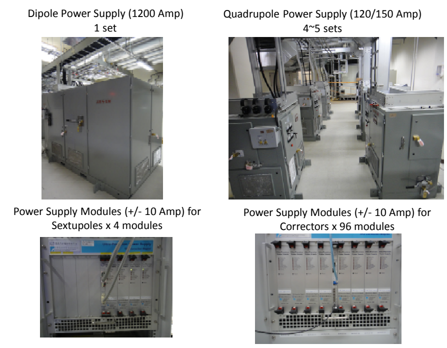

Figure 1: Large and small power supplies for the dipole, quadrupole, sextupole and correctors of TPS booster synchrotron respectively.

CONTROL INTERFACE OF BOOSTER MAIN POWER SUPPLY

The booster main power supplies are composed of one dipole power supply with maximum current 1200 Amperes and four family quadrupole power supplies with maximum current of 120/150 Amperes. These power supplies support analog input for power supply current setting (DC and AC). Serial to Ethernet adapter are used to interface between the booster main power supplies and EPICS IOC.

ONLINE RADFET READER FOR BEAM LOSS MONITORING SYSTEM

D. Lee, Y. S. Cheng, C. H. Huang, K. H. Hu, C. Y. Wu, J. Chen, K. T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

To investigate the beam loss and its distribution during operation of synchrotron light sources at NSSRC, a sixteen-channel readout box is designed and implemented to read the threshold voltage of the RadFETs installed at the accelerator tunnel. To simplify the design, the reader plays a role of remote I/O for EPICS IOC. The IOC collects voltage from readers distributed in the accelerator to deduce the integrated dose and dose rate. User interface is shown in the control console for real-time display, and the archived data are processed off-line.

INTRODUCTION

The radiation-sensing field-effect transistor (RadFET) is a discrete p-channel metal-oxide-semiconductor field-effect transistor optimized for ionizing radiation [1]. The threshold voltage between the gate and source changes due to radiation-induced charges in the oxide layer when applying a constant drain current. The reader of the RadFETs acts by applying constant drain current and read the threshold periodically. The voltage is proportional to accumulated exposure dose, and the slop of the accumulated dose is dose rate. Many different designs are reported for high energy detector and accelerator systems [1,2,3] with various considerations. Some are with simple interfaces and some are with intelligence ones. For a synchrotron light source, the RadFET will be a useful device to detect beam loss caused by the various mechanisms. A simply and low cost reader designed and implemented for beam loss study will be summary in following paragraph.

OVERVIEW OF THE READER IMPLEMENTATION

In order to achieve the high-density installation of the RadFETs, the reader is designed to link up to sixteen RadFETs using unshielded-twisted-pair network cables with standard RJ-45 connector, as shown in Fig. 1. In the radiation exposure period, the gate voltage is zero-biased or apply specific positive bias to increase sensitivity. In the readout period, a constant specific current is applied to the drain of RadFET to measure the threshold voltage (V_{th}) of the reader. The readout period is one minute now and the threshold voltage is readout one by one through a 24-bit analog-to-digital convertor (ADC). The control processes are programmed in the input/output controller (IOC) of the experimental physics and industrial control system (EPICS) and PVs are published into the control network, shown in Fig. 2. An operation interface is designed to show the threshold voltage of each RadFET, accumulated dose, dose rate even dose rate distribution. The threshold voltage of each RadFET is recorded in the archive server for the further analysis.

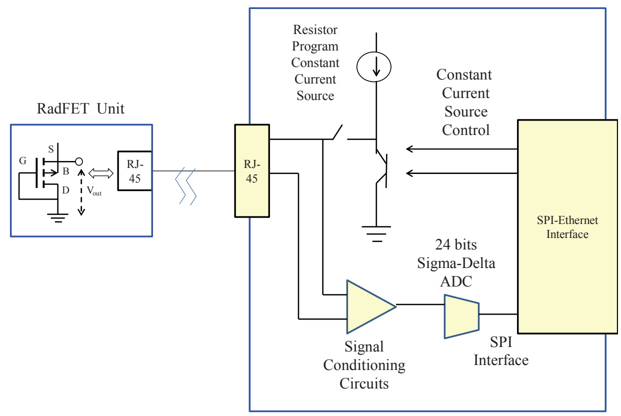

Figure 1: Simple schematic diagram of an individual RadFET reading hardware.

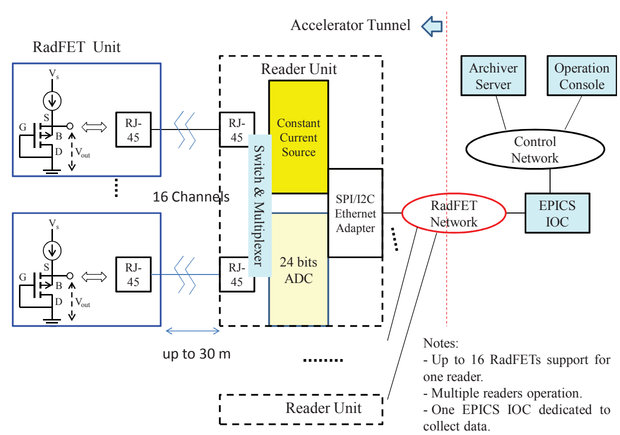

Figure 2: Block diagram of the RadFET readers system.

HARDWARE CONSIDERATION

Several issues have been identified during functionality discussion phase. To simplify software development cycle, it was decided that the reader just plays as roles of remote I/O units without local intelligence from viewpoints of control system. It needs not to do software programming at the reader side. To make easily cable to the data acquisition controller, the interface is Ethernet. Minimizing the interconnecting inside the reader is achieved by SPI interface to read threshold voltage of

FPGA BASED GLOBAL ORBIT FEEDBACK IN THE TAIWAN LIGHT SOURCE

C. H. Kuo, P. C. Chiu, K. H. Hu, Demi Li, Y. S. Cheng, K. T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

The global orbit feedback for the 1.5 GeV electron storage ring of TLS has been operated more than ten years. This system uses general processors to control feedback loop with 1 kHz rate. It is very important for various operation of storage ring now, but some hardware components could have been out of stock in the future. As a prototype, a FPGA based fast global orbit feedback at a 10 kHz data acquisition rate has been developed. A micro-TCA liked platform with FPGA board is used to implement control algorithm and acquire BPM data from Libera Brillance. The correction algorithm is written in VHDL and connected to power supply with AURORA digital links. The system architecture will be discussed in this report.

INTRODUCTION

Orbit feedback system operation of general processors is integrated with Libera Brilliance since 2008. The Brillance supports many beam position functions: slow position data acquisition, post mortem and tune measurement in the TLS. The group topology of Libera Brilliance to acquire fast data at 10 kHz rate has been under testing to verify long-term reliability and stability. The general processors are enough for orbit control. There are two reasons to migrate general processor to FPGA. One, single processor is hard to handle many individual PID control algorithm calculation; another is general cpu platform and operation system that couldn't be upgraded in the future. From maintenance points of view, keep control system of TLS and TPS to be same can reduce this cost. The grouping latency of Libera have been measured and tested that is satisfied for orbit feedback system. It is reliable. The new system is still following this structure. On the other hand, the corrector power supply control is also migrated to FPGA with rocket I/O interface from general cpu with VME bus. Integration of all of the new switching power supplies will be accomplished recently.

THE FPGA BASED FEEDBACK PLATFORM

Feedback System Overview

The TLS Fast Orbit Feedback Application runs in the micro-TCA liked chassis from commercial product. The BPM incoming data comes from the group of Libera Brilliance and is received through the SFP slot (GbE interface) in the GDX module [1]. The FOFB calculations and magnet output are implemented in the GDX module. Global orbit position is concentrated by a group of Libera Brilliance devices. Libera Grouping must be configured as per unit. The FOFB control algorithm runs in two same chassis of GDX, one for horizontal and one for vertical plane. Two Libera Brilliance devices from the group must be selected as master Liberas to output the global orbit position. The general overview is presented in Fig. 1.

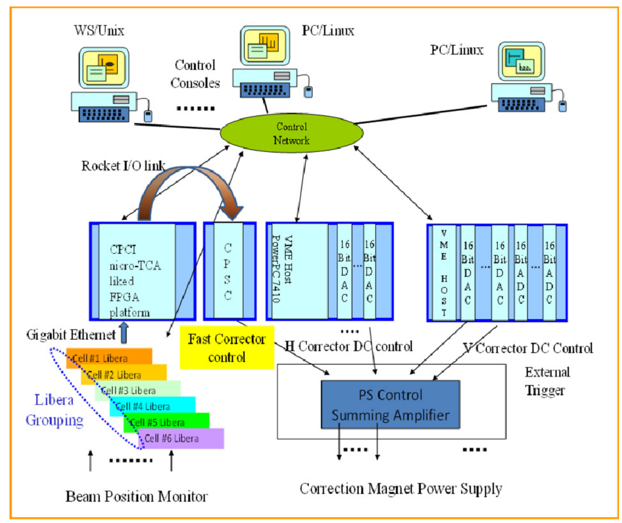

Figure 1: The overview system block diagram.

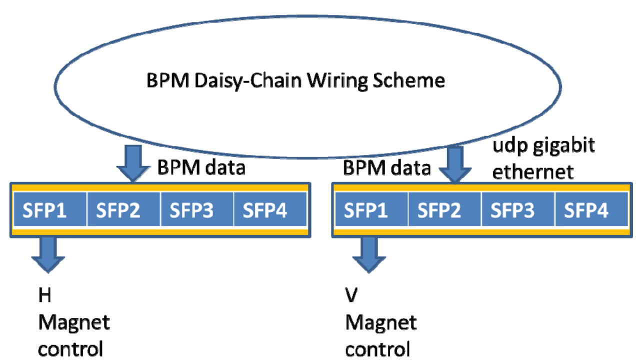

Figure 2: Feednack system is integrated by daisy-chain wiring bus of bpm with GDX module.

The global orbit data packet is received in the GDX of micro-TCA liked chassis, it is written to the circular buffer and it enters the FOFB calculation process which ends with DAC setting output on a SFP1 slot with AURORA 2.5 Gbps duplex protocol. It is then led to the Corrector Power Supply Controller Interface (CPSC) which provides analog output to corrector magnets [2]. The communication block diagram is shown in Fig. 2. The feedback platform photo is presented in Fig. 3.

BEAM LOSS STUDY OF TLS USING RadFETs

C. H. Huang, S.H. Lee, Y.S. Cheng, K. H. Hu, C. Y. Wu, J. Chen, K. T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

To realize the beam loss during the operation of Taiwan light source, P-type radiation-sensing field-effect transistors are setup around the storage ring. A sixteen-channel readout box is used to read the threshold voltage of the radiation-sensing field-effect transistors during irradiation. The beam loss distribution and mechanism at the injection period, decay mode and top up injection for routing operation will be studied in this report.

INTRODUCTION

The radiation-sensing field-effect transistor (RadFET) is a discrete p-channel metal-oxide-semiconductor field-effect transistor optimized for ionizing radiation [1]. Through detecting the voltage between the gate and source caused by the radiation-induced charges in the gate oxide during a forcing current, the radiation dose is obtained by a pre-recorded calibration curve.

For the last two decades, RadFETs have been found wide applications in the particle accelerator environment [2], space and clinical control. For a synchrotron light source such as Taiwan light source (TLS), the RadFET will be a useful device to detect beam loss due to the Touschek effect, the residual gas scattering, the intra-beam scattering and so on [3].

TLS is a synchrotron light source which equips with six-fold symmetry and three-bend achromatic (TBA) cells in storage ring. Its circumference is 120 m and the operating energy is 1.5 GeV. It equips with insertion devices including U50, U90, EPU56, W200, superconducting wavelength shifter (SWLS) and superconducting wiggler (SW60) in six 6-m long straight sections. Three identical superconducting wigglers (IASWR2, IASWR4, IASWR6) are installed in achromatic cells between the first and the second bending magnets of the second, fourth and sixth TBA cells.

RADFET READER SYSTEM

In order to achieve high density installation of the RadFETs, the reader is designed to link up to sixteen RadFETs with RJ-45 connectors and unshielded-twisted-pair network cables, as shown in Fig. 1. In the radiation exposure period, the gate voltage is zero-biased now or +5V for the positive-biased applications. In the readout period, a DC current with 12.5 μA is forcing into the gate for several seconds to obtain the threshold voltage (V_{th}) in the reader circuit configuration. The readout period is one minute now and the threshold voltage is readout one by one through a 24-bit analog-to-digital convertor (ADC). The control processes are programmed in the input / output controller (IOC) of the experimental physics and industrial control system (EPICS) and process variables (PVs) are published into the control network. An operation interface is designed to show the threshold voltage of RadFETs, accumulated dose, dose rate and dose rate distribution. The threshold voltage of RadFETs are recorded in the archive server for further analysis after the experiment [4].

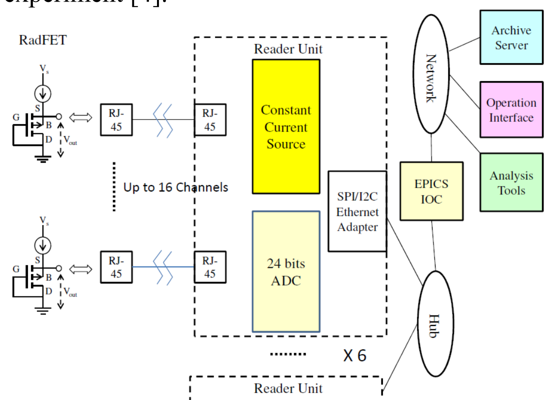

Figure 1: Block diagram of the RadFET readers' setup.

EXPERIMENTAL SETUP AND RESULTS

Six readers are setup below the girder of the second bending magnet in each cell of the storage ring to minimize the possible radiation damage, shown in Fig. 2(a). The uplink cables of six readers are connected to an Ethernet switch to form as a private network and then connect to the IOC in the equipment area of the TLS. In the first step, the two RadFETs are setup in the blue square position of Fig. 3 with one in the inside wall of the vacuum chamber shown in Fig. 2(b) and the other in the outside wall of the chamber in the storage ring.

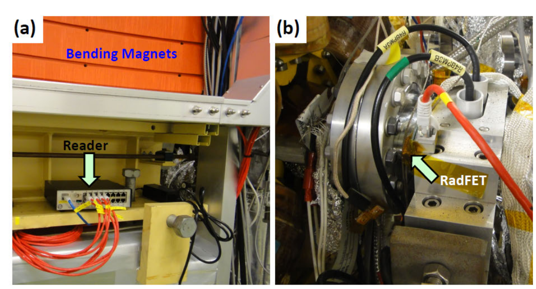

Figure 2: The setup of the (a) reader and (b) RadFET.

As the machine operates on the top-up mode, the detected radiation in the inside wall of the chamber is mostly larger than that in the outside wall, shown in Fig 4. That is because the beam loss caused by Touschek effect contributes into both sides but the beam loss caused by Bremsstrahlung only contributes to the inside wall. The detected dose rate is smaller than 0.3 Gy/hr except the

Abstract

Booster synchrotron for the Taiwan photon source (TPS) project which is a 3 GeV synchrotron light source constructed at NSRRC had ramped beam to 3 GeV successfully in December 16 2014 and later the stored beam in the storage ring had achieved 5 mA in December 31. The BPM electronics Libera Brilliance+ [1-2] are adopted for booster and storage ring of TPS. The provided BPM data is useful for beam commissioning where it can be used to measure beam position, rough beam intensity along the longitudinal position and also for tune measurement. This report summarizes the efforts on BPM measurement and related diagnostic tools during TPS booster commissioning.

INTRODUCTION

The TPS is a state-of-the-art synchrotron radiation facility featuring ultra-high photon brightness with extremely low emittance [3]. Civil constructions had been completed in early 2013. The TPS accelerator complex consists of a 150 MeV S-band linac, linac to booster transfer line (LTB), 0.15–3 GeV booster synchrotron, booster to storage ring transfer line (BTS), and 3 GeV storage ring. The booster has 6 FODO cells which include 7 BD dipoles with 1.6 m long and 2 BH dipoles with 0.8 m long in each cell. Its circumference is 496.8 meters and it is concentric with the storage ring in the same tunnel. At September 2014, booster BPM commissioning had committed with beam commissioning. After some hardware improvement such as power supply tuning, chamber and magnet re-alignment, demagnetization of chamber, kicker and septum improving and etc., booster had achieved beam ramped to 3 GeV at December 16 2014. Diagnostic system played a helpful rule to provided beam profile and information during booster commissioning. This report will focus on the booster BPM related environment, functionalities and measurement.

BOOSTER BPM FUNCTIONALITIES AND COMMISSIONING

The TPS booster ring has six cells where each cell is equipped with 10 BPMs which can be used to measure beam position and rough beam intensity along the longitudinal position. Fig. 1 shows the mechanical drawing of booster BPM which shapes 35x20 mm elliptical and button diameter 10.7 mm. The calibration factor Kx and Ky is 8.25 and 9.66 mm respectively.

The conceptual functional block diagram of the BPM electronics is shown in Fig. 2. It will provide several data type for different application. ADC and TBT data is acquired on demand by trigger; 10 Hz slow data is for DC average orbit and 10 kHz fast data could be applied for booster ramping orbit or fast orbit feedback application. It is also embedded with EPICS IOC for control, monitor and configuration. The timing AMC module would provide functionalities of synchronization, trigger, interlock and post-mortem. To support operation of the BPM electronics, functionalities like cold start, shutdown, housing, control system interface should meet the requirements. The delivered units also had been performed functionality and performance test to ensure compliance with this specification.

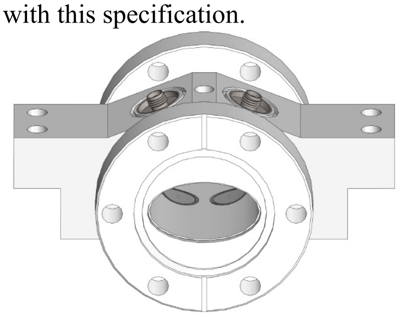

Figure 1: Button-type BPM for TPS Booster.

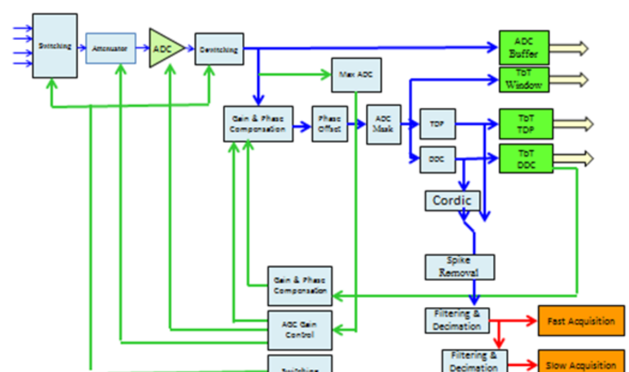

Figure 2: BPM platform functional block diagram.

At early September, the first turn of the booster beam had achieved soon after correctors steering. There are only few buttons of BPM found to have contact problems quickly by observing ADC data with extremely low count compared to other buttons. The real BPM calibration factor was agreed with the designed values by measuring and comparing the optical function of machine model.

BOOSTER BPM MEASUREMENT

For TPS booster BPM, there are 60 sets of phase-trimmed 0.240” form polyethylene coaxial cables connected between the buttons and BPM electronics. The gain variation of BPM electronics is less than 5%. The equal length of all cable sets will contribute the same

H.P. Hsueh, S.Y. Hsu, K.H. Hu, K.T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

Taiwan Photon Source (TPS) is a third generation 3 GeV synchrotron light facility. The synchrotron radiation from a dipole can be used to observe the beam parameters. The synchrotron radiation monitor (SRM) systems were designed and implemented for the booster synchrotron and storage ring. The SRM for the booster synchrotron can serve to diagnose the energy ramping process. The beam size decreases when the energy increases was observed. In the storage ring, the streak camera was preferred to observe the beam behaviour of the consecutive bunches. The bunch length and longitudinal instability were observed. The preliminary beam test results are summarized in this report.

INTRODUCTION

The Taiwan Photon Source (TPS) is a state-of-the-art synchrotron radiation facility featuring ultra-high photon brightness with extremely low emittance. The TPS accelerator complex consists of a 150 MeV S-band linac, linac to booster transfer line (LTB), 0.15–3 GeV booster synchrotron, booster to storage ring transfer line (BTS), and 3 GeV storage ring. The storage ring has 24 DBA lattices cells with 6-fold symmetry configuration [1]. The TPS commissioning is separated into two phases. Phase I commissioning was done in the first quarter of 2015 with two Petra 5-cells cavities and without insertion devices. Phase II commissioning is scheduled to start in the third quarter of 2015 with two superconducting RF cavities and insertion devices.

The synchrotron radiation monitors are designed in the booster and storage ring of the TPS, which play an important role during the commissioning. The SRM for the booster synchrotron serves to characterize energy ramping process. In the storage ring, SRM can be used to measure the beam size, bunch length and beam behaviour, and fill pattern by X-ray pinhole camera, streak camera, and photon counting technique, respectively. The design overview and preliminary beam test results are presented in this paper.

SYSTEM DESIGN

Synchrotron Radiation Monitor for Booster

The SRM design of booster synchrotron was shown in Fig. 1. The light leads to the wall via a four-piece adjustable mirror, focusing through a lens (f = 1 m) and band-pass filter to GigE Vision camera. The camera trigger is synchronized with the machine cycle; change the delay time will change the energy point of observation. A 1-inch size CCD is used to quickly and easily to find a first-time beam spot. During the commissioning, a few times entering the tunnel is necessary to adjust the lens until the light beam is within the CCD's sensing area. This synchrotron light monitoring port was used for streak camera measurement for linac beam and booster stored beam also.

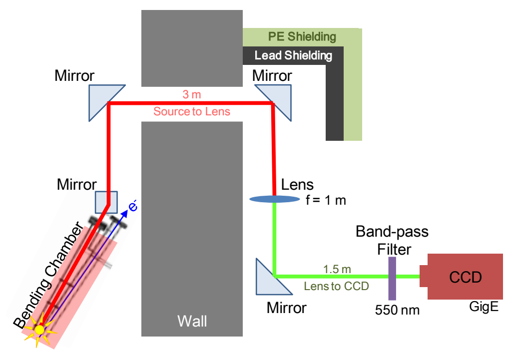

Figure 1: A side-view scheme of the synchrotron radiation monitor for the booster ring.

Diagnostics Beamline for Storage Ring

The photon diagnostics beamline for the TPS storage ring utilized visible light and X-ray of the synchrotron radiation which generated in a bending magnet. The photon diagnostics devices are summary in Table 1. The X-ray pinhole camera design as shown in Fig. 2, which is imaging the electron beam from bending magnet for the beam size and emittance measurements. They offer the required resolution and the dynamic range to measure the electron beam size accurately at all currents. The visible light of synchrotron radiation was design for streak camera, interferometer and fill pattern measurements, as shown in Fig. 3.

Table 1: The SRM Diagnostics Devices for Storage Ring

Monitor	Beam parameters
X-ray pinhole camera	Beam size and emittance
Fill pattern monitoring	Fill pattern and isolated bunch purity
Visible light interferometer	Alternative beam size
Visible light streak camera	Bunch length and behaviour

VIBRATION MEASUREMENT OF THE MAGNETS IN THE STORAGE RING OF TPS

C. H. Huang, P. C. Chiu, Demi Lee, C. Y. Liao, Y. S. Cheng, K. T. Hsu
NSRRC, Hsinchu 30076, Taiwan

Abstract

Taiwan photon source is a 3rd generation synchrotron light source which is in beam commissioning at NSRRC. Orbit stability within 100 nm range is essential for such a small emittance light source. Technical noise from the vacuum pumps, water flow, etc. will cause the vibration of quadrupoles and deleterious orbit stability. In order to investigate the magnitude of vibration in the magnets of the storage ring, the vibration spectra of the lattice quadruples; the coherence between the magnets, girders and ground will be systematic investigated in this report.

INTRODUCTION

Taiwan photon source (TPS) is a low emittance, third-generation light source in NSRRC. Its circumference is 518.4 m with 24 double-bend achromat (DBA) cells [1]. There are 6 long-straight sections and 18 standard-straight sections to accommodate insertion device. The vertical beam size at the centre of the standard cell of insertion devices straight is around 5 µm. This imposes a stringent requirement for the orbit stability. To obtain a high quality light source, the beam orbit motion needs to be controlled at least within 0.5 µm.

Ground vibration and the technical noise such as vacuum pumps and water flow will cause the magnet vibration and then leads to the distortion of the close orbit. The frequency of such vibration is much smaller than the revolution frequency of the electron beam so the vibration of the magnet can be treated as a constant displacement or beam offset [2]. The dominant effect is produced by the quadrupole and it introduces a kick angle (θ) to the beam: $\theta = eckyL/E$. k is the quadrupole strength; y is the beam offset to quadrupole center; L is the quadrupole length; E is the beam energy [3]. The closed orbit distortion (Δy_j) at j-th position caused by i-th quadrupole would be $\Delta y_j = \theta_i \sqrt{\beta_i \beta_j} \cos(\pi\nu - |\psi_j - \psi_i|)/(2\sin\pi\nu)$. Here β, ψ and ν are the beta function, phase and tune.

In this paper, we focus on vibration in the 240 quadrupoles of the storage ring. The vibration of devices and mechanical supports which may cause the magnets vibration will also be summary here. At last, the correlation between quadrupoles, girder and ground will also be studied.

PROBES AND DATA ACQUISITION SYSTEM

Low noise three-components seismometers, LE-3Dlite Mark II [4], with frequency range 1- 100 Hz is used in this study. The data acquisition unit (Data Translation DT8837), which is complied with LXI class C standard, provides Ethernet accesses via SCPI command to acquire data. Multiple DT8837s are synchronized by wired trigger bus (WTB) interface. To extend length limit of WTB cable, an in-house made small interface adapter from RJ-45 to Micro D is installed at the WTB connector of the DT8837 side. It allows unshielded twisted pair (UTP) cables to replace WTB cables and to send the trigger, sync and clock single from the timing system adapter to DT8837 more than 100 m. Coherent data acquisition can also be achieved by the aid of global timing system. A Matlab script can be running in the sever for the long-term measurement or in the laptop for the short-term measurement, shown in Fig. 1.

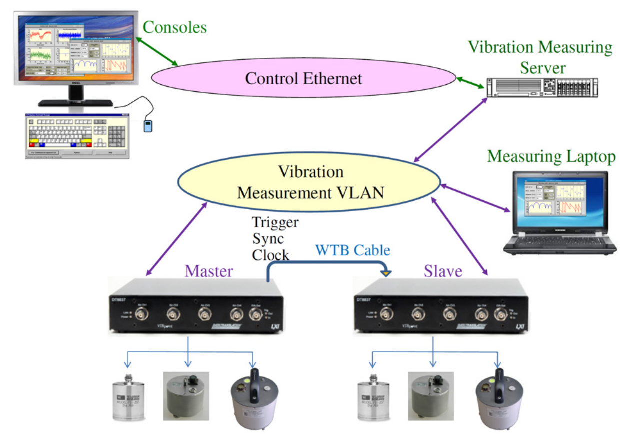

Figure 1: Configuration of vibration measuring system.

MESASURMENT RESULTS

Vibration of Quadrupoles and Dipoles

In the beginning of the commissioning of the storage ring, the vibration of quadruples and dipoles in all storage are measured to realize the relationship between vibration and beam motion. From the displacement spectra of magnets of the 21th cell as shown in Fig. 2 for example, there is a sharp resonance around 29 Hz. The maximum displacement amplitude is larger than 200 nm in vertical direction and 600 nm in horizontal direction within all the quadrupoles of the storage ring, shown in Fig. 3. This vibration frequency is caused by the turbo pumps. Although the turbo pumps do not directly contact to the magnets, the vacuum chambers which connect to turbo pumps are supported by the girders. Unfortunately, the vertical resonance frequency of the girder is around 30 Hz in which vibration would be magnified and translated into the magnets above the girder.

DEVELOPMENT OF EPICS APPLICATIONS FOR THE TAIWAN LIGHT SOURCE

Y. S. Cheng, Jenny Chen, C. Y. Liao, P. C. Chiu, C. H. Huang, K. T. Hsu
National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract

The TLS (Taiwan Light Source) is a third generation of synchrotron light source, and it has been operated since 1993. The TLS control system is a proprietary design. It was performed minor upgrade several times to avoid obsolete of some system components and keep up-to-date during last two decades. The control system of the TPS project (Taiwan Photon Source) is based upon the EPICS framework. To save resources for TLS control system maintenance, adopt EPICS for newly developed and rejuvenated subsystems for some of the TLS control interfaces includes BPM system, insertion devices, bunch-by-bunch feedbacks, electronics instruments interface and so on. Some EPICS related applications have been developed, and EPICS graphical user interface is also operated at the TLS control consoles environment normally. Current system allowed two kinds of control environments working together. The efforts will be described at this report.

INTRODUCTION

The TLS is a third generation of synchrotron light source built at the National Synchrotron Radiation Research Center (NSRRC) site in Taiwan, and it has been operated since 1993. The TLS consists of a 50 MeV electron Linac, a 1.5 GeV booster synchrotron, and a storage ring with 360 mA top-up injection. The TLS Control system is a proprietary design [1]. Several minor upgrades had been performed to avoid obsolete during last two decades. It consists of console level workstations and VME based intelligent local controller (ILC) to interface with subsystems. Hardware and software on console level workstation change several times due to evolution of fast evolution of computer technology. PC running Linux is the current configuration. Due to the well design of the original control software structure, port to new platform without difficult.

The EPICS (Experimental Physics and Industrial Control System) is a set of open source software tools, libraries and applications developed collaboratively and used to create distributed soft real-time control systems for scientific instruments such as the particle accelerators and large scientific experiments [2]. Many particle accelerator facilities adopt EPICS framework for their control systems and gain good experiences. Many resources and supports are available as well as numerous applications for accelerator have been developed.

The EPICS toolkits were chosen as control system framework for the Taiwan Photon Sourece (TPS) of 3 GeV synchrotron light source [3]. The TPS control system with the EPICS mechanism has been integrated and commissioned. On the other hand, in order to adopt update technology and re-use expertise of manpower, the upgrade and maintenance for TLS control system adopts the EPICS as its framework. Moreover, some new installed subsystems runs EPICS control environment to reduce working load and use the same expertise of manpower.

In the TLS, the control console can continuously operate on the existing control system environment and develop additionally in the EPICS framework for the subsystem upgrade in the meanwhile.

Utilizing the EPICS channel access mechanism with the specific toolkits, the data can be accessed between the IOCs (Input Output Controller) and the clients. The various operation processes are developed and tested according to the various operation modes. The implementation of subsystems is introduced as followings.

EPICS ENVIRONMENT OF TLS CONTROL SYSTEM

To implement the EPICS support for some subsystems, the control environment of the IOC is set up with the specific EPICS base, modules and extensions at the Linux operation system. To control and monitor subsystems based on EPICS environment via Ethernet, the clients should be installed the specific EPICS base and the graphical operation toolkits, such as EDM (Extensible Display Manager) and MATLAB (channel access via the labCA module) for EPICS channel access.

Most of EPICS related files at control consoles are mounted from the file server by using the NFS service (Network File System) to simplify software version control. Various directories are created and saved into various versions of related files for various hosts and purposes. Various directories provide a mount point for hosts mounted according to various purposes. The directories include EPICS base, modules, extensions, saved data, temporary data and etc.

RUN EPICS IOC ON AN ILC OF TLS CONTROL SYSTEM

An EPICS IOC is activated on an ILC to support homogenous access from TLS console computers. TLS ILCs broadcast their dynamic data, DDB, at 10 Hz to simplify data transaction between consoles and ILCs; with SDB and database-access-library installed TLS console APs manipulate the signals efficiently. The TLS control system is an isolated system. To have the rich support of EPICS, the plans of two insertion devices control system upgrade had adopted the EPICS framework. To support access from existing TLS

CONTROL INTERFACE OF PULSE MAGNET POWER SUPPLY FOR TPS PROJECT

C. Y. Wu, Y. S. Cheng, C. S. Fann, Jenny Chen, C. Y. Liao, S. Y. Hsu,
Demi Lee, C. H. Huang, K. H. Hu, K.T. Hsu, K. K. Lin
National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract

The TPS (Taiwan Photon Source) is low emittance 3 GeV synchrotron light source. The design and implementation of a pulse magnet power supply control system for beam injection and extraction were done. The EPICS embedded programmable logic controller (PLC) was applied to control pulse magnet power supply. The system comprises various input/output modules and a CPU module with built-in Ethernet interface. The control information (status of the power supply, ON, OFF, warn up, reset, reading/setting voltage, etc.) can be accessed remotely using EPICS client tools. The TPS timing system provide trigger signals for pulse magnet power supplies. The Ethernet-based oscilloscope is employed to observe current waveform of pulse magnet power supply with EPICS support. This paper describes control interface and operation GUI for the TPS pulse magnet power supply.

INTRODUCTION

The TPS [1] is a latest generation of high brightness synchrotron light source which has been under construction at the National Synchrotron Radiation Research Center (NSRRC) in Taiwan since February 2010. The civil construction works are finished in early 2014. The TPS pulse magnets consist of booster injection septum and kicker, booster extraction septums and kickers, storage ring injection septum and kickers, and storage ring diagnostic kickers (pingers). The pulse magnets installation and system integration were done soon after site available. The pulse magnets power supplies functionalities and performance were successfully verified with beam commissioning [2].

Table 1 lists main parameters of TPS kickers and septa pulse magnets. The EPICS IOC embedded PLC, F3RP61-2L IOC, was adopted for the pulse magnet power supply control. The F3RP61-2L IOC is compact, easy troubleshooting, and cost effective for pulse magnet power supply control. The pulse magnet power supply (pulser) requires small amount of I/O points, therefore, the F3RP61-2L IOC is more suitable compared with the applications of the TPS standard 6U CompactPCI platform with high I/O density.

The EPICS [3] was adopted as the TPS control system framework. A typical PLC in control environment is supervised by a remote IOC through serial link or Ethernet connections. It needs more work for developing both side of control software compared with using F3RP61-2L IOC. This report will summarize the pulse magnets power supplies related control environment, functionalities and measurement.

Table 1: Main Parameters of TPS Pulse Magnets

Magnet Type	Type	Operating Current (A)	Pulse Duration (μs)	Quantity
Booster Injection Kicker	PFN	~250	~1	1
Booster Extraction Kicker	PFN	~350	~1	2
Storage Ring Injection Kicker	Half-sine	~1100	~5	4
Storage Ring Pinger	Half-sine	-	~ 3	2
Booster Injection Septum	Half-sine	~2300	~400	1
Booster Extraction Septum	Half-sine	~10000	~400	2
Storage Ring Injection Septum	Half-sine	~10000	~400	2

SYSTEM CONFIGURATION

The control environment for TPS pulse magnets power supplies is shown in Fig. 1. The F3RP61-2L IOC is used to monitor status and control the pulse magnets power supplies. To support remote access of the current waveforms, oscilloscopes are managed by one dedicated EPICS IOC. To capture current transformer waveform of pulse magnets power supplies, the LAN extension for Instrumentation (LXI) or Ethernet-base oscilloscopes are connected to EPICS IOC via Ethernet interface.

Event based timing system is implemented to support commissioning and operation for the TPS [4-5]. The timing system is based on the events coming from event generator (EVG). EVG handles the accelerator synchronization and trigger the injection and the extraction pulse device. The timing IOC equipped with event receiver (EVR) will distribute trigger signal of the pulse magnets power supplies to synchronize the operation of the accelerator system. The TPS pulse magnets power supplies will be operated in 3 Hz repetition rate.

The I/O modules configuration of Yokogawa F3RP61-2L IOC is shown in Fig. 2. It includes power supply module, 16 bit digital input module, 16 bit digital output module, 8 channel analog input module (16 bit ADC) and 8 channel analog output module (16 bit DAC). The I/O modules are mastered by F3RP61-2L CPU module. The interlock function of pulse magnet power supply is handled by local hardware circuits. It uses relay and timer

Abstract

24 sets of Laser PSD positioning system are parts of the TPS girder autoalignment system. Laser PSD positioning systems are installed in the straight section girders of TPS storage ring. The Laser PSD systems are assembled and calibrated in the Lab beforehand. The Laser and PSDs are assembled on girder and transported to TPS storage ring and Installed. During construction the system deviates from the normal position caused by variant temperature and external influence. For absolute position precision, another laser calibration system should be built to recalibrate the laser PSD system. This paper describes the installation of Laser PSD system in TPS storage ring and the status of the PSD system. A new absolute position calibration method for precision upgrade is also discussed.

INTRODUCTION

A precise auto-alignment scheme is developed to align and adjust the storage ring girders of Taiwan Photon Source (TPS). [1] Laser PSD system, part of auto-alignment scheme, is designed and developed to align two girders on both sides of the straight section. There are 6 sets of Laser PSD system for the 18m long straight section and 18 sets for 12m short straight section. To achieve high accuracy, a laser and position sensing device, PSD, with the accuracy of micrometer-scale has been designed and arranged for girder positioning [2-4].

The Laser PSD system is constructed by several main portions, including Laser, PSD, beam splitters and isolation tubes. The Laser with Gaussian distribution during working propagation distance, plays a role as a reference line of the girders of the straight-section, as shown in fig1.

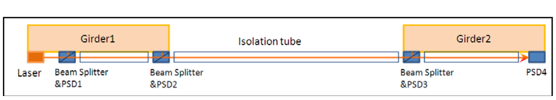

Figure 1: Architecture of Laser -PSD position system.

The PSD modules are adjusted and positioned within the error of micro-meter scale in advance. The PSD correction factors are calibrated. The absolute displacement accuracy of the Laser PSD system can be within 25 um by comparing with the Laser tracker. [5] After 24 sets of PSD system is assembled on girders in the lab, the girders system are transported to TPS storage ring and installed within the standard procedure for storage ring construction.

INSTALLATION OF LASER PSD SYSTEM IN TPS STORAGE RING

The Laser -PSD positioning system is constructed by several main portions, including Laser, PSD, beam splitters and isolation tubes. The Laser beam propagates in the isolation tubes, to prevent noise caused by temperature and flow of air due to the air conditioning system.

The first procedure of girder installation is to install the pedestals and positioning it in the tunnel. Followed by girders that are placed on the pedestals, and the isolating tube related fixtures which is positioned and assembled. The support of the isolation tube are adjusted and positioned in the straight section. The isolation tubes are connected and thermal insulation material are wrapped up around both sides of the tube to prevent air disturbance.

Figure 2: Laser potion and isolation tube of Laser -PSD system are assembled on the side of girder in lab. Then magnet girders are transported back and placed on pedestals in TPS tunnel.

Figure 3: The support of isolation tube are adjusted and positioned on the exact location of ground in the straight section of TPS storage ring.

A MULTI-BAND SINGLE SHOT SPECTROMETER FOR OBSERVATION OF MM-WAVE BURSTS AT DIAMOND LIGHT SOURCE*

A. Finn†, P. Karataev, JAI at Royal Holloway University of London, Egham, UK
G. Rehm, Diamond Light Source, Oxfordshire, UK

Abstract

Micro-bunch instabilities (MBI) have been detected at many light sources across the world. The bursts produced as a result of this instability occur in the millimetre regime. More needs to be determined about the dynamics of MBI in order to confirm the simulations. Consequently, a single shot spectrometer has been created to investigate this instability at Diamond Light Source (DLS). Due to their low noise, ultra-fast response and excellent sensitivity, Schottky detector diodes make up this spectrometer. Currently, seven Schottky detectors are in place covering a range of 33-750 GHz. Unlike previous measurements carried out, each of the Schottky detectors has been characterised thus making the results obtained comparable to simulations. In this paper, we present the assessment of each Schottky detector in the spectrometer; the first results of the spectrometer's use in the beam and future plans for the spectrometer.

INTRODUCTION

Micro-bunching instabilities are common at many lights sources around the world [1–3]. They are known to limit the operation of the storage ring, as bursting can affect user experiments. As a result of this, light sources usually endeavour to avoid the conditions which result in these additional bursts. MBI produce coherent synchrotron radiation (CSR), bursts of CSR to be more precise. CSR from the whole bunch occurs when the wavelength of radiation exceeds the bunch length. CSR is also produced when structure in the longitudinal profile is of short length, and in this case the CSR can even enhance that structure further.

