# Foreword

The XXIV International Linear Accelerator Conference, LINAC08, was hosted by TRIUMF and took place during the week of September 29th to October 3rd, 2008 at the Conference Centre in the Canadian city of Victoria, British Columbia. This conference provided a unique opportunity for linear accelerator specialists from around the world to interact professionally and culturally in a relaxed and inspirational atmosphere. Attendance at the conference is by invitation. The large response to the invitations, the quality of the papers and presentations, the participation of many young researchers, the variety of exhibitors and the number of sponsorships all indicate an ongoing and diverse vitality within the Linac community throughout the various world regions.

The venue for the conference was the Victoria Conference Centre and the historic Fairmont Empress Hotel, both located at the heart of the City of Victoria. In order to encourage informal interactions among the delegates, breakfast and lunch were provided in the exhibition floor of the conference centre.

The conference registrations (including the students) totalled 353 from 17 different countries. In addition there were 28 exhibitors with 49 registrations. The conference staff (including the editorial team) totalled 25. Twenty-three students who presented posters at a special session on Sunday were sponsored from conference revenues. These proceedings include 347 of the 382 contributions presented at LINAC08.

Papers were processed during the conference by editors from the JACoW collaboration, under the local leadership of the proceedings coordinator Martin Comyn. We would like to thank the JACoW collaboration for supporting the conference with their well-trained, professional staff. After the conference, Martin together with Jana Thomson and Lorraine King prepared the processed papers for publication. Significant contributions came from Volker Schaa who aided Martin in preparing the proceedings for upload to the JACoW site www.JACoW.org. We apologize for the delay in the circulation of these proceedings; the preparations for the PAC09 conference hosted by TRIUMF proved to be somewhat overwhelming.

One of the goals of the conference programme was to highlight, where possible, young researchers in the field. To this end the conference was opened by Marco Marchetto, a young accelerator physicist from TRIUMF who gave an overview talk on the TRIUMF present and future linear accelerators. In addition, twenty-three students presented their work at a special poster session at the Sunday reception. The winner of the poster session, Joshua Wilson, with his research on twisted waveguides, gave an excellent presentation of his work during the oral programme. There were many significant contributions during the conference from all areas of the linac community. A highlight from the electron community was the progress report on the X-FEL project which promises to be the flag bearer for electron machines over the coming years. The machine is a tremendous technical and industrial challenge and will give the most significant data to date for mass cavity production and performance in the lead up to an ILC decision. On the hadron front there were performance talks from SNS and J-PARC as well as project status presentations from SARAF and SPIRAL-II and future projects Project-X and IFMIF. Several excellent overview presentations summarized the many technical achievements of the community over the last few years. Reports from the fields of laser and plasma acceleration were truly inspiring. The conference was closed by an illuminating address by Nigel Lockyer, Director of TRIUMF, on the significance of the on-going search for the Higgs Boson.

The cultural programme included a reception at the Royal British Columbia Museum where guests were officially welcomed by the City of Victoria and given an opportunity to sample some of the traditional food of the region, a sea excursion to observe first-hand the local whales in their natural habitat and a visit to the spectacular Butchart Gardens. The conference concluded with an opportunity for registrants to visit the TRIUMF laboratory in Vancouver.

The local organizing team under the leadership of Amiya Mitra and the conference coordination under the leadership of Sandi Miller managed the conference logistics professionally.

We wish to thank delegates, exhibitors, students and staff for making this conference a rewarding experience.

# ISAC-II OPERATION AND FUTURE PLANS

M. Marchetto, TRIUMF, Vancouver, BC V6T 2A3, Canada

*Abstract*

The ISAC-II superconducting heavy ion linac now accelerates radioactive ion beams with the highest gradient of any operating SC ion facility in the world and provides a 20 MV boost to the ISAC accelerated beams. The addition of a further 20 MV of SC linac, with cavities made in Canada, will be installed by the end of 2009. The ISAC-III project scheduled to begin in 2010 will see the installation of an additional driver beam of 50 MeV electrons to produce RIBs by photofission, an expanded target area, and new front-end ion accelerators to expand the capability to three simultaneous radioactive beams for experiments.

## INTRODUCTION

ISAC at TRIUMF is one of the major existing facilities for the production of radioactive ion beams (RIB). There are two commonly used methods for RIB production [1].

The first one is the in flight or fragmentation method. The facility using this method has a main accelerator that accelerates heavy ions toward a thin target. The heavy ion breaks apart going through the target producing a variety of radioactive ions. The ions, already at the final velocity, are selected through a fairly complex mass separator system and sent to the experiment.

The second method is the isotope separation on line or ISOL method. In this case an accelerator, called a driver, accelerates light projectiles, the primary beam, toward a thick target. The light projectiles, protons or light ions, break the target nuclei producing neutral radioactive isotopes. These neutral atoms are then transported into a source where they are ionized and extracted at source potential. The radioactive ions are magnetically separated and post accelerated to reach the final energy requested.

The two methods are complementary. The in flight is a fast production method that allows to deliver isotopes of very short half-lives (ms or less) but with a beam of relatively large emittance . The ISOL method on the contrary produces high quality emittances but the complicated and relatively slow process reduces the possibility of extracting isotopes with few ms half-lives. The in flight methods RIB has energy of several tens of MeV/u while the ISOL method can deliver beam of few keV/u.

## ISAC OVERVIEW

The ISAC facility at TRIUMF is an ISOL facility. It has the highest power (50 kW) primary proton beam. The overview of the facility is represented in Fig. 1. The ISAC facility produces the most intense beam for certain species, an example being the exotic $^{11}$Li.

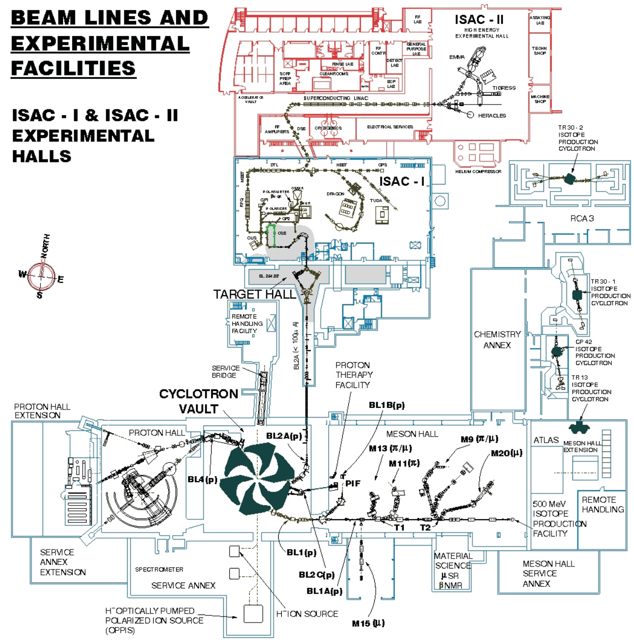

Figure 1: Overview of the TRIUMF site. The main machine is the H$^-$ 500 MeV cyclotron used also as driver of the ISAC facility.

The facility uses silicon carbide or tantalum targets for ion production. Two target configurations are available: low and high power respectively for proton beam powers up to 20 kW and 50 kW. Most recently beam production with a UOx target was successfully completed.

### *Driver*

The TRIUMF H$^-$ cyclotron is the largest cyclotron in the world and has operated for almost 35 years. It accelerates H$^-$ ions up to an intensity of 250 $\mu$A to a maximum energy of 500 MeV. The H$^-$ are then stripped and protons are extracted in three different beam lines at different energies the maximum being 500 MeV. One of these beam line is dedicated for the ISAC radioactive beam production. In this case the beam is extracted at 500 MeV and up to 100 $\mu$A.

The simultaneous extraction of multiple beams with stable delivery is challenging. Nevertheless a 90% availability of the proton beam for the ISAC facility is regularly achieved.

The capability of multiple extractions can be expanded by refurbishing a fourth existing extraction beam line giving two simultaneous proton beams for RIB production [2] as represented in Fig. 2. This possibility together with an upgrade of the cyclotron [3] is one of the goals for the next

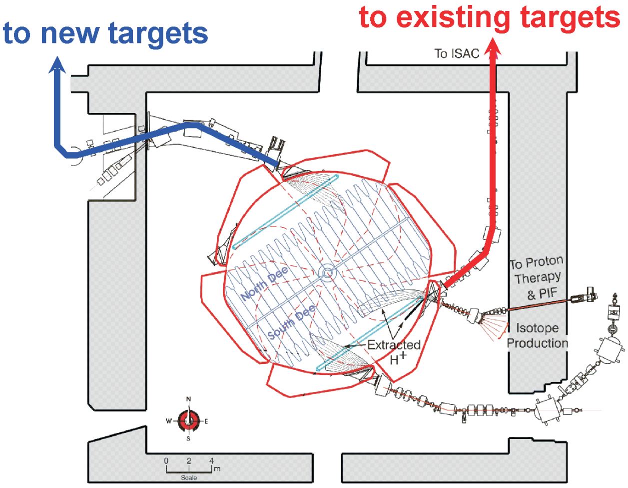

Figure 2: Schematic of the TRIUMF cyclotron. Three operating extraction beam lines in the SE side. One existing extraction beam line in the NW side.

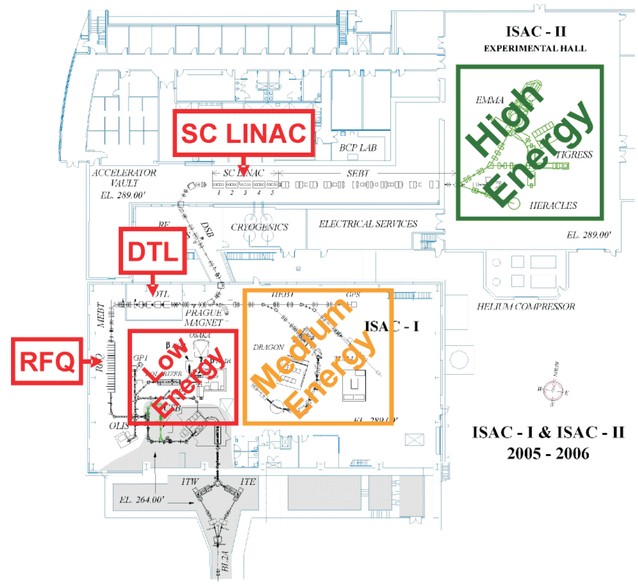

Figure 3: Overview of the ISAC facility at TRIUMF. The ISAC-II linac is superconducting while in ISAC-I the RFQ and the DTL are room temperature machines.

five year plan as explained in the last section of this paper.

### *Target Station and Mass Separator*

The ISAC facility has two independent target stations. This allows service on one target station while producing and delivering radioactive beams with the other.

Each target station is composed of five modules. The entrance module houses the diagnostic and protection monitors for the proton beam. The target module contains the target and the source; this module is routinely removed to change both target and source. Four target modules are available. The beam dump module is located downstream of the target module. The last two are the extraction modules housing the optics elements. They are oriented perpendicular to the proton beam direction.

Downstream of the targets there is a common preseparator. The target modules and preseparator are inside a concrete shielded area. The preseparator reduces the radioactivity transported outside the shielded area in the downstream beam line.

After the preseparator the RIBs are selected using the mass separator. This device is installed on a biased platform to increase the resolution.

After selection it is possible to boost the charge state of the radioactive ion by diverting them through an electron cyclotron resonance ion source (ECRIS). This charge breeder allows post acceleration of masses A>30.

The target stations and the separator area are located underground. Once produced and selected the RIB is then transported to ground level where the post accelerator and experiments are located.

### *Post Accelerators*

The RIBs can be delivered to three experimental areas as represented in Fig. 3: a low energy area where the ions are accelerated at source potential (up to 60 kV),a medium energy area ($\beta$=1.8%$\rightarrow$6%) or a high energy area ($\beta$=6%$\rightarrow$15%) where the ions are post accelerated with linacs.

The first stage of acceleration uses a radio frequency quadrupole (RFQ) acting as an injector [4]. The RFQ boosts the energy from 2 keV/u to 150 keV/u. It can accelerate mass to charge ratio of $3\leq$A/Q$\leq$30. The RFQ is a room temperature CW machine operating at 35.36 MHz. The eight meter long resonant structure is composed of nineteen split rings supporting the electrodes. The RFQ doesn't have a bunching section; the beam is prebunched at the entrance with a three harmonics RF buncher, the fundamental being 11.78 MHz. This configuration produces a high quality longitudinal emittance after the RFQ (0.22 $\pi$ keV/u·ns). Part of the beam transmitted but not accelerated is stopped into a fixed collimator downstream of the RFQ [5]. The beam inside the longitudinal emittance after the slit is around 80% of the injected.

After the RFQ the charge state of the ions is increased by stripping the ions through a thin carbon foil (4 $\mu$g/cm$^2$). As a general rule the most populated charge state is selected using magnetic benders as long as the mass to charge ratio is within $2\leq$A/Q$\leq$6 set by the following drift tube linac (DTL). The efficiency of the stripping foil depends on the mass of the stripped ions; in most of the cases it ranges between 30% to 50%.

The DTL [6] is a variable energy machine covering the entire range of energies 150 keV/u$\leq$E$\leq$1.8 MeV/u. The DTL is a separated function machine composed of five IH interdigital structure accelerating tanks and three split ring bunchers located between the first four tanks. This layout produces good beam quality for each energy. After the fourth tank the beam quality is already sufficient that no buncher is required. The resonance frequency of the tanks and bunchers is 106.08 MHz and they operate at room temperature in CW mode. Transverse focus through the linac is provided by quadrupoles triplets between each tank. The transmission of this linac is greater than 95%. The DTL is also used as an injector for the ISAC-II superconducting (SC) linac.

The SC linac [7] is at present composed of five cryomodules. Each cryomodule houses four superconducting cavities and one superconducting solenoid. The superconducting cavities are bulk niobium quarter wave resonators at 106.08 MHz operating at 4 K. All twenty cavities installed, fabricated in Italy by Zanon, meet or exceed the ISAC specification being 30 MV/m peak surface field at 7 W of helium consumption. In fact the SC linac is now operating for two years at an average gradient of 35 MV/m peak surface field (7 MV/m of acceleration) at 7 W. During this period there is on average no significant degradation in the cavities performance. Each cavity is independently phased at -25° synchronous phase. The transmission through the SC linac is 100%.

### *Beam Delivery*

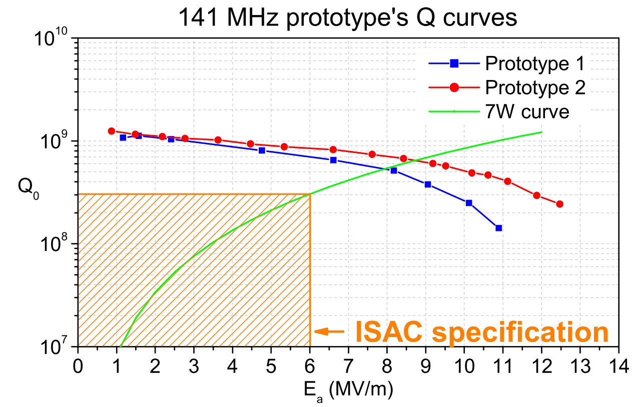
The post accelerator sections are tuned by means of the pilot beam technique. This technique consists in setting the beam lines and accelerators with a beam of stable ions with the same mass to charge ratio as the RIB. This is necessary because the intensity of the radioactive beam typically ranges between $10^3$ and $10^6$ particle per second. In order to match the radioactive beam coming from the charge breeder an electron cyclotron resonance (ECR) source that can produce stable ions with higher charge states is now installed. The switchover procedure from the pilot beam to the radioactive is straightforward. The transmission of the RIB is checked using several low intensity detectors (like silicon detector, photodiode or channeltron) distributed along the beam line.

The delivery of RIBs is challenging considering the long chain of production, selection and post acceleration. In order to transport the radioactive ions to the experiment every single component has to function properly. The availability of the ISAC linacs is 98%.

## ISAC-II UPGRADE

A linac upgrade is underway [8]. The upgrade consists of twenty more cavities housed in three cryomodules installed downstream of the existing section. The first two cryomodules house six superconducting cavities and one superconducting solenoid while the last one has eight superconducting cavities and a superconducting solenoid.

This upgrade increases the ISAC-II linac voltage capability to 40 MV. This voltage will boost the beam energy above the Coulomb barrier for all masses. Since the SC linac always operates at the maximum possible voltage for stable operation, the final energy depends on the mass to charge ratio of the accelerated species. We anticipate an energy of 22 MeV/u for A/Q=2 and 8 MeV/u for A/Q=6 as represented in Fig. 4 (lower graph).



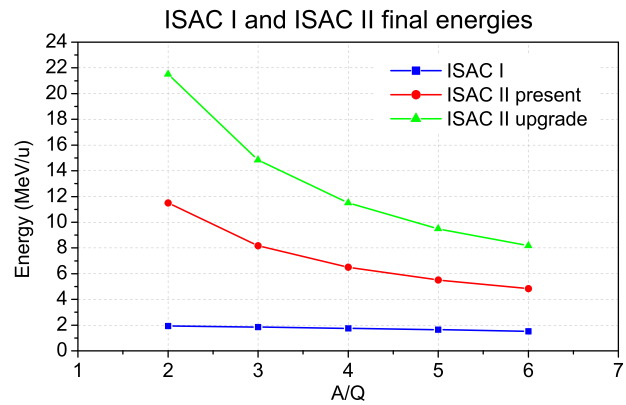


Figure 4: (Upper) Characteristic Q curves of the two new 141 MHz bulk niobium quarter wave resonator fabricated by PAVAC. (Lower) Expected final energies for the ISAC-II SC linac.

Figure 5: The first superconducting cavity produced by PAVAC Industries: the 141MHz quarter wave bulk niobium resonator for the ISAC-II linac upgrade.

The new superconducting cavities are quarter wave bulk niobium resonators operating at the higher frequency of

141.44 MHz.

The fabrication of the new cavities is done through a collaboration between TRIUMF and a local Canadian company, PAVAC Industries. PAVAC machines and electron beam welds the niobium material provided by TRIUMF (see Fig. 5). The pre welding chemical etch, as well as the final etch, is done by TRIUMF. All fabrication steps are followed by TRIUMF experts.

The first two niobium prototypes fabricated by PAVAC are already tested. They both exceed the design specifications of 30 MV peak surface field at 7W of helium consumption. The characteristic Q curves of these two cavities (Fig. 4, upper graph) show that at 7 W the accelerating fields are around 8 MV/m. This result is a significant achievement being the first cavities produced by PAVAC Industries.

The cryomodules are scheduled for installation and commissioning by the end of 2009.

## FUTURE PLANS

TRIUMF is funded in a five year cycle, the next being 2010-15. A proposed upgrade of the ISAC facility, commonly called ISAC-III [9], is contained in the published five year plan.

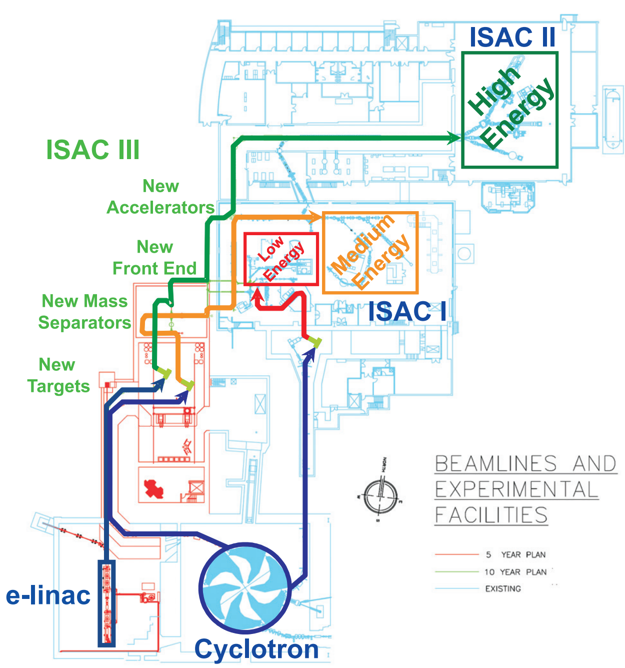

Figure 6: Layout of the proposed ISAC-III upgrade. In the picture a possible delivery schematic of three simultaneous RIBs is outlined.

At present the ISAC facility is limited by the possibility of delivering only one RIB at any given time to one of the twelve experimental stations distributed in the three experimental areas. This limits the development of new radioactive beams since this takes beam time from experiments.

It is then proposed to expand the ISAC facility with two new target stations for RIB production, two new mass separators, and a second post acceleration path (new RFQ and DTL similar to the existing ones) that can inject the beam directly into the SC linac without going through the ISAC-I accelerators.

The expansion foresees also the installation of a new electron driver (e-linac). In this way the new target stations can use as primary beam either the electrons from the new driver (e-linac) or the protons from the fourth extraction beam line (see Fig. 2) of the cyclotron.

Each one of the two new target stations will have a dedicated preseparator inside a shielded area. Two mass separators, one low resolution the other high resolution, are going to be available. The new targets and mass separators are planned to be connected via an electrostatic switchyard that gives the possibility of sending the beam from either target to either mass separator or bypass them.

Another flexible switchyard after the new separators allows to send each of the RIBs to either of the experimental areas.

The layout of the future expanded facility is represented in Fig. 6; in this picture a possible delivery schematic of three simultaneous RIBs is outlined.

The primary goal is to produce three simultaneous radioactive beams making TRIUMF the future leading ISOL facility. Figure 7 show the expected ISAC RIB production in the next decade based on the proposed upgrade.

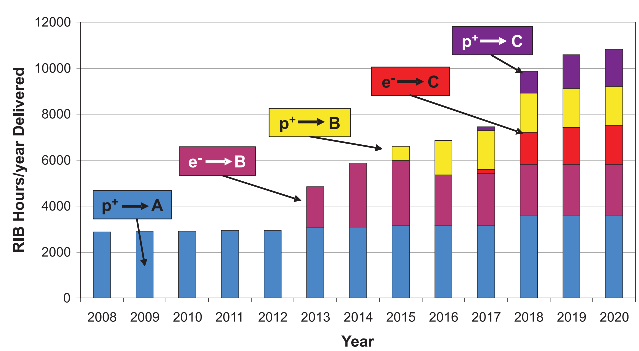

Figure 7: Expected RIB delivery in the next decade for the proposed ISAC-III upgrade. A is one of the two existing target stations, B and C are the new target stations.

### *e-linac*

It is possible to produce radioactive ion beams through photofission [10]. The photons (Bremsstrahlung radiation) are produced by an electron beam. This method produces a higher yield of certain isotopes with respect to proton production, but it doesn't cover the entire nuclide chart as represented in Fig. 8. The two production methods then, photofission and proton induced, are complementary.

In this context an electron driver for RIB production makes ISAC a facility capable of delivery a complete spectrum of radioactive species. The electron driver (e-linac) is

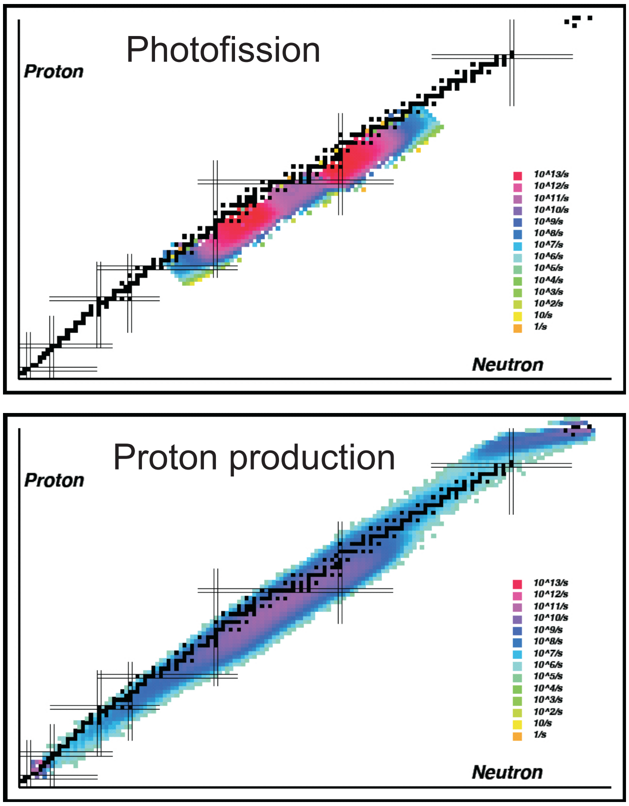

Figure 8: Simulated yield for photofission (upper) and proton (lower).

going to play a fundamental role in making ISAC the future leading ISOL facility.

The e-linac is envisaged as a 0.5 MW machine with a final energy of 50 MeV and an average current of 10 mA [11]. The linac operates in CW mode using superconducting elliptical cavities at 1.3 GHz and operating at 2 K. The layout of the machine foresees an electron gun followed by a buncher, an injector module and an accelerator composed of four nine cells cavities hosted in two cryomodules.

At present the cyclotron is shutdown for four months each year for maintenance. The e-linac is going to be independent from the cyclotron meaning the RIB production can cover the entire year.

### *New SCRF Activities*

TRIUMF has a world class expertise in low $\beta$ superconducting RF (SCRF) gained through the ISAC-II SC linac. This expertise is going to be extended to the $\beta$=1 region with the design and construction of the e-linac.

A new series of SCRF activities are being initiated at TRIUMF [12]: a new vertical cryostat is tested for 2 K operation and being readied for single cavity test. A single cell elliptical cavity test is scheduled this Fall. A RRR measurement apparatus is used to test the electron beam welding quality of niobium material. PAVAC Industries, in collaboration with TRIUMF, is testing fabrication procedures to produce elliptical cavities. All these activities are supported also by external collaborators like the University of Toronto, VECC laboratory in Calcutta and Fermilab.

## CONCLUSION

The ISAC facility at TRIUMF is one of the major ISOL facilities for radioactive ion beam production. It can provide the most intense beams for certain species. Through the next five year plan TRIUMF wants to overcome some existing limitations and become the leading ISOL facility for RIBs. Furthermore TRIUMF has planned to be an R&D center for SCRF activities covering the entire range of $\beta$.

## ACKNOWLEDGEMENTS

I want to acknowledge the scientific committee for the opportunity given to a young physicist, at the beginning of his career, of presenting this talk at the LINAC08 conference. I want also to thank Rick Baartman, Bob Laxdal and Lia Merminga for the comments and suggestions given during the rehearsals of my talk.

# THE EUROPEAN XFEL SC LINAC PROJECT

R. Brinkmann, Deutsches Elektronen-Synchrotron (DESY), D-22607 Hamburg, Germany for the XFEL Team

*Abstract*

The European XFEL project is entering the construction phase, based on the very successful experience of the TESLA linac technology and the SASE FEL concept, now serving the FLASH user facility at DESY.

The EU-XFEL will be realized by a widespread international collaboration and it is also relevant for the ILC planning. A description of the overall layout of the facility, of the tchnical developments and industrialization efforts for the accelerator components, and of the international collaboration will be given.

## INTRODUCTION

The XFEL was originally proposed as part of the TESLA facility, first in a version integrated with the linear collider using the same linac [1,2], in a later version with its own separate linac [3]. In February 2003 the German Government announced the decision that the XFEL should be realized as a European project, with at least 40% funding contributions requested from partner countries. After this decision an intense preparation phase followed in which DESY, together with partner institutes, pushed forward the work necessary to achieve the status of readiness for start of construction. Besides the optimization of the overall design, main objectives in this phase where preparations for the site and civil construction, industrialization of major technical components and detailed studies of beam physics and the FEL process. The XFEL has a strong link to the FLASH (VUV-FEL) facility at DESY [4 – 6], which is in nearly all respects (accelerator technology, FEL operation, photon beam lines and user experiments) truly a pilot facility for the future project.

The project organization at the international level is supervised by a steering committee (ISC) with members from all countries interested in participating in the project. In 2005 ISC nominated a European Project Team (EPT), with the main charge to deliver the technical and administrative documents required for the process of negotiations and decisions at the political level towards achieving the final go-ahead for the project. In July 2006, an updated Technical Design Report (TDR) was completed [7] and delivered to ISC. The progress in the negotiations with the partner countries on contributions to the project then led to the official go-ahead for project construction on June 5, 2007, on the basis of an initially de-scoped startversion of the facility (see below). The nominal construction cost (in year 2005 prices) of the start version amounts to 850 M€, to which approximately 90 M€ have to be added for project preparation and commissioning.

Up to date, 14 countries have made commitments to contribute to the project (Figure 1), summing up to a total of 1,060 M€ (on year 2005 basis). In addition to covering the cost for the startversion including preparation and commissiong, there remains an overhead which will with first priority be used to cover cost risks, but which may to a limited extent also permit to remove part of the initial de-scoping of the facility.

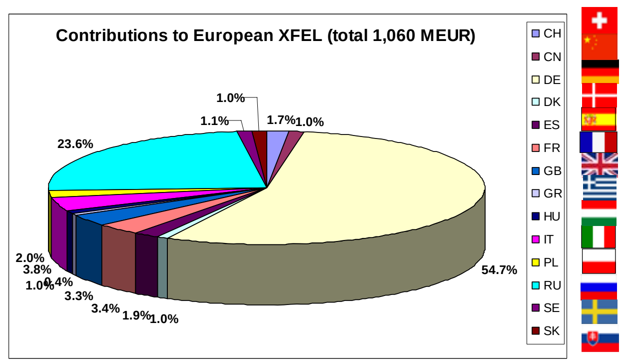

Figure 1: Distribution of funding contributions to the European XFEL project. Contributions are in cash as well as in-kind.

The administrative documents, in particular the Intergovernmental Convention, are essentially ready for signature by the partner countries. After that event, foundation of the XFEL company, of which all partners are shareholders, will take place. The company has the overall supervision and responsibility for the European XFEL and will also manage the civil construction and photon beam systems parts of the project. For the accelerator complex, an international consortium is being set up, which will contribute the entire accelerator and the related technical infrastructure essentially as an in-kind contribution to the project. At present 17 institutes from 10 of the XFEL member states have joined the consortium. DESY will provide approximately 60% of the in-kind contributions to the accelerator complex and act as the consortium coordinator.

## LAYOUT AND PARAMETERS

The main components of the XFEL Facility are the injector, the linear accelerator, the beam distribution system, the undulators, the photon beam lines, and the instruments in the Experiments Hall (see Figure 2).

These components are distributed along an essentially linear geometry, 3.4 km long, starting on the DESY campus in the northwest part of the city of Hamburg, and ending in the neighbouring Federal State of Schleswig-

Holstein, south of the city of Schenefeld, where the Experimental Hall is located. Permission for construction and operation on this site was obtained in July 2006, concluding a so-called Plan Approval Procedure. After the official project start in 2007, the call-for-tender procedure for civil construction was launched. The offers from different civil construction companies are at present being evaluated and placing of the orders for underground construction is expected to happen before the end of 2008.

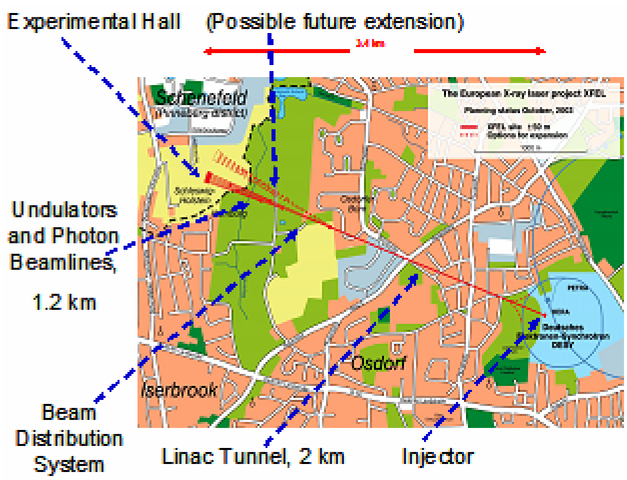

Figure 2: Site and schematic layout of the European XFEL Facility.

The main sections of the facility, as schematically shown in Figure 2, are the following: In the injector, electron bunches are extracted from a solid cathode by a laser beam, accelerated by an electron RF gun and directed towards the linear accelerator with an exit energy of 120 MeV. In the linear accelerator, consisting of a 1.6 km long sequence of superconducting accelerating modules, magnets for beam steering and focusing, and diagnostic equipment, the electrons are accelerated to energies of up to 17.5 GeV, which is the energy foreseen for the standard mode of operation of the XFEL facility at 0.1nm FEL wavelength. The original design energy of 20 GeV was reduced by shortening the linac as part of the initial de-scoping scenario of the startversion. A later upgrade back to the full linac length as foreseen in the TDR remains possible. Along the accelerator, two stages of bunch compression are located, to produce the short and very dense electron bunches required to achieve saturation in the SASE process. At the end of the linac follows a beam transport section with collimation, stabilization feedback and diagnostics systems, after which the individual electron bunches are fed into one or the other of two electron beam lines by the beam distribution system. The linac and beam transport line are housed in a 2.1 km long underground tunnel (Figure 3).

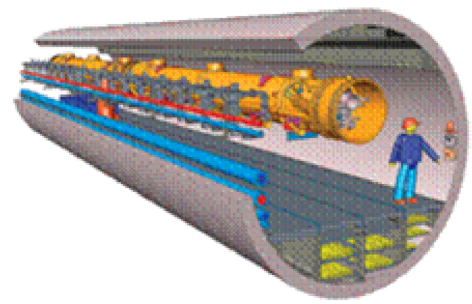

Figure 3: Layout of the 5.2 m diameter linac tunnel.

In the startversion the user facility has 3 SASE-FEL undulator beam lines (Figure 4) with in total 6 experimental stations (Figure 5). The space foreseen for two more undulator beam lines remains initially unoccupied, but since the buildings, technical infrastructure and electron beam line remain unchanged w.r.t. the TDR layout, these beam lines and 4 additional experimental stations can be added at any time as soon as funding permits. Furthermore, the site layout also allows for a later extension of the facility by another 5 beam lines.

Independent wavelength tuning by undulator gap variation is foreseen and, together with electron beam energy variation, a total wavelength range of 0.1 – 5 nm (FEL) can be covered. The peak brilliance of FEL radiation is in the range $10^{32}$ - $5{\cdot}10^{33}$ photons/0.1%bw/s/mm$^2$/mrad$^2$. The baseline operating point for 0.1nm wavelength (SASE1) at 17.5 GeV electron energy has been chosen on the basis of extensive studies of the FEL process with a relatively conservative assumption on the minimum undulator gap (10mm). At the design electron beam emittance of $\varepsilon_N$ = 1.4 mrad·mm very good transverse coherence of the FEL radiation is predicted [8]. The magnetic lengths of the undulators include a safety margin w.r.t. the calculated saturation lengths.

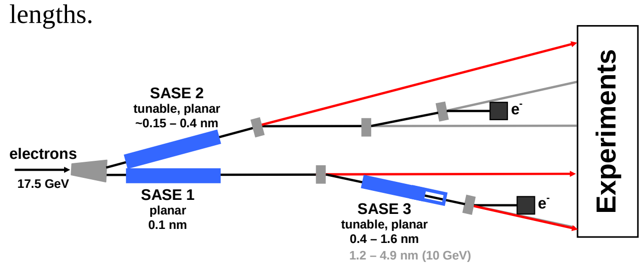

Figure 4: Schematic layout of the beam lines in the user facility.

| | Instrument | Brief description of the instrument |
|---|---|---|
| Hard X-rays | SPB | Ultrafast Coherent Diffraction Imaging of Single Particles, Clusters, and Biomolecules – **Structure determination of single particles: atomic clusters, bio-molecules, virus particles, cells.** |
| | MID | Materials Imaging & Dynamics –**Structure determination of nano- devices and dynamics at the nanoscale.** |
| | FDE | Femtosecond Diffraction Experiments – **Time-resolved investigations of the dynamics of solids, liquids, gases** |
| | HED | High Energy Density Matter – **Investigation of matter under extreme conditions using hard x-ray FEL radiation, e.g. probing dense plasmas.** |
| Soft X-rays | SQS | Small Quantum Systems – **Investigation of atoms, ions, molecules and clusters in intense fields and non-linear phenomena.** |
| | SCS | Soft x-ray Coherent Scattering –**Structure and dynamics of nano-systems and of non-reproducible biological objects using soft X-rays.** |

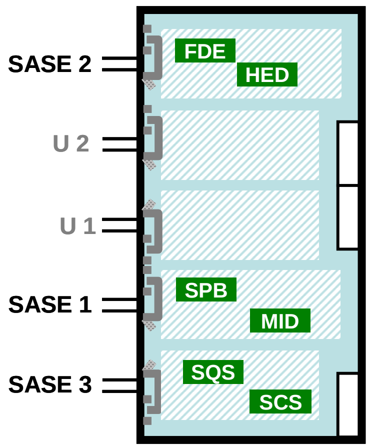

Figure 5: Selection of first scientific instruments and their arrangement in the experimental hall.

## ACCELERATOR COMPLEX

The layout of the accelerator is schematically shown in Figure 6 and its main parameters are summarized in Table 1. The beam energy required for 0.1 nm photon wavelength in the SASE1 and SASE2 beam lines is 17.5 GeV. The required peak power per RF station is well below the limit of the 10 MW multibeam klystrons (for recent test results from one of the three XFEL MBK prototype manufacturers, see [9]. This de-rated mode is beneficial for highly reliable operation on one hand and for an upgrade potential regarding beam energy or duty cycle on the other. Likewise, the cryogenic system is laid out with an overhead of 50% with similar operational benefits.

The electron beam is generated in a laser-driven photocathode RF gun and pre-accelerated in a single superconducting accelerator module. The injector is housed in an underground enclosure separate from the linac tunnel, so that it can be commissioned at an early stage, well before installation work in the linac tunnel is completed. Furthermore, there is space foreseen for a completely separate and radiation-shielded second injector, which can be constructed, commissioned and maintained independently from the operation of the first injector.

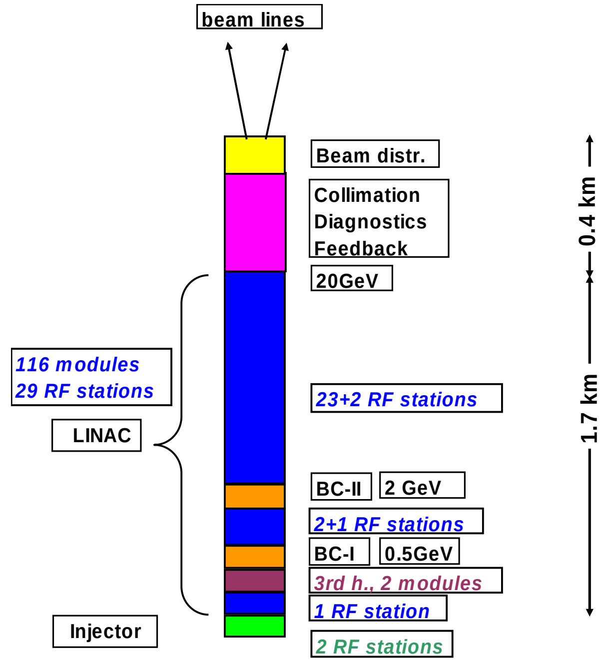

Figure 6: Schematic layout of the accelerator as described in the TDR. In the startversion 4 RF stations and 16 accelerator modules will initially not be installed.

Table 1: Main Parameters of the XFEL Accelerator for the Startversion with 17.5 GeV Design Energy. Numbers in Brackets Correspond to the Full TDR Version

| | |
|---|---|
| Design beam energy | 17.5 GeV *(20 GeV)* |
| # of installed accelerator modules | 100 *(116)* |
| # of cavities | 800 *(928)* |
| Accelerating gradient | 23.6 MV/m |
| # of installed RF stations | 25 |
| Klystron peak power (24 active stations) | 5.2 MW |
| Loaded quality factor $Q_{ext}$ | $4.6 \times 10^6$ |
| RF pulse length | 1.4 ms |
| Beam pulse length | 0.65ms |
| Repetition rate | 10 Hz |
| Max. average Beam power | 600 kW |
| Unloaded cavity quality factor $Q_0$ | $10^{10}$ |
| 2K cryo load (incl. transfer line losses) | 1.7 kW |
| Max. # of bunches per pulse | 3,250 |
| Min. bunch spacing | 200 ns |
| Bunch charge | 1 nC |
| Bunch peak current | 5 kA |
| Emittance (slice) at undulator | 1.4 mm×mrad |
| Energy spread (slice) at undulator | 1 MeV |

The results from simulation studies of the RF gun show that a normalized beam emittance below 1mrad·mm at the design RF field of 60MV/m on the cathode is achievable, even if the thermal emittance is somewhat larger than originally expected, as measurements performed at the PITZ facility (DESY-Zeuthen) indicated [10]. Emittance measurements at PITZ with high gun gradient [11] indicate a beam quality very close to the XFEL design goal [12]. The programme at PITZ continues with emphasis on further optimization of the laser profile and reduction of the gun dark current [13] at high gradients.

After transfer to the main accelerator tunnel (see the layout sketched in Figure 7), the beam is further accelerated by one linac unit (4 accelerator modules with 8 cavities each, driven by one RF station) to an energy of 0.5 GeV before entering the first bunch compression stage. A third harmonic (3.9 GHz) RF system is foreseen to optimize the longitudinal phase space properties. In order to suppress micro-bunching instabilities, the uncorrelated bunch energy spread is intentionally increased by a laser heater [14] after the injector. After acceleration to 2 GeV with three linac units the beam enters the second (final) compression stage, after which the 1nC bunch peak current has increased to 5 kA ($\sigma_z$ = 23μm for a 1nC bunch), a factor of 100 higher than the initial peak current from the RF gun. Considerable attention has been paid to foresee beam diagnostics stations in order to assess the beam phase space properties after the compression process in great detail. Beam simulation studies of the compression system show that the slice emittance growth due to space charge and CSR effects can be kept at a low level and there is room for further parameter optimization beyond the nominal design bunch parameters.

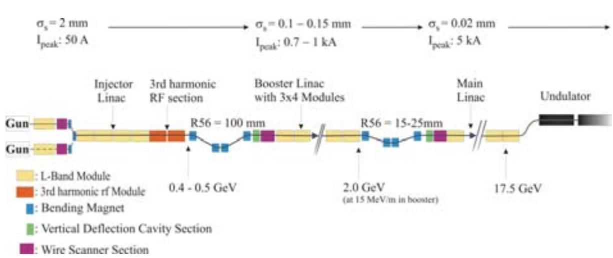

Figure 7: Layout of the XFEL bunch compression system.

The large compression factor and resulting short bunches (70fs rms) require timing, synchronization and diagnostics devices at the fs level as well as excellent RF field control. A considerable R&D program is ongoing in these fields, see e.g. [15 - 21] for recent developments.

Final acceleration to the nominal maximum beam energy of 17.5 GeV takes place in the main part of the linac, consisting of 25 RF stations and 100 accelerator modules in total (an extension to the full scope of the TDR layout with 116 modules and 29 RF stations remains possible). Out of the 25 stations, two are reserve for energy management in case of RF system failures. For the linac technology R&D and industrialization programme, the new cryomodule test bench (CMTB) at DESY, operational since autumn 2006, permits RF tests of cold modules independent from FLASH operation [22]. So far, four modules have passed through extensive test procedures (three of which are now installed at FLASH), a $5^{th}$ module was used for an intentional "crash test" [23]. Besides verifying good performance in terms of accelerating gradient, important results also include short RF coupler processing times and cold-warm cycling without performance degradation. Regarding the 9-cell superconducting Niobium cavities [24], important progress towards industrialization of series production was achieved by successfully commissioning and operating electropolishing facilities at two companies.