Since 2009, the Diamond storage ring is often operated in a dedicated low alpha mode [4], whereby the momentum compaction factor α is set to be between 17 and 70 times smaller than normal user mode. At DLS there are two varieties of low alpha modes to provide coherent radiation for THz/IR experiments and short-pulse radiation for pump-probe experiments. Due to the nature of the low alpha modes, i.e. the smaller bunch lengths, the MBI regularly occurs.

SCHOTTKY DETECTOR DIODES

Schottky Barrier Diodes (SBD) are best known for their fast response [5], low noise and excellent sensitivity. Operating at room temperature, SBDs are able to detect mm-waves and hence are often used as detectors within this wavelength range. The detector diodes that we have chosen are housed within waveguides and fed signal using horn antennas. A spectrometer has been designed using seven SBDs, with each detector covering a specific frequency band from 33-750 GHz. Table 1 shows the properties of the chosen SBDs.

† aiveen.finn.2013@live.rhul.ac.uk

Table 1: SBD Specifications

Detector Model	Stated Range	Sensitivity
DXP-22 [6]	33-50 GHz	1200 V/W
DXP-12 [6]	60-90 GHz	700 V/W
DET-08 [6]	90-140 GHz	600 V/W
WR5.1ZBD [7]	140-220 GHz	2000 V/W
WR3.4ZBD [7]	220-330 GHz	1500 V/W
WR2.2ZBD [7]	330-500 GHz	1250 V/W
WR1.5ZBD [7]	500-750 GHz	750 V/W

SPECTROMETER/DETECTOR ARRAY

DLS hosts a viewport which is dedicated to the investigation of CSR. The viewport transports the synchrotron radiation from bending magnet B06 to the viewport window. It is there that the detector array is placed on three motion stages for movement in x, y and z directions. The detector array is shown in Fig. 1 on its motion stages.

The plate shown (Fig. 1) is designed in such a way that all detectors are as close together as possible and observe as much signal as available. All horn antennas are at the same distance to the viewport to remove the risk of shadowing.

It is important for the cables between the detectors and the voltage amplifiers to be short. The input impedance of the amplifiers is high (10 kΩ), thus to accommodate a good signal-to-noise ratio around the revolution frequency, the cable capacitance must be low. In order to lower the capacitance, shorter cables were used, thus a plate housing the amplifiers was attached to the detector array allowing for minimal cable length. Following the voltage amplifiers the signals are carried out of the tunnel, where the signals are fed into a simultaneous 16-channel sampling digitiser.

DATA ANALYSIS

For a specified period of time, the data are captured with an external 5 Hz trigger. The data are then analysed in MATLAB. Due to limited bandwidth Ethernet, from the digitiser to the relevant computer for processing, it is impossible to continually stream data from the digitising unit to our computers for analysis, hence the snapshots of data being acquired. A digital down conversion (DDC) of the data is carried out, with the analysis locking in at the revolution frequency of the storage ring, (533.820 kHz). The information

BEAM INSTRUMENTATION OF THE PXIE LEBT BEAM LINE *

R. D'Arcy†, B. Hanna, L. Prost, V. Scarpine, A. Shemyakin
Fermilab, Batavia, IL 60510, USA

Abstract

The PXIE accelerator [1] is the front-end test stand of the proposed Proton Improvement Plan (PIP-II) [2] initiative: a CW-compatible pulsed H- superconducting RF linac upgrade to Fermilab's injection system. The PXIE Ion Source and Low-Energy Beam Transport (LEBT) section are designed to create and transfer a 1-10 mA H^- beam, in either pulsed (0.001–16 ms) or DC mode, from the ion source through to the injection point of the RFQ. This paper discusses the range of diagnostic tools – Allison-type Emittance Scanner, Faraday Cup, Toroid, DCCT, electrically isolated diaphragms – involved in the commissioning of the beam line and preparation of the beam for injection into the RFQ.

PXIE LEBT DIAGNOSTICS REQUIREMENTS

The PXIE LEBT beam line, described in [3] and shown in Fig. 1, consists of a 30 keV H^- ion source, three solenoids with a pair of dipole correctors in each, a chopping system inserted between the last two solenoids, and a set of diagnostics combined with collimation systems.

Some of the peculiarities of the PXIE LEBT are related to the plan to commission PXIE first in a short-pulse mode and then to increase the pulse length, eventually operating in true DC mode. This will ultimately be accomplished with the LEBT chopper, capable of forming 0.001-16.6 ms pulses with a rise time of ~100 ns at a frequency of up to 60 Hz. For the tuning of the LEBT itself, and to decrease the load to the LEBT chopper absorber, the ion source has been equipped with a modulator that can pulse the extraction electrode, also at 60 Hz but with a rise time of ~1 μs. The chopper starts forming the final pulse length after the first ~ 1 ms of the modulator pulse, allowing the neutralisation near the ion source to reach a steady-state.

Correspondingly, diagnostics are required to provide information about the beam in two modes: DC and pulsed. In the latter, the control system provides separate time triggers for the diagnostics channels upstream of the chopper and remaining part of the LEBT. The initial nominal pulse length for PXIE commissioning is 5 μs, chosen as a compromise between the chances of damaging the SRF section and the need for reasonable measurement accuracy of downstream beam instrumentation.

The LEBT diagnostics can be divided into three groups: current monitors, apertures and scrapers, and the emittance scanner.

DIAGNOSTIC TOOLS

Current Monitors

The beam current can be measured by a DC Current Transformer (DCCT), an AC transformer (a.k.a. a toroid), and, at the commissioning stage, by the Faraday Cup (FC) at the end of the LEBT. Some indication of the beam current is also given by the ion source bias supply current but, because of a significant electron component at the ion source output, the latter may be up to 2 times higher.

The DCCT is installed downstream of the first solenoid and measures the beam current in DC or long-pulse (≥ 500 μs) modes. Its sensitivity to external magnetic fields requires a significant longitudinal space to ensure enough separation from both the first solenoid and a future bending magnet to be installed just downstream. Whilst the DCCT is currently the main tool used to measure the beam current the possibility of replacing it with a toroid during transition to the configuration with the bend is being discussed.

The LEBT toroid is installed downstream of the chopper. To measure the beam loss in the RFQ down to 1%, an identical toroid will be placed at the RFQ exit. A procedure to cross-calibrate both toroids with a relative accuracy at the 1% level is in development.

The Faraday Cup (FC) is a copper cylinder with an aperture radius, R, of 49.4 mm and a length, L, of 144.5 mm. By using the electrode in front of the FC (EID5) as a suppressor of secondary electrons it is shown that the capturing inefficiency is < 1%, in agreement with a simple estimation of $\sim 0.1 \times (L/R)^2$.

The resolution and bandwidth of the current monitors are shown in Tab. 1.

Isolated Electrodes and Scrapers

The PXIE LEBT beam line includes several Electrically Isolated Diaphragms (EIDs) (see Fig. 1), each biased with an individual +50 V floating power supply. The EIDs are copper, water-cooled tori with varying opening diameters depending on location (see Fig. 1 for sizes). Special circuitry allows measurement of the beam loss to an EID in DC and pulsed (> 1 μs) modes. In addition to beam control (physically scraping beam tails and altering neutralisation

Table 1: Parameters of the PXIE LEBT Current Monitors

	Resolution	Bandwidth
DCCT	< 10 μA	DC to 4 kHz
Toroid	< 10 μA	10 Hz to 4 MHz
Faraday Cup, Isolated Electrodes	< 5 μA	DC to 20 MHz

PROGRESS TOWARDS ELECTRON-BEAM FEEDBACK AT THE NANOMETRE LEVEL AT THE ACCELERATOR TEST FACILITY (ATF2) AT KEK

N. Blaskovic Kraljevic, D. R. Bett, T. Bromwich, P. N. Burrows, G. B. Christian, M. R. Davis, C. Perry,
John Adams Institute, Oxford, UK

Abstract

Ultra-low latency beam-based digital feedbacks have been developed by the Feedback On Nanosecond Timescales (FONT) Group and tested at the Accelerator Test Facility (ATF2) at KEK in a programme aimed at beam stabilisation at the nanometre level at the ATF2 final focus. Three prototypes were tested: 1) A feedback system based on high-resolution stripline BPMs was used to stabilise the beam orbit in the beamline region c. 50m upstream of the final focus. 2) Information from this system was used in a feed-forward mode to stabilise the beam locally at the final focus. 3) A final-focus local feedback system utilising cavity BPMs was deployed. In all three cases the degree of beam stabilisation was observed in high-precision cavity BPMs at the ATF2 interaction point. Latest results are reported on stabilising the beam position to below 100 nanometres.

INTRODUCTION

A number of fast beam-based feedback systems are required at future single-pass beamlines such as the International Linear Collider (ILC) [1]. For example, at the interaction point (IP) a system operating on nanosecond timescales within each bunch train is required to compensate for residual vibration-induced jitter on the final-focus magnets by steering the electron and positron beams into collision. The deflection of the outgoing beam is measured by a beam position monitor (BPM) and a correcting kick applied to the incoming other beam. In addition, a pulse-to-pulse feedback system is envisaged for optimising the luminosity on timescales corresponding to 5 Hz.

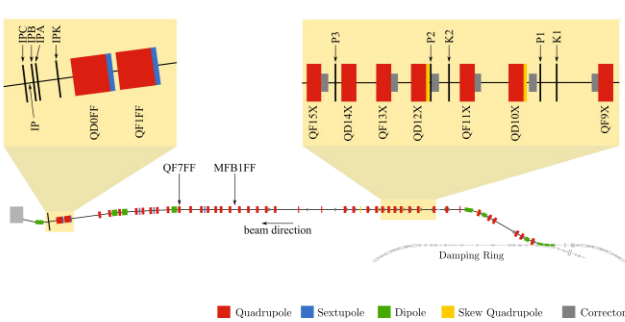

Figure 1: Layout [7] of the ATF extraction and final focus beamline with the FONT regions zoomed in.

The Feedback on Nanosecond Timescales (FONT) project has developed ILC prototype systems, incorporating digital feedback processors based on Field Programmable Gate Arrays (FPGAs), to provide feedback correction systems for sub-micron-level beam stabilisation at the KEK Accelerator Test Facility (ATF2) [2]. Previous results [3], [4] have demonstrated an upstream closed-loop feedback system that meets the ILC jitter correction and latency requirements. Furthermore, results demonstrating the propagation of the correction obtained using the upstream stripline BPM feedback system at ATF2 are reported in [5]. The ultimate aim is to attempt beam stabilisation at the nanometre-level at the ATF2 IP [6]. We report here the latest developments and beam testing results from the FONT project using a cavity BPM [7] to drive local feedback correction at the IP.

FONT5 SYSTEM DESIGN

An overview of the extraction and final focus beamlines at the ATF, showing the positions of the FONT5 system components in the IP region, is given in Fig. 1. The IP feedback system comprises a C-band cavity BPM (IPB) [7] and a short stripline kicker (IPK). The final focus magnets (QF1FF, QD0FF) can be used to steer the beam by introducing a position offset or to move the x and y beam waists longitudinally along the beamline. The offset of the QF7FF magnet can be used to change the pitch of the beam trajectory through the IP region.

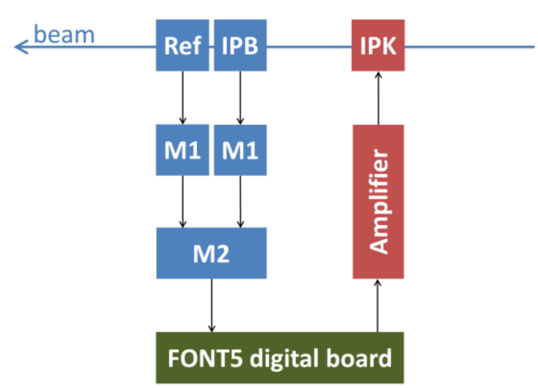

Figure 2: Schematic of IP feedback system showing the cavity BPM (IPB), reference cavity (Ref), first and second down-mixer stages (M1 and M2), FONT5 digital board, amplifier and kicker (IPK).

A schematic of the IP feedback system is given in Fig. 2. Determining the position of the beam at IPB requires both the dipole mode signal of IPB and the monopole mode signal of a reference cavity (Ref). The cavities were designed such that the y-port frequency of both signals is 6.426 GHz [8]. The signals are down-

DESIGN, TESTING AND PERFORMANCE RESULTS OF A HIGH-RESOLUTION, BROAD-BAND, LOW-LATENCY STRIPLINE BEAM POSITION MONITOR SYSTEM

N. Blaskovic Kraljevic, D. R. Bett, T. Bromwich, P. N. Burrows, G. B. Christian, M. R. Davis, C. Perry,
John Adams Institute, Oxford, UK

Abstract

A high-resolution, low-latency beam position monitor (BPM) system has been developed for use in particle accelerators and beamlines that operate with trains of particle bunches with bunch separations as low as several tens of nanoseconds, such as future linear electron-positron colliders and free-electron lasers. The system was tested with electron beams in the extraction line of the Accelerator Test Facility at the High Energy Accelerator Research Organization (KEK) in Japan. The fast analogue front-end signal processor is based on a single-stage RF down-mixer. The processor latency is 15.6 +- 0.1 ns. A position resolution below 300 nm has been demonstrated for beam intensities of around 1 nC, with single-pass beam.

INTRODUCTION

A number of in-construction and proposed future particle accelerator designs feature trains of particle bunches with bunch-separation intervals in the ranges of nanoseconds to tens or hundreds of nanoseconds. For example, the International Linear Collider (ILC) design [1] calls for bunch trains comprising thousands of bunches separated in time by around 500 ns with a train repetition frequency of 5 Hz; the Compact Linear Collider (CLIC) design [2] specifies bunch trains comprising several hundred bunches separated in time by around 0.5 ns, with a train repetition frequency of 50 Hz. Free-electron lasers based on similar accelerating technologies as ILC and CLIC will have similar bunch-train time structures, such as the European XFEL [3], which will have a minimum bunch spacing of 200 ns and a repetition rate of 10 Hz. Beam control at such facilities calls for beam position monitors (BPMs) that can resolve bunches on an intra-train (ideally bunch-by-bunch) timescale, with submicron position resolution in single-pass mode. The design of such a BPM system is presented here.

FONT5 SYSTEM AT ATF2

The system was developed by the Feedback on Nanosecond Timescales (FONT) group [4] and it was deployed, commissioned and tested at the Accelerator Test Facility (ATF) [5] at KEK. The layout of the BPMs is shown in more detail in Fig. 1. The design goal for the FONT5 system is to stabilize the vertical beam position to the 1 µm level at the entrance to the final-focus system. This requires BPMs capable of resolving bunches separated in time by around 100 ns, and with a position resolution at the submicron level. For tests of the FONT5 system the ATF is operated in a mode whereby a train of two or three bunches is extracted from the damping ring and sent down the ATF2 beam line. The bunch separation is determined by the damping ring fill pattern and typically is chosen to be between 140 ns and either 154 ns (3-bunch mode) or 300 ns (2-bunch mode).

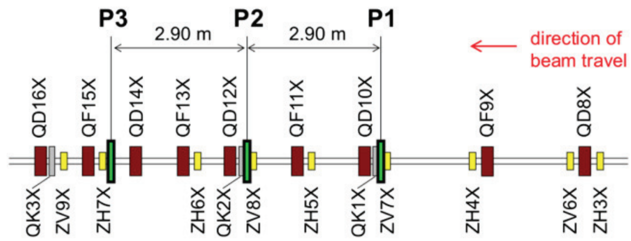

Figure 1: Layout of the FONT5 BPMs (P1, P2 and P3) in the ATF2 extraction line; quadrupole ("Q") and dipole corrector ('Z') magnets are indicated.

The FONT5 BPM system (Fig. 2) consists of three stripline BPMs (Fig. 3) each of which is instrumented with an analogue processor, and a custom multichannel digitizer. Stripline BPMs were used due to their inherently fast, broadband response and capability to resolve bunches with the required time resolution. In the FONT5 system, only the vertical plane of the BPMs is routinely instrumented.

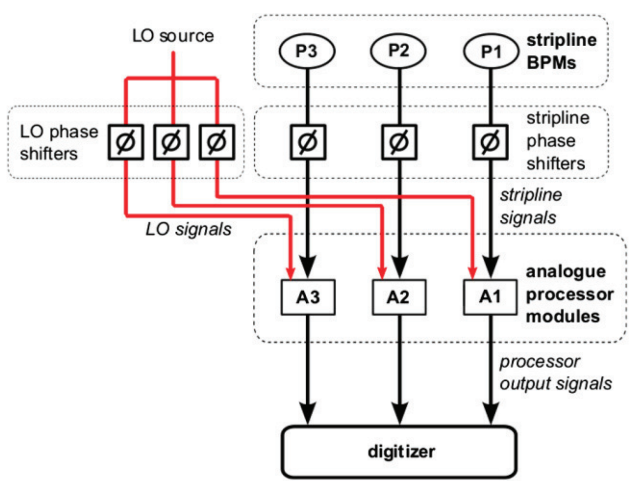

Figure 2: Schematic of the FONT5 BPM system. For each BPM, a phase shifter is used on one of the stripline signals to adjust the relative path lengths of the two input signals at the BPM processor, and another phase shifter is used to adjust the phase of the LO signal at each processor.

Abstract

In the CLIC two beam acceleration scheme 100 MV/m normal conducting cavities are fed with RF power extracted from a secondary high power but low energy drive beam. To ensure the efficiency and luminosity performance of CLIC the phase synchronisation between the high energy main beam and the drive beam must be maintained to within 0.2 degrees of 12 GHz. To reduce the drive beam phase jitter to this level a low-latency drive beam phase feedforward correction with bandwidth above 17.5 MHz is required. A prototype of this system has been installed at the CLIC test facility CTF3 to prove its feasibility, in particular the challenges of high bandwidth, high power and low latency hardware. The final commissioning and first results from operation of the complete phase feedforward system are presented here.

INTRODUCTION

The RF power used to accelerate the main beam in the proposed linear collider CLIC is extracted from a second 'drive beam'. To ensure the efficiency of this concept a drive beam 'phase feedforward' system is required to achieve a timing stability of 50 fs rms, or equivalently a phase stability (jitter) of 0.2 degrees of 12 GHz (the CLIC drive beam bunch spacing) [1–3]. This system poses a significant hardware challenge in terms of the bandwidth, resolution and latency of the components and therefore a prototype of the system has been designed, installed and commissioned at the CLIC test facility CTF3 at CERN. Phase feedforward is hereafter referred to as "PFF".

A schematic of the CTF3 PFF system is shown in Fig. 1. The phase is corrected utilising two kickers placed prior to the first and last dipole in the pre-existing chicane in the TL2 transfer line. By varying the voltage applied to the kickers the beam can be deflected onto longer or shorter paths through the chicane, thus inducing a phase shift. The goal is to demonstrate a 30 MHz bandwidth phase correction with a resolution of 0.2 degrees of 12 GHz. The required hardware consists of three precise phase monitors [4, 5] and two strip line kickers [5] designed and fabricated by INFN/LNF Frascati, and a kicker amplifier and digital processor [6] from the John Adams Institute at Oxford University. More detailed descriptions can be found in [7].

The latency of the PFF system, including cable lengths and the latency of each component, is below the 380 ns beam time of flight between the first monitor and the first kicker. This allows the same bunch that was originally measured to be corrected.

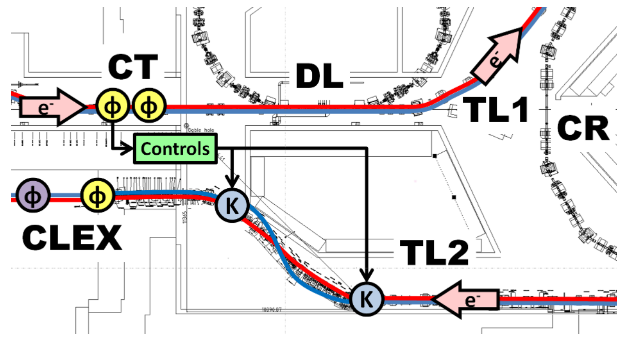

Figure 1: Simplified schematic of the PFF system. Red and blue lines depict orbits for bunches arriving late and early at the first phase monitor, ϕ, respectively. The trajectory through the TL2 chicane is changed using two kickers, K.

COMMISSIONING

The complete PFF system became available in October 2014. Previous results from commissioning of the optics and phase monitors are presented in [8].

The first prototype kicker amplifiers used for the tests presented here provide an output voltage of 340 V. They will be upgraded in stages over the course of 2015, ultimately providing the nominal voltage of 1.2 kV. Constant kick tests demonstrated that applying the maximal 340 V to the PFF kickers resulted in a phase shift of ±3.5°, thus verifying the functionality of the amplifiers, kickers and chicane optics (Fig. 2). The 30 ns rising and falling edges of the response to the kick correspond to 12 MHz amplifier bandwidth when rising from zero to maximum output. This is slew-rate limited and the bandwidth is expected to be 50 MHz for smaller variations.

The PFF algorithm on the digital processor varies the drive signal to the amplifier based on the upstream phase (measured in the CT line, see Fig. 1) in order to correct the downstream phase (after the correction chicane in CLEX) with 30 MHz bandwidth. Its performance was verified by observing the response in a BPM after the correction chicane whilst applying the PFF correction to one kicker at a time. Figure 3 proves that the applied kick has the same shape as the upstream phase.

During the commissioning it was apparent that the upstream phase jitter of up to 1° increased to as much as 4°

BUNCH LENGTH MEASUREMENTS USING SYNCHROTRON LIGHT MONITOR*

M.M. Ali, M.G. Tiefenback, Jefferson Lab, Newport News, VA 23606, USA

Abstract

Bunch length is measured at CEBAF using an invasive technique. The technique depends on applying an energy chirp for the electron bunch and imaging it through a dispersive region. Measurements are taken through Arc1 and Arc2 at CEBAF. The fundamental equations, procedure and recent results are given.

INTRODUCTION

CEBAF is a folded transfer line, with no natural stable bunch structure. Bunch length measurement and control are important for CEBAF because a too-long bunch would generate excessive energy spread, resulting in interrupted beam delivery due either to beam loss or failure to satisfy user requirements. Bunch length is commonly measured in the injector beam dump at up to 123 MeV using the "zero-phasing" method [1] before injection into the North Linac (NL). However, to mitigate periodic problems with control of bunch "tails," the beam undergoes a final magnetic compression in the injection chicane (four dipoles and nine quadrupoles) linking the injector and NL. After exiting the NL at up to 1.2 GeV, the beam follows the semi-circular arc 1A to its injection point into the South Linac (SL). Arc 2A returns the beam for reinjection into the NL. This cycle may be repeated for up to six passes through the NL, after which beam is delivered to Hall D (up to 12 GeV). The first two recirculation arcs incorporate high dispersion points at the central dipoles ($\eta_x \sim 5$ meters), enabling synchrotron radiation (SR) imaging to monitor energy stability and other beam properties. Bunch length measurement generally parallels that described in [2]. We discuss the relationship between measurement of bunch length and of transverse emittance and how we have used this approach to measure the steady-state bunch length for high-power CW beam.

To minimize the energy spread for users, the beam is accelerated at peak energy gain (on-crest). By altering the global ("gang") phase of a linac, the z-correlated energy spread may be increased. Off-crest acceleration increases the energy spread and the transverse beam size at the high dispersion monitor, enabling measurement of the bunch length. The early arcs of CEBAF are isochronous (M_{56}=0), so the longitudinal bunch structure is preserved. Shifting the linac phase by equal amounts of opposite polarity results in turn-by-turn compensation of the added energy spread while allowing observation in the 1A synchrotron light monitor (SLM). Under these conditions, bunch length measurement is possible at high CW beam current while maintaining lossless transport to the appropriate beam dump.

SLM ANALYSIS

We begin with a coordinate system (x,y,z,δ) following the beam, where (x,y) are transverse coordinates, z is the longitudinal coordinate, and δ is the relative deviation of a particle from the average bunch energy. We simplify by ignoring transverse momenta until we discuss initial state asymmetries below. When the beam is accelerated off-crest, a z-p_z correlation (often called a chirp) is induced. Longitudinal position is re-mapped into transverse position in regions with significant dispersion. With E_{inj} as the injector energy and E_{NL} as the linac energy gain,

$$E = E_{inj} + E_{NL}\cos(kz + \phi) \tag{1}$$

The linac energy gain is sinusoidal with k as the RF wave number, z as the longitudinal deviation from the bunch center at z=0, and ϕ is the phase shift of the accelerating RF. For short bunches and large ϕ, we consider kz < ϕ.

During off-crest acceleration, the average energy would decrease due to the cosine function. To keep the beam within the energy acceptance, the RF accelerating gradient is adjusted to hold beam energy constant.

$$E = E_{inj} + \frac{E_{NL}}{cos(\phi)}\cos(kz + \phi) \tag{2}$$

We re-write this to first order in kz as

$$E = E_{inj} + E_{NL} - E_{NL}kz\tan(\phi) \tag{3}$$

so that

$$\frac{E - \overline{E}}{\overline{E}} = \frac{-E_{NL}}{E_{inj} + E_{NL}}kz\tan\phi \tag{4}$$

where $\overline{E}$ is the average beam energy and is equal to (E_{inj} + E_{NL}). We take the initial beam to be sufficiently symmetric that the distribution function $F(x, y, z, \delta)$ is uncorrelated pairwise in x, z, and δ. The initial mean square energy spread and bunch length may be represented as

$$\langle z_0^2 \rangle = \int\int\int\int d\delta dz dx dy \quad z^2 \quad F \tag{5}$$

$$\langle \delta_0^2 \rangle = \int\int\int\int d\delta dz dx dy \quad \delta^2 \quad F \tag{6}$$

Adding a linear energy chirp shears the distribution in the δ-z plane in such a way that the altered distribution G may be written in terms of the initial function F evaluated at $\hat{\delta} = \delta - \lambda z$:

$$G(x, y, z, \delta) = F(x, y, z, \hat{\delta}) \tag{7}$$

$$\lambda = \frac{E_{NL}k\phi}{E_{inj} + E_{NL}} \tag{8}$$

LASERWIRE EMITTANCE SCANNER AT CERN LINAC4

K.O. Kruchinin*, G. Boorman, A. Bosco, S.M. Gibson, P. Karataev,
John Adams Institute at Royal Holloway, University of London, Egham, Surrey, TW20 0EX, UK

J. Pozimski, Imperial College, London, UK
A.P. Letchford, STFC/RAL/ASTeC, Chilton, Didcot, UK

Abstract

Linac 4 presently under construction at CERN is designed to replace the existing 50 MeV Linac 2 in the LHC injector chain and will accelerate the beam of high current negative hydrogen ions to 160 MeV. During the commissioning a laserwire emittance scanner has been installed allowing non-invasive measuring of the emittance at 3 MeV and 12 MeV setups. A relatively low power infrared fibre coupled laser was focused in the interaction region down to ~150 µm and collided with the ion beam neutralising negative ions. At each transverse laser position with respect to the ion beam the angular distribution of the neutral particle beamlets was recorded by scanning a diamond detector across the beamlet at a certain distance from the interaction point while the main beam of the H^- ions was deflected using the dipole magnet installed upstream the detector. Measuring the profile of the beamlet by scanning the laser across the beam allows to directly measure the transverse phase-space distribution and reconstruct the transverse beam emittance. In this report we will describe the analysis of the data collected during the 3 MeV and 12 MeV operation of the Linac 4. We will discuss the hardware status and future plans.

INTRODUCTION

The Linac 4 project located at CERN in Geneva, Switzerland was started in 2003 [1] and aims to build a 160 MeV H^- linear accelerator that will replace the existing proton Linac 2 as the injector to the Proton Synchrotron Booster (PSB). Injection of H^- instead of protons into the PSB would reduce the beam losses and provide more flexible operational conditions. At the end of commissioning the injection beam provided by Linac 4 is expected to double the brightness and intensity of the beam from the PSB. Linac 4 project is an essential step in the High Luminosity LHC upgrade required to future improvement of the CERN accelerator complex towards higher performance [2, 3]. Main parameters of the Linac 4 are presented in Table 1.

Table 1: Main Linac4 Parameters

Parameter	Value	Units
Overall Linac length	76.33	m
Output energy	160	MeV
Bunch frequency	352.2	MHz
Maximum repetition rate	2	Hz
Beam pulse length	400	µs
Max. beam duty cycle	0.08	%
Average pulse current	40	mA
Beam transverse emittance	0.4π	mm mrad
Beam power	5.1	kW

To successfully inject the beam from Linac 4 into PSB the transverse emittance at the machine top energy of 160 MeV has to be measured precisely. The conventional slit and grid beam diagnostics is precluded due to the excessive stopping range of a high energy H^- ions at 160 MeV in any possible slit material. Other methods, like the three - profile measurement, can be heavily affected by space charge effects and cannot handle the nominal Linac 4 pulse length of 400 µs. To overcome these problems a non-destructive method based on laserwire technology has been developed.

EXPERIMENTAL SETUP

In order to characterize the H^- ion beam at different stages of the LINAC4 commissioning a movable, temporary test bench has been used. After finishing the commissioning of the 3 MeV and 12 MeV stage the test bench was placed at the exit of the copper and first DTL section respectively. It was used to characterize the ion beam using various diagnostic tools such as beam current transformers, wire scanners, beam position monitors, bunch shape and halo monitors, a slit and grid emittance meter and a spectrometer line [4, 5].

The laserwire interaction is taking place inside the vacuum chamber that was initially designed to accommodate the movable graphite slit which is a part of the slit and grid emittance scanner [6]. The laser enters the vacuum chamber through a vacuum window, specially coated to reduce back reflections in the infrared range of wavelengths. After interaction the laser beam is dumped into one of the slit blades. Such location of the laserwire proved to be very useful because it allows to perform measurements using two different methods and cross-check the results.

The laserwire system consists of a remotely controlled pulsed laser mounted in a rack in the accelerator tunnel connected via an optical fibre to a laser delivery system which controls the size and position of the laser beam delivered to the interaction point (IP). A detection system was installed downstream of a dipole magnet to record the angular distribution of the neutralized particles from the H^- beam.

NOVEL SINGLE SHOT BUNCH LENGTH DIAGNOSTIC USING COHERENT DIFFRACTION RADIATION

R. Fiorito*, C. Welsch, H. Zhang, Cockcroft Institute, University of Liverpool, Daresbury, WA44AD, UK
A. Shkvarunets, IREAP, University of Maryland, College Park, MD, 20901, USA

Abstract

Current beam bunch length monitors that measure the spectral content of beam-associated coherent radiation to determine the longitudinal bunch form factor usually require wide bandwidth detection, Fourier transformation of spectral or interferometric data, phase retrieval algorithms and multiple beam pulses to obtain the bunch length. In this paper we discuss progress in the development of a novel single shot method that utilizes the frequency integrated angular distribution (AD) of coherent diffraction radiation (CDR) to measure the RMS bunch length directly. We also present simulation results that show how the AD changes with bunch length for two electron beam linacs, where we are planning to test this new method, our single shot measurement technique and plans for comparison to other bunch length monitors.

INTRODUCTION

Conventional RF accelerators as well as plasma wakefield accelerators have the ability to generate very short pulses of electrons (~10fs), and schemes are being developed to produce even shorter pulse lengths. A number of techniques have been developed to measure bunch length and even the longitudinal distribution of bunches down to ~10 fs in duration. These include Fourier transform interferometry, direct spectroscopy and various electro-optic techniques that sample either the Coulomb field of the bunch itself or the radiation field produced by the bunch interacting with a physical structure or an electromagnetic field. However, the experimental techniques required are usually complex and difficult to implement particularly for single shot measurements.

Frequently, measurement of the rms bunch length rather than the detailed longitudinal profile of the bunch is sufficient for tune up and accelerator monitoring. To meet this need we propose to develop a novel rms bunch length method that is noninvasive, easy to implement, simple to analyze, capable of bunch length measurements over a very wide range and has the potential for single-shot measurements.

BACKGROUND

For most cases of interest, the AD of the CDR can be calculated as the integrated spectral angular density of DR from single electron multiplied by the longitudinal form factor of the pulse:

$$\frac{dI^{CDR}_{bunch}}{d\Omega} \approx N_e^2 \int_{\Delta\omega} \frac{d^2 I_e^{DR}}{d\omega d\Omega} S_z(\sigma_z,\omega) d\omega \qquad (1)$$

The single electron spectral angular density, the first term of the integrand depends on the shape and size of the radiator as well as the frequency. This can be calculated for any size/shape radiator [1]. The second term of the integrand is the longitudinal bunch form factor, which is a function of the bunch length (σ_z). Assuming a model (e.g. a Gaussian) for the longitudinal bunch form factor and an appropriate frequency band, Eq. (1) can be integrated and fit to the measured AD data to produce the rms bunch length [1].

The method has been validated experimentally in a proof of principle experiment done at the Paul Scherrer Institute using repetitive picosecond electron beam pulses with energy E=100 MeV and a Golay cell to scan the angular distribution of the CDR in both the horizontal and vertical directions [2]. However, the measurement was time integrated, i.e. averaged over many repetitive macro-pulses and provided only 1D scans for the fit.

We propose to measure the entire AD projected onto the plane of an imaging detector to improve the accuracy of the measurement and to demonstrate single shot capability. The method will be tested at two accelerators with widely different bunch lengths and beam energies: the ALICE accelerator at Daresbury Laboratory and the FACET accelerator at SLAC.

EXPERIMENTS

ALICE

The beam parameters that are planned for our initial CDR AD imaging experiments on ALICE are: E=26 MeV, τ_{rms} = 0.7-1.3 ps, Q = 100 pC/micro-bunch, 1-4000 micro-bunches per macro-pulse and macro-pulse repetition rate f_{rep} = 10 Hz.

CDR will be created as each picosecond micro-bunch passes through a simple circular annular aperture inclined at 45^0 to the velocity of the electron beam. The CDR will emerge at 90^0, passing through a vacuum window and be imaged onto a pyroelectric array.

We have calculated the frequency integrated AD of CDR for an annular radiator (outer radius = 8mm and inner radius = 4mm) over the wavelength band 18-200 µm, which corresponds to a frequency band 0.15 - 2 THz, for different bunch lengths. In this band the longitudinal bunch form factor is most sensitive to changes in the bunch size. The results of our calculations are shown in Figure 1. The widths of the three distributions correspond to rms bunch widths: 0.7, 1.0 and 1.3 ps. The intensities are normalized to their respective peak values.

EMITTANCE AND OPTICS MEASUREMENTS ON THE VERSATILE ELECTRON LINEAR ACCELERATOR AT DARESBURY LABORATORY*

B.L. Militsyn, D.J. Scott, STFC/ASTeC, Daresbury, UK
S.D. Barrett, C. Topping, A. Wolski, University of Liverpool, Liverpool, UK

Abstract

The Versatile Electron Linear Accelerator (VELA) is a facility designed to provide a high quality electron beam for accelerator systems development, as well as industrial and scientific applications. Currently, the RF gun can deliver short (of order a few ps) bunches with charge in excess of 250 pC at up to 5.0 MeV/c beam momentum. Measurement of the beam emittance and optics in the section immediately following the gun is a key step in tuning both the gun and the downstream beamlines for optimum beam quality. We report the results of measurements (taking account of coupling and space charge) indicating normalised emittances of order 0.5 μm at low bunch charge.

INTRODUCTION: VELA LAYOUT

The injection beamline of VELA [1] (Fig. 1) comprises a 2.5 cell S-band photocathode gun with copper photocathode. The gun is driven with the third harmonic of a short (<76 fs rms) pulsed Ti:Sapphire laser with a typical pulse energy of 1 mJ. The size of the laser spot on the photocathode is typically below 0.5 mm. The gun is immersed in the magnetic field of a main gun solenoid which provides emittance compensation and focusing of the beam in the initial section of the injection line. A bucking coil located beside the gun zeroes the field on the photocathode. Further focusing is provided by four quadrupole magnets, each with a length of 0.1 m. These magnets are also used in the procedure for emittance measurement. Beam diagnostics include a wall current monitor for charge measurement, and three combined diagnostic stations containing YAG screens installed at 45° to the beam line. The emittance measurements presented in this paper are based on beam images observed on the YAG screens with high-sensitivity, high-resolution CCD cameras. Vertical and horizontal slits on YAG-02 and YAG-03 allow alternative methods for emittance characterization. A Transverse Deflecting Cavity (TDC) which is presently under commissioning will complete the diagnostic suite for 6D beam characterisation.

EMITTANCE AND OPTICS MEASUREMENTS WITH COUPLING

In general, the solenoid fields around the VELA gun (and especially any uncompensated magnetic field on the photocathode) will introduce coupling in the beam. Furthermore, space charge effects are expected to be significant, or even dominant, in many parameter regimes of interest for VELA. The techniques used for emittance and optics measurements therefore need to take into account both coupling and space charge. For the present, we assume that at low bunch charge (of order 10 pC) it is possible to include transverse space charge effects in a linear approximation: this will be discussed in more detail later.

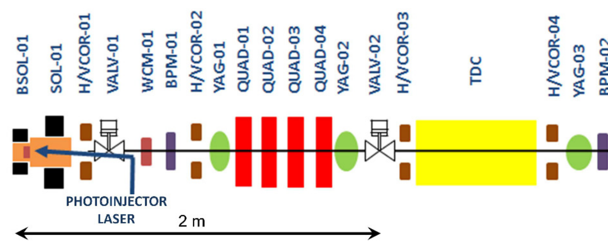

Figure 1: Layout of the VELA injection line.

Our goal is to determine the transverse emittances and Courant–Snyder parameters for the beam in the section of the VELA beam line immediately following the gun. Longitudinal effects will play some role, especially in the presence of space charge, and we plan to include the longitudinal dynamics in future work. For now, we assume that the relevant beam properties can be described by the 4×4 transverse covariance matrix Σ with elements $\Sigma_{ij} = \langle x_i x_j \rangle$, where x_i is an element of the phase-space vector $\vec{x} = (x, p_x, y, p_y)$ for a single particle, and the brackets $\langle\cdot\rangle$ indicate an average over all particles in the bunch. x and y are respectively the horizontal and vertical co-ordinates of a particle, and p_x and p_y the horizontal and vertical momenta scaled by a reference momentum P_0 (= 4.5 MeV/c in the present case). The eigenemittances are constant for a given beam under linear symplectic transport, and can be obtained from the covariance matrix Σ using the fact that the eigenvalues of ΣS are $\pm i\varepsilon_{\mathrm{I}}$ and $\pm i\varepsilon_{\mathrm{II}}$, where S is the 4×4 antisymmetric matrix with block diagonals:

$$S_2 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \tag{1}$$

and ε_{I}, $\varepsilon_{\mathrm{II}}$ are the eigenemittances [2]. The Courant–Snyder parameters can be obtained from the eigenvectors of ΣS. To determine the eigenemittances and Courant–Snyder parameters at a given point in the beamline, we therefore need to determine the elements of the covariance matrix Σ at that point in the beamline. This can be done using quadrupole scans, as follows.

DEVELOPMENT OF A SUPERSONIC GAS-JET MONITOR TO MEASURE BEAM PROFILE NON-DESTRUCTIVELY

H. Zhang[1,#], V. Tzoganis[1,2], A. Jeff[1,3], C. Welsch[1]
[1]Cockcroft Institute and university of Liverpool, Warrington, WA44AD UK
[2]RIKEN Nishina center, Japan
[3]CERN

Abstract

The measurement of the transverse beam profile is a great challenge for high intensity, high brightness and high power particle beams due to their destructive effects and thus non-destructive methods are desirable. Current non-destructive methods such as residual gas monitors and beam induced fluorescence monitors either requires a longer integration time or higher surrounding pressure to make a meaningful measurement. As a potentially improved technique, a supersonic gas-jet beam profile monitor has been developed by the QUASAR Group at the Cockcroft Institute, UK.

In this monitor, a 45 degree supersonic gas curtain is generated and interacts with beam when the beam crosses it. Ions generated by this process are then accelerated by an extraction electric field and finally collected by a Micro Channel Plate (MCP). Beam images are obtained via a phosphor screen and a CCD camera.

In this contribution, we briefly describe the working principles and present better beam profile measurement of a low energy electron beam using this monitor with newly installed pulsed valve.