Downstream from the linac follows a conventional beam line for installation of the beam collimation and trajectory feedback systems, as well as providing distribution of the beam [25] into the different undulator beam lines, including the connection to a future upgrade of the user facility with more beam lines. A combination of slow and fast switching devices permits to generate bunch trains of different time patterns for different experiments without having to generate and accelerate bunch trains with strongly varying transient beam loading. A fraction of each bunch train will be used to accurately stabilize the following bunches in position and energy by means of a fast feedback system.

In the undulator sections, the effects of undulator gap errors and quadrupole misalignments on the SASE process have been studied [26, 27]. The results show that errors up to a few μm are permitted before the gain length or the peak radiation power are seriously affected. Investigations of quadrupole magnets and on the optimization of the focusing lattice are also ongoing [28, 29].

After having passed through the undulators, the "spent" beam is stopped in radiation shielded solid absorbers. An additional beam dump is installed in the beam distribution shaft XS1, just upstream from the undulator beam lines. It allows to commission or to operate the accelerator while installation or maintenance work is ongoing in the undulator tunnels.

### *Operational Flexibility*

The single set of basic reference parameters in Table 1 does not cover the full range of operational flexibility of the linac. There is, within certain limits, a considerable flexibility regarding operation parameters, based on built-in performance reserves of its technical components. Operation at lower beam energy, thus extending the photon wavelength range to softer X-rays, is an obvious possibility. On the other hand, based on the experience gained with the superconducting TESLA cavities, it can be realistically expected that the linac can be operated at an accelerating gradient somewhat above the specified design value of 23.6 MV/m. An increase of the gradient may thus permit beam energies well above the design value, thus significantly extending the photon wavelength range to harder X-rays, provided that simultaneously also an improved injector beam quality becomes available to be able to maintain saturation of the SASE FEL process. In addition to the possibility of higher beam energies, the available reserve in the RF and cryogenic systems can also be used for increasing the linac repetition rate and thus the duty cycle of the pulsed linac. At sufficiently low beam energy, a 100% duty cycle, i.e. continuous wave (CW), mode of operation is conceivable, an option which is only possible with a superconducting linac. This option (see table 2) is viewed as not being part of the first stage of the XFEL facility but is considered as a future option.

Table 2: Sketch of Possible Parameters for a Future Option of Operating the Linac in CW Mode

| | |
|---|---|
| Beam energy | 7 GeV |
| Accelerating Gradient | 7.5 MV/m |
| # of CW RF stations | 116 |
| RF power per accelerator module | ≈20 kW |
| Beam current | 0.18 mA |
| Loaded quality factor $Q_{ext}$ | $2 \times 10^7$ |
| Bunch frequency | 180 kHz |
| Unloaded quality factor $Q_0$ | $2 \cdot 10^{10}$ |
| 2K cryogenic load | ≈3.5 kW |

## CONCLUSION

After an intense phase of preparation at the scientific-technical, organizational and political level, the European XFEL project is now entering into its realization phase. An approximately 6 year construction phase is lying ahead and we are looking forward to seeing the first photon beam at this facility in 2014.

# SNS SUPERCONDUCTING LINAC OPERATIONAL EXPERIENCE AND UPGRADE PATH*

Sang-ho Kim, ORNL, Oak Ridge, TN 37831, U.S.A.

*Abstract*

The Spallation Neutron Source (SNS) Superconducting Linac (SCL) has been providing a main acceleration in two different accelerating sections with 33 medium beta and 48 high beta superconducting radio-frequency (SRF) 6-cell cavities. The use of superconducting elliptical cavities for particles whose velocity are less than speed of light (beta<1), make this accelerator a very important milestone for learning operating conditions of this type of cavities. Since the SNS SCL is the first large-scale high energy pulsed-superconducting proton linac that provides high beam power utilizing H- beams, many aspects of its performance were unknown and unpredictable. A large amount of data has been collected on the pulsed behavior of cavities and cryomodules at various repetition rates and at various temperatures. This experience will be of great value in determining future optimizations of SNS as well in guiding in the design and operation of future pulsed superconducting linacs. This paper describes the details of the RF properties, performances, path-forward for the SNS power ramp-up goal, and upgrade path of the SNS superconducting linac.

## INTRODUCTION

The SNS accelerator complex consists of a negative hydrogen (H-) RF volume source, a low-energy beam transport (LEBT) line with a first-stage beam chopper, a 4-vane radio-frequency quadrupole (RFQ) up to 2.5 MeV, a medium-energy beam transport (MEBT) line with a second-stage chopper, six drift-tube linac (DTL) tanks up to 87 MeV, four coupled-cavity linac (CCL) modules up to 186 MeV, a superconducting linac (SCL) with 11medium-beta cryomodules (up to 379 MeV) and 12 high-beta cryomodules (up to 1000 MeV), a high energy beam transport (HEBT) line, an accumulator ring with associated beam transport line, a ring-to-target beam transport (RTBT) line, and a mercury target. At a full duty, the linac will produce 38-mA peak, chopped $H^-$ beam for 1-ms long at 60 Hz. In the ring, 700-ns long midi-pulse beam is accumulated over 1060 turns reaching an intensity of $1.5 \times 10^{14}$ protons per pulse. After beam accumulation in the ring, the beam is extracted using the extraction kickers during 300-ns long midi-pulse gap in a single turn is transported to the mercury target through the RTBR line. Figure 1 shows the layout of the SNS.

A series of the beam commissioning, initiated in 2002 and completed in May 2006, was performed in seven commissioning runs for Front-End, DTL Tank 1, DTL Tanks 1-3, CCL, SCL, Accumulator Ring, and beam on target.

* SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy

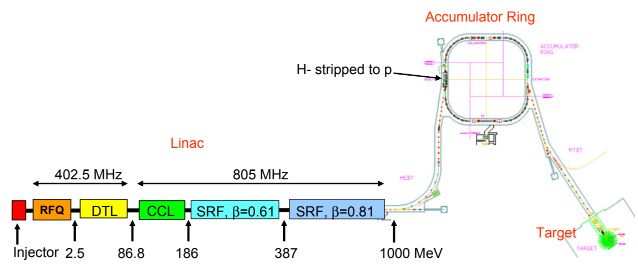

Figure 1: Layout of the SNS accelerator system.

Official SNS operations for scheduled neutron scattering experiments has been started since October 2006. The SNS is now nearly two years into the initial operations phase [1, 2].

The SRF cavities and the cryomodules were designed and developed at Jefferson Lab and installed at the SNS site in 2005. Major parameters are summarized in Table 1. As the first operational pulsed superconducting linac, many of the aspects of its performance were unknown and unpredictable. A lot of experiences and data have been gathered on the pulsed behavior of cavities and cryomodules at various repetition rates and at various temperatures during the commissioning of its components and beam operations. Careful balance between safe operational limits and the study of conditions, parameters and components that create physical limits has been achieved [3, 4]. The SCL is running at about 0.9-GeV output energy and is presently one of the most reliable systems in SNS. Figure 2 shows the accelerating gradients of SCL cavities at 60Hz in 2008 for the neutron production, which is set based on the 60 Hz collective limits achieved. Power ramp up plan to reach the design goal is set and various efforts are in progress.

Table 1: Major Design Parameters of the SNS SCL

| Cryomodule Parameter | β=0.61 Section | β=0.81 Section |
|---|---|---|
| Output Energy (MeV) | 379 | 1000 |
| No. of Cryomodules | 11 | 12 |
| No. of cavities per cryomodule | 3 | 4 |
| **Cavity Parameter** | **β=0.61 Cavity** | **β=0.81 Cavity** |
| Geometric beta | 0.61 | 0.81 |
| EoT (MV/m) | 10.1 at β=0.61 | 15.8 at β=0.81 |
| Epeak (MV/m) | 27.5 | 35.0 |
| Hpeak (kA/m) | 46.2 (580 Oe) | 59.7 (750 Oe) |
| Q*Rs (Ω) | 176 | 228 |
| r/Q at design beta | 279 | 483 |
| Equivalent Cavity Length (cm) | 68.2 | 90.6 |

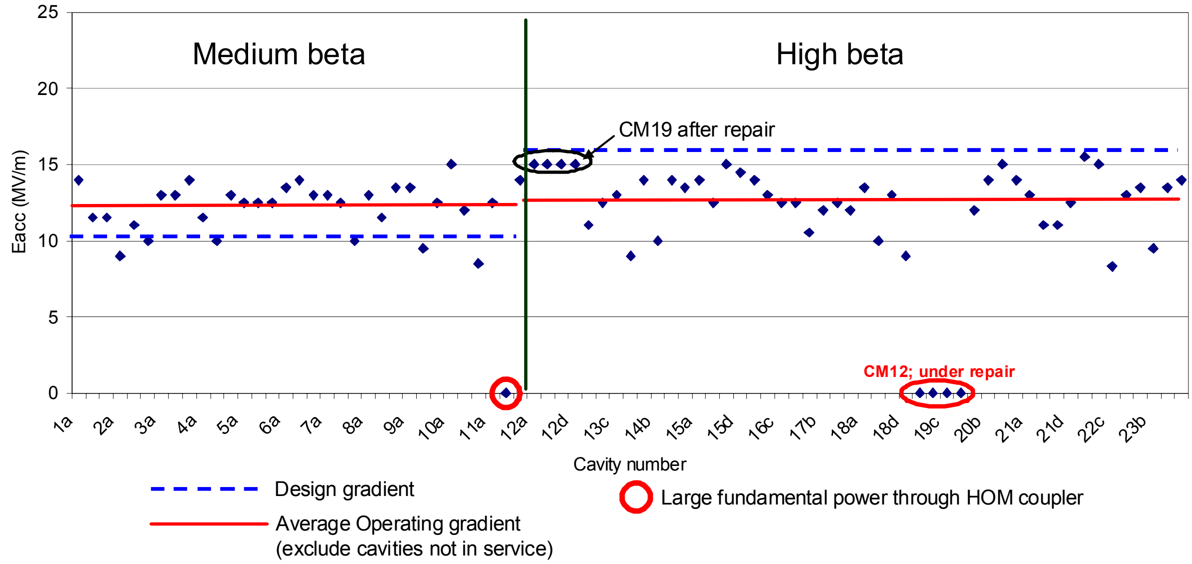

Figure 2: Operating setpoints of SCL SRF cavities at 60 Hz for the neutron production in 2008.

## OPERATIONAL EXPERIENCES

Extensive testing on the SNS superconducting RF modules has been conducted starting in late 2004. Behavior peculiar to the SNS cavities and the overall design, as well as due to the pulse nature of the operation have been observed. These and other limitations have requires extensive studies and close attention in setting gradients which are both necessary for adequate energy gain and for reliable operation.

### *Operational Flexibility*

One of the main characteristics of the superconducting linac is its flexibility and adaptability to adding or removing cavities. In many occasions, cavities' fields had to be temporarily or permanently changed, or in some cases cavities had to be removed from service. The linac flexibility has demonstrated itself in allowing complete retuning and rephrasing of the linac over times of the order of a few minutes. This characteristic is important as not just cavities, but other systems that may be removed temporarily from service and operations interrupted only for a modest amount of time [5].

### *Operating Temperature*

The transient nature of pulsed operation allows larger variation of temperatures within the niobium surface, so that during the pulse the surface resistance of the material can change substantially (see Fig. 3). The operating conditions of the SNS SRF cavities were reviewed and cavity parameters and their interplay were reevaluated, giving details on the possible range of operating parameters which can be achieved at SNS in pulsed conditions [6]. Due mainly to the pulsed nature of the SNS operation and the relatively low operating frequency the cavities can still be operated at 4.2 K up to the critical field. Both calculations and experiments tell us that there's no difference in performances of the SNS SRF cavities as long as the operating temperature is lower than 4.5 K.

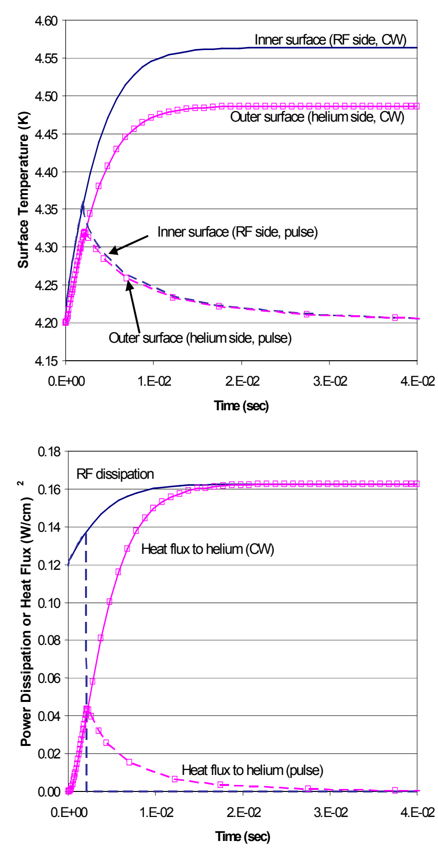

Figure 3: Comparisons of thermal parameters between CW and pulsed operations. Both cases are stable. (solid line; CW operation, dashed line; pulsed operation, lines with symbols; for surface at helium side, lines without symbols; for surface at RF side).

## *Electron Activities and Collective Behaviors at High Repetition Rate*

Most of the cavities exhibit heavy field emission and/or multipacting which directly or indirectly (through heating of end groups) limits the gradients achievable in normal operation with beam. The overall phenomena are complex and the final operational cavity gradients need to be determined individually for each cavity based on the equilibrium between electromagnetic, electron emission and thermal phenomena, each affecting the overall stability of the system on a pulse by pulse basis. In addition to individual cavity field emission limitations, collective effects have been observed which affects neighboring and second neighbor cavities. Bigger heating by these collective effects is clearly observed when the repetition rate is 30 Hz or higher. Heating of cavity elements are driven not only by the amplitude, but also by the relative phase of neighboring cavities. Since in the SCL neighboring cavities' amplitudes and phases are correlated, operation into heavy field emission is prevented by stability concerns, thus limiting the final available energy. Figure 4 compares the average limiting gradients at three different conditions. At low repetition rate (20 Hz or less), individual (powering one cavity at a time) limits are about same as collective limits (powering all cavities in a cryomodule at the same time) at the same low repetition rate, which enabled 1-GeV demonstration at 15 Hz. The difference between limits in open and closed loops results from llrf regulation and much longer duration at the highest field in closed loop.

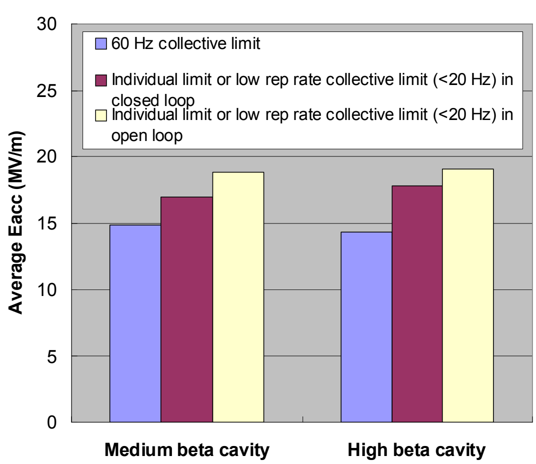

Figure 4: Comparisons of average limiting gradients at 60 Hz collective, individual (or low rep rate collective) in closed loop and that in open loop.

## *Equipment and Sub-components*

Some sub-components have shown peculiar behaviors. The cold cathode gauges, which provide interlock protection to the fundamental power coupler window, have behaved erratically, with a response which is often not correlated at all with other independent measurements of gas pressure at the window.

The Higher Order Mode (HOM) notch RF filters, which are designed to extract RF power at frequencies potentially harmful to the stability of the beam, have shown signs of multipacting, discharges and transient detuning, which can lead to critical components damage.

One high beta cryomodule (CM19) had been removed from the tunnel and been repaired at the SNS SRF test facility by removing HOM coupler feedthroughs from one cavity. Two thermal diodes (TD) were installed where the possible multipacting places according to the analysis as shown in Fig. 5. During the test at the SNS SRF test cave, very aggressive electron activities were observed from the signals of TD ranges from 5 MV/m to 15 MV/m, which led drops of gradients by several percents and detuned cavity bandwidth that corresponds to a few kW deposition of RF power to electrons. All were processed very carefully, which was possible by removing HOM coupler feedthroughs. The first explorer such as the first turn-on, pushing limits, increasing repetition rate must be closely watched and controlled since aggressive multipacting and burst of field emitter could damage weak components. Also we experienced similar situations during subsequent turn-ons after long shutdown and thermal cycle.

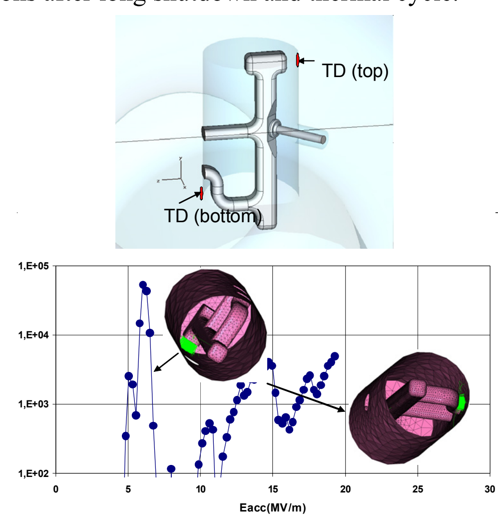

Figure 5: Thermal diodes locations of the 19b after removing the feedthrough (top). Multipacting simulation of the SNS high beta cavity HOM coupler [7] (bottom).

## *Limiting Factors of SRF Cavities*

Statistics of limiting factors achieved during 60-Hz collective tests are summarized in Fig. 6. Two cavities are showing larger mechanical resonances at higher repetition rate while dynamic detuning of all others can be managed by RF feedback and feed-forward only. So far piezo-tuner compensation has not been used in operation. Three cavities are limited by hard quench at a relatively low gradient (around 10 MV/m). One cavity is not in service due to the large power coupling with RF only. The limit tests are stopped for five cavities at about 15 W of fundamental power coupling through HOM coupler. About fourteen cavities are limited by coupler heating, but they are close to the limits by radiation heating. All others are limited by electron loading that leads end group heating, gas burst and quench. Actual operating gradients are set around 85-95 % of limiting gradients achieved at 60-Hz collective tests.

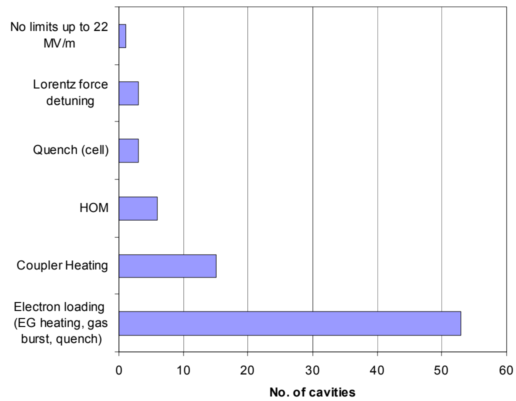

Figure 6: Statistics of limiting factors at 60 Hz collective condition.

### *SRF Cavity Operating Regime*

As seen in Fig. 2 cavities in the medium beta section of the SCL are operating above the design gradient of 10.1 MV/m whereas those in the high beta sections of the SCL are operating below the design one of 15.8 MV/m mainly due to radiations and related heating effects.

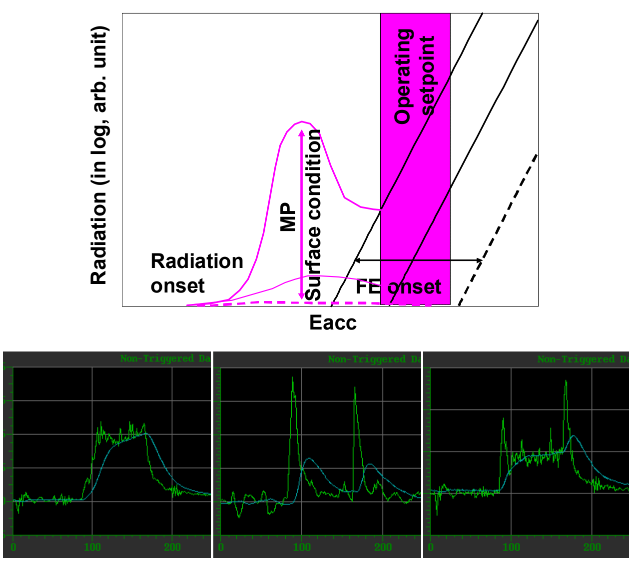

Figure 7: SNS SRF cavity operating regime at 60 Hz and radiation waveforms from RF operations depends on contents of electron activities in a cavity.

Figure 7 is schematically explaining operating regime of most of the SNS SRF cavities, which is higher than big multipacting region and/or lower than the considerable field emission region. During commissioning, testing, and 3-yrs long operation so far, mild contaminations must have been gone, which causes multipacting or mild field emission. In an operational cryomodule, removing a bad contamination is quite difficult. The field emitters on the processed surfaces are known to be very stable. Majority of the SNS SRF cavities are showing radiation waveforms of field emission like the radiation waveform in the bottom left in Fig. 7, while some are showing multi-pacting dominant radiation waveform (bottom center in Fig. 7) and some others are showing both field emission and multipacting (bottom right in Fig. 7).

Since the lack of the final linac output energy, the gradient of each cavity is set to maximize the gradient based on the collective limiting gradients that was achieved through a series of SRF cavity/cryomodule performance test at SNS, rather than having uniform gradients as designed.

## POWER RAMP-UP

Most of equipment in SNS requires substantially higher operational ratings compared to existing accelerators, since the design beam power is almost an order of magnitude higher compared to existing neutron facilities. As beam power increases at higher duty factor during previous runs, down-times of some equipment such as LEBT and high-voltage convertor modulator led lower machine availability than expected. Some systems like the SNS SCL are the first attempt for pulsed operation. Many of the aspects of its performance were unknown and unpredictable, for which it takes time to understand the systems as a whole and/or needs additional performance improvements. A power ramp-up plan has been revised based on the operation experiences and understandings of limits and limiting conditions through extensive studies, which emphasizes more on machine availability (Fig. 8). The plan covers main driving factors for beam power such as chopping efficiency, ion source improvement, high voltage convertor modulator (HVCM) improvement, and SCL output energy. The followings are short descriptions of issues and plans for the power ramp-up at the SCL side.

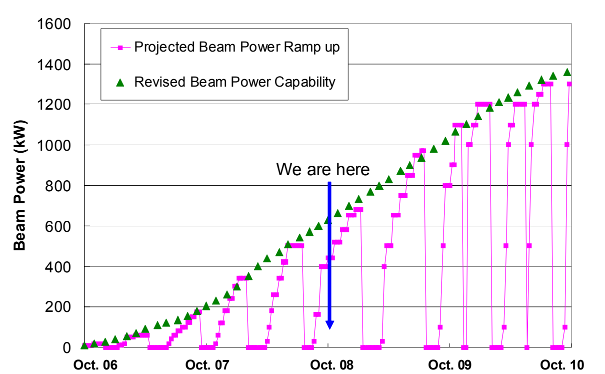

Figure 8: SNS beam power ramp-up history and plan.

The final output beam energy mainly depends on SCL gradients. Presently the SCL is providing output energy of 900 MeV without reserve, which is lower than the design energy due to the facts mentioned in the previous section. The goal of the SCL performances is 1-GeV output energy with 30- to 40-MeV energy reserve for fast recovery of operation from unexpected long-lead down time of not only cavities but also the related systems. Cryomodule repair works are in progress to get all 81 cavities in service [8]. One cavity in the cryomodule 11 is not operable due to the large power coupling through the HOM port from the RF operation. One high beta cryomodule (CM12) was removed from the linac tunnel for repair in the SNS SRF test facility, which had beam line vacuum leaks and showed biggest radiation from RF operation. It is revealed that the beam line leak was resulted from the HOM feedthroughs. Three leaky feedthroughs (plus one feedthrough at the cavity with a leaky feedthrough) were removed out of eight HOM coupler feedthroughs. This cryomodule will be brought in service after RF performance tests in the SNS SRF test facility in the next year. As mentioned above CM19 had been repaired and has been back in service in the slot of CM12 since March, 2008 and is the best performing cryomodule in the SNS SCL. Very recently one cavity, SCL-10b was repaired in the tunnel, which showed noisy field probe signals and had been turned off for about a year at 30- and 60-Hz operations. The final output energy is expected to be about 950 MeV after having all cavities available. For the design energy with some energy reserve like 40 MeV, an active effort for improvement of cavity performance is needed especially for high beta cavities. An R&D program is just started to develop an in-situ surface processing such as helium processing and plasma processing to get about 100-MeV additional output energy.

Each SCL cavity is fed by an individual klystron rated 550-kW RF output at saturation and has independent RF control systems. Eighty one klystrons for the SCL are powered by seven HVCMs; four HVCMs running at 69 kV for twelve klystrons each and three HVCMs running at 71 kV for eleven klystrons each. The voltage of HVCMs needs to be increased up to 75 kV to utilize the rated RF power of the klystrons. To ensure a high intensity beam loading with a good machine availability, a decision was made to have one additional HVCM for the SCL, which is planned to be installed in early next year, so that most of SCL HVCMs will power 10 klystrons at 75 kV with fair reliability.

The beam pulse width is presently major driving factor for the SNS power ramp-up mainly depends on HVCM pulse width and stability of chopper. There will be another beam pulse extension by reducing SCL cavity filling time form 300 μs to 250 μs with the additional HVCM for the SCL mentioned above.

## POWER UPGRADE

Many of the accelerator subsystems are designed to be able to support higher beam intensities and higher beam energy. Upgrades to the SNS accelerator and target systems to increase the beam power to at least 2 MW, with a design goal of 3 MW, are in the planning stages. A beam power upgrade to 3 MW can be achieved by increase the linac beam energy from 1.0 GeV to 1.3 GeV by adding 9 additional high-beta cryomodules in the already prepared empty slots in the linac tunnel and by increasing beam current from 38 mA to 59 mA. The duty factor will be kept at 6 % and most of beam transport lines and ring have capability for 2 MW, 1.3 GeV operations. The newly defined Power Upgrade Project (PUP) includes only the beam energy upgrade portion and the beam current increase and target improvement will be accomplished through R&D activities and so-called Accelerator Improvement Project (AIP). The SNS power upgrade project is waiting for CD-1 approval and the planned project period is from 2011 for about 4 years.

## SUMMARY

The SNS has begun the official operations since October 2006 after completion of the construction project in June 2006. The SNS is in the middle of three-year power ramp-up period to reach the design specifications and high availability for the user services. The presently achieved beam power for the neutron production is about 0.62 MW. From the series of tests and operational experiences more understandings of systems and their limiting conditions in pulsed mode are being obtained at high duty operation. The machine availability is steeply increasing concern as a user facility. The trip rate from the cavity/cryomodule side is now approaching zero and the SCL is providing beam acceleration for the neutron production as one of the most reliable systems. Beam power is keeping on track with the power ramp-up plan that is generated based on the previous operational experiences and studies. The Power upgrade project for energy upgrade from 1 GeV to 1.3 GeV is in planning stage and is waiting for CD-1 approval, which will double the beam power up to 3 MW, incorporated with so-called Accelerator Improvement Project (AIP).

## ACKNOWLEDGEMENT

The author extends his thanks to all his SNS colleagues who have contributed to this work. SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy.

# PROGRESS IN THE BEAM COMMISSIONING OF J-PARC LINAC AND ITS UPGRADE PATH

M. Ikegami, KEK, Tsukuba, Ibaraki 305-0801, Japan

## Abstract

The beam commissioning of J-PARC linac was started in November 2006, and its initial stage was completed in October 2007. Since then, we start to provide the linac beam for the beam commissioning of downstream facilities. During this period, we have performed occasional high-power demonstrations, where we have recently achieved the linac beam power of 12.7 kW (210 kW from RCS) for a limited period of time. We have also confirmed that the short-term beam stability and beam availability of the linac have already reached a sufficient level. The final goal of 1 MW from RCS is to be pursued though a staged upgrades.

## INTRODUCTION

J-PARC (Japan Proton Accelerator Research Complex) is a multi-purpose high-intensity proton accelerator facility jointly constructed by KEK (High Energy Accelerator Research Organization) and JAEA (Japan Atomic Energy Agency). J-PARC accelerator consists of a 400-MeV linac, 3-GeV RCS (Rapid Cycling Synchrotron), and 50-GeV MR (Main Ring). Figure 1 shows the schematic layout of J-PARC facilities.

J-PARC linac serves as an injector for the entire J-PARC facility. The output beam from linac is injected into RCS, and that from RCS is delivered to both MR and a neutron production target. We also have a muon production target through which a proton beam penetrates before reaching the neutron target. Meanwhile, MR is accommodated with two beam extraction systems. One is a slow extraction system, and the other is a fast extraction system. The beam extracted with the slow extraction system is utilized for studies on hadron physics, and the fast-extracted beam is delivered to a neutrino production target for a long-baseline neutrino oscillation experiment. The final goal of the project is to deliver a 1-MW beam from RCS and 0.75-MW beam from MR.

To achieve the final goal, a phased approach is taken in the J-PARC project as discussed in a later section. We are currently in the first phase of the project, where the output energy from linac and MR are 181 MeV and 30 GeV, respectively. In this phase, the linac consists of a 50-keV negative hydrogen ion source, 3-MeV RFQ (Radio Frequency Quadrupole linac), 50-MeV DTL (Drift Tube Linac), and 181-MeV SDTL (Separate-type DTL). The schematic layout of the linac is shown in Fig. 2. The operation frequency of these accelerating cavities is 324 MHz, and the RF power is fed by 3-MW klystrons. Aside from these accelerating cavities, we also have two buncher cavities and two chopper cavities in MEBT (Medium Energy Beam Transport) between RFQ and DTL. In addition, two debuncher cavities are installed in the beam transport line between the SDTL exit to RCS, to which we refer as L3BT (Linac-to-3-GeV RCS Beam Transport). In 181-MeV operation, two SDTL tanks are temporarily utilized as debunchers.

At this point, the initial commissioning of RCS is approaching its completion [2]. The first neutron and muon beams were respectively produced in May and September 2008. Then, neutron production runs are to be started in December 2008. The initial commissioning of MR has recently been started with a beam storage mode, and the acceleration up to 30 GeV will be tried in December 2008 [3]. We plan to deliver the beam to the hadron experimental facility by February 2009, and to the neutrino production target by June 2009.

In this paper, we summarize the achieved performance in J-PARC linac after briefly reviewing its commissioning history. We also show the recent situations with emphasis on the stability of the beam operation and the machine activation experienced to date. Finally, we will present an upgrade path planned for J-PARC linac.

## COMMISSIONING HISTORY AND PRESENT SITUATION

The beam commissioning of J-PARC linac was started in November 2006, and its initial stage was completed in October 2007 [4, 5, 6]. During the beam commissioning, the design beam energy of 181 MeV was achieved in January 2007. Then, the output beam power of 1.2 kW (3.3 % of the design value) was demonstrated in June 2007. From February to May 2007, fundamental tunings have been conducted including the phase scan tuning for the RF set-points [7, 8, 9], orbit correction, and transverse match-

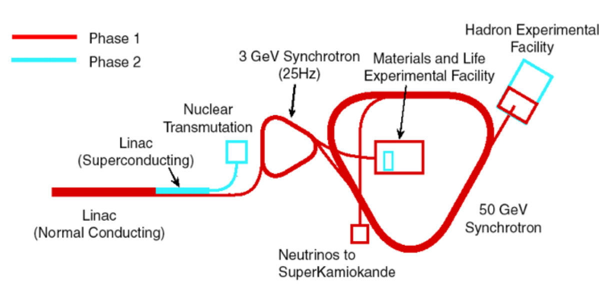

Figure 1: Schematic layout of J-PARC facility.

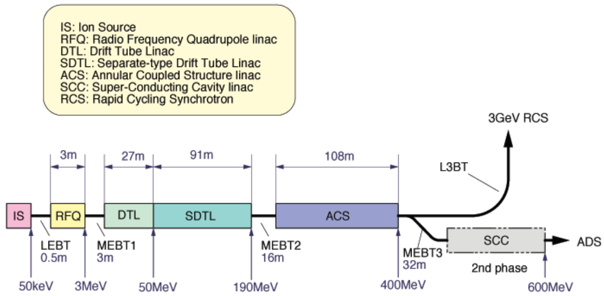

Figure 2: Schematic layout of J-PARC linac.

ing [10]. Subsequently, the output beam from the linac was delivered to RCS in October 2007.

The beam power of 1.2 kW (which corresponds to 20 kW from RCS) is the commissioning goal set for the year 2008, and it is assumed for the initial neutron production run planned in December 2008. Then, we marked the completion of the initial beam commissioning for the linac with achieving 1.2 kW beam power and the beam delivery to RCS without notable beam losses. After completing the initial commissioning for the linac, the beam commissioning of RCS and then MR has been started subsequently [2, 3]. Consequently, the emphasis has been put on the stable beam supply in the linac operation with the minimum beam study for the linac tuning.

As we have focused on the operational stability in this period, some emphasis will be put on this topic in the next section. Needless to say, good stability of the linac is a key to the success in the beam commissioning of the downstream facilities.

## ACHIEVED BEAM PARAMETERS AND THEIR STABILITIES

Currently, the beam power is kept very low for most commissioning runs to avoid excess machine activation at downstream facilities. Then, the high-power operation is performed as a demonstration for limited period of time. The main beam parameters achieved to date are summarized in Table 1. The chopping ratio in this table is defined to be the chopper beam-on ratio during a macro-pulse. Then, parameters with an asterisk is those obtained in a high-power demonstration sustained for only 70 seconds due to a limitation from the beam dump capacity.

The design peak current of 30 mA has already been achieved at the exit of RFQ with the pulse width of 0.25 ms. However, the peak current delivered to RCS is currently limited to around 27 mA. The transmission efficiency is mostly determined by the small aperture of the chopper system in MEBT. Besides, the transmission efficiency of RFQ in this operation was 90 %.

We have performed a high-power demonstration with the reduced peak current of 15 mA. In the demonstration, the macro-pulse width is widened to the design value of 0.5 ms. The repetition rate is also increased to the design value

Table 1: Beam parameters achieved to date

| Parameter | Design | Achieved | Remark |
|---|---|---|---|
| Beam energy [MeV] | 181 | 181 | |
| Peak current [mA] | 30 | 30 | at RFQ ext. |
| | | 27 | at RCS inj. |
| Beam power [kW] | 36 | 3.1 | 27 mA |
| | | 3.4 | 15 mA |
| | | 12.7* | 15 mA |
| Pulse len. / repetition / chop. ratio [ms/Hz/%] | 0.5/25/53 | 0.1/2.5/100 | 27 mA |
| | | 0.5/2.5/100 | 15 mA |
| | | 0.5/25/40* | 15 mA |
| RF width/ repetition [ms/Hz] | ≥0.5/25 | ≥0.5/25 | |

of 25 Hz. Accordingly, the duty factor is the design value of 1.25 %. This operation is sustained for only 70 seconds due to dump capacity limit. The highest beam power from the linac has also been marked in this operation, where the beam power of 12.7 kW is delivered to RCS and 210 kW from RCS with tolerable beam loss rate. The beam intensity of $2.93 \times 10^{13}$ protons per pulse (corresponding to 352 kW with 25 Hz repetition) has also been achieved in a single-shot operation. The stable operation for the neutron target is currently performed with a few kW beam power. The RF source has been operated with the design duty factor since a very early stage of the beam commissioning.

The normalized rms emittance at the SDTL exit is around 0.4 $\pi$mm·mrad with the peak current of 27 mA. The observed emittance is larger than the design value of 0.3 $\pi$mm·mrad due to emittance growth in DTL [11].

As for the stability of beam parameters, we have measured the jitter of the beam centroid energy and the beam centroid position. Figure 3 shows a typical histogram of the measured beam centroid energy, where the energy jitter is monitored for nine hours with TOF (Time Of Flight) measurement utilizing FCT's (Fast Current Transformers). The rms jitters are respectively 39 keV, 15 keV, and 16 keV at the exit of SDTL, the first debuncher, and the second debuncher. The 100 % jitter is sufficiently smaller than the design goal of 333 keV or 0.1 % in momentum.

A typical histogram of the measured beam position is also shown in Fig. 4, where the position jitter is monitored for 30 minutes with two BPM's (Beam Position Monitors). These two BPM's are located at the end of L3BT. The two BPM's are 4.1 m apart with one quadrupole magnet in-between. The rms jitter is found to be around 60 $\mu$m for both BPM's, which is sufficiently small.

It is also noteworthy that the beam availability of J-PARC linac has already exceeds 90 % in recent beam commissioning runs [6, 12].

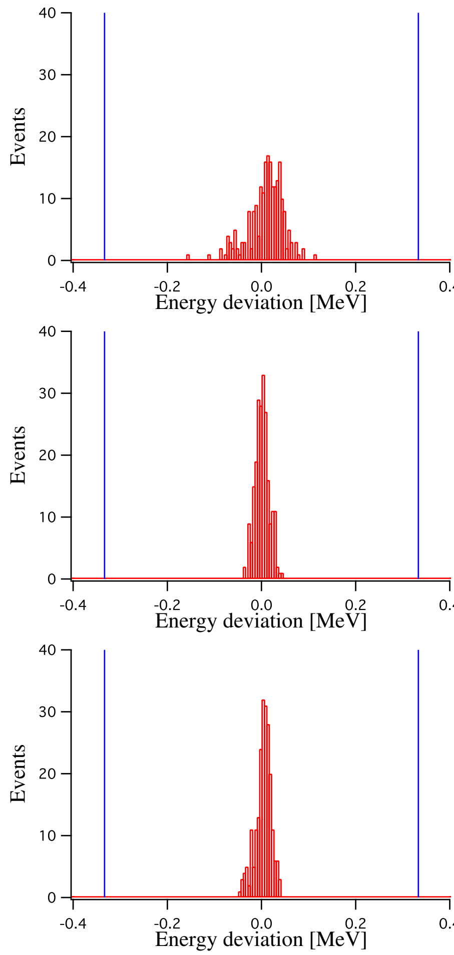

Figure 3: Energy jitter at the SDTL exit (top), the fist debuncher exit (middle), and the second debuncher exit (bottom). The blue vertical lines show the specification of $\pm 0.1$ % in momentum.

## MACHINE ACTIVATION

The machine activation is often the limiting factor for the achievable beam power for a high-intensity accelerator. In spite that the average beam power is mostly kept very low at present, we have already experienced some machine activation due to uncontrolled beam losses.

We have narrow sections at two debunchers installed in L3BT, because the last two SDTL tanks are temporarily utilized for debunchers in 181-MeV operation. Machine activation is mostly localized in the vicinity of the debunchers. We experienced the highest activation when we performed the fine phase-scan tuning for SDTL cavities for the first time with the beam power of 0.12 kW. In that run, the residual radiation level reached 250 $\mu$Sv/h at the second debuncher with contact to the vacuum chamber 6-hour after beam shutdown. Conducting precise tuning of machine parameters, the radiation level was gradually reduced. Then, the typical radiation level at the debunchers became 10 to 40 $\mu$Sv/h at the end of the initial commissioning in spite

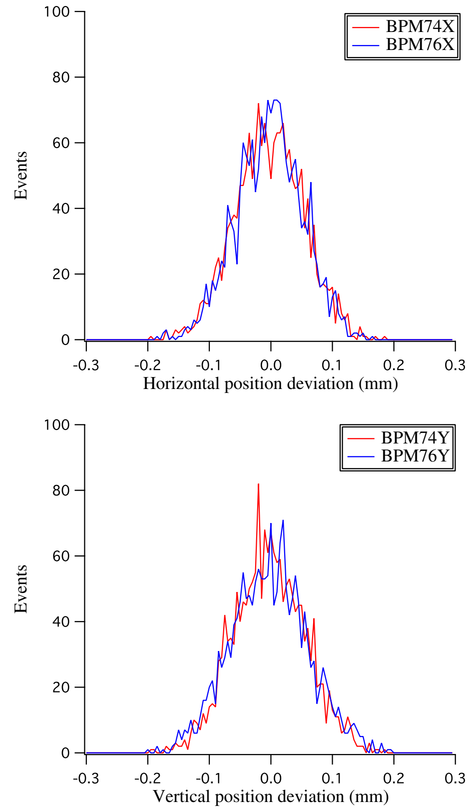

Figure 4: Beam position jitter for the last two BPM's in L3BT. Top: horizontal, bottom: vertical.

of the increased beam power to around 0.6 kW. We also see slight activation in the beam transport line between two debunchers and the arc section after the second debuncher, but it was typically kept below 10 $\mu$Sv/h.

After the commencement of the RCS commissioning, the radiation level has been reduced with the factor of several to ten. However, most of the reduction in the machine activation might be attributable to the single-shot or low-duty factor operations totally employed in the recent runs. As we are entering the stage where we seek beam power ramp-up, we plan to carefully monitor the trend of machine activation in the forthcoming stable beam operations. It is expected to provide valuable information to predict the activation level with the nominal operation with higher beam power.

## BEAM-POWER RAMP-UP

We are now entering the stage where we seek higher beam power in tandem with the further RCS tune-up. The neutron production run will be started in December 2008 with a 20-kW beam delivered from RCS. In the present plan for the beam power ramp-up, the immediate goal is to deliver a 100-kW beam from RCS until February 2009. Then, the next goal is 250 kW until June 2009. The corresponding linac beam power is 6 kW for February 2009 and 15 kW for June 2009. In the present planning, 20 %

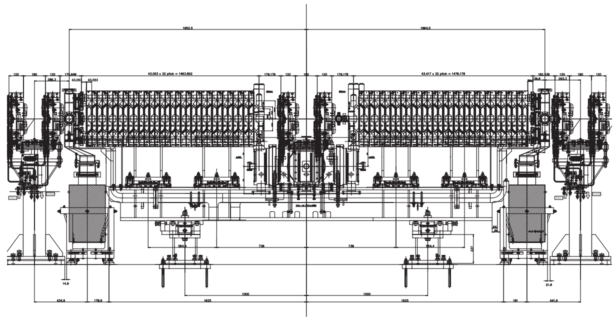

Figure 5: The layout of an ACS module. Two ACS tanks are connected with a bridge coupler. Quadrupole doublets are placed between ACS tanks to provide the transverse focusing.

of the goal beam power is considered to be the minimum requirement for each stage.

The limiting factor for the available beam power is currently the authorized beam dump capacity, and it is to be increased to accommodate the above beam power goals. The machine activation levels and its build-up should also be carefully monitored with a long-term operation.

## UPGRADE PATH

To achieve the final beam power of 1 MW from RCS, we plan to take a phased approach. In the first phase, we start the beam operation of the linac with the lower energy of 181 MeV and the lower peak current of 30 mA. In this phase, the design output beam power from linac is 36 kW and that from RCS is 0.6 kW. We are currently in the beam commissioning stage of this phase.

In the second phase, the linac beam power is increased to 133 kW to achieve the beam power of 1 MW from RCS. The linac output energy is increased to 400 MeV in this phase, and the linac peak current to 50 mA. Instead of moving up to the second phase at a stretch, we plan to take intermediate steps toward the second phase to smoothly ramp-up the output beam power as discussed below.

### [illegible]

In 181-MeV operation, we are aiming at the output beam power of 0.6 MW from RCS. However, this goal is challenging because the space-charge effect is significant in the injection period in RCS. Actually, the space-charge effects in this case is more profound than that in the final stage, where the beam power of 1 MW is aimed with the injection energy of 400 MeV. A simple energy scaling of the space-charge effect results in the beam power of 0.33 MW with 181-MeV injection. Then, we anticipate to face with significant beam losses in achieving 0.6 MW with the injection energy of 181 MeV.

To avoid the potential beam loss problems, we plan to upgrade the linac energy as an intermediate step before proceeding to the second phase. In the energy upgrade, the linac output energy is increased to 400 MeV to ease the space-charge effects in the injection period. Then, the linac output power is increased to 80 kW to achieve the beam power of 0.6 MW from RCS.

The energy upgrade is to be realized by adding an ACS (Annular Coupled Structure linac) section after the existing SDTL section [13]. The ACS is a variation of CCL (Coupled-Cavity Linac), where the emphasis is put on the axial symmetry of its geometry. The J-PARC ACS has been developed based on the former JHF-ACS [14] after an extensive optimization studies with regard to the frequency change [15].

The operation frequency of 972 MHz is adopted for ACS. Then, a 16-m long beam matching section with two buncher modules is to be provided between SDTL and ACS. The primary objective of this matching section is to smoothly absorb the transitional effects due to the three-fold frequency jump [13].

The ACS section consists of 21 ACS modules, and each ACS module is comprised of two ACS tanks. Each ACS module is to be driven by a 3-MW klystron. Figure 5 shows the layout of an ACS module. Three prototype ACS modules have been fabricated and high-power-tested to date [16]. The remaining one and half prototype modules are currently in the final stage of their fabrication. In parallel with the trial manufacturing, the design polishing for the mass production is now under way [17]. Three prototype 972-MHz klystrons have also been fabricated and high-power-tested successfully [18].

We have a four-year plan to fabricate and install ACS modules in the energy upgrade. In the current upgrade plan, it is supposed to take three years to mass-produce the ACS modules. The 972-MHz RF systems, utilities, and cables can be installed during nominal shutdown periods with little interruption of the 181-MeV operation. The ACS modules will be installed in the tunnel during an extended shutdown period. The assumed duration of the extended shutdown period is eight months including that for the following cavity aging and the beam commissioning.

A fraction of the construction budget for ACS has been approved this fiscal year, and we are seeking a government approval of the full construction budget.

### [illegible]

After the energy upgrade, we plan to increase the peak current from 30 mA to 50 mA. Accordingly, the linac output beam power is increased to 133 kW to deliver a 1-MW beam from RCS. The intensity upgrade involves a replacement of the ion source and RFQ. It is also likely to be accompanied with a significant modification of MEBT to accommodate chopper improvement. With increased peak current, the heat load for the chopper system is supposed to be a crucial issue.

As for the 50-mA RFQ, a prototype has been fabricated and low-power-tested successfully [19]. In the trial manufacturing, the upstream one third of the RFQ module has been fabricated.

The 50-mA ion source is naturally the most essential component for the intensity upgrade, for which an extensive R & D has been continued. The peak current of 70 mA has been achieved with a cesium-seeded ion source [20]. However, the available peak current is currently limited to 38 mA without cesium seed [21]. We are continuing the effort to increase the peak current with a cesium-free ion source to avoid potential undesirable effects to the following RFQ.

### [illegible]

In the second phase of the project, it is also foreseen to add an SCL (Super-Conducting Linac) section after ACS to increase the linac output energy to 600 MeV. The 600-MeV beam is not assumed to be injected into RCS, but it will be dedicated to the fundamental studies for ADS (Accelerator-Driven nuclear-waste transmutation System). The 400-MeV beam from ACS will be shared between RCS and SCL. We are planning to increase the linac repetition to 50 Hz, and to utilize 25 Hz of them for ADS studies without reducing the RCS beam power. A prototype cryomodule for SCL has been fabricated and high-power-tested successfully [22].

## SUMMARY

The beam commissioning of J-PARC linac has been started since November 2006, and its initial phase has been completed in October 2007. In October 2007, we started to provide a beam to downstream facilities for their beam commissioning. Since then, the emphasis of the linac operation has been put on providing stable beams to downstream facilities.

In a high-power demonstration for a limited period of time, the beam power of 12.7 kW has been achieved in the linac, which corresponds to 210 kW from RCS. The beam stability and availability of the linac have already reached the sufficient level, and we are entering the stage where we seek beam power ramp-up in tandem with further RCS tuning. We have already experienced a certain machine activation due to uncontrolled beam losses. However, its level is kept sufficiently lower than the tolerable limit.

In J-PARC project, a phased approach is taken to achieve the final goal of 1-MW beam power from RCS and 0.75 MW from MR. In the upgrade path toward the final phase, we plan to take a few intermediate steps for the linac upgrade to smoothly ramp-up the beam power on target. The upgrade is to be started with an energy upgrade by adding ACS section after SDTL. Then, it is followed by an intensity upgrade and another energy upgrade with SCL cavities. Extensive R & D studies are now underway for every front of the staged upgrades. A fraction of the ACS construction budget has been approved this fiscal year, and we are seeking an approval of its full construction.

*Abstract*

China Spallation Neutron Source (CSNS) consists of an $H^-$ linac as an injector of a rapid cycling synchrotron of 1.6 GeV. The 324 MHz rf linac is designed with beam energy of 81 MeV and a peak current of 30 mA. The linac design and R&D are in progress. A test stand of a Penning ion source is under construction. RFQ technology has been developed in ADS study, with beam energy of 3.5 MeV, a peak current of 46 mA at 7% duty factor and a beam transmission rate more than 93%. The first segment of the DTL tank is under fabrication. A full-scale prototype of resonant high-voltage pulse power supply for klystron has been successfully demonstrated. This paper will introduce the design and R&D status of the linac.

## INTRODUCTION

The CSNS accelerator is the first large-scale, high-power accelerator project to be constructed in China[1]. CSNS accelerator mainly consists of an H- linac and a proton rapid cycling synchrotron. It is designed to accelerate proton beam pulses to 1.6 GeV kinetic energy at 25 Hz repetition rate, striking a solid metal target to produce spallation neutrons, as schematically shown in Figure 1. The accelerator is designed to deliver a beam power of 120 kW with the upgrade capability up to 500 kW by raising the linac output energy and increasing the beam intensity, as listed in Table 1[2].

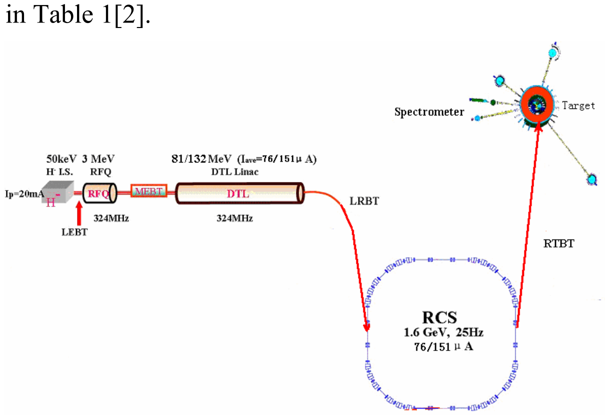

Figure 1: CSNS schematics.

This paper will introduce the design and R&D status of the linac. In the next section, physics design of the linac will be described. Then some R&D activities in the key technology, including ion source, RFQ, DTL and a new type of RF source power supply, will be briefly introduced.

Table 1: CSNS Primary Parameters in Baseline and Upgrade Phases

| Project phase | I | II | II' |
|---|---|---|---|
| Beam ave. power, kW | 120 | 240 | 500 |
| Proton energy, GeV | 1.6 | | |
| Ave. current, *I*, μA | 76 | 151 | 315 |
| Repetition rate, Hz | 25 | | |
| Proton per pulse, $10^{13}$ | 1.88 | 3.76 | 7.83 |
| Pulse length, ns | <500 | | |
| Linac energy, MeV | 81 | 132 | 230 |
| Linac length, m | 50 | 76 | 86 |
| Linac rf freq. , MHz | 324 | | |
| Macro ave. *I*, mA | 15 | 30 | 40 |
| Macro duty factor, % | 1.1 | 1.1 | 1.7 |
| Ring circumference, m | 247 | 247 | 247 |
| Ring filling time, ms | 0.5 | 0.5 | 0.8 |
| Uncontroled loss, W/m | < 1 | | |

## CSNS LINAC PHYSICS DESIGN[3]

CSNS linac consists of an H- ion source, an LEBT, a 3MeV RFQ linac at 324MHz RF frequency, an MEBT and a 324MHz DTL linac. The output beam of the DTL linac is 81MeV with peak current of 15mA in the first phase. CSNS upgrade plan has been taken into the physics design. Beam pulse current will be increase to 30mA or even 40mA, while the beam energy will be increased to 132MeV or even 230MeV respectively so as to keep an acceptable space charge tune spread during the injection into the RCS. Some space in the linac-RCS beam line is now reserved for the additional accelerating structure for the upgraded CSNS linac.

For a low beam loss during the injection to the RCS, injected beam needs to be chopped for pre-bunching in the ring RF bucket. The chopped beam pulse structure is illustrated in Figure 2. To realize such a macro-pulse of 468ns, a pre-chopper is designed in the LEBT. In the case that the chopping is not clear, another fast chopper may be added in the MEBT.

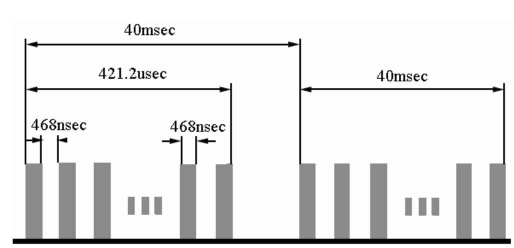

Figure 2: The linac beam pulse structure after chopping.

## *H⁻ Ion Source and LEBT*

CSNS requires the ion source with a high reliability rather than a very high beam current for its first phase. Considering these factors as well as low cost, Penning surface source is preferred. The major design parameters are listed in Table 2. Beam dynamics in extraction was studied with PBGUN code.

Table 2: Major parameters of the ion source

| Ion | $H^-$ |
|---|---|
| Extract energy (keV) | 50 |
| Extract current (mA) | >20 |
| Emittance $\varepsilon_{n,rms}$ ($\pi$ mm-mrad) | <0.20 |
| Rep. frequency (Hz) | 25 |
| Beam duty factor (%) | 1.3 |
| Lifetime (month) | >1 |

The LEBT is mainly composed of three solenoids and an electrostatic chopper for beam matching and chopping, respectively, as shown in Figure 3.The beam from the extraction slit of the ion source is converted to a round beam at the entrance of the RFQ by the three solenoids. To reduce space charge effect, the LEBT is space charge neutralized except for the section of the electrostatic chopper after the last solenoid. Beam optics was studied with TRACE3-D code with 90% neutralization.

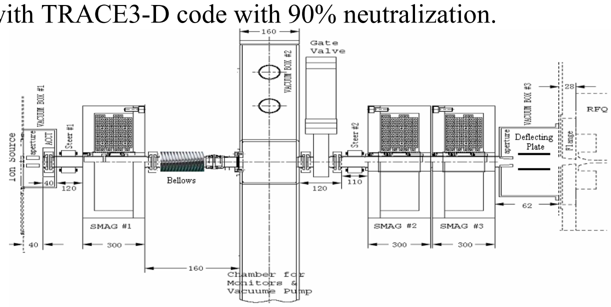

Figure 3: LEBT layout with three solenoids and an electrostatic chopper.

In our previous design, magnetic-alloy loaded induction cavity was design in the LEBT to decelerate the beam for chopping with the following RFQ longitudinal acceptance. Now we proposed to replace the induction cavity with an electrostatic deflector. Correspondingly, the chopper location shifts from the downstream of the first solenoid to the third solenoid, so that the space charge neutralization can be kept in the most space of the LEBT. The transversal acceptance of the RFQ will chop the deflected beam according to PARMTEQ simulation. In this figure, the beam at the RFQ entrance is deviated from the beam axis with x=2.65mm and x'=50mrad. At the exit of the RFQ, no particles emerged, which means the deflected beam is clearly chopped by the RFQ.

The deflector is designed with a length of 40mm and a gap of 30mm. The transit time through the deflector for a 50KeV beam is about 13ns. The applied voltage to generate the beam center deviation of x=2.65mm and x'=50mrad at the entrance of the RFQ is only 3.75kV. Dependence of the RFQ beam transmission on the applied deflecting voltage is plotted in Figure 5. During power source rise time and beam transit time, beam pulse will be partially deflected and thus, chopping becomes unclear. Increase of the deflecting voltage can alleviate this case. Voltage of 3.75kV is so low and so easy to get, and thus we are going to use a higher voltage power supply without much addition cost. In fact, the cost the electrostatic deflector system is much cheaper than our original induction cavity system that requires 150kW pulse power supply for the required decelerating voltage of 8.5kV, while the new deflector requires only 180W pulse power supply at the deflecting voltage of 4.5kV.

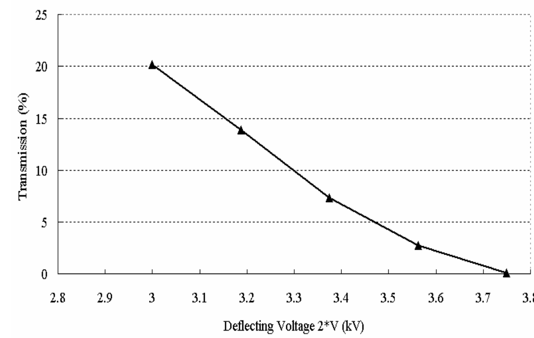

Figure 4: RFQ transmission rate versus deflector voltage.

Most of the deflected beam is lost at the entrance area of the RFQ without further acceleration. So the beam power dumped on the RFQ vanes is rather low, only 25W in average at 50% chopping rate.

## *RFQ Design*

Beam dynamics design with PARMTEQM code indicates a transmission rate higher than 97% for 40mA pulse current. The major design parameters are plotted in Figure 5.

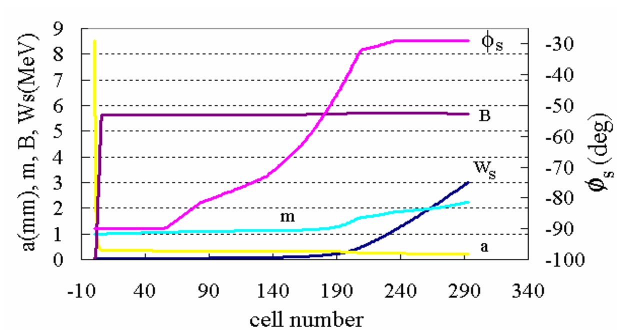

Figure 5: Major parameters along the RFQ.

Four-vane type structure is selected and the total vane length is 3.6m. The cavity is divided into two segments and then resonantly coupled together. Each segment consists two technological modules. Undercut and coupling cell have been carefully designed with 3D code. RF structure design study resulted an acceptable mode separation: the working quadrupole mode has a 3MHz gap from the nearest quadrupole mode and a 5.2MHz gap from the nearest dipole mode. For tuning of the resonant frequency and field distribution, 12 tuners are arranged in each quadrant, as shown in Figure 6. Structure thermal behavior has been studied and some cooling channels are design on the vanes and the cavity wall, as shown in Figure 6. The cooling water serves for two tasks: one for cavity cooling and another for frequency tuning during operation. Simulation indicates that the frequency shift sensitivity on the cooling water temperature is –5kHz/$^0$C.

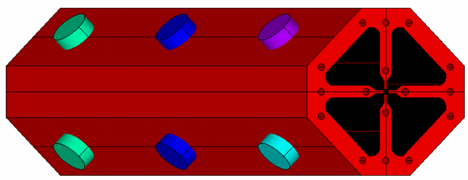

Figure 6: One technological module of the RFQ cavity.

## *MEBT Design*

The major tasks for MEBT are to chop the beam with a fast rise time for low beam loss and to match the beam from RFQ with DTL, again for low beam loss. However, meanwhile fulfilling these two tasks, some beam emittance growth and halo formation may be introduced, resulting in beam loss in the downstream beam transportation. In our case that the chopping task is not demanded in the MEBT in the first phase, we are going to leave a space for a RF chopper in the MEBT, and install it in the second phase for beam power upgrade. RF chopper is preferred so that we can share its successful experience in J-PARC linac.

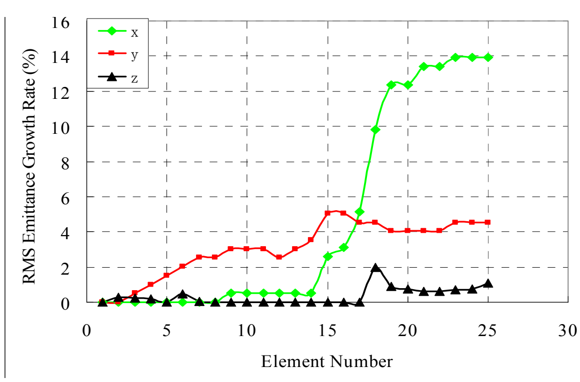

Figure 7: RMS emittance growth in three directions for 40mA beam in MEBT.

RMS emittance growth for 40mA beam is 14%, 4.5% and 1.1% in x, y and z directions respectively, as plotted in Figure 7. In this simulation, beam is chopped in x direction and beam envelope presents a large modulation. Emittance growth in x direction becomes half for half beam current of CSNS first phase linac. MEBT is recognized as most difficult section in the linac in terms of the control of emittance growth and halo formation, due to the combined function of beam chopping and beam matching in three directions.

## *DTL Design*

A conventional DTL was designed with four tanks for 81MeV Phase-I linac and additional three tanks for 132MeV Phase-II linac. Table 3 lists the major parameters of the seven tanks. It is found the field variation pattern given by MDTFISH simulation using the cell data from PARMILA output becomes obviously different from the design value in the PARMILA input file. Cell tuning was hence applied in the tank design to restore the filed distribution back to the PARMILA input data[4] . One of our design goals is to make the RF power consumption in each tank almost the same so as to maximize the utilization efficiency of the RF power source.

Table 3: DTL Tank Parameters

| Tank number | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
|---|---|---|---|---|---|---|---|
| Output energy (MeV) | 21.76 | 41.65 | 61.28 | 80.77 | 98.86 | 115.8 | 132.2 |
| Length(m) | 7.99 | 8.34 | 8.5 | 8.85 | 8.69 | 8.57 | 8.67 |
| Number of cell | 61 | 34 | 29 | 26 | 23 | 21 | 20 |
| Cavity RF power (MW) | 1.41 | 1.41 | 1.39 | 1.45 | 1.45 | 1.45 | 1.49 |
| Total RF power (MW) | 1.97 | 2.01 | 1.98 | 2.03 | 1.99 | 1.96 | 1.98 |
| Accelerating field (MV/m) | 2.2-3.1 | 3.1 | 3.1 | 3.1 | 3.1 | 3.1 | 3.1 |
| Synchronous phase | -30--25 | -25 | -25 | -25 | -25 | -25 | -25 |

FD lattice is chosen for strong focusing with a low envelope modulation, resulting in almost no emittance growth in multi-particle simulation. EMQ is preferred for convenient in beam commissioning. The physics design of the quadrupoles in the DTL drift tubes were conducted with POISSON code.

# KEY TECHNOLOGY DEVELOPMENT

R&D of the key technology in the CSNS linac was started three years ago with a small amount budget from Chinese Academy of Sciences and the site local government of Guangdong Province. It is crucial to make some prototypes for CSNS linac key technology because it has many challenges that we have never touched.

## *R&D of H Ion Source*

We have no experience to make such a high-current, low-emittance and long-lifetime $H^-$ ion source in China. Owing to the collaboration with ISIS, such an $H^-$ ion source is now under development. As a key part of the Penning source, a few source bodies, including discharge chamber and extractor, were fabricated and they were tested at ISIS ion source stand. The results are encouraging. We obtained a beam current of 55mA with beam pulse length of 500 μm at 50Hz., as shown in Figure 8. The emittance measurement gave almost the same value as that of ISIS operating ion source. So we have reason to believe the source can meet for CSNS linac demand.

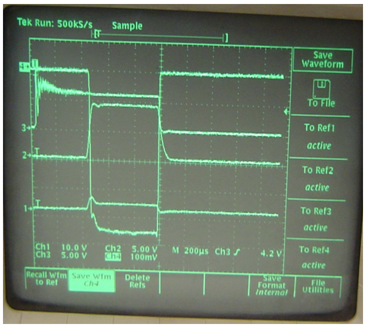

Figure 8: CSNS ion source body tested at ISIS with a beam current of 55mA.

An ion source test stand is now constructed at IHEP. Design of the source was completed (Figure 9) and all elements of the ion source have been fabricated. Assembly of the source is foreseen in recent. Various power sources, high voltage stand, vacuum system, water and gas cooling systems, as well as control system are all in progress.

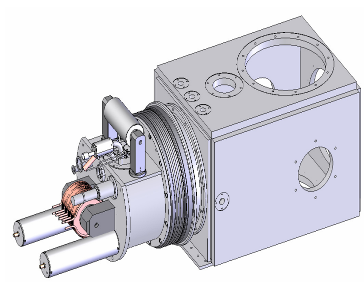

Figure 9: Design of the Penning $H^-$ source for CSNS.

## *LEBT Chopper*

To demonstrate the electrostatic chopper in the space charge neutralized LEBT, we are going to do some experiments on the existing RFQ developed for ADS study at IHEP. The LEBT of the RFQ linac has two solenoids and a beam collimator at the entrance of the RFQ. We will replace the collimator with an electrostatic chopper. It is found a couple of tapered electrostatic plates conforming the shape of the strongly focused beam at the entrance of the RFQ can provide more deflection to the beam at the same applied voltage. The pulse power source has been designed with two solid -state fast switches at the rise and fall ends of the pulse. The switch time is about 8ns at 6kV. A fast beam transformer will also added to the RFQ downstream beam line for beam diagnostics of the chopping effect. By this experiment we want to clarify our concerns: whether the RFQ vane will be damaged by the dumped beam, if spark occurs in the electrostatic chopper which is close to the space charge neutralized region, and if the chopping is fast enough for clear gaps. If it reaches a satisfactory result, we will consider the possibility to omit the MEBT so as to avoid beam degradation in it. In this case, a direct match design between the RFQ and DTL in CSNS linac will be considered.

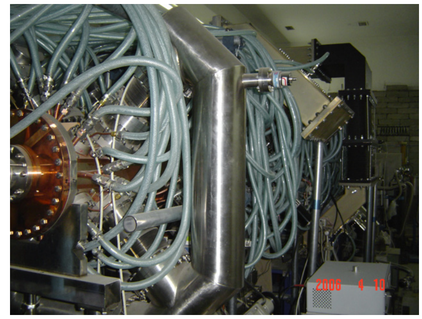

Figure 10. RFQ at 352 MHz for ADS Study.

## *RFQ Developed for ADS Study*

We have no R&D program for CSNS RFQ because we have built a high-current proton RFQ in our ADS research program. The ADS RFQ (Figure 10) has higher beam energy and beam current, and thus all the technology can be applied for CSNS RFQ. .

The major parameters of the ADS RFQ are listed in Table 4. This 3.5MeV RFQ is about 5 $\lambda$ long. To address the longitudinal field stability, it is separated into two resonantly coupled segments. Each segment consists of two technological modules of nearly 1.2m in length. More detailed information about the design and development of the RFQ can be found in reference [5]. From Table 4 it noticed the duty factor is from 6% to 100%. It means the RFQ is designed with 100% duty in terms of the cavity and RF power source, but, as the first step, it was commissioned at 6% duty factor. In the end of this year, we are going to raise its duty factor to 15%. In fact, we have successfully finished high-power RF conditioning at this duty factor in recent. The initial commissioning result will be introduced in the following.

Table 4: RFQ Major Design Parameters

| | |
|---|---|
| Input Energy | 75keV |
| Output Energy | 3.5MeV |
| Peak Current | 50mA |
| Structure Type | 4 vane |
| Duty Factor | 6%-100% |
| RF Frequency | 352.2MHz |
| Maximum $E_s$ | 33MV/m |
| Beam Power | 170kW |
| Structure Power | 420kW |
| Total Power | 590kW |
| Total Length | 4.75 m |

In 2006 we started the beam commission at a low duty factor at IHEP. And gradually the duty factor reached 7% with 1.43ms pulse length at 50Hz. An output beam current of 46mA was obtained with an input beam current of 49mA, resulting in a beam transmission rate more than 93%, as shown in Figure 11. During the operation, the cooling water temperature was tightly controlled for fine tuning of the RFQ cavity resonant frequency. A digital RF control system based on FPGA was developed at IHEP and added to the RF system, which was provided by CERN by kind. With this new feedback system the operation stability became better in the case of long pulse and heavy beam loading. The RF amplitude and phase stability reached $\pm 1\%$ and $\pm 1^0$ respectively.

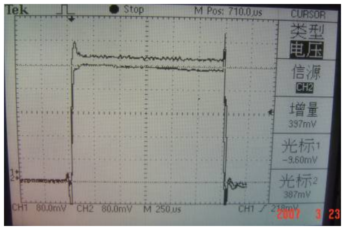

Figure 11: Input and output beam current of the RFQ.

## *R&D on DTL*

A prototype DTL tank was developed. It is the first module of the first tank. This module contains 28 drift tubes with a tank length of 2.9m. Before fabrication, several short tanks were tested to search for the feasible technology. Early attempts to fabricate DTL tank prototypes using the explosive-forming methods failed due to complications in fabrication of various ports on the tank. Periodic reverse electroforming method was successfully adopted by the domestic vendor in the tank fabrication. J-PARC type electromagnetic quadrupoles were fabricated with hollow conductor coils made with PR electroforming method. The drift tube is made of bulk copper and formed with electron-beam welding. Figure 12 shows the DTL tank under final machining of the drift tube holes, a hollow coil in drift tube and a bulk copper drift tube after EBW.

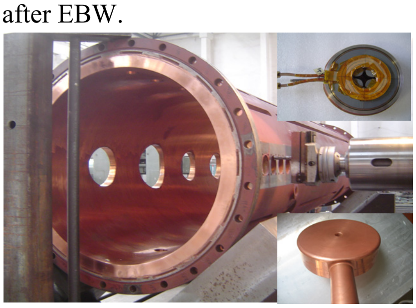

Figure 12: The DTL tank and quadrupole in drift tube of bulk copper.

For the magnetic measurement of the DTL quadrupole, various means, including Hall probe (HP), single stretched wire (SSW), rotating coil (RC), were adopted in order to verify the design specifications and fabrication technology. By carefully adjusting the DTL quadupole position relative to the harmonic coil in the rotating coil measurement, the dipole component can be controlled less than $6\text{X}10^{-4}$, and the magnetic center can be controlled within 0.003mm. More details can be found in a paper for this conference[6].

## *Prototype of Resonant HV Pulse Power Supply*

A new type AC series-resonant high-voltage pulse power supply was proposed by IHEP for the purpose to drive the klystron of the CSNS RF linac. The principle diagram is plotted in Figure 13. This new scheme has no step-up high voltage transformers and multi-phase high-voltage rectifiers. One of obvious advantages of this HV power supply over other types is its simplicity, leading to an easy maintenance and low trip rate during operation.

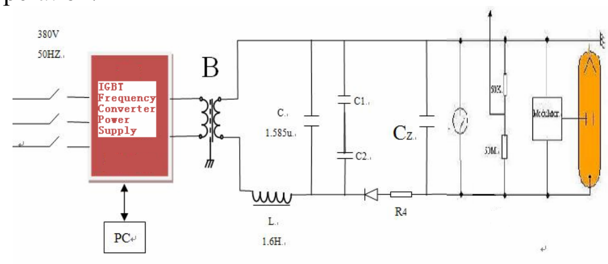

Figure 13: The proposed AC series resonance HV power supply for the klystron.

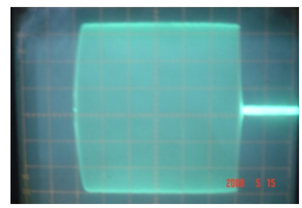

Figure 14: Klystron output pulse (1ms, 420kW) driven by the new prototype pulse power supply.

We have developed a full-scale prototype. Its highest output voltage reached 120 kV, with pulse discharging repetition frequency at 25 Hz or 50 Hz. We obtained an output power of 250 kW. Operation test together with the klystron of ADS RFQ was successful, with an AC-DC conversion efficiency up to 88%, a nice stability and flat-top, as shown in Figure 14. Consequently, the feasibility of the new power supply scheme was demonstrated. In the next step, we will strive for a more compact system.

## ACKNOWLEDGEMENTS

We are very grateful to Y.Yamazaki, K.Hasegawa and F.Naito from J-PARC for their kind assistance and fruitful discussion. Many thanks go to D.Findly, A.Letchford, and D.Faircloth of ISIS for their kind support on the ion source development. We thank all colleagues of CSNS linac team for their great efforts in the design and R&D work.

*Abstract*

The Soreq Applied Research Accelerator Facility, (SARAF) is currently under construction at Soreq NRC. SARAF will be a multi-user facility for basic research, medical and biological research, neutron based non-destructive testing and radio-pharmaceuticals research, development and production. SARAF is based on a continuous wave (CW), proton/deuteron RF superconducting linear accelerator with variable energy (5–40 MeV) and current (0.04-2 mA). The accelerator is designed to enable hands-on maintenance, which implies beam loss below $10^{-5}$ for the entire accelerator. Phase I of SARAF consists of a 20 keV/u ECR ion source, a low energy beam transport section, a 4-rod RFQ, a medium energy (1.5 MeV/u) beam transport section, a superconducting module housing 6 half-wave resonators and 3 superconducting solenoids, a diagnostic plate and a beam dump. Phase II will include 5 additional superconducting modules. The ECR source is in routine operation since 2006 and the RFQ has been operated with ions and is currently under characterization. The superconducting module is installed in the beam line and its RF performance is being characterized. Phase I commissioning results, their comparison to beam dynamics simulations and beam dynamics simulations of Phase II are presented.

## SARAF OVERVIEW

SARAF is currently under construction at Soreq NRC [1]. It will consist of a medium energy (up to 40 MeV) high current (up to 2 mA) RF superconducting linac of protons and deuterons, beam lines and a target hall with several irradiation stations for the abovementioned applications.

The facility schematic layout, its required parameters and a technical description of its components are given in Ref. 2. For a review of its operation concept and control system see Ref. 3.

Due to the technical novelty in the accelerator, the project has been divided to two phases. Phase I includes the ECR ion source, the RFQ, a prototype superconducting module (PSM), the design of the full accelerator (based on beam dynamics simulations [4]) and the design and risk reduction of the foreseen applications. Phase II includes construction of rest of the accelerator and its applications.

This paper presents recent commissioning results of phase I, including comparison to beam dynamics simulations [5], selected results of simulations for Phase II and a calculation of the expected residual activation due to beam loss in Phase II.

#mardor@soreq.gov.il

## PHASE I COMMISSIONING

The SARAF accelerator is designed, manufactured, installed and commissioned by Accel Instruments GmbH [6], in close collaboration with Soreq NRC personnel.

Phase I is fully installed on site, as is shown from 2 views in Figs. 1 and 2.

Figure 1: Upstream view of Phase I as installed on site at Soreq NRC. From right to left: ECR ion source (EIS), Low energy beam transport (LEBT), RFQ and Prototype Superconducting Module (PSM).

Figure 2: Downstream view of Phase I of SARAF. From right to left: PSM, Diagnostic plate (D-Plate), low power (Beam dump 1, copper, 6 kW) and high power (Beam dump 2, tungsten, 20 kW) beam dumps.

In the following sub-sections we describe the commissioning status of each main component.

## *Ion Source and LEBT*

The SARAF ion source is of type ECR, to ensure stable high quality performance and minimal maintenance. The ECR frequency is 2.45 GHz and the plasma is confined via two electromagnetic solenoids.

The ion source is followed by a low energy beam transport line (LEBT) which consists of three focusing solenoids, steerers, a bending magnet, which acts as an ion filter and beam diagnostics, which include two Faraday cups and a slit-wire system for emittance measurement

In Table 1 we show the commissioning results for the ion source. Proton, deuteron and $H_2^+$ beams in the specified range of 0.04 – 5.0 mA have been successfully generated. The emittance of all ion beams in both the X and Y planes was measured by a slit and wire system in the LEBT. Results for protons and deuterons are within the specified value, $\varepsilon_{rms\_norm\_100\%}$ = 0.2 π·mm·mrad. For the $H_2^+$ beam, the emittance is higher.

Table 1: Ion source measured rms, normalized, 100% emittance at both planes for all ions. Emittance for $H_2^+$ at 0.04 mA was not measured.

| Beam current | ε Protons (X/Y) | ε $H_2^+$ (X/Y) | ε Deuterons (X/Y) |
|---|---|---|---|
| [mA] | r.m.s, normalized, 100% [π·mm·mrad] | | |
| 5.0 | 0.20 / 0.17 | 0.34 / 0.36 | 0.13 / 0.12 |
| 2.0 | 0.13 / 0.13 | 0.30 / 0.34 | 0.14 / 0.13 |
| 0.04 | 0.18 / 0.19 | NA | 0.05 / 0.05 |

Possible reasons for the reduced performance for $H_2^+$ are poor ionization efficiency for molecular hydrogen, due to optimization for protons and deuterons, and molecular breakup and ion neutralization of the hydrogen molecules in the beam line's residual gas ($5\times10^{-6}$ mbar H in the LEBT in operation).

Further details on the construction and commissioning of the ion source and LEBT can be found in Ref. 7.

## *RFQ*

The SARAF RFQ is a 176 MHz 4-rod CW RFQ [8]. The main challenge in this RFQ is removing 250 kW from its ~3.8 meter rods, an unprecedented heat density. A high flow water cooling system, including flow inside the rods, has been incorporated in the RFQ.

The RFQ commissioning is comprised of two processes which are being executed in parallel:

- RF conditioning up to 65 kV, the voltage that is required for acceleration of a CW 4 mA deuteron beam to 3.0 MeV.
- Beam commissioning, mainly with protons that require half of the deuteron field.

A few hundred hours of RF conditioning has been performed over the last 2 years in an effort to reach the specified field for CW deuterons. This field implies an input power of approximately 260 kW. Two conditioning schemes were used: setting the input power to a value of 280 kW at a duty cycle of approximately 1% and increasing the duty cycle and starting from a low value of CW power and gradually increasing the power.

So far we were able to reach a 15% duty cycle at 280 kW and CW operation at 195 kW. These values are not stable yet and the sources of these instabilities are currently being investigated. In an effort to improve the slow conditioning progress, several actions were taken at the beginning of 2008:

- The rods were dismantled and sharp edges at their bottom part were rounded off.
- While dismantled, the rods were cleaned with a special cleanser.
- A circuit for fast recovery after sparks was installed.

These measures improved performance for a while but still below the CW deuteron specification. To understand how the input power is converted to the electric field between the rods, the square of the voltage that was measured by one of the RFQ pickups was compared to the input power. The result is shown in Fig. 3.

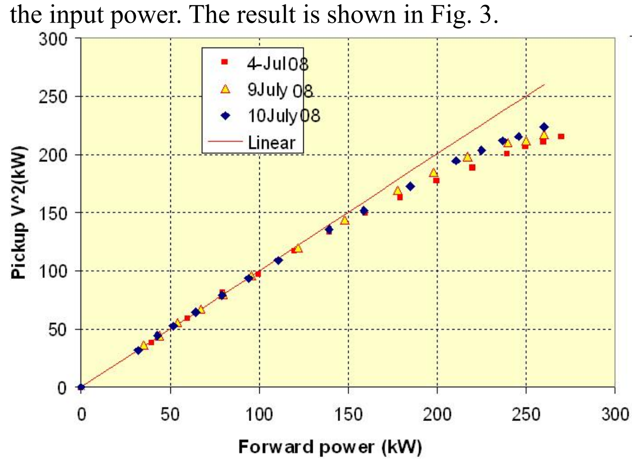

Figure 3: RFQ rod voltage squared versus the RFQ input power. Parting from the linear relation probably indicates onset of dark current due to poor conditioning.

It can be seen that the curve parts from the linear relation below 150 kW. This indicates that the input power generates current that flows between the rods instead of a sustained voltage between them.

The cause of this effect is not certain yet. Following action taken in other installations to circumvent excessive sparking and limited performance (e.g., [9]), an in-situ bake was recently performed by applying ~900 W of CW RF power with the cooling water switched off. The electrode temperature was monitored with PT100 probes that were inserted through the dried water cooling pipes into the rods and rose to 70 – 80 °C, accompanied by a vacuum pressure rise from $5\times10^{-7}$ to $4\times10^{-6}$ mbar. No significant vacuum pressure reduction (such as reported in Ref. 9) was observed after 3 days of baking. The vacuum returned to its base value after turning off the power. The effect of this process on the maximal attainable field in the RFQ will be investigated in the near future.

A description of RFQ beam commissioning, including preliminary results, is given in [10, 11]. Table 2 provides an updated summary of the proton beam performance of the RFQ. Emittance measurements were performed with a low duty cycle beam carrying total power of less than 200W, which is the maximum that the beam intercepting diagnostics can withhold [10]. Energy was measured by the Time-of-Flight (TOF) method using the summed output of beam position monitors in the MEBT and phase probes in the D-Plate. Current was measured by a MPCT and by a FC, both located at the D-Plate.

Table 2: RFQ measured performance. Values in parentheses are the specifications.

| Parameter | Protons |
|---|---|
| Output energy [MeV/u] | 1.5 (1.5) |
| Maximal CW current [mA] | 4.0 (4.0) |
| Transverse emittance r.m.s., normalized, 100% [π·mm·mrad]<br>(at 0.5 mA, closed LEBT aperture)<br>(at 4.0 mA, open LEBT aperture) | <br><br>0.17 (0.30)<br>0.25 /0.29 (0.30) |
| Longitudinal emittance, r.m.s [π·keV·deg/u] (at 3.0 mA) | 30 (120) |
| Transmission [%] (at 0.5 mA)<br>(at 2.0 mA)<br>(at 4.0 mA) | 80 (90)<br>70 (90)<br>65 (90) |
| Required RF power (protons) [kW]<br>(deuterons) [kW] | 62 (55)<br>248 (220) |

The transverse and longitudinal bunch profile measurements were closely followed by beam dynamics simulations [5] using the code TRACK [12]. In Fig. 4 we show the comparison of the measured results with the simulations, which demonstrates good agreement.

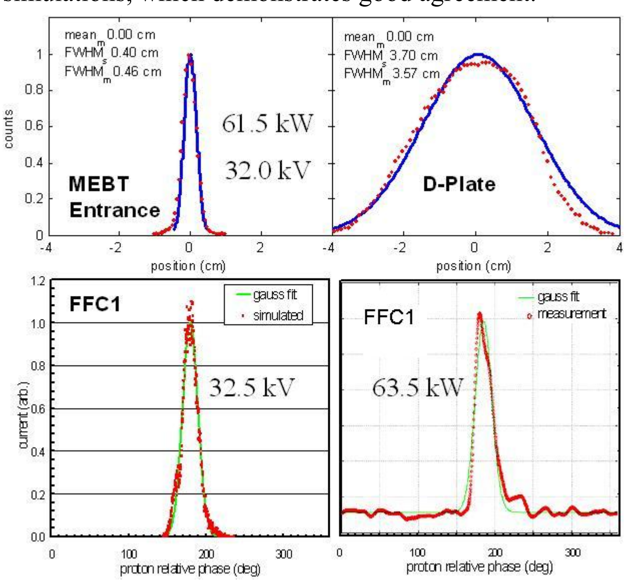

Figure 4: Comparison of post-RFQ measured results and beam dynamics simulations. Top left – Transverse profile at the MEBT entrance. Top right – Transverse profile at the D-Plate. Bottom left – simulated longitudinal profile at the upstream Fast Faraday Cup (FFC) at the D-Plate. Bottom right – measured longitudinal profile.

Short runs of very low duty cycle ($10^{-4}$) deuteron and $H_2^+$ beams were performed. The energy of a $H_2^+$ beam was established to be 3.0 MeV via TOF. The first RFQ transmission measurement for deuterons yielded 70%, without any optimization of LEBT parameters. Further deuteron and $H_2^+$ runs are foreseen following additional conditioning of the RFQ.

### *Prototype Superconducting Module*

The prototype superconducting module (PSM) includes six 176 MHz, β=0.09 half wave resonators (HWR) made of bulk Nb and three 6 T superconducting solenoids inserted amongst them. Further details, along with single cavity vertical cold tests results are described in [13]. RF commissioning results for single cavities inside the PSM, using a voltage controlled oscillator operated at closed loop, are given in [11].

The most recent PSM RF measurements were performed by using the full LLRF system [14], which drives the cavities tuners in a generator driven resonator (GDR [15]) type closed loop. Cavity tuning is based on the forward and transmitted phase signals. An additional coupler was added before the drive amplifier in order to reduce the influence of the reflected signal on forward phase measurements. A further improvement was modification of the tuning loop software in order to include compensation of the piezo tuner hysteresis.

Due to the combination of microphonics, Lorentz force detuning and a possible effect by LHe-pressure variations, which reached peaks of 10 mbar, the cavities frequency variation turned out to be too large for tuning solely by piezo tuners. Therefore, the stepper motor control loop was modified to engage when the voltage input to the piezo approaches 80% of its maximal value.

These modifications enabled PSM operation with the tuners in closed loop. Preliminary results are given in Table 3.

Table 3: PSM RF performance of single cavities. Cavities operated with tuners in closed loop.

| Cavity | $V_{peak}$ [MV] | $E_{peak}$ [MV/m] | Phase stability [°] | Amplitude stability [%] |
|---|---|---|---|---|
| 1 | 0.8 | 23.5 | ±0.3 | 0.5 |
| 2 | 0.7 | 20.6 | ±0.3 | 0.5 |
| 3 | 1.0 | 29.5 | ±0.3 | 0.5 |
| 4 | 0.9 | 26.5 | ±0.3 | 0.5 |
| 5 | 1.14 | 33.5 | ±0.3 | 0.5 |
| 6 | 1.03 | 30.3 | ±0.3 | 0.5 |

The specified $E_{peak}$ for the PSM cavities is 25 MV/m. Cavities 1 and 2 could not be raised to higher fields due to loss of lock. The phase and amplitude stability values are peak-to-peak and are determined by the ADC's least significant bit. It is expected that the actual stability is even better. These values are within specifications.

Operation times in this commissioning run were limited to a few minutes for each cavity, since each cavity was driven separately due to missing couplers.

An additional commissioning run was completed very soon before submission of this paper, where all six cavities were operated simultaneously with the tuners in closed loop. The data is still under analysis, but preliminary qualitative results indicate that it was possible to run the PSM continuously for several hours at an average $E_{peak}$ of slightly less than 20 MV/m .

### *Summary and Outlook*

The commissioning of Phase I of SARAF is on-going. The current challenges include conditioning the RFQ to enable acceleration of CW deuteron and $H_2^+$ beams and optimizing the PSM to enable beam acceleration through it. Beam commissioning of protons and deuterons through the entire Phase I is foreseen for the winter of 2008.

## PHASE II

Phase II of SARAF will include an additional SC accelerating module (SM) similar to the PSM (six β=0.09 HWR cavities and three solenoids) and four additional SMs, including eight β=0.15 HWR cavities and 4 solenoids each.

In this section we shortly describe the extensive beam dynamics simulation effort that is undertaken, in order to ensure that the SARAF design will enable reaching the specified energy, current and emittance, with beam loss that will enable hands on maintenance.

### *Beam Loss Criterion*

The beam loss criterion for the SARAF linac is defined as the beam loss value that generates residual activation of 2 mRem/hr after one year of operation, 30 cm away from the beam line, four hours after accelerator shut down.