INTRODUCTION

Beam profile monitoring is essential for any accelerator system in diagnosing the transverse property of particle beams. Many existing methods could be chosen based on the type, energy and lifetime of the specific particle beam as well as the system requirement such as vacuum condition and beam loss control. For an example, the beam diagnostic in the Ultra-low-energy Storage Ring (USR) [1] at GSI, in order to preserve a longer lifetime of the stored low energy antiproton beam, a vacuum condition of ~10^{-11} mbar is required. Meanwhile, considering the costly antiproton, a non-destructive method is preferred. These requirements basically limit the choice from the existing mature transverse diagnostics. Gas-based monitor, such as residual gas ionization monitor or fluorescent monitor, could be the potential candidate for USR project, because it reserves the vacuum condition quite well and disturbs the beam very little. However, a low ionization or fluorescent rate due to the low vacuum pressure requires a long integration time to obtain a meaningful profile and usually the measurement is in one dimension. In the USR case, the intrinsic integration time could be more than 100 ms which brings additional prerequisite for the primary beam stability. To reduce the integration time while keeping the non-destructive feature by using gas molecules, a novel 2-dimentional supersonic gas-jet ionization monitor is designed in Cockcroft Institute [2]. Previously, using the same principle, a magnetically focused oxygen molecular beam was implemented in HIMAC for fast heavy ion profile measurement [3] and a mechanically skimmed nitrogen beam in JPARC for the intense proton beam [4]. In this method, the localized gas intensity could increase by more than 5 orders of magnitude by the jet, which increases the ionization rate and thus shortens the integration time about the same order. Meanwhile, the vacuum is affected little due to the directionality of the supersonic gas-jet. In this paper, we will discuss the design and working condition of this monitor as well as recent results from an in-house low energy electron beam. Although the application is based on the USR due to its highly specialized requirement, this monitor could be generally used in any accelerators where the gas load is allowed.

WORKING PRINCIPLE AND TEST STAND

The schematic of the whole setup is shown in Fig. 1. The design is based on the Reaction Microscope [5]. To generate the supersonic gas flow, differential pumping technique is used in the nozzle chamber, the gas flow through a 30 um orifice from a high pressure area (few bar) to a low pressure area (about 10^{-1} to 10^{-2} mbar). With this large pressure difference, the gas will experience a free expansion process, and a supersonic flow will form inside a Mach disk. By placing the first conical skimmer (180 um in diameter) inside the Mach disk (less than 2 cm from the nozzle), we can guide a part of the supersonic flow into the following chambers to form a molecular flow and meanwhile avoid the effect from turbulence and other shock waves. An additional conical skimmer (400 um in diameter) is positioned 25 mm away from the first skimmer to further collimate the flow. In order to have a two dimensional measure of the primary beam profile, a third rectangular skimmer of 4*0.4 mm^2 is placed at 325 mm from the first skimmer before the interaction chamber under an angle of 45 degrees to create a screen-like jet. Detailed design and gas dynamics consideration including

A MULTI-PINHOLE FARADAY CUP DEVICE FOR MEASUREMENT OF DISCRETE CHARGE DISTRIBUTION OF HEAVY AND LIGHT IONS*

Prabir K. Roy†, Stephen Taller, Ovidiu Toader, Fabian Naab, Shyam Dwaraknath, Gary S. Was
MIBL, NERS, University of Michigan, Ann Arbor, MI 48109, USA

Abstract

A new multi-pinhole Faraday cup (MPFC) device was designed, fabricated, and tested to measure ion beam uniformity, over a range of centimeters. There are 32 collectors within the device, and each of those is used as an individual Faraday cup to measure a fraction of the beam current. Experimental data show that the device is capable of measuring the charged particles distribution - which is either in the form of a raster scan, or a defocused beam.

INTRODUCTION

Materials degradation due to irradiation is a limiting factor in nuclear reactor lifetimes. Traditionally, materials have been irradiated in test reactors, such as the Fast Flux Test Facility (FFTF) or the BOR-60 fast nuclear reactor. Ion irradiations, using accelerated charged particles, to induce damage at high dose rates have been successful in emulating the microstructural features of materials irradiated in reactor [1, 2]. In ion irradiation experiments, a high energy beam is either raster scanned, in which the beam is scanned at high frequencies [3], or defocused, to distribute charge particles in a nearly uniform manner, over the material specimens. The measurement of the uniform distribution of particles over the sample surface is crucial to quantify the ion dose in these experiments. A Faraday cup, an optical system such as a scintillator and CCD camera, and a beam profile monitor (BPM) are typical devices used to measure distributions of charged particles in space. A Faraday cup measures the total current of a beam for the full aperture geometry of the instrument, resulting in a flux measurement for the cross sectional area of the cup without any additional spatial resolution. The photon conversion efficiency, and damage to the scintillator by the beam bombardment, limit the practicality of a scintillator based imaging system for assessing the spatial resolution over an extended period of time. A BPM has the ability to provide partial or discrete distribution of an integrated beam profile. The BPM measures the current from secondary electrons on a metal shell surrounding a rotating wire. The BPM, however, does not discriminate between ions and electrons, the latter of which can be problematic for assessing the full beam profile. To provide a better description of the beam density in spatial dimensions, we have designed a multi-pinhole Faraday cup (MPFC) device, to overcome some of the limitations of traditional measurement systems. This work serves to present the design and performance of this device under ion irradiation relevant conditions.

SCIENTIFIC AND TECHNICAL BASIS

In a typical Faraday cup, an electrode, or collector, is used to capture particles. As the Faraday cup measures the electric charge of a beam over time, electrons or ions from outside of the beam are undesirable. A suppressor electrode is used to reduce the entrance of any amount of unwanted particles. To make an effective Faraday cup, there are several guidelines to follow. These are: (1) Charged particles should not physically contact the suppressor. This allows for the suppressor to maintain constant electrical properties. (2) The collector should be relatively deep to minimize secondary electrons loss. (3) The voltage of the suppressor should be negative compared to the collector. (4) The collector may have its own voltage potential applied to minimize the entrance of secondary electrons from the vacuum, or to retain electrons those are generated from within the collector. A beam of scattered or stray particles can create secondary electrons from collisions with the walls of the vacuum system. A negative potential suppresses background electrons, but attracts ions. These low energy ions are rejected using a positive voltage on the collector. If the suppressor is touched by beam particles, especially with an intense or dense beam, the potential of the beam itself can alter the electron suppression. A measured beam current should not be sensitive to the bias voltages once the secondary electrons and plasma ions are properly suppressed [4]. If a Faraday cup functions ideally, the suppressor should not receive any beam current. Since the suppressor is capacitively coupled to the beam charge, a high beam density may result in a temporary spike in the suppressor current (if measured) when the beam strikes. The same scenario may true for a collector.

Based on these criteria, the MPFC was designed and fabricated. Figure 1(a) shows a computer rendering of the multi-pinhole Faraday cup. The device, when viewed at the most basic level, consists of a (1) front plate, (2) suppressor plate, and (3) 32 collectors to satisfy the desirable qualities of a Faraday cup. Table 1 shows parameters of the physical device. Figure 1(b) shows a WARP [5] code simulation to demonstrate equipotential lines and electrical force patterns between the grounded front plate, the suppressor plate held at -150V, and the collectors held at +90V.

The Tantalum front plate has 32 pinholes in line with the collectors to allow the beam to pass. Tantalum was selected because of its high melting temperature, to withstand beam heating, and for its low sputter yield. Because of the relative size of these pinholes to the full beam, the amount of particles passed to the collectors is much less than the number of primary particles. Using a geometric argument, a uniform, evenly distributed beam would have a percentage

DESIGN AND DEVELOPMENT OF A BEAM STABILITY MECHANICAL MOTION SYSTEM DIAGNOSTIC FOR THE APS MBA UPGRADE*

R. Lill, B. Yang, G. Decker, N. Sereno
Advanced Photon Source, Argonne National Laboratory, Argonne, IL 60439 USA

Abstract

The Advanced Photon Source (APS) is currently in the conceptual design phase for the multi-bend achromat (MBA) lattice upgrade. In order to achieve long-term beam stability goals, a mechanical motion system (MMS) has been designed to monitor critical in-tunnel beam position monitoring devices. The mechanical motion generated from changes in chamber cooling water temperature, tunnel air temperature, beam current, and undulator gap position causes erroneous changes in beam position measurements causing drift in the x-ray beam position. The MMS has been prototyped and presently provides critical information on the vacuum chamber and beam position monitor (BPM) support systems. We report on the first results of the prototype system installed in the APS storage ring.

INTRODUCTION

In order to achieve the one micron long-term drift beam stability requirements seen in Table 1, all sources of mechanical motion of critical in-tunnel beam position monitoring devices must be carefully evaluated and appropriately addressed. Experiments conducted at the Advanced Photon Source (APS) clearly confirm that the thermal distortion of the vacuum chamber leads to movements of the BPMs up to 10 µm/˚C, or a 0.5 µm peak-peak for a cooling water temperature change of 0.05˚C peak-peak. This distortion is incompatible with the new beam stability requirements for the planned APS multi-bend achromat (MBA) upgrade. Research to quantify motion specifically for the APS accelerator tunnel and experiment hall floor has been ongoing for over five years [1].

The plan for the MBA upgrade is to use insertion device vacuum chambers (IDVCs) similar to what APS has installed today. Mechanical stability of BPM pickup electrodes mounted on these small-gap IDVCs potentially places a fundamental limitation on long-term x-ray beam stability for insertion device beamlines. The mechanical motion system (MMS) studies have opened a new window of understanding into how to measure and correct for these complex nonlinear mechanical movements with environmental changes. The MBA MMS design will monitor the position of the BPM in real time during user beam operations to compensate for the distortion of the insertion device vacuum chamber (IDVC).

Vertical	0.4 µm 0.17 µrad	1.0 µm 0.5 µrad

MMS SYSTEM OVERVIEW

One of the most critical locations for electron beam stability is at the insertion device points. The existing APS IDVC is extruded aluminum, shown in Fig. 1, with integrated beam position monitor electrode housings machined out at each end. The wall thickness of the completed chamber at the beam orbit position is 1 mm. The design uses a rigid strongback that limits deflection of the chamber under vacuum despite the thin wall. The IDVC beam position monitors (BPMs) provide the critical steering data necessary to maintain beam stability through the insertion device. The BPM button electrodes mounted in the machined platforms have a 4-mm diameter. There are two button electrodes mounted on a single miniature vacuum flange [2].

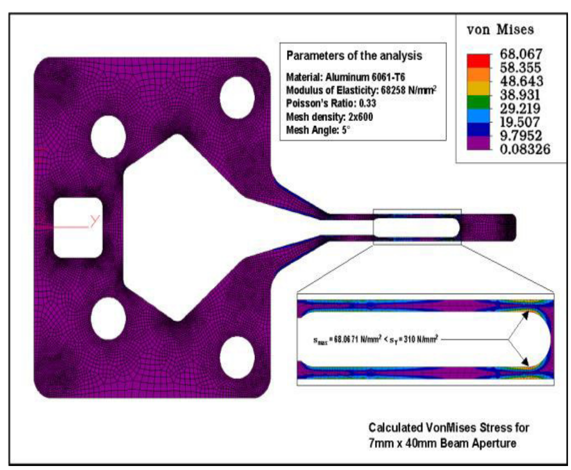

Figure 1: Existing storage ring IDVC cross section.

The rf and x-ray BPMs can be erroneously affected by changes in vacuum chamber cooling water temperature, tunnel air temperature, and beam current fluctuations. The block diagram shown in Fig. 2 illustrates the plan for instrumenting the MMS. Each ID location and grazing-incidence insertion device x-ray beam position monitor (GRID-XBPM) will be instrumented with capacitive detectors and hydrostatic detectors. The MMS is a real-time position monitoring system that measures the

BEAM STABILITY R&D FOR THE APS MBA UPGRADE*

Abstract

Beam diagnostics required for the APS Multi-bend acromat (MBA) are driven by ambitious beam stability requirements. The major AC stability challenge is to correct rms beam motion to 10% the rms beam size at the insertion device source points from 0.01 to 1000 Hz. The vertical plane represents the biggest challenge for AC stability, which is required to be 400 nm rms for a 4-micron vertical beam size. In addition to AC stability, long-term drift over a period of seven days is required to be 1 micron or less. Major diagnostics R&D components include improved rf beam position processing using commercially available FPGA-based BPM processors, new X-ray beam position monitors based on hard X-ray fluorescence from copper and Compton scattering off diamond, mechanical motion sensing and remediation to detect and correct long-term vacuum chamber drift, a new feedback system featuring a tenfold increase in sampling rate, and a several-fold increase in the number of fast correctors and BPMs in the feedback algorithm. Feedback system development represents a major effort, and we are pursuing development of a novel algorithm that integrates orbit correction for both slow and fast correctors down to DC simultaneously. Finally, a new data acquisition system (DAQ) is being developed to simultaneously acquire streaming data from all diagnostics as well as the feedback processors for commissioning and fault diagnosis. Results of studies and the design effort are reported.

INTRODUCTION

The small emittance of the Multi-bend acromat (MBA) lattice translates into much smaller beam dimensions in the horizontal plane at the insertion device (ID) source points compared to the present APS lattice [1]. Since beam centroid motion of an appreciable fraction of the beam size results in increased effective emittance for users, AC beam stability requirements for the MBA upgrade are defined as 10% of the minimum expected beam size at the insertion device (ID) source points over the band 0.01 - 1000 Hz. Furthermore, long-term drift from 100 seconds to a period of seven days is defined as an estimate of diffusive ground motion over the long term. Table 1 summarizes these requirements. Beam stability R&D for the MBA upgrade focuses on developing diagnostics and controls systems to meet or exceed these requirements.

MBA DIAGNOSTICS INTEGRATION

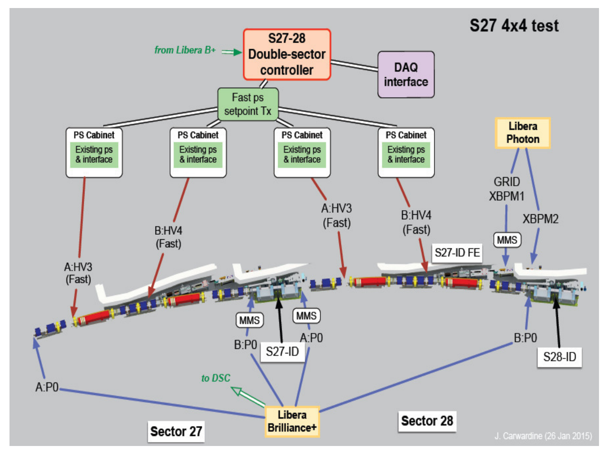

Figure 1: MBA diagnostics integrated R&D in APS storage ring sector 27. The P0 labels are ID BPMs and the HV labels are fast correctors.

Figure 1 shows the suite of diagnostics to be integrated and tested together as part of the MBA R&D plan. At the insertion device as well as the MBA arcs, we will use new commercial rf BPM electronics with a low noise floor. New high-power X-ray BPMs (called GRID for grazing-incidence insertion device) based on X-ray fluorescence off copper, and much less sensitive to background radiation coming from the ring multipoles, have been installed. A low power version of these X-ray BPMs based on Compton scattering off diamond is being developed for canted undulator beamlines. New hard X-ray intensity monitors will be installed to insure long-term reproduceability and relative flux calibration. A mechanical motion sensing system will be used to monitor position changes due to temperature, vibration, and ground motion at the ID rf BPMs as well as the X-ray BPMs. All these systems will be tied together using a distributed real-time orbit feedback system (RTFB) that will additionally take information from two pinhole cameras to correct coupling. The new RTFB system will include an increase of at least 15 in sampling rate (to 22 kHz) over the present system, increasing the closed-loop bandwidth to 1

CONCEPTUAL DESIGN AND ANALYSIS OF A STORAGE RING BEAM POSITION MONITOR FOR THE APS UPGRADE*

B. Stillwell, R. Lill, R. Lindberg, M. O'Neill, B. Rocke, X. Sun, ANL, Argonne, IL 60439, USA
A. Blednykh, BNL, Upton, NY 11973, USA

Abstract

A conceptual design has been developed for a radio frequency (rf) pickup-type beam position monitor (BPM) for use in a multi-bend achromat (MBA) storage ring under consideration by the APS Upgrade project (APS-U) [1]. Beam feedback systems are expected to require fourteen rf BPMs per sector with exceptional sensitivity and mechanical stability. Simultaneously, BPM insertion length must be minimized to allow lattice designers the greatest freedom in selecting magnet lengths and locations. Envisioned is a conventional four probe arrangement integrated inside of a pair of rf-shielded bellows for mechanical isolation. Basic aspects of the design are presented along with the results of analyses which establish expected mechanical, electronic, and beam physics-related performance measures.

DESIGN OBJECTIVES

The ultimate goal of the BPM is to generate a set of electronic signals that precisely indicate the arrival time and lateral location of the passing particle beam. Perhaps the most challenging issue is maintaining adequate positional stability in the presence of synchrotron radiation heating of adjacent vacuum chambers, vibrational energy due to water cooling of vacuum chambers and magnets, and rf-induced heating of the BPM itself. The present guidance is that the BPMs should be vibrationally stable to an rms amplitude tolerance of 32 nm horizontally and 56 nm vertically at frequencies between 1 and 1000 Hz. BPM offset values will be established after storage ring systems have stabilized thermally under full-current operation, however the maximum acceptable aggregate of initial and thermally-driven misalignment prior to establishing the offsets has been found to be 500 µm. Once the offsets have been established, the contribution of long-term (thermal) drift to BPM reading error must be no more than 10 µm. Another limitation is available space. The presently envisioned magnet configuration provides a minimum of 125 mm to insert many of the BPMs at required locations.

INTERFACE CONSTRAINTS

There are many constraints that are imposed on the design to ensure that the BPM does not significantly compromise the performance of other technical systems. Foremost among these is that the BPM be compatible with the ultrahigh vacuum environment. Outgassing from internal surfaces must be limited so that average vacuum pressures across the sector can be maintained at a maximum of roughly 2 nTorr during operation. In addition, where BPMs are in close proximity with vacuum chambers coated with non-evaporable getter (NEG) material, the outgassing should not include species such as fluorine or chlorine that are known to cause permanent poisoning of the NEG material or be so excessive that the required thermal activation cannot be accomplished. The assembly should accommodate some degree of misalignment of the flanges on adjacent vacuum chambers. This flange misalignment has been estimated to be no more than 500 µm, a value which sums expected chamber fabrication and alignment tolerances. Also critical is that the BPM should not act to distort fields from the adjacent magnets and should not introduce unacceptable impedance effects on the particle beam. Finally, the BPM should tolerate the radiation environment, thermal-mechanical cycling, and ambient conditions for an expected machine lifetime of 20 years.

CONTROL SYSTEM FOR THE LCLS II UNDULATOR PROTOTYPE*

Joseph Z. Xu[1], Nikita Strelnikov[1,2], Isaac Vasserman[1] and Richard Farnsworth[1]
[1]Advanced Photon Source, Argonne National Laboratory, Argonne, Illinois 60439, USA
[2]Budker Institute of Nuclear Physics, Novosibirsk 630090, Russia

Abstract

The Linac Coherent Light Source (LCLS) has been successfully operated for more than 6 years. In order to expand the capability and capacity of the LCLS, LCLS-II has been planned and funded by the Department of Energy. Advanced Photon Source (APS) at the Argonne National Lab is tasked with building the prototype of the LCLS-II undulator based on the concept of magnetic force dynamic compensation. The control system for the prototype is responsible for four motion and feedback channels with sub-micron level accuracy, eight load cells that monitor how the forces act on the system in real time, and multiple temperature sensors. A detailed description of the control system and its operation is reported.

INTRODUCTION

As the world's first x-ray free electron laser in operation, the LCLS facility at the Stanford Linear Accelerator Center (SLAC) has plans to be expanded in both capability and capacity to meet the needs of the scientific community. Different from the original fixed gap undulators, the LCLS-II will be equipped with adjustable gap undulators.

APS is to build a prototype of the LCLS-II undulator. The device is a 3-meter long adjustable gap undulator with a minimum gap of 7.0 mm and better than 10 micron tolerance [1]. Due to the magnetic force change in the scale of several thousands of kilograms in different gaps during operation, the magnetic force dynamic compensation scheme has been adopted [2].

The control system for the prototype is a windows based PXI system from National Instruments. It is capable of handling four motion axes, four absolute position feedbacks, eight load cell force sensors, and eight temperature sensors. Application software is LabVIEW based with field programmable gate array (FPGA) technology in monitoring the positions and the forces in real-time.

SYSTEM DESCRIPTION

The control system for the LCLS-II undulator prototype consists of a PXI crate with a windows based control card, an FPGA card, and a Digital Multimeter (DMM) card, all from National Instruments.

The peripherals of the system comprise the positioning control system and the positioning feedback system. The control system has four motors that drive the positioning systems. The motors are SmartMotor servomotors from the Animatics Corporation, with the motor control integrated in the back of each motor including an RS-232 serial interface. Each two motors drive one of the two ID strongbacks into the desired position to form the gap as needed. The motors are connected to the control card via an RS-232 serial interface. All four motors are connected in serial.

The position feedback system has four absolute digital linear encoders with Synchronous Serial Interface (SSI) from Fagor Automation. The resolution of the encoders is 0.1 micron. The maximum range of the encoders is 120 mm. The encoders are programmable. They are configured to 32 bits with non-grey code. The encoders are connected to the digital I/O interfaces of the FPGA card.

The forces acting on the actuators are monitored with eight load cells from Omega Engineering Inc. The load cells are bi-directional. They are powered by a voltage power supply that supplies a 10 volts dc excitation source. The voltage excitation power supply is from Agilent Technologies. The voltage is monitored by a DMM card. The analog outputs of the load cells are monitored by 16-bit analog-to-digital channels embedded in the FPGA card. The load cell signals are normalized by the excitation voltage to compensate the fluctuation of the excitation voltage. The precision of the force monitoring is about 0.2 lbs.

The temperatures are monitored with a web-enabled temperature measurement module equipped with eight RTD sensors. The module is from Omega Engineering Inc. It communicates with the control card via http protocol through a TCP/IP network. The precision of the temperature monitoring system is 0.1 degree Celsius. Figure 1 shows the schematic layout of the prototype device control system.

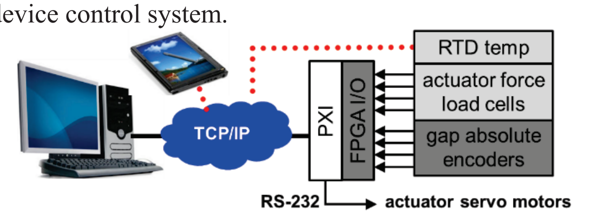

Figure 1: Schematic layout of the prototype device control system.

SOFTWARE

LabVIEW-based system software has been developed to coordinate the motion control and sensor data monitoring. The system can be accessed via the internet from anywhere, anytime through the facility's virtual

DESIGN AND DEVELOPMENT FOR THE NEXT GENERATION X-RAY BEAM POSITION MONITOR SYSTEM AT THE APS*

B.X. Yang#, G. Decker, S. H. Lee, Y. Jaski, F. Westferro, N. Sereno, and M. Ramanathan
Advanced Photon Source, Argonne National Laboratory, Argonne, IL 60439, USA

Abstract

The planned Advanced Photon Source (APS) Upgrade will bring storage ring beam sizes down to several micrometers and require x-ray beam directional stability in 100 nrad range for undulator power exceeding 20 kW. The next generation x-ray beam position monitors (XBPMs) are designed to meet these requirements. We present commissioning data on the recently installed grazing-incidence insertion device x-ray beam position monitor (GRID-XBPM) based on Cu K-edge x-ray fluorescence from limiting absorbers of the front end for two inline undulators. It demonstrated a 30-fold improvement for signal-to-background ratio over existing photoemission-based XBPMs. Techniques and results for calibrating the XBPMs are also discussed.

INTRODUCTION

The planned APS Upgrade (APS-U) will dramatically reduce the electron beam size and divergence in the horizontal plane [1]. A major improvement in beam stability is required for APS users to benefit from this upgrade. Table 1 lists the stability goals, which are approximately 10% of the expected beam sizes. A new FPGA-based orbit feedback system and several new diagnostics are being developed to support this goal [2]. Among them, a new class of x-ray beam position monitors (XBPM) sensitive to only hard x-ray excitations is being developed. For the high heat load front end in the APS-U, two inline undulators will deliver up to 20 kW of x-ray power. We developed a grazing-incidence XBPM (GRID-XBPM) using the Cu K-edge x-ray fluorescence (XRF) from the front-end apertures to infer the undulator beam's core position [3]. A prototype test showed a significant reduction in bend magnet (BM) background [4]. Following this successful demonstration, two GRID-XBPMs were designed and constructed in the new front end and installed in 2014 [5]. In this work, we report the commissioning results of the first production XBPM and present its performance in a front end.

Table 1: MBA Upgrade Beam Stability Requirements

	AC rms Motion (0.01-1000 Hz)	Long-term Drift (100 s - 7 Days)
Horizontal	1.7 μm / 0.25 μrad	1.0 μm / 0.6 μrad
Vertical	0.4 μm / 0.17 μrad	1.0 μm / 0.5 μrad

BEND MAGNET BACKGROUND

In a previous test [5], the prototype XBPM was located downstream of a 4.5-mm front end exit aperture, with a 0.2 mrad horizontal acceptance angle. In the front end, however, the XBPM is located at 18.6 m from the source, downstream of a 10.6-mm aperture, with a 0.6-mrad horizontal acceptance angle. The increase in horizontal aperture is expected to increase BM background. Therefore, characterizing its impact became our first task. We measured the sum signal of all diodes / blades with the undulator gap fully open and then as a function of undulator gaps. Figure 1 shows the ratio of the undulator signal over the BM background for the best group of PIN diodes in the GRID-XBPM, along with those for installed APS photoemission XBPMs. We can see that the hard x-ray XBPM improves the signal-to-background ratio by 30 fold. To further reduce the impact of the BM background, we built three groups of PIN diodes into the GRID-XBPM. Not surprisingly, while the "best" group is most sensitive to the photons originated near the undulator axis, the "worst" group of PIN diodes is located furthest away from the undulator axis and is more sensitive to the BM background by a factor of eight. Subtracting a small fraction of the "worst" PIN signals from the "best" PIN signals will further reduce the impact of BM background by another factor of 5. This requires a special 6-channel XBPM electronics. In the remaining part of this work, however, we will continue with the conventional 4-channel electronics for presenting our commissioning experience.

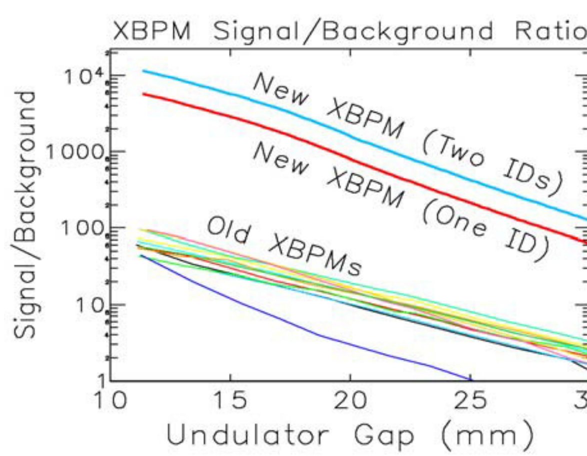

Figure 1: Ratio of undulator signal over BM background for the hard x-ray GRID-XBPM shows a 30-fold improvement over old style photoemission XBPMs.

A LOW TIME-DISPERSION REFRACTIVE OPTICAL TRANSMISSION LINE FOR STREAK CAMERA MEASUREMENTS

J. G. Power[1#] and G. Ha[1,2]
[1]Argonne National Laboratory, Argonne, IL 60439, USA
[2]Department of Physics, POSTECH, Pohang, Gyeongbuk 790-784, KOREA

Abstract

Streak camera measurements of the electron bunch length are limited in resolution by several factors. These include: (1) the light source itself (e.g. OTR, Cherenkov, Synchrotron radiation), (2) dispersion from the refractive optical transport line (OTL) between the light source and the streak camera, and (3) the streak camera itself. The limiting resolution for pulses length of a few psec is caused by the OTL due to the very broad bandwidth of the light pulse (hundreds of nm). While an all-reflective OTL can eliminate dispersion, the system is complicated and expensive.

In this paper, we examine the time spread of the light pulse due to the dispersion in the lenses of the OTL. We present an analysis of the dispersion and benchmark it to measurements of the time dispersion for several different lens materials. Finally, we conclude with recommendations of the proper design of the refractive OTL to minimize the time dispersion while maximizing the signal.

STREAK CAMERA MEASURMENTS OF THE ELECTRON BUNCH LENGTH

Streak camera measurements of the electron (in general, charged particle) bunch length are well suited for the regime of greater than a few picoseconds. Our examples are based on a Hamamatsu [1] C1587 streak camera with a resolution of 2ps since this is the camera we own at the Argonne Wakefield Accelerator (AWA) Facility. Note that there exist streak cameras with significantly better resolution such as the Hamamatsu Fresca-200 with a resolution of 200 femtoseconds. In any case, the examples here can be extended to any particular case as long as one requires that the dispersion introduced by the optical transport line is less than one third of the minimum bunch length one desires to measure since this only introduces an error of less than ~5% ($\sqrt{1^2 + 0.33^2} = 1.05$).

A typical setup for the measurement of the electron bunch length is shown in Fig. 1. (1) The process begins when the electron bunch passes through the radiator (e.g. OTR) and generates a prompt, broadband, light pulse, of similar transverse and longitudinal profile to the electron bunch. (2) To avoid damage to the streak camera it is typically located far from the radiator and therefore the light pulse is often transported through a long, refractive, optical transport line (OTL) made up of a series of *glass* lenses [2]. Other solutions are possible, such as an all reflective OTL or to locate the streak camera near the radiator with adequate shielding, but we only consider the case of a long, refractive OTL in this paper. (For the remainder of the paper, we use the shorter phrase "OTL" to refer to "a long, refractive OTL".) The problem with the OTL is that light pulse length increases as it travels through the OTL due to the variation of the group velocity with frequency (a.k.a. group velocity dispersion) in the glass (pulse at bottom of Fig. 1). This means that by the time the light pulse arrives at the streak camera its length is significantly longer than the electron's bunch length. A bandwidth filter of ~10nm is typically used to reduce the lengthening to an acceptable level. (3) Finally, the light pulse arrives at the streak camera for measurement. Proper use of the streak camera is beyond the scope of the paper so we limit comments to bandwidth requirements of the streak camera since it has direct bearing on the subject of this paper. The bandwidth of the streak camera is determined by the input optics and the photocathode quantum efficiency. The AWA streak camera uses the N1643 streak tube with bandwidth of [200-850nm] and we used this for the examples in this paper.

REFRACTIVE AND GROUP INDEX

Dispersive media are characterized by a wavelength (or frequency) dependent susceptibility $\chi(\lambda)$, refractive index $n(\lambda)$, and group index $n_g(\lambda)$ [3]. The refractive index of

DEVELOPMENT OF A VERSATILE BUNCH-LENGTH MONITOR FOR ELECTRON BEAMS AT ASTA*

A. H. Lumpkin#, R. Thurman-Keup, D. Crawford, D. Edstrom Jr., J. Ruan, and J. Santucci,
Fermi National Accelerator Laboratory, Batavia, IL 60510 USA

Abstract

We have installed a versatile bunch length monitor system at a location after the chicane in the ASTA beamline. Options for generating radiation from a metal screen and transporting coherent radiation to the Martin-Puplett Interferometer and optical transition radiation to a synchroscan streak camera are provided. There is also a chicane bypass line so this station can evaluate the uncompressed beam as well. The system will be used to characterize the bright beams of the photoinjector.

INTRODUCTION

The generation of bright electron beams at the Advanced Superconducting Test Accelerator ASTA/IOTA facility [1] at Fermilab has motivated implementation of a versatile bunch-length monitor located after the 4-dipole chicane bunch compressor for electron beam energies of 20-50 MeV and integrated charges in excess of 10 nC. The station includes both a Hamamatsu C5680 synchroscan streak camera and a Martin-Puplett interferometer (MPI). An Al-coated Si screen will be used to generate both optical transition radiation (OTR), coherent transition radiation (CTR), and coherent diffraction radiation (CDR) during the beam's interaction with the screen. A chicane bypass beamline will allow the measurement of the bunch length without the compression stage at the same downstream beamline location using OTR and the streak camera. The UV component of the drive laser has previously been characterized with a Gaussian fit sigma of 3.5 ps [2], and the uncompressed electron beam is usually expected to be similar to this value at low charge per micropulse. Elongation of the pulse to >15 ps at 250 pC per micropulse has been recently predicted [3]. In addition, OTR will be transported to the streak camera from the focal plane of the downstream spectrometer to provide an E-t distribution within the micropulse time scale. This application relies heavily on the synchronous sum of micropulses in order to obtain an image with adequate statistics. Commissioning of the system and initial results with beam will be presented.

EXPERIMENTAL ASPECTS

The high-power electron beams for the ASTA/IOTA facility [1] were generated in a photoinjector based on a UV drive laser and the L-band rf photocathode (PC) gun cavity. The system has a 3-MHz micropulse repetition rate with micropulse charges selectable from 2 pC to 3.2 nC by adjusting the UV laser intensity. The quantum efficiency of the Cs_2Te photocathode is 1-2 %, and the photoelectrons exit the gun at up to 5 MeV energy. After the rf gun there is a diagnostics station that includes an insertable profile screen, two rf BPMs, and an insertable Faraday cup to characterize the 4-5 MeV beam. The beam is captured in an L-band superconducting rf accelerator structure with 15-22 MV/m nominal gradient. This is followed by a beamline with a suite of diagnostics including rf BPMs, two toroids, a wall current monitor, a series of loss monitors, and 7 beam-profiling stations. Three of these are configured in the chicane, the bunch longitudinal profiling station, and in the focal plane of the electron spectrometer. A schematic of the beamline is shown in Fig. 1. There is a chicane bypass line which we employed in initial commissioning. Since the bunch length monitor is after the chicane, using the bypass line we can measure the bunch lengths without chicane based compression and then with chicane compression once it is commissioned.

The Bunch Length Monitors

The bunch length monitor architecture was intended to provide a central collection point for the various source points whose radiation is transported into the MPI box. As indicated in Fig. 2, the coherent and optical synchrotron radiation ((CSR) and (OSR), respectively) sources from two chicane dipoles, OTR, CTR, and CDR from the X121 station, and the OTR from the spectrometer focal plane are also available to the system as described previously [4]. However, for this initial commissioning period with no compression, we emphasize the streak camera implementation. The streak camera was located outside of the tunnel in a small enclosed optical table. This involves an ~15 m transport with eight mirrors. The mirror system is adjusted using alignment laser beams.

Readout from the streak camera is performed using a Prosilica 1.3 Mpixel GiG-E vision camera with a 2/3" CCD and with fiberoptic coupling from the tube phosphor. We had previously used both the online Java-based ImageTool and the offline MATLAB-based ImageTool processing programs [5,6] in the commissioning of the laser lab streak camera system. Initial measurements of the UV component indicated the bunch length Gaussian fit sigma to be ~ 4 ps, Unless noted otherwise, the streak camera's synchroscan unit was phase locked to the master oscillator, which operationally provides the rf sync for the linac, rf gun, and UV drive laser. We provided a description of the commissioning of the streak camera system and image acquisition tools and the application to the drive laser previously [7].

BEAM EXTINCTION MONITORING IN THE Mu2e EXPERIMENT*

E.J. Prebys, P. Kasper, A. Gaponenko, Fermilab, Batavia, IL 60510, USA
L. Bartoszek, Bartoszek Engineering, Aurora, IL 60506, USA

Abstract

The Mu2e Experiment at Fermilab will search for the conversion of a muon to an electron in the field of an atomic nucleus with unprecedented sensitivity. The experiment requires a beam consisting of proton bunches of 250 ns FW, separated by 1.7 μsec, with no out-of-time protons at the 10^{-10} fractional level. The verification of this level of extinction is very challenging. The proposed technique uses a special purpose spectrometer that will observe particles scattered from the production target of the experiment. The acceptance will be limited such that there will be no saturation effects from the in-time beam. The precise level and profile of the out-of-time beam can then be built up statistically, by integrating over many bunches.

INTRODUCTION AND REQUIREMENTS

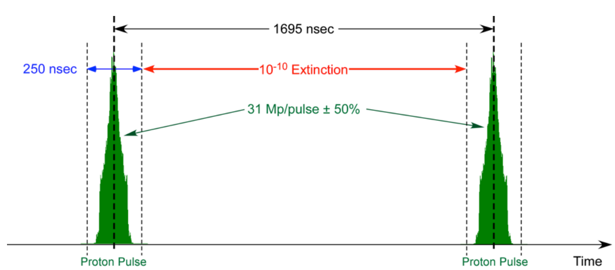

Figure 1: The proton bunch structure required by the Mu2e experiment.

The goal of the Mu2e experiment [1] is to search for the conversion into an electron of a muon that has been captured by a nucleus ($\mu N \rightarrow eN$). This manifestly violates the conservation of charged lepton flavor number, and its obvervation would therefore be an unambiguous indicator of physics beyond the Standard Model.

A key component of the experimental technique is the proton beam structure, which is illustrated in Figure 1. The primary beam consists of short (250 ns FW) proton bunches with 8 GeV kinetic energy, separated by approximately 1.7 μsec, which are used to produce pions, which subsequently decay to muons. To suppress backgrounds, it's vital that the interval between the bunches be free of protons at a level of at least 10^{-10} relative to the beam in the bunches. The technique used to achieve this level of extinction is described elsewhere [2]. It is achieved in two parts. The formation of the bunches in Fermilab Recycler and Delivery ring is expected to have extinction on the order of 10^{-5}. The remaining extinction will be accomplished in the primary beam line with a system of resonant dipoles and collimation, configured to allow only the in-time beam to be transmitted.

It is of course vital to verify that this level of extinction has been achieved, so the experiment has specified that a level of extinction of 10^{-10} or lower can be measured within a few hours of running at the nominal intensity.

* Work supported by the United States Department of Energy under Contract No. DE-AC02-07CH11359

TECHNIQUE

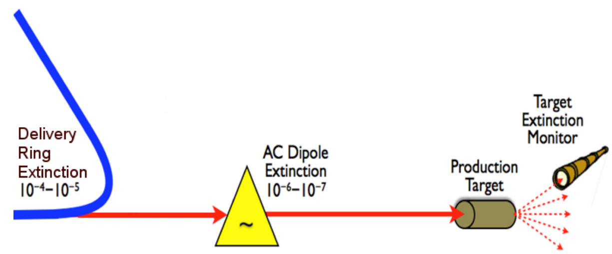

Figure 2: Concept for the statistical extinction monitoring technique.

Each bunch in the Mu2e experiment has roughly 3×10^7 protons, so our desired extinction level corresponds to less than one out-of-time proton every 300 bunches. Unfortunately, measuring single protons in the presence of such large bunches would require a dynamic range that is beyond state of the art for current beam instrumentation. We choose instead to focus on a statistical technique, as illustrated in Figure 2. The pion production target will be monitored by a dedicated spectrometer, the acceptance of which has been designed such that it will not be saturated by the particles observed from the in-time bunch. The spectrometer will then detect a small fraction of out-of-time particles, so that over many bunches, an accurate time profile can be integrated for both the in- and out-of-time protons. Over time, a measurement of the out-of-time beam can be made with increasing sensitivity, limited ultimately by the rate of fake background tracks.

It must be stressed that our aim is not to veto individual events occurring near out-of-time protons, but rather to verify that the total rate of such protons is below that which we have determined to be acceptable.

This technique is conceptually very similar to techniques that have been used for precision measurement of transverse beam halo [3].

DESIGN

The layout of the Mu2e pion production target is shown in Figure 3. Primary protons are incident on a Tungsten target that is within a superconducting solenoidal magnet. The experiment itself uses low momentum, backscattered

NEW HADRON MONITOR BY USING A GAS-FILLED RF RESONATOR *

K. Yonehara†, A.Tollestrup, R.M. Zwaska, Fermilab, Batavia, IL 60510, USA
G. Flanagan, R.P. Johnson, Muons, Inc., IL 60510, USA
G. Fasce, CNI, Rome, I-00187, Italy

Abstract

A novel pressurized gas-filled RF-resonator beam monitor is proposed that will be simple and robust in high-radiation environments for intense neutrino beam facilities and neutron spallation sources. Charged particles passing through the resonator produce ionized plasma, which changes permittivity of the gas. Radiation sensitivity is adjustable using gas pressure and RF amplitude. The beam profile will be reconstructed by X, Y, and U hodoscopes using strip-shaped gas resonators.