In order to generate a conservative criterion, several meticulous assumptions were made:

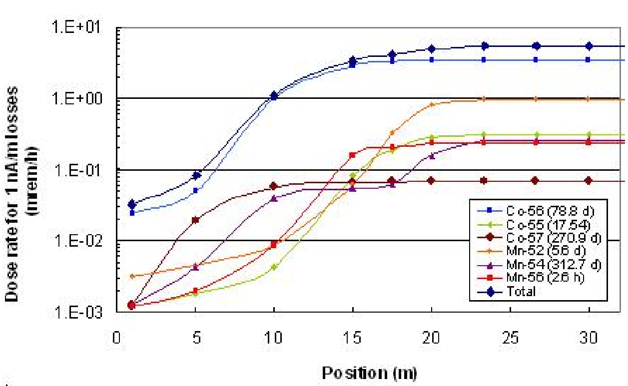

Figure 5: The dose rate along the 22 m long linac and an additional 10 m long beam line, after one year irradiation with beam loss of 1 nA/m, under the meticulous assumptions described in the text.

- The accelerator is operating 365 days per year.
- Only deuterons are accelerated all the time, and to the maximum energy of 40 MeV.
- The accelerator is made entirely of stainless steel.

These assumptions introduce a safety margin of a factor of 2-4. Based on these assumptions, the residual activation per lost deuteron was calculated [16] and this lead to the conclusion that the beam loss criterion is 0.4 nA/m at 40 MeV. As mentioned above, relaxation of the meticulous assumptions that we took may increase this limit by a factor of 2-4. Figure 5 shows the contribution of each isotope, all of which are produced by activation of $^{56}$Fe, to the residual activity assuming beam loss of 1 nA/m. The residual activity is given along the 22 m long linac and an additional 10 m long beam line that leads the beam to the irradiation targets.

### *Beam Dynamics Simulations*

We applied the tail emphasis method [17] in order to study particle losses along the linac. The method is based on the assumption that losses begin longitudinally, and problematic particles begin at the periphery of the longitudinal phase space at the RFQ exit (originate in the boundaries between the downstream bunches at the dc current entering the RFQ buncher section).

This method allows us to calculate losses along the SARAF accelerator at the 1 nA level with limited computational efforts: A Tail Emphasis deuteron beam with 2.1 million macro particles at the RFQ entrance is equivalent to the simulation of 3 bunches containing 42.6 million macro-particles (each 1:10, equivalent to 0.3 nA) for 4 mA CW at 176 MHz.

The reduced computation time allows us to run a large number of simulations in a relatively short span of time. This enables exploration of the effect of manufacturing and operational errors on the beam and estimate losses due to these factors. The values of the errors used on this study are given in [17] and [4].

Figure 6 shows an example of series of 200 simulation runs, each having slightly different manufacturing and operational parameters, which are generated from the distributions described in [17] and [4]. This result is from an application of the tail emphasis method using the simulation code GPT [18].

The result displayed in Fig. 6 is for a 32k/193k core/tail particle distribution of a deuteron beam, which exits the RFQ with a current of 3.4 mA and a normalized rms transverse emittance of 0.23 π·mm·mrad. The outer most macro particle is equivalent to a current of 1 nA. The bore radius is 19 mm within the solenoids and 15 mm everywhere else.

The conclusion from this simulation is that even when considering reasonable manufacturing and operational errors, no beam loss is expected within a simulation resolution of 1 nA. This is consistent with the beam loss criterion for hands on maintenance discussed above.

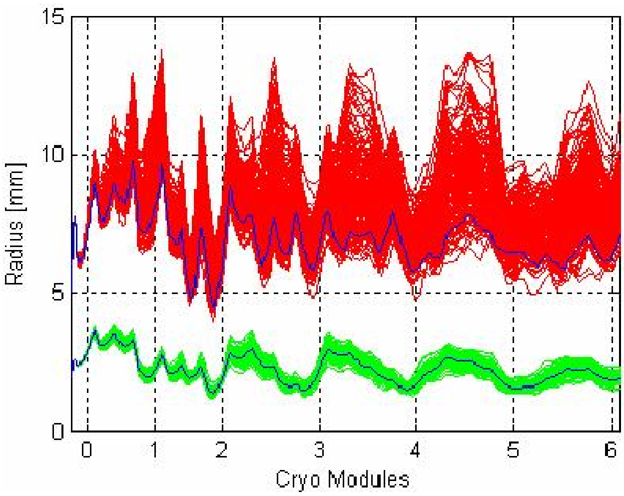

Figure 6: Deuterons transverse envelope (red) and rms radius (green) for a series of 200 error simulation runs through the six SC accelerating modules of the SARAF accelerator.

## SUMMARY AND OUTLOOK

In this paper we presented the current status of the commissioning of Phase I of the SARAF accelerator, and briefly described selected results from the beam dynamics simulation effort which is a major part of the SARAF project.

The commissioning of Phase I is foreseen to be concluded towards the end of 2008 and it is expected that work on Phase II will commence at that time. Currently, Phase II is scheduled to be completed around the year 2013.

## ACKNOWLEDGEMENTS

The authors wish to acknowledge the contribution of B. Bazak, G. Feinberg, S. Halfon, A. Pernick, A. Shor and Y. Yanay to the beam dynamics simulations and the dose rate calculations that are described in this paper.

# THE INJECTOR SYSTEMS OF THE FAIR PROJECT

W. Barth
Gesellschaft für Schwerionenforschung, D-64291 Darmstadt, Germany

*Abstract*

The present GSI accelerator chain will serve as an injector for FAIR (**F**acility for **A**ntiproton and **I**on **R**esearch). The linear accelerator UNILAC and the heavy ion synchrotron SIS18 should deliver up to $1{\cdot}10^{12}$ $U^{28+}$-particles/sec. In the past two years different hardware measures and a careful fine tuning of the UNILAC resulted in an 35% increase of the beam intensity to a new record of $1.25{\cdot}10^{11}$ $U^{27+}$-ions per 100 µs or 2.3 $10^{10}$ $U^{73+}$-ions per 100 µs. The increased stripper gas density, the optimization of the Alvarez-matching, the use of various newly developed beam diagnostics devices, and a new charge state separator system in the foil stripper section comprised the successful development program. The contribution reports results of beam measurements during the high current operation with uranium beams (beam pulse power up to 0.65 MW). The UNILAC-upgrade for FAIR will be continued by assembling a new front-end for $U^{4+}$, stronger power supplies for the Alvarez quadrupoles, and versatile high current beam diagnostics devices. Additionally, the offered primary proton beam intensities will be increased by a new proton linac, which should be commissioned in 2013. We acknowledge the support of the European Community – Research Infrastructure Activity under the FP6 "Structuring the European Research Area" program (CARE, contract number RII3-CT-2003-506395). Work supported by the European Community INTAS Project Ref. no. 06-1000012-8782.

## INTRODUCTION

Meeting the FAIR science requirements higher intensities have to be achieved in the present GSI-accelerator complex, through faster cycling and, for heavy ions, lower charge state which enters quadratically into the space charge limit (SCL). The desired energy of up to 1.5 GeV/u for radioactive beam production is delivered by the synchrotron SIS 100, which also generates intense beams of energetic protons up to 30 GeV for pbar-

Figure 1: The future accelerator facility FAIR at GSI in Darmstadt [1].

Table 1: FAIR-design Uranium Beam Parameters at UNILAC and SIS 18 Injection [2]

| | HSI entrance | HSI exit | Alvarez entrance | SIS 18 injection | |
|---|---|---|---|---|---|
| Ion species | $^{238}U^{4+}$ | $^{238}U^{4+}$ | $^{238}U^{28+}$ | $^{238}U^{28+}$ | $^{238}U^{73+}$ |
| El. Current [mA] | 25 | 18 | 15 | 15.0 | 5.5 |
| Part. per 100µs pulse | $3.9{\cdot}10^{12}$ | $2.8{\cdot}10^{12}$ | $3.3{\cdot}10^{11}$ | $3.3{\cdot}10^{11}$ | $5.0{\cdot}10^{10}$ |
| Energy [MeV/u] | 0.0022 | 1.4 | 1.4 | 11.4 | |
| ΔW/W | - | $4{\cdot}10^{-3}$ | $\pm1{\cdot}10^{-2}$ | $\pm2{\cdot}10^{-3}$ | |
| $\varepsilon_{n,x}$ [mm mrad] | 0.3 | 0.5 | 0.75 | 0.8 | |
| $\varepsilon_{n,y}$ [mm mrad] | 0.3 | 0.5 | 0.75 | 2.5 | |

production. Highly charged heavy ion beams with a maximum energy of 30 GeV/u have to be accelerated in the slower cycling synchrotron SIS 300. SIS 300 can also be used as a stretcher for radioactive beams, which can be injected, cooled, and stored in a system of rings with internal targets and in-ring experimentation.

In the last years GSI put effort in increasing the uranium intensities delivered to the SIS 18. An advanced upgrade program for the UNILAC is still in progress to meet the FAIR requirements. For uranium (FAIR reference ion) the UNILAC has to deliver $3.3{\cdot}10^{11}$ $U^{28+}$-particles per 100 µs (see Table 1). Besides for a 15 emA $^{238}U^{4+}$ beam from the High Current Injector HSI [2] up to $5.5{\cdot}10^{10}$ $U^{73+}$ particles should be delivered to the GSI heavy ion synchrotron SIS 18 (during 100 µs), while the SIS 18 SCL is reached by a 15 turn injection into the horizontal phase space.

In the 36 MHz-HSI [3] comprising ion sources of MEVVA-, MUCIS- or Penning-type, the IH-RFQ, a short 11 cell adapter RFQ (Super Lens), and two IH-tanks, the beam is accelerated up to 1.4 MeV/u. In the gas stripper section the charge state is increased and after charge separation the high intensity $U^{28+}$-beam is matched to the Alvarez DTL. After acceleration up to the final UNILAC-beam energy the transfer line (TK) to the synchrotron provides for a foil stripper and a new compact charge state separator system.

The UNILAC brilliance for proton beams is at least two orders of magnitude below the FAIR-requirements. For the proposed time sharing scenario proton beam intensities of 35 mA and an energy of 70 MeV are required. Accordingly, a dedicated proton injector linac [4] being designed within FAIR will be operated independently from the existing UNILAC.

The UNILAC serving as a high duty factor heavy ion linac for physics experiments is in operation since more than 30 years. After completion of the FAIR complex in 2015 the running time for the accelerator facility will be 20 years at least, while the UNILAC will then be in operation for more than 60 years. Different proposals for a new advanced short pulse, heavy ion, high intensity, high energy linac, substituting the UNILAC as a synchrotron injector are still in discussion. This new "High Energy-UNILAC" will allow for complete multi-ion-operation, and should provide for reliable beam operation in the future.

The decelerator for HITRAP (Heavy Ion TRAP) is also a (linac-) project providing for ions of selected charge states up to $U^{92+}$ at cryogenic temperatures. One of the HITRAP features will be the ability to decelerate heavy highly-charged ions from 4 MeV/u down to rest after ejection from the Experimental Storage Ring (ESR). After three years of operation at the ESR the HITRAP set-up will be an integral part of FAIR behind the NESR (New Experimental Storage Ring).

## HSI FRONTEND-UPGRADE

Table 2: Main RFQ Parameters

| | New Design | Existing Design |
|---|---|---|
| Voltage, kV | 155.0 | 125.0 |
| Average radius, cm | 0.6 | 0.52-0.77 |
| Electrode width, cm | 0.84 | 0.9-1.08 |
| Maximum field, kV/cm | 312.0 | 318.5 |
| Modulation | 1.012-1.93 | 1.012-2.09 |
| Synch. Phase, degree | -90 to -28 | -90 to -34 |
| Aperture, cm | 0.41 | 0.38 |
| Min. transverse phase advance, rad | 0.56 | 0.45 |
| Norm. transverse acceptance, cm mrad | 0.086 | 0.73 |
| Output energy, MeV/u | 0.120 | |
| Electrode length, mm | 9208.4 | |

The bottleneck of the whole UNILAC is the front-end system of the High Current Injector. It is shown in an upgrade design study that the transverse RFQ-acceptance can be significantly increased while the emittance growth can be reduced. Both goals are achieved with only a moderate change of the RFQ electrode geometry; the intervane voltage rose from 125 kV to 155 kV [5], but keeping the design limit of the maximum field at the electrode surface. The changing resonant frequency can be compensated with a relatively small correction of the carrying rings. The beam parameters in the final focusing elements of the LEBT were optimized together with the improved design of the input radial matcher; the length of the gentle buncher section was considerably increased to provide slow and smooth bunching resulting in a reduced influence of space charge forces. The baseline design was optimized for an $U^{4+}$ beam current of 20 emA and a total transverse emittance of 280 mm·mrad (unnorm.). These values were chosen on the base of the measurements in front of the RFQ (15 mA, 210 mm·mrad) assuming the same brilliance. The main parameters of the new design are summarized in Table 2. [6]

A comparison of the existing and the new RFQ is illustrated in Fig. 2. The beam current inside a given transverse emittance at the RFQ output is shown for both designs. Beam dynamics simulations were done for the same beam current (25 mA) and emittance (210 mm·mrad), but with different matching for each case. The new RFQ design provides for an increase of more than 40 % of the beam current compared to the old design. Higher beam emittance behind the new RFQ is formed by a few percent of the particles, while the core of the beam (20 mm·mrad) contains the required beam current. The HSI-RFQ upgrade will start in spring 2009.

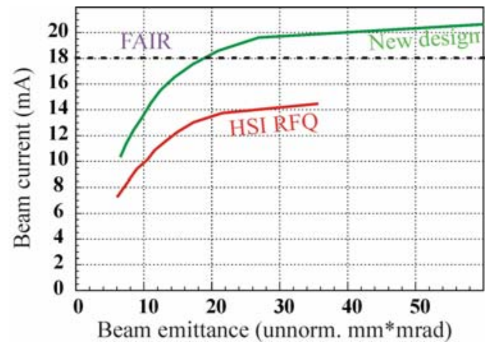

Figure 2: Beam current inside a given emittance at RFQ-output for the existing (red) and the new design (green).

## HSI END TO END SIMULATIONS

The beam dynamics for the HSI were simulated with different codes; the geometry of both RFQ designs were introduced in the DYNAMION-code. Alternatively PARMTEQ-M was used to cross check beam dynamics results; the simulation results of both codes showed high agreement. The DYNAMION macro particle distribution was directly matched to the intertank section comprising a magnetic quadrupole duplet and the super-lens, were the beam is matched to a 20 m IH-section simulated by LORASR. Fig. 3 shows a comparison of the beam performance at the IH-output for the existing and the new RFQ-design. A significant increase of beam brilliance for the total HSI-performance is visible if the new RFQ-design is considered. For a transverse emittance of 20 mm·mrad an $U^{4+}$-current of more than 18 emA is enclosed, meeting the FAIR-requirements. Further simulations will be performed to evaluate the overall improvement at the end of the whole UNILAC. The full FAIR-performance should be reached when the planned installation of ion source terminal and Compact LEBT [7] will be realized (2010-2011).

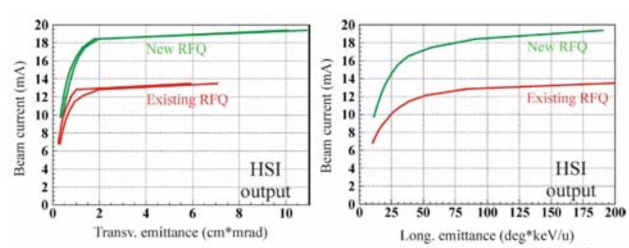

Figure 3: Beam current inside a given transverse (left) and longitudinal (right) emittance at HSI-output for the existing (red) and the new design (green). [6]

## GASSTRIPPER PERFORMANCE

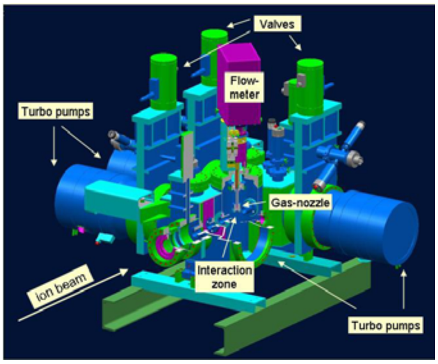

Figure 4: New gas stripper box.

With a reduction of the beam apertures in the old stripper box, it was possible to increase the stripper gas density by 50 %. For medium intense uranium beams this leads to the expected gain for the desired charge state 28+ (up to 12.8 % of the total particle number). The desired equilibrium charge state distribution was reached for a 70 % higher gas density. During long term operation the pumping speed of the old vacuum pumps was not sufficient to compensate this gas load. For high current operation, as required for FAIR, the defocusing effect of the space charge forces leads to particle loss in the transport section after the stripping area. In the new gas stripper box (as shown in Fig. 4) [8] the high stripper gas density for the necessarily enlarged apertures is provided by enhanced vacuum pumping speed.

## BEAM MATCHING TO THE ALVAREZ

The improvement of beam quality at the end of the UNILAC Alvarez DTL section is a major concern with respect to the availability of the design beam parameters. The DTL comprises 177 accelerating gaps and 184 quadrupoles for periodic transverse beam focusing. The high currents arise non-linear space charge forces leading to emittance growth. This emittance growth depends on the beam envelope shape, which can be varied by the transverse phase advance $\sigma$. In case of low currents the zero current phase advance $\sigma_o$ is calculated analytically considering the field strength of the quads.

The beam envelope also depends on the matching to the DTL injection. A beam is matched if its envelope inhabits the same periodicity as the focusing structure, mismatching is quantified by the mismatching factor M. In machine experiments the dependency of emittance growth on $\sigma_o$ and M for the Alvarez DTL was investigated. The design beam for FAIR is 15 emA of $^{238}U^{28+}$ being space charge equivalent to 7.1 emA of $^{40}Ar^{10+}$. Since $^{40}Ar^{10+}$ is available with higher intensity and allows for a larger spectrum of focusing strengths, $^{40}Ar^{10+}$ was used. Phase space distributions were measured in front of the DTL. From the transverse measurements the rms-emittances were extracted. The DTL was set to different values of $\sigma_o$. From the measurement in front of the DTL M was calculated for

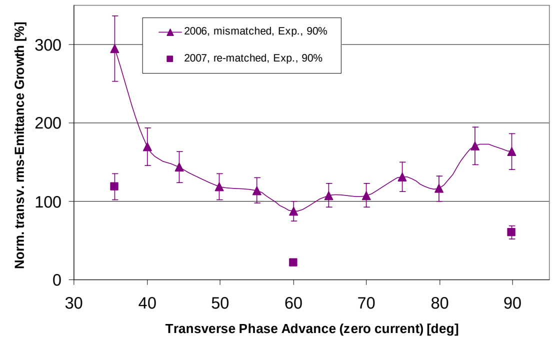

Figure 5: Measured transverse emittance growth as function of the phase advance [9]

each value of $\sigma_o$ and corresponding Alvarez-emittances were measured. Emittance growth rates as function of $\sigma_o$ are plotted in Fig. 5. The mismatch was large for low and for high phase advances. A minimum mismatch occurred at $\sigma_o \approx 55°$, resulting in a minimum emittance growth. Highest growth rates of 300 % were measured at $\sigma_o = 35°$. It decreases down to 100 % at about 60° and increases again to almost 200 % for highest $\sigma_o$. Compared to the 2006-campaign mismatch was reduced for all phase advances. The corresponding emittance growth rates are shown. It was demonstrated that by reducing M, emittance growth rates of just 20 % can be achieved. [9] A sufficient phase advance $\sigma_0 > 50°$ is also required for an improved high current beam brilliance for the SIS-injection of heavy ions. New stron-ger power supplies feeding the quads will be mounted in the winter shutdown 2008/2009 providing for the necessary quadrupole field strength for $U^{28+}$-operation.

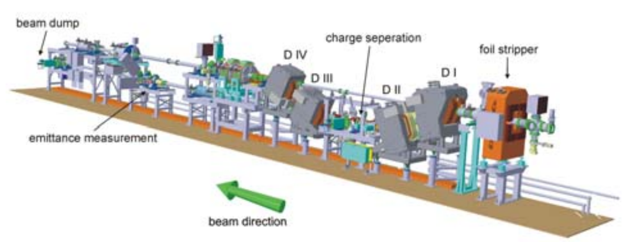

Figure 6: New Charge state separator system, integrated in the TK comprising the foil stripper, the four 35°-Dipole magnets (DI - DIV), and a beam diagnostics bench.

## NEW CHARGE STATE SEPARATOR

A new charge state separator system was installed in the transfer line to the SIS 18 in December 2007. After commissioning of all components, in January 2008 beam commissioning was performed successfully with a medium intensity uranium beam and a high intensity argon beam; the measured beam transmission is close to 100 % for low and high current beams. The sweeper operation was tested with a high intensity argon beam as well as with an uranium beam. In general no emittance growth effects is driven by the sweeper operation. The stripping efficiency measured with the charge separator as a spectrometer is as expected. The improved charge separation capability was simulated with the PARMILA

Transport code and confirmed for heavy ion beams as well as for high current operation. Simulated and measured emittance growth effects for low current operation are caused by small angle straggling; additionally the vertical emittance inside the charge separator is increased by dispersion. Space charge forces act in the short drift length between stripper foil and charge separation in D I only – the space charge influenced emittance growth is 10 % (hor.) resp. 20 % (vert.). [10] The measured high current emittance potentially meets the FAIR requirement. With an advanced beam diagnostics bench behind dipole III high current beam measurements are accomplished to prepare for the injection into the SIS 18. Besides ion current the beam profile and position, the emittance, the beam energy, and the bunch structure can be measured.

## $^{238}$U-BEAM INTENSITIES FOR THE SIS 18

In Fig. 7 the achieved uranium intensities in the UNILAC and TK are summarized (2001-2007), reached by ongoing upgrade measures and by an extended experimental program dedicated to improve the overall UNILAC performance for heavy ion high current operation. In June 2007 an $U^{73+}$ intensity of 2.7 emA (37.1 pμA) was reached for the first time, which corresponds to $2.3 \cdot 10^{10}$ particles per 100 μs. Before foil stripping 5.7 emA (203 pμA) of $U^{28+}$ beam intensity was achieved ($1.25 \cdot 10^{11}$ particles per 100 μs). The optimized total particle transmission through HSI, stripper section,

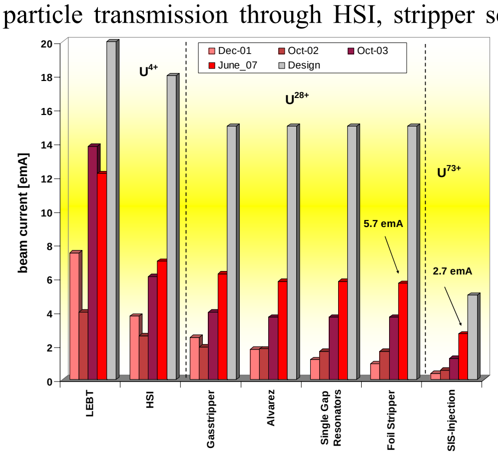

Figure 7: Improvement of the UNILAC-uranium beam intensities during the last three years.

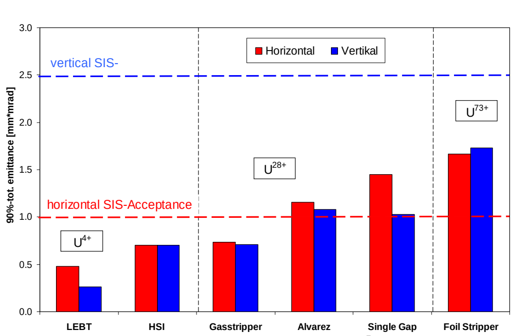

Figure 8: High current beam emittance measured during the measurement campaign in June 2008.

Alvarez DTL, Single gap resonator chain, and TK is larger than 50 % if the particle losses during charge state separation behind the two strippers are taken into account. The measured transverse beam emittance (see Fig. 8) exceeds the acceptance of the synchrotron. The planned front end upgrade and the resulting improvement of the beam brilliance will serve to overcome these bottlenecks.

## LAYOUT OF THE FAIR-PROTON LINAC

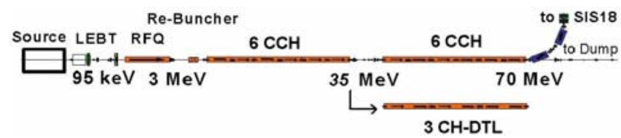

Figure 9: Two proposed schemes for the FAIR p-linac. [11]

To provide the primary proton intensities a dedicated proton linac is planned comprising a proton source, an RFQ, and a DTL, both with an operation frequency of 325 MHz allowing for acceleration up to 70 MeV. For the first time normal conducting Crossed-bar H-cavities (CH) are used. The beam pulses with a length of 36 μs, a current of 35 mA, and total transverse emittances of 7 μm will allow filling the existing synchrotron SIS 18 within a multi-turn-injection up to its SCL of $7 \cdot 10^{12}$ protons. The GSI Proton injector will be the fist machine based on CH-DTL cavities applying a KONUS beam dynamics scheme. The beam dynamics layout has been designed assuming an input current up to 70 mA, twice the value required during operation. Two different layouts are still under investigation, the first design appropriates coupled cavities only and the second makes use of a standard cavity in the high energy section. Beam dynamics investigations including loss studies show that both designs can fulfil the FAIR requirements, and they are robust enough against inevitable errors. At present time technical drawings of the second resonator of the proton injector are in preparation; after validating the coupling scheme with the construction of a scaled model. The construction of the FAIR Proton injector should start in 2010, while the commissioning phase should be finished in 2013. [11]

## COMMISSIONING OF THE HITRAP DECELERATOR

Accelerated and highly stripped heavy ions from the GSI accelerator complex are stored, decelerated down to 4 MeV/u, and finally cooled in the ESR. After beam extraction the ions have to be further decelerated down to 6 keV/u. An IH drift tube cavity and a 4-rod RFQ, both operating at 108 MHz, decelerate the beam down to the final beam energy in two steps. Longitudinal matching to the IH structure is applied by a double-drift-buncher combination comprising a 108 MHz λ/4-resonator and a 2nd harmonic cavity. A third rebuncher of spiral type is located between IH and RFQ. Finally, a low power spiral type debuncher inside the RFQ tank provides for the reduced beam pulse spread sufficient for beam capture in the super conducting penning trap. Within three commissioning periods the technical and physical functionality of the HITRAP-decelerator was proofed (see Fig. 10). No major problems occurred. Additional magnetic steering devices turned out to be necessary for proper beam transport tuning, the setting values were slightly modified by experience, and the working points of the rf-structures were fixed. For improved beam energy analysis a bending magnet and an additional scintillation screen will be installed temporarily behind the IH tank. The RFQ high power conditioning already began. The tank will be finally installed in autumn 2008. HITRAP commissioning will be finished until mid of 2009. [12]

## LONGTERM PERSPECTIVES

After recommissioning of the UNILAC with the highest heavy ion beam intensities, the replacement of the existing Alvarez-DTL is proposed, leading to a sustain operation for the next decades. Additionally a dedicated new cw-Linac could deliver high duty factor beams for the SHIP experiment with energies up to 7.5 MeV/u. A first conceptual layout is shown in Fig. 11. Behind the HSI a new 4 MV/m 108 MHz IH-LINAC (50 m total length) provides a high intensity 5 MeV/u $U^{4+}$-beam. The existing gas stripper section is reused to perform a beam intensity of 24 emA in charge state 42+. The present LINAC-tunnel may house a high efficient 325 MHz-CH-LINAC (35 m), able to boost the beam energy up to 30 MeV/u. In the transfer line to the SIS 18 the foil stripper and the new compact charge state separator will be able to provide for charge state 82+. If the gas stripper will be replaced by a solid state stripper a beam energy of 42 MeV/u (charge state 63+) will be realized. A further upgrade option may provide a second 100 m-CH-LINAC (325 MHz) to enhance the beam energy to up to 100 MeV/u ($U^{41+}$)/150 MeV/u ($U^{63+}$), sufficient to feed the FAIR 100 Tm synchrotron directly. [13]

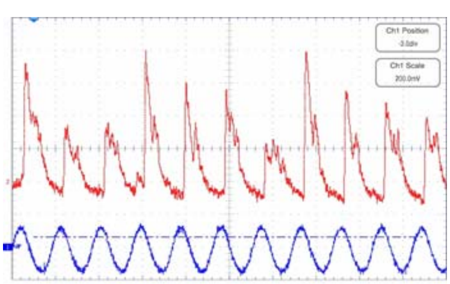

Figure 10: Bunch measurement of a 4 MeV/u $^{20}Ne^{10+}$- beam with the diamond detector (top) and 108 MHz reference signal (bottom) [12]

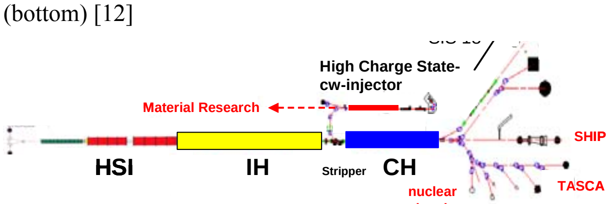

Figure 11: Conceptual layout of a multipurpose high intensity heavy ion linac at GSI [13]

## OUTLOOK

- The UNILAC-upgrade program for FAIR will be finished until 2011; the required $U^{28+}$-beam intensity of 15 emA (for SIS 18 injection) should be available especially after the complete front end upgrade.
- The replacement of the Alvarez-DTL by a new 5 MeV/u, high Bρ IH-DTL and an advanced 30 MeV/u high energy linac is advised to provide a robust and safe operation for the next decades.
- An additional linac-upgrade option sufficient to boost the beam energy up to 150 MeV/u will help to reach the desired heavy ion intensities in the SIS 100.
- An enhanced primary beam intensity at the target is required for different experimental programs with heavy ion beams up to an energy of 7.5 MeV/u. It is recommended to build a cw-heavy heavy ion-LINAC.
- A design study of a multipurpose high intensity heavy ion injector considering all future requirements will be prepared.

*Abstract*

The Fermilab High Intensity Neutrino Source (HINS) Linac R&D program is building a first-of-a-kind 60 MeV superconducting H- linac. The HINS Linac incorporates superconducting solenoids for transverse focusing, high power RF vector modulators for independent control of multiple cavities powered from a single klystron, and superconducting spoke-type accelerating cavities starting at 10 MeV. This will be the first application and demonstration of any of these technologies in a low-energy, high-intensity proton/H- linear accelerator. The HINS effort is relevant to a high intensity, superconducting H- linac that might serve the next generation of neutrino physics and muon storage ring/collider experiments. An overview of the HINS program, machine design, status, and outlook is presented.

## INTRODUCTION

Fermilab has long considered options to replace its aging 8 GeV injector complex to support future accelerator-based physics programs that will demand high intensity proton beams, including neutrino physics and muon storage ring/collider experiments. A technologically advanced, enhanced performance version of the classical Fermilab Linac/Booster system is a natural concept to pursue and a great deal of effort has been invested to develop the physics and engineering details of this option [1][2]. With recent advances in superconducting (SC) RF cavity science and technology, the possibility of a full 8 GeV linac became realistic. Plans for such a machine that would leverage the best aspects of RIA, SNS, and TESLA/ILC developments were born [3] and matured [4].

By late 2005, strong interest in pursuit of the International Linear Collider (ILC) and the U. S. high energy physics community's commitment to PEP-II B-Factory and Tevatron Collider operations left little room to support construction of an 8 GeV linac. Nevertheless, it was recognized that a machine of this caliber might be a key to maintaining a strong U.S. presence in accelerator-based physics before ILC construction. This provided the basis, in the name of neutrino physics, for R&D funding to pursue the novel technical aspects of the linac and thus the Fermilab High Intensity Neutrino Source (HINS) R&D linac.

*Operated by Fermi Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the United States Department of Energy.

## HINS R&D SCOPE

The full scope of the HINS R&D program has included studies of various accelerator physics issues of importance to a facility expected to deliver high intensity, high energy beams for exploration of neutrino physics. With Fermilab steering the overall efforts, collaborating laboratories have also made important contributions. Argonne National Laboratory provides the major resources for the accelerator physics design and particle tracking simulations for both the HINS and the 8 GeV linacs. Argonne's experience in the design and development of SC spoke-type RF cavities [5] [6] serves as the foundation for Fermilab's entry into this technology and Argonne continues to provide resources for cavity processing in the construction phase. Lawrence Berkeley National Laboratory's participation in the HINS program has included studies of electron cloud issues, especially as related to the Fermilab Main Injector and Recycler Rings, development of linac Low Level RF system hardware and firmware, and design and fabrication of two buncher cavities for the HINS 2.5 MeV transport section. Brookhaven National Laboratory has reviewed an 8 GeV H- beam transport line design, provided consultation on H- injection and stripping, and built a prototype H- beam profile monitor based on laser neutralization to be used in the HINS Linac. The Oak Ridge Spallation Neutron Source has provided a copy of their Low Level RF system hardware modified for the HINS frequency.

This paper concentrates on the design, status and outlook for the HINS Linac.

## HINS R&D LINAC OBJECTIVES

The HINS Linac R&D program will address accelerator physics and technology questions for a new concept, low-energy, high intensity, long-pulse H- SC linac. In particular, the specific goals of the program are to demonstrate:

- acceleration of beam using SC spoke-type cavity structures starting at a beam energy of 10 MeV
- use of high power RF vector modulators to control multiple RF cavities driven by a single high power klystron for acceleration of a non-relativistic beam
- control of beam halo and emittance growth with an axially symmetric optics design using solenoid focusing
- performance of a fast, 325 MHz bunch-by-bunch, beam chopper at 2.5 MeV

The plan is to achieve these goals within the context of the once-proposed Fermilab 8 GeV Superconducting Linac Proton Driver front-end design [7]. The 60 MeV HINS Linac, comprising a 50 keV H- ion source, a 2.5 MeV RFQ, a medium energy beam transport section with chopper, a 10 MeV room temperature (RT) linac with SC solenoids, two cryomodules of $\beta = 0.2$ spoke cavities and one cryomodule of $\beta = 0.4$ spoke cavities, is to be constructed and operated. The longer vision is that the HINS Linac itself might eventually become the front-end of a high energy linac. The scope of the HINS linac effort includes development of relevant accelerator design tools, RF and SC RF related technologies, components, and test facilities.

The HINS R&D program seeks to achieve these goals by the end of fiscal year 2012.

## HINS LINAC

### *Parameters*

The basic operating parameters for the HINS Linac, shown in Table 1, are consistent with those for the Proton Driver Linac to deliver 2 MW of 8 GeV beam power.

Table 1: HINS 60 MeV Linac Operating Parameters

| | | |
|---|---|---|
| RF Frequency | 325 | MHz |
| Particles/ Pulse | 37.5* | E13 |
| Pulse Length | 3/1 | msec |
| Average Pulse Current | ~20 | mA |
| Pulse Rep. Rate | 2.5/10 | Hz |
| Chopping ~6% @ 89KHz and 33% @ 53MHz | 0-37.5 | % |
| Bunch Current | 32 | mA |
| Bunch Intensity | 6.1<br>98 | E8<br>pCoul |

* full un-chopped 3 msec pulse at klystron-limited 20 mA

The 325 MHz RF frequency choice is the result of a confluence of influential circumstances. It is the 4$^{th}$ sub-harmonic of the ILC frequency, consistent with the idea that this might be the front-end of a high energy linac based on ILC technology. It is near that of the 345 MHz spoke cavities developed at Argonne. Equally important, minor modifications to the J-PARC 324 MHz high power klystron design provide an economical path to a suitable RF power source.

The Fermilab Proton Driver design was staged for two operational phases: initially, 9 mA in a 3 msec pulse at rates up to 2.5 Hz to support 2 MW beam energy at 120 GeV from the Main Injector; then, with RF system upgrades, 27 mA in a 1 msec pulse to deliver 2 MW at 8 GeV. The HINS Linac can operate in either mode although the maximum current is expected to be klystron power limited at 20 mA. This current, however, can be available for either a 1 or 3 msec pulse length.

Chopping in 2.5 MeV transport line will demonstrate production of a beam time structure ultimately suitable for injection into the Main Injector ring. A 700 nsec chop at 89 kHz preserves an abort gap in the Main Injector with multi-turn injection. Chopping at 53 MHz 'pre-bunches' the beam to match the Main Injector RF frequency.

The desire to include as part of the program at least one cryomodule of $\beta = 0.4$ SC spoke cavities establishes the final energy of the HINS Linac at 60-65 MeV.

### *Design*

The accelerator physics design philosophy of the HINS Linac, described in depth in [8], is naturally tightly coupled to the concepts and technologies the machine is intended to prove. It is punctuated by multiple independent RT accelerating cavities, SC solenoids for axially symmetric focusing, and a transition to SC spoke-type accelerating cavities at 10 MeV. Analysis of the transition energy question indicated an optimum at 10 MeV, where the energy gains per cavity can be equal in the RT and the SC sections and the beam energy is sufficiently high to allow the short drift space necessary to physically accommodate the warm–cold transition.

A 50 keV ion source provides beam to a 2.5 MeV four-vane RFQ with radial matching sections at the input and output ends that form the axially-symmetric beam. The RFQ is followed by a Medium Energy Beam Transport (MEBT) section that provides space for the beam chopper [9] while maintaining desired transverse and longitudinal beam characteristics with two RF buncher cavities and three SC solenoid magnets. The subsequent accelerating section up to 10 MeV comprises 16 RT crossbar H-type (RTCH) cavities [10] and 16 SC solenoid magnets [11]. The first four RTCH cavities are made with three spokes; the remaining 12 have four spokes. As a matter of economics, a subsequent design modification reduced the number of unique RT cavity designs required; nine unique designs fill the complement of 16 RT cavities. The solenoids, even in the RT section of the machine, will be superconducting. Field strengths of six Tesla are necessary to produce the short focal lengths required by the beam optics and for matching into the SC cavity section.

From 10 to 30 MeV, eighteen SC single-spoke cavities of a common $\beta = 0.2$ design are employed [12]. They are foreseen to be divided between two cryomodules. The cavities alternate with eighteen SC solenoids. The final 30 MeV is achieved with a single cryomodule of six solenoids and eleven SC spoke cavities of $\beta = 0.4$ design.

Extensive particle tracking simulations of the HINS and Proton Driver Linacs have been conducted using both TRACK and ASTRA codes [13] [14] [15]. This effort has proven extremely beneficial not only for the machine design, but also for the codes themselves. They have been rigorously benchmarked against each other and improvements in both features and performance have been implemented in each code.

The HINS RF power distribution and control system design is particularly demanding in light of the goal to employ a single high-power klystron to drive multiple cavities accelerating a non-relativistic beam. The physics design calls for each cavity to operate at an individual

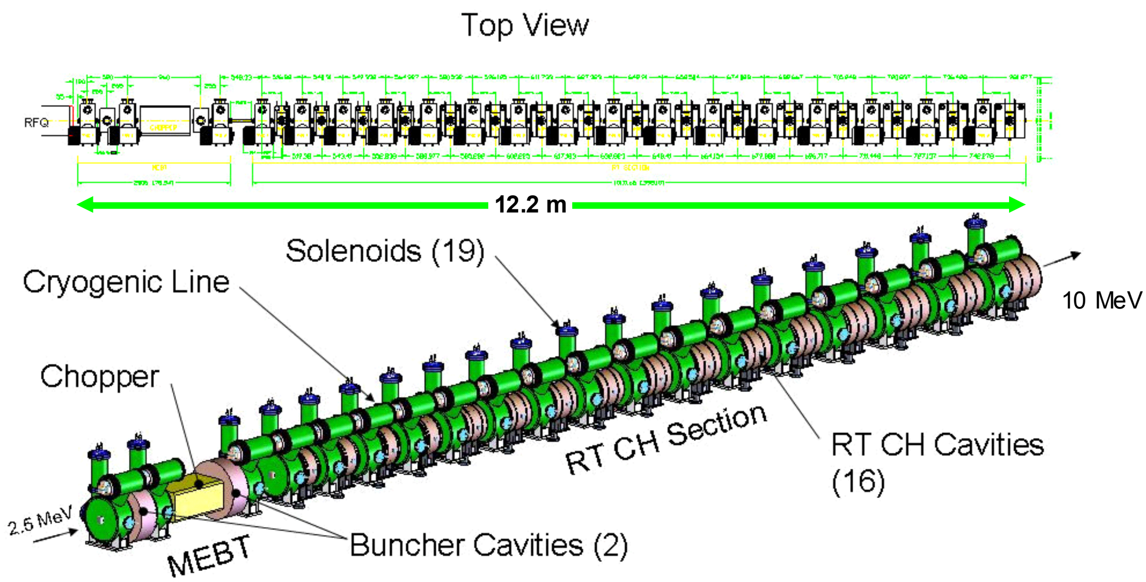

Figure 1. Layout of the first 10 MeV of the HINS linac.

gradient and synchronous phase and thus each experiences different beam loading. To meet tight amplitude and phase tolerances under these dynamic conditions, each cavity requires an individual amplitude and phase control element operating at the full power level of the cavity. This function is served by high power RF vector modulators [16]. Performance simulations of the vector modulator control under realistic RF and beam conditions are on-going. Further complicating the situation, the original HINS concept includes combining both RT and SC cavities on a single klystron. Adding a second klystron to the same modulator to separate the RT from the SC cavities remains a fall-back position.

### *Layout*

The layout of the first 10 MeV of the HINS Linac, including the MEBT and RT section is shown in Figure 1. Conceptual drawings of the SC spoke cavity cryomodules are in Figure 2. The 60 MeV HINS linac, approximately 42 meters in length, followed by a diagnostic beam line with a spectrometer and beam absorber is being assembled in the Fermilab Meson Detector Building. In addition to the linac itself, the Meson HINS facility includes the modulator and klystron RF power system, a

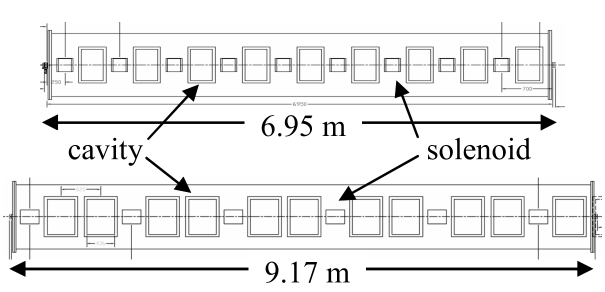

Figure 2. β=0.2 (top) and β=0.4 (bottom) SC spoke cavity cryomodule layouts.

shielded cave supporting both RT cavity testing and a cryostat for dressed SC spoke cavity testing, and an RF shielded high power RF component test area.

### *Status*

The HINS RF power system with one 325 MHz Toshiba E3740A(Fermi) 2.5 MW klystron has been operational since April 2007 to serve vector modulator development and testing of RT cavities.

A 50 keV proton ion source is commissioned and waiting to serve the RFQ. The program will begin beam operations with protons while development of a suitable H- source is completed. H- is expected to be available in mid-2009.

The HINS RFQ [17] [18] [19], pictured in Figure 3, has been manufactured by ACCSYS Technologies, Inc. It is now undergoing final inspections at Fermilab prior to high power RF conditioning that is expected to commence in October 2008.

The two MEBT buncher cavities are being machined at LBL and are expected to be finished in early 2009.