INTRODUCTION

The Long Baseline Neutrino Facility (LBNF) is the flagship experiment at Fermilab. Hadron monitors play an important role to measure quality of the secondary charged particles and to precisely direct the beam to the neutrino detector located hundreds of kilometers away. An ionization chamber is a standard device to use as the hadron monitor in the NuMI beam line at Fermilab. Operational failure of the hadron monitor due to high radiation is the present issue. A custom hardline cable is used to bring the electrical connections across the body of the hadron monitor to each of its feedthroughs. Since these cables lie in the beam they are subject to radiation damage and possible signal pickup. To guard against both, the cables are designed with both polyimide and ceramic insulators around the conductor and enclosed in aluminum tubing [1]. These materials significantly improved the lifetime. However, the conventional hadron monitor still has a limited lifetime and the cabling structure is complicated. Especially, future hadron monitors must operate in even higher radiation environments. The LBNF beam line design beam power for the primary protons is > 2 MW, which is three times higher than the NuMI facility. There is no particle detector device currently working in such an extremely high radiation environment.

A gas-filled RF-resonator hadron monitor will be simple and radiation-robust in this environment. The gas-filled RF resonator has been originally developed for muon beam ionization cooling channels [2]. A conceptual drawing is shown in fig. 1. When the charged beam passes throughout the gas-filled resonator it produces a large amount of electron-ion pairs by interacting with gas. The permittivity in the resonator is changed proportional to the number of incident charged particles. The beam profile will be reconstructed by X, Y, and U hodoscopes using strip-shaped gas resonators.

† yonehara@fnal.gov

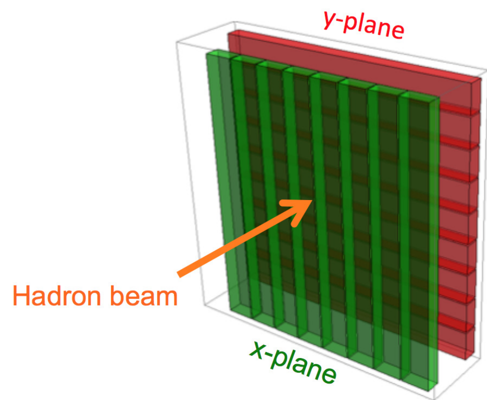

Figure 1: Schematic of the gas-filled RF hadron monitor.

PERMITTIVITY IN GAS-FILLED RF RESONATOR WITH PLASMA

The characteristic of permittivity is determined by electrons rather than ions since the ion mass is three orders of magnitude heavier than electron mass. We start our discussion from the equation of motion for a single electron in an RF field in gas,

$$m\ddot{\vec{r}} = -e\vec{E}e^{-i\omega_{RF}t} - m\nu\dot{\vec{r}}, \tag{1}$$

where ν is the collision frequency of the electron with gas molecules. The first term is acceleration of the electron by the external RF field while the second one is the frictional force caused by interactions with the gas. The electron motion is expected to be $r = r_0 e^{-i\omega t}$ where the position vector is assumed to be parallel to the electric field ($\vec{r} \| \vec{E}$). Putting this into eq. (1) results in

$$r_0 = -\frac{eE_0 e^{-i(\omega_{RF}-\omega)t}}{m(\omega^2+\nu^2)}\left(1 + i\frac{\nu}{\omega}\right). \tag{2}$$

The polarization of the gas plasma is given as

$$P = \frac{n_e e^2 E_0 e^{-i(\omega_{RF}-\omega)t}}{m(\omega^2+\nu^2)}\left(1 + i\frac{\nu}{\omega}\right) \equiv \varepsilon_0 \chi_e E(t), \tag{3}$$

where n_e is the total number of electrons in the resonator and χ_e is the susceptibility of the gas plasma. Assuming that ionization electrons are oscillating in phase with the RF electric field, i.e. $\omega = \omega_{RF}$, eq. (3) can be simplified, and the relative permittivity of gas plasma is derived as

$$\frac{\varepsilon}{\varepsilon_0} = 1 + \chi_e \simeq 1 + \frac{n_e e^2}{\varepsilon_0 m(\omega^2+\nu^2)}\left(1 + i\frac{\nu}{\omega_{RF}}\right). \tag{4}$$

This assumption is valid if the gas pressure is sufficient to cool electrons down to an equilibrium condition within one

DEVELOPMENT OF SIMPLE TRACKING LIBRARIES FOR ALS-U*

H. Nishimura#, D. Robin, K. Song, C. Steier, C. Sun, W. Wan
LBNL, Berkeley, CA 94720, USA

Abstract

A conceptual lattice design study of a new diffraction-limited light source requires complex and numerically intensive calculations due to increasing number of fitting parameters. This paper reports our ongoing effort of upgrading accelerator modeling and simulation libraries to carry out such design studies efficiently.

THE TRACY LIBRARIES

Tracy[1] is an accelerator modeling and simulation code developed as a part of the Advanced Light Source (ALS) conceptual design study[2] in late 1980's. The original version was written in Pascal, and its accelerator library was extracted and rewritten in C/C++ and later in C#.

The C/C++ version of the library was called Goemon, which is now Tracy++[3]. One of its applications is the use with multi-objective genetic algorithms (MOGA)[4] to optimize the existing ALS lattice[5], and the new lattice for a diffraction-limited light source called ALS-U[6] by using OpenMPI[7].

It is not common to use C# for scientific computing yet, however, the development effort of Tracy was moved to the C# version called Tracy#[8] a decade ago for better development efficiency and horizontal integrability than the C/C++ version but with some performance penalty at run time.

Taking the design study of ALS-U as an opportunity, the upgrade of these Tracy libraries have started. Cleaning up and simplifying the internal structures, they are upgraded to take benefit of the modern software and hardware technologies. These new version is called Tracy.Lite that comes in both C++ and C# versions.

TRACY.LITE

Goals

The goal is to create simpler, faster, and more reliable and flexible libraries than the Tracy++ and Tracy# combination. We do this first by limiting our scenario to the first phase of the conceptual lattice design studies where lattice errors are not considered but many parameter optimizations with multiple objectives and also straightforward scans are required. The modeling of realistic lattice errors is for the second phase.

Tracy.Lite supports multiple usage modes; a highly-parallelized batch execution mode for both MOGA and straightforward scan, and interactive mode using scripts.

*Work supported by the U.S. Department of Energy under Contract No. DE-AC02-05CH11231
H_Nishimura@lbl.gov

Based on our experience with Tracy++ and Tracy#, Tracy.Lite also has two implementations; Tracy.Lite++ in C++ and Tracy.Lite# in C#. Tracy.Lite++ is for the use on the HPC clusters and also on modern many-code CPUs. Tracy.Lite# is for the development efficiency, flexibility and the use from Python. By developing these two versions simltaneously, a better compatibility is established than the previous case.

Simplification

This is to make both design and implementation simple and concise to improve maintenance ability, development efficiency, execution speed and reliability.

The Element class models building blocks of the beam lines, such as drift spaces, various magnets, monitors and RF cavities. Tracy++ and Tracy# have the root class Element and its descendants which form a tree. This hierarchy has been removed and the single Element class supports all the Elements by distinguishing the types of building blocks by using the object attributes. This may look like a degeneration as a general Object-Oriented Programming practise, however, it makes external call from other programming languages, such as Python, much more transparent and feasible.

The lattice definition was done by using operation overloading effectively. As Tracy++ required complex memory management for it, Tracy.Lite++ uses generic containers as in Tracy# and Tracy.Lite#.

These effects are reflected in the library sizes as shown below.

Table 1: The Library Code Length in Lines

Library	Language	Core	ALS
Tracy++	C++	35K	6K
Tracy#	C#	22K	11K
Tracy.Lite++	C++	6K	2K
Tracy.Lite#	C#	5K	5K

Core is the body of the library not dedicated to ALS.
ALS is the model of various ALS lattice configurations.

Execution Speed

The speed up comes in the two directions; one is in a single thread mode by removing the hot spots where CPU time is wasted by using CPU profiling, and also simplifying the algorithms that are physically redundant in the ideal lattice design phase. The second is by multi-threading; Tracy.Lite++ uses OpenMP[9] and Tracy.Lite# uses Parallel.For[10] that is similar to OpenMP and a part of the .NET Framework.

B. Chase, E. Cullerton, P. Varghese, FNAL, Batavia, IL 60510, USA

Abstract

The SLAC National Accelerator Laboratory is planning an upgrade (LCLS-II) to the Linear Coherent Light Source with a 4 GeV CW superconducting (SCRF) linac. The SCRF linac consists of 35 ILC style cryomodules (eight cavities each) for a total of 280 cavities. Expected cavity gradients are 16 MV/m with a loaded QL of ~ 4 x 10^7. The RF system will have 3.8 kW solid state amplifiers driving single cavities. To ensure optimum field stability a single source single cavity control system has been chosen. It consists of a precision four channel cavity receiver and two RF stations (Forward, Reflected and Drive signals) each controlling two cavities. In order to regulate the resonant frequency variations of the cavities due to He pressure, the tuning of each cavity is controlled by a Piezo actuator and a slow stepper motor. In addition the system (LLRF-amplifier-cavity) is being modeled and cavity microphonic testing has started. This paper describes the LLRF system under consideration.

INTRODUCTION

In the summer 2013 the LCLS-II project made the decision to build a superconducting electron linac in the first 10 sections of the SLAC tunnel. The new linac is using a TESLA-ILC 1.3 GHz style cryomodule similar to the ones being produced for the European X-FEL. The primary difference being that these cryomodules must support cw operation. The linac consists of an RF gun, buncher cavity, 35 eight cavity cryomodules and two eight cavity 3.9 GHz cryomodules for harmonic linearization. The linac will support cw beam currents up to 100 μA.

The 1.3 GHz cavities are optimized to support 16 MV/m gradients. The loaded Q is relatively high 4 x 10^7, implying a cavity bandwidth of 32 Hz. The Q_L can be adjusted through the coaxial coupler if further optimization is needed. Originally the project had chosen to power multiple cavities off of one large klystron using vector sum control. As the design progressed, the project made the decision to power and control each cavity individually. Therefore each cavity is powered by a 3.8 kW solid state amplifier (SSA). Microphonic detuning is expected to be a maximum of 10 Hz peak detuning (1.5 Hz rms.).

Cavity resonance control is provided by both a slow stepper motor and a fast piezo tuner. Care must be taken in operating both tuners because they are within the insulating vacuum of the cryomodule. For this reason the temperature of the stepper motor is continuously monitored. There are four redundant piezos for each cavity and they are configured to be driven two at a time. The cavity can have up to three of the piezos fail and still be operational.

Cavity field control is specified to be 0.01% and 0.01° for time periods faster than 1 Hz. For time slower than 1 Hz the accelerator must rely on beam based feedback to maintain the proper beam parameters (energy spread and shape). In addition the linac is segmented into four sections each with different beam-phase relationships. Figure 1 shows the linac and these segments. For these slower times phase and amplitude control is greatly relaxed to the 5-10% and 5-10° levels [1].

LLRF CONCEPTUAL DESIGN

The design is being developed collaboratively between LBNL, FNAL, SLAC and JLAB. The LLRF design builds upon recent design experiences at those laboratories [2, 3, 4]. Figure 2 shows a block diagram of the conceptual LLRF design. Not shown is the second RF station controlling the two other cavities. The layout is designed around the SLAC gallery to cryomodule foot print that the project has settled on; four SSA's/tunnel penetration. Given that footprint the LLRF system for each cryomodule is divided between two penetrations. Four cavities are powered and controlled for each penetration. LLRF control is split between a precision receiver chassis (PRC) which processes four cavity signals and the RF station that processes the forward and reverse power and provides the drive signal to the SSA. Each RF station controls two cavities. For economy and maintainability RF, IF and FPGA hardware are shared between the PRC and the RF stations.

Abstract

Multi-color Free-electron Lasers (FELs) have been developed on linac based FELs over the past two decades. On the storage ring, the optical klystron (OK) FEL in its early days was demonstrated to produce lasing at two adjacent wavelengths with their spectral separation limited by the bandwidth of single wiggler radiation. Here, we report a systematic experimental study on the two-color operation at the Duke FEL facility, the first experimental demonstration of a tunable two-color harmonic FEL operation of a storage ring based FEL. We demonstrate a simultaneous generation of two FEL wavelengths, one in infrared (IR) and the other in ultraviolet (UV) with a harmonic relationship. The experimental results show a good performance of the two-color FEL operation in terms of two-color wavelength tunability, power tunability and power stability.

INTRODUCTION

Since the theoretical prediction and the first experimental demonstration by John Madey in 1970s [1,2], free-electron lasers (FELs) have seen great development over the past few decades and have become increasingly attractive light sources to several scientific research fronts. A common FEL configuration requires an optical cavity to oscillate and amplify electron beam radiation and is thus called an oscillator FEL [3]. An oscillator FEL can be driven either by an electron storage ring or a linac. Oscillator FELs mainly operate in the spectral region from IR to UV. Since early 1990s, multi-color, especially two-color FEL operations have been frequently discussed and realized on several linac based FELs. The first two-color FEL operation was realized on CLIO [4], an oscillator FEL operating in the mid-infrared regime, where two FEL wavelengths were produced by the same electron beam and two undulators with different undulator strengths inside a single optical cavity. Two more linac based oscillator FELs reported their successful two-color operations later on [5,6]. Another FEL configuration, the so-called single-pass FEL, is mainly driven by linacs and do not use an optical cavity. In these FELs, FEL beam amplification is realized via the interaction between the electron beam and the radiation it emits [7,8] or an external laser [9,10] in a single pass. Single-pass FELs are the dominant coherent light sources in the vacuum UV (VUV) and x-ray regimes. Recently two-color operations have also been experimentally demonstrated on several single-pass FELs [11–15] in the short-wavelength spectral regions.

Unlike in a linac, an electron beam in a storage ring is recycled and participates in the FEL interaction repeatedly over many passes. Therefore, the physics challenges for the two-color operation of a storage-ring FEL include the control and management of two competing lasing processes and maintanance of simultaneous lasing at two wavelengths in multiple passes. In this article, we report a systematic experimental study on the two-color operation at the Duke FEL facility, the first experimental demonstration on the multi-color operation of a storage ring based FEL in both IR and UV, in which, a simultaneous generation of two FEL wavelengths (IR and UV) with a harmonic relationship has been realized. The experimental results illustrate a good performance of our two-color FEL operation in terms of two-color wavelength tunability, power tunability and power stability. In addition, the two-color FEL can serve as a photon source for the two-energy gamma-ray production via Compton backscattering at the High-Intensity γ-ray Source (HIGS) [16].

EXPERIMENTAL SETUP

The operation of the Duke FEL system can use a variety of wiggler configurations with four available electromagnetic wiggler magnets, two planar OK-4 wigglers and two helical OK-5 wigglers (see Fig. 1), which provides the possibility of operating two-color FEL using the same electron beam at a single beam energy. In the harmonic two-color FEL research, three wigglers as shown in Fig. 1 are powered up, including the upstream helical OK-5 wiggler (OK-5A) and two planar OK-4 wigglers (OK-4A and OK-4B) in the middle section. The downstream OK-5 wiggler (OK-5D) was disconnected. Upstream OK-5A wiggler is used to lase at the fundamental wavelength in IR, and two downstream OK-4 wigglers in the optical klystron configuration is tuned to lase at the second harmonic in UV. The lasing wavelengths are varied by changing the strength of the magnetic field in the OK-5 and OK-4 wigglers, respectively. Two bunchers, $B1$ between OK-5A and OK-4 wigglers and $B2$ sandwiched by two OK-4 wigglers, are used to provide fine tuning of the harmonic FEL lasing. The harmonic two-color FEL lasing is realized at the fundamental wavelength

DEVELOPMENT PLAN FOR PHYSICS APPLICATION SOFTWARE FOR FRIB DRIVER LINAC *

M. Ikegami, G. Shen, Facility for Rare Isotope Beams, Michigan State University, MI 48824, USA

Abstract

Facility for Rare Isotope Beams (FRIB) is a high-power heavy ion accelerator facility currently under construction at Michigan State University. We recently decided to adopt EPICS V4 for the architecture for commissioning application software development for FRIB linac. In this paper, we present our plan for the commissioning application development with its present status.

INTRODUCTION

Facility for Rare Isotope Beams (FRIB) is a high-power heavy ion accelerator facility currently under construction at Michigan State University under a cooperative agreement with the US DOE [1]. Its driver linac operates in CW mode and accelerates all stable ions to energies above 200 MeV/u with the beam power on target up to 400 kW. The linac has a folded layout as shown in Fig. 1, which consists of a front-end, three Linac Segments (LSs) connected with two Folding Segments (FSs), and Beam Delivery System (BDS) to deliver the accelerated beam to target. The linac is located in a tunnel underground with the exception of two ECR ion sources located on the ground level (not shown in Fig. 1). The beam is delivered to the linac tunnel through a vertical beam drop. LSs consist of two types of superconducting QWRs (Quarter Wave Resonators) with geometrical β of 0.041 and 0.085, and two types of superconducting HWRs (Half Wave Resonators) with geometrical β of 0.29 and 0.53. LS1, LS2, and LS3, respectively, have 14, 24, and 6 cryomodules. The total number of superconducting cavities is 332 including rebuncher cavities in FSs. The linac has four tuning beam dumps, BD FS-1a, BD FS-1b, BD FS-2, and BD BDS, as shown in Fig. 1.

FRIB driver linac is substantially larger both in scale and beam power than existing facilities of a similar kind, which poses significant challenges in realizing beam commissioning or initial tuning of operating parameters. Efficient commissioning is essential to minimize the risk of component damage by beam loss during the commissioning. Then, high level application software assisted by online model is essential to realize efficient commissioning. In addition, we expect frequent change of accelerated ion species to meet the request from users once user operation is started. Judging from the present operation cycle of coupled cyclotron facility in Michigan State University, we may change ion species once in a week or two. Then, swift retuning after switching ion species is essential to realize high beam availability. It will require physics application to support model based retuning. We present our plan to develop physics applications to serve these purposes in this paper while our present emphasis is put on those to support commissioning. We here define physics applications as high level application software for commissioning utilizing model. We also discuss our plan to develop software infrastructure to support those applications and their development in this paper. Our discussion here does not include simple OPIs (Operator Interfaces) to show and set values for PVs (Process Variables) which is supposed to support accelerator operation.

* Work supported by the U.S. Department of Energy Office of Science under Cooperative Agreement DE-SC0000661.

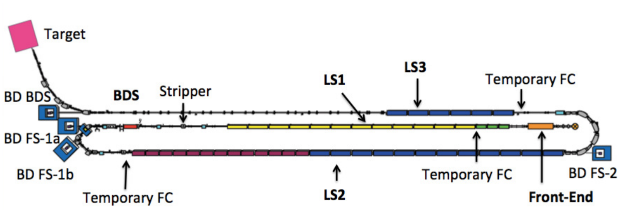

Figure 1: Schematic layout for FRIB driver linac.

ARCHITECTURE FOR PHYSICS APPLICATION SOFTWARE

While we have assumed OpenXAL [2] for the architecture for physics application software development, we recently decided to adopt EPICS V4 [3] for the architecture instead of OpenXAL. EPICS V4 has been rapidly developed to support recent commissioning of NSLS-II, and we can take advantage of the most up-to-date developments by adopting it. Its nobel design features include three-tier structure with middle layer services which enables efficient development of high level applications (See Fig. 2).

One of the advantages of OpenXAL is the integrated online model. However, OpenXAL model does not support features specific but essential to FRIB linac including multi-charge state acceleration, non-axial symmetric field of an RF cavity, etc. It necessitates significant extension of func-

ACCELERATOR ONLINE SIMULATION PLATFORM*

P. Chu#, Y. Zhang, MSU, East Lansing, MI 48824, USA

Abstract

A platform for accelerator online beam simulation has been established for various accelerators. This modelling platform supports multiple simulation codes for different sections of the complex machine which cannot be properly modelled with a single online simulation tool. Model data for the platform is stored in a relational database which is designed to accommodate most simulation data. The stored data is accessible with physics intuitive data API (Application Programming Interface). Presently, the platform is supporting Open XAL, MAD-X and IMPACT simulation codes. In addition to the model data storage and access, tools such as data comparison and simple graphing capability are also included in the platform.

INTRODUCTION

Modern accelerators with high precision requirements often rely on good online model for their machine tuning. However, each machine is likely having its own unique physics simulation issues which requires different modelling tools to deal with. For example, some lower energy machines are sensitive to space charge effects which need a good space charge code, while higher energy machines can be calculated without space charge. This model dependent machine simulation usually requires customized software code for each simulation tool. On the other hand, a properly designed platform with minimal overhead can provide a universal solution for various machines. Such a platform has been developed and prototyped.

One relatively easy way to achieve a platform for various modelling tools is shown in Fig. 1 as centre piece of the physics application architecture. The key components in this approach for the online simulation platform are a data container which can accommodate model data for different modelling tools, a set of common data access APIs for the data container, and data adapters between the data container and various modelling codes. For this model platform implementation, the model data container is a relational database, as shown in the middle of Fig. 1, which will be described in the next section. Besides the database itself, it is necessary to provide a set of data access API instead of tedious SQL (Sequential Query Language) statements for querying the saved model data. For each modelling tool, the input data should be generated programmatically so the model run can be automated, while the model output data should be parsed and saved into the database via convenient API. These tools are the model data adapters which will be explained in details later.

Additionally, both offline and online model data can utilize the same platform. Open XAL [1] as a physics application framework provides the interface to the control systems. Even fitted empirical machine model can be included in this platform.

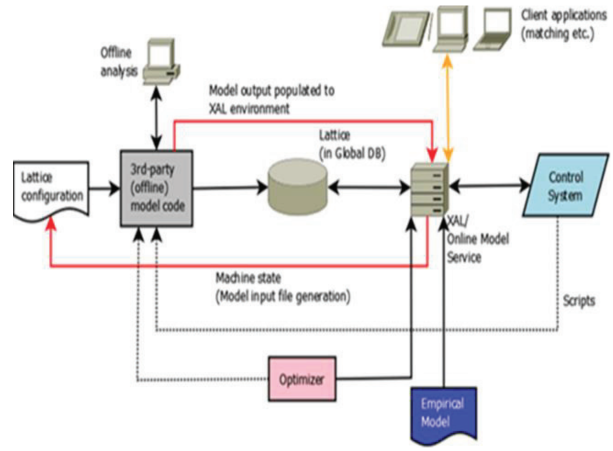

Figure 1: Online Model Platform schematic diagram.

MODEL DATABASE

The model database used for the data container is part of an accelerator database effort from the collaboration among FRIB, NSLS-II (National Synchrotron Light Source II) and ESS (European Spallation Source). The blue print for this database was from IRMIS-3 [2]. Originally there were two separate sub-schemas, one for lattice data including device settings and the other one for model run data. Because there is significant overlap between these two data areas, it is efficient to merge them into one schema to minimize data duplications. There are 20 tables in this database schema with a potential hook point to another part of the accelerator database, namely the Configuration Database which is for accelerator hardware data. The key feature for this database is to use "property name and value" pair to store most model data, i.e. the model parameter names are also part of data as opposed to the traditional way of defining the parameter names as database column labels. The detail of the Lattice and Model database tables can be found in the Lattice/Model Schema and API Release Note from the Open EPICS Model download area [3].

DATA ACCESS API

Besides the database itself, there is a set of data access APIs also developed as part of the Lattice and Model package. The software package is Java based which takes full advantage of the latest Object to Relational Mapping (ORM) technology, a mapping mechanism between

PHASE AND AMPLITUDE TUNING ALGORITHMS FOR THE FRIB SUPERCONDUCTING CAVITIES *

Yan Zhang#, Paul Chu, Zhengqi He
FRIB, Michigan State University, East Lansing, MI 48824, USA

Abstract

FRIB driver linac will deliver all heavy ion beams up to uranium for beam energy above 200 MeV/u and maximum beam power on fragment target 400 kW for nuclear physics researches. Phase and amplitude tuning of all the FRIB superconducting cavities – 332 of them in the linac, are important to low power beam commissioning as well as high power operations. Because of relatively low beam energy and high acceleration gradient, the particle velocity changes significantly in the cavity RF gaps and the beam bunch structure cannot be preserved perfectly in the further downstream beam diagnostics, beam longitudinal tuning algorithms are studied for different types of FRIB cavities and for various beam energies, which include acceleration cavities as well as re-buncher cavities.

INTRODUCTION

The FRIB, Facility for Rare Isotope Beams, is currently under construction on the campus of MSU, Michigan State University. The project is funded by the US Department of Energy Office of Science, MSU, and the State of Michigan. The total budget of the project is about 730 million dollars, and it will be completed in 2022 [1].

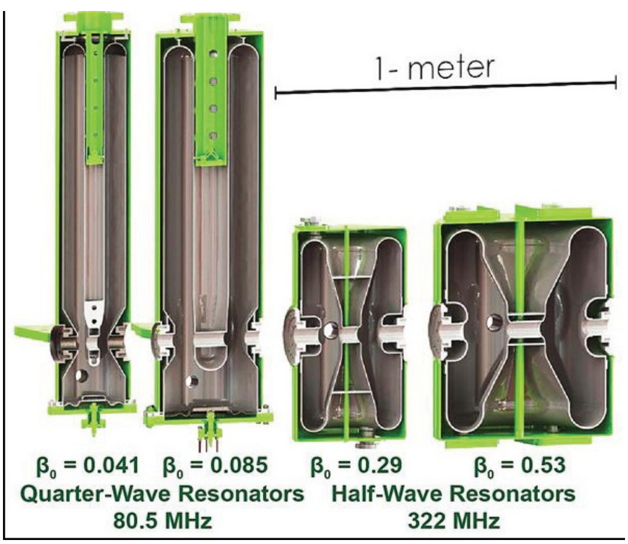

Figure 1: The FRIB cavities: beta 0.041 and 0.085 QWRs, 80.5 MHz; beta 0.29 and 0.53 HWRs, 322 MHz.

The FRIB driver linac is a state-of-the-art high power CW linac, and it includes 4 different types of SRF cavities as shown in Figure 1. Two types of quarter wave resonators (QWR) accelerate beams from 0.5 to 20 MeV/u, and then two types of half wave resonators (HWR) accelerate beams to above 200 MeV/u [2]. Because the acceleration gradient of the FRIB cavities goes up to 8 MV/m and the beam velocity increases from beta about 0.03 to 0.6 through the driver linac, the maximum velocity change in a single low beta cavity for a 2-pi phase scan can be above 10%, and the beam bunch structure may only survive a few meters downstream of the cryomodule, tuning of the cavity phase and amplitude is very difficult compare with that of a high energy linac. In this paper, SRF cavity phase and amplitude tuning algorithms are studied.

TUNING OF THE HWR CAVITY

In a RF linac for proton beam or heavy ion beams, Delta-T [3], and phase scan signature matching [4] techniques are widely applied to tune cavity phase and amplitude in which beam position/phase monitor (BPM) pairs are utilized to measure the absolute beam phase while scanning the cavity phase and amplitude; the synchronous phase as well as the acceleration gradient of the cavity can then be precisely determined by signature matching of the BPMs' time-of-flight (TOF) measurements against the RF cavity model. In this paper, we mainly focus on the applications of phase scan signature matching techniques.

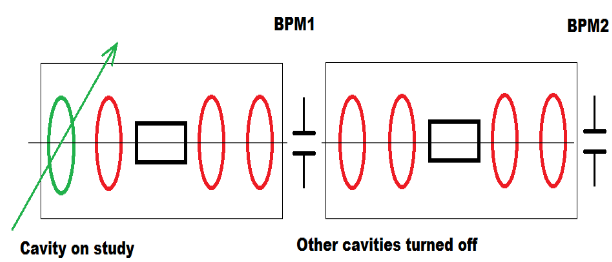

Figure 2: Schematic configuration of cavity phase scan

Figure 2 shows a schematic configuration of the cavity phase scan measurements. A pair of BPMs is downstream of the RF cavity on study, with all other cavities between the BPMs and the scanning cavity turned off, a 2-pi phase scan of the cavity is performed and the beam phase is recorded with the BPM pair. Because the beam current is low compare with that of a pulsed SRF linac such as the SNS, beam loading induced RF fields in the off cavities downstream may not significantly affect the measurements which is different to the SNS linac [5].

In the studies, IMPACT [6] is used for generation of the beam absolute phases exactly at the locations of the BPM pair. Then a thin-lens model of the RF cavity is applied:

TRANSVERSE MATCHING OF HORIZONTAL-VERTICAL COUPLED BEAMS FOR THE FRIB LINAC *

Yan Zhang #, Paul Chu, Zhengqi He, Steve Lund, Dylan Maxwell
FRIB, Michigan State University, East Lansing, MI 48824, USA

Abstract

FRIB driver linac will deliver all heavy ion beams up to uranium with energy above 200 MeV/u and maximum beam power on fragment target 400 kW. Strong horizontal-vertical coupling exists in the linac since superconducting solenoids are installed to focus multi charge state beams. Further, the low beta SRF cavities have raised quadrupole field components, and the combined effects make beam transverse matching challenging. In this paper, we study transverse matching of horizontal-vertical coupled beams based on beam profile measurements with multiple wire scanners. Issues such as the initial beam conditions fit with coupling not unique, and errors of beam diagnostics and magnets introduce further complications are addressed. Nonetheless, the simulation studies show that satisfactory transverse matching can be achieved with proper tuning.

INTRODUCTION

The FRIB, Facility for Rare Isotope Beams, is currently under construction on the campus of MSU, Michigan State University. The project is funded by the US Department of Energy Office of Science, MSU, and the State of Michigan. The total budget of the project is about 730 million dollars, and it will be completed in 2022 [1].

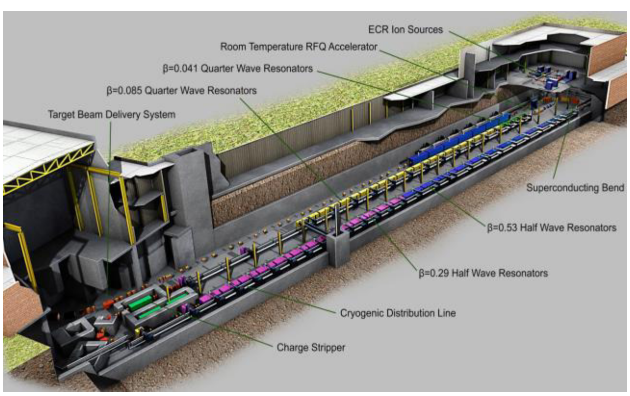

Figure 1: Layout of the FRIB driver linac.

The major accelerator system of the facility is a SRF continue-wave (CW) linac, the FRIB driver linac, which consists of a front end, three linac segments (LS), two 180° achromatic isochronous folding segments that connect the three LS, a liquid lithium charge stripper for more efficient accelerations of high power heavy ion beams, and a beam deliver system which transport the primary beams onto the fragment target for production of rare isotopes for nuclear physics research. The FRIB drive linac will be installed underground about 10 meters deep on the campus of MSU. Figure 1 shows the layout of the driver linac [2]. To reach the design beam power for the heaviest ions, multi charge beams are accelerated simultaneously in the linac: in the design, two charge states in LS1, and up to 5 charge states in LS2 and LS3. In the linac, superconducting solenoids are used for transverse beam focusing.

Because the injection beam is generated within a strong magnetic field from an ECR ion source [3], the beam distribution has strong correlation. Since generally beams emerging from ECR ion sources are not axisymmetric, the ion particles are born with x-y coupling. In addition, beam asymmetries further develop due to dispersions in bending magnets of the folded linac lattice. Even in the solenoid lattice of the straight linac segment, significant dipole and quadrupole components within the quarter wave resonators (QWRs) impact on the beam acceleration and transport, particularly at low energy, usually the beam is significantly deviated from axisymmetric [4]. Due to these effects, for transverse matching of the FRIB linac, we have to deal with a strongly coupled beam which is not axisymmetric.

PARAMTERS OF X-Y COUPLED BEAM

To describe a horizontal-vertical (x-y) coupled beam, second order moments of 4D beam matrix are applied:

$$\sigma = \begin{pmatrix} \langle \boldsymbol{xx} \rangle & \langle \boldsymbol{xx'} \rangle & \langle xy \rangle & \langle xy' \rangle \\ \langle \boldsymbol{xx'} \rangle & \langle \boldsymbol{x'x'} \rangle & \langle x'y \rangle & \langle x'y' \rangle \\ \langle xy \rangle & \langle x'y \rangle & \langle \boldsymbol{yy} \rangle & \langle \boldsymbol{yy'} \rangle \\ \langle xy' \rangle & \langle x'y' \rangle & \langle \boldsymbol{yy'} \rangle & \langle \boldsymbol{y'y'} \rangle \end{pmatrix} \tag{1}$$

Because of symmetry, there are 10 independent variables in the matrix. Two parameterizations are often utilized to deal with linear coupling: Edwards-Teng [5] and Ripken [6]. Implements of these two parameterizations can be found in, e.g. MAD-X [7] and Elegant [8]. Relationships between the two methods are analysed by Lebedev and Bogacz [9]. We use Ripken's parameterization method.

The 10 parameters chosen are: 4 alpha functions, 4 beta functions, and 2 emittances (β_{1x}, β_{1y}, β_{2x}, β_{2y}, α_{1x}, α_{1y}, α_{2x}, α_{2y}, ε_1, ε_2). Additionally, for beam envelop solution 2 phase advances (ν_1, ν_2) are needed [9]. The phase advances can be derived from these alpha and beta functions. Measurable beam rms sizes along x, y, and at 45° diagonal (d) are [9]:

$$\begin{aligned} \sigma_x &= \sqrt{\varepsilon_1\beta_{1x} + \varepsilon_2\beta_{2x}} \\ \sigma_y &= \sqrt{\varepsilon_1\beta_{1y} + \varepsilon_2\beta_{2y}} \\ \sigma_d &= \frac{\sqrt{\sigma_x{}^2 + \sigma_y{}^2 + 2\delta\cdot\sigma_x\sigma_y}}{\sqrt{2}} \end{aligned} \tag{2}$$

where, $\delta = \dfrac{\sqrt{\beta_{1x}\beta_{1y}}\,\varepsilon_1 \cos\nu_1 + \sqrt{\beta_{2x}\beta_{2y}}\,\varepsilon_2 \cos\nu_2}{\sigma_x\sigma_y}$

OPEN XAL CONTROL ROOM EXPERIENCE*

P. Chu#, D. Maxwell, Y. Zhang, MSU, East Lansing, MI 48824, USA
C.K. Allen, T. Pelaia, A.P. Shishlo, ORNL, Oak Ridge, TN 37831, USA

Abstract

This paper reports the control room experience, lessons learned, and quick deployment approach for the Open XAL application environment. Open XAL is a java-based framework for building high-level accelerator applications, it is a major revision of the XAL framework which was developed at the Spallation Neutron Source (SNS). Open XAL is site neutral and may be deployed at multiple accelerator facilities. Currently, Open XAL is installed at SNS and at the Re-Accelerator facility of Michigan State University. At SNS we are in the final process of replacing the old XAL environment with Open XAL; we describe the upgrade process and our accelerator operations experience using Open XAL. At Michigan State University (MSU), Open XAL has been tested during a cryomodule commissioning and results will be shown.

INTRODUCTION

The XAL [1] based applications have been successfully applied to SNS commissioning and early operation. Open XAL [2], on the other hand, is the updated version of XAL with international collaboration effort. Besides any common software practice, it is particularly important for software usability and customer satisfaction, especially for a new version of an already-successful software. Control room tests for Open XAL also can uncover issues which cannot be found with any offline tests. Unique challenges such as co-existence of operation for XAL and the new Open XAL applications are described below. New applications based on the Open XAL library are also demonstrated.

SNS CONTROL ROOM EXPERIENCE

Given that SNS is fully operational, it provides both challenges and opportunities for migrating from the mature XAL platform to the new Open XAL platform. The primary opportunity is to verify the code in a real operational environment while the primary risk is failure of the software affecting machine performance for production. To mitigate this risk as well as to facilitate software verification, we have chosen to deploy both XAL and Open XAL side by side which itself presents a challenge.

Following the summer of 2014 maintenance period, we have positioned Open XAL as the default accelerator physics toolset, and the old XAL code has been frozen and kept as a fallback and a benchmark source. All new applications and scripts are written against Open XAL.

XAL and Open XAL Coexistence

Running Open XAL alongside of XAL presents several challenges due to requirements and incompatibilities. XAL was built to run against Java 6, while Open XAL was built against Java 7. Due to a performance issue discovered in Java 7, it is not feasible to run XAL under Java 7. To support Java 6 for XAL and Java 7 for Open XAL, separate launch environments for XAL and Open XAL were configured using BASH scripts.

Services presented a challenge since XAL uses XML-RPC and Open XAL uses JSON-RPC over WebSockets. Services and their associated clients must both be running on the same software platform (either XAL or Open XAL) to communicate with each other. A service such as the PV Logger which both logs continuously and on demand from a client creates a problem since both XAL and Open XAL clients must continue to work and be able to request the PV Logger to log on demand. To address this issue, the PV Logger service was modified to allow an optional on-demand-only mode. The Open XAL variant is configured to log both on demand and continuously (normal mode) while the XAL variant logs just on demand to support XAL client requests without generating duplicate logs.

Both XAL and Open XAL can read and write the same documents, but the accelerator optics input is different due to a new format for the online model configuration in Open XAL and ongoing device changes in Open XAL. Since it is common for documents to reference the associated accelerator optics, we needed to address this problem of a user opening a document referencing an XAL or Open XAL accelerator optics in an application running under the wrong platform. To address this issue, the Open XAL optics file includes a new version attribute which is set to 2.0 and the absence of this version or version 1.0 implies XAL. Both XAL and Open XAL code was modified to verify the accelerator optics version, alert the user and load the compatible optics file.

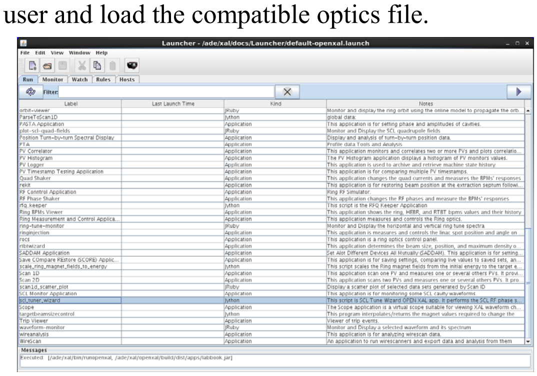

Figure 1: Open XAL Application Launcher.

With these changes XAL and Open XAL can coexist without issue and both versions can open documents

INITIAL EXPERIMENTAL RESULTS OF A MACHINE LEARNING-BASED TEMPERATURE CONTROL SYSTEM FOR AN RF GUN

A.L. Edelen#, S.G. Biedron, S.V. Milton, Colorado State University, Fort Collins, CO, USA
B.E. Chase, D.J. Crawford, N. Eddy, D. Edstrom Jr., E.R. Harms, J. Ruan, J.K. Santucci, Fermi National Accelerator Laboratory*, Batavia, IL, USA
P. Stabile, ADAM, Geneva, Switzerland

Abstract

Colorado State University (CSU) and Fermi National Accelerator Laboratory (Fermilab) have been developing a control system to regulate the resonant frequency of an RF electron gun. As part of this effort, we present initial test results for a benchmark temperature controller that combines a machine learning-based model and a predictive control algorithm. This is part of an on-going effort to develop adaptive, machine learning-based tools specifically to address control challenges found in particle accelerator systems.

INTRODUCTION

The electron gun at the advanced superconducting test accelerator [1-3] is a 1½ cell normal-conducting copper RF photoinjector operating at 1.3 GHz. It is water-cooled and shows a 23-kHz shift in resonant frequency per °C change in cavity temperature. Thus, establishing satisfactory control of the water temperature at the cavity entrance is the first step toward ensuring the gun is kept at the proper resonant frequency. Existing requirements state that this water temperature should be regulated to within ±0.02°C [2]. This regulation loop can then be nested within another control algorithm that determines what the water temperature needs to be in order to either a) directly minimize the detuning or b) achieve an operator-specified cavity temperature set point. As an intermediate result, this discussion considers the latter case. This also facilitates comparison with the existing controller.

Water System Overview

A simplified schematic of the water system is given in Fig. 1. A detailed description is given in Ref. [4]. The two controllable variables are 1) the flow control valve setting and 2) the heater power setting. For this particular system there are several control challenges:

- Due to water transport and thermal time constants, long time delays exist in the system responses (~10s from the valve to T02, ~30s from T02 to TIN, ~20s from TIN to TCAV, and ~60s from TOUT to T06).
- Without compensation, any change in the temperature of the water exiting the gun (either due to an increase in waste heat from the gun or a change in the temperature of the water entering the gun) will circulate back into the mixing chamber and have a secondary impact on the cavity temperature.
- There are fluctuations in the low conductivity water (LCW) supply temperature. While it is nominally regulated to within ±0.5°C, larger spikes can occur.

Due to the TCAV sensor location and the cavity geometry, the temperature recorded will be higher than the cavity wall temperature under RF power. Thus, for resonance control using operator-specified TCAV set points, it is important to note that the set point required to maintain the proper resonant frequency will increase with increasing average RF power.

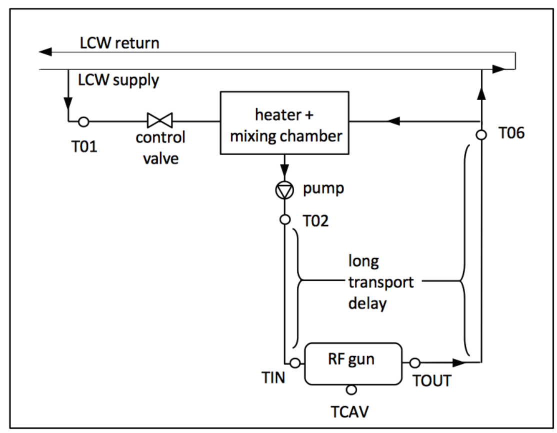

Figure 1: Layout of the water system and relevant instrumentation. T01, T02, TIN, TCAV, TOUT, and T06 are temperature sensors.

Existing Controller

Presently, the cavity temperature is being regulated by a feedforward/PI controller developed at Fermilab that adjusts the valve setting such that a TCAV set point is reached. An older version of the controller is described in [4], and a recent response to a 1-°C step change in the set point is shown in Fig. 2. This is under no RF power.

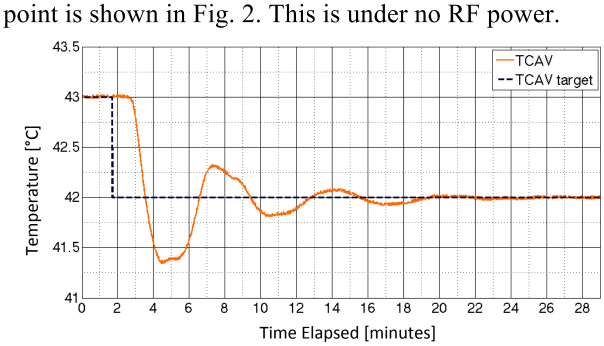

Figure 2: A 1-°C step change under the existing PI controller. The oscillations are due to water recirculation.

ELECTRON BOMBARDMENT OF ZnTe EO BUNCH CHARGE DETECTOR FOR SIGNAL LIFETIME STUDIES IN RADIATION ENVIRONMENT

J. Williams, S. Biedron, S. Milton CSU, Fort Collins, CO 80523, USA
S. Benson, S. Zhang, JLab, Newport News, VA 23606, USA

Abstract

Electro-optic(EO) detection of bunch charge distribution utilizing the nonlinear Pockel's and Kerr effect of materials has been implemented at various facilities as a method of passive detection for beam preservation throughout characterization[1-12]. Most commonly, the inorganic II-VI material ZnTe is employed due to its strong Pockel's EO effect and relatively high temporal resolution (~90 fs)[2]. Despite early exploration of radiation damage on ZnTe in exploration of semi-conductor materials in the 1970's, full characterization of EO response over radiation exposure lifetime has yet to be performed. The following paper presents a technique for ZnTe crystal characterization studies throughout radiation exposure at various energies and dosages by analyzing the changes in index of refraction including bulk uniformity, and THz signal response changes.

INTRODUCTION

The development of non-invasive charge distribution detectors based on the electro-optic properties of materials has seen various implementations at electron accelerators [1-4], and particularly in free-electron laser facilities. Though there are various electro-optic detector arrangements that range in method of data encoding and measurement, the typical electro-optic bunch detector is arranged to measure the passing profile of the electric field of relativistic electron bunches by probing the polarization shift in the electro-optic material with a synched laser. This polarization shift arises out of the electro-optic effect induced in a particular material (e. g. ZnTe, GaP, DAST, etc) by the strong electric field of the passing bunches. These EO-materials have a high 1st order non-linear coefficient, resulting in an index of refraction anisotropy that is linearly proportional to the applied field.

In contrast to the previously referenced facilities which employ EO detectors, the JLab and CSU facilities operate at a higher average current. It is suspected that this higher average current environment may present a greater hazard to the crystals. Studies that look into damage induced by either the probing laser beam or radiation environment seen by the materials within the accelerator vacuum are limited [5] and thus so is a direct correlation between detector signal and crystalline lattice defects induced while in operation. In order to develop a thorough understanding of signal properties throughout an EO material's lifetime, studies of material lattice properties (index of refraction, electro-optic coefficient, etc) before and after bombardment by electrons of various energies and at varying doses is laid out in this paper.

METHODS

It is planned that a picture of the material properties throughout its lifetime within an accelerator environment can be simulated through exposure of the materials to electron beams of various energies (2-16 MeV) at varying doses. The exposed materials will be characterized before and after exposure using an assortment of optic analysis tools to get a thorough picture of the complex index of refraction, electro-optic coefficient, and any other perturbations of the original material properties. This information will help develop an accurate picture of material response throughout its lifetime and help to deconvolve signal error arising from defects within the material itself or other sources.

Exposure Procedure

Exposure is planned on an operational cancer therapy machine with available electron beam energies between 2-16 MeV and various dosing rates. The crystals will be placed at a proper distance and covered by a suitable amount of material to deposit the beams' energy at the desired location within the crystals.

As different defects may arise at different energies and intensities, a different crystal sample will be exposed for each electron beam energy. After each dosing, optical characterization of the materials will help paint a picture of material properties over lifetime within a radiation environment.

Material Characterization

Prior to exposing these materials, a complete picture of material optical properties will be assessed using an assortment of optical diagnostics. The complex index of refraction, its homogeneity throughout the material, absorption and luminescence spectra, and electro-optic response are to be measured using an ellipsometer, Mach-Zehnder interferometer, absorption and luminescence spectrometers, and a THz-kit, respectively. The purpose and data produced by the various devices is outlined below:

- ***Ellipsometer*** -Produces a map of the complex index of refraction for the materials over a range of wavelengths (200-2000nm). Both transmission and reflection geometries for both faces is planned. Changes in the complex index of refraction may be

LOW EMITTANCE TUNING WITH A WITNESS BUNCH *

D. Rubin, R. Meller, J. Shanks
CLASSE, Ithaca, NY 14850

Abstract

Electron positron damping rings and colliders will require frequent tuning to maintain ultra-low vertical emittance. Emittance tuning begins with precision beam based measurement of lattice errors (orbit, transverse coupling, and dispersion) followed by compensation with corrector magnets. Traditional techniques for measuring lattice errors are incompatible with simultaneous operation of the storage ring as light source or damping ring. Dedicated machine time is required. The gated tune tracker (the device that drives the beam at the normal mode frequencies) and the bunch-by-bunch, turn-by-turn beam position monitor system developed at CESR are integrated to allow synchronous detection of phase. The system is capable of measuring lattice errors during routine operation. A single bunch at the end of a train of arbitrary length, is designated as the witness. The witness bunch alone is resonantly excited, and the phase and amplitude of the witness is measured at each of the 100 beam position monitors. Lattice errors are extracted from the measurements. Corrections are then applied. The emittance of all of the bunches in the train is measured and the effectiveness of the correction procedure demonstrated.

INTRODUCTION

Ultra-low vertical emittance is essential to achieve high luminosity in electron/positron colliders. In a linear collider, the sources of the low emittance beams are the damping rings. The vertical emittance specification for the International Linear Collider is 2pm-rad (at 5GeV) [1]. In circular colliders, the equilibrium emittance of the electron and positron storage rings likewise determines the luminosity. In SuperKEKB the vertical emittance target is 1.5pm-rad (7GeV) [2].

The principle source of vertical emittance in collider damping rings is misalignment of the guide field magnets. Transverse coupling is generated by tilted quadrupoles, and vertical dispersion by tilted dipoles and displaced quadrupoles. Low emittance tuning is the procedure to minimize the effects of the misalignments. The sources of dispersion and coupling are determined with beam based measurements. Corrector magnets are then deployed to compensate those sources. The emittance targets for both ILC and SuperKEKB have been achieved in storage rings (mostly light sources) with emittance tuning [3] [4].

Traditional emittance tuning procedures require dedicated machine time for the beam based measurements. Instrumentation has been developed at CESR for beam based measurements based on a single witness bunch, and thus allow continuous monitoring of coupling, betatron phase advance, dispersion, and orbit during normal operation. Lattice parameters are measured and corrector strengths adjusted without interruption. The witness bunch (perhaps the bunch at the end of a train) is resonantly excited at horizontal, vertical and, in principle, longitudinal normal mode frequencies, and the turn by turn position of the bunch measured at each of the 100 beam position monitors (BPMs) in the storage ring. The phase and amplitude of the response at the resonant frequencies characterizes the lattice functions.

BEAM BASED MEASUREMENT OF LATTICE PARAMETERS

The lattice properties are determined by measuring the linear mapping (transfer function) between BPMs. The mapping is extracted from measurements of a large number of non-degenerate trajectories. In the orbit response method (ORM) [5] [6], the distinct trajectories are generated by varying the strength of horizontal and vertical dipole correctors to create a matrix of position versus corrector. Typically there are many more measurements than BPMs and the system is overconstrained. The matrix is inverted by singular value decomposition to yield transfer functions. The ORM method is very powerful and can provide information about the calibration of the dipole correctors and beam position monitors as well as the linear transfer function from one BPM to the next. However, the measurements are incompatible with normal operation. Dedicated machine time is needed to make the orbit measurements. The measurements can be time consuming, as each steering must be varied sequentially and orbits collected at each step. Finally, the measurement time will scale with the circumference (or at least the number of beam position monitors and corrector magnets) of the ring.

In a storage ring equipped with BPMs capable of turn-by-turn position measurements, the set of non-degnerate trajectories can be collected much more quickly. A bunch can be excited simultaneously at the three normal mode tunes (horizontal, vertical, and longitudinal) by fast kickers, with width less than the minimum bunch spacing. (Two tune trackers are presently implemented in CESR, thus limiting simultaneous measurement to two of the three planes.) In CESR the bunch-by-bunch feedback kickers are used to drive the beam. As long as the betatron and synchrotron tunes are non integer, each turn will provide a distinct trajectory and each is recorded by the BPMs. The linear mapping between BPMs is extracted from the trajectory data as before. The signal noise is reduced by filtering the data at the normal mode tunes. In particular, an amplitude and phase is identified at each of the four BPM electrodes, for each of the

MICROWAVE MODELING FOR ELECTRON CLOUD DENSITY MEASUREMENTS AT CESRTA*

J.P. Sikora†, Y. Li, CLASSE, Ithaca, New York 14853 USA
S. De Santis, LBNL, Berkeley, California 94720 USA

Abstract

The electron cloud (EC) density in accelerator beam-pipe has been measured using resonant microwaves. The resonances are produced by changes in beam-pipe geometry that generate reflections and standing waves, with typical behavior being similar to a section of waveguide with shorted ends. The technique uses fact that the EC density will shift the resonant frequencies. In previous analysis, we have made the simplifying approximation that the standing waves are multiples of a half-wavelength and that the magnitude of the electric field is symmetric about the longitudinal center of the resonance. In this paper we show that some changes in beam-pipe geometry will result in asymmetric electric field magnitudes along the resonant length. When this is combined with an EC density that varies along this length, the magnitude of the frequency shift will be altered. We present our initial attempt to correct for this effect by modeling the existing beam-pipe using CST Microwave Studio® to obtain a more realistic electric field distribution. This correction is then applied to data taken with beam at several resonant frequencies. The measurements were made at the Cornell Electron Storage Ring (CESR), which has been reconfigured as a test accelerator (CESRTA) providing electron or positron beams ranging in energy from 2 to 5 GeV.

INTRODUCTION

The resonant microwave technique for measuring electron cloud (EC) density has been developed at Cornell over the past several years. Beam-pipe resonances are produced by microwave reflections – a common source being the longitudinal slots at the location of ion pumps, which interrupt the transverse currents of TE waves. The resonant response is obtained by coupling microwaves in/out of the beam-pipe using beam position monitor (BPM) buttons. The measurement technique uses the fact that the beam-pipe's natural frequency ω_0 will be shifted an amount $\Delta\omega$ by the presence of an electron cloud density n_e according to Eq. 1, where E_0 is the magnitude of the resonant electric field, e and m_e are the charge and mass of an electron, ε_0 is the vacuum permittivity and V the resonant volume.

$$\frac{\Delta\omega}{\omega_0} \approx \frac{e^2}{2\varepsilon_0 m_e \omega_0^2} \frac{\int_V n_e E_0^2 \, dV}{\int_V E_0^2 \, dV} \tag{1}$$

An outline of the technique is given in Ref. [1]. In that initial presentation, the simplifying assumption is made that the EC density n_e is uniform over the resonant volume. Equation 1 shows that under these conditions, the resonant field does not need to be known, since the integrals will cancel.

A model for the beam-pipe is a section of waveguide with its ends shorted. The resonant frequencies correspond to m half wavelengths with an envelope $E_0 sin[m\pi(z/L)]$, where m is an integer ≥ 1, z is the location along the beam-pipe and L is the length of the resonant section. This will have resonances at frequencies given by

$$f^2 = f_c^2 + (mc/2L)^2 \tag{2}$$

with f_c the waveguide cutoff frequency and c the speed of light. There is one location, 43E in CESR, where the measured response follows Eq. 2 reasonably well. At that location there is a set of BPM buttons between two ion pumps (with longitudinal slots) and no other changes in geometry. Using Eq. 2, the cutoff frequency f_c of the CESR aluminum beam-pipe extrusion was determined to be 1.8956 GHz. However elsewhere in the storage ring, the beam-pipe resonances do not match this series of frequencies very well. Figure 1 shows the physical layout at the location 15E in CESR, along with the beam-pipe response. The triangles at the top of the plot show the resonant frequencies expected based on the 1.8956 GHz cutoff frequency of the extrusion and the 2820 mm distance between the ion pumps. The larger dark triangle is the cutoff frequency f_c. Dotted lines on the plot connect the observed resonances with the frequencies expected with a shorted waveguide. The first resonance is well below the beam-pipe cutoff frequency.

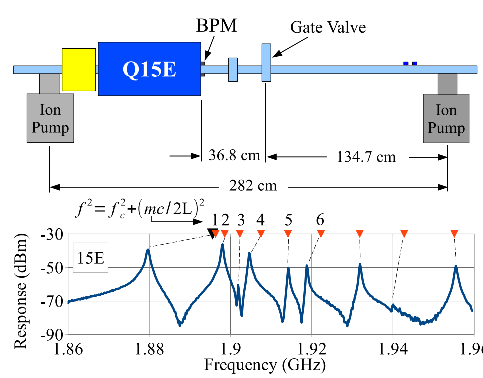

Figure 1: Sketch of the beam-pipe section at 15E along with its resonant response. Triangles show the predicted frequencies for a simple shorted waveguide. Dotted lines connect those frequencies with the measured response peaks.

ANALYSIS OF PRIMARY STRIPPER FOILS AT SNS BY AN ELECTRON BEAM FOIL TEST STAND

E.P. Barrowclough, C.S. Feigerle, University of Tennessee, Knoxville, TN 37996, U.S.A.
C.F. Luck, L.L. Wilson, R.W. Shaw, M.A. Plum, Oak Ridge National Laboratory, Oak Ridge, TN 37831, U.S.A.

Abstract

Diamond foils are used at the Spallation Neutron Source (SNS) as the primary strippers of hydride ions. A nanocrystalline diamond film, typically 17 x 45 mm with an aerial density of 350 µg/cm^2, is deposited on a corrugated silicon substrate using plasma-assisted chemical vapor deposition. After growth, 30 mm of the silicon substrate is etched away, leaving a freestanding diamond foil with a silicon handle that can be inserted into SNS for operation. An electron beam test facility was constructed to study stripper foil degradation and impact on foil lifetime. The electron beam capabilities include: current up to 5 mA, 0.300 mm^2 focused spot size, and rastering in the x- and y-directions. A 30 keV and 1.6 mA/mm^2 electron beam deposits the same power density on a diamond foil as a 1.4 MW SNS beam. Rastering of the electron beam exposes a similar area of the foil as SNS beams. Experiments were conducted using the foil test stand to study: foil flutter and lifetime; effects of corrugation patterns, aerial densities, foil crystallite size (micro vs. nano), and boron doping; temperature distributions and film emissivity; and conversion rate of nanocrystalline diamond into graphite.

BACKGROUND

Diamond stripper foils have been developed at Oak Ridge National Laboratory (ORNL) for use within the SNS since 2003 [1-2]. The foils are grown on a semiconductor grade (100) silicon wafer using plasma-assisted chemical vapor deposition, and include nanocrystalline diamond, microcrystalline diamond, and occasionally boron-doped nanocrystalline diamond. The design size and aerial density of the foils have varied greatly over the years, with the current size and aerial density being a 17 mm x 45 mm and 350 µg/cm^2. This aerial density corresponds to a diamond film of approximately 1.0 µm thick. Once the foils are grown, 30 mm of the silicon substrate is chemically etched away to leave a free-standing portion of diamond at the bottom of the foil that is 17 mm x 30 mm and a silicon handle at the top that is 17 mm x 15 mm. A variety of lithography patterns are implemented on the silicon growth surface that transfers into the conformal to help give the needed rigidity and flatness when the silicon substrate is etched away. The growth and processing of these diamond foils has been optimized and routinely produces high quality stripper foils for use within the SNS.

The current status of SNS is providing researchers with a pulsed beam of 0.94 GeV, 1.0 to 1.4 MW, at a pulse rate and width of 60 Hz/975 µs. In the past few years, several obstacles have delayed the progress of SNS to provide a constant design value of 1.4 MW. These obstacles are the result of growing pains of a decade old machine. Some examples that SNS employees have faced in recent months include multiple mercury target failures; water contamination in various portions of the linac; multiple components that have either failed completely or have limited operation; issues with foil brackets; and the rare foil failure. Despite these issues, SNS employees have been able to successfully diagnosis and resolve these problems.

In order to further develop the foil program at ORNL and meet the growing needs of SNS, a team of researchers from ORNL, SNS, and the University of Tennessee (UTK) formed the Foil Development Team (FDT) in 2001. This group consists of both highly skilled technicians in foil growth and development, experts in chemical vapor deposition, and experts in accelerator physics. The mission of this group is to design and develop foils for use in the SNS to maintain current operating conditions of 1.0 to 1.4 MW, along with developing foils for future SNS upgrades to 2.0 and 3.0 MW. One aspect of this team that is of particular interest to this work is developing and characterizing a variety of foils to determine how well the foils will perform under SNS operating conditions. This includes the use of an electron beam test stand to help determine how foils will perform under various thermal loads experienced in the SNS.

FOIL TEST STAND

Since the SNS started full operation in 2006, it has been desirable to provide high reliability the various users coming from around the world. Therefore it was difficult to experiment with the different foil composition and types that were being developed, and it severely limited the foil development program. In 2009 the FDT deemed it necessary to develop a table top test stand that would allow a more adaptable approach to testing foil properties than what could be done during normal operation at SNS. This test stand would allow a variety of foils to be examined, along with determining the various properties that influence the success of a foil within the SNS. Since having an accelerated H$^-$ beam was not feasible as a table top source, a source was required that would both meet the size restriction but still apply the same thermal load that the foils experience actual operation. Therefore it was calculated that a 30 keV beam could apply a high enough current density to simulate the thermal load of the SNS. This device became known as the Electron Beam SNS

ADVANTAGES TO AN ONLINE MULTI-PARTICLE BEAM DYNAMICS MODEL FOR HIGH-POWER PROTON LINACS*

L.J. Rybarcyk#, X. Pang and S.A. Baily, LANL, Los Alamos, NM 87545, USA

Abstract

High-power proton linacs like the 800-MeV LANSCE accelerator typically use a physics-based approach and online single-particle and envelope beam dynamics models to establish nominal set points for operation. However, these models are not good enough to enable immediate transition to high-power operation. Instead, some amount of empirical adjustment is necessary to achieve stable, low beam-loss operation. At Los Alamos, we have been developing a new online model, which employs multi-particle beam dynamics, as a tool for providing more information and insight to the operations staff, especially during this transition to high-power operations. This presentation will discuss some of the advantages and benefits of using this type of tool in the tune-up and operation of a high-power proton linac.

INTRODUCTION

Examples of high-power proton linear accelerators (linacs) range from the relatively compact yet powerful LEDA CW RFQ that once demonstrated 670 kW of beam at 6.7 MeV [1] to a more extensive system like the SNS pulsed linac that has recently provided over 1.2 MW of beam at 940 MeV [2]. At present, the 800-MeV linac at the Los Alamos Neutron Science Center (LANSCE) operates at 120 Hz and provides proton and H^- beam macro-pulses, with a combined power of over 100 kW, to several target stations in support of basic and applied research. However, one thing that these and other high power linacs have in common is the need to minimize beam losses and the resultant deleterious effects on the structure and to the operation.

A physics-based tune-up approach is generally used to establish operational set points of beam-line devices in order to simultaneously produce beams with the desired characteristics and low loss. This approach utilizes online single-particle and beam-envelope models, e.g. [3-5], that enable the accelerator operations staff to set beam centroids and rms widths to their desired trajectories and matched sizes, respectively. However, at many high-power facilities, the model-based tuning is not the final solution. In addition, some amount of empirical loss-based tuning is required to achieve loss-levels necessary for sustained high-power operation [6].

It is this shortcoming with the existing approach that has motivated us to pursue a new online multi-particle beam dynamics model for our linac. A multi-particle model brings a higher level of realism and accuracy to the process and should begin to enable operations staff to reach a more complete tune-up solution as well as monitor on-going performance. Previously, multi-particle simulations were confined to offline analysis due to computational limitations. This new model [7], however, combines well-established beam dynamics algorithms and high-performance GPU technology in a workstation-class computer with access to the accelerator set points via the control system to provide rapid results of the actual linac operation to personnel 24/7. This new model can be operated in continuous mode, where the results are constantly being updated as machine variables are modified, or as a script-based tool to analyze measurement results or carry out beam simulations studies. In this paper we will explore some of the advantages of this new approach.

MODEL ADVANTAGES

A multi-particle beam dynamics model has several advantages over existing online single-particle and envelope models currently used on proton linacs. Some of these are features that machine designers have benefited from for years. First, the multi-particle model is not limited to simple beam representations but can utilize more realistic beam distributions. Secondly, important emittance growth mechanisms are included in the model. Thirdly, beam losses can now be included in evaluating machine settings. Fourthly, virtual measurements provide feedback on the effect of set-point adjustments and tuning. These benefits are discussed below.

Realistic Beam Distributions

The use of multi-particle distributions in modeling is especially advantageous in high-power proton linacs where transverse and longitudinal tails can contribute to beam losses. For example, at LANSCE each beam species is accelerated up to 750 keV using Cockcroft-Walton (C - W) technology. Following each C-W is a low-energy beam transport (LEBT) that contains a number of elements including quadrupole magnets and a single-gap 201.25-MHz buncher cavity. Just upstream of the 201.25-MHz drift-tube linac (DTL) the two beam species (H^+, H^-) are merged into a common LEBT that contains four matching quads and another identical buncher cavity. Since each C-W produces DC beam within a macropulse, the two RF cavities are used to prebunch these beams and increase the longitudinal capture in the DTL. This prebunching results in significant tails on the beam distributions. Shown in Fig. 1. are the simulated H^+ beam phase space distributions at the end of the LEBT. The input beam to the simulation is a combination of a transverse 4-D hypersphere, generated with Twiss

ADAPTIVE ACCELERATOR TUNING *

Alexander Scheinker, LANL, Los Alamos, NM 87545, USA†

Abstract

A recently developed, model-independent feedback controller is presented, which is robust to measurement noise, and able to tune an arbitrary number of coupled parameters of an unknown system, simultaneously, based only on a user-defined cost function. Unlike genetic algorithms, which are a useful model-based tool for the optimization of a well known fixed system, the algorithm presented here is actually useful for implementation in hardware on actual machines as a feedback tuning and control loop, because it can compensate for the unknown time-varying disturbances/changes that all large machines experience. We present recent in-hardware experimental results obtained at the Los Alamos Neutron Science Center and at the Facility for Advanced Accelerator Tests (FACET), demonstrating the schemeÕs ability to simultaneously tune many parameters and its robustness to noise and system time-variation.

INTRODUCTION

Model-based schemes have been utilized for the design and optimization of particle accelerators, genetic algorithms (GA) in particular have become popular in recent years. When sufficient computer resources are available, lengthy GA searches have successfully found good starting points for machine designs by sampling a large parameter space. However, large complex machines are time-varying systems with time dependent, unpredictable disturbances and uncertainties including misalignments, thermal cycles, phase drifts, damage, and regions with limited beam measurements. Therefore, following a GA-based or any other model-based optimization approach, once an actual machine is constructed, many parameters have to be re-tuned, and re-tuned often as the system's characteristics drift with time.

When performing feedback on the beam or RF systems, there is a need for model-independent controllers which can handle the time-varying systems, especially for future accelerators such as MaRIE [1]. We present a model-independent feedback controller [2, 3], which is robust to measurement noise, and able to tune an arbitrary number of coupled parameters of an unknown system, simultaneously, based only on a user-defined cost function. The algorithm is especially useful for implementation in-hardware on actual machines as a feedback tuning and control loop, because it can compensate for the unknown time-varying disturbances/changes that all large machines experience.

OPTIMIZATION SCHEME

In an accelerator there are many important parameters

$$\mathbf{x}(t) = (x_1(t), \ldots, x_m(t)), \tag{1}$$

some of which are observable and others that can only be estimated or averaged, such as RMS beam width, various measures of emittance, beam current, etc... These evolve according to some complicated nonlinear, time-varying dynamics, such as

$$\frac{\partial \mathbf{x}(t)}{\partial t} = \mathbf{f}(\mathbf{x}(t), \mathbf{s}(t), \mathbf{p}(t), t), \tag{2}$$

where $\mathbf{f}(\mathbf{x}(t), \mathbf{s}(t), \mathbf{p}(t), t)$ is usually linearized or approximated in some other way so that the dynamics (2) can be numerically evaluated. In these dynamics there may be an arbitrary number of uncertain, uncontrollable, time-varying parameters

$$\mathbf{s}(t) = (s_1(t), \ldots, s_m(t)), \tag{3}$$

which include misaligned components, noise, disturbances, jitter, magnetic fields that depend on currents in an uncertain way due to hysteresis, and environmentally caused temperature variations which lead to phase drifts, to name a few, which makes the simulation of anything other than an estimate of of the actual system impossible. Also, there may be an arbitrary number of controlled parameters

$$\mathbf{p}(t) = (p_1(t), \ldots, p_n(t)), \tag{4}$$

including magnet current settings, phase and amplitude set points in RF systems, and control loop feedback gains, to name a few. The goal of the adaptive scheme presented here is the same as the goal of beam physicists and operators: the minimization of some chosen "cost" associated with accelerator performance such as the tuning of magnet and RF systems to minimize beam loss along the accelerator or to minimize the deviation of the final beam energy from a desired set point. The cost is some analytically unknown, but available for measurement function of the many controlled and uncontrolled parameters and states of the system, $C(\mathbf{x}(t), \mathbf{s}(t), \mathbf{p}(t), t)$. In practice, the actual cost, C, is rarely available for measurement, rather a noise-corrupted version $\hat{C} = C + n(t)$ is what arrives at the control system. The adaptive scheme is incredibly robust to random noise, the parameter tuning dynamics are

$$\frac{\partial p_i}{\partial t} = \sqrt{\alpha\omega_i} \sin\left(\omega_i t + k\left[\underbrace{C(\mathbf{x}, \mathbf{s}, \mathbf{p}, t) + n(t)}_{\hat{C}(\mathbf{x}, \mathbf{s}, \mathbf{p}, t)}\right]\right), \tag{5}$$

where $\omega_i \neq \omega_j$ for all $i \neq j$, which for large $\omega_i \gg 1$, results in average parameter dynamics

$$\dot{\bar{p}}_i = -\frac{k\alpha}{2}\frac{\partial C(\mathbf{x}, \mathbf{s}, \bar{\mathbf{p}}, t)}{\partial \bar{p}_i}, \tag{6}$$

a gradient descent which minimizes the *actual* C, not $\hat{C}$, as long as the noise is random, a result that is both mathematically proven and demonstrated in hardware [3, 5]. This

CHARACTERIZATION OF VISIBLE SYNCHROTRON RADIATION POLARIZATION AT SPEAR3*

Jeff Corbett and Andrew Kiss, SLAC National Accelerator Laboratory, Menlo Park, USA
Chunlei Li, East China University of Science and Technology, Shanghai, China
Mark Boland, Synchrotron Light Source Australia, Clayton, Australia

Abstract

Schwinger's equations predict the angular- and spectral distribution of synchrotron radiation across a wide band of the electromagnetic spectrum. Using a visible-light diagnostic beam line, it is possible to characterize the electric field polarization state as a function of vertical observation angle and compare with theory. Complications include accounting for σ- and π-mode transmission factors at mirror surfaces and precise alignment of the polarizing optics with the principle beam axes. The Stokes parameters are measured and beam polarization ellipse reported.

INTRODUCTION

Synchrotron radiation has both partially-coherent and fully polarized electromagnetic field properties, each used for a wide range of scientific research. With the advent of high-power, short-pulse free-electron lasers, applications depending on the spatial beam coherence are increasing at a rapid rate. Similarly elliptically polarized x-rays have become an increasingly powerful tool to study magnetic dichroism and chirality at both storage rings and FEL facilities. At SPEAR3, a visible-light diagnostic beam line originally constructed to study transverse and longitudinal electron beam dynamics has recently been used to study both the transverse spatial coherence [1] and polarization state of the beam [2].

The polarization state can be characterized by measuring beam power transmitted through linear polarizing elements oriented at systematic angles with respect to the beam axis. In this way is it possible to obtain 'slice' measurements of the beam polarization ellipse which can be combined to concisely express the beam polarization state in terms of the Stokes parameters [3,4]. Using the visible SR component, polarization measurements can be made with conventional optical elements in a relatively straightforward manner.

To cross-check the measurements it is also possible to calculate the Stokes parameters and corresponding beam polarization ellipse using Schwinger's equations for the SR field [5]. The 'classical' Schwinger equations express the electric field in terms of both radiation frequency and, conveniently, vertical observation angle. Hence it is possible to both measure and calculate the SR polarization state in the visible light regime as a function of vertical observation angle.

SPEAR3 DIAGNOSTIC BEAM LINE

The visible-light diagnostic beam line at SPEAR3 contains a horizontal 'cold finger' to block the on-axis hard x-ray beam followed by a rhodium-coated mirror to horizontally reflect the SR light down the beam line [6]. The cold finger intercepts ±0.6 mrad of the beam at the midplane and the remaining beam line apertures have

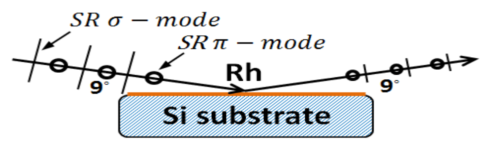

Figure 1: Visible light extraction mirror. Note *E*-field attenuation and relative phase shift upon reflection.

an acceptance of 3.5 mrad x 6 mrad. For measurements reported here only ±2.2 mrad was available in the vertical plane. As indicated in Fig. 1, the dipole-radiation SR beam hits the Rh mirror at a shallow angle of 9° causing attenuation and phase shift of the σ-mode (horizontal) and π-mode (vertical) visible light components.

For beam polarization measurements, we constructed a remote-controlled system with rotatable polarizer, 532nm bandpass filter (BP) and power meter all on a continuous-scan vertical stage [7]. An insertable quarter waveplate (QWP) shown in Fig. 2 is optically matched to the bandpass filter and used to determine beam helicity for Stokes parameter measurements [3, 4].

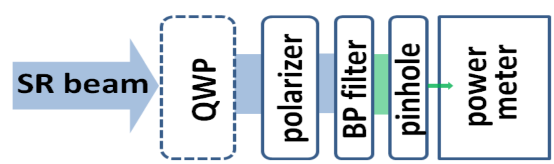

Figure 2: Stokes parameter measurement apparatus.

SR FIELD REPRESENTATION

The well-known Schwinger equations for synchrotron radiation express the SR radiation field in terms angular frequency ω and vertical emission angle $\psi^\dagger$ [5]

$$E_{x0} \triangleq \tilde{E}_\sigma(\omega,\psi) = C_0 K_{2/3}(\omega,\psi) \tag{1a}$$

$$E_{y0} \triangleq \tilde{E}_\pi(\omega,\psi) = C_0 \frac{-i\gamma\psi}{\sqrt{1+\gamma^2\psi^2}} K_{1/3}(\omega,\psi). \tag{1b}$$

where C_0 is a function of ω and ψ, γ is the electron beam Lorentz factor and K are modified Bessel functions.

†standard frequency and angle normalizations implied

INVESTIGATION OF CONTINUOUS SCAN METHODS FOR RAPID DATA ACQUISITION*

C. L. Li, East China University of Science and Technology, Shanghai 200237, China
A. M. Kiss#, SLAC National Accelerator Laboratory, Menlo Park, CA, 94025, USA
W. J. Zhang, University of Saskatchewan, Saskatoon S7N5A9, Canada

Abstract

It is common practice to perform spatially resolved X-ray data acquisition by automatically moving components to discrete locations and then measuring beam intensity with the system at rest. While effective, scanning in this manner can be time consuming, with motors needing to accelerate, move and decelerate at each location before recording data. Information between data points may be missed unless fine grid scans are performed, which accounts for a further increase of scan time. Recent advances in commercial hardware and software enables a continuous scan capability for a wide range of applications, which saves the start and end of step motors. To compare scanning performance, both step and continuous scan modes were examined using the SPEC command language with both commercial and in-house hardware. The advantages and limitations of each are discussed.

INTRODUCTION

Step scan data collection can be achieved by a motor moving with intermittent motion and the signal collected when the system is at rest. Several studies have been made with the step scan method to acquire data [1-4]. One advantage with this method is that high position precision can be achieved. It is also a direct and simple method to collect scan data. However, there are some disadvantages with the step scan method such as induced start/stop vibrations and an increase in data collection time.

Each data point during a step scan requires the detector to accelerate, move, and decelerate, causing vibrations. A settling time can be defined to allow vibrations to dampen but this will further increase the data collection time which is already increased by the need to start and stop the motors. For example, in a typical scan application a detector moves in angle from 0° to 60° with a step size of 0.01° so the data set contains 6,000 points. As acceleration and deceleration time is required to move the motor to each point, an extra 0.5 s must be allocated for each step of the scan [5]. An extra 3,000 s is therefore required to complete the scan. The extra time can be reduced if large step sizes are used during the experiment, but significant diffraction peaks may be missed. It is therefore desirable to minimize scan time while reducing vibrations in the system.

*Work supported by Department of Energy contract DE-AC02-76SF00515 and the China Scholarship Council.
andykiss@slac.stanford.edu

Continuous scanning on the other hand bypasses vibrational problems and reduces latency time. One technique that can benefit from a continuous scan is basic X-ray diffraction (XRD), often used to study the crystal structure of samples. A typical XRD experimental system is comprised of monochromatic X-rays, motion controller, a diffraction signal detector and a data processing system. The detector is moved along a path where the diffraction signal from the sample is distributed. The detector acquires an angle-dependent diffraction signal to analyse the electronic sample structure. In the past, several approaches to continuous scan measurements have been used for X-ray diffraction experiments [6-8].

This paper presents a new method for continuous scan measurements using SPEC as the command language with both commercial- and in-house motor controllers and detector read back electronics. The continuous scan mode is defined here as uninterrupted motor movement with continuous data acquisition. The motion of the detector can maintain a constant velocity or change velocity during the scan to account for changes in X-ray diffraction signal strength. As a result, vibrations in the system as well as total data acquisition time are reduced.

Abstract

We present the expanded system implementation and operational experience details for the "Demo" technology platform commissioned at the SPS in January 2015. The system has been expanded during the LS1 shutdown with added features. The upgraded system has enhanced performance and more robust synchronization to the beam and accelerator timing system. Central to the new features are 1 GHz bandwidth kickers and RF amplifiers (including associated equalizers) which allow excitation and control of higher modes within the 2 ns bunch. We highlight the expanded features, and present their details.

BACKGROUND

Following the success of the initial run of the CERN LHC, the LHC injector complex is being upgraded to provide higher intensity and brightness beams to enable the discovery of new physics. As part of the LHC Injectors Upgrade (LIU) project, the entire injector chain from Linac4 to the SPS is being upgraded [1]. One performance limitation in the SPS is the formation of transverse vertical intra-bunch instabilities due to electron cloud instability (ECI) and transverse mode coupled bunch instability (TMCI) effects. These effects limit the intensity of the beam injected into the LHC.

A collaborative research and development project to mitigate these intra-bunch instabilities involving simulation and modelling [2], hardware development and measurement efforts has been undertaken. One outcome of this work has been the development of a feedback control demonstration system. This demonstration system has provided encouraging results [3] in Machine Development (MD) studies at the SPS, undertaken during LHC Run1, just prior to Long Shutdown 1. The next step in the evolution of the demonstrator system is the upgrade of several key components.

OVERVIEW OF SYSTEM

The feedback demonstrator or demo system [4] consists of multiple components as shown in the diagram of Figure 1. Items targeted for upgrades are indicated here as well. Vertical beam displacement is sensed using a stripline BPM pickup structure and the Δ output of a hybrid is filtered, equalized and amplified by the analog front end. The analog signal is then digitized by the feedback processor, which is essentially a reconfigurable high speed digital signal processor. Sampling at 4GSa/s the system takes 16 samples across a single 4ns SPS injection bunch. We treat these 16 samples or slices independently and process each with a separate 16-tap FIR filter inside the processor. The FIR coefficients are the same for each slice. The filtered data is translated back into the analog domain by a 4GSa/s DAC. The converted analog signal is presented to the analog back end where it is filtered, equalized, amplified and split before being sent to the power amplifiers and finally to the kicker structure which applies a corrective field to the beam.

Additional components include the frequency multiplier which generates the 2GHz sample clock (both edges are used, giving 4GHz effectively) from the 200MHz SPS RF reference. And the excitation system which allows us to generate a perturbation signal onto the beam for driven motion studies. Finally, a set of adjustable delay lines are required to provide phase alignment of the timing of the beam arrival with the sampling operation at the pickup and the application of correction and excitation signals with beam in the kicker.

WORK TO DATE

The demo system platform in being upgraded in two phases as described in [5], [6]. Phase 1 upgrades include mitigation of ADC spectral lines driven by noise pickup and ground loops inside the feedback processor chassis. Improvements in the timing and synchronization of the reference and sampling clocks; and the migration of the excitation function to inside the feedback processor, allowing feedback and excitation signals to be summed digitally. Phase one upgrades have been completed, while phase 2 work is now underway. These include the expansion of processing beyond one bunch to handle 16 bunches. As well as the addition of an orbit offset compensation mechanism to dynamically remove the beam orbit offset, which limits the overall dynamic range of the system. Beyond these, some additional features and improvements have been and are being made to the feedback processor. Central to the effectiveness of the feedback system are the RF power amplifiers and kicker structure, which are also being upgraded.