The RTCH cavities are in fabrication. Four are

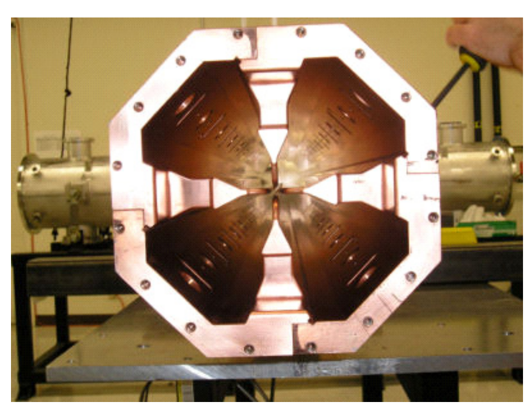

Figure 3. HINS RFQ made by ACCSYS.

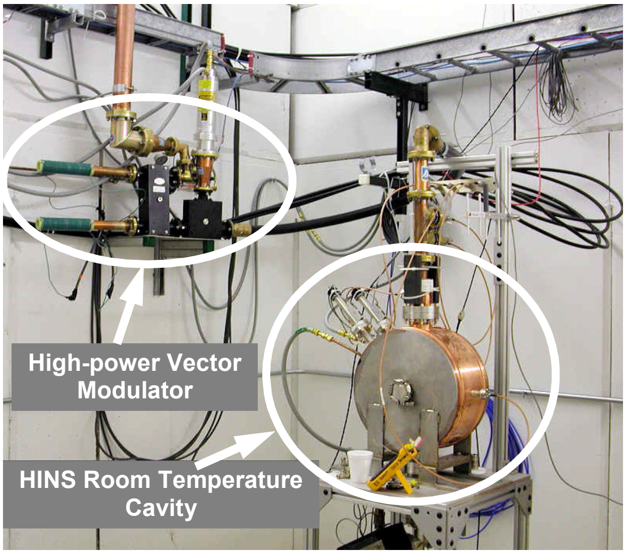

Figure 4. RT cavity coupled with prototype vector modulator on test stand.

completed; three have been successfully RF conditioned to full power [20], the fourth awaits its turn on the test stand. The remaining twelve RTCH cavities are expected to be delivered by this year's end. Figure 4 shows the first RTCH cavity coupled with a prototype vector modulator on the cavity test stand.

Prototype vector modulators for the RTCH cavities have been successfully tested [21] to 70 kW. Phase control rates in excess of 4 degrees per microsecond and an amplitude control range of 13 db have been demonstrated. One very high power vector modulator, for the RFQ, has operated successfully up to >500 kW. Problems have been experienced in obtaining the required high power performance for a companion circulator.

A prototype SC solenoid for the RT section has been successfully tested and production units are now being fabricated [22].

Two $\beta = 0.2$ SC spoke cavities have been fabricated; only one has yet been processed. The processed, bare cavity, pictured in Figure 5, has undergone several test cycles in the Fermilab SC cavity Vertical Test Stand. Results have been very encouraging despite some problems. Figure 6 shows Q vs. gradient performance for three test dates. The two curves starting at Q≈1E10 are for 2°K operation; the other two curves are for 4.4°K. Electron multipacting [23] in the cavity has been observed and overcome at various field levels (see discontinuities in Q curves). The Q slope at 2°K is steeper than expected. Obtaining reproducible results has been complicated by difficulty maintaining acceptable cavity vacuum and, in the latest test, a helium leak into the cavity that was traced to a bad RF antenna feedthrough. Nevertheless, the cavity has achieved an impressive accelerating gradient of 18 MV/m at the HINS operating temperature of 4.4°K. It has performed marginally below the target Q of 5E8 at 10 MV/m. Test results are described in detail in [24]. Further tests are planned.

Figure 5. First SC Spoke Cavity prepared for vertical test.

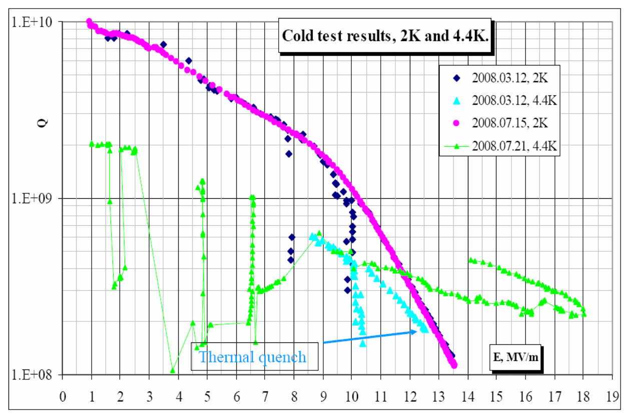

Figure 6. First SC Spoke Cavity Q vs. Gradient results.

## HINS PROGRAM OUTLOOK

Following RF conditioning, the RFQ will be coupled to the proton ion source. The first 2.5 MeV beam is expected by December this year. The linac shielding cave will then be constructed, followed by staged commissioning of the MEBT and RT sections. Full 10 MeV operations are not expected before late 2009. The first beam test of SC spoke cavities is anticipated about one year later using one cryomodule of the $\beta = 0.2$ cavities.

In late 2007, the Fermilab Project X [25] [26] proposal, including an 8 GeV H- linac as a centerpiece, was announced. This followed alignment of important H- linac beam and operating parameters with those of the ILC and a realization that ILC construction is unlikely for a decade. Subsequently, in May 2008, the U.S. Particle Physics Project Prioritization Panel (P5) stated in its ten year strategic plan report [27] "The panel recommends proceeding now with an R&D program to design a multi-megawatt proton source at Fermilab and a neutrino beamline to DUSEL …" Project X is well aligned with this recommendation and Fermilab is now leading a national effort to obtain Department of Energy critical decision approval to carry out the conceptual design.

This will impact the identity of the HINS R&D program. At some stage, it will likely be absorbed into the Project X organizational structure. An evaluation of the HINS technologies, based on performance, cost and risk, will determine how and if these technologies might be incorporated into the eventual Project X Linac design. The current HINS program can positively influence this by delivering on its goals at the earliest possible date.

## SUMMARY

The HINS program has ambitious goals to demonstrate the feasibility and performance of technologies never before applied to a low-energy, high intensity proton or H- linac. The program is actively designing, building, and testing accelerator components to be integrated into a novel 60 MeV superconducting H- linac. It is hoped that this might serve as the front-end to an 8 GeV linac that is a key element of the Project X proposal.

## ACKNOWLEDGEMENTS

The authors wish to acknowledge the persistent efforts of all the individuals, too numerous to name, from Fermilab and collaborating institutions who drive the progress of the HINS program and have contributed to the preparation of this paper.

# OVERVIEW OF RECENT RFQ PROJECTS *

A. Schempp
Institut für Angewandte Physik, J. W. Goethe-Universität, D-60486 Frankfurt am Main, Germany

RFQs are the new standard injector for a number of projects. The development of the 4-Rod RFQ structure has led to interesting developments, which will be discussed with actual projects as examples. Recent work on the FAIR - p linac, the GSI - high charge state injector upgrade, the GSI - HITRAP, the new BNL - EBIS-RFQ, and the RFQ of the MSU-CW Reaccelerator will be presented and the status of these projects will be discussed.

## INTRODUCTION

Accelerators have been developed as tools for atomic, nuclear and particle physics. From these technologies numerous applied research did develop. The "production" of secondary particles as purpose of a facility was another big step in accelerator technology, because the production rates can be increased by optimizing the beam energy and target arrangement and of course by increasing the beam current to the target.

In case of heavy ion beams the duty factor of the machines had to be large because of the limits of sources for (multiple charged) heavy ions. For protons and deuterons the beam currents from ion sources could be pushed up to the 100 mA region, so the duty factors of the accelerators could be modes tlike for spallation sources with beam powers of up to 1MW and the synchrotron injectors, drivers for neutron production or for sources of radioactive beams with beams of some kW.

Accelerators for radioactive beams have low power beams but require high duty factors for compensation of the low production rates.

The Frankfurt IAP was involved in the planning phase for GSI and the cooperation with GSI in the 70s by post accelerator structure applications (helix, spiral) could be kept up until today with respect to the FAIR project.

A big step were the new ideas about RFQs in the late 70s for low energy acceleration [1,2].

Application for heavy ions and lower frequency and the need for practical solutions led to the development of the 4-rod RFQ structure. First prototyps and beam tests were rather simple, but the big point was the chance to develop and built structures for other labs, at first GSI, DESY and MSI, which pushed the development and besides beam dynamics, the importance of issues like rf- and mechanical technologies and reliability.

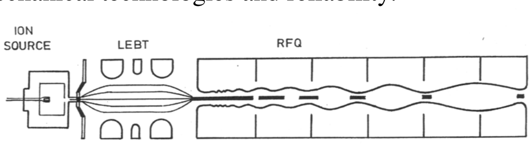

Figure 1: Scheme of a RFQ injector.

## RFQ DESIGN

The design of RFQs is at first the choice of basic parameters like frequency, input output energy, which are mostly determined by the application or the ion source or the following bigger accelerator system.

Next steps in the beam dynamics design is the choice of electrode voltage U, beam current, input and output energy and emittances ε and the cell parameters along the RFQ: cell length $L_i$, aperture $a_i$, modulation $m_i$. The result is an RFQ with certain total length L and power consumption N which adiabatically bunches and focuses the dc beam from the ion source with small Δε and high transmission [3].

RFQ design is sometimes treated as being completed, when the beam dynamics design is finished. Especially for high power beams it is crucial to have a balanced design which takes into account the special rf-problems as well as the engineering to ensure tolerances, to handle the rf-losses, the beam with losses, the diagnostics and also maintenance possibilities and control.

While for smaller neutron generators RFQ aspects can dominate the choice e.g. of the frequency and length and rf-power consumption to simplify alignment and tuning, for bigger projects the optimization of the total accelerator, the availability of power sources and naturally costs will set some design input parameters and e.g. will increase the frequency to lower the charge per bunch, to avoid funneling and ease emittance growth and matching problems or reduce crucial beam losses.

Reducing losses and emittance growth and high duty factors or beam powers require even new solutions and prototype developments not showing up in beam dynamics simulation which sometimes are described as “physics design”.

To generate the quadrupole fields we use the 4 rod RFQ structure, which we have developed in Frankfurt It can be described as a chain of interlaced λ/2-resonators in π–0-mode. The electrodes can be typical rods, or small vane shaped electrodes. with unchanged rf-properties. The radial dimensions of the 4-rod RFQ are appr. half as for a 4-Vane $TE_{210}$-structure at the same frequency. Beam dynamics and experimental results for emittances and transmission are the same as for 4-Vane RFQs.

While the power consumption is also roughly the same, there are some advantages because the 4-rod structure cannot show dipoles and longitudinal coupling is stronger

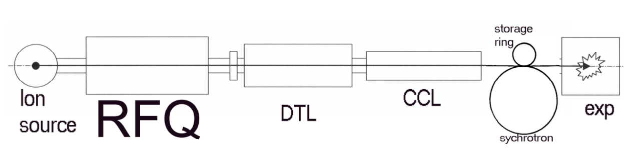

Figure 2: Accelerator system.

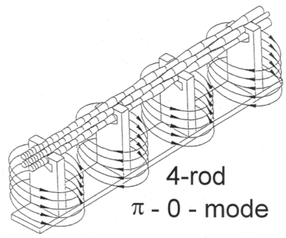

Figure 3: Scheme of a 4-Rod-RFQ resonator insert.

The rf-fields are confined in the resonant insert. A change of tank dimensions results in very little change of the frequency, so ports in the tank and e.g. the top lid along the tank do not change fields and coupling in the structure. So long RFQs can be aligned, tuned and inspected through such a top lid and tank contacts are not critical because less than 10% of the rf-power is dissipated in the tank , most of it close to the insert.

## RFQ PROJECTS

One of the early RFQ- projects was the HLI injector RFQ for GSI. This HLI (108.5 MHz, 2.5keV/u-1.4 MeV/u, U28+) was the first ECR-RFQ-IH combination, which was built and operated. The duty factor was 25%, so also from the duty factor point of view it was a very advanced. It served as example for the Lead Injector of CERN and many other heavy ion machines. Also the injector for the HIT medical synchrotron is a scaled version of the HLI.

The HLI is operating since 1991 routinely with various ions and charge states. Not optimal were the injection with a rather step angle because of the low injection energy.

A new ECR ion source with higher frequency will give higher charge states and beam currents. The extraction energy can be higher and with that the matching problem can be reduced. The maximum cw-power of 60kW can be applied and an optimized cw injector for “superheavy production” can be built [4]. This HLIn is now under construction. Its design is close to the old one, cooling and mechanics are improved using the operational experience.

New beam dynamics design results in a much shorter cavity. The beam should have very small emittance and nearly no emittance growth. The RFQ should be operational in 2009.

### □□□□□□□

In a collaboration with the GSI in Darmstadt an RFQ-Drifttube-Combination for the Heidelberg cancer therapy center HICAT has been designed, built and successfully tested with a H-beam at the IAP Frankfurt. The integration and combination of both an RFQ and a rebunching drifttube unit inside a common cavity forming one single resonant RF-structure has been realized for the first time with this machine.

The 217 MHz RFQ [5] is a part of the HICAT accelerator complex, which consists of a RFQ-IH-linac for pre-acceleration of $^{12}C^{4+}$ up to 7 MeV/u.

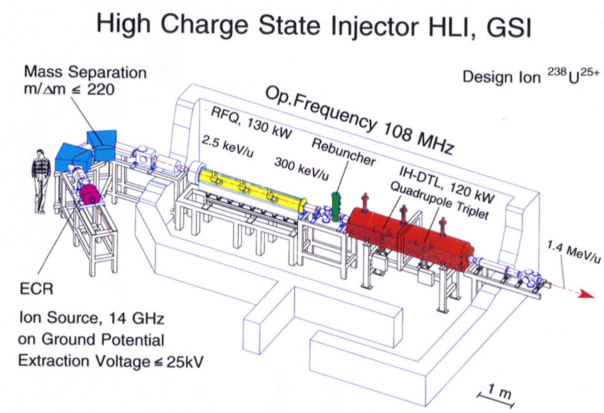

Figure 4: The HLI-injector of GSI.

Table 1: HLI-RFQ Parameters

| PARAMETER | HLI | HLI-n |
|---|---|---|
| Frequency [MHz] | 108.48 | 108.48 |
| A/q | 8.5 | 6 |
| Input Energy [MeV/u] | 0.0025 | 0.004 |
| Output Energy [MeV/u] | 0.3 | 0.3 |

| Electrode Length [cm] | 305 | 199.5 |
| Duty factor [%] | 25 | 100 |

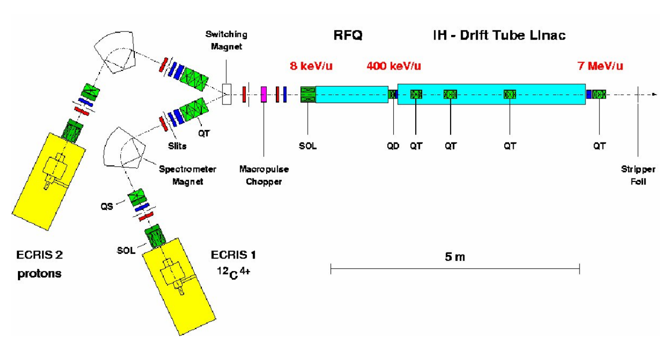

Figure 5: Layout of the HICAT injector.

Table 2: Med-RFQ Parameters

| | |
|---|---|
| Operating frequency | 216.816 MHz |
| Ion species | $^{12}C^{4+}$, protons |
| Length of tank | 1.40 m |
| # of RFQ cells | 219 |
| Input/output energy | 8 / 403 keV/u |
| Input emittance | $\varepsilon_{x,y}$=150 π mm mrad |
| Electrode voltage | 70 kV |
| Power consumption | 165 kW |

In the following synchrotron ring-structure completely stripped $^{12}C^{6+}$ ions are accelerated to final energies between 50 and 430 MeV/u. This linac has been set up and tested at Heidelberg. Also the Synchrotron and the huge Gantry are operational. First patient treatment is planned for Dec.08.

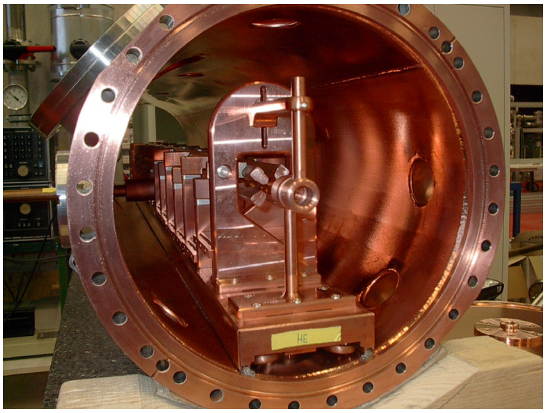

Figure 6: View of the HIT-RFQ with rebunching section.

Three new Med-RFQs have been built by industry since. We have supported by aligning and tuning these twins of the Heidelberg HIT-RFQ, which can be treated as prototype for a chain to clones come?

### □□□□□□-RFQ

The HITRAP-linac at GSI will decelerate ions from 5 MeV/u to 6 keV/u for experiments with the large GSI Penning trap. The ions, provided by the GSI accelerator facility, will be decelerated at first in the existing experimental storage ring (ESR) down to an energy of 5 MeV/u and then injected into a new IH decelerator and decelerated to 500 keV/u. The following 4-Rod RFQ will decelerate the ion beam from 500 keV/u to 6 keV/u. The properties of the RFQ decelerator and the status of the project will be discussed.

The design of the HITRAP 4-rod-RFQ is closely related to the design of the 108 MHz structure of the GSI-HLIn LINAC. The low A/q allows a short structure of 127 cells that is only 1.9 m long. A maximum rod voltage of 77.5 kV is required. The 45° phase spread of the ion bunches extracted from the IH-structure needs to be matched to the RFQ acceptance of 20°. Thus, in the matching section between IH-structure and RFQ two gap-1o8 MHz spiral Rebunchers will be installed [6,7].

### □□□□□□□□□□□□□□

To provide sufficient primary proton intensities a new proton linac is planned for the antiproton physics program for future Facility for Antiproton and Ion Research (FAIR) at GSI-Darmstadt. The proposed linac consists of an ECR proton source, a RFQ, and a normal conducting CH-structure. It will have a final energy of 70MeV and deliver an output current of up to Ip= 90 mA. The operation frequency will be 325 MHz. The RFQ will accept a beam at 95 keV and accelerate to 3 MeV for injection into the IH-type DTL.

### □□□□□□□□□□□□□□□□□□

The new EBIS preinjector at BNL will accelerate ions from the EBIS source with specific mass to charge ratio of up to 6.25, from 17 keV/u to 2000 keV/u to inject into the Booster synchrotron, expanding experimental possibilities for RHIC and NASA experiments [8].

Table 3: Basic Proton-RFQ Parameters

| | |
|---|---|
| Frequency | 325 MHz |
| Input energy | 95 keV |
| Output energy | 3.0 MeV |
| Beam current | 70/90 mA |
| output emittance rms norm. | 0.4 $\pi$ mm mrad |
| energy spread rms | 150 deg keV |
| Electrode voltage | 80 kV |
| RFQ length | 3.22 m |

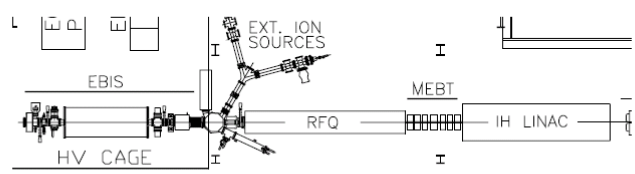

Figure 9: Layout of the EBIS Linac at BNL.

Table 4: BNL-RFQ Beam Dynamics Design Parameters

| | |
|---|---|
| Frequency | 100.625 MHz |
| Input energy | 17 keV/u |
| Output energy | 0.3 MeV/u |
| Mass to charge ratio | 6.25 |
| Beam current | 10 mA |
| Outp trans. emitt rms norm. 90% | < 0.38 $\pi$ mm mrad |
| Output long. emittance 90% | < 220 deg keV/u |
| Transmission | 98% |
| Electrode voltage | 70 kV |
| RFQ length | 3.1 m |

The RFQ has been designed and manufactured. The resonant insert has been aligned with a precision of ±0.03 mm and the flatness is better than ±2%. Tuners and rf-coupler have been built, tested and matched. Vacuum tests have been done and the EBIS-RFQ has been prepared for transport to BNL in the week before LINAC 08 [9].

### [illegible]

The Frankfurt Neutron Source at the Stern-Gerlach-Zentrum (FRANZ) will comprise a short 175 MHz linac sequence consisting of a 1.75 m long 700 keV 4-rod type RFQ [10] followed by a 60 cm IH-DTL for proton acceleration up to 2 MeV to create a nsec pulsed high current beam on a n-target for n production.

The beam current is 200 mA at pulsed and up to 30 mA at c.w. operation. The aim is to have a very compact device driven by only one rf-amplifier to reduce costs and required installation space. A strong coupling between the RFQ and the IH resonators will be realized by a direct connection between the last stems of each resonator through the common end wall. The accelerators could also be driven separately by just removing these brackets. The distance between the end of the RFQ electrodes and the midplane of the first DTL gap is only 5 cm leaving some place for a x-y-steerer. Preliminary rf-simulations have been carried out together with accompanying measurements on rf-models.

The needed high average power levels require improved cooling of the RFQ-resonant insert. A short prototype has been built to develop a structure for such high thermal loads.

### [illegible]

A complete Radio Frequency Quadrupole system presently is designed and fabricated for NSCL [12].. The 4-Rod RFQ structure matches the parameters given by the NSCL beam dynamics layout of the RFQ-electrodes, the 80.5 MHz structure is 3.35 m long and should need less than 150 kW rf-power. The rf-design has been made with the MWS-code and agrees with extrapolations from earlier experiments with 100 and 108 MHz RFQs.

The mechanical design was aiming at a solid structure, similar to the ones we had built recently. Changes had to be made to modify the structure following the request of a minimum number of brazings, water to vacuum and a less complex structure and the question of raw material availability.

Our new layout was using a rectangular cavity, where stems were inserted and sealed from the outside. We modified the cooling of the elctrodes with a cooling tube outside the stem. By this we had only one braze (the rectangular tube-electrode connection and a plug at this end of the electrode). The cooling tube than runs along the stem outside and is sealed at the base plate outside.
Another new feature is the use of a thick wall Al-tank with welded stainless steel flanges, which avoids copper plating and cooling problems at high duty factors.

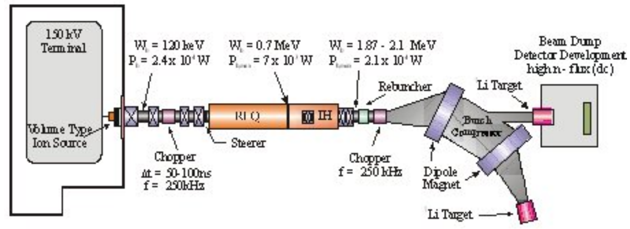

Figure 10: Layout of the FRANZ accelerator

Table 4: FRANZ-RFQ Parameters

| | |
|---|---|
| Frequency | 175 MHz |
| Input energy | 120 keV |
| Output energy | 0.7 MeV |
| Beam current | 150/200 mA |
| output emittance rms norm. | 0.1 $\pi$ mm mrad |
| Long. Emittance | 20keV*30degr. |
| Electrode voltage | 75 kV |
| RFQ length | 1.75 m |
| cell number | 95 |

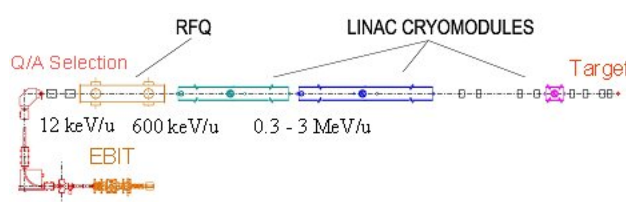

Figure 12: Layout of the MSU reaccelerator.

Table 5: MSU-RFQ Parameters

| | |
|---|---|
| Frequency | 80 MHz |
| Input energy | 12 keV/u |
| Output energy | 0.6 MeV/u |
| Charge to mass ratio | > 0.2 |
| output emittance rms norm. | 0.1 $\pi$ mm mrad |
| Long. Emittance | 30keV/u*degr. |
| Electrode voltage | 87 kV |
| RFQ length | 3.35 m |
| cell number | 93 |

By plugging in the electrode support stems from the outside, all cooling drills are without brazes of the stem and the cooling can be plugged on via Festo/Rectus standard connectors.

Funneling is a method to increase beam currents in several stages. The maximum beam current of a linac is limited by the beam transport capability at the low energy end of the linac: For a given ion source current and emittance the linac current limit is proportional to $\beta =$ [illegible] for electric and to $\beta^3$ for magnetic focusing channels and ideal emittance conservation. The funneling scheme is making use of the higher current limits at higher beam energies.

The Frankfurt Funneling Experiment is a prototype of such a stage. The experimental setup consists of two ion sources with electrostatic lens systems, a Two-Beam RFQ accelerator, a funneling deflector and a beam diagnostic system. The two beams are bunched and accelerated in a Two-Beam RFQ and the last parts of the RFQ electrodes achieve a 3d focus at the crossing point of the two beam axis. A funneling deflector combines the bunches to a common beam axis.

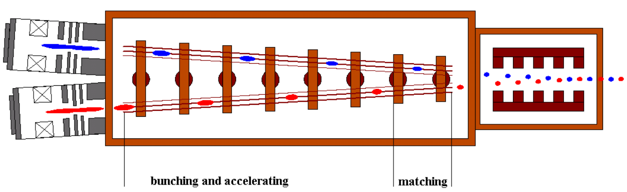

Figure 13: Scheme of the experimental setup.

The two-beam RFQ accelerator consists of two sets of quadrupole electrodes arranged with an angle of 75 mrad in one common resonant structure (fig. 2) [1]. The beams are bunched and accelerated with a phase shift of 180°. The quadrupole sets with a total length of approx. 2 meter are divided into two sections: The first section bunches and accelerates the beam to a final energy of 160 keV. The matching section focuses the beam longitudinally and radially to the beam crossing point at the deflector with low acceleration to 179keV.

The experiments have shown, that the system does funnelling, but beam emittances have to be better to reduce losses. At present the ion sources are improved and the section in front of the deflector is redesigned to give a better focusing at the funnelling section [12].

Other projects are the Saraf-RFQ for the SOREQ sc-linac for 40 MeV p,d beams, were we designed, tuned an CW-RFQ in collaboration with NTG [13]. This cw-RFQ at 175MHz has accelerated protons to 1.5 MeV and now is conditioned for 250 kW cw-operation.

The MAFF-RFQ, an IH-RFQ designed and built by the Munich group for the acceleration of radioactive beams with A/q=6.3 at 100MHz from 3keV/u to 300keV/u, has been set up and beam tests are prepared [14].

For RIKEN we have built a 2 m long RFQ at 100 MHz, which was successfully accelerating a $C^{6+}$ beam of more than 50mA, proving the direct injection scheme with a Laser ion source [15].

## CONCLUSIONS

These projects show the wide range of applications we worked and work on. Besides these projects we have done preliminary designs for advanced medical injectors and compact heavy ion machines and n-generators as well as for high power accelerator projects like IFMIF.

The range of parameters which is characteristic for IFMIF and similar ADS-projects in Asia and Europe comparable with the LANL LEDA project, is requiring power loads and structure length, as basic critical parameters, and efforts in engineering which we cannot provide. Our limited resources force us to work on compact machines.

## ACKNOWLEDGEMENTS

I want to thank my colleagues and our RFQ-group for help and good teamwork, which is necessary for successful projects and thesises. I have to thank the partners in our collaborations for entrusting us with such work, for patience and understanding which sometimes is necessary, because of the special style of University people, old and young ones, and for the Germanenglish.

*Abstract*

The Frankfurt Neutron Source at the Stern-Gerlach-Zentrum (FRANZ) [1] will comprise a short 175 MHz linac sequence consisting of a 1.75 m long 700 keV 4-rod type RFQ [2] followed by a 60 cm IH-DTL [3] for proton acceleration up to 2 MeV. The beam current is 200 mA at pulsed and up to 30 mA at c.w. operation. The aim is to have a very compact device driven by only one rf-amplifier to reduce costs and required installation space. A strong coupling between the RFQ and the IH resonators will be realized by a direct connection between the last stems of each resonator through the common end wall. The accelerators could also be driven separately by just removing the coupling. The distance between the end of the RFQ electrodes and the midplane of the first DTL gap is only 5 cm leaving some place for a x-y-steerer. Preliminary rf-simulations have been carried out together with accompanying measurements on rf-models.

## INTRODUCTION

The coupling of different rf-components is very attractive for most recent accelerator development. It leads to more compact devices using a common rf-amplifier and control system. Thus the overall size and the costs of the set up can be reduced drastically.

Many examples are planned or already in existence. For instance a coupled RFQ-drifttube combination that has been developed for medical application at the HICAT (Heavy Ion Cancer Therapy) center in Heidelberg by the IAP, where a 4-rod-RFQ and a 2 gap rebuncher sequence are merged [4]. This concept has been applied recently to other treatment facilities by industry several times [5]. Coupled CH-DTL cavities are a major achievement in the development of the FAIR Proton Injector at GSI [6, 7].

Two coupled rf-systems with same resonance frequency can be driven in 0 or in $\pi$-mode, which can lead to very interesting applications. When they are excited both at the same time, the resulting beat resonance can be used to reduce thermal load where pulsed operation is not feasible like in the case of the former LEP normal conducting accelerator at CERN, where the accelerator cavity was coupled to a low loss spherical resonator [8].

Presently investigations on a resonant coupling between RFQ an IH-DTL for FRANZ are performed. Unlike the aforementioned medicine RFQ, both parts are tuned to the same resonance frequency and are clearly separated by means of a metallic wall.

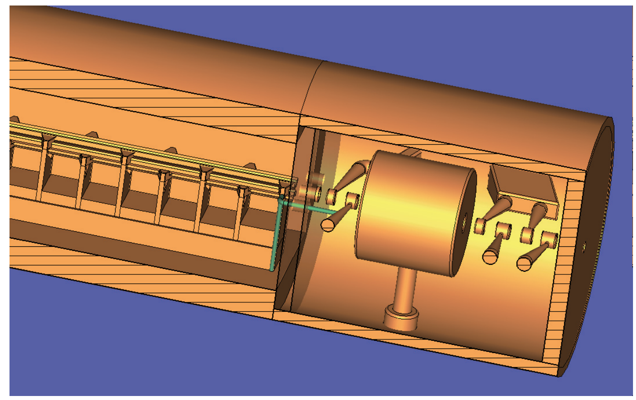

Figure 1: The coupled 4-rod-RFQ-IH-DTL structure. The coupling bridges are colored in green.

Table 1: Main Parameters

| | |
|---|---|
| Operating frequency | 175 MHz |
| Ion species | protons |
| Length of RFQ | 1.75 m |
| Length of IH-DTL | 0.6 m |
| Tank diameter IH | 510 mm |
| Height of RFQ-Stems | 145 mm |
| # of RFQ cells | 97 |
| # of matching in cells | 4 |
| # of IH-gaps | 8 |
| Input energy | 120 keV |
| Input emittance (absolute) $\varepsilon_{x,y}$ | 150 π mm mrad |
| Electrode voltage (RFQ) | 75 kV |
| Max. gap voltage of IH-DTL | 300 kV |
| Exp. Power consumption RFQ | 150 kW |
| Exp. Power consumption IH | 45 kW |
| Current | max. 200 mA |
| Output energy RFQ | 700 keV/u |
| Output energy IH-DTL | 2 MeV |
| Coupling factor $k$ | ≈0.03 |

## COUPLING

The distance between 0 and $\pi$-mode is given by $\Delta\omega = \omega_0 \cdot k$, where $\omega_0$ is the uncoupled resonance frequency and $k$ is the coupling strength. The coupling should be sufficiently strong ($k > 0.01$), to guarantee a good separation between the modes.

As a first approach two galvanic coupling bridges between IH-structure and 4-rod-RFQ were under investigation. They are connecting the last two RFQ stems to the first two DTL stems (fig. 1). Microwave Studio (MWS) [9] simulations resulted in a preliminary coupling factor of $k \approx 0.03$ depending on the exact geometry, which is not fixed in every detail yet. They have to be water cooled at c.w. operation, which could be done by a coaxial cooling system entering at the RFQ side or just by a simple tube geometry with a one way passage of the water. The cavities could also be operated separately by removing the bridges and a subsequent tuning of the RFQ. An alternative coupling over a short external power transition line could also be realized.

## TUNING CONCEPT

One of the most challenging aspects is the tuning of the coupled system during operation. Not only the resonance frequency of the whole system has to be stabilized, the amplitude relation between the cavities has to be kept constant.

The voltage ratio between two coupled resonators can be controlled by a variation of their individual resonance frequency. If the intrinsic resonance frequency of one resonating cell is tuned down, the voltage will increase here and decrease in the other resonator at 0-mode and vice versa at π-mode. This can be shown by treating local frequency detuning within a chain of coupled resonators by means of perturbation theory, which results in field contributions from other unperturbed modes [10]. In the case of the 4-rod RFQ for instance, the field distribution is tuned by means of variable tuning plates. They increase the intrinsic resonant frequency of one cell, which decreases the voltage locally at 0-mode [11].

For the coupled RFQ-DTL combination frequency and amplitude control can be performed by rf-tuning devices (plungers), as illustrated in fig. 2. Both states of the system must be monitored and controlled in separated time slots to avoid instabilities.

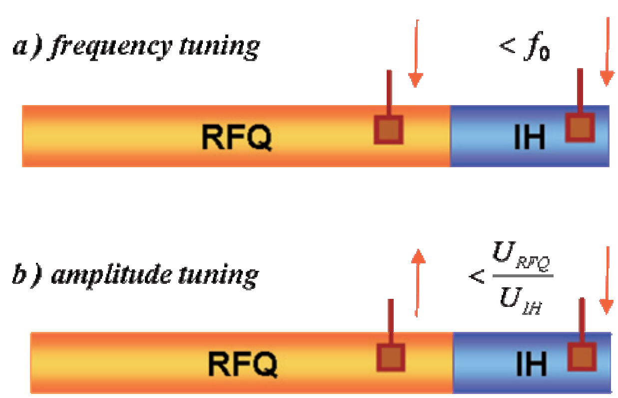

Figure 2: Tuning of frequency and amplitude during operation. Both tuners are acting inductively.

## IMPACT ON RFQ DESIGN

The coupling will have a substantial effect on the field distribution within each cavity. For instance the electrode voltage within the RFQ increases towards the end where the IH-structure is connected to, which can be balanced by tuning plates. For this purpose detailed investigations with MWS have been performed to get information on how the range of the plates respectively the height of the stems has to be extended in comparison to the uncoupled case. To get reliable results it is important to include the aperture progression along the structure implying a sufficient mesh resolution to cover these details. A detailed investigation on the precision of MWS-simulations regarding RFQ-resonators can be found in reference number [12]. Since the exact RFQ beam dynamics is not yet fixed in detail, a reasonable aperture progression with an average of $\bar{a}$ = 5.44 mm for a 1.6 m structure with electrode voltage $U_{el}$ = 85 kV is assumed for these calculations on the basis of a preliminary design proposal [13].

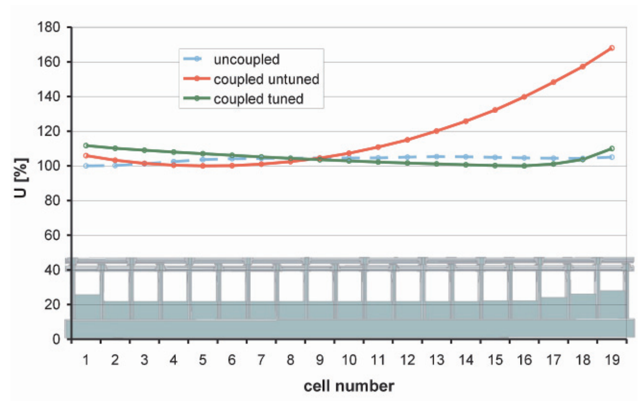

Figure 3: Simulation of the field distribution on RFQ-axis. The different height of tuning plates is indicated for the coupled and tuned case. The aperture is held constant here.

In a first step the positions of the tuning plates for a balanced field distribution were simulated for the uncoupled case assuming a 20 stem structure. Then the coupling was introduced, which gave a field distortion of +70% (fig. 3) towards the end of the RFQ, where it is connected to the IH-structure. To rebalance this disturbing effect, the tuning plates had to be moved up in that region to flatten the field distribution again. To compensate the consequent raise of the resonance frequency, the height of the stems had to be extended by $\Delta s$ = 5 mm which results now in an upper limit for the distance between beam axis and tuning plates of 145 mm, giving some safety margin of 30 mm to cover both cases. It shall be emphasized again that these investigations have been carried out under the assumption of some reasonable but not yet exactly fixed design parameters (aperture progression, number of stems, electrode voltage etc.), which will have to be included successively in future simulations.

## IH-DTL DESIGN

The IH-DTL will comprise eight accelerating gaps and one focussing triplet lens for an energy gain of 1.3 MeV within 60 cm. The structure has been optimized to get maximum field concentration on beam axis. The gap voltages are well tuned to the values given by beam dynamics simulations with LORASR (fig. 4). The field distortion of the IH-structure due to the coupling to the RFQ can be cancelled out by choosing the right position to where the bridges are connected to the IH-stem. The optimum close to the point the voltage corresponds to the voltage on top of the RFQ-stem.

The expected power consumption of the IH-DTL is 45 kW. For c.w. operation it is mandatory to do investigations on power dissipation and thermal load. Cooling of tank and drift tube stems of the IH structure are mandatory. A heating of less than $\Delta T = 20$ K is considered to be uncritical in terms of a stable operation. Thus the maximum acceptable power dissipation on the drift tube averages to $\overline{P}_{DT} = 1.5$ W/cm$^2$ if a direct water cooling of all stems is assumed. Calculations have been executed under the assumption of a linear progression of power dissipation from $P_{\mathrm{DT,max}} = 3$ W/cm$^2$ on bottom to zero on top of the Drifttube (fig.5).

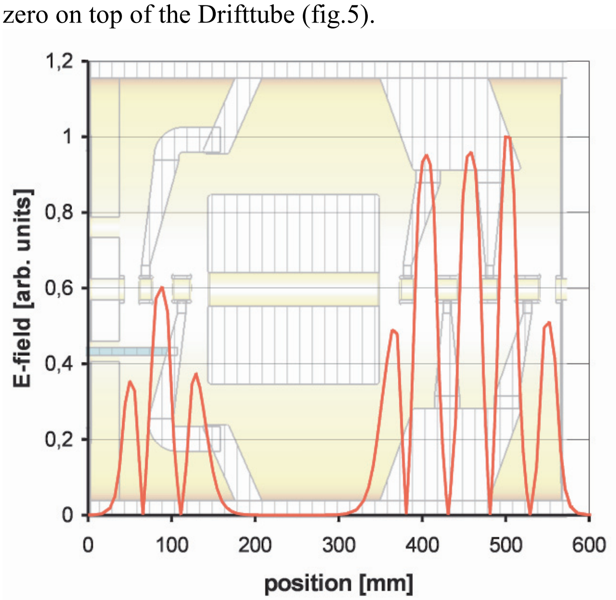

Figure4: Field distribution on beam axis along IH-DTL.

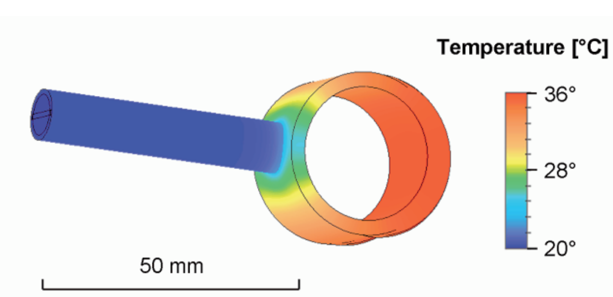

Figure 5: Simulation of thermal load on an IH-drifttube.

## CONCLUSIONS

For the FRANZ project the technique of coupled rf-cavities yields very attractive applications options. Simulations on a coupled RFQ-DTL combination are rather promising. The tuning concept has been demonstrated by means of a "prove of principle" experiment on two coupled pillboxes. It is planned to build up a more sophisticated rf-model that reflects the design of the RFQ-IH-combination more in detail. In addition further investigations on thermal load on the rf-cavities are required. Next step will be the improvement of the coupling design with respect to more detailed beam dynamics simulation data.

## ACKNOWLEDGEMENT

Many thanks to all the people involved to the FRANZ project for inspiring collaboration. We also would like to thank Dipl. Phys. J. Rehberg for making things converging and Dr. P. Fisher for his friendly support on RFQ design. Also thanks to the technicians and the staff of our workshop. This work has been supported by GSI and BMBF under contr. no. 06F134I.

*Abstract*

The Frankfurter neutron source at the Stern-Gerlach-Zentrum (FRANZ) uses a 2 MeV proton LINAC as a driver for the $^7$Li(p,n) neutron production. A volume type ion source will deliver a 120keV, 200mA proton beam continuously. A LEBT section consisting of four solenoids is under construction to transport the beam and to match it into the acceptance of the RFQ. A chopper system between solenoid 2 and 3 will provide beam pulses with a length of about 50 to 100 ns with a repetition rate of up to 250 kHz. The RFQ and the following IH drift tube LINAC will be coupled together to achieve an efficient beam acceleration. Furthermore only one power amplifier will be needed to provide the RF power for both accelerator stages. The Mobley type bunch compressor will merge 8 micro bunches formed in the accelerator module to one single 1ns bunch with an estimated peak current of up to 9.6 A. A rebuncher will provide the post acceleration to final beam energy adjustable between 1.8 and 2.2 MeV. The whole system is optimized for high beam intensity causing high space charge forces. As a consequence new accelerator concepts and beam diagnostic concepts have to be developed.

## INTRODUCTION

FRANZ comprises two experimental areas allow different types of neutron capture measurements. The compressor mode offer time of flight measurements in combination with a 4π $BaF_2$ detector array. The proton beam will be compressed to a 1ns pulse with a peak current of about 9.6 A and a repetition rate of 250 kHz. On the other hand activation mode uses a continuous neutron flux. Primary cw proton beams with a current up to 8 mA on solid targets and up to 30 mA on liquid metal targets as a later option are feasible.

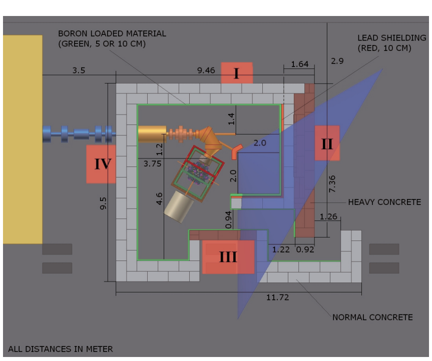

Figure 1: Scheme of the FRANZ facility with targets and detector and iradiation and neutron shielding.

FRANZ is not only a neutron generator but also a test bench for new accelerator and diagnostic concepts for intense ion beams. The envisaged proton beam properties on the target lead into a challenging accelerator design to overcome the space charge forces.

## ION SOURCE

A volume type ion source was chosen for FRANZ to extract the proton beam from a hot filament driven gas discharge plasma [1]. Figure 2 shows this source type. The life time of the filament is limited about one month of operation. On the other hand the plasma temperature of a gas discharge at moderate arc power is as well as the confining magnetic field very low compared with other source types e.g. ECR sources. Therefore the beam emittance is small and gives the possibility to investigate causes of emittance growth during beam transport and acceleration along the whole LINAC.