UPGRADES

Feedback Processor

The feedback processor was built to initially process a single SPS bunch at injection. The system is being expanded to handle multiple bunches with processing occurring is a parallel, pipelined manner. The ADC snapshot memory currently uses internal FPGA SRAM limiting capture lengths to 32000 turns. An upgrade

Abstract

Multi-input multi-output (MIMO) feedback design techniques can be helpful to stabilize intra-bunch transverse instabilities induced by electron-clouds or transverse mode couplings at the CERN Super Proton Synchrotron (SPS). These MIMO techniques require a reduced order model of intra-bunch dynamics. We estimate a linear reduced order MIMO models for transverse intra-bunch dynamics and use these models to design model based MIMO feedback controllers. The effort is motivated by the plans to increase currents in the SPS as part of the HL-LHC upgrade. Parameters of the reduced order models are estimated based on driven beam SPS measurements. We study different types of controllers. We test the model based designs using macro particle simulation codes (CMAD and HEADTAIL) and compare its performance with FIR filters tested during beam measurements of the feedback system in SPS machine development (MD) studies.

INTRODUCTION

Electron clouds and machine impedance can cause intra-bunch instabilities at the CERN Super Proton Synchrotron (SPS). The high current operation of the SPS for LHC injection requires mitigation of these problems. Modern control techniques can be used to stabilize the bunch. These techniques are powerful tools allowing us to evaluate and understand the performance and the limits of the system beforehand. Yet, they require reduced order models of intra-bunch dynamics to design optimal or robust controllers. System identification techniques can be used to get these required reduced order models.

The feedback system senses the vertical positions at multiple locations within the nanosecond-scale bunch. Control filters use these measurements to calculate correction signals and apply them back onto the bunch using the kicker as an actuator. A 4 Gs/Sec. digital feedback system has been developed to process the motion signals and generate the correction actions [1]. Due to the very fast intrinsic time requirement of the system, a parallel computation control filter architecture has been used developed.

In this paper, we show the use of system identification techniques to estimate parameters of linear models representing single bunch dynamics. We define the form of the reduced order model. We show an example of identification applied to data from SPS measurements. We use reduced order models to design model based controllers. We compare a model based IIR controller with an existing FIR filter for a specific case using nonlinear macro particle simulation codes.

REDUCED ORDER MODEL AND IDENTIFICATION

Any linear dynamical system can be represented in state space matrix form. A discrete time system sampled at every revolution period k with p inputs and q outputs is represented by

$$\begin{aligned} X_{k+1} &= AX_k + BU_k \\ Y_k &= CX_k \end{aligned} \tag{1}$$

where $U \in R^p$ is the control variable (external excitation), $Y \in R^q$ is the vertical displacement measurement, $A \in R^{n\times n}$ is the system matrix, $B \in R^{n\times p}$ is the input matrix, and $C \in R^{q\times n}$ is the output matrix. For a MIMO system, the model order n determines the complexity.

$$Y(z) = \left[D^{-1}(z)N(z)\right] U(z) \tag{2}$$

where [] represents the transfer function matrix ($\in R^{q\times p}$) for a system with p inputs and q outputs in z domain. $D(z)$ and $N(z)$ represent denominator and numerator of discrete time transfer function matrix between input-output couples.

$$\left[N_r \mid -D_r\right] \begin{bmatrix} U(k) \\ Y(k) \end{bmatrix} = 0 \tag{3}$$

Given the input $U(k)$ and output $Y(k)$ signals, the estimation of the transfer function coefficient matrices N_r and D_r is obtained by solving the last linear equation using time domain data. Assuming full observability of the system, we can represent our state space in discrete time observable canonical form. This enables us to represent the system with the minimum number of model parameters [2] [3] [4].

SPS Measurements - Bunch Dynamics Identification

Multiples MDs have been conducted at the CERN SPS ring driving the bunch with different excitations (open loop) and testing feedback controllers to stabilize the bunch dynamics (closed loop). Those measurements were conducted using a single bunch in the machine with intensities of about $1-2\times10^{11}$ protons at the injection energy, 26 GeV and Q26 lattice configuration.The driven tests with different excitation signals have been designed such that the kicking signal

BEAMLINE INSERTIONS MANAGER AT JEFFERSON LAB *

M. Johnson†, Jefferson Lab, Newport News, VA, 23606

Abstract

The beam viewer system at Jefferson Lab provides operators and beam physicists with qualitative and quantitative information on the transverse electron beam properties. There are over 140 beam viewers installed on the 12GeV CEBAF accelerator. This paper describes an upgrade consisting of replacing the EPICS based system tasked with managing all viewers with a mixed system utilizing EPICS and high level software. Most devices, particularly the beam viewers, cannot be safely inserted into the beam line during high-current beam operations. Software is partly responsible for protecting the machine from untimely insertions. The multiplicity of beam-blocking and beam-vulnerable devices motivate us to try a data-driven approach.

The beamline insertions application components are centrally managed and configured through an object-oriented software framework created for this purpose. A rules-based engine tracks the configuration and status of every device, along with the beam status of the machine segment containing the device. The application uses this information to decide on which device actions are allowed at any given time.

VIEWER SYSTEM

CEBAF Operations at Jefferson Lab run continuously 24/7 to support a program of experimental physics and accelerator studies. Control system software supports this effort in part by providing operators with the tools needed to diagnose and resolve issues with accelerator hardware and instrumentation. The software system that controls the insertion and retraction of viewers and other devices, dubbed "Insertables", has been rewritten using object-oriented programming methods and deployed to give operators and support personnel the ability to diagnose and resolve problems at all hours.

This new software system provides better encapsulation, separating device configuration from device behavior. A comprehensive view of insertable beamline components makes it easier to find configuration anomalies, such as device channel assignments that do not follow established patterns. Device failures during off hours have been diagnosed using debug screens and resolved quickly. Overall, faster problem diagnosis and resolution has resulted in a reduction in down time caused by this type of component.

In the following sections, we describe the context, requirements, and techniques employed in implementing this system.

Figure 1: Beam Spot on Viewer

SOFTWARE REQUIREMENTS

The operation of the CEBAF accelerator at Jefferson Lab relies on a wide variety of devices which must be physically inserted into the beam line when needed. Beam viewers measure beam profile and provide information about transverse beam characteristics. Faraday cups measure beam intensity at several points around the accelerator. Insertable dumps provide device protection and control of beam transport to the experimental end stations. These devices and a variety of others are critical to the delivery of a precisely tuned electron beam.

To support this heterogeneous and frequently changing hardware configuration, the software system must:

- Provide a hardware-domain description of each device in a format useful to engineers
- Reduce the duty-cycle of the beam in response to a request to insert a vulnerable device
- Change device-protection strategy when accelerator zones change between active and inactive.
- Allow an inactive experimental end-station to work with viewers without interfering with an active experiment
- Respond to unauthorized device motion by protecting the machine
- Track device motion and find faults in behavior (broken switches, inactive actuators)

THE CEBAF ELEMENT DATABASE AND RELATED OPERATIONAL SOFTWARE*

T. Larrieu, M. Joyce, M. Keesee, C. Slominski, R. Slominski, D. Turner
JLAB, Newport News, VA 23606, USA

Abstract

The newly commissioned 12GeV CEBAF accelerator relies on a flexible, scalable and comprehensive database to define the accelerator. This database, coined the CED (CEBAF Element Database) delivers the configuration for CEBAF operational tools, including hardware checkout, the downloadable optics model, control screens, and much more. The presentation will describe the flexible design of the CEBAF Element Database (CED), its features and assorted use case examples.

BACKGROUND

The Jefferson Lab CEBAF accelerator is a superconducting recirculating linear accelerator capable of delivering continuous wave electron beams simultaneously to multiple experimental halls. Previously capable of delivering 6GeV, CEBAF recently underwent an extensive multi-year $338M upgrade project to double its energy capacity to 12GeV and add a fourth experimental hall (Fig. 1). The upgraded accelerator was commissioned successfully between November 2013 and May 2014. The CEBAF Element Database (CED) was an indispensable tool during the commissioning.

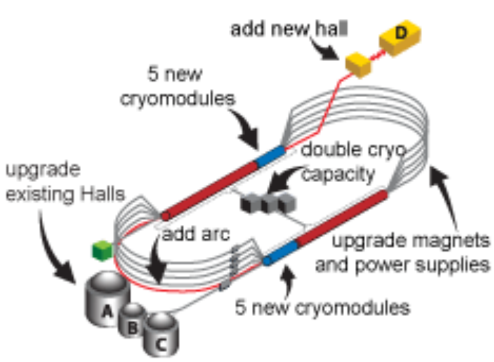

Figure 1: The CEBAF 12GeV Upgrade Project.

DATABASE DESIGN

The CED design is based upon a modified Entity-Attribute-Value with Classes and Relationships (EAV/CR) data model [1]. Whereas in a traditional schema adding support for new accelerator hardware would involve adding additional tables and columns to the database, the EAV/CR data model employed by the CED is introspective – defining a new class of accelerator hardware in the CED simply involves adding rows to the already-existing metadata "catalog" tables. Once defined in the catalog, existing software is fully capable of interacting with the new entities after discovering their properties from the metadata tables.

A major benefit of the EAV/CR data model is that its static schema is well suited to integration with Oracle Workspace Manager [2] to provide timestamp-based versioning of table rows, named save points, and multiple independent workspaces (akin to branches in a software version control system).

DATABASE IMPLEMENTATION

Layout

To optimize performance for the different use cases, the CED database instance is distributed among three database users/schemas as shown in Figure 2. The operational schema stores the current machine configuration and is optimized for performance. The historical schema provides efficient storage and access to (read-only) historical save points (snapshots). And the development schema is used to create workspace branches where data can be edited and prepared before being promoted to the operational schema.

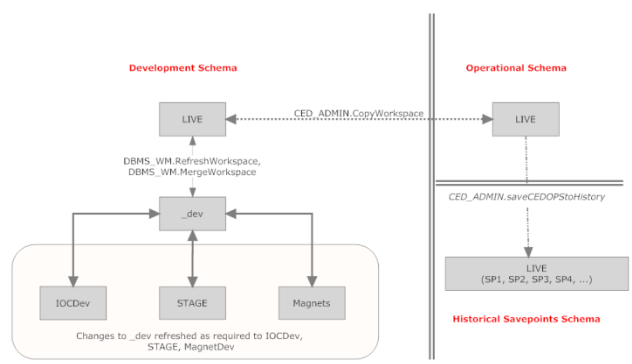

Figure 2: The CED three schema layout.

The details of the three schema layout are transparent to non-administrative users who need simply specify an optional workspace or savepoint name when interacting with the database.

Workspaces

As a rule, users do not directly edit data in the operational schema. Instead, updates are prepared in a development workspace and merged into OPS upon request. A database administrator receiving a merge request will audit the proposed changes for validity and then promote the changes to the operational schema. Administrators make use of a web-based management

eDT AND MODEL-BASED CONFIGURATION OF 12 GeV CEBAF *

D. Turner, Jefferson Lab, Newport News, VA 23606, USA

Abstract

This paper discusses model-driven setup of the Continuous Electron Beam Accelerator Facility (CEBAF) for the 12GeV era, focusing on the `elegant` Download Tool (`eDT`). `eDT` is a new operator tool that generates magnet design setpoints for various machine energies and pass configurations. `eDT` was developed as a tool to facilitate reducing machine configuration time and reproducibility by way of an accurate accelerator model.

MOTIVATION

An accurate accelerator model is critical for accelerator operations, as it enables comparisons of expected and observed beam behavior and helps identify root causes of discrepancy [1]. A well-modeled machine ensures predictability and reproducibility.

CEBAF supports a highly dynamic nuclear physics program. Energy and pass changes occur rather frequently. In an extreme case, we performed eleven pass changes and three energy changes in a one month period. Reducing tune time is crucial for such a program. An infrastructure of tools and procedures that systematically identify differences between the machine and the model will permit convergence which will lead to reductions in tune time, faster recovery from failures, and a better understanding of CEBAF 12GeV accelerator controls and dynamics.

`eDT` is a major component of the new infrastructure and operational paradigm supporting model-driven setup and operation of 12GeV CEBAF. `eDT` computes magnet design setpoints directly from the CEBAF model and applies them to the machine.

OVERVIEW OF CEBAF

CEBAF is a 5.5-pass, 12GeV continuous wave (CW) electron accelerator. It utilizes a photoinjector source capable of delivering greater than 85% spin polarization. CEBAF is comprised of two anti-parallel superconducting RF linacs connected by two sets of recirculation arcs. Jefferson Lab recently completed the upgrade of CEBAF from a 5-pass, 6GeV machine to 5.5-pass, 12GeV. See Fig. 1.

MACHINE SETUP DURING THE 6GeV ERA

Operators would initially configure the machine for a given energy and passes by using a software tool which scaled machine settings from previous configurations which were believed to be well-tuned. This usually didn't work without excessive tuning time as the machine was not modeled well and the magnet mapping was incomplete. The mode of operations would then be a cycle of tweaking, measuring, and tweaking again. Using these methods, pass and energy changes would take from several hours to several shifts.

During 6GeV, there was no central source for configuration control. Occasionally, hardware changes did not propagate to operator tools and screens. There was also no feedback into the model. The model was not updated to reflect operational experience.

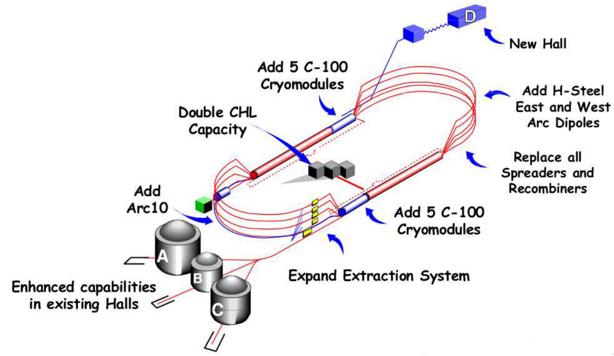

Figure 1: Scope of the 12GeV CEBAF upgrade.

MACHINE SETUP FOR 12GeV

To address the problems with configuring and modeling CEBAF, the CEBAF Modeling Team was formed to establish tools and procedures for model-driven configuration for 12GeV [1]. The Modeling team meets weekly while CEBAF is running, and semiweekly during scheduled maintenance periods.

The Modeling Team switched to `elegant` [2] to model CEBAF. `elegant` is a 6-D accelerator simulation code that does particle tracking, optimization, synchrotron radiation, scattering, and others. It is open-source code developed at the Advanced Photon Source (APS) at Argonne National Laboratory and it is actively maintained and continuously improved by both APS and the worldwide accelerator community. It has a large user base and it is more "industry standard" than the `OptiM` or `Art++` modeling tools previously used at CEBAF [6]. `elegant` is a command line tool that works well behind the scenes as an engine to drive operator tools. `elegant` is parallel capable for large scale simulations. `elegant` integrates well with the fully developed Self Describing Data Sets (`SDDS`) [3] toolset and infrastructure, making large scale data processing simpler [4], [5]. `elegant` also has better (and better tested) functionality to incorporate magnet errors which is an important part of reconciling online modeling with machine measurements [6].

ARCHITECTURAL IMPROVEMENTS AND NEW PROCESSING TOOLS FOR THE OPEN XAL ONLINE MODEL*

C.K. Allen, T.A. Pelaia II, ORNL, Oak Ridge, Tennessee 37831 USA
J. Freed, University of South Carolina, South Carolina 29208 USA

Abstract

The *online model* is the component of Open XAL providing accelerator modeling, simulation, and dynamic synchronization to live hardware. Significant architectural changes and feature additions have been recently made in two separate areas: 1) the managing and processing of simulation data, and 2) the modeling of RF cavities. Simulation data and data processing have been completely decoupled. A single class manages all simulation data while standard tools were developed for processing the simulation results. RF accelerating cavities are now modeled as composite structures where parameter and dynamics computations are distributed. The beam and hardware models both maintain their relative phase information, which allows for dynamic phase slip and elapsed time computation.

BACKGROUND

Open XAL is an open source development environment used for creating accelerator physics applications, scripts, and services [1]. The project has seen collaboration among SNS, CSNS, ESS, GANIL, TRIUMF and FRIB. Open XAL was born out of XAL, an application framework originally developed for the SNS in the early 2000s [2]. Open XAL is configurable for multi-site operation and the project facilitates multi-institutional development. It was initially released at the end of 2010 and is currently working toward its 6th milestone. For a status report on Open XAL see Pelaia [3]. For information on using Open XAL see the USPAS 2014 course *Control Room Accelerator Physics* material [4]. For material on the architecture of Open XAL see [5].

One significant component of Open XAL is the *online model*. This paper is concerned with two recent upgrades to the online model, data processing and the RF cavity model. For a perspective of these upgrades consider the overall architecture of online model; it is built according to the Element/Algorithm/Probe software architecture of Malitsky and Talman [6], which offers a robust implementation strategy for accelerator system modeling. Figure 1 is a UML diagram of the online model. A class,

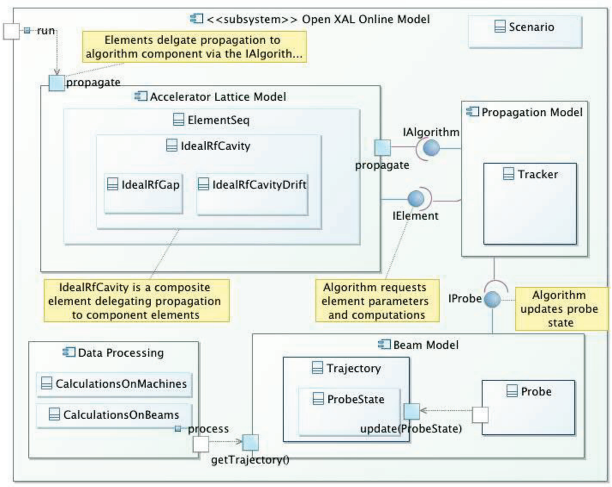

Figure 1: Open XAL online simulator architecture.

`Scenario`, encapsulates most of the online model and has the entry port `run()`. Also shown in the figure are four major components of the online model, the Accelerator Lattice, the Propagation Model, the Beam Model, and the Data Processing component; the three former components correspond to Element, Algorithm, and Probe, respectively, of Malitsky and Talman's architecture. The last component is not technically part of the online model. However, since it so closely ties to the model and it is a topic of the paper it is shown bound more tightly than implemented. The Accelerator Lattice represents hardware and computes hardware parameters. The Propagation Model component performs the dynamics interaction for hardware objects and the beam then updates the Beam Model with the results. The Beam Model represents some aspect of the particle beam, a single particle, the RMS envelopes, a transfer map, etc. The first topic of this paper, simulation data management and processing, is shared between the Beam Model and the Data Processing. The second topic, RF cavity modeling, is a part of the Accelerator Lattice component.

SIMULATION DATA AND ANALYSIS

The representation, storage, and analysis of online model simulation data are significantly improved. A new architecture for data handling was implemented which separates data maintenance and data analysis. This refactoring reduced code support by ten classes.

OPEN XAL BUILD SYSTEM*

T. Pelaia II#, ORNL, Oak Ridge, TN 37831, USA

Abstract

Open XAL is an accelerator physics software platform developed in collaboration among several facilities around the world. The build system is implemented through Apache Ant build files and features zero configuration simplicity based on directory patterns. These directory patterns allow for correctly building the Open XAL environment including the core and site specific applications, services, extensions, plugins and resources. Options are available for deployment and custom application packaging. This paper describes the Open XAL build rules, options and workflows.

INTRODUCTION

The Open XAL [1, 2] build system was designed from scratch to build multiple components with zero configuration while allowing for optional customization. Apache Ant was chosen as the build tool. Components include the core, extensions, plugins, services, applications and scripts. The final products are a single shared library plus the applications and services that depend on that shared library. Scripts don't require any build processing except to be copied for deployment. The goal of the build system is to provide zero configuration builds driven by convention.

BUILD REQUIREMENTS

Apache Ant [3] was chosen as the build tool since it is mature, commonly available, well supported and currently the standard build tool for Java. The version of Ant must be at version 1.9 or later to support all of the build commands and settings used in this project. Java J2SE 7 or later is required for compiling the current source code. The Open XAL project contains all the source code and libraries required to build the project.

ZERO CONFIGURATION

The Open XAL project delivers on the goal of building the entire project using a single command with zero configuration. Simply typing the command, "ant" in a terminal at the root of the project will build all executables. A second command, "ant install" can optionally be used for installing the executables in a deployment directory whose path can optionally be configured. Typing the command, "ant help" will display the list of all available build commands. Build files also exist throughout the project to allow builds at different levels of the tree. For example, one can build just a single application.

It is notable that zero configuration is true even when adding new components to the project. This is possible because the Open XAL build system is founded upon two principles: component separation and convention over configuration.

Component Separation

Component separation means that allowable dependencies between components are restricted. This separation facilitates efficient compilation and deployment and provides well defined dependency rules. Components are categorized as the core, plugins, extensions, services, applications and scripts.

The core consists of common foundation packages and has no compile time dependencies on any other components. Plugins provide runtime support for the core. For example, a plugin could provide a branded database driver that is required at runtime for the core's generic database tools. Extensions provide additional support packages to be shared among applications, scripts and services. Plugins and extensions can depend upon each other and on the core. Applications, scripts and services [4] are the end use executables and they may depend upon the core, extensions and plugins. Applications and services may also explicitly provide extensions. For example, a service provides an extension containing the public remote interface that clients will use to communicate with the service.

While not enforced, it is encouraged that any external library be wrapped so as to abstract functionality from the details of the external library. This allows for flexibility in replacing external libraries. Furthermore, it makes it easier to identify missing components since component packages follow an Open XAL naming convention whereas external library package names are not under our control.

Convention over Configuration

The build system uses convention over configuration to determine how to assemble and build components. The directory layout and naming convention determine how components are identified and how to package each component.

At the top level, component directories are appropriately named apps (for applications), core, extensions, plugins, scripts and services. A component bundle placed under any of these directories will be interpreted accordingly. Except as noted, a component

OPEN XAL SERVICES ARCHITECTURE*

T. Pelaia II#, ORNL, Oak Ridge, TN 37831, USA

Abstract

Open XAL is an accelerator physics software platform developed in collaboration among several facilities around the world. It includes a powerful new services extension that allows for natural remote procedure calls. The high level services interface is based upon custom implementations of modern standard protocols such as JSON-RPC and WebSockets. This choice of modern protocols allows for flexibility such as seamless communication with web clients free of plugins plus rich object type support. The JSON parser was designed for convenient data type transformations with easy extensibility, high performance and low memory overhead. The Open XAL services architecture features a simple application programming interface, high performance, memory efficiency and thread safety.

INTRODUCTION

Open XAL [1, 2] is a Java based platform for building accelerator physics software. The software products can be categorized as either application or standalone service. Here, an application refers to software with a user interface that is launched by an end user and runs until the user quits the application. A standalone service is software that runs perpetually unattended and has no user interface. Other client applications may communicate with a service for management or to display data from the service. Services are useful for monitoring, logging and certain calculations that are best suited to be offloaded from the client.

The Open XAL services framework is designed to provide a high level API to discover and communicate with services over standard protocols implemented internally. The communication protocols were chosen to allow for both thick application and thin web browser clients.

FEATURES

The services framework is designed to provide a high performance, low overhead remote communication mechanism that translates local Java calls into remote messages without having to provide stubs. Furthermore, it provides for dynamic registration and lookup which eliminates the need for configuring service addresses and allows services to be launched from any server on the local network rather than tied to one specific server. The implementation is thread safe and can process multiple concurrent calls.

PROTOCOLS

The services framework is built upon three standard protocols: multi-cast DNS, JSON-RPC [3] and WebSocket [4]. The multi-cast DNS protocol is implemented using the external JmDNS [5] library. The JSON-RPC and WebSocket protocols have been implemented directly in Open XAL. All three protocols are wrapped in the services framework so as to allow the public API to be independent of these internal protocols. Most of the interaction with the services framework is through the ServiceDirectory class and specifically the default singleton of this class known as the "default directory."

Multi-cast DNS

The open source JmDNS library provides the implementation of multi-cast DNS that is used in Open XAL. Multi-cast DNS allows for dynamic registration and lookup of services. A service is registered by name and type pair and are bound to the provided IP address and port. Clients can lookup services using the name and type pair and the IP addresses and ports of matching services are provided.

The services framework hides the details of the underlying JmDNS library. A service is simply registered using the default directory passing only the service name, a Java interface and the service provider implementing the Java interface. Internally, the fully qualified lowercase name of the Java interface is converted to a properly formatted multi-cast DNS type by replacing periods with underscores and appending "_tcp.local." to provide a unique type that conforms to the requirements.

JSON-RPC

A variant of JSON-RPC is the messaging protocol that is used to encode messages with JSON constructs. This protocol is hidden from the caller as method calls are automatically converted to the messaging protocol. Internally, a message request is encoded as a JSON [6] object (also known as a dictionary) using the "message," "params" and "id" keys. The message parameter consists of the service name followed by the method name separated by "#" such as "*MyService#doSomething*" for example. The params are an array of JSON encoded parameters to pass. The id parameter is an incremented integer that is used to uniquely identify the request.

A custom JSON implementation is used to efficiently encode and decode JSON to and from Java objects. This

Abstract

Open XAL is an accelerator physics software platform developed in collaboration among several facilities around the world. The Open XAL collaboration was formed in 2010 to port, improve and extend the successful XAL platform used at the Spallation Neutron Source for use in the broader accelerator community and to establish it as the standard platform for accelerator physics software. The site-independent core is complete, active applications have been ported, and now we are in the process of verification and transitioning to using Open XAL in production. This paper will present the current status and a roadmap for this project.

INTRODUCTION

Open XAL [1] is an open source accelerator physics software platform written in Java. The Open XAL project began in mid 2010 as a response to requests from the international accelerator physics community to adopt an open source accelerator physics platform based on XAL [2] from the Spallation Neutron Source (SNS) at Oak Ridge National Lab (ORNL) and establish a standard platform for accelerator physics software.

The goals of the project are to provide a common accelerator physics core to be developed in collaboration, provide a rapid development environment and to modernize the source code. Since the last status report [3], the development effort has shifted from porting code to verification, modernization and new functionality. The API has stabilized, and the project is production ready. This paper covers the collective contributions of the collaboration.

SOFTWARE HIERARCHY

The software is grouped among the core, extensions, plugins, services, applications and scripts. The core consists of packages that include the accelerator object graph, the online model, abstract channel interface and general supporting tools such as common math libraries, archiving, messaging, database access and concurrency. This core is intended to be shared in common across all Open XAL distributions, and it has no compile time dependency on other components.

Extensions and plugins are components which may optionally depend on other extensions and plugins and the core. A plugin differs from an extension in that the core depends on a plugin being implemented (but not the actual implementation) whereas the core has no dependency on an extension. Plugins consist of controls channel access support and database adaptors. For example, the core specifies generic database tools, but a database adaptor plugin provides support for a specific database driver. Extensions include packages of general use in applications, scripts and services but not in the core. Examples of extensions include the application framework, service framework, lattice generation, fitting, scanning and widgets such as plotting tools.

Applications, scripts and services are executables and may depend upon the core, plugins and extensions. Applications and scripts are launched by users and have a user interface whereas services are headless and run perpetually in the background independent of user interaction. Applications differ from scripts in that applications are written in Java and are thus fully compiled prior to runtime versus scripts that may be written in a Java variant of Ruby or Python scripting languages and are not compiled prior to runtime.

A top level site directory contains optional site specific resources and configurations that take precedence over resources and configurations of the same name in the

RESPONSIVITY STUDY OF DIAMOND X-RAY MONITORS WITH nUNCD CONTACT

M. Gaowei [#], J.Smedley, Brookhaven National Laboratory, Upton, NY, 11973, USA
T. Zhou, E. Muller, Stony Brook University, Stony Brook, NY, 11794, USA
A. Sumant, Argonne National Laboratory, Argonne, IL, 60439, USA

Abstract

Nitrogen doped ultrananocrystalline diamond (nUNCD) grown on the surface of a CVD single crystal diamond is tested at various beamlines covering an x-ray photon energy range of 200eV to 28 keV. The nUNCD has much lower x-ray absorption than metal contacts and is designed to improve the performance of our device. The responsivity of nUNCD diamond x-ray detector is compared with the conventional platinum coated diamond x-ray beam position monitor and the results are presented in this paper.

INTRODUCTION

The ultrananocrystalline diamond (UNCD) thin films exhibit similar physical properties to single crystal diamond in the aspects of mechanical, thermal and resistance to radiation damage. Current UNCD thin films are prepared by microware plasma chemical vapor deposition (MPCVD) or hot filament chemical vapor deposition (HFCVD) with mixed H_2/CH_4 or Ar/CH_4 plasma chemistries. Nitrogen is introduced to UNCD thin film to improve its electrical conductivity to semi-metallic level, and therefore can be considered as a replacement of metal to function as an electrode in various applications like biomedical devices, biosensors, and in our case the x-ray monitors. [1, 2]

In this paper, a diamond device prepared with nitrogen doped ultrananocrystalline diamond (nUNCD) on both sides as electrodes is studied and results are compared with the device fabricated with traditional platinum contact.

EXPERIMENTAL

In order to improve the performance of the diamond x-ray monitor, nUNCD layers of 200 nm ~ 500 nm are grown on a 4 mm × 4 mm × 0.3 mm electronic grade ([N] ~ppb) single crystal CVD diamond as contact electrodes at Argonne National Laboratory (ANL).

X-ray white beam topography and birefringence images were recorded for this sample prior to device fabrication. X-ray topography was performed at Beamline X19C, National Synchrotron Light Source (NSLS) and birefringence images were taken using a polarized microscope. 2D current maps and calibrated responsivity vs photon energy of this diamond were collected at various beamlines in NSLS, covering a photon energy range of 0.2~28keV. Beamline U3C provides monochromatic beam of photon energy from 0.2~1 keV, while beamline X8A provides x-ray from 1~6.5 keV and beamline X15A from 6.5~28 keV, with an intensity ranged from 10^{-9}~10^{-6} W/mm^2. [3] Measurements at U3C are performed in a vacuum level of 10^{-7}torr and at X8A in a vacuum of 10^{-6} torr due to the high absorption rate of air for low energy photons, and is in air at X15A. Incident x-ray power is calibrated using silicon photodiodes at both U3C and X8A (with thickness of 25 µm and 52 µm respectively), while air-filled ionization chamber is used at X15A. Various biases in the saturated range of either DC level or in the form of square wave with adjustable magnitude, frequency and duty cycle, were applied on tested diamond plates to assure full collection of desired charge carriers (positive biases for hole collection and negative biases for electron collection).

RESULTS AND DISCUSSION

Figure 1 shows the compared results of the 2 imaging techniques. The nUNCD contact is completely transparent under the white beam at X19C (Fig.1a). The dark circled area in Fig.1b indicates the nUNCD contacts on both sides of the diamond. Prominent contrast of slip bands in diamond single crystal was observed in both topography and birefringence images.

Abstract

This paper gives an overview of the opportunities and challenges of high-intensity, low-energy light-ion accelerators for neutron production. Applications of this technology range from the study of stellar nucleosynthesis and astrophysical phenomena to medical applications such as Boron neutron capture therapy (BNCT). The paper includes details of the FRANZ facility, under development at Frankfurt University.

INTRODUCTION

Applications of Neutron Beams

Neutrons are an important tool for probing the structure of matter. They are electrically neutral, but sensitive to the magnetic properties of the material, as well as for different isotopes, providing excellent opportunities for material sciences [1]. Their high penetration depth in material and their strong sensitivity for light elements facilitate neutron imaging techniques [2, 3].

Nuclear Astrophysics The investigation of neutron capture processes is especially relevant to provide a deeper understanding of stellar nucleosynthesis and astrophysical phenomena. About 50% of the element abundances beyond iron are produced via the slow neutron capture process or s-process. This process takes place mostly inside of asymptotic-giant-branch (AGB) stars. Here, the neutron temperature ranges from 8 keV to 90 keV. Therefore, a proper modeling of the stellar nucleosynthesis requires the knowledge of neutron capture cross-sections between 1 keV and 400 keV [4, p. 14].

BNCT There are increasing efforts to use neutron beams for cancer therapy. Presently, there are eight initiatives in the world to develop accelerator-based Boron Neutron Capture Therapy (BNCT) [5]. If boron-10 that has been selectively incorporated into the tumor tissue captures a neutron, it decays into short-ranging alpha particles and lithium-7 nuclei, which can efficiently destroy the cancer cells [6]. Epithermal neutrons of up to 10 keV are required to assure sufficiently high penetration depth into the tissue while still having a sufficiently high capture cross section.

Neutron Production

Since free neutrons are unstable, dedicated production setups are required. Traditionally, nuclear fission reactors have been used for neutron production. They provide a high average neutron (n) flux of typically up to 1×10^{15} n s^{-1}cm^{-2}. Recently, spallation neutron sources combine a comparable or even higher flux than reactors with a flexible time structure.

Complementary to these large-scale facilities, small-scale accelerator-driven neutron sources based on light ion beams at low energy can provide intense neutron beams with flexible time structure in the energy range from keV to MeV.

SMALL-SCALE ACCELERATOR-DRIVEN FACILITIES

Opportunities

Typical small-scale accelerator-driven neutron sources employ light ions at several MeV energy to generate neutrons via nuclear reactions as the ^{7}Li(p,n)^{7}Be, the ^{9}Be(p,n)^{9}B or the ^{9}Be(d,n)^{10}B reaction. For low proton energies, the ^{9}Be(p,n) reaction produces less (and higher-energetic) neutrons than the ^{7}Li(p,n) reaction [7]. However, the target material might be easier to handle.

The ^{7}Li(p,n)^{7}Be reaction as the most prolific reaction has a relatively low production threshold of 1.88 MeV. The resulting neutron energy lies in the keV to hundreds of keV range, depending on the primary proton energy. This includes the relevant energy spectrum for stellar nucleosynthesis as well as for BNCT application.

In contrast, reactors or spallation neutron sources provide neutrons in a wide energy spectrum, including much lower and much higher energetic neutrons. In a reactor, the fission neutrons, starting with several MeV energy, are typically moderated down to thermal energies. In spallation processes, some neutrons can reach energies up to the incident proton energy of hundreds of MeV, with the larger part having energies around 1 MeV to 10 MeV.

At small-scale facilities, the neutron energy spectrum can be further refined by adjusting the primary beam energy and the thickness of the production target [4, p. 23]. This allows to limit the neutron spectrum to the region of interest for the given application, reducing the background that is induced by higher energy neutrons and creating a neutron flux for the energy region of interest that is comparable to the flux in large-scale facilities.

This effect is increased for the ^{7}Li(p,n)^{7}Be reaction when proton energies just above the production threshold are employed. In this case, due to kinematic collimation, neutrons are only emitted in a forward cone with an opening angle of 120°, significantly increasing the neutron flux at the sample position [4].

UPGRADE OF THE UNILAC FOR FAIR

L. Groening, S. Mickat, R. Brodhage, A. Adonin, X. Du, R. Hollinger, O.K. Kester, A. Orzhekhovskaya, B. Schlitt, G. Schreiber, H. Vormann, C. Xiao, GSI, Darmstadt, Germany
H. Hähnel, U. Ratzinger, A. Seibel, R. Tiede, Goethe University of Frankfurt, Frankfurt, Germany

Abstract

The UNIversal Linear Accelerator (UNILAC) at GSI serves as injector for all ion species from protons to uranium since four decades. Its 108 MHz Alvarez type DTL providing acceleration from 1.4 MeV/u to 11.4 MeV/u has suffered from material fatigue. The DTL will be replaced by a completely new section with almost same design parameters, i.e. pulsed current of up to 15 mA of $^{238}U^{28+}$ at 11.4 MeV/u. A dedicated source terminal & LEBT for operation with $^{238}U^{4+}$ is currently constructed. The uranium source needs to be upgraded in order to provide increased beam brilliances and for operation at 2.7 Hz. In parallel a 70 MeV / 70 mA proton linac based on H-mode cavities is under design and construction.

THE FAIR PROJECT

GSI is currently constructing the Facility for Ion and Antiproton Research (FAIR) [1]. It aims at provision of $2{\times}10^{11}$/s uranium ions at 1.5 GeV/u. Due to its high rigidity uranium imposes the highest challenges to the accelerator chain wrt fields and machine protection. Additionally, a total of $2{\times}10^{12}$/s cooled anti-protons are to be delivered. The complete accelerator chain is depicted in Fig. 1 and its more detailed description as well as its current status of design and construction is given in [2]. These proceedings are on the injector linacs of the facility. The existing UNIversal Linear ACcelerator UNILAC will provide all primary ions but protons. A dedicated proton linac is currently under design and construction. In order to deal with the FAIR requirements in the upcoming decades the UNILAC needs a considerable upgrade. These upgrade activities are described in the next section. Afterwards the proton linac is presented together with its current status wrt design, construction, and commissioning of components.

UPGRADE OF THE UNIVERSAL LINEAR ACCELERATOR UNILAC

The existing UNILAC (Fig. 2) serves as injector for FAIR together with the subsequent synchrotron SIS18. The UNILAC has three ion source terminals that can be operated in pulse-to-pulse switching mode at 50 Hz. One terminal is equipped with an ECR source providing highly charged ions. Another terminal houses a Penning source providing low intensity beams at intermediate charge states. The third terminal is dedicated to provision of intense beams of low-charged ions. It can be equipped with various source types as MUCIS and CHORDIS for light to intermediate-mass ions for instance. Intense heavy ion beams are produced in a MEVVA or VARIS source at 2.2 keV/u. Beams are bunched

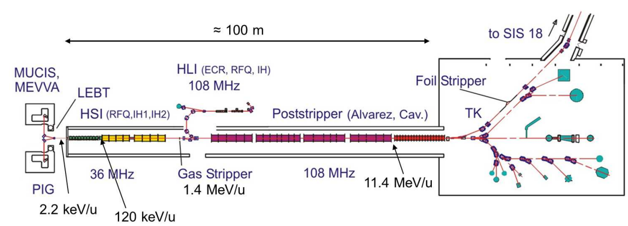

Figure 2: The UNIversal Linear ACcelerator (UNILAC) at GSI.

and pre-accelerated to 120 keV/u along a 9 m long RFQ operated at 36 MHz. Afterwards two IH-cavities provide for acceleration to 1.4 MeV/u. For uranium the highest particle numbers are obtained by using the charge state $^{238}U^{4+}$. After the IH-DTL the acceleration efficiency is increased by passing the beam through a gaseous stripper which delivers a mean charge state of $^{238}U^{28+}$ at its exit. This increase of charge state is at the expense of intrinsic particle loss as about 89% of the uranium ions are stripped to a charge state different from 28+. After dispersive selection of the desired charge state the beam is matched to the subsequent post stripper Alvarez DTL. The latter is operated at 108 MHz and comprises five tanks. Its exit beam energy is 11.4 MeV/u being the injection energy for the synchrotron SIS18. The UNILAC design parameters are listed in Table 1. The age of the UNILAC together with the requirement to provide reliable and intense beams for the upcoming FAIR era calls for a revision of the UNILAC. In the following the planned upgrade activities are illustrated.

Source, LEBT, MEBT, and RFQ

In order to provide the mean uranium intensity required for FAIR the source has to be operated with a repetition

700 kW MAIN INJECTOR OPERATIONS FOR NOνA AT FNAL *

P. Adamson†, Fermi National Accelerator Laboratory, Batavia, IL 60510, USA

Abstract

Following a successful career as an antiproton storage and cooling ring, the Fermilab Recycler was repurposed as a proton stacker as part of the NOνA project, in order to increase the maximum NuMI beam power from 400 kW to 700 kW. Using the Recycler to prepare beam for acceleration in the Main Injector, we have been able to increase the beam power delivered to NuMI to a sustained weekly average in excess of 400 kW and a best hourly average of 482.8 kW. I discuss the commissioning progress to date, and describe the remaining steps along the way to achieving the 700 kW design goal.

NOνA

The NOνA [1], [2] (NuMI Off-axis ν_e Appearance) long-baseline experiment in the Fermilab NuMI neutrino beam aims to make precision measurements of muon-neutrino survival and muon- to electron-neutrino oscillation for both neutrino and antineutrino beams traveling from Fermilab to a "Far Detector" 810 km away in Ash River, MN. It aims to address the outstanding questions in neutrino physics—whether the neutrino mass eigenstates have "normal" or "inverted" mass ordering (whether the dominant components of the electron neutrino are the lightest or the heaviest states); whether the mixing angle θ_{23} is maximal, or if it differs from 45°, whether it is larger or smaller; whether the CP symmetry is violated in the neutrino sector; and whether the three-flavor PMNS matrix is sufficient to explain neutrino oscillations, or if new physics is required.