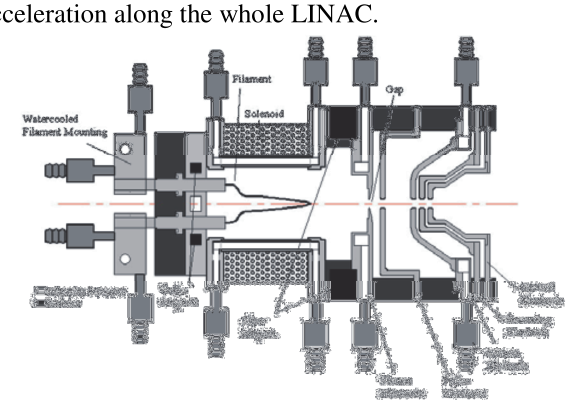

Figure 2: crossectional view of the volume type ion source under construction.

For the planned beam intensities a pentode extraction system keeps quite well the beam emittance during the extraction and pre acceleration phase when compared with other extraction schemes [2]. Figure 3 shows a preliminary numerical simulation of the beam extraction by the use of the IGUN code [3] and under respect of a multi species beam with approximately $H^+$ = 80%, $H_2^+$ = $H_3^+$ 10%.

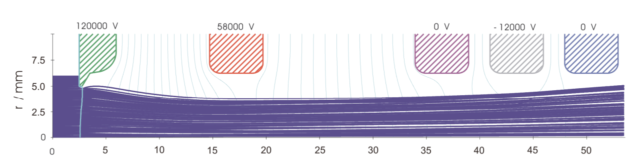

Figure 3: Illustration of a preliminary IGUN calculated beam profile along a pentode extraction system.

The chosen aspect ratio of S = 0.2, an emission area of 0.78 $cm^2$ and an extraction field strength of 6.2 kV/mm result in a beam radius of $r_{beam}$ = 5 mm, $\varepsilon_{rms}$ = 0.06 π mm mrad and a divergence angle of r' = 74.5 mrad.

## LEBT SECTION WITH CHOPPER

The LEBT section consists of 4 solenoids for beam focussing and includes partial of space charge compensation due to residual gas ionisation. Figure 4 shows a scheme of the planned LEBT. The first and second solenoid will be used for separation of ion species and to match the proton beam into the chopper system. Downstream of the chopper two solenoids will focus the beam into the acceptance of the RFQ. Two pumping and diagnostic tanks will be used for several non interceptive diagnostics e.g. optical beam profile measurement and beam potential measurements using a residual gas ion energy analyzer.

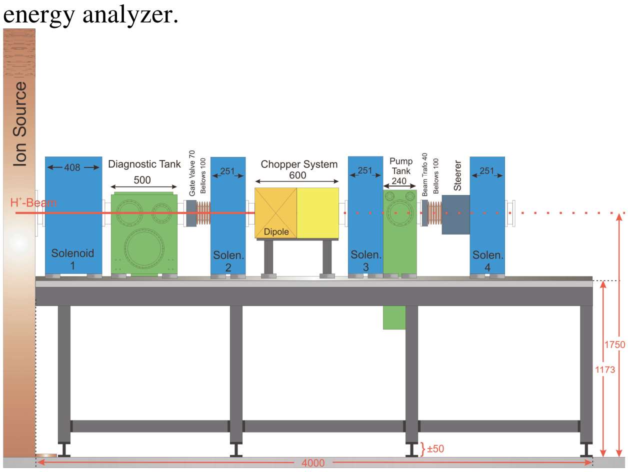

Figure 4: Scheme of the LEBT section with four solenoids and the chopper device.

The chopper system consisting of a kicker and a septum magnet combined with a slit provide the 100 ns proton beam pulses. Figure 5 shows the arrangement of the chopper system.

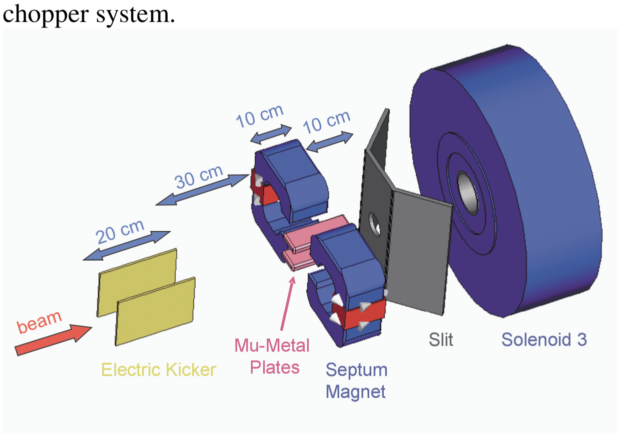

Figure 5: schematic drawing of the chopper system consisting of a fast kicker, a septum magnet and an apertur.

A fast magnetic or electric kicker deflects the beam with a repetition rate of 250 kHz whereas the static septum magnet provides the post separation and a pulse with a flat top of at least 50 ns. Comparison of electric and magnetic kicker systems by the use of numerical simulation shows an influence of secondary electrons. The high production rate of electrons in the chopper system gives the possibility for partial space charge compensation of short beam pulses. Preliminary studies result in approximately 30% of space charge compensation by the use of a magnetic kicker system. For an electric kicker the secondary electrons bear the risk of sparking and sputtering from the electrodes [4]. Beam transport and chopping leads into an emittance growth by a factor of 4. It seems possible to reduce this value by further optimization of beam transport with respect to the filling degree of the solenoids and more detailed description of space charge compensation. Pulsed beam with proton densities of $n_p = 8.2{\cdot}10^{14}\ m^{-3}$, generalized perveance of $K = 3.1{\cdot}10^{3}$ and time structure shown in figure 6 will be injected in the coupled RFQ-IH DTL.

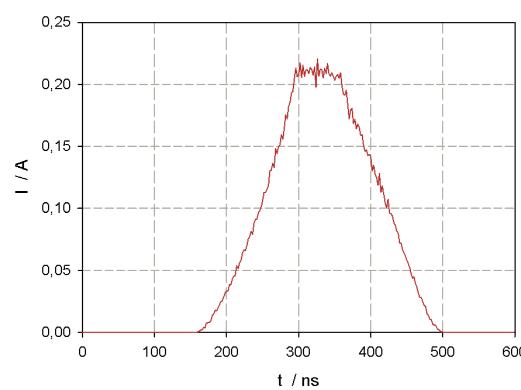

Figure 6: Simulated beam current as a function of time at the entrance of the RFQ, Pulse duration of about 50 ns and repetition rate of 250 kHz.

## COUPLED RFQ-IH DTL

In order to minimize installation costs and to use one compact common rf amplifier a coupling of the RFQ and IH-DTL is foreseen [5]. Figure 6 shows a crossectional view of the coupled accelerator stages. Both of the cavities can also be used separately. The RFQ is 1.75 m long and needs an input power of 150 kW [6]. Numerical simulations using the PARMTEQM [7] code show a beam transmission efficiency of 95 % with acceptable emittance growth at the design current I = 200 mA for an electrode voltage of about 75 kV. Output energy of the RFQ will be 0.7 MeV. The IH-DTL will boost the proton beam to its final beam energy of 2 MeV. The power consumption of the IH cavity is in a range of about 45 kW to establish a gap voltage of 300 kV. Due to the fact that a RFQ acts like a buncher the incoming proton beam will be compressed longitudinally. In result of the beam transport simulation the micro bunch phase width is in a range of 60 degree. The average bunch current increases up to 1.2 A and the resulting compression ratio is η = 6. At beam energy of 2 MeV downstream of the accelerator stages the proton density is $n_p = 8.2{\cdot}10^{14}\ m^{-3}$ and the space charge forces expressed by the generalized perveance decreases of about $K = 2.7 \cdot 10^4$. Figure 7 shows the micro bunch current as a function of time at the exit of the accelerator stages. The average current of one micro bunch is equal to the peak current.

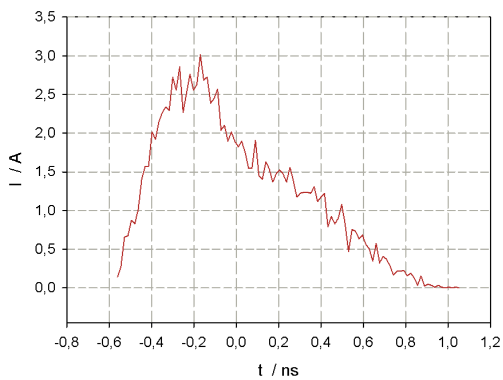

Figure 7: Micro bunch current as a function of time about 1 m behind the LINAC, increase of pulse duration of about 1.2 ns due to the large energy spread and space charge forces.

## BUNCH COMPRESSOR

By applying the bunch compressor concept of the Mobley type [8] for high current beams a split magnetic dipole array include edge focusing was chosen [9]. The periodic deflection by the RF kicker at one focus of the bending system guides up to 8 bunches on different paths to the final focus, where the neutron production target is located. As shown in figure 8 two rebuncher cavities are needed to focus the beam longitudinally.

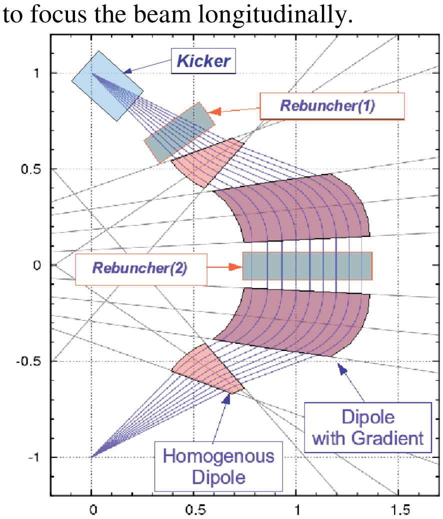

Figure 8: Scheme of the Mobley type bunch compressor.

By choosing adequate parameters all 8 bunches will overlap at the target and produce a 1.1 ns proton pulse with a proton density of $n_p = 8.2 \cdot 10^{14}$ $m^{-3}$. Space charge forces become dominant, the generalized perveance is $K = 2.2 \cdot 10^3$. Figure 9 shows the bunch current as a function of time, the peak current is 9.6 A. The compression ratio downstream of the whole proton injector is of $\eta = 48$.

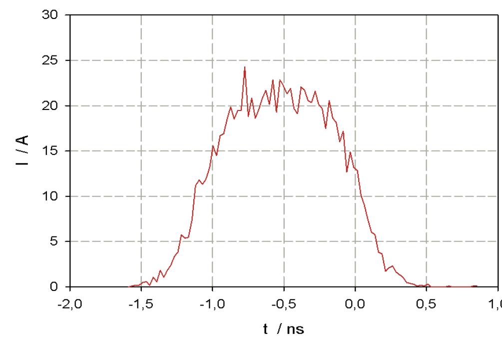

Figure 9: Beam current of the compressed bunch as a function of time at the target, Pulse duration of about 1.1 ns at a repetition rate of 250 kHz.

## CONCLUSIONS

The hardware of the planned proton injector is under construction. More detailed multi particle transport simulations show that the activation mode using a 30 mA cw beam will be limited by the rf power consumption, target power deposition and radiation safety. The compression ratio of the compressor mode is 48. The resulting proton density and space charge force leads into increasing beam spot sizes and pulse duration at the $^7Li(p,n)$ target.

*Abstract*

LINAC of J-PARC began to operate in November, 2006, and a achieved an initial performance in January, 2007. Afterwards, the beam supply to RCS begins, and it is operating extremely with stability up to now[1]. The fundamental condition of the control system design is to defend the beam loss detecting it as early as possible because it controls the radiation by the large strength beam to the minimum. This requirement influences from the level of the basic function of high-speed interlock to the level of an advanced application that needs the predictive control. It describes what work distribution, how much man power were necessary for the control system construction.

## CONCEPT OF DESIGN

The requirement to minimize the beam loss and to reduce the residual radiation makes large difference from the control system of a past experimental accelerator in the point that operating the trial and error is not permitted. This control system protects LINAC from miss-operation, but flexibility of operation absolutely must be kept for the development of 1MW operation[2]. We set the robustness of protection in the middle-ware, and set the free-stage enclosed that middle-ware for the application.

Basic policies of the strategy are :

- Middle-ware (process communication tools, device drivers, database libraries) gives the perfection as much as possible.
- Least making and maximum recycling by OOP is used.
- End user presents a necessary function of th program, and doesn't make the program itself.

At the debugging, it is severe to find bugs of middle-ware. It takes most of the debugging time that finding the reason of unexpected behaviour of poor libraries or cheep drivers. There is an idea with driver's structure simply to avoid this, too. However, it gives origin to an excessive complexity of a high-level application. We were initially given using EPICS. To make the best use of the advantage of the flat scope of EPICS records, we limited the use of record-link. The use of the record-link is a rapier, and it is necessary to use it under the total management. Even the record file should not be individually described. (Sometimes, the file written at the device test survives still.) The database application that confirmed parsing, matching and grammar was developed. End user, who are the expert of device or equipment, are not always good programmer, and don't know the detail of our function hierarchy. If sharing an individual application by the common device model is attempted, the quiet sleep at the term of all-day operation can be secured. We concentrated on the competent understanding of the function of the application that the user requested.

LINAC components are categorized into :

- Vacuum system (several kind of pumps, vacuum gauge, rough pumping system, gate valve, fast closing valve)
- RF cavity system (cavity, tuner, cooling water, temp meas., )
- High-power RF source (klystron, HV-PS, LLRF, wave-guide, tuner)
- Magnet system (bend, q-singlet, doublet, steer)
- Monitor system (position, profile, current)

And, each device communicates with :

- Timing System (TS)
- Machine Protection System (MPS)
- Personnel Protection System (PPS)
- Parameter Data Base (DB1)
- Measurement Data Base (DB2)

We described all function of each cell in the matrix that is made of device column and sub-system line. On the result of this detailed examination, we aimed at sharing software by adapting low-level application of each device to common skeleton based on the machine model.

MPS and PPS was required very complicated function because J-PARC is a multi-purpose facility. Though it is preferable to achieve it by hardware logic, it is impossible to achieve it only by the relay logic. We decided using PLC for PPS, and FPGA is used for MPS to realize the required response time.

## MAN POWER AND STRATEGY

The control system design started in 2002. It had 4 years to beam operation, but we aimed to use the actual application for factory test of individual equipment after three years. Requested man power was ;

- Five experts those who can develop device driver, process communication.
- Five programmers those who have a experience of medium scale application.

At the beginning, we started 8 members. Fortunately, 4 of us are ex-colleague of SPring-8 LINAC. Machine model, OOP driver and special needs of J-PARC LINAC became our common recognition at once. To cancel the lack of man power, the detailed design of network system was done in outsourcing. And the coverage of the machine model had been expanded to Rapid Cycle Synchrotron, long BT-line and muon magnets.

At the initial phase, new comer tried to adaption of machine model to vacuum component or simple magnet, supervised by the experts. 4 experts, 1 system manager of development system and 3 new programmers changed into 6 experts 2 high-level application developer and 3 OPI programmers.

It worries whether the software by a different method can achieve a necessary function because the person in charge of the devices has an original control specification demand. Especially, the person who takes charge of the device of simple function might see excessive estimation the machine model application for the software sharing. This conflict disappeared when the application in this method showed robustness for the function change in the acceptance test at factory on the devices. The person in charge of the control should make an effort about the device of controlled object to become detailed equally to the person in charge of the device. About the software specification presentation, they are not necessarily the skill people. Even the control people might not describe the software design.

## PERFORMANCE OF CONTROL SYSTEM

At the beginning of LINAC commissioning, we were not able to exclude a local operation completely though we aimed at the achievement of the full remote control.

- All devices of the vacuum system are controlled in remote operation. Changing of gauge values from reference value range signs to operator for attention. Exceeding of the gauge value is signed to operator for attention. Beam line gate-valve are controlled as a device of MPS.
- All interlock and tuner position of RF cavity system are shown and controlled in remote.
- All information of the high-power RF source are monitored and controlled in remote. But Start up sequence after the discharge fault was not fixed yet. Then a RF staff started it up manually. Now, auto-recovery sequence is working well.
- All magnets are controlled in remote at the first operation.
- Data of each monitors acquired in remote, but data processing sequence were not fixed. Some new algorithm are developed to determine the beam energy for the phase scan of every cavity[3]. These data processing are done by high level application.

A part of high-power RF system and the ion-source was left in local control at the first operation. This is caused of the difficulty of treating of discharge event. It is another reason of taking time that many PLC are used. Some PLC were brought in with black-box ladder which made by factory. The cost must be estimated by not only hardware but software including the maintenance.

The subsystem of the whole control system operated from the commissioning beginning well.

- TS worked well. Single shot and arbitral train of pulse repetition was able to be set. This was contributed to effective study to avoid residual radiation. This timing system is operated with scheduled type train. But the delay tables can be written synchronously by using reflective memories, and synchronous delay trimming is enable[4].
- MPS has independent communication bus. Two kind of input modules are developed, and the beam loss monitor signal triggers fast response line to avoid a damage of beam bombardment at the low energy region. Less than 5-micro seconds response is achieved and the noise error is less than 1% of unscheduled downtime( ~5% of operation time)[2].
- PPS has dual network, dual CPU, dual power supply and dual limit switches. PPS is the safety grounds of legal permission of this accelerator.
- DB1 deal with device information and operation parameters. DB1 also works as a record-file generator.
- DB2 is the collector of monitor data, and the data archiver. Data viewer is continuously modified by users request. Now we meet tread off between reducing the size of storage and quick response of viewer cause of data format.

The number of device driver, which is originally developed, is 21.

- 9 kinds of VME IO boards.
- 2 kinds of TS sender/receiver
- 2 kinds of PLC
- 5 kinds of oscilloscope
- 2 kinds of spectrum analyser
- 1 kind of AWG
- Soft IOC

These drivers are working with no bug for two years. Oscilloscope and spectrum analyser for the monitor device are rather complicated, and necessary function is added on fly when it is required. To identify the behaviour of each shot, we brought the shot ID in. The combination of the shot counter, wave-endless recorder (event recorder) and reflective memory network enable to correct shot number between the many measurement devices. This function is prepared to collect data to which the cause of the beam fluctuation was not treated as the statistical data but the causal relation was able to be presumed.

At the initial operation, ideal parameters were calculated by offline simulation code. But XAL and JCE began to run including SAD script interpreter at the second term of the beam operation. Our application is written in JAVA excluding OPI of pilot version. The integrated OPI has so many record connections, and performance tuning is needed. Handling of multi-processing requires high level skill and knowledge of OS behaviour. We control people are shifting high-level application development. The experience of coding primitive software effects quick debagging of the application. Of course most of bugs are found in high-level description.

Feed back of RF amplitude and phase for long time range is started, and its result shows the effect of temperature of klystron gallery. The macro perturbation, caused by atmosphere temperature, cooling water temperature or voltage of electric power station, is quantitatively analysed by a self-regression model. Accelerator control is fundamentally required to stabilize the beam. High precision stability of each devices are inevitable, but achieving the extra-high current beam needs dynamic control for long time span based on the identifying multivariate analysis. The more specialist of the control theory is requested.

## SUMMARY

The control system of J-PARC LINAC successfully established initial requirement. For three to five years from now, this LINAC should aim the 1MW beam power. This control system works as a platform of high-level application. We prepared JCE to merge the components of XAL and other simulation codes. Total analysis of beam behaviour can be done by unified description through LINAC to the ring.

The large scale accelerator is constructed as a project, and keeping the schedule is required. The number of the kind of component of accelerators is not so many, and the state change of each device is not so complex (excluding special destructive monitor).

### *Experimental Accelerator*

If you construct a experimental accelerator of mono-purpose and the life of the accelerator is several years, the control system can be constructed by out-sourcing or by 5 experts of programming. It will take one and half years to make the control system. The middle-ware may make it without sticking to the function hierarchy. Rapid application development must be the first priority. First half year is spent for the design of whole function of the control system. If the number of klystron is greater than 5, the number of control people should be increased. Especially, the variation of monitor device expands quickly. Accessibility of that device has high dependency on bender spec (sometimes it is not opened). There will be many monolithic program described and it is maintained by the author himself. It is not necessary to read the other person’s code. When reading is required, it is ok to write another code.

### *Facility Accelerator*

It is necessary to design the accelerator that operation for users is obligated to integrate the whole in the control system. It doesn’t depend on the scale to construct the control system of this kind of accelerator, and about ten of control people and four years are required. The member must be contained some persons who are expert of :

- OS, compiler and driver design
- Signal, semaphore and Que
- Event driven message procedure

At the beginning of construction, the detail of the specification of each device is not fixed. That is the chance to involve every device to be defined the state flow and machine model in common. It is necessary to spend the first one year on the optimization of a hierarchical distribution of the software function. Do not let the work of the programmer with low skill level be limited to easy application development. The concept can be shared by the initial entire design, the driver design and the function distribution.

Contributing from the development phase of an individual device is indispensable to come to an agreement about the control specification as the person in charge of the device. Finally integrating a lot of machines by which of each produced the control part in an original idea becomes big dangerous for the normal operation securing. The control system can be constructed with the same man power even if it is a LINAC of 100 klystrons scale if succeeding in sharing machine model and the negotiation with the person in charge of the device.

The emphasis is put on the hardware selection, and the importance of the software structure is not recognized enough still. A cheap control equipment is selected, and excessive load is put on the software production, and a lot of examples decreased the entire performance are seen especially in a small-scale accelerator.

The estimation of the performance of the control system is difficult, because that quantitative description of total balance is impossible. Keeping the schedule, suppressing resources and achieving efficiency of operation show that.

*Abstract*

The beam commissioning of the J-PARC linac started in November 2006 and 181 MeV acceleration was successfully achieved in January 2007. The linac has delivered beams to the 3 GeV Rapid Cycling Synchrotron for its commissioning, and then, the subsequent Main Ring Synchrotron and the neutron target commissioning. The linac uses a Cs-free $LaB_6$-driven ion source and 20 units of 324 MHz klystrons. As of June 2008, the operation times are about 3,000 and 6,000 hours for the ion source and the RF source, respectively. The operating experience of the linac is described.

## INTRODUCTION

The J-PARC (Japan Proton Accelerator Research Complex) is a multipurpose facility with 1 MW class proton beam[1]. The facility is under construction at the JAEA/Tokai site as a joint project between the Japan Atomic Energy Agency (JAEA) and the High Energy Accelerator Research Organization (KEK). The J-PARC accelerator consists of a linac, a 3 GeV rapid cycling synchrotron (RCS), and a 50 GeV main ring synchrotron (MR). At the initial stage of the project, the linac accelerates a negative hydrogen beam up to 181 MeV with a current of 30 mA, a pulse width of 0.5 msec and repletion of 25 Hz.

The linac consists of an RFQ, a Drift Tube Linac (DTL) and a Separated-type Drift Tube Linac (SDTL). The features of the linac are described in [2]. High power conditioning of the cavities and beam test started in October and November 2006, respectively, then 181 MeV energy acceleration was achieved in January 2007. Since then, the linac beams have been used for the linac commissioning for its own, for the RCS commissioning, for neutron production, and for RF capture experiment at the MR.

We have adopted a three to four weeks commissioning cycle, which consists of a two or three week beam commissioning run and a one or two week interval. Adjusting the terms of intervals to accommodate appropriate maintenance periods, 17 beam commissioning cycles have been experienced from November 2006 to June 2008. Detailed beam commissioning results are described in [3].

## FRONT END

The J-PARC linac uses a Cs-free, $LaB_6$-driven, multicusp $H^-$ ion source[4]. The diameter and the length of the plasma chamber are 100 and 120 mm, respectively. The source plasma is confined by the multicusp magnetic field by 18 rows at the sidewall and four rows at the upper flange. The filament is a cylindrical spiral structure $LaB_6$ and the size is 29.5 mm and 49 mm in diameter and height, respectively.

Figure 1 shows the history of the ion source operation. During intervals between commissioning cycles, we have performed maintenance or ion source study. The pink and green bars denote the typical $H^-$ beam current in the commissioning days and the ion source study days, respectively. The maximum beam current from the ion source is 38 mA at the arc duty factor of 0.8 % (0.32 msec in pulse width and 25 Hz). Since the commissioning tasks doesn't always require a high peak $H^-$ beam current, the ion source has been operated either at the low current mode of 5 mA or at the high current mode of 30 mA. To keep the condition of the plasma chamber surface good, the ion source keeps running of the filament or beam extraction during the nighttime in the commissioning days. Operation time of the source has been reached to 3,360 hours as of June 2008.

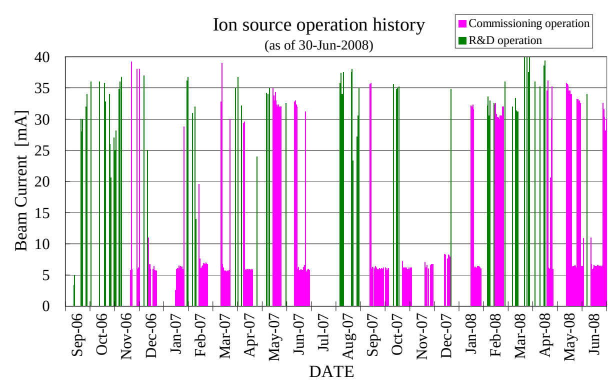

Figure 1: Operation history of the ion source.

On October 6 and December 18, 2006, filament had troubles of short-circuit to the neighboring spirals. The troubles were caused by filament deformation due to the arc power heating. Then the filament shape was modified to have a wider gap between spirals from 0.3 to 0.6 mm. We have not had similar troubles since then.

On August 21, 2007, we had a cutting off of the filament. We consider that the filament was broken by some strong mechanical stress because the filament showed no signs of remarkable consumption. The filament was replaced with a studious care. That filament lasted by June 28, 2008. The beam time was 2,030 hours,

#hasegawa.kazuo@jaea.go.jp

which consists of 780 hours in high current mode and 1,250 hours in low mode. We have not had enough statistics regarding the lifetime, but we have a confidence that the $LaB_6$ filament is of practical use for a few weeks user run.

## DTL/SDTL CAVITIES

The DTL consists of 3 tanks operating at 324 MHz with final output energy of 50 MeV. The transverse focusing is arranged in an FD lattice utilizing electro-magnet. After high-power conditioning of the DTL was completed up to 1.2 times as high as the nominal power level, the beam commissioning of the DTL was achieved in the second run, December 2006[5,6].

We have 32 SDTL tanks but two of them are used as debunchers. The inter-tank sections contain electromagnet quadrupole doublets with beam position monitors inside. Either steering magnet, wire scanner, or gate valve is arranged in between the doublet. The 181 MeV acceleration was achieved on January 24, 2007. We haven't had noteworthy troubles for the DTL/SDTL cavities during the commissioning.

We have 111 and 33 Q-magnet power supplies in the DTL and the SDTL sections, respectively. We had several troubles for these power supplies: replacement of the IGBT unit (2), repair of control unit (2), loose connection of switch (2), and others (1). Some of them happened or found during the maintenance period and not all the failures caused the beam trip. The downtime of the beam is 2 or 3 hours when the failed power supply is replaced by a spare.

We had water leakage in the accelerator tunnel twice due to the flow meter glass breakage. The cause was assumed that small cracks made in the fabrication or in the installation process grew by some shock. All the 64 flow meters, which were the same type of the broken ones, were replaced by commonly used type and installed carefully in summer, 2007. Since then, we have not had the similar troubles.

## RF SYSTEM

Figure 2 shows the RF subsystem. Six high voltage DC power supplies (HVDCPSs) supply the pulsed power to the 20 klystrons. Transmitter systems that control the klystrons and solid-state amplifiers provide RF power to the structures. Stabilization of the cavity fields is well performed with a feed-back and feed-forward control system[7].

The HV trip rate as a function of run number is shown in Fig. 3. At the early stage, we had occasional malfunctions of the crowbar circuit in the HVDCPS. That was improved by replacement of the registers at the current transformer (CT). However, in runs 14 and 15, fault rate increased suddenly. This was caused by discharges between the CT for modulation anode current measurement and the neighbouring wire. The insulator near the CT was replaced as a temporary measure, and we are planning to modify the arrangement around the CTs as a permanent measure.

Other than the power supply itself, HV trips have been caused by timing related matters such as setting error, timing signal failure, 12 MHz master oscillator failure. In these cases, the interlock stops the system because the monitor shows the abnormal state. These issues have been settled one by one based on these experiences.

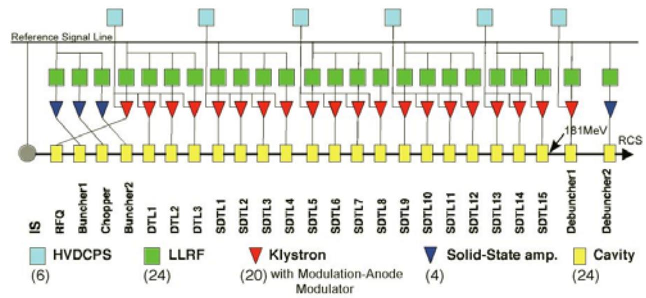

Figure 2: J-PARC linac RF system.

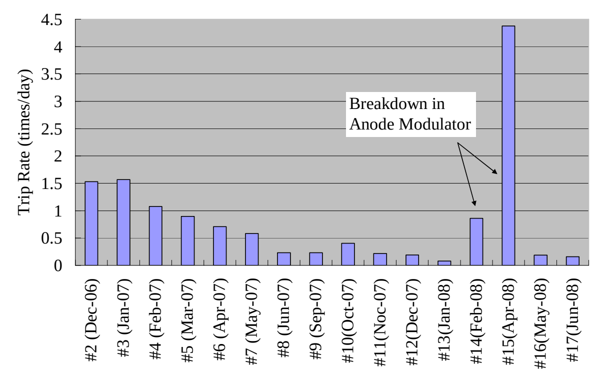

Figure 3: HV trip rate as a function of run number.

We have totally 23 klystrons (Toshiba E3740A) including 3 spares. Figure 4 shows the operation hours of the klystrons in use. The current average operation time is 6,460 LV-on (filament) hours and 5,960 HV-on hours as of June 2008.

Klystrons are consumables (limited lifetime) and costly parts for linac. Reliability engineering approach is taken to estimate the lifetime. So far, we have no failed klystrons, but we can assume the lower limit of Mean Time To Failure (MTTF). If we assume the exponential failure distribution $\alpha=\exp(-\lambda T)$, that refers to the random failure, where $\lambda$, $1-\alpha$ and T are failure rate, confidence level and operation time, respectively. If we take a confidence level of 90 %, failure rate is

$$\lambda = -\ln(1-0.9)/T = 2.30/T \quad (1)$$

If we put the total operation time T=129,292 (hours) for all 20 klystrons, upper limit of failure rate and lower limit of $MTTF_{lower}$ are

$$\lambda_{upper} = 1.78\times10^{-5}\ (1/hour) \quad and$$

$$MTTF_{lower} = 1/\lambda_{upper} = 56{,}200\ (hours)$$

The Poisson distribution denotes probability of klystron failure as the similar manners in [8]

$$f(x) = \frac{\mu^x}{x!} e^{-\mu} \qquad (2)$$

Then, with 20 klystrons and 5,000 hours per year operation, we expect the average number of consumption per year is

$$\mu = N\lambda t = 20 \times 1.78 \times 10^{-5} \times 5{,}000 = 1.78$$

Figure 5 shows the number of failure klystrons after one or two year operation. Above analysis shows that the average consumed number in one year is about 2, but there are high probability of 3 or more klystron failures. It may be said that the 3 spares we have are too short to keep operating for user run. In addition, above estimation would be somewhat optimistic because it is based on the random failure, or constant failure rate (CFR) distribution. This kind of failure tends to follow the increase failure rate (IFR) distribution. Some of them would fail almost simultaneously. In the latest run in September 2008, meaningful emission degradation for 5 klystrons is observed. We should carefully keep an eye on them.

## UTILITIES

We have had unscheduled stop three times due to the cooling water pump trip. This brings almost all the linac system sudden stop including high power RF system. It takes several hours to resume the operation. This pump is for the cooling system of the cavity tanks, which is made of steel. Rust has accumulated and sticks into the magnetic field of the canned pump. Then the line current increases and reaches to the breaker trip level. We have taken a careful quality control of the cooling water and monitoring the pump current for the time being. The type of the pump itself is reconsidered as a permanent measure.

At the initial stage of the beam commissioning, we had occasional stops by the flow rate interlock due to the total cooling water flow decrease and flow balance change. We have had accumulated these operation experiences and the frequency of such failure is going down.

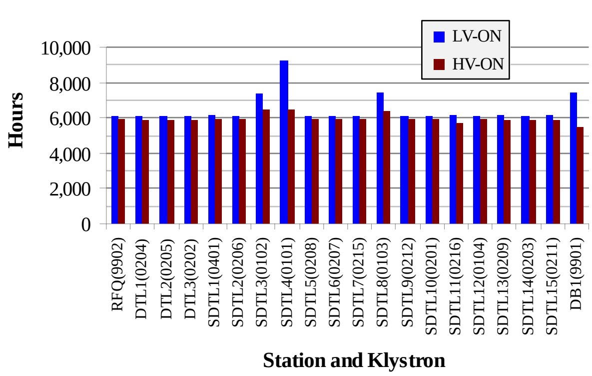

Figure 4: Total klystron operation hours.

## SUMMARY

The J-PARC linac has been successfully commissioned and operational experiences have been accumulated. The Cs-free, $LaB_6$ filament driven ion source demonstrates good performance from a point of view of beam current and lifetime. The DTL and SDTL cavities have been operated without serious troubles. The trip causes are overcome one by one for the RF source and trip rate has been greatly decreased. The average operating hour of the klystrons exceeds 6,000 and the spare issues are discussed. Although we had many cooling water related failures at the initial stage, they are improved and the availability has been increased. Based on these experiences, we will go into a new phase of the user run from December 2008.

# BEAM TEST RESULTS OF THE PEFP 20 MEV PROTON ACCELERATOR AT KAERI*

Yong-Sub Cho#, Han-Sung Kim, In-Seok Hong, Ji-Ho Jang, Dae-Il Kim, , Hyeok-Jung Kwon, Bum-Sik Park, Kyung-Tae Seol, Young-Gi Song, Sang-Pil Yun, KAERI, Daejon 305-353, Korea

*Abstract*

A 20 MeV proton accelerator, which consists of a 50 keV injector, a 3 MeV RFQ and a 20 MeV DTL, has been tested by Proton Engineering Frontier Project (PEFP) at Korea Atomic Energy Research Institute (KAERI). The operation conditions are 20 MeV, 20 mA peak current, 50 μs pulse length with a 1 Hz repetition rate due to the limited radiation shielding. The accelerator was tuned to reach to the above operating conditions. Moreover, an irradiation facility with external beam has been installed to supply the proton beam for the user and irradiation test. In this paper, we present results from tuning operation and the irradiation tests.

## INTRODUCTION

The Korean Government launched the Proton Engineering Frontier Project (PEFP) in 2002 to help realize potential applications of high-power proton beams. The primary goal of the project is to develop a high-power proton linear accelerator to supply 100-MeV proton beams and to construct user beam line facilities, whose users can utilize proton beams with a wide range of energies and currents for their research and development programs [1]. In addition, the 100-MeV accelerator can be used as a proton injector for the next-stage high-power accelerators, such as a high-energy linac or rapid cycling synchrotron [2].

A 20-MeV proton linear accelerator has been developed as the front end of the 100-MeV accelerator, which consists of a 50-keV proton injector, a 3-MeV RFQ, a 20-MeV DTL, and RF systems, as shown in Fig. 1.

## THE 20-MEV PROTON LINEAR ACCELERATOR

### The Proton Injector [3]

The injector includes a duoplasmatron proton source and a low-energy beam transport (LEBT). The beam current extracted from the source reached a current of 50 mA. The extracted beam has a normalized emittance of 0.2 πmm-mrad from a 90% beam current, where the proton fraction is > 80%. To achieve pulsed operation, a high-voltage switch has been installed in the high-voltage power supply, whose rise and fall times are < 50 ns. The pulse length and the repetition rate can be easily changed using this semiconductor switch. The LEBT consists of two solenoid magnets that can filter the $H^{2+}$ ions and two steering magnets that can control the beam's position and angle at the entrance of the RFQ.

### The 3 MeV RFQ [4,5]

The PEFP RFQ is designed to accelerate a 20-mA proton beam using a voltage from 50 keV to 3 MeV and has the usual four-vane-type design. The entire structure is separated into two segments that are resonantly coupled for field stabilization. The RF power is fed into the cavity through two iris couplers in the third section.

A 3-MeV, 350-MHz PEFP RFQ has been fabricated, tuned, installed, and tested. The low-power field tuning satisfied the design requirements. High-power RF conditioning experiments for the RFQ were carried out up to a peak power of 450 kW, a pulse length of 80 μs, and a repetition rate of 1 Hz. The time required for this conditioning was about 8 h. The RF signals shown in Fig. 6 are the signals detected after the conditioning, which were very stable. Beam tests were carried out by adjusting the LEBT and the RF parameters.

### The 20-MeV DTL

The PEFP 20-MeV DTL consists of four tanks that accelerate the 20 mA proton beam from 3 MeV to 20 MeV. The total length of the DTL is about 20 m. The PEFP DTL structures were designed for a beam duty of 24%, and the FFDD lattice configuration has a magnetic field gradient of 5 kG/cm and an effective field length of 3.5 cm.

The DTL was fabricated using electroplating technology for the tanks and e-beam welding technology for the drift tube. A laser tracker was used to align the drift tubes in the tanks. Figure 8 shows the inside of a tank. The tuning goals for the PEFP DTL were such that the deviation in frequency was less than ±5 kHz from the design value, and the field distribution was less than ±2 %

throughout a tank with a tilt sensitivity against perturbations of less than 100%/ MHz.

For the 20-MeV DTL, a single klystron drives four DTL tanks simultaneously. For this multicavity driving concept, temperature control systems and mechanical phase shifters were installed in each tank. High-power RF tests were carried out. The peak RF power to each tank was 150 kW.

### *The RF System [6]*

The accelerator facilities at the KAERI test stand include the 20-MeV accelerator itself, two sets of 1-MW, 350-MHz RF systems, two sets of –100-kV, 20-A DC high-voltage power supplies for the klystron, two sets of 2-MW cooling systems for the cavity, and the RF system. The design duty of the 20-MeV accelerator was 24%, and two 1-MW, 350-MHz klystrons were used to drive the 20-MeV accelerator: one was for the RFQ, and the other was for the DTL. All the other ancillary facilities, such as the klystron power supply and cooling system, were designed for an operational duty of 100%. During the low-duty operational tests at the KAERI test stand, the RF system operated such that the electron beam of the klystron was in the continuous wave (CW) mode, and only the input RF signal was modulated for low-duty pulse operation. TED Model TH2089F klystrons (350 MHz, 1 MW CW, Thales Electron Devices) were used as the RF source for the 3-MeV RFQ and for the 20-MeV DTL. Two high-voltage power supplies and two modulating anode power supplies were fabricated and tested for the klystrons. In addition, iris-type input couplers were developed and installed in the RFQ and the DTL.

The digital LLRF system was developed, and the stability requirements of the RF field were: amplitude = 1% and phase = 1°. Our digital feedback control system was based on a commercial field-programmable gate array (FPGA) card hosted on a virtual machine environment (VME) board. A control logic based on feedback and feed-forward control was implemented in the FPGA by using a very high-speed integrated circuit hardware description language (VHDL).

### *Target Station for 20-MeV Proton Beam Users*

The operational license for the 20-MeV proton linac installed at the KAERI site was issued in 2007 by the Korea Institute of Nuclear Safety (KINS). According to our operational license, a 20-MeV beam with an average current of 1,000 nA can be supplied to users for their applications. At the exit of the 20-MeV DTL, a target station has been prepared to supply beams to the user, as shown in Fig. 2. The 20-MeV proton beams are transported with quadrupole magnets to expand the beam size and change the beam shape, for example, circular shape, and extracted into air through an aluminum beam window. Radiation is shielded with lead and concrete bricks.

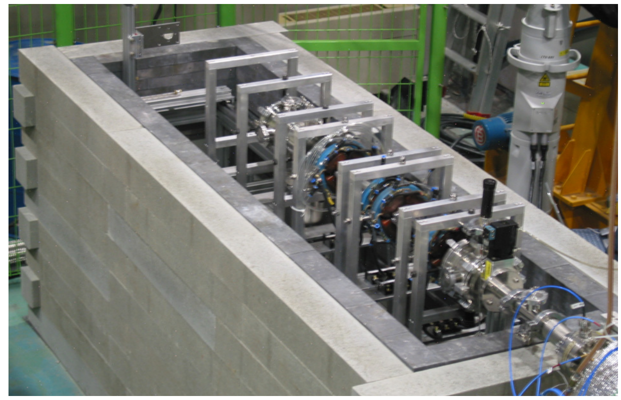

Figure 2: 20MeV proton beam target station.

## BEAM TEST

The beam test of the proton injector and RFQ was done to check the operation characteristics after the slight modification of the front-end system [7]. An ACCT (AC Current Transformer) was installed to measure the input beam current to the RFQ and a Tuned-CT was installed to measure the output beam current from the RFQ. A collimator was installed not only to shield the ACCT from stray magnetic field but also to eliminate the spurious beam signal induced by the secondary electrons. Also an electron trap was installed in front of the RFQ to protect the electron flow from the LEBT. The RFQ output beam current was measured depending on the LEBT parameters – mainly solenoid magnet currents. The results showed typical characteristics of the RFQ transmission. The optimum solenoid current sets were good agreement with the TRACE-3D results within 3%. The beam transmission rate was measured as a function of the RF power. The measured value was compared with the PARMTEQ simulation results as shown in Fig. 3. We could determine the operating set point of the RF power based on the measurement. After the adjustment of the operating parameters such as LEBT steering magnet current, solenoid magnet current, RFQ RF power, we could get 20mA peak current from the RFQ.

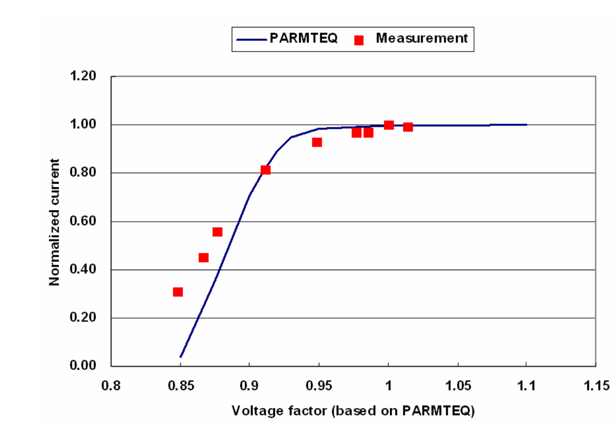

Figure 3: RFQ transmission rate depending on the vane voltage.

After the test of the RFQ, the beam test of the DTL started. The beam transmission through the DTL was about 80%. During test, the beam loss pattern was measured using pocket dosimeter (ALOKA, PDM-192) in every 20cm along the DTL. The result was such that a few numbers of noticeable localized peaks were measured as shown in Fig. 4. A beam dynamics study using PARMILA was done to investigate the cause of the localized beam loss pattern. The results showed that the cause of the first peak was estimated from the polarity reversal of the 30$^{th}$ electromagnet of the 2$^{nd}$ DTL tank. The beam loss pattern after the polarity reversal of the above quadrupole magnet is shown in Fig. 4. It could be seen that the first peak disappeared. In this case, the transmission rate through the DTL was nearly 100%. The second and third peak could not be explained from the polarity reversal of the electromagnet. And the peak could be greatly reduced by the stabilization of the tank resonance conditions. A 20mA peak proton beam could be accelerator up to 20MeV with the above conditions and the typical beam signal is shown in Fig. 5. The beam currents from the proton injector, RFQ and DTL were measured by ACCT, Tuned-CT and FCT respectively. The operating conditions were such that the RF pulse width was 50µs and the repetition rate was 1Hz.

## CONCLUSIONS

We have developed the technology required for the construction of a proton linac. Using this technology, a 20-MeV proton linac was developed and installed at the KAERI site in Daejeon. 20MeV 20mA peak current was achieved at a low duty (1Hz, 50us) and has been used to supply a 20-MeV beam to users with an operational license to supply an average current of 1000 nA.

In April 2009, the ground breaking for the construction will be started and the 20MeV machine will be moved and installed in 2011. In 2012, we will perform the full 24% duty operation of the 20MeV machine. Fig. 6 shows the new site at Gyeonju.

# STABILITY OF NORMAL CONDUCTING STRUCTURES OPERATION WITH HIGH AVERAGE HEAT LOADING

V. V. Paramonov *, INR RAS, 117312 Moscow, Russia

## [illegible]

Instead of proved application of superconducting structures for high energy part of intense linear proton accelerators, Normal Conducting (NC) structures are still considered for medium and low energy parts below $200 MeV$. Operation with accelerating rate of $\sim 4\frac{MeV}{m}$ and duty factor $\sim 5\%$ results for standing wave NC structure in an average heat loading of $\sim 30\frac{kW}{m}$. Due to the high heat loading an operating mode frequency shift is significant during operation. In this paper conditions for field distribution stability against small deviations in time of individual cell frequencies are considered. For $\frac{\pi}{2}$ structures these conditions were formulated by L. Young and Y. Yamazaki. General case of 0, $\frac{\pi}{2}$ and $\pi$ operating modes is considered with common approach.

## INTRODUCTION

In projects of modern particle accelerators NC structures are consideration for application with the strong heat loading due to high average RF power dissipation. It can be the sequence of a high accelerating gradient $E_0T$, or long RF pulse, or high RF pulse repetition rate or combinations of these factors. Together with bi-periodical (or compensated) structures, simple periodical structures with 0 or $\pi$ operating modes are under consideration too due to a simpler design and construction. As it is known well, simple 0 or $\pi$ mode structures are sensitive in electric field distribution to small deviations of cells frequencies. To ensure required accelerating field homogeneity, not so large number of simple structure periods $N_p \sim 5 \div 10$ should be in the cavity and coupling coefficient should be so high, as reasonable.

Nevertheless, let us suppose the cavity with the simple periodic or bi-periodic structure is tuned for required field distribution and another parameters. But during a high RF power operation a question of thermal stability arises.

## THERMAL STABILITY

During a high RF power operation the temperature of the cavity increases and own cavity frequency $f_0$ decreases due to cavity expansion. For the fixed cooling conditions the cavity frequency shift is linearly proportional to the average dissipated RF power. For a heat loading of $\geq 20\frac{kW}{m}$ the cavity frequency shift $df$ can be of $df \geq 2.0 \cdot 10^{-4} f_0$. The cavity frequency for high RF power operation should be adjusted by the change of cooling water temperature.

Suppose we have a steady-state high RF power operation with a reference field distribution in the cavity. Let us suppose, that in one moment the cell with the number $j$ got a small frequency deviation $\Delta f_j$ due to some random reasons. Mostly possible reason is a fluctuation of a turbulent flow in cooling channels, because the turbulent flow is stable in average. For distinctness we will suppose $\Delta f_j < 0$, assuming cooling ability reduction. The small frequency change of the $j-th$ cell immediately will results in the change of the field distribution along the cavity and the change of relative field balance between cells. Depending on the structure dispersion properties, two options are possible.

In the first case the field in the $j-th$ cell relatively decreases. RF power dissipation in this cell decreases, the cell temperature decreases, the cell frequency increases, canceling initial cell frequency deviation. After some time the structure returns to operation with the reference field distribution. Such structures are thermally stable.

In the second case the field in the $j-th$ cell relatively increases. RF power dissipation in this cell also increases, the cell temperature increases, the cell frequency decreases, amplifying initial cell frequency deviation. Self-amplifying process starts. At least, such process can lead to the change in the filed distribution, because the cooling and control systems operate for the cavity as a whole. Such structures are thermally unstable.

## [illegible]

Suppose we know the total set of modes in the reference unperturbed cavity - frequencies $f_\nu$ and field distributions $E_\nu, H_\nu$, normalized as:

$$\int_V Z_0^2 H_n H_\nu^* dV = \int_V E_n E_\nu^* dV = \delta_{n\nu} W_0, \qquad (1)$$

where $Z_0 = \sqrt{\frac{\mu_0}{\epsilon_0}}$ and $V$ is the cavity volume. The field distribution in the cavity with a small dimension deviation $\Delta V$ can be describe as [1]:

$$E = E_n + \sum_{\nu \neq n} E_\nu \frac{f_\nu^2}{f_n^2 - f_\nu^2} \frac{1}{W_0} \int_{\Delta V} (Z_0^2 H_n H_\nu^* - E_n E_\nu^*) dV. \qquad (2)$$

In all periodical accelerating structures the field distribution along the axis can be described as:

$$E_{m\nu} = E_{\nu 0} cos(m\nu\pi), \qquad (3)$$

where $E_{m\nu}$ is the field amplitude in the $m$-th cell, $\nu\pi$ is the phase shift per structure period. Here we assume the phase

* paramono@inr.ru

shift for operating mode $n\pi, n = 0, 1$. Transforming (2) with using perturbation theorem, one can get, remembering frequency detuning only in the $j$-th cell:

$$E = E_n + \sum_{\nu \neq n} 2E_\nu a_\nu \frac{\Delta f_j}{f_j} cos(jn\pi)cos(j\nu\pi), \quad (4)$$

where $a_\nu = \frac{f^2}{f^2 - f_\nu^2}$. The similar relation for descriprion of a field perturbation in the chain of coupled cavities is given in [2] with a matrix form.

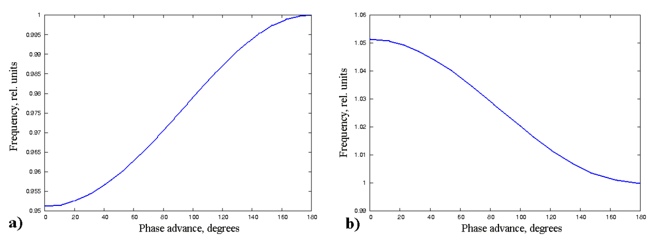

Figure 1: Dispersion curves for simple structures with positive (a) and negative (b) dispersion.

Dispersion curve for a simple periodical chain of coupled cells can be described by the equation:

$$f_\nu = \frac{f_c}{\sqrt{1 + k_c cos(\nu\pi)}}, \quad (5)$$

where $f_c$ is the own cell frequency and $k_c$ is the coupling coefficient. Depending of $k_c$ sign, the chain can have a positive dispersion, $k_c > 0$, $\frac{\partial f}{\partial \nu} > 0$, Fig. 1a, or a negative one, $k_c < 0$, $\frac{\partial f}{\partial \nu} < 0$, Fig. 1b.

Examples of simple structures are shown in Fig. 2. The

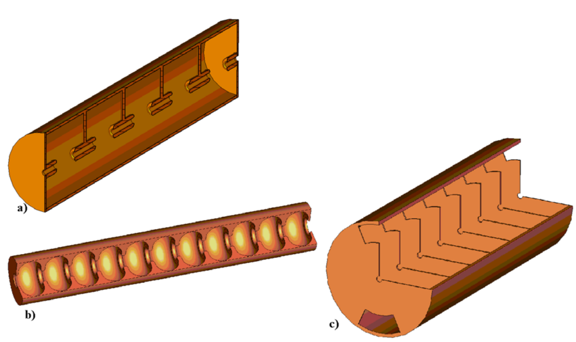

Figure 2: Examples of simple structures.

separated DTL structure [3] with operating 0 mode and positive dispersion is shown in Fig. 2a. Also positive dispersion has the structure with coupling through bore hole and operating $\pi$ mode, [4], Fig. 2b. Negative dispersion has a structure with coupling slots and $\pi$ operating mode, Fig. 2c.

For thermal stability of the structure coefficients $a_\nu$ in (4)

Table 1: Thermal stability of simple structures

| Operating mode | Dispersion | Thermal stabiliuty |
|---|---|---|
| 0 ($2\pi$) | positive | No |
| 0 ($2\pi$) | negative | Yes |
| $\pi$ | positive | Yes |
| $\pi$ | negative | No |

should be positive. With the negative $j-th$ cell detuning and positive $a_\nu$ value the perturbed field value in $j$-th cell will be decreased. One can check it by calculations in (2). It means for operating 0 mode the negative dispersion and for operating $\pi$ mode the positive dispersion. Results of thermal stability definition for all combinations of operating mode type and dispersion sign are summarized in the Table 1.

To confirm this conclusion, direct numerical simulations of the field distribution in $\pi$ mode structures with negative (slot coupled, Fig. 2c) and positive (bore hole coupled, Fig. 2b) dispersion and detuned first cell. Parameters of the structures are - $k_c = -5.0 \cdot 10^{-2}, N_p = 7, \frac{\Delta f}{f} = -5.2 \cdot 10^{-4}$ for slot coupled structure and $k_c = 1.25 \cdot 10^{-2}, N_p = 11, \frac{\Delta f}{f} = -4.4 \cdot 10^{-4}$ for bore hole couples one, where $N_p$ is the number of periods (number of accelerating gaps). Large detuning value, due to conducting cylinder at the cell axis, is chosen to do effect evident. In Fig. 3 the calculated $E_z$ distribution is for the perturbed operating mode are shown. One can see clear filed tilt in the filed distribution. For the $\pi$ mode structure with negative dispersion the field in the detuned cell is larger, Fig. 3a, and this structure is thermally unstable. For the $\pi$ - mode structure with positive dispersion we see the lower field in the detuned cell, Fig. 3b.

Important value is a rate of amplification $\frac{\partial E}{\partial(\Delta f)}$, which

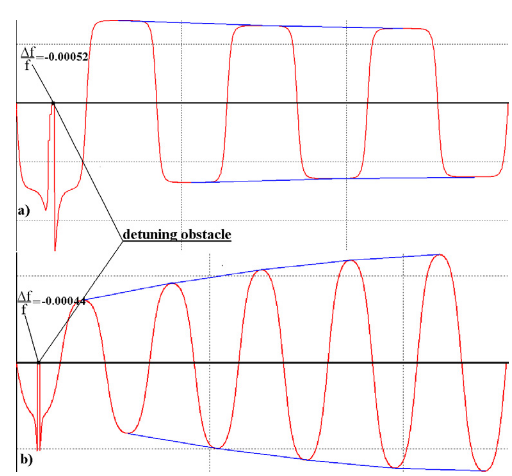

Figure 3: Calculated field distribution in $\pi$-mode structures with negative (a) and positive (b) dispersion with the detuned first cell.

is proportional to $a_\nu$. The main contribution in the field perturbation provides the nearest mode with $a_1$ coefficient. Supposing dispersion curve is described by (5), $a_1 \sim \frac{2N^2}{\pi^2 k}$. For $\pi$ mode structures, considered for Fig. 1, $a_1 = -1.57 \cdot 10^2$ and $a_1 = 1.62 \cdot 10^3$, respectively. Dispersion curve of the separated DTL, Fig. 2a, due to strong coupling is not described well by the relation (5). With direct simulations one can get $a_1 = 1.67$ for $\beta = 0.314$ and $a_1 = 3.75$ for $\beta = 0.553$ - rather small value.

## [illegible]

Let us remember, that a 'compensated' is named a structure in which at operating frequency coincide frequencies of two modes (accelerating $f_a, E_a$ and coupling $f_c, E_c$ modes) with different parities of field distribution with respect to symmetry plane [5]. Examples are well known structures, Side Coupled, Annular Coupled, On-axis Coupled, Disk and Washer, DTL with posts and so on. Dispersion curve of the compensated structure is shown in Fig. 1a, assuming operating $\pi$ mode, and consists from two branches. In practice frequencies of accelerating and coupling modes do not coincide perfectly and between branches there is a stop band with the width $\delta f = f_c - f_a$. The relations for description of dispersion curve (Fig. 4b)

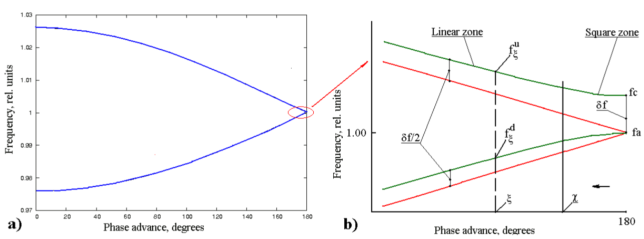

Figure 4: Dispersion curve for compensated structure (a) and behavior in the vicinity of operating point (b).

and field distributions of modes in the vicinity of operating point are given in [6] both for closed $\delta f = 0$ and open $\delta f \neq 0$ stop band.

For $\delta f \neq 0$ in the nearest vicinity of operating point $\xi \leq \chi$, 'square zone', where $\xi = \pi - \nu, \chi = \frac{2\delta f}{k\ f}$, [6], the field distributions for modes at upper $f^u_\xi$ and bottom $f^b_\xi$ branches of dispersion curve strongly differ and should not be modes in this region, $\nu_m = \frac{m\pi}{N}, \xi_m = \pi - \nu_m, \xi_m > \chi$. On the contrary, the structure has no properties of compensated one. It should be done in structure tuning by appropriate stop band width $\delta f$ decreasing.

In the 'linear zone' $\xi \geq \chi$ the behavior of the upper $f^u_\xi$ and the bottom $f^b_\xi$ curve branches is approximated as [6]:

$$f^{u,b}_\xi \approx f_a + \frac{\delta f}{2} \pm \frac{f_a k_c \xi}{4} - \frac{f_a k_c^2 \xi^2}{8}, \quad (6)$$

In this zone the branches of the dispersion curve are shifted at $\delta f/2$ value, but come parallel with respect to the branches for an ideal case $\delta f = 0$. The field distributions for modes at upper and bottom branches of dispersio curve are similar. We have to consider a simultaneous contribution of modes $\xi_m = \pi - \nu_m$ type in the field perturbation (4):

$$a_\xi = a^u_\xi + a^b_\xi = \frac{(f^u_\xi)^2}{f_a^2 - (f^u_\xi)^2} + \frac{(f^b_\xi)^2}{f_a^2 - (f^b_\xi)^2}. \quad (7)$$

Taking into account (7) and (6), considering the main part of the field perturbation due to nearest modes $m = 1, 2, 3...$ in the linear zone, and neglecting second order terms in $\xi_m$ and $\frac{\delta f}{f}$, one can get for perturbed field distribution (4):

$$E = E_a\left(1 + \sum_m \frac{64\delta f \Delta f_a N_p \cos j\theta_m \cos i\theta_m}{f_a^2 m^2 k_c^2}\right) \quad (8)$$

These contributions of nearest modes are partially compensated and a residual is proportional to the $\delta f$ value. As one can see from (8), for thermal stability of the structure should be $\delta f \geq 0$. For compensated structures this conclusion has been done before, [7], [8] basing on coupled circuits approach [2].

Estimating coefficient $a_1$ of contribution for nearest modes into perturbed field distribution, for $k_c = 0.05, N_p = 50, \frac{\delta f}{f} = 10^{-4}$ one gets $a_1 = 32$ - a smaller value as for simple $\pi$ mode structures with the same coupling coefficient but of order smaller number of periods.

## SUMMARY

For compensated, or bi-periodical structures, thermal stable operation all time can be achieved by appropriate structure RF tuning. In simple periodical structures existence or absence of thermal stability is the property of the structure. Thermal run away probability depends on the amplification rate value for field perturbation.

# STATUS OF THE LINAC4 PROJECT AT CERN

M. Vretenar, C. Carli, R. Garoby, F. Gerigk, K. Hanke, A.M. Lombardi, S. Maury, C. Rossi, CERN, Geneva, Switzerland

*Abstract*

Linac4 is a new 160 MeV, 40 mA H- accelerator which will be the source of particles for all proton accelerators at CERN from 2013. Its construction has started in 2008, as part of a programme for the progressive replacement or upgrade of the LHC injectors during the next decade. Linac4 will initially inject into the PS Booster and at a later stage into a 4 GeV Superconducting Proton Linac (SPL), which could ultimately be upgraded to high duty cycle operation. For this reason accelerating structures, RF infrastructure and shielding of Linac4 are dimensioned for higher duty cycle from the initial phase.

Linac4 is normal-conducting, 80 m long and consists of an RF volume ion source, an RFQ, a beam chopping section and a cascade of three different types of 352 MHz accelerating structures. Its main design requirements are high reliability, high beam brightness and low beam loss. The accelerator will be housed in an underground tunnel on the CERN Meyrin site, which can eventually be extended to the SPL, with equipment installed in a surface building above.

The main parameters, the status of the main components, the planning, the project organisation and the civil engineering infrastructure are presented.

## THE CERN INJECTOR UPGRADE

A programme for the progressive replacement or upgrade of the LHC injectors has been recently defined at CERN [1]. The first goal of this programme is to increase the LHC luminosity beyond nominal by improving beam brightness from the injector complex, which is now the main limiting factor towards higher luminosity. A second motivation is the replacement of the present cascade of injectors, which has been built between 1959 and 1978 and in the past few years has been giving rising concerns for its long-term reliability, with a more modern, reliable and easier to maintain system, where transfer energies and beam parameters are optimised for the LHC needs. Moreover, new low energy accelerators can be made compatible with operation at higher beam power that could be required by future physics needs.

The present sequence of accelerators used as LHC injectors is based on a proton linac of a relatively low energy (Linac2, 50 MeV) followed by the 1.4 GeV PS Booster (PSB), by the 26 GeV Proton Synchrotron (PS) and finally by the 450 GeV Super Proton Synchrotron (SPS). The new injector sequence would use an H⁻ high-energy linear accelerator, the 4 GeV Low-Power Superconducting Proton Linac (LP-SPL), whose normal-conducting section of 160 MeV, to be built in a preliminary stage, is called Linac4 [2]. The LP-SPL can be eventually upgraded to a High-Power SPL operating at multi-MW beam power [3]. The SPL will be followed by a new 50 GeV Proton Synchrotron (PS2). Present and future injection lines are schematically presented in Fig. 1.

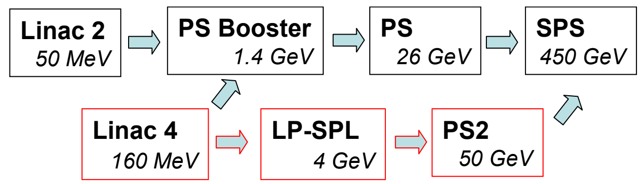

Figure 1: Scheme of the old and new LHC injectors.

A staged construction is possible because Linac4 can inject in a preliminary phase H⁻ ions into the existing PSB. The higher injection energy coupled with the benefits of H⁻ charge exchange injection are expected to increase brightness out of the PSB by a factor of 2, making possible a first increase in the LHC luminosity around 2013, when the nominal luminosity should have been attained in the LHC and a programme of upgrades to the ring and to the experiments aiming at higher luminosity could be implemented.

In June 2007, the CERN Council has approved the construction of Linac4 as a high-priority project for the period 2008-2013. At the same time, it has approved the detailed design of SPL and PS2, whose construction could start in 2012 and be terminated between 2015 and 2017

Linac4 will be housed in a 12 m deep underground tunnel, connected to the Linac2-PSB line. A surface equipment building will house klystrons and linac equipment. The Linac4 tunnel can be later on extended to the SPL. Figure 2 shows a view of the CERN Linac-PSB-PS complex, indicating the position of Linac4 and of the future extension to the SPL. Figure 3 presents the layout of the foreseen Linac4 infrastructure.

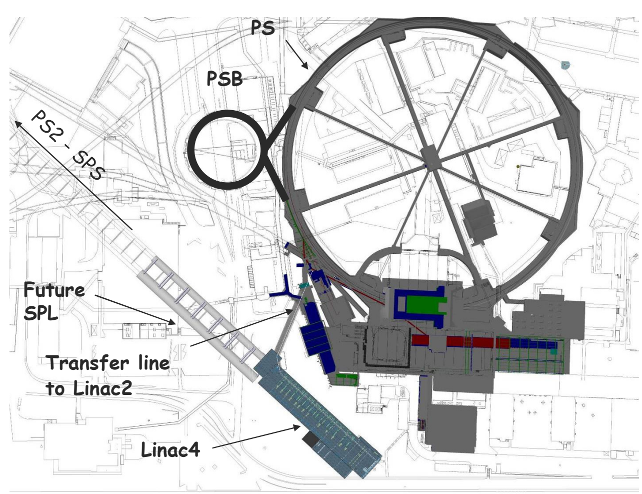

Figure 2: View of the PS Complex at CERN, showing the position of the new Linac4.

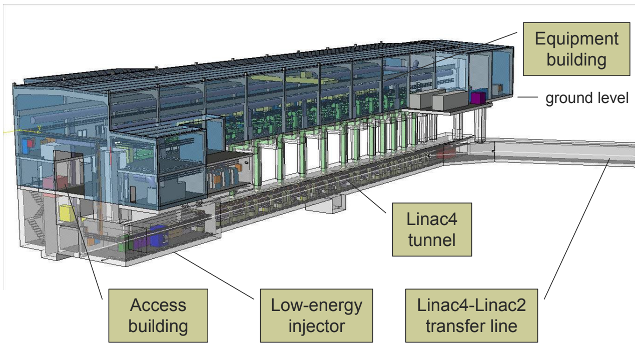

Figure 3: The Linac4 installations.

## LINAC4 DESIGN

The design of Linac4 is dictated by the requirement to operate in three different modes during its lifetime, depending on the characteristics (repetition frequency, pulse current and pulse duration) of the machine that it has to supply with beam:

1. PSB injector, 2013-2017: 1.1 Hz, 40 mA, 400 µs.
2. LP-SPL injector, from 2017: 2 Hz, 20 mA, 1.2 ms.
3. HP-SPL injector, after 2020: 50 Hz, 40 mA, 400 µs.

After a first phase as PSB injector the Linac4 beam pulse length will increase to 1.2 ms, whereas its current will go down by a factor 2. At a later stage, if the high-power programme is approved, Linac4 would operate at 50 Hz with a beam current going up again to 40 mA.

The main consequence on the Linac4 design is that civil engineering and in particular radiation shielding have to be dimensioned from the beginning for high-power operation. Accelerating structures and klystrons will be specified as well for high duty operation, whereas power supplies, electronics, and all electrical and cooling infrastructures will be dimensioned only for low beam power operation and will be replaced or upgraded when required for the SPL at full beam power. Additional space has been foreseen in the surface building for larger power supplies and for the additional SPL equipment.

In the design of machine and infrastructure particular care has been given to solutions providing the high reliability required for the first accelerator in the injection chain. Fault rate should be comparable to that of Linac2, ~1.5% of scheduled beam time. Particular attention has been given to the control of transverse and longitudinal emittance growth, for clean PSB and SPL injection, and of losses along the machine, to limit activation for the full-SPL mode of operation [4]. The main Linac4 design parameters are reported in Table 2.

Table 2: Main Linac4 Design Parameters

| | | |
|---|---|---|
| Output Energy | 160 | MeV |
| Bunch Frequency | 352.2 | MHz |
| Max. Rep. Rate | 2 | Hz |
| Max. Beam Pulse Length | 1.2 | ms |
| Max. Beam Duty Cycle | 0.24 | % |
| Chopper Beam-on Factor | 65 | % |
| Linac pulse current | 40 | mA |
| N. of particles per pulse | 1.0 | $\times 10^{14}$ |
| Transverse emittance | 0.4 | π mm mrad |

Three different accelerating structures will be used in Linac4 after the RFQ, all at 352 MHz frequency [5]. In particular, the Side Coupled Linac (SCL) at 704 MHz foreseen in a previous design [2] has been replaced with a Pi-Mode Structure (PIMS) operating at the basic linac frequency [6]. The Linac4 scheme with the transition energies is reported in Fig. 4.

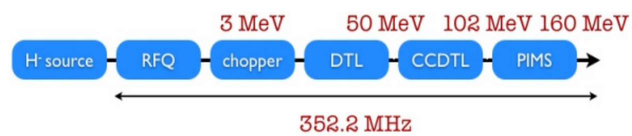

Figure 4: Linac4 layout.

Some 352 MHz klystrons and other equipment from the old LEP accelerator will be re-used for Linac4. In the first stage (Fig. 5, top), 13 old LEP klystrons at 1.3 MW and 6 new pulsed klystrons at 2.6 MW will feed the accelerating structures. Most of the LEP klystrons will be connected in pairs to a single modulator, allowing for the progressive replacement of pairs of LEP klystrons with one klystron of the new type. In the final configuration (Fig. 5, bottom) 9 new klystrons will feed two RF cavities each.

## LINAC4 STATUS

The pre-integration of machine components required for the definition of the building has started in May 2007 and has allowed tendering of the civil engineering works in April 2008. Construction work will start in October 2008; building and tunnel should be delivered at end 2010. In parallel, safety requirements have been addressed, and a preliminary Safety File has been submitted in June 2008 to the CERN Safety Authorities.

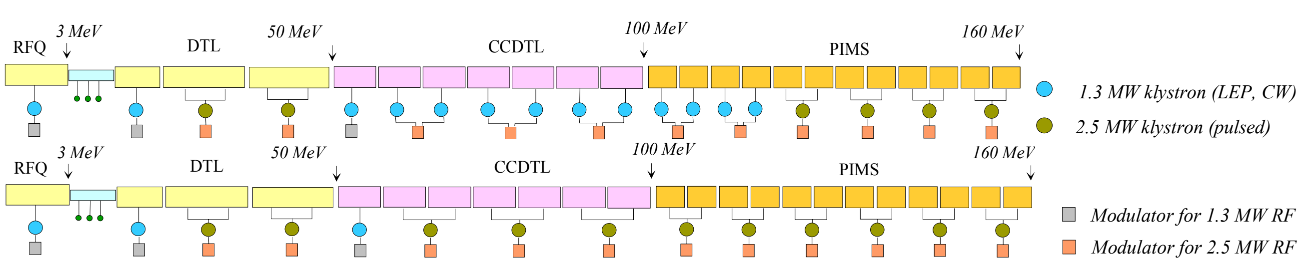

Figure 5: RF power distribution at installation (top) and after the end of the stock of LEP klystrons (bottom).

Construction of the ion source, RFQ [7] and chopper line is progressing. They will be successively installed in the Linac4 Test Stand (Fig. 6), where the Front End beam parameters will be extensively measured before installation in the tunnel. First beam measurements from the RF volume ion source are foreseen for the end of 2008. The chopper line elements have been built and the line is being assembled on its support. First beam tests at 3 MeV are foreseen after installation of the RFQ in March 2010. The prototype modulator and a LEP klystron operating in pulsed mode have been already successfully tested in the Test Stand.

Figure 6: The Test Stand with klystron and modulator (right), ion source cage (top).

The mechanical design of the Drift Tube Linac (DTL) is now completed. The DTL will use Permanent Magnet Quadrupoles mounted in drift tubes precisely aligned inside the tanks, without adjustments after assembly [8]. Construction of a DTL prototype is well advanced, first high-power tests are foreseen for the beginning of 2009 and construction of the first tank will start immediately afterwards. Two prototypes of the first Cell-Coupled DTL (CCDTL) module have been successfully tested at high power and the construction of the complete CCDTL is being organised [9]. The design of the PIMS structure has been completed, and construction of a full prototype of the first module is presently starting in the CERN Workshops [6]. The 70 m long transfer line connecting to the Linac2 line is in the detailed design phase. Procurement of RF and other equipment is starting.

## PROJECT SCHEDULE

The planning of the project (Fig. 7) depends on the schedule of the civil engineering works. After delivery of the building at end 2010, parallel installation of infrastructure and machine components will take place in 2011. In 2012 the different linac sections will be progressively commissioned. The connection of the transfer line and the modifications to the PSB for H$^-$ injection will take place during the 2012/13 CERN machine shut-down. It is foreseen that Linac4 will provide particles to all CERN users from June 2013.

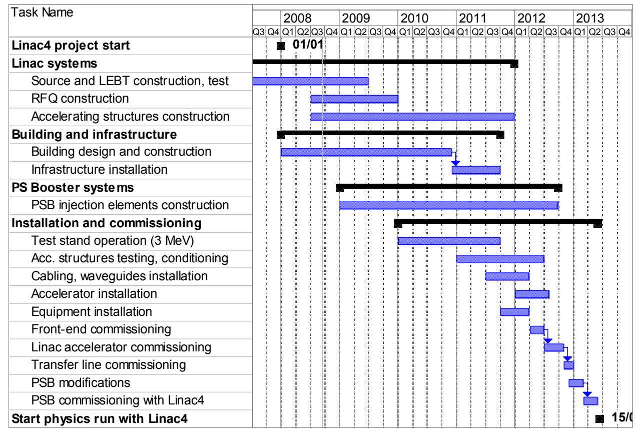

Figure 7: Linac4 Masterplan.

*Abstract*

The 352 MHz CCDTL will accelerate the Linac4 beam from 50 to 102 MeV. It is the first structure of this kind that will be used in a proton linac. Three short DTL-type tanks, each having two drift tubes, are connected by coupling cavities and form a chain of resonators operating in the stable π/2 mode. The CCDTL section is made of 7 such 5-resonator chains, each fed by a 1.3 MW klystron. Focusing quadrupoles are placed between tanks, easing their alignment with respect to a conventional DTL thus making the structure less sensitive to manufacturing errors. In order to validate the design and to develop the production technology, two prototypes have been constructed and successfully tested. The first prototype, built at CERN, consists of two half-cavities and one coupling cell, whereas the second, larger one, having two full cavities and one coupling cell, was built at VNIITF and BINP in Russia within the frame of an R&D contract funded by the ISTC Organisation. Both prototypes have been tested at CERN slightly beyond their nominal power level, at the design duty cycle of 10%. In this paper we present the results of high-power tests, the results of the technological developments prior to production, and the final design of the CCDTL.

## INTRODUCTION AND BASIC DESIGN

The Cell-Coupled Drift Tube Linac (CCDTL) was originally developed at LANL as a structure providing higher shunt impedance than conventional Drift Tube Linacs (DTL) for intermediate-velocity particles [1]. In the original design the CCDTL was used at twice the basic linac frequency (800 MHz) and when the principle was tested on a CW prototype it appeared that surface power density was too large for stable operation. To avoid these problems, CERN started to develop a CCDTL at the basic linac frequency of 352 MHz and for applications as the Superconducting Proton Linac (SPL), limited at a duty cycle of less than 10% [2]. Different combinations were analysed and tested, to finally adopt for the Linac4 project [3] the CCDTL configuration shown in Fig. 1. This CCDTL is made of 3-gap DTL-like accelerating tanks, connected by off-axis coupling cells bridging the focusing quadrupoles. Whereas the shunt impedance of this CCDTL configuration remains similar to that of a DTL with permanent quadrupoles, its main advantages are the easy access, alignment and cooling of the quadrupoles and the simpler construction and alignment of the tanks, the drift tube alignment tolerances being no longer dominated by the tight requirements of the quadrupoles.

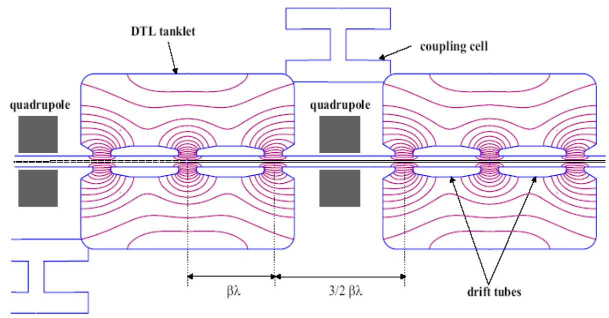

Figure 1: Linac4 CCDTL structure with indication of the electric field lines.

The RF configuration of Linac4 limits the peak power per resonator to about 1 MW. For this reason, the CCDTL tanks are grouped in modules of 3 tanks connected by two coupling cells (Fig. 2). The basic Linac4 CCDTL resonator is therefore made of 5 coupled cells operating in the π/2 mode. The CCDTL starts at 50 MeV, an energy that allows placing quadrupoles within the 3/2 βλ distance between neighbouring gaps. The geometry of the coupling cell and coupling slot is kept constant for all modules to simplify construction. This is achieved by shifting the end-walls of the tanks.

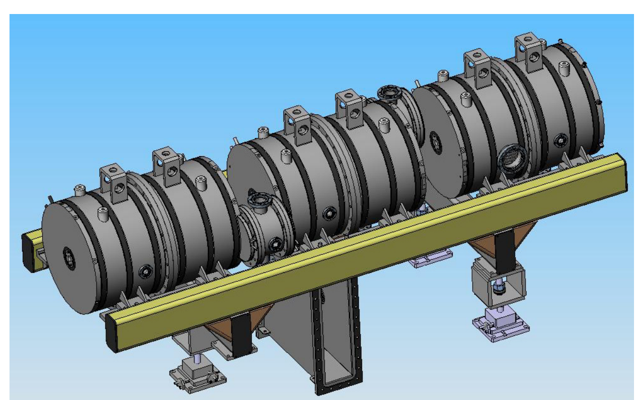

Figure 2: 3D view of a Linac4 CCDTL module with support structure and rectangular RF port.

At higher energies the shunt impedance of the CCDTL falls considerably, together with the coupling factor between CCDTL cells, inversely proportional to the stored energy per tank. Both these factors impose an upper energy limit of about 100 MeV for this structure.

The main parameters of the seven CCDTL modules are given in Table 1. The calculated copper power takes into account the effect of stems and slots and is then increased by a safety factor of 20%. Adding the beam power gives the values quoted in Table 1. The overall length of the CCDTL section is 23.38 m.

Table 1: Linac4 CCDTL Modules

| | $E_{out}$ [MeV] | $G_{acc}$ [MV/m] | $P_{RF}$ [MW] | length [m] | $E_{max}$ [Kilp.] |
|---|---|---|---|---|---|
| 1 | 57.1 | 4.00 | 0.96 | 2.64 | 1.6 |
| 2 | 64.6 | 4.10 | 1.0 | 2.82 | 1.6 |
| 3 | 72.1 | 4.20 | 1.0 | 2.98 | 1.6 |
| 4 | 79.9 | 4.30 | 1.0 | 3.14 | 1.7 |
| 5 | 87.8 | 4.23 | 1.0 | 3.29 | 1.7 |
| 6 | 95.6 | 4.16 | 1.0 | 3.43 | 1.6 |
| 7 | 102.9 | 4.10 | 1.0 | 3.57 | 1.6 |

## RF AND MECHANICAL DESIGN

The diameter of the cells has been optimized for maximum shunt impedance and is fixed for all cavities at 520 mm [4]. Each cavity is then tuned by changing the ratio of gap length over $\beta\lambda$. The gradient has been adjusted to keep the total RF power per cavity at a level of ~1 MW and the maximum surface fields below 1.7 Kilpatrick. Similarly all other geometric parameters were analyzed and the RF properties of the cavities were fully parameterized as a function of the geometric $\beta$ and the accelerating gradient.

A circuit model of a single module has been analysed with PSpice [5] to estimate the voltage errors in the cells due to frequency deviations. These errors can be classified in two types: the first one is caused by residual tuning errors and can be considered as static error; the second one (dynamic errors) comes from, for example, the change of the external temperature or variation of the cooling water temperature or flow speed.

For static errors, we consider the worst case of the CCDTL section, i.e. the last module with a coupling coefficient of k=0.59%. We assume a residual frequency error of ±20 kHz in the cavities using various distribution functions [5]. For this case the tilt sensitivity with respect to the average voltage has been calculated as 10.55%/MHz yielding a maximum field error of 0.2%.

For dynamic errors, the frequency variation due to the maximum expected temperature variation of $\Delta T$=10 K is estimated to be lower than 50 kHz. This variation is compensated with a movable tuner in the central accelerating cavity, requiring a tuner range of 150 kHz. In this condition the maximum voltage error in the accelerating cavities can rise up to 0.4%, which is fully acceptable for beam dynamics. In conclusion only one motorized tuner is necessary for each CCDTL module.

The prototype half-tanks were made by welding (electron beam or TIG) steel cylinders onto the end walls. Two half-tanks are then joined by a Helicoflex® gasket, which provides the RF contact and ensures vacuum tightness. For the series production the half tanks will be made of pre-shaped steel pieces, thus avoiding the welding step, improving the material properties, and speeding up construction. Since the alignment of drift tubes is not as critical as in a DTL, the drift tubes of the prototypes were welded to the tank walls while being fixed into position by a bar penetrating the drift tubes. Since every circular weld has an overlap in the start/end-point, there is a risk of deformation after the alignment bar is taken out. Therefore, for the series production will be adopted an alignment mechanism similar to that of the Linac4 DTL, which relies on the machining tolerances of a “stem holder” in a girder above the tank as shown in Figure 3 [6]. The RF and vacuum contacts between stems and tank are made with Helicoflex® gaskets, which are compressed by the spring-loaded “stem holder”.

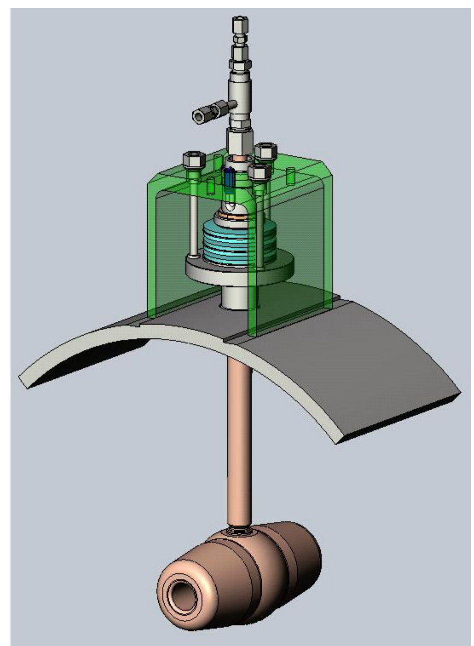

Figure 3: Drift tube fixation on the tank.

A critical point is the vacuum tightness of the rectangular iris, which connects to a rectangular wave-guide stub, and which is used to feed RF power into the central tank. The connection has been studied at VNIITF on a mock-up with HN and HNV type Helicoflex® gaskets using flanges with and without copper plating. The flanges were rectified to a roughness of Ra≈0.3 and cleaned, and after a series of vacuum leak tests it was concluded that the best solution is to use HN type gaskets on non-plated surfaces.

## PROTOTYPE TESTING

Two CCDTL high-power prototypes have been designed and built, both for the critical tanks at low energy (50 MeV). The first prototype, designed and built at CERN, was made of two half tanks closed by flat covers, connected by a coupling cell. This is the minimum configuration required to study RF and thermal properties. The second prototype (see Fig. 4), made of two complete tanks connected by a coupling cell, has been built in Russia by VNIITF (Snezhinsk) and BINP (Novossibirsk) within the frame of an R&D contract funded by ISTC. The mechanical design has been adapted to the production capabilities of the two laboratories. Construction and copper plating of the tanks was done in Snezinsk whereas construction and welding of drift tubes and final assembly and tuning were done in Novossibirsk.

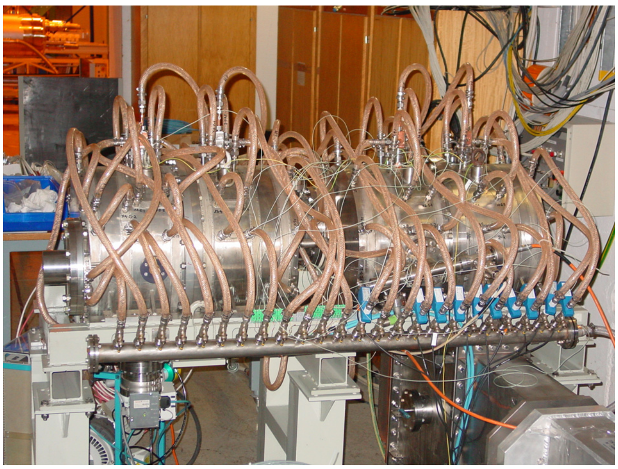

Figure 4: Second CCDTL prototype (VNIITF-BINP).

Both prototypes were tested at CERN, at low power and at high-power at the SM18 Test Stand. Table 2 reports the result of the low-power measurements. The Q-value of the first prototype is lower because the flat covers increase considerably the losses. For the second prototype, the Q-value was about 82% of the calculated one. Field flatness was in both cases within the measurement precision.

Table 2: Results of low-level measurements.

| | CERN prototype | ISTC prototype |
|---|---|---|
| frequency [MHz] | 352.35 | 352.14 |
| coupling factor [%] | 0.86 | 0.90 |
| unloaded Q | 27281 | 36700 |

High-power conditioning up to the Linac4 operating condition was straightforward for both prototypes, and increasing the duty cycle from the Linac4 value (0.1%) to the SPL duty cycle (10%) was relatively easy. No multipacting activity was observed in the first prototype, and only very limited activity was observed in the second one. Conditioning of the first prototype to 290 kW, corresponding to 1.09 times the design voltage, and to the Linac4 duty cycle took less than a day, and extending the duty cycle to 10% took 2 days. The temperature was measured in different critical positions on the tanks by means of thermocouples. The temperature of the drift tube holder, coupling iris and plunger tuner reached 58, 76 and 80 degrees, respectively. Conditioning of the second prototype took about a week. Power levels in excess of 330 kW at both Linac4 (0.1%) and SPL duty cycle (5%) were measured in the cavity, corresponding to 1.03 times the nominal operating level. The temperature monitoring indicated that at 5% duty cycle the temperature on the external part of the drift tube increased by 40 degrees, while the tuners in the accelerating cell (which were not equipped with cooling circuits) went up to 100 degrees. It was possible to stabilize the temperature at 330 kW power level at 11% duty cycle. For a duty cycle of 2.5% the measured temperatures have been compared with ANSYS simulations from VNIITF/BINP and an excellent agreement was found for 10 out of 12 thermocouples.

## CONSTRUCTION PROCEDURE AND PLANNING

It is planned to build the complete CCDTL in the frame of two ISTC projects, one funded entirely by CERN and the other one funded by the ISTC. As for the prototype, tanks and support will be built at VNIITF. After copper plating and pre-assembly the modules will be shipped to BINP. BINP will manufacture and install the drift tubes and take care of the RF tuning. The tuning will be checked after transportation to CERN together with vacuum tightness and a pressure test of the cooling channels. RF conditioning for all the 7 modules will be done at CERN, and installation in the Linac4 tunnel is foreseen from January 2011. Construction is foreseen to start in January 2009, with the first module being delivered to CERN in December 2009. The subsequent 6 modules will be delivered in batches of 2 with the last batch arriving at CERN in December 2010.

## ACKNOWLEDGEMENTS

We acknowledge the support of the European Community-Research Infrastructure Activity under the FP6 “Structuring the European Research Area” programme (CARE, contract number FII3-CT-2003-506395). We further acknowledge the support of the ISTC for the construction of a CCDTL prototype under contract number 2875.