In order to accomplish these goals, as well as building a massive (14 kT) Far Detector, the NOνA project [3] upgraded the beam power delivered to the NuMI facility from a nominal 400 kW to a nominal 700 kW.

BEAM DELIVERY TO NUMI

The NuMI beam begins as H^- ions accelerated to 400 MeV in a normal-conducting linac. On injection to the Booster, they pass through a stripping foil which converts the H^- to protons. The injected beam typically wraps the Booster circumference about 13 times to achieve a normal intensity of around 4×10^{12} protons per Booster batch. The booster is a 15 Hz resonant synchrotron, and accelerates protons to 8 GeV KE (8.9 GeV/c momentum). Not all 15 Hz cycles contain beam or rf voltage. An overview of the Fermilab accelerator complex is shown in figure 1.

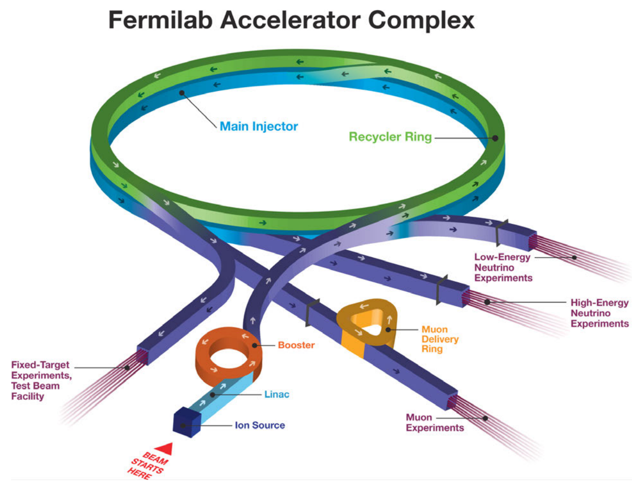

Figure 1: Fermilab accelerator complex in 2015.

In the Collider era, the Booster was injected into the Main Injector, and accelerated to 120 GeV/c. The Main Injector circumference is seven times that of Booster, allowing six Booster batches to fit around the machine once a gap to accommodate the rise time of the extraction and abort kickers has been left. Slip-stacking [4] was used to combine two Booster batches into one for five of these six batches. The need to provide two kicker gaps in order to share this beam between the antiproton source and the NuMI beamline precluded slip-stacking the final batch.

The NOνA upgrade moves the slip-stacking process from the Main Injector to the Recycler—an 8.9 GeV/c permanent magnet machine in the Main Injector tunnel no longer needed in its prior role as an antiproton storage and cooling ring. Separating the time-consuming accumulation of Booster batches at 8 GeV from the acceleration allows the Main Injector to continuously ramp up and down, while the Recycler accumulates and slip-stacks the beam for the next pulse. As shown in figure 2, for 12-batch slip-stacking, Recycler has begun preparing the next pulse before Main Injector has extracted the previous one.

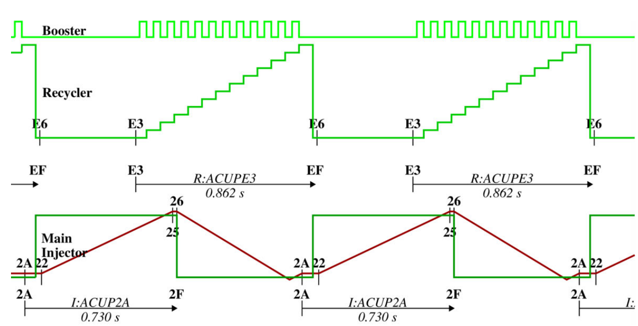

Figure 2: Relative timing of Booster, Recycler and Main Injector cycles for NOνA-era NuMI operation. Beam in each machine is shown in green, and Main Injector momentum in red. The start and end of cycle clock events for MI and Recycler are also shown.

Abstract

SuperKEKB is designed based on the 'nano-beam scheme' with the target luminosity of 8×10^{35} cm^{-2}s^{-1}. The design of the interaction region (IR) with a very low β_y* at the interaction point (IP) is discussed. The status of the installation and the injector commissioning of SuperKEKB is reported.

INTRODUCTION

The previous project KEKB was an e−/e+ collider that is used for physics experiments mainly conducted at the Υ(4S) resonance. KEKB has the highest peak luminosity in the world, 2×10^{34} cm^{-2}s^{-1}. KEKB has been in operation until 2010. Afterward, upgrading of KEKB has been initiated toward SuperKEKB. The target luminosity is 8×10^{35} cm^{-2}s^{-1}, which is 40times higher than that of KEKB. The required integral luminosity is 50 ab^{-1}. For the upgrade, the KEKB tunnel is being reused, and the KEKB components are being reused as much as possible in SuperKEKB.

Luminosity mainly depends on three parameters: the beam currents (I), the beam-beam parameter (ξ_y), and the vertical beta function (β^*_y) at the interaction point (IP). For achieving 40 times higher luminosity than that of KEKB, the current I is doubled, the beam-beam parameter ξ_y is kept almost at the same level, and β^*_y is reduced to 1/20 of the KEKB value, based on the 'nano-beam scheme'. Table 1 shows the SuperKEKB machine parameters. As the nano-beam collision scheme, beams collide at a large crossing angle, 83 mrad. Thus, the length of the overlap region of the two beams at the IP is expressed as σ_x*/ϕ. For realization of the small β^*_y, low horizontal emittance ε_x and small β^*_x are necessary. The value of β^*_y at the SuperKEKB is 0.3 mm.

As part of an additional design concept, beam energies are changed. The LER energy is increased for longer Touschek lifetime and mitigation of emittance growth owing to the intra-beam scattering. In HER, as the energy is decreased, emittance becomes lower and synchrotron radiation (SR) power decreases. For the low SR power, the KEKB beam chamber can be reused.

Table 1: SuperKEKB Machine Parameters

Parameters	units	LER	HER
Beam energy	GeV	4	7.007
Half crossing angle ϕ	mrad	41.5	
Num. of bunches		2500	
H emittance ε_x	nm	3.2	4.6
Emittance ratio	%	0.27	0.25
Beta functions β^*_x/β^*_y	mm	32/0.27	25/0.30
Beam currents I	A	3.6	2.6
Beam-beam param.ξ_y		0.088	0.081
Bunch length	mm	6.0	5.0
H beam size σ_x*	µm	10	11
V beam size σ_y*	nm	48	62
Luminosity	cm^{-2}s^{-1}	8×10^{35}	

The estimated beam lifetimes for both rings are ~6 min, obtained without the consideration of without beam-beam effect. An effect of the beam-beam interaction to the beam lifetime and other beam-beam related issue are discussed elsewhere [1]. Therefore, high bunch charge

ACCELERATOR PHYSICS IN ERL BASED POLARIZED ELECTRON ION COLLIDER*

Yue Hao†, C-A Dept. Brookhaven National Laboratory, Upton, NY 11973, USA

Abstract

This talk will present the current accelerator physics challenges and solutions in designing ERL-based polarized electron-hadron colliders, and illustrate them with examples from eRHIC and LHeC designs. These challenges include multi-pass ERL design, highly HOM-damped SRF linacs, cost effective FFAG arcs, suppression of kink instability due to beam-beam effect, and control of ion accumulation and fast ion instabilities.

INTRODUCTION

Deep inelastic scattering already have taught us on the inner structure and dynamics inside nucleon. To get a much greater insight of the nucleon structure, including the distribution of the momentum, spin and flavor of the quarks and gluons, a high luminosity electron ion collider (EIC) is required.

In an EIC, the ion beam is accelerated to desired energy and stored in an synchrotron ring, while the electron accelerators has two options. An electron storage ring, together with its injector and booster, can be built and form a 'ring-ring' collision scheme with the ion ring. Alternatively, an energy recovery linac (ERL) can serve as electron accelerator, and form a 'linac-ring' scheme, or an ERL based EIC. In an ERL, the electron beam gain energy from the RF cavities (usually superconducting) with the accelerating phase. After the electron beam collides with the ion beam, it will be decelerated in the same RF cavity, with the decelerating phase which is ensured by the pass length of the electron beam. The energy is then used to accelerate the new electron bunches. This energy recovery process enables high collision rate, hence high luminosity. Therefore in an ERL based collider, the electron beam is always fresh, however, its energy is re-used.

There are several benefits of an ERL based EIC over a 'ring-ring' counterpart, which include:

- The beam-beam limit of the electron beam is removed due to a single collision for every electron bunch, which leads to an higher luminosity,
- The electron can be dumped at a much lower energy,
- The simpler synchronization of the electron beam with various ion energies.

Currently, there are two ERL based EIC proposed. One is the eRHIC [1] project in Brookhaven National Laboratory, the other is LHeC [2] in CERN. eRHIC uses the operating RHIC (Relativistic Heavy Ion Collider) to provide up to

Table 1: The Baseline Parameters of eRHIC and LHeC

Parameters	eRHIC		LHeC

250 GeV proton and 100 GeV/n heavy ion and a new ERL electron accelerator to provide polarized electron beam from 1.3 GeV to 21.2 GeV. eRHIC will achieve 4×10^{33} cm^{-2}s^{-1} luminosity from collision of 250 GeV proton and 15.9 GeV electron beam. The LHeC use 7 TeV proton beam from the LHC and add an ERL to provide 60 GeV polarized electron beam, with the luminosity reaching 10^{33} cm^{-2}s^{-1}. Table 1 lists the baseline parameter of both ERL base EIC designs. For both designs, a multi-pass ERL scheme is adopted to save cost on the expensive Superconducting RF structure, i.e. the electron beam passes the linac with accelerating phase several times to accumulate energy before collision. eRHIC also adopts the non-scaling FFAG concept to avoid large number of ERL recirculating passes. Table 2 summarize the ERL parameters.

Abstract

The Medium-energy Electron Ion Collider (MEIC) at JLab is designed to provide high luminosity and high polarization needed to reach new frontiers in the exploration of nuclear structure. The luminosity, exceeding 10^{33} cm^{-2}s^{-1} in a broad range of the center-of-mass (CM) energy and maximum luminosity above 10^{34} cm^{-2}s^{-1}, is achieved by high-rate collisions of short small-emittance low-charge bunches made possible by high-energy electron cooling of the ion beam and synchrotron radiation damping of the electron beam. The polarization of light ion species (p, d, ^{3}He) can be easily preserved and manipulated due to the unique figure-8 shape of the collider rings. A fully consistent set of parameters have been developed considering the balance of machine performance, required technical development and cost. This paper reports recent progress on the MEIC accelerator design including electron and ion complexes, integrated interaction region design, figure-8-ring-based electron and ion polarization schemes, RF/SRF systems and ERL-based high-energy electron cooling. Luminosity performance is also presented for the MEIC baseline design.

INTRODUCTION

The proposed MEIC at JLab is designed to meet the requirements of science program outlined in the EIC white paper [1]. The overall MEIC design strategies [2,3] towards achieving high luminosity and high polarization have not changed since 2006 but technical design aspects have evolved. In particular, the updates from the 2012 MEIC design report [3] are the results of an ongoing optimization process for performance, cost, technical risk and potential for phasing and future upgrades.

Main changes with respect to the design report in 2012 are given as follows [4].

- Ion and electron collider ring circumferences have been increased from 1.5 to 2.2 km.
- Electron collider ring is designed reusing PEP-II components (magnets, vacuum chambers, RF, etc.).
- Ion collider ring is designed based on super-ferric magnet technology.
- Only one single 8 GeV figure-8 shape booster is needed based on super-ferric magnets.

In this paper, we provide technical descriptions of the main subsystems on the baseline design and present the resulting luminosity performance.

MEIC BASELINE DESIGN

The MEIC is designed to be a traditional ring-ring collider. The central part of this facility is two figure-8 shape collider rings that are vertically stacked and housed in the same underground tunnel, as shown in Fig. 1. The figure-8 crossing angle is 81.7°, partitioning a collider ring into two arcs and two long straights. The ion beam executes a vertical excursion to the plane of electron ring for a horizontal crossing for electron-ion collisions. Two collider rings have nearly identical circumferences of approximately 2.2 km, and fit well in the Jefferson Lab site.

ENGINEERING CHALLENGES OF FUTURE LIGHT SOURCES

R.T. Neuenschwander*, L. Liu, S.R. Marques, A.R.D. Rodrigues, R.M. Seraphim, LNLS, Brazil

Abstract

We review some of the present engineering challenges associated with the design and construction of ultra-low emittance storage rings, the 4th generation storage rings (4GSR). The field is experiencing a growing interest since MAX-IV, followed by Sirius, started to build storage rings based on multi-bend-achromat (MBA) lattices. It was the recent progress in accelerator technology that allowed these facilities to base their designs on this kind of lattice. Although the challenges are starting to be overcome, many issues are still open and a lot of R&D is required until the 4GSR achieve optimal performance.

INTRODUCTION

Over the past few years an explosion of activities in the field of storage-ring based light sources has started, marking the beginning of a new generation in the history of storage rings, the fourth generation, where the electron beam emittance is reduced by at least an order of magnitude with respect to third generation machines, approaching the diffraction limit for multi-keV photons. The first audacious step was taken by the MAX-IV project in Sweden [1], a 3 GeV storage ring using a 7BA lattice that is based on quite a few new accelerator technological concepts. Following the path initiated by MAX-IV is the Sirius project in Brazil [2] with a 3 GeV 5BA lattice, similar emittance and circumference, but with its own set of particularities that reflects both a different user community and a different local industry condition. Both are green-field projects that are presently under construction. Other green-field projects that are being planned include BAPS in Beijing [3] and ILSF in Iran [4]. A big part of the recent activities in the field involve the plans of existing facilities in converting third generation machines into fourth generation ones. Some of these projects are well advanced, like ESRF [5], APS [6] and Spring-8 [7]; and others are at different conceptual stages, including ALS [8], Soleil [9], Diamond [10], SSRF [11], and others. Figure 1 shows a survey of emittances for some existing machines that are in operation for users, for machines under construction or in commissioning phase and for planned green-field or upgrade to existing machines.

The activity in the field can also be assessed by the great number of recent workshops [12-14] and special publications [15-16] on the subject.

The scaling laws in a storage ring that relate the emittance, the total number of dipoles, the beam energy and the ring circumference have been known for a long time. The first lattices based on MBA cells were proposed in the early 1990's [17], but their practical implementation had to wait for the technological advances that came about 20 years later. To understand the difficulties, we recall that the basic idea for emittance reduction using MBA lattices is that a large number of dipoles, and thus small deflection angle per dipole, allows the dispersion function to be kept focused to small values in the dipoles. The dispersion function plays an important role in determining the equilibrium emittance because it is directly related to the excitation of oscillations when a particle's energy is changed due to the emission of a photon. To keep the dispersion function small, strong focusing quadrupoles are needed between the dipoles. The strong quadrupoles and the small dispersion, in turn, require strong sextupoles to compensate for chromatic aberration effects. The strengths required have a big impact on the design of the magnets: the bore radius has to shrink and consequently the aperture available for the vacuum chambers is also reduced. The small vacuum chamber aperture has a big impact on the vacuum system because the conductance of the vacuum pipe is reduced (it scales as the cube of the pipe radius) and a new approach with distributed pumping is needed to keep the pressure low. Also the resistive wall impedance becomes an issue and may require a material with higher electrical conductivity for the chambers to minimize its effects.

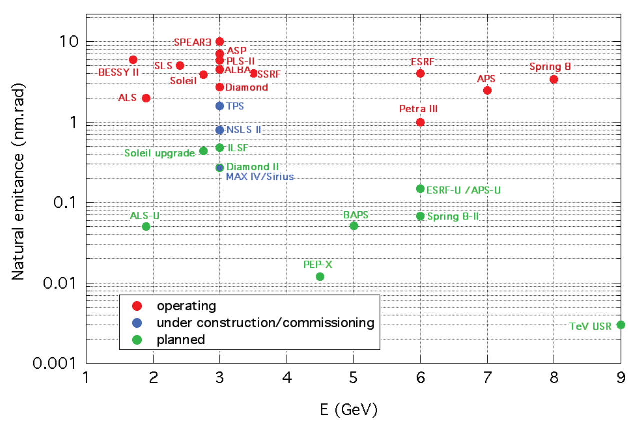

Figure 1: Survey of emittances versus energy for some existing machines that are in operation for users, for machines under construction or in commissioning phase and for some planned green-field or upgrade to existing machines.

The strong magnetic field gradients also imply high orbit amplification factors: the orbit amplitude becomes very sensitive to alignment errors of the magnets. The high amplification factors combined with the very small beam sizes impose stringent tolerance requirements for the magnets alignment and vibration amplitude, which translate into tight tolerances for the floor and girder vibrations. The high orbit stability requirement is also pushing the technology of beam diagnostics, fast feedback systems, special injection hardware to minimize

COMMISSIONING OF THE TAIWAN PHOTON SOURCE

C. C. Kuo, J. Y. Chen, M. S. Chiu, P. J. Chou, Y. C. Liu, H. J. Tsai,
F. H. Tseng, K. T. Hsu, G. H. Luo and C. T. Chen
National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

Abstract

The Taiwan Photon Source (TPS) is a 3-GeV third-generation synchrotron light source located in Hsinchu, Taiwan. After ground breaking on February 7, 2010 and five years of construction and hardware developments, commissioning of the beam began on December 12, 2014. The booster ring reached the design energy of 3 GeV on December 16. Beam transferred to the storage ring and first accumulation at 3 GeV produced the first synchrotron light on December 31. This report presents results and experience of the TPS commissioning.

INTRODUCTION

The 3-GeV TPS is located on the campus of NSRRC in Hsinchu Science Park together with the 1.5-GeV Taiwan Light Source (TLS) which has been in operation since 1993. To expand the capacity for research with synchrotron light and its capability at NSRRC, we initiated in 2004 a feasibility study for the construction of a medium energy and low emittance light source. Funding of the TPS project was approved in 2007 and a ground-breaking ceremony of TPS was held on February 7, 2010. The civil construction required about four years to complete. The installation of TPS accelerator components began in October 2013 when beneficial occupancy was available. Most installation work for the Linac and booster ring was completed by the end of July 2014. Permission for commissioning the TPS with beam was issued by the AEC on August 1. Tests of the system and improvements of the harware with beam have proceeded since then.

The 150-MeV beam from the Linac to the booster was available in mid August and tests of the booster power supplies conducted in parallel. Hardware optimizations were in progress like reducing the post-pulse residual field in the booster injection kicker or repair of a burned booster-dipole power supply due to overheating of the ground-current protection circuit-board during a full power ramping test.

At the beginning of September, a multi-turn circulating beam was observed in the booster ring. The beam survived up to 35 ms in mid September, but capture and storage of the beam did not succeed with the RF turned on. Attempts to correct orbit distortions within 4 mm still failed to capture beam. We found also that the corrector strengths required to get many turns were three times the simulated values. The beam pipes of the booster ring, made of stainless steel 304, have an elliptical shape, 35 mm (H) and 20 mm (V), and thickness of 0.7 mm. Distortion and misalignment of the pipes could be critical. Care was taken to realign the chambers and magnet positions. On November 12 it was recognized that the relative permeabilty (ranging from 1.2 to 2.0) of the pipes arising from the cold-drawn process of the pipe manufacture was too large. The magnetic fields of the combined-function dipoles (including quadrupole and sextupole gradients in dipole magnets) at 150 MeV could generate errors an order magnitude higher than tolerances. These chambers were taken apart and heat treated up to 1050 °C and then reinstalled within three weeks [1]. The relative permeability of the pipes after heat treatment was reduced to less than 1.01 [2].

Soon the beam survived 50 ms on December 11 and a beam was stored on December 12. Tests of the energy ramping began on December 15 and 3 GeV were reached the next day.

To prepare the extraction from the booster ring and its injection into the storage ring TPS was shut down from December 19 to 23. During this period, installation work and subsystem tests of the booster to storage ring transfer line (BTS) as well as the storage ring continued. The DC extraction septum operating at 3 GeV severely affected the booster capture at 150 MeV and ramping efficiency because of residual leakage field from the shielded septum chamber. Without further effort to shield the leakage field, we extracted a 1.5-GeV beam instead and injected it into the storage ring on December 26; the beam was stored the next day. After adding extra correctors nearby the DC extraction septum, extraction at 3 GeV became feasible on December 30 and an accumulated beam of up to 5 mA could be stored on December 31, 2014. The DC septum was replaced with an AC type in January, 2015.

Two 5-cell PETRA cavities were used to commission the storage ring in Phase I. The maximum stored current of 100 mA was achieved on March 26 after improvement of the RF feedback loop. Cleaning with synchrotron light (an accumulated beam dose up to 35 A.h before shutdown in April) could effectively improve the vacuum conditions for the commissioning in Phase II with superconducting RF (SRF) cavity modules.

During the commissioning period, the rules for radiation safety were strictly adhered to. In user mode the integrated dose should be less than 2 μSv per 4 h.

Before shutdown for the installation of the SRF and insertion devices (IDs) beginning in April, the hardware improvements, lattice characterization and system optimization etc. proceeded. Diagnostic and control systems played a major role during the commissioning stage [3,4,5]. We adopted middle-layer, high-level

Abstract

Stable multi-GeV electron beams were obtained in a laser plasma accelerator via precision control over capillary discharge plasma parameters and alignment. The plasma density was determined by measuring the group velocity of laser pulses propagated through the plasma channel. The channel depth was measured using laser centroid oscillations. Improved pointing control was achieved by accurate alignment of capillary angle and position. The pointing fluctuation was 0.6 mrad rms, which was comparable to the electron beam divergence. Simulations showed electron beams in reasonable agreement with experiment via strong self-focusing and injection into multiple plasma periods behind the laser pulse. These processes are strongly parameter dependent, reinforcing the need for precise plasma target control.

INTRODUCTION

Over the past decade laser plasma accelerators (LPAs) [1,2] have produced electron beams with energy $\gtrsim$ GeV using cm-scale plasmas [3–6], motivating their use for a wide range of light sources [7–12] and as a path towards a TeV-class linear collider [13,14]. For these and other applications it is important to reduce the laser pulse energy required to reach a given electron energy, since the size and cost of the LPA is dominated by the laser system. A preformed plasma channel can achieve this by mitigating diffraction of the laser beam and extending the acceleration length. In 2006, experiments with laser pulses of energy 2 J demonstrated the generation of electron beams with energy of 1 GeV using a preformed plasma channel [3]. Subsequently other experiments without preformed channels achieved electron beams with tails up to 1.45 GeV with laser energy a few times greater [4]. With the availability of petawatt class lasers, electrons were accelerated in non-preformed plasmas with energy up to 2-3 GeV using laser energy $\approx$ 100 J [5] and 25 J [6].

In this paper two electron acceleration experiments are presented. The first shows the generation of electron beams with energy up to 4.2 GeV using just 16 J of laser energy coupled to a preformed plasma channel [15]. As will be discussed, analysis of the beam parameters on input conditions was complicated by the electron beam angle fluctuation, and the limited angular acceptance of the magnetic spectrometer, which was between ±0.5 mrad and ±1.1 mrad, depending on electron beam energy and applied magnetic field. For the second experiment more accurate capillary alignment techniques were developed and the input laser pulses were spatially filtered to mitigate capillary damage. The electron beam pointing fluctuation was reduced to 0.6 mrad rms, which allowed for consistent observation of electron beams with full-width-half-maximum (FWHM) divergence < 1 mrad.

EXPERIMENTAL SETUP

In the experiments, laser pulses at a wavelength λ = 815 nm with bandwidth 40 nm were generated by the 1 Hz repetition rate Ti:sapphire-based BELLA (BErkeley Lab Laser Accelerator) petawatt laser [16]. The laser pulses were focused to a spot size of $w_0 = 52 \pm 2$ µm (Fig. 1) using an off-axis parabolic mirror with focal length of 13.5 m, where w_0 is defined as the radius at which the intensity decreased by $1/e^2$ of the peak value. The maximum total laser pulse energy delivered at the focal location was $\approx$ 16.6 J, as measured by a power meter inserted into the beam before the off-axis paraboloid. Typical pulse durations at optimum compression were $\tau_0 = 39 \pm 4$ fs (FWHM) as measured by a frequency resolved optical gating (FROG) system. The use of a deformable mirror and wavefront sensor enabled high focal spot quality (Strehl ratio 0.8 ± 0.1) and an associated normalized laser strength $a_0 \gtrsim 1.6$ for 16 J input energy, where $a_0 = 8.5 \times 10^{-10}\, \lambda\, [\mu\mathrm{m}] \sqrt{I_0 [\mathrm{W\,cm^{-2}}]}$ and I_0 is the peak intensity of the laser pulse.

The electron beam profile and position at 11.1 m from the exit of the plasma structure were measured using a calibrated phosphor screen imaged onto a CCD camera. The phosphor screen had field of view ±3 mrad, but only the center ±1 mrad of the electron beam passed through the hole in the optical wedge and power meter. Outside of this angle the electron beam passed through 46 mm of Aluminum and 81 mm of glass, which will approximately double the beam size on the phosphor screen for electron energy of 2 GeV and initial divergence 0.5 mrad. The electron beam energy and charge were measured using a 2.5 m-long magnetic spectrometer of design similar to the spectrometer used in Ref. [3].

As with previous experiments the laser was guided by a capillary discharge plasma channel [17–21] to maximize the electron energy gain [3,22]. In the present experiments the channel length was increased to 9 cm, and density lowered to between 6×10^{17} cm^{-3} and 11×10^{17} cm^{-3} to increase the acceleration length and electron beam energy. In addition the capillary diameter was increased to 500 µm to minimize damage from the increased laser pulse energy. The capillary discharge was operated with hydrogen using a current pulse of the form $I_{\max} \exp(1 - e^{-t/t_w} - t/t_w)$, where $I_{\max}$ = 250 A and t_w = 88 ns. The laser pulses arrived $\approx$ 30 ns after the peak of the current pulse. Two capillaries

SCALING DOWN SYNCHRONOUS ACCELERATION: RECENT RESULTS, CURRENT STATUS, AND FUTURE PLANS OF A SUBRELATIVISTIC DIELECTRIC LASER ACCELERATION PROJECT*

J. McNeur†, M. Kozak, A. Li, N. Schoenenberger, A. Tafel, P. Hommelhoff
Friedrich-Alexander-University, Erlangen, Germany
Max-Planck-Institut für die Physik des Lichts, Erlangen, Germany

Abstract

The current status of subrelativistic acceleration via optical-scale Dielectric Laser Accelerators (DLAs), with an emphasis on those developed and tested at Friedrich-Alexander University in Erlangen, Germany, is reviewed. This promising field of accelerators has demonstrated proof-of-principle results in multiple energy regimes and current efforts are moving towards developing miniaturized standalone relativistic electron sources. The near-term experiments necessary to reach this goal are detailed.

INTRODUCTION

Dielectric laser accelerators (DLAs) aim to leverage commerically available near-infrared and optical lasers and the well-developed field of dielectric nanofabrication to accelerate charged particles with gradients approaching 10 GeV/m [1]. DLAs operate under the same principle of synchronous acceleration employed by numerous RF linear accelerators worldwide and first theorized by Wideroe in 1928 [2]. This principle was adapted towards laser-use via inverse Smith-Purcell radiation [3] and inverse Cherenkov radiation [4] in the 1960s and the idea of introducing dielectrics was conceived in the 1990s [5, 6]. The field gradients from commerically available lasers and the breakdown thresholds of candidate DLA materials allow DLAs to both scale down in size and scale up in field gradient in comparison to their RF brethren [7].

Recent experiments have demonstrated the principle of dielectric laser acceleration of both subrelativistic (30 keV [8] and 100 keV [9]) and relativistic (60 MeV [10]) electron beams. The demonstration of acceleration of 30 keV electrons in Erlangen is documented in detail here. The future directions of the Erlangen DLA project, aimed towards development of a miniaturized standalone relativistic electron source, are then outlined.

THE SINGLE GRATING DLA

The specific geometry used to accelerate 30 keV electrons is the 'single grating DLA', a fused silica phase mask with grating teeth of periodicity on the order of the incident laser wavelength. It has been designed, fabricated and tested. A cross-section of this fused silica grating mask along with the longitudinal electromagnetic fields (of the accelerating mode) excited when the grating is struck by an incident laser, is shown in Figure 1. Although Figure 1 displays the third harmonic field pattern excited by the incident laser, all harmonics of this fundamental mode are excited, each with a phase velocity of $\frac{c\lambda_p}{n\lambda}$ where c is the speed of light, λ_p is the periodicity of the single grating, n is the order of the harmonic, and λ is the central wavelength of the incident laser. As described above, synchronous acceleration occurs if and only if the phase velocity of one of the excited harmonics matches the velocity of electrons traversing the near-field profile above the grating (travelling from left to right in Figure 1).

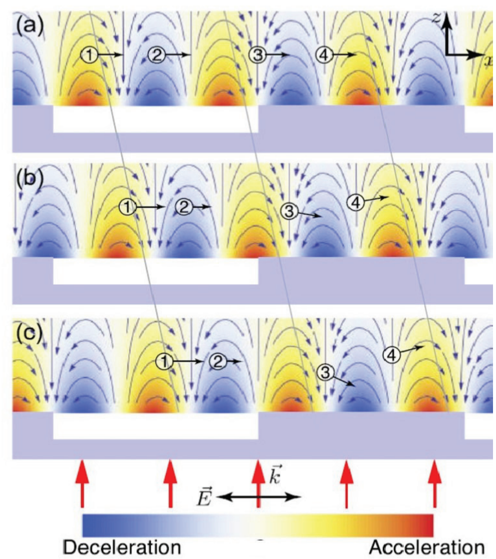

Figure 1: Three consecutive snapshots in time of the evolution of the third harmonic of the excited fields along with the evolution of four different injection phases corresponding to acceleration (1), deceleration (2) or deflection (3,4).

Two features of the field patterns in Figure 1 are of note (and described in more detail elsewhere [11]): 1) for an electron beam that samples all phases of the accelerating mode (such as the beam used in the experiment described below), half of the electron beam will see accelerating fields whereas half will see decelerating fields, and 2) only those electrons that are injected within the transverse evanescent decay length of the accelerating mode (within 200nm of the grating surface in the below experiment) will traverse fields of significant magnitude. The latter of these conditions then requires that the electron beam must be aligned to within 200nm of the grating surface. However, clipping of

CORRECTION OF NONLINEAR COUPLING RESONANCES IN THE SPRING-8 STORAGE RING

M. Takao*, K. Soutome, K. Fukami and Y. Shimosaki
JASRI/SPring-8, Hyogo, Japan

INTRODUCTION

At recent light source rings, the top-up operation, in which the beam is injected during the user experiments, is widely used to make up the short lifetime and to keep the current constant. Since the beam is injected in the magnet array gap of the insertion device closing, it is important to protect the insertion devices from the electron irradiation.

The injection efficiency decreases as the vertical scraper closing as shown in Fig. 1. This implies that, although the injected beam initially oscillating in horizontal direction with a large amplitude, the vertical spread of the injecting bean is generated by a coupling resonance [1–3].

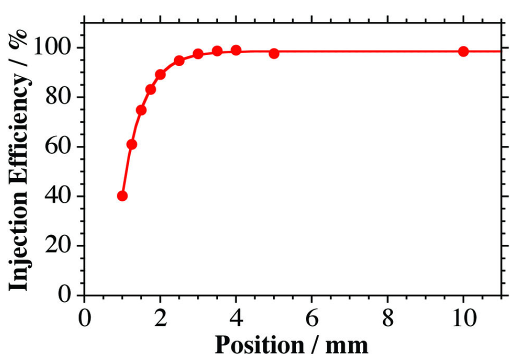

Figure 1: Injection Efficiency vs. Vertical Scraper position.

This is true for a particle scattered by Thouschek effect, i.e. the collision within a bunch. Figure 2 shows the typical dependence of the Touschek lifetime on the RF accelerating voltage. The electron scattered at the nonzero dispersion starts to oscillate in horizontal direction with an amplitude proportional to the momentum deviation. Although in low RF voltage the lifetime is limited by the longitudinal dynamics, it is dominated by the transverse dynamics in high RF voltage. Similar to the injection efficiency, the lifetime decreases as the vertical scraper closing, which implies that the coupling plays important role in beam loss mechanism [1–3].

At the spring-8 storage ring one of the insertion devices generates the strong coupling resonance, i.e. the skew octupole resonance, affecting the injection efficiency and the beam lifetime. Here we report the correction of the coupling resonance by using the skew octupole magnet. Furthermore, the simulation study for the improvement of the momentum acceptance by means of the skew sextupole magnet.

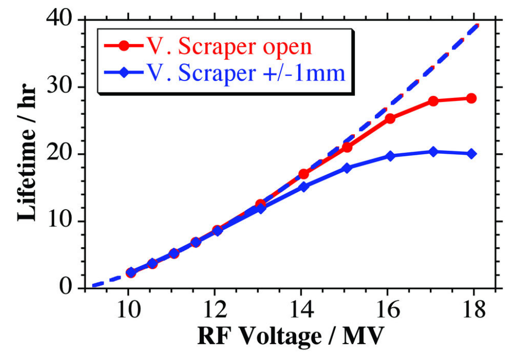

Figure 2: Lifetime vs. Vertical Scraper position.

COUPLING RESONANCE INDUCED BY AN INSERTION DEVICE

The insertion device ID07 of the SPring-8 is a special one composing of 8 figure-8 (4 horizontal and 4 vertical) undulators [4]. It is found that the vertical figure-8 undulator strongly excites the skew octupole coupling resonance so as to reduce the injection efficiency and the beam lifetime. Figure 3 shows the variation of the injection efficiency as the gap of ID07 closing under the condition of the vertical scraper gap 2mm. To emphasize the effect of the coupling resonance, we close the scraper to 2 mm. Since ID07 is out-vacuum undulator, the reduction is caused by the dynamical effect, i.e. the coupling resonance.

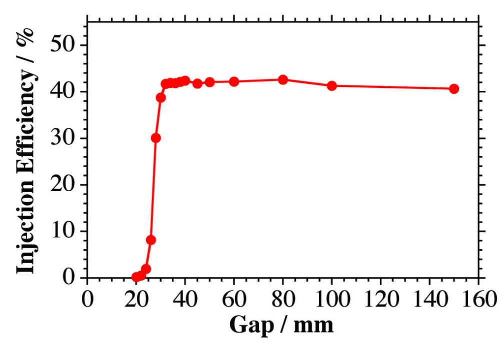

Figure 3: Injection Efficiency vs. ID07 gap.

To understand the dynamics, we measure the beam oscillation by using the turn-by-turn beam position monitor (BPM). We kick the stored single bunch beam to give a large amplitude like an injection beam by means of the bump magnet. Figures 4 show the beam oscillation with the initial amplitude 10 mm, which is a typical amplitude of the injection beam. The left (right) figure at the upper row shows the hor-

FIRST COLLECTIVE EFFECTS MEASUREMENTS IN NSLS-II WITH ID'S

A. Blednykh#, B. Bacha, G. Bassi, W. Cheng, J. Choi, Y. Hidaka, Y. Li, B. Podobedov, V. Smalyuk, T. Shaftan, T. Tanabe, G. Wang, F. Willeke, L.-H. Yu
BNL, NSLS-II, Upton, NY, 11973-5000, USA

Abstract

As another important milestone towards the final goal to store an average current of 500mA, the average current of 200mA, distributed within ~1000 bunches, was recently achieved in the NSLS-II storage ring after the installation of three Damping Wigglers and four In-Vacuum Undulators. First measurements of the collective effects and instability thresholds, both in single- and multi-bunch mode, are discussed.

INTRODUCTION

The new 3GeV NSLS-II storage ring is in operation with the first six beam-lines designed as a part of the project. The average current of 200mA within ~1000 bunches has been stored as another important milestone in intensity increasing with the final goal of 500mA. For the current lattice configuration with three damping wigglers (3DW's), two Elliptically Polarizing Undulators (EPU's) and four In-Vacuum Undulators (4IVU's) installed and one SC CESR-B 500MHz RF cavity with $V_{RF} = 1.78MV$ used for operation, the estimated RMS bunch duration at low current is $\sigma_s = 6mm$ with energy spread $\sigma_\varepsilon = 8.8 \times 10^{-4}$ (Bending Magnets (BM) + 3DW's). The RMS bunch duration, for the bare lattice with DW magnet gaps open, is $\sigma_s = 3.4mm$ with energy spread $\sigma_\varepsilon = 5 \times 10^{-4}$. Some key parameters for the collective effects beam studies are given in Table 1.

Table 1: NSLS-II Parameters for Collective Effects Studies

Energy, $E_0(GeV)$	3
Revolution period, $T_0(\mu s)$	2.6
Momentum compaction, α	3.7 x 10^{-4}
Energy loss, $U(keV)$	287 (BM) 674 (BM+3DW's)
RF voltage, $V_{RF}(MV)$	1.78
Synchrotron tune, ν_s	6.8 x 10^{-3}

SINGLE BUNCH

The stabilizing effect of positive chromaticity on the single bunch threshold current has been studied for a lattice with 3DW's and 4IVU's magnet gap closed (beamline operations). The single bunch current is limited due to the vertical Transverse Mode Coupling Instability (TMCI). The measured bunch current threshold is $I_{th} = 0.95mA$ at zero chromaticity (Fig. 1a), $I_{th} = 3.2mA$ at chromaticity $\xi_{x/y} = +5/+5$ (Fig. 2a) and $I_{th} = 6mA$ at chromaticity $\xi_{x/y} = +7/+7$. There is no significant effect on increasing the accumulated Single Bunch (SB) current up to chromaticity $\xi_{x/y} = +5/+5$. The horizontal tune shifts as a function of SB current (Figs. 1b, 2b) indicates a stronger effect of the broad-band quadrupole impedance due to installed 4IVUs, to be compared with the results for a bare lattice (w/o ID's) presented in [1], where the horizontal tune shifts were independent of the SB current.

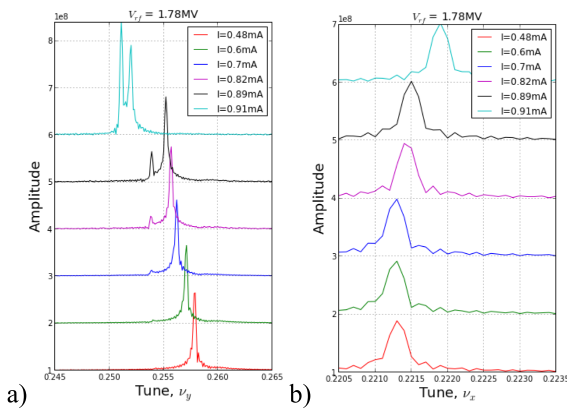

Figure 1: Chromaticity $\xi_{x/y} = 0/0$. All ID's gap closed.

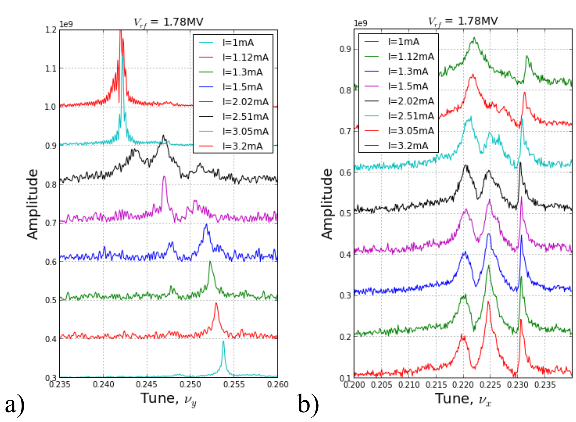

Figure 2: $\xi_{x/y} = +5/+5$. All ID's gap closed.

To adjust the linear chromaticity from zero to $+7/+7$, only the settings of the chromatic sextupoles have been changed. The injection efficiency was 50% at chromaticity $+7/+7$ without further lattice optimization. Betatron oscillations have been excited by kicking the bunch in both directions with horizontal and vertical pingers. The measured spectra (Figs. 1,2) from Turn-by-Turn (TbT) data are plotted with arbitrary offsets and

CHROMATICITY EFFECTS FOR SPACE CHARGE DOMINATED BEAMS IN THE CERN PS BOOSTER

V. Forte*, CERN, Geneva, Switzerland - Université Blaise Pascal, Clermont-Ferrand, France
E. Benedetto, F. Schmidt, CERN, Geneva, Switzerland

Abstract

In view of the LHC Injectors Upgrade (LIU) project, an extensive campaign is on-going in the CERN PS Booster (PSB) to study collective effects for the future operation with the 160 MeV injection from Linac4. In operation, the machine is running with uncorrected natural chromaticity. This paper focuses on the study of the effects of chromaticity on losses and beam blow-up.

INTRODUCTION

The CERN PS Booster is the first synchrotron in the LHC accelerator chain. In the framework of the LIU project, a campaign of renovations takes place to host the new H$^-$ injection energy of 160 MeV from Linac4, instead of the present 50 MeV proton injection from Linac2 [1]. The main physical reason for this change is the large incoherent space charge (s.c.) tune spread that presently limits the brightness of the beams (especially for those meant for the LHC). Through the Linac4 it will be possible to tailor the transverse and longitudinal emittances in the PSB to fit the requirements of the high-luminosity future LHC beams [2]. The purpose of this paper is to investigate the effects of the chromaticity in this machine in combination with space charge. To date, the PSB is always operated with the uncorrected natural chromaticities of (ξ_x = -0.8, ξ_y = -1.6). The chromatic detuning can be modulated via one family of 16 normal chromatic sextupoles, distributed one per period along the machine. This limitation leads to a coupled control of the horizontal and vertical chromaticities, as shown in Fig. 1.

The interaction between chromaticity and space charge will be taken into account for negative chromaticities, to avoid the development of coherent instabilities, since the PSB is operating below transition. At an energy of 160 MeV PSB experiments close to two different resonances are being discussed to underline the correlation between the incoherent space charge tune spread and the chromatic one. The simulations are being performed with the PTC-ORBIT code [3]. Lastly, a prediction for future LHC operations is being attempted for different chromatic conditions.

SPACE CHARGE AND CHROMATICITY

The space charge field has a defocusing effect in both the horizontal and vertical plane, see e.g. [4]. Each particle feels a s.c. detuning, which depends on the line density (protons/m) and the size of the transverse amplitudes. In addition to that, the chromaticity also induces a detuning

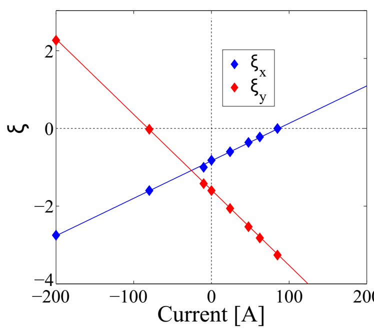

Figure 1: Measured vertical (red) and horizontal (blue) chromaticities vs. current [A] in the chromatic sextupoles.

which is proportional to the particle momentum offset Δp/p and the chromaticity ξ itself.

The particles in a bunch will in general feel both effects. Figure 2 shows the path of a particle with a large synchrotron amplitude, which goes from regions in which both the line density (s.c. component) and the momentum offset (chromatic component) are large, to the head or the tail of the bunch, in which the space charge tune shift is almost zero while the Δp/p can have a large excursion. In particular, one can consider three "branches" in its motion:

- AB - the space charge detuning is large. For positive Δp/p (and negative chromaticity, such as in the PSB) both effects are defocusing and they sum up;
- BC - in the vicinity of the bare tune, when the particle is sitting in the head or the tail of the bunch, the s.c. component is almost absent and the tune is moving on a line which slope depends on the ration between horizontal and vertical chromaticity;
- CD - the space charge component is large again, however for negative Δp/p, the chromatic detuning is positive, i.e. goes in the opposite direction with respect to the space charge one.

The orientation and the length of these three "branches" depends on the chromaticity value, on the synchrotron amplitude and on the particle actions in the horizontal and vertical plane, as explained in details in [5].

According to the chromatic working point, indeed, the entire tune footprint changes, as is shown in Fig. 3, and for the same bare tune it may or may not touch a given resonance line, e.g. the $3Q_y = 13$, in the case studied in this paper. Similarly to Fig. 2, Figure 4 analyses (in red) the different tune evolutions of particles performing large synchrotron oscillations, for different chromaticities: these particles are good candidates to be perturbed through the periodic resonance crossing mechanism [6].

CHARGE STRIPPER DEVELOPMENT FOR FRIB*

F. Marti#, P. Guetschow, FRIB, East Lansing, MI, USA
Y. Momozaki, J. A. Nolen, C. B. Reed, ANL, Argonne, IL 60439, USA
A. Hershcovitch, P. Thieberger, BNL, N.Y., USA

Abstract

The Facility for Rare Isotope Beams (FRIB) at Michigan State University is building a heavy ion linac to produce rare isotopes by the fragmentation method. The linac will accelerate ions up to U to energies above 200 MeV/u with beam powers up to 400 kW. At energies between 16 and 20 MeV/u the ions will be stripped to higher charge states to increase the energy gain downstream in the linac. The main challenges in the stripper design are due to the high power deposited by the ions in the stripping media (~ 30 MW/cm^3) and radiation damage if solids are used. For that reason self-recovering stripper media must be used. The baseline stripper choice is a high-velocity, thin film of liquid lithium with an alternative option of a helium gas stripper. We present in this paper the status of the R&D and construction of the final stripper. Extensive experimental work has been performed on both options.

INTRODUCTION

Michigan State University was charged by the Office of Science of the Department of Energy of the US to design and build the Facility for Rare Isotope Beams (FRIB) at the end of 2008. The facility is funded by the Office of Nuclear Physics with contributions and cost share from Michigan State University. The goal of the facility is the production of rare isotopes produced by the in-flight separation method. This method provides fast development time for any isotope and allows short lived isotopes to be available. The facility will provide fast, stopped and reaccelerated beams of secondary ions.

One of the main components of the facility is a driver linac capable of producing beams of ions from the low mass region up to U at energies above 200 MeV/u and with a total beam power on target of 400 kW [1]. The linac is folded in three segments running parallel to each other with two 180 degree bends in between. After the first segment linac and before the first bend a charge stripper is located to increase the Q/A of heavy ions by more than a factor two.

This paper describes the options considered for the charge stripper and the status of their design and construction.

CHARGE STRIPPER CHALLENGES

Traditional charge strippers in accelerators are designed utilizing thin films of solid materials, in many cases carbon [2]. The main difference between FRIB and accelerators that strip intense H^- beams is that even though the currents are lower in FRIB, the energy loss per ion per unit length is much higher for heavy ions than for protons (see Figure 1).

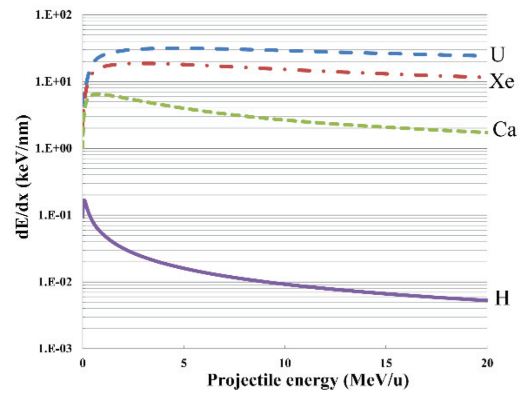

Figure 1: Comparison of the energy loss per unit length in carbon foils for some heavy ions and protons. A single U ion deposits three orders of magnitude higher power than a proton of the same velocity. Stripping energies at FRIB are between 16 and 20 MeV/u.

There appears to be a critical threshold in the linear energy deposition for the formation of tracks in graphite of the order of 7 keV/nm, with a track produced for every ion with energy above 18 keV/nm [3]. Heavy ions like Xe and U have a dE/dx higher than this threshold, while protons are much lower.

Besides the radiation damage, the thermal effects are also important. At the energies of the FRIB stripper the U beam would deposit about 30 MW/ cm^3 power densities in the carbon foil.

Given the above considerations we have looked at two options for the charge stripper, liquids and gases. Both can be made to survive the high power deposition and no lattice damage occurs.

OPTIONS

Liquid Lithium Stripper

A liquid lithium charge stripper was first proposed by J. A. Nolen [4] from Argonne National Laboratory (ANL). A fast moving film (~ 50 m/s) would be able to carry away the thermal energy deposited by the beam before reaching high temperatures (below boiling). Lithium has some very attractive properties when used as stripping media, it has a very low vapor pressure at the melting temperature (181 C and 1.5 10-9 Torr) compared with other potential liquids like mercury (2 mTorr at room temperature). It has a high boiling point (1342 C) and it

THE ACCELERATOR FACILITY OF THE FACILITY FOR ANTIPROTON AND ION RESEARCH

Oliver Kester#, Peter Spiller, Frank Becker, Oleksiy Dolinskyy, Lars Groening, Klaus Knie, Hartmut Reich-Sprenger, Wolfgang Vinzenz, Martin Winkler
GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany
Dieter Prasuhn, Forschungszentrum Jülich, Germany

Abstract

The accelerators of the facility for Antiproton and Ion Research – FAIR are under construction. The very sophisticated system of accelerators is designed to produce stable and rare isotope beams with a significant variety of intensities and beam energies. FAIR will explore the intensity frontier of heavy ion accelerators and the ion and antiproton beams for the experiments will have highest beam quality for cutting edge physics to be conducted. The main driver accelerator of FAIR will be the SIS100 synchrotron. In order to produce rare isotope beams (RIB), which are several orders of magnitude more intense compared to beams provided by existing RIB facilities, a unique superconducting fragment separator is under construction. A system of storage rings will collect and cool secondary particles from the FAIR. As the construction of the FAIR accelerators and the procurement has started, an overview of the designs, procurements plans and infrastructure preparation can be provided.

INTRODUCTION

The FAIR facility in the Modularized Start Version (MSV) [1] will consist of six circular accelerators (SIS18, SIS100, CR, HESR, ESR and CRYRING), of two linear accelerators (p-Linac, UNILAC) and of about 1.5 kilometres of beam lines see Fig. 1. The existing GSI UNILAC-SIS18 accelerators will serve as injector to the FAIR SIS100 synchrotron. GSI is in charge of the SIS100, the HEBT, Super-FRS and the overall technical coordination of the FAIR accelerator complex. Many systems are constructed in consortia with international partners. The Research Centre Jülich will build the HESR - High Energy Storage Ring - for the research with high-energy antiprotons using the PANDA detector; BINP Novosibirsk takes care of the construction of the collector ring CR.

The driver accelerator of FAIR is the fast ramping, superconducting heavy ion synchrotron - SIS100 - that allows the acceleration of the most intense beams of stable elements from Protons (30 GeV) to Uranium (10 GeV/u) [2]. The FAIR driver accelerator will provide high energy/ high intensity proton and heavy ion beams to the various experimental stations. The CBM- Plasma- and Biomat-experiments are directly supplied with primary beams from the SIS100. Two target stations for the generation of secondary beams (pbar and RIBs) allow the conversion of primary ions into secondary particles.

#o.kester@gsi.de

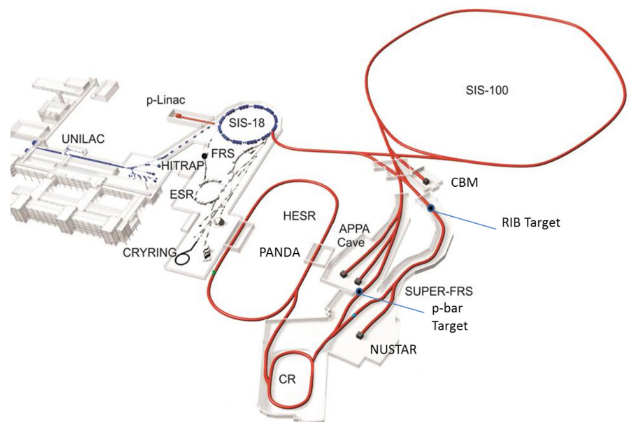

Figure 1: Overview of the GSI and the FAIR accelerator facility.

The Super-FRS will be the most powerful in-flight separator worldwide for exotic nuclei up to relativistic energies. Rare isotopes of all elements up to uranium can be produced and spatially separated within some hundred nanoseconds, thus very short-lived nuclei can be studied efficiently. The Super-FRS is a large-acceptance superconducting fragment separator with three branches serving different experimental systems. The accelerator facility is complemented by a system of storage rings. The main task of the collector ring (CR) is stochastic cooling of radioactive ions or antiproton beams from the production targets. In addition, this ring offers the possibility for mass measurements of short-lived ions, by operating in isochronous mode. The high-energy storage ring (HESR) is optimized for antiprotons of energy up to 14 GeV. This ring will operate with an internal target and associated detector set-up (PANDA).

OPERATION SCENARIOS

The main system parameter of the FAIR accelerators shown in Table 1, are the basis for the operation of the facility. The following typical operation scenarios of the FAIR accelerator facility are foreseen:

A) High intensity, high energy proton beams at energies up to 29 GeV: The proton linac injects protons into the SIS18 at 70 MeV beam energy, which will then be accelerated to 4 GeV in the SIS18. Merging of four proton bunches from SIS18 into a single bunch and subsequent compression into a 50 ns pulse for acceleration up to 29 GeV is accomplished in the SIS100. Thereby a single bunch of up $2*10^{13}$ protons will be delivered to the anti-

RECENT PROGRESS OF J-PARC RCS BEAM COMMISSIONING - TOWARD REALIZING THE 1-MW OUTPUT BEAM POWER

Hideaki Hotchi for the J-PARC RCS beam commissioning group
J-PARC center, Japan Atomic Energy Agency, Tokai, Naka, Ibaraki, 319-1195 Japan

Abstract

J-PARC RCS is now in the final beam commissioning phase aiming for the design output beam power of 1 MW. This paper presents our approaches to beam loss issues that we faced on the process of the beam power ramp-up toward 1 MW.

INTRODUCTION

The J-PARC 3-GeV Rapid Cycling Synchrotron (RCS) is the world's highest class of high-power pulsed proton driver aiming at the output beam power of 1 MW [1]. The injector linac delivers a 400-MeV H^- beam to the RCS injection point, where it is multi-turn charge-exchange injected through a 350-μg/cm^2-thick HBC stripping foil over a period of 0.5 ms. RCS accelerates the injected protons up to 3 GeV with a repetition rate of 25 Hz, alternately providing the 3-GeV proton beam to the Material and Life Science Experimental Facility and to the 50-GeV Main Ring Synchrotron by switching the beam destination pulse by pulse.

Recently the hardware improvement of the injector linac has been completed, by which the injection energy was upgraded from 181 MeV to the design value of 400 MeV in 2013, and then, the injection peak current was upgraded from 30 mA to the design value of 50 mA in 2014. In October, 2014 after completing these series of injector linac upgrades, RCS started the final stage of beam commissioning aiming for the design output beam power of 1 MW. This paper presents our approaches to beam loss issues that we faced on the process of the beam power ramp-up toward 1 MW.

550-kW BEAM TEST CONDUCTED AFTER THE INJECTION ENERGY UPGRADE (RUN#54)

In April, 2014 (Run#54), RCS conducted a 550-kW high intensity beam test with the upgraded injection energy of 400 MeV, using a 0.5 ms-long injection pulse with a peak current of 24.6 mA and a chopper beam-on duty factor of 60%. In this beam test, the operating point was set at (6.45, 6.42), where systematic beam loss measurements were performed with various injection painting parameters, and compared with the old data taken with the lower injection energy of 181 MeV.

In order to minimize space-charge induced beam loss, RCS employs injection painting for both transverse and longitudinal phase spaces [2]. On the transverse plane, correlated painting with a painting emittance of 100π mm mrad (ε_{tp}) was applied in this beam test. On the other hand, for longitudinal painting [3,4], the momentum offset injection of 0.0, −0.1 and −0.2% (Δp/p) was tested in combination with superposing a 2nd harmonic rf with an amplitude of 80% (V_2/V_1) of the fundamental rf. As an additional control in longitudinal painting, the phase sweep of the 2nd harmonic rf was also employed during injection from −100 to 0 degrees (ϕ_2) relative to that of the fundamental rf.

Painting parameter ID

Parameter ID	ϵ_{tp} (π mm mrad)	V_2/V_1 (%)	ϕ_2 (degrees)	$\Delta p/p$ (%)
1	–	–	–	–
2	100	–	–	–
3	–	80	−100	–
4	–	80	−100	−0.1
5	–	80	−100	−0.2
6	100	80	−100	–
7	100	80	−100	−0.1
8	100	80	−100	−0.2

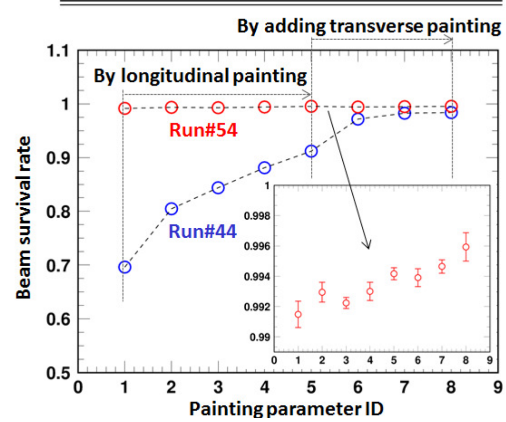

Figure 1: Beam survival rates measured with various combinations of transverse and longitudinal painting (IDs 1 to 8), where the red circles correspond to the data taken with the upgraded injection energy of 400 MeV with a beam intensity of 553 kW, while the blue ones are the old data taken with the lower injection energy of 181 MeV with a similar beam intensity of 539 kW.

Figure 1 shows the beam survival rates measured with various combinations of transverse and longitudinal painting (IDs 1 to 8). In this figure, the red circles correspond to the data taken in this beam test with a beam intensity of 553 kW (4.60×10^{13} ppp), while the blue ones are the old data (Run#44 in November, 2012) taken with the lower injection energy of 181 MeV with a similar beam intensity of 539 kW (4.49×10^{13} ppp). As shown by the blue circles, the larger parameter dependence was observed for the lower injection energy of 181 MeV, since the space-charge effect is more critical. In this case, 30%-big beam loss appeared with no painting. But, this beam loss was drastically decreased from ID 1 to ID 5 by longitudinal painting, and from ID 5 to ID 8 by adding

BEAM INSTRUMENTATION AND DIAGNOSTICS FOR HIGH LUMINOSITY LHC

R. Jones, E. Bravin, B. Dehning, T. Lefevre, H. Schmickler, CERN, Geneva, Switzerland

Abstract

The extensive array of beam instrumentation with which the LHC is equipped, has played a major role in its commissioning, rapid intensity ramp-up and safe and reliable operation. High Luminosity LHC (HL-LHC) brings with it a number of new challenges in terms of instrumentation that will be discussed in this contribution.

INTRODUCTION

The following sections will describe the main beam instrumentation and diagnostic developments underway or foreseen as part of the High Luminosity Upgrade Project of the LHC, HL-LHC [1].

BEAM LOSS MEASUREMENT

Monitoring of beam losses is essential for the safe and reliable operation of the LHC. While the existing system [2] is believed to meet the needs of the HL-LHC for the arc regions, this will no longer be the case for monitors in the high luminosity interaction points, and for monitors located in high radiation areas.

Beam Loss Monitors for the Triplet Magnets

The HL-LHC high luminosity insertions region magnets will be subjected to an enhanced continuous radiation level due to the increase in collision debris resulting from the higher luminosity. With the presently installed configuration of ionisation chambers in this region, outside of the cryostats, the additional signal from any quench provoking accidental loss would be completely masked by that coming from collision debris.

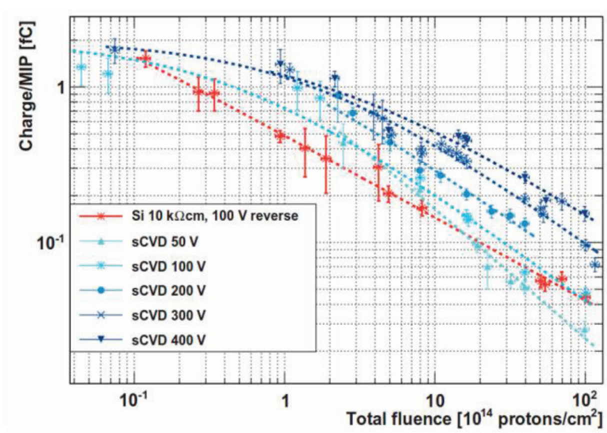

Figure 1: Charge collection efficiency for silicon and diamond detectors with increasing radiation fluence in a cryogenic environment.

The option of placing radiation detectors inside the cryostat of the triplet magnets as close as possible to the superconducting coils is therefore under study. The dose measured by such detectors would correspond more precisely to the dose deposited in the coils, which ultimately sets the quench level. Three detectors have been investigated as candidates for operation in a high radiation, cryogenic environment [3]: single crystal chemical vapour deposition (CVD) diamond; p+-n-n+ silicon wafers; liquid helium ionisation chambers.

Irradiation at cold up to several Mega-Gray showed a degradation of the charge collection efficiency by a factor of 15 in both CVD diamond and silicon (Fig. 1). The major downside of silicon compared to diamond at room temperature, its much higher leakage current when irradiated, is seen to disappear at liquid helium temperatures. Tests of detectors mounted inside the cryostats of existing LHC magnets are currently ongoing with the aim of gaining experience with the long term performance of such detectors under operational conditions.

Radiation Tolerant Beam Loss Monitor ASIC

The quench levels estimated for 7 TeV running are, for some detectors, very close to the noise level of the acquisition system. The noise is mainly determined by the length of cable required to bring the signal from the radiation hard detector to the less radiation tolerant front-end electronics. Development has started to implement this electronics in a radiation hard Application Specific Integrated Circuit (ASIC). This ASIC is still based on the current to frequency conversion used in the existing system, but packaged in a compact, radiation-tolerant form with an increased dynamic range (Fig. 2). The technique employed allows the digitisation of bipolar charge over a 120dB dynamic range (40fC - 42nC) with a 40µs integration time and an adjustable, temperature compensated conversion current reference [4].

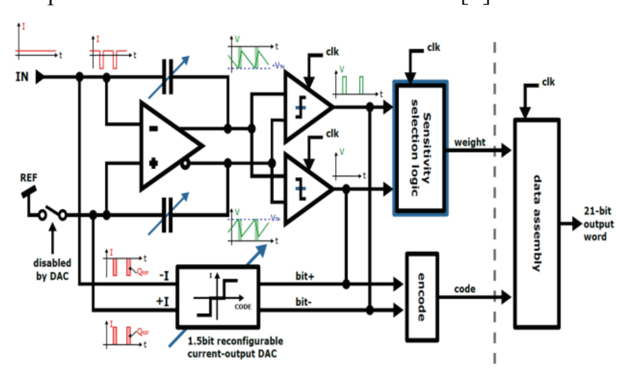

Figure 2: Schematic of the BLM ASIC implementation.

Total Ionizing Dose (TID) effects have been investigated using an X-ray beam with 20 keV peak energy. The characteristics of the device were measured

WIDEBAND VERTICAL INTRA-BUNCH FEEDBACK AT THE SPS - 2015 RESULTS AND PATH FORWARD*

J.D. Fox, J. Dusatko, C. Rivetta, O. Turgut,
Stanford Linear Accelerator Center Stanford, CA USA
W. Hofle, U. Wehrle CERN Geneva, Switzerland
S. De Santis LBL Berkeley, CA USA

Abstract

We present experimental measurements taken from CERN SPS machine development studies with a wideband intra-bunch feedback channel prototype. The demonstration system is a digital processing system with recently installed wideband kicker and amplifier components. This new hardware extends the bandwidth up to 1 GHz and allows driving and controlling multiple vertical transverse modes in the bunch. The studies are focused on driving the bunch with spectrally controlled signals to identify a reduced model of the bunch dynamics and testing model-based feedback controllers to stabilize the bunch dynamics. The measurements are structured to validate reduced MIMO models and macro-particle simulation codes, including the dynamics and limits of the feedback channel. Noise effects and uncertainties in the model are evaluated via SPS measurements to quantify the limits of control techniques applied to stabilize the intrabunch dynamics.

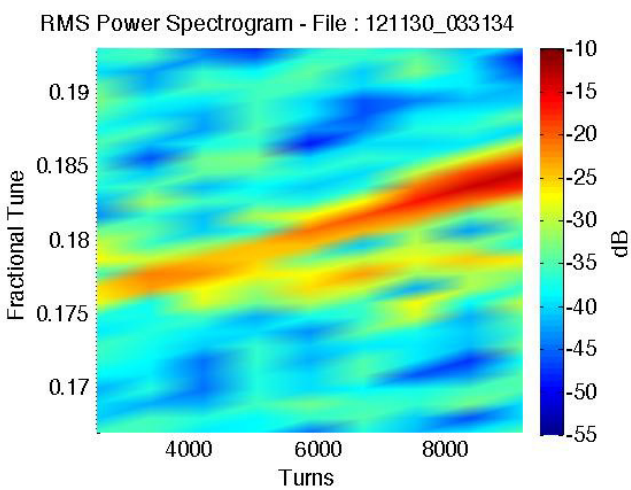

Figure 1: Open-loop vertical beam response chirp spectrogram measurement (no feedback). A 16 sample modulated excitation is driven by the kicker unto the SPS beam for 10,000 turns. The chirp excitation passes through the mode zero tune of 0.177 at turn 4000, and then the mode 1 upper synchrotron sideband at turn 8000 (Q20 lattice). The color code shows the amplitude of the motion for the detected signal.

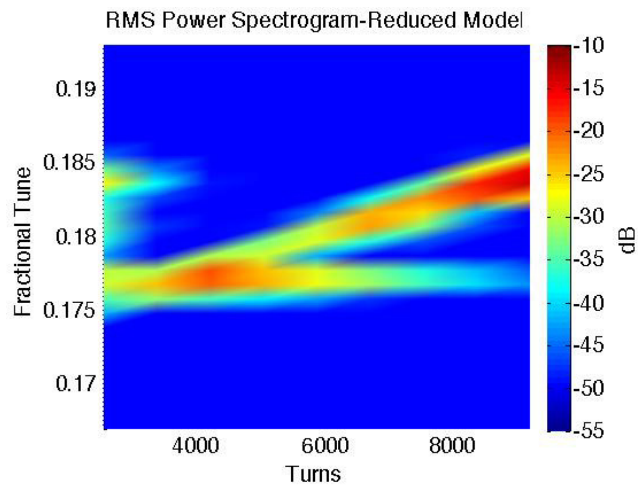

Figure 2: Beam motion spectogram response for the reduced beam model (same excitation as Figure 1). Comparing with the physical measurement we see very close agreement between the oscillation frequencies and the amplitudes of the excited motion.

EVALUATING THE UPGRADED SYSTEM PERFORMANCE

A single-bunch wideband digital feedback system was initially commissioned at the CERN SPS in November 2012[1]. The project is part of a larger LHC injector upgrade[2]. In 2014 during the shutdown interval this system has been expanded with installation of wideband kickers and associated RF amplifiers[3]. While the original bandwidth-limited system achieved control of mode zero and mode 1 unstable beams, we must explore the achieved performance of the wideband kickers, and understand necessary capabilities to control beam conditions anticipated in the HL operating scenario. Our goal in testing the demonstration system is to validate the performance as achieved, and using simulation tools predict behavior for high-current and HL upgraded injector conditions. We cannot expect the limited-function Demonstration System to have the capability of the final system, instead we want to confidently predict the behavior and margins of a more complex full-featured system. To do this, we need methods to simulate realistic future beam conditions interacting with possible feeback systems, and methods to compare the behavior of the Demonstration system and beam against simulations. In this near term we must study the system under a sub-set of HL beam conditions, and validate that our

OPTIMIZATION OF BEAM LOSS MONITOR NETWORK FOR FAULT MODES*

Z. Liu#, D. Liu, S. Lidia, Z. He, Q. Zhao, FRIB, East Lansing, MI 48824, USA

Abstract

Beam Loss Monitoring (BLM) System is an essential part to protect accelerator from machine faults. Compared with the empirical or uniform BLM arrangement in most accelerators, our new optimization approach proposes a “minimum spatial distribution” for BLM network. In this distribution, BLMs shall be placed at a small set of “critical positions” that can detect all failure / FPS trigger-able events of each fault mode. In additional, to implement a more advanced function of fault diagnosis, BLM should also be placed at “discrimination points” for fault-induced loss pattern recognition. With examples of FRIB failure event simulations, the author demonstrates the proof of concept to locate these “critical positions” and “discrimination points” for the minimum spatial distribution of BLMs.

INTRODUCTION

As an essential part of Machine Protection System (MPS) input, the BLM system plays an important role to detect and diagnosis machine faults. This imposes categorized functional requirements for BLM system. For example, the fault detection requires BLM device to have fast response for big losses, while the fault diagnosis requires BLM device sensitive enough to diagnose issues with beam tuning/slow losses and able to differentiate between controlled and uncontrolled losses. These requirements determine the type and structure of BLM system, e.g., FRIB BLM system including fixed position Halo Monitor Ring, BCM and movable radiation detectors. In this paper, we are not going to discuss the structural determination of BLM system, instead, we will focus on the spatial optimization of a pre-assumed BLM system.

Our goal of spatial optimization for fault detection is to minimize the number of BLMs while still be able to detect all Fast Protection System (FPS) trigger-able failure events that generate significant losses. To achieve this, we need to quantify correlations between BLM locations for classes of events, so that at least one BLM at the “critical positions” can trigger FPS when a component-failure event induces significant losses. Section 2 introduces the methodology to find the ensemble of “critical points”, with the simulation example of single cavity failures.

Fault diagnosis, or loss pattern recognition, is a more advanced functional requirement for BLM network. It was typically determined empirically at most accelerators. To prepare for loss pattern recognition, we need to put detectors at “discrimination points” that can distinguish patterns. Section 3 shows how to identify discrimination points for a fault mode with the principal component analysis (PCA) [1] method.

CRITICAL POSITIONS

As the first goal of spatial optimization for BLM network, we are looking for a set of “critical positions”, where at least one BLM can trigger FPS when a failure event induces over-threshold losses.

Example Fault Mode Simulation

In order to demonstrate the methodology to find “critical positions”, we simulated loss distributions of single cavity quenching events. In the simulation, every accelerator element in the FRIB lattice was considered a loss point. In total there are 572 element/loss points in FRIB lattice. To simulate cavity failure event, we turned off one cavity’s voltage and phase completely, did particle tracking and simulated particle loss power with IMPACT [2]. By turning off the 332 accelerating and bunching cavities one by one, we got 241 loss distributions. The other 91 cavities are in the high energy part, where transverse emittance growth from longitudinal mismatch takes longer distance and therefore the failures do not necessarily generate losses.

Using the same terminology in Statistics, the loss positions are “variables” or “dimensions”, and the cavity failure are “observations”. The loss matrix for single-cavity-failure mode is therefore 572 variables × 241 observations.

Correlation Matrix

As we mentioned in the introduction, the “critical positions” are defined based on quantifying correlations between BLM locations, i.e. loss points, for classes of failure events. If a group of adjacent loss positions are highly correlated with each other in positive direction, they can be considered as a “localized loss area” and only one BLM needs to be placed there.

To quantify the “localized loss area”, we need to compute the correlation matrix $R_{n\times n}$ for matrix $X_{m\times n}$, whose element $R(i,j)$ is the correlation coefficient of i$^{\text{th}}$ column and j$^{\text{th}}$ column:

$$R(i,j) = \frac{Cov(X_i,X_j)}{\sigma(X_i)\cdot\sigma(X_j)}\,.$$

$cov(X_i,X_j)$ is the covariance of the i$^{\text{th}}$ and j$^{\text{th}}$ column/loss position, and $\sigma(X_i)$ is the standard deviation of i$^{\text{th}}$ column. In our case for beam loss monitoring, we

Abstract

The Compact Energy Recovery Linac (cERL) is a superconducting test accelerator aimed at establishing technologies for the ERL-based future light source. After its construction during 2009 to 2013, the first CW beams of 20 MeV were successfully transported through the recirculation loop in February 2014. In the autumn of 2014, we installed a laser Compton scattering (LCS) system which can provide high-flux X-ray to a beamline. We report our progress in the cERL including recent advances in beam tuning, an increase in the beam current, and successful commissioning of the LCS system.

INTRODUCTION

Superconducting (SC) linacs can provide both low-emittance and high average-current electron beams that are very useful for producing ultra-brilliant X-rays [1] or for driving X-ray free-electron lasers in continuous wave (CW) operation [2]. In Japan, we have been conducting R&D effort for the ERL-based synchrotron light source [3]. To demonstrate critical technologies for the ERL-based light source, we constructed the Compact ERL (cERL). The principal parameters of cERL are given in Table 1.

Figure 1 shows the statistics of beam operation time (that is, the time while the beam was on) during FY2013-2014. The first CW beams of 20 MeV were successfully transported through the recirculation loop in February 2014 [4,5]. After the commissioning, various accelerator studies have been carried out. They include an establishment of start-up tuning, correction of beam optical functions, study on beam losses [6], and measurements of beam emittances in a recirculation loop. Some of the results of these studies are reported in the next section.

Table 1: Principal Parameters of the cERL

	Design	In operation
Beam energy	35 MeV	20 MeV
Injector energy	5 MeV	2.9 - 6 MeV
Normalized emittance	0.1 µm·rad@7.7 pC 1 µm·rad@77 pC	under study
Beam current	10 mA	80 µA

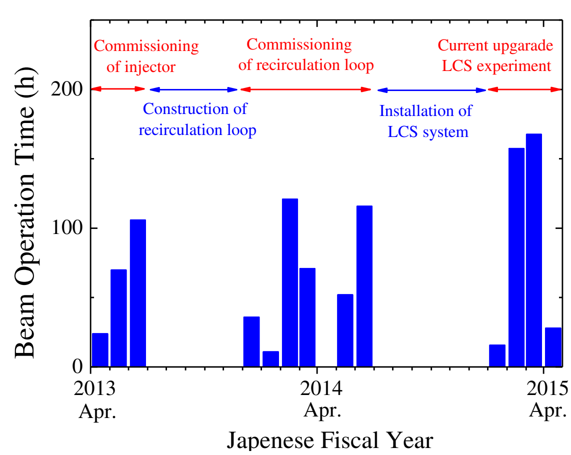

Figure 1: Statistics of beam operation time per month.

MULTI-GHz PULSE-TRAIN X-BAND CAPABILITY FOR LASER COMPTON X-RAY AND γ-RAY SOURCES*

D. J. Gibson†, G. G. Anderson, S. G. Anderson, R. A. Marsh, M. J. Messerly, M. A. Prantil, C. P. J. Barty, LLNL, Livermore, CA 94550, USA

Abstract

A wide variety of light-source applications would benefit from increased average brightness, which generally corresponds to increasing average current in the driving accelerator. Presented is an accelerator architecture that is capable of producing hundreds of electron bunches, spaced as close together as every RF cycle, which provides the chance to increase current while maintaining beam quality. This system relies on an X-band photoinjector and a photoinjection drive laser that is driven by the same rf source to ensure synchronization, and an interaction laser system designed to match the duty cycle of the electron pulse train. Results of the photoinjector laser performance and initial experimental measurements of beam quality in accelerated bunch trains are presented, along with a discussion of the impact on the performance of tunable, narrow-bandwidth x-ray and γ-ray beams based on Compton-scattering.

INTRODUCTION

While some photonic applications, such as time resolved imaging, require a large number of photons in a short time (i.e. a high peak brightness), many applications (medical imaging, nuclear resonance fluorescence measurements, material assay, etc.) don't have such a stringent requirement and can benefit from increasing not only the peak brightness of the source, but also the average brightness.

In a Compton-scattering based source, a high intensity laser beam scatters of a high brightness electron beam and generates x-rays with an energy of

$$E_\gamma = \frac{2\gamma^2 (1 - \cos\varphi)}{1 + \gamma^2\theta^2} h\nu$$

ignoring recoil, where γ is the electron Lorentz factor, φ is the incidence angle between the electrons and photons, θ is the observation angle relative to the electron direction of travel, and ν is the laser frequency. Properly apertured, such a beam can provide a very narrow bandwidth, easily tunable x-ray or γ-ray source. The number of scattered x-rays depends on the overlap integral between the laser and electron beam and therefore is a function of electron and photon density. To increase the flux from an electron bunch, the options include: focusing the beam harder, which increases the angular spread and therefore broadens the bandwidth; increase the charge, which will increase the beam emittance, with a similar result on the spectrum; or increase the laser energy, which is limited by the introduction of nonlinear scattering effects with also broaden the beam bandwidth.

As has been discussed elsewhere [1], very little of the laser energy is used in the scattering process. Sending more electron bunches, rather than more electrons in a single bunch, can make efficient reuse of the unscattered laser photons. This is the motivation for putting electrons into every accelerating RF bucket, increasing in the average current of between 10x and 100x and resulting in a comparable increase in x-ray flux. Accomplishing this in practice requires a photoinjector-based accelerator architecture capable of pumping energy into the electrons without inter-bunch wakefield effects destroying the beam, a photoinjection laser system capable of generating precisely timed multi-GHz pulses to generate the electrons, and an interaction laser designed to interact with a train of pulses, rather than a single pulse.

DRIVE LASER

The architecture for a laser capable of generating a multiple-GHz pulse train is described in detail in Ref. [2]. The 11.424 GHz RF that drives the accelerator is frequency divided to 5.712 GHz and used to an electro-optic modulator. A 1040-nm cw laser pulse passes through the modulator and is carved into an 11.424 GHz pulse train. This pulse train then passes through a series of amplifiers and acousto-optic modulators, resulting in 50 ns bursts of pulses at a 28 kHz repetition rate with 150 mW of average power. This beam then passes through 300 m of single mode optical fiber, where self phase modulation generates bandwidth with a nearly linear chirp on the individual pulses. These chirped pulses then pass through a large-mode-area photonic crystal fiber and a small grating pair compressor, resulting in a laser with 5 μJ per micropulse, 500 micropulses per burst, and a 28 kHz burst rate.

To allow accelerator demonstration in parallel with laser development, an Amplitude Ti:Sapphire laser system is used in place of the multi-GHz system. Up to 20 mJ of uncompressed 780 nm laser light at 10 Hz is transported to the accelerator hall, where the pulses are compressed to 200 fs and frequency tripled to 260 nm. In order to generate multiple pulses, a hyper-Michelson pulse stacker [3] is used. Tests to date have been conducted with four pulses, but up to 16 can be generated with the exisiting system hardware. The beam is then apertured to provide a sharp radial edge, typically with a 0.5 mm diameter, but other diameter are available. The apertured beam is then relay imaged to the photoinjector cathode, providing typically 10 μJ per pulse in the UV.

RECENT RESULTS FROM FEL SEEDING AT FLASH*

Abstract

The free-electron laser facility FLASH at DESY operates since several years in SASE mode, delivering high-intensity FEL pulses in the extreme ultraviolet and soft x-ray wavelength range for users. In order to get more control of the characteristics of the FEL pulses, external FEL seeding has proven to be a reliable method to do so. At FLASH, an experimental setup to test several different external seeding methods has been installed since 2010. After successful demonstration of direct seeding at 38 nm, the setup is now being operated in HGHG and later in EEHG mode. Furthermore, other studies on laser-induced effects on the electron beam dynamics have been performed. In this contribution, we give an overview of recent experimental results on FEL seeding at FLASH.

INTRODUCTION

Fully coherent radiation in the extreme ultra-violet (XUV), soft-, and hard X-ray spectral range is highly demanded for a variety of scientific fields. In combination with the demand for highest spectral brightness, this lead to the development of free-electron lasers (FEL) [1–4]. These devices have been operated for more than a decade using the principle of self-amplified spontaneous emission (SASE) [5, 6]. In this operation mode, the FEL radiation has a high degree of transverse coherence but it suffers from a poor longitudinal coherence due to the stochastic shot-noise, which is the startup source for the SASE amplification process. In contrast to that, an external seed source which initiates the FEL process allows to maintain the good coherence properties of the seed. Two different schemes for FEL seeding have been proposed and demonstrated in the past: Firstly those, which manipulate the electron bunch distribution such that a strong microbunching is created at the seed wavelength. The harmonic content of the density modulation is able to drive the FEL at high harmonics as in the high-gain harmonic generation (HGHG) [7] and the echo-enabled harmonic generation (EEHG) [8] operation modes. Secondly those, which initiate the FEL process directly at the target wavelength. Seed sources are either a high-harmonic generation (HHG) [9] source driven by conventional lasers (HHG seeding) [10] or a SASE FEL with a subsequent monochromator in so-called self-seeding schemes [11].