Pozimski (Imperial College of Science and Technology, London; STFC RAL, Didcot, UK), C. Gabor, C. Plostinar (STFC ASTeC, Didcot, UK), J.J Back (University of Warwick, Coventry, UK)

*Abstract*

High power proton accelerators (HPPAs) with beam powers in the several megawatt range have many applications including drivers for spallation neutron sources, neutrino factories, waste transmuters and tritium production facilities. The UK's commitment to the development of the next generation of HPPAs is demonstrated by a test stand being constructed in collaboration between RAL, Imperial College London, the University of Warwick and the Universidad del Pais Vasco, Bilbao. The aim of the RAL Front End Test Stand is to demonstrate that chopped low energy beams of high quality can be produced and is intended to allow generic experiments exploring a variety of operational conditions. This paper describes the current status of the RAL Front End Test Stand.

## BACKGROUND

In order to minimise the need for remote or active handling of accelerator components, beam loss in future HPPAs must be kept to levels comparable to those of current facilities. With beam powers an order of magnitude or more greater than those currently achieved, fractional beam loss must necessarily be reduced by a similar factor. Beam chopping is one approach to reducing loss and will be an important feature of the next generation of HPPAs.

### *Beam Chopping*

In circular machines a significant source of beam loss occurs when the continuous linac beam is trapped and bunched in the ring RF bucket. Trapping efficiency can be improved with higher harmonic RF systems but to achieve the improvements necessary for MW scale beams, the linac beam must be chopped at the ring revolution frequency. This chopped beam allows for the ring RF bucket to be precisely filled with little trapping loss. The low levels of beam between bunches also reduces loss at extraction.

Everywhere downstream of the RFQ the linac beam has RF structure, this structure typically being at some 100s of MHz. Partially chopped bunches can occur in the linac if the chopping is not precisely synchronised with the linac beam RF bunch structure. With less charge than normal and possibly off axis or off momentum, these partially chopped bunches may lead to beam loss in the linac. The ideal is perfect chopping where the chopper switches on and off in the time between two successive linac beam bunches which is typically a few ns. This very fast switching requirement coupled with the increasing stiffness and power of the beam at higher energies dictates that chopping is carried out at the front of the linac, downstream of the RFQ at around 2.5 – 3 MeV.

### *Front End Test Stand*

The Front End Test Stand (FETS) project at RAL [1][2][3][4] has several goals. The primary goal is to demonstrate a high quality, high current, chopped $H^-$ beam. This is a generic objective and does not have a single future application in mind. FETS is funded by the Science and Technology Facilities Council (STFC) as part of their HPPA and Megawatt Spallation Source programme [5] and as a generic work package of the UK Neutrino Factory (UKNF) project [6].

A secondary goal of FETS is to encourage the study of accelerator technology within UK universities and foster international collaborations on HPPA research. High energy and particle physics has been well served by UK universities who are enthusiastic users of accelerator facilities and contributors to detector and physics projects however accelerator theory and technology has traditionally been less well served.

## TEST STAND COMPONENTS

The front end test stand consists of an $H^-$ ion source, magnetic low energy beam transport (LEBT), 324 MHz RFQ, medium energy beam transport (MEBT) chopper line and comprehensive diagnostics.

### *Ion Source*

FETS will use an ion source based on the well-proven and highly successful Penning type $H^-$ surface plasma source (SPS) [7] which is in routine operation on ISIS producing currents in excess of 50 mA at a duty factor of ~1%. Its use with an RFQ pre-injector has been previously demonstrated [8].

Following previous work which concentrated on increasing the current and duty factor of the source [9][10][11], recent work has focussed on understanding the beam transport and optics with a view to decreasing the emittance to the FETS specification. Considerable experimental and computational effort, using CST EM & Particle Studies [12] plus General Particle Tracer (GPT) [13], is leading to a much better understanding of the beam behaviour [14][15][16]. Figure 1 shows the predicted and measured beam profile at low extraction voltage.

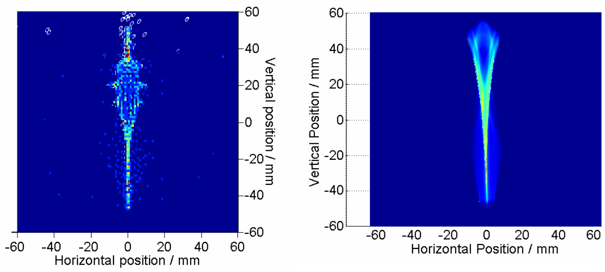

Figure 1: Left, simulated and right, measured beam profile.

In addition to furthering the theoretical understanding, installation of the ion source infrastructure in the FETS building at RAL is nearing completion [17]. Figure 2 shows part of the installation. First beam is anticipated in autumn 2008.

Figure 2: The high voltage cage and 65 kV high voltage platform.

## *Magnetic LEBT*

A 3 solenoid magnetic LEBT has been chosen for FETS [18][19]. In part this decision was informed by the successful combination of such a LEBT with the Penning ion source in the ISIS RFQ pre-injector upgrade [8]. An electrostatic Einzel lens LEBT, although offering some advantages, was rejected for this application due to fears about operating such a LEBT in close proximity to the highly caesiated ion source.

Figure 3 shows the simulated beam envelopes in the LEBT, calculated with GPT and based on the latest ion source measurements. Calculations suggest that from 0 – 100% space charge neutralisation can be accommodated by varying the solenoid fields.

Manufacture of the solenoids has been completed by Elytt/Neureus in Spain.

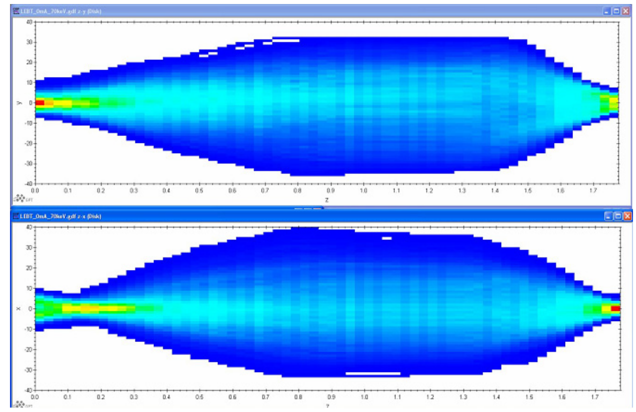

Figure 3: LEBT beam envelopes calculated with GPT.

Design of the LEBT support structures is complete with 2 of the 3 solenoids installed. Figure 4 shows the full LEBT design and one of the completed solenoids.

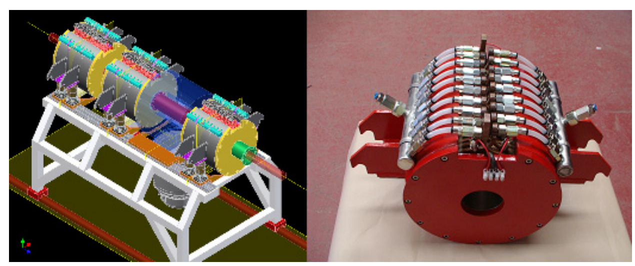

Figure 4: Layout of the FETS LEBT and one of the completed solenoids from Elytt.

## *RFQ*

A frequency of 324 MHz has been chosen for the FETS RFQ, determined by the ready availability of the Toshiba E3740A klystron developed for the JPARC linac [20]. One of these klystrons has been purchased and is at RAL. A contract has been signed for a HV power supply and solid-state modulator from Diversified Technologies, Inc [21] for delivery late in 2008.

A design for a 4-vane RFQ is well advanced with a cold model completed and extensively measured and compared to simulations [22][23][24]. Figure 5 shows the cold model during tests at Imperial College.

## *MEBT and Chopper*

FETS will use the novel fast-slow chopper scheme developed at RAL [25][26]. Having previously demonstrated operation of the 'fast' high voltage pulsers, attention has now focussed on the 'slow' pulsers [27] and prototyping the slow wave deflector structures [28].

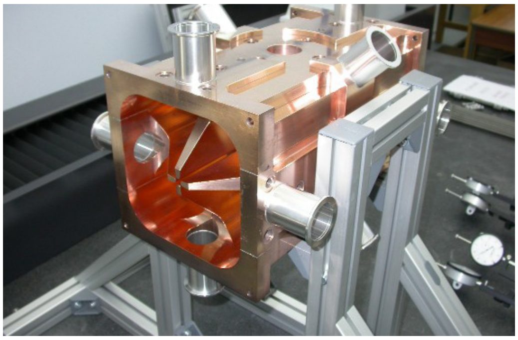

Figure 5: The RFQ cold model under test at Imperial College.

An optical design has been chosen as the FETS baseline for the MEBT. Compact PMQ/EMQ magnets are under investigation [29]. It is hoped to develop cavity cold models soon.

### *Diagnostics*

High quality diagnostics are essential to fully exploit the test stand. In addition to a suite of traditional diagnostics devices, non-destructive laser stripping techniques will also be employed. Non-destructive techniques are attractive due to the high beam power. A laser stripping transverse emittance measurement system is under investigation [30] as is a laser wire beam tomography system for determining beam density profiles [31]. The laser diagnostic vessel is manufactured and ready for installation.

# A FAST CHOPPER FOR THE FERMILAB HIGH INTENSITY NEUTRINO SOURCE (HINS)*

R. Madrak, D. Wildman, FNAL, Batavia, Illinois, 60510, U.S.A.
A. Dymokde-Bradshaw, J. Hares, P. Kellett, Kentech Instruments Ltd., Wallingford, U.K.

*Abstract*

A fast chopper capable of kicking single 2.5 MeV $H^-$ bunches spaced at 325 MHz, at rates greater than 50 MHz is needed for the Fermilab High Intensity Neutrino Source (HINS) [1]. Four 1.2 kV fast pulsers, designed and manufactured by Kentech Instruments Ltd., will drive a 0.5 m long meander made from a copper plated ceramic composite. Test results showing pulses from the first 1.2 kV pulser and meander results will be presented.

## INTRODUCTION

As a demonstration of the feasibility of a high intensity 8 GeV proton source, Fermilab is constructing a 60 MeV $H^-$ linac (HINS). This would serve as the front end to a superconducting 8 GeV linac, which would deliver beam to the Main Injector. Since the operating frequency of this linac is 325 MHz, not a multiple of the Main Injector's 53 MHz, we are compelled to chop out approximately one out of every six beam bunches. This avoids beam losses due to bunches which would not be captured in a Main Injector RF bucket.

The chopping is to be done in the 2.5 MeV (MEBT) section of the linac. This requires extremely fast (width < 6 ns) high voltage (±2.4 kV) pulses which propagate at the same speed as the beam ($\beta$=0.073) along a two plate deflecting "meander" structure. The requirement on the width is such that only one bunch at a time may be removed.

The two meander structures are 50 cm long, each with an impedance of 100 ohms. To obtain the necessary deflection, the beam must be kicked by the electric field (due to the high voltage pulse) for the entire length of the meander.

## FAST PULSER

Fermilab has procured from Kentech Instruments, Ltd. [2] a prototype 500V pulser, in June 2006, and a 1.2 kV pulser in November 2007. The average chopping rate imposed by the HINS pulse parameters is close to 1MHz however the switching losses in high voltage (kilovolt) semiconductor switching devices becomes excessive at these pulse rates. In order to obtain fast rise and fall, together with a high pulse repetition rate, the output is generated from an array of custom packaged low voltage (100 volt) semiconductor switches. These relatively low voltage parts have a bandwidth of ~500MHz allowing nanosecond rise and fall times.

The 1.2 kV pulser is based on an array of twenty four 50V pulse cards. The cards are floating, each with an output impedance of ~2 ohms. This output from each card is transported by 12 parallel 25 ohm semi-rigid coax cables and is taken to a summing point. When combined, this yields the 1.2 kV, 50 ohm output.

Figure 1: Kentech 1.2 kV pulser.

Each card has a floating power supply together with PECL trigger logic, burst width and duty cycle limit circuitry and power supply monitoring, all of which are remotely controlled. The TTL burst pattern input trigger signal is regenerated in PECL circuitry on each card before being amplified to a 50V pulse output. Individual cards can be enabled or disabled for testing purposes and the correct operation of the card can be confirmed via the link.

The pulser incorporates load fault detection (open or short circuit) and has an embedded controller for set up and control functions. It may be operated in either a 1 ms or 3 ms mode, triggered by an arbitrary TTL pattern with the option of a 325MHz clocked data input. The maximum total on-time during a 1 ms burst is 0.75 ms. A photograph of the 1.2 kV pulser is shown in Fig. 1. Figure 2 shows the pulser output (attenuated by 60dB). The top scope photo shows several 1.2 kV pulses spaced by ~20 ns. The bottom shows a full 3 ms burst of this pulse pattern.

## MEANDER STRUCTURES

We began our meander R&D with a $Z_0 = 50\Omega$ prototype structure given to us by F. Caspers (CERN) [3]. This is a double meander structure printed onto alumina substrate ($\varepsilon$=9.8). We scaled this design (by scaling the width of the trace pattern) to account for the difference in $\beta$ of ~8%. The new scaled structure is the first shown in Fig. 3.

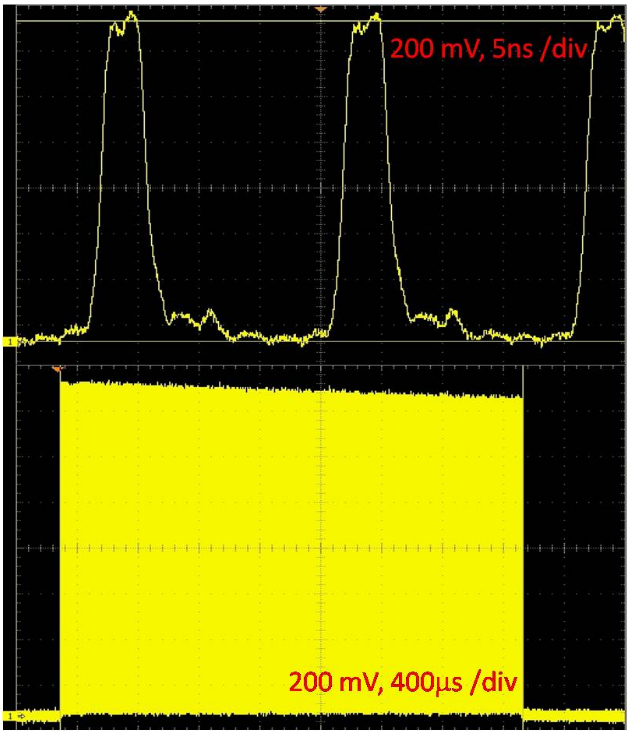

Figure 2: Kentech 1.2 kV pulser output, with 60dB attenuation. The top trace shows several 1.2 kV pulses with ~20 ns spacing. The bottom trace shows this pattern repeated for 3 ms.

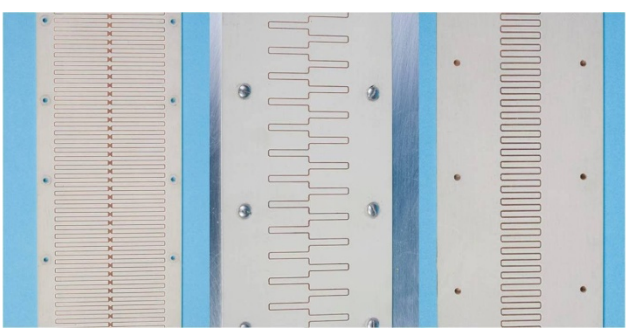

Figure 3: Double meander (left, $Z_0 = 50\Omega$), low dispersion single meander (middle, $Z_0 = 100\Omega$) and high coverage factor single meander (right, $Z_0 = 100\Omega$).

Rogers TMM10i was chosen instead of alumina for the new meander structure. This material also has $\varepsilon$=9.8, however, the material allows for complete meanders to be made very quickly. Laminates may be procured in 18x24″ sheets with copper cladding on one or both sides. The meander pattern can then be quickly routed out on a small programmable milling machine for PC boards which is available in-house.

To test for suitable behavior of Rogers TMM10i in vacuum, we baked a 24x13 cm sample for 90 hours at 170 C. After the bakeout we obtained a pressure of 8E-08 torr at 55 C (the predicted operating temperature of the meander, given losses) with a relatively low pumping speed of 0.63 L/s. Given that the surface area of the sample is a factor of 3 lower than that of the two meanders which will comprise the final chopper, we expect to be able to attain vacuum levels on the order of $10^{-8}$ torr. (using a larger vacuum pump) without much difficulty.

We have explored three designs for the meander structure. The first, already mentioned, is a 50 ohm double meander structure. The second and third have a single trace with 100 ohm impedance. These are shown in Fig. 3 and are termed the 'low dispersion single meander' (LDSM) and the 'high coverage factor single meander' (HCSM). Each structure uses ⅛″ thick Rogers TMM10i High Frequency Laminate Circuit Material with 70 µm Cu cladding. The prototype structures are 18″ (46 cm) long. The transverse extent of the traces is 78 mm for the double meander, 40 mm for the LDSM and 20 mm for the HCSM. In each case the width of the trace is 0.015″.

### *Pulse Behavior*

Figure 4 shows the pulse behavior at the beginning, middle and end of the three meanders. Also shown is the (low voltage) input pulse. Both single meanders show little increase in the pulse width as it progresses down the structure, though the degradation is the least in the LDSM.

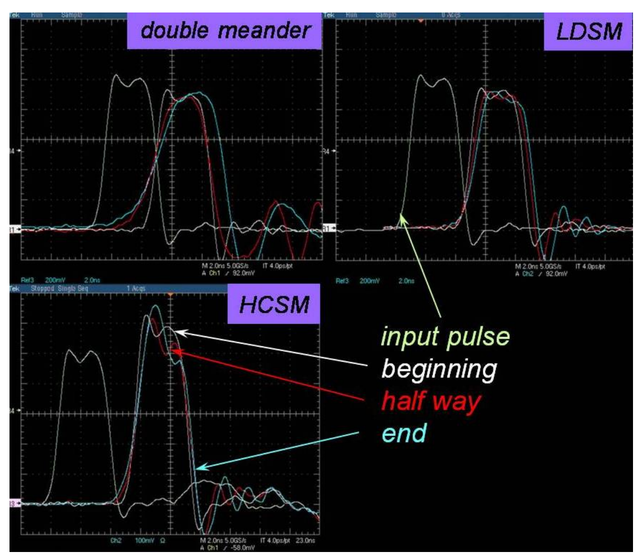

Figure 4: Pulse behavior along the meander structure.

### *Coverage Factor*

Since the metal traces of the meander are not solid conductor (on the scale of the beam size), the effective electric field is less than the voltage difference between two structures divided by their separation. The leads to the definition of the coverage factor, which is $E/(\Delta V/d)$, where E is the actual electric field between the plates, $\Delta V$

is the voltage difference, and d is the separation. We have measured the coverage factor as a function of transverse position for each meander, using the fixture shown in Fig. 5, along with a network analyzer. This is an $S_{21}$ measurement with Port 1 connected to the meander traces and Port 2 connected to a HP85024A high frequency probe which serves as a pickup. The probe tip is the same distance away from the meander surface as the beam (8 mm) and is surrounded by a ground plane. The probe is mounted on micrometer adjustable stages so that it may be moved in the x and z directions.

For normalization, a wide (25 mm) stripline is used. In this case, the probe tip is located at one of the stripline groundplanes. Each groundplane is 8mm from the stripline center conductor. Measurements for 100 ohm meanders are corrected for reflection due to the impedance mismatch between the network analyzer and the meander. For the double, LDSM and HCSM we measure coverage factors of 71%, 48%, and 74%. We also measure the coverage factor for the double meander in a slightly different configuration: with 0.062″ spacers between the double meander and groundplane. Here the double meander has 100 ohm impedance; we measure a coverage factor of 87%. Simulations of the CERN SPL double meander chopper structure [3], which has the same trace density as the double meander discussed here predict a coverage factor of 80%. Microwave Studio (MWS) simulations at FNAL predict a slightly lower coverage factor of 75%. Figure 6 shows measurements of the coverage factor versus transverse position on the meander.

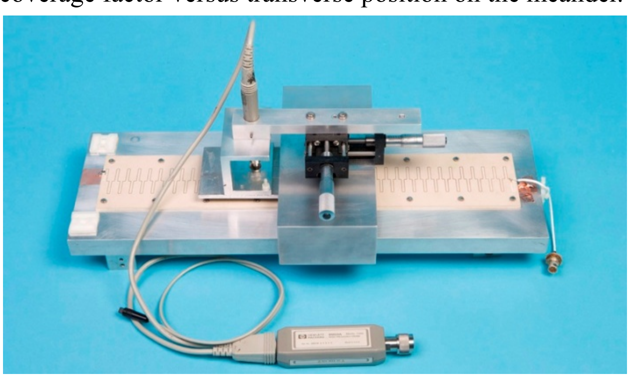

Figure 5: Coverage factor measurement fixture.

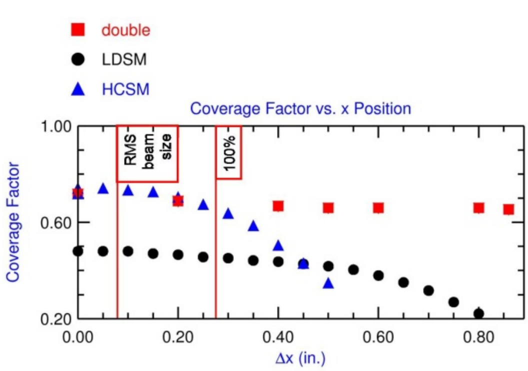

Figure 6: Coverage factor vs. transverse position.

## FINAL DESIGN

The final chopper will consist of two 50 cm long meander structures with a spacing of 16 mm. Obtaining the necessary beam deflection angle of 24 mRad imposes the requirement $\Delta V$(plates) = 4.8 kV (accounting for a coverage factor of 80%).

Figure 2 shows that a high quality 53 MHz 1.2 kV pulser is possible. Thus, we plan to combine the output of two 1.2 kV/50 ohm pulsers into one 2.4 kV/100 ohm pulser. This can be done for both polarities (for ± 2.4 kV) and will yield the desired 4.8 kV, when used with a 100 ohm meander structure. It is this reasoning which initially led us to explore the 100 ohm meander design as opposed to the more common 50 ohm version. Of the 100 ohm single meanders, the LDSM exhibits the best pulse behavior along the length; however, the coverage factor is much too low. Thus we have chosen for our final design the HCSM, which has good pulse behavior along the length of meander as well as a high coverage factor.

We have built a combiner, or coaxial cable impedance transformer, using 46 turns of Andrew FSJ2-50, ⅜″ heliax superflexible foam coaxial cable, wrapped around five 1″ thick cores. These are MN60 cores with an OD and ID of 11″ and 4.5″. We have tested the combiner using the Kentech 0.5 and 1.2 kV pulsers. We obtain good quality output pulses of approximately 1.6 kV, shown in Fig. 7.

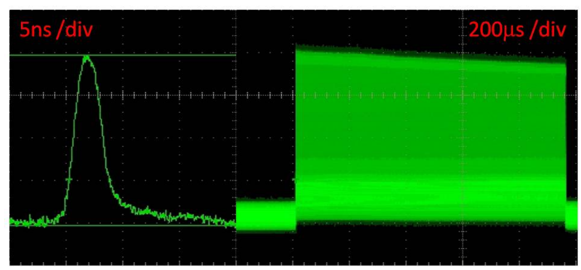

Figure 7: Combiner output.

## ACKNOWLEDGEMENTS

We wish to thank F. Caspers (CERN) for many useful discussions and for providing the double meander structure with which we began our studies.

We also wish to thank Gennady Romanov (FNAL) for the MWS simulation predicting the coverage factor for the meander structure, and Terry Anderson (FNAL) for performing the TMM10i vacuum test.

*Abstract*

Modern technology allows us to consider operating an 8 GeV SC linac in a CW mode to accelerate a high-current $H^-$ beam. By using appropriate accumulation rings, the linac could provide simultaneous beams for direct neutrino production, neutrino factories, fixed target experiments, and muon colliders. Several other unique accelerator applications could also be served and improved by the same continuous beam, including studies of energy production and nuclear waste reduction by transmutation, rare muon decay searches, and muon catalyzed fusion. A comparison of CW and pulsed operation is strongly dependent on the choice of accelerating gradient, and a first look at refrigeration requirements for a gradient of 20 MV/m is included in this study. Methods for accumulating the beam from a CW linac to serve the special needs of the potential future Fermilab programs mentioned above are considered. In this paper we also examine the use of a cyclotron as a source of high current beams to reduce the cost and complexity of the linac front end. Although the refrigeration system would be large for 20 MV/m gradient, a 3 mA CW $H^-$ beam at 8 GeV looks feasible, with potential beam power up to 24 MW to access the intensity-frontier for muon and neutrino physics and also be an essential step to an energy-frontier muon collider.

## INTRODUCTION

Modern proton accelerators or storage rings use multi-turn $H^-$ charge exchange injection and strip at high energy, where the Laslett tune shift is smaller, to achieve high proton bunch intensities. This approach has been used in several new machines, and the next step that is being proposed is to provide a powerful 8 GeV $H^-$ linac that could feed any number of accumulation rings or accelerators for planned and as yet undreamt-of purposes.

A plan for Project-X [1], to replace the aging Fermilab 8 GeV rapid cycling Booster proton synchrotron, has centered on a 1.3 GHz superconducting (SC) linac, which could also act as a string test for the ILC. The purpose of this paper is to consider a CW $H^-$ linac as an option for Project-X, which would not be limited by any ILC constraints and, by virtue of high potential 8 GeV beam power, be best suited to the needs of any future Fermilab research program. Nevertheless, as a large-scale SRF system, it would act as a significant demonstration of many aspects of ILC technology.

Since its design in the late 1960's, the Fermilab Booster has at times been both the world's most intense proton source and almost always the bottleneck in the Fermilab research program, where proton economics have determined which experiments could be scheduled or even were possible. If the Booster is replaced as planned, it will have served in this way for about 45 years. It is quite likely that its replacement will have a similar function for a similar time.

Recent studies of proton driver requirements for muon colliders and neutrino factories [2] have indicated that the present parameters for Project-X may limit these machines because the proton beam power will be insufficient and the repetition rate too low. Even with optimistic muon collection and cooling efficiencies, at least 4 MW of 8 GeV proton power will be required for muon collider designs. The natural repetition rate for muon machines is suggested by the muon lifetime in its final storage ring. For a 5 TeV center of mass collider, for example, the muon lifetime is about 50 ms so that the natural repetition rate is about 20 Hz. For lower energy storage rings, the natural repetition rate is higher.

For the study reported here, the RF gradient G has been chosen to be low enough such that resistive losses, proportional to $G^2$, are not too large. In the next section we calculate the wall-plug power for the case of G=20 MV/m for ILC-like RF structures. This is to be compared to the 25 to 30 MV/m presently favored by Project-X. A gradient of 20 MV/m implies a linac that would be about 27/20 times longer than the baseline, but has the compensating virtue of easier technology for the RF cavities and klystrons.

## CW CRYO POWER REQUIREMENTS

CW operation results in much higher dynamic heating in the RF cavities and input couplers and higher cryogenic cooling power requirements. Table 1 shows a comparison of the power requirements for the components of a TESLA linear accelerator operated as a pulsed machine compared to CW operation.

*Supported in part by the US DOE under contracts DE-AC02-07CH11359 and DE-AC05-84ER40150 and STTR grant DE-FG02-08ER86350.
#rol@muonsinc.com

Table 1: cryogenic power loads per 8-cavity cryomodule for a CW versus Pulsed TESLA-style linac.

| Cryomodule | TESLA | | CW | |
|---|---|---|---|---|
| | Static | Dynamic | Static | Dynamic |
| Temperature Level | 2K | | | |
| Static, dynamic sum | 1.1 | 7.6 | 1.3 | 159 |
| 2K Sum [W] | 8.8 | | 160 | |
| | | | | |
| | 5K - 8K | | | |
| Static, dynamic sum | 11.7 | 7.0 | 10.6 | 58 |
| 5K Sum [W] | 18.7 | | 68 | |
| | | | | |
| | 40K - 80K | | | |
| Static, dynamic sum | 91.5 | 82.7 | 59.1 | 2870 |
| 40K Sum [W] | 174.1 | | 2930 | |

The basic parameters to estimate the dynamic losses in the RF cavities at 2 K in Table 1 are:

1. Beam energy U 8 GeV
2. Beam power W 20 MW
3. Gradient G 20 MV/m
4. Quality factor Q $\sim 2\times 10^{10}$ (ILC-like structure, 2K)
5. Number of cavities N 350
6. R/Q 1050 Ohm/cavity

A simple estimate of the total RF load for the high energy part of the linac (from 1 to 8 GeV) at 2 Kelvin is:

$$P = \frac{G^2}{Q\times(R/Q)} N = 19W/cavity \times 350 = 6700W.$$

Note that 8 cavities/cryomodule implies 152 W at 2 K of dynamic heating per cryomodule just due to the RF load.

Table 2: Cryogenic system power requirements

| Temperature level | 40 K to 80 K | 5 K to 8 K | 2 K |
|---|---|---|---|
| Total cryomodule heat load (W) | 2930 | 68 | 160 |
| Number of cryomodules | 44 | 44 | 44 |
| Total linac heat load (kW) | 129 | 3 | 7 |
| Conversion factor to wall plug power | 16.5 | 200 | 700 |
| Power at each level (MW) | 2.1 | 0.6 | 4.9 |
| Total operating power (MW) | 7.7 | | |
| Cryogenic system margin | 1.5 | | |
| Total installed power (MW) | 11.5 | | |
| Installed 4.5 K equivalent (kW) | 52.3 | | |

Dynamic heating at the 5 K to 8 K and 40 K to 80 K temperature levels is dominated by the input coupler. A rough estimate of those heat loads comes from scaling experience with TTF-III input couplers. However, the TTF-III input coupler would not actually handle CW loads; the 40 K heat may be overestimated here. For CW operation, a different design such as that from Cornell [3] would be used. A 1.3 GHz, CW coaxial-type TW coupler for ERL was developed and tested up to 61 kW at Cornell. This coupler may be a prototype for a cavity of the CW linac.

Table 2 provides an estimate of total cryogenic power required for the linac, 11.5 MW, equivalent to 52.3 kW of cooling at 4.5 K, which would require two very large cryoplants, each about the size of that of the LHC.

The power required for one ILC – like cavity is more than 50 kW for an acceleration gradient of 20 MV/m. Fifty kW is required for acceleration, and about 20% is overhead for the feedback system, etc. One of the possible options is to use CW IOT tubes to feed each 1 m ILC-like cavity. There are 1.3 GHz 30 kW, CW IOT available, developed by CPI [4]. The CPI Company has offered to examine technical feasibility of a CW operating 1.3 GHz tube providing output power of 60 and 120 kW. Very preliminary modeling shows no fundamental technical difficulty to build such a tube [4].

## ACCUMULATORS AND BUNCHERS

In both the pulsed and CW linac options, the basic idea is that an 8 GeV accumulator ring would be used to strip the $H^-$ ions to store sufficient proton charge. The protons would then be bunched either in the accumulator ring or in a second ring where short bunches can be extracted for muon production. Additional relatively inexpensive accumulator rings could be added as new opportunities arose for new experimental programs. Present plans for uses of the Project-X beam at Fermilab have considered the recycler ring, the present pbar accumulator and debuncher rings, and the Main Injector as places where the $H^-$ ions could be used to form intense proton beams.

The baseline Project X plan is to inject from a pulsed linac into the Recycler via a stripping foil for a total of 3 ms. To facilitate the creation of intense short bunches in a multi-megawatt driver for a neutrino factory or a muon collider, a much smaller accumulation ring with much larger transverse acceptances is preferable. Filling such a ring from a CW linac implies a longer injection time, raising the issue of multiple passages of circulating protons through a stripping foil. Ideally that issue ought to be addressed by simulations. For now a numerical example may suffice to suggest that the issue is not a show-stopper.

A repetition rate of 100 Hz implies an injection time of 10 ms compared with 3 ms in the Recycler. If the accumulation ring is ~5 times smaller than the Recycler, then the circulating beam passes through the injection region 5*10/3~17 times more than in the Recycler. However, the multi-megawatt accumulation ring must have transverse acceptances ~10 times larger than the Recycler in order to control transverse space-charge effects. Painting into both transverse planes then implies 100 times more phase-space volume to work with. So the number of times that each circulating proton passes through the stripping foil might be lower than in the Recycler by a factor of ~100/17~6. Alternatively, the development of magnetic plus laser stripping may solve the problem [5].

## LINAC FRONT END

### *Conventional Front End*

Front end schemes for high-power CW proton accelerators are already well established [6,7]. Typically they have four parts in series: 1) normal conducting (NC) 50-75 keV proton or $H^-$ minus source, 2) Radio-Frequency Quadrupole (RFQ), 3) low- and intermediate-energy section containing the NC to SC transition, and 4) (SC) high energy section.

The proton beam out of the source is a continuous beam that needs to be bunched at (a subharmonic of) the frequency used for the intermediate and high energy sections of the accelerator. This task, and an initial acceleration boost up to a few (5 to 7) MeV is performed by an RFQ. Several CW proton RFQs have been built or designed recently [8,9,10].

While there is a wide international consensus on the use of an Electron Cyclotron Resonance (ECR) $H^-$ source and RFQ for energies up to 5 to 6 MeV, different ideas have been pursued for the intermediate energy section up to approximately 100 MeV. Many projects have used different combinations of traditional normal conducting RF systems such as classical Drift Tube, Coupled Cavity Drift Tube, and Coupled Cavity Linacs. However, the use of SC cavity technology seems to be most promising in terms of the needed accelerator plug power efficiency. Some projects have investigated the possibility of extending the SC part of the accelerator down to low energies with independently phased low-velocity SC cavities, where the most promising are spoke and re-entrant SC cavities because of their simplicity and good RF parameters. The choice of NC or SC technology for the intermediate acceleration stages may be an issue for pulsed machines, but for CW beams the intermediate velocity SC structures are favored. Also a very big advantage of CW operation is the absence of Lorentz force detuning problems, which are especially severe for low-beta SC cavities in pulsed mode.

### *Cyclotron Front End*

A somewhat unorthodox alternative choice for the front end of the CW linac is a cyclotron. An $H^-$ cyclotron with peak magnetic field of just over 1T can safely achieve 100 MeV without significant Lorentz stripping. Such cyclotrons exist or are being built, but since they use a stripper foil to extract, the common varieties are wrong for this application. We would like to retain intact the $H^-$ ions, so a separated turn scheme is required. This can be achieved with sufficient RF voltage. A good example of such a machine is the PSI Injector 2 [11], which accelerates up to 2 mA of protons to 72 MeV. Compared with bare protons, single turn extraction of $H^-$ ions is technically simpler because the ions that would be intercepted by the septum can be pre-stripped and thus re-directed to a beam dump.

It is projected that such a cyclotron can accelerate over 3 mA average current [12] from an injected current of as little as 9 mA. DC $H^-$ ion sources have provided as much as 20 mA into a normalized rms emittance of 0.4 microns [13]. The width at extraction resulting from this emittance is only about 3 mm. The space charge effect in an isochronous machine is to create round bunches; this means bunch lengths are also about 3 mm, allowing them to fit easily into the 325 MHz linac buckets.

The most delicate region of the cyclotron is the center. If the RF frequency is too high and the injection energy too low, it is not possible to launch circular bunches cleanly matched to the focusing structure. For this reason, the beam frequency would be a relatively low 54 MHz (=325 MHz/6), and the injection energy a relatively high 1 MeV.

Since the energy spread tolerated by the cyclotron is very small, the cyclotron injector should not be an RFQ but a DC device as exists at PSI.

## NEXT STUDIES

From the standpoint of an accelerator that will be the Fermilab workhorse for the next four or five decades and will take several years to build, the existence of immediately available off the shelf components is not the most relevant question. Nevertheless, it is useful to look at the components such as power couplers, klystrons, and SC RF that are available and to imagine which devices could be improved with an appropriate amount of R&D.

To extend the studies reported here, all linac system parameters (RF frequency, and other cavity, klystron, and coupler choices, refrigeration system, the conventional construction and infrastructure, etc.) will be examined as a function of accelerating gradient to arrive at a CW system to compare to the pulsed option for Project-X. Other, more speculative approaches are also being considered, such as the use of a Jefferson Lab style recirculating linear accelerator, the use of lower energy protons for muon and neutrino production, and the possibility to use the proton accelerator to simultaneously accelerate cooled muons [14].

# HIGH POWER TEST OF ROOM TEMPERATURE SPOKE CAVITIES FOR HINS AT FERMILAB *

W-M. Tam #, G. Apollinari, T. Khabiboulline, R. Madrak, A. Moretti, L. Ristori, G. Romanov, J. Steimel, R. Webber, D. Wildman, Fermilab, Batavia, IL 60510

*Abstract*

The High Intensity Neutrino Source (HINS) R&D program at Fermilab will build a new 65 MeV test linac to demonstrate new technologies for application in a high intensity hadron linac front-end. The HINS warm section is composed of an ion source, a radio frequency quadrupole, a medium energy beam transport and 16 room temperature Crossbar H-type (RT-CH) cavities that accelerate the beam to 10 MeV ($\beta$=0.1422). The RT-CH cavities are separated by superconducting solenoids enclosed in individual cryostats. Beyond 10 MeV, the design uses superconducting spoke resonators. In this paper, we illustrate the completion of four RT-CH cavities and explain latest modifications in the mechanical and radio frequency (RF) designs. Cavities RF measurements and tuning performed at Fermilab are also discussed. Descriptions of the HINS R&D Facility including high power RF, vacuum, cooling and low level RF systems will be given. Finally, the history of RF conditioning and the results of high power tests of RT-CH cavities will be discussed.

## INTRODUCTION

Fermilab is considering an 8 GeV superconducting H- linac with the primary mission of enabling 2 MW beam power from the 120 GeV Fermilab Main Injector for a neutrino program [1]. The front end linac in the energy range from 10 MeV to 400 MeV is foreseen as based on 325 MHz superconducting spoke resonators. New paradigms introduced into the front end design include the adoption of short, high field SC solenoids as primary lattice focusing elements and a low energy transition at 10 MeV from RT to SC RF acceleration. The HINS R&D program is underway to demonstrate these concepts in a 65 MeV prototype linac [2].

Our studies show that the most appropriate RT accelerating structure in the energy range 2.5-15 MeV is a CH type cavity [3, 4] operating at 325 MHz. We have successfully fabricated, fully dressed and high power tested the first three RT-CH resonators. The next one is now ready for high power tests. We are currently fabricating the remaining twelve resonators.

## CAVITY RF DESIGN

The RF design of the RT-CH cavities is reported in [2, 3]. In order to accelerate the manufacture of the remaining twelve cavities, five different designs are used instead of twelve. So there are 2-3 identical cavities in each of the five groups. Due to the reduction in the overall efficiency of acceleration, the power loss in the warm section is increased by 2%.

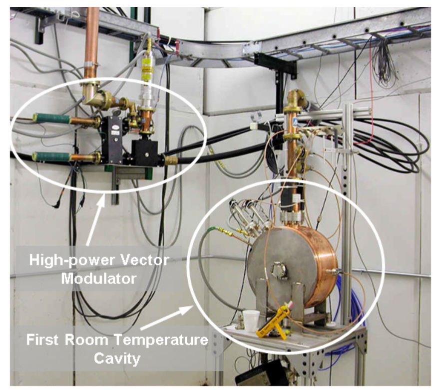

Figure 1: Cavity completed with coupler, tuners, cooling pipes, vacuum, and vector modulator.

## RF POWER SYSTEM AND TEST STAND

The cavity under test is completed with a power coupler, a pair of motor-driven tuners (now reduced to one) and cooling pipes and is mounted on a test stand sitting inside a cavity test cave for radiation shielding purpose (See Fig.1). This cavity assembly is then leak-checked with helium and is connected to low conductivity water (LCW), vacuum pumps and gauges, high power RF directional coupler and cable, and low-level RF (LLRF) signal cables.

RF power is supplied by a 325 MHz 2.5 MW Toshiba E3740A klystron which is protected by a 2.5 MW circulator (See Fig.2). Two RF power lines, 25 kW and 250 kW, are available for the cavity test cave. The 25 kW line was used in the test.

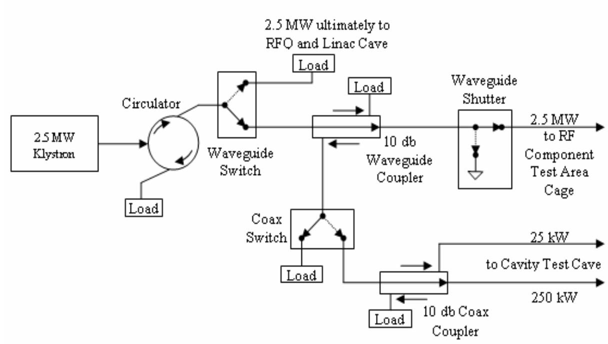

Figure 2: RF power and distribution system diagram.

*This work was supported by the U.S. Department of Energy under contract number DE-AC02-76CH03000.
#watam@fnal.gov.

LCW is maintained at a temperature of approximately 97.0 ± 0.5 $^0$F by a heater feedback circuit and at a flow rate of about 1 gal/min. A turbo molecular pump is attached to the cavity for pump-down, after which an ion pump alone can maintain cavity vacuum. An ionization vacuum gauge and the ion pump current provide monitors of the vacuum pressure. A base pressure of $2\times10^{-7}$ Torr before application of RF power was considered acceptable for beginning power tests.

Reflected power from the cavity, vacuum pressure, and water flow rate are part of the fast interlock system which is capable of inhibiting the RF power to protect the cavity assembly and the RF power system from being damaged in case of abnormal behavior.

## HIGH POWER TESTS

The first three of the sixteen RT-CH cavities have been successfully RF conditioned and tested. These tests include measuring the tuning range provided by motor-driven plunger tuners and deducing the cavity resonant frequency sensitivity to coolant temperature and RF power level. Detail is described in this section.

### *RF Conditioning*

The RF conditioning of RT-CH#1 was done by gradually increasing the RF power to the conditioning target, 8 kW, 3 ms and 2 Hz. Multipacting was observed at several power levels. The cavity was allowed to pump down overnight in case of persisting multipacting behavior. Vacuum trips occurred occasionally when power or pulse length increase; this is normal behavior resulting from high emission inside cavity due to imperfections such as unclean surface. This cavity took a total of 34 hours of RF power to complete conditioning.

The second cavity, RT-CH #2, was baked for 4 days at 300 $^0$F before conditioning. The target for this cavity is 13.5 kW, 3.5 ms and 2 Hz. Although multipacting and vacuum trips were still observed, the total conditioning time was significantly shortened to 6 hours plus one overnight pump down. It is believed that the baking contributes to this improvement.

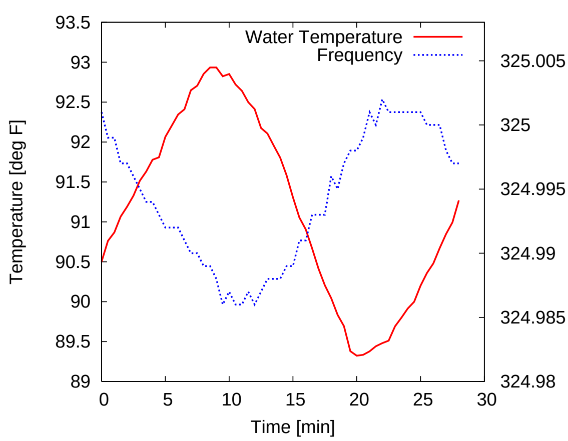

Figure 3: Cavity resonant frequency measured against coolant temperature.

### *Temperature Dependence of Resonant Frequency*

Temperature dependence of cavity resonant frequency was studied for RT-CH #1 at zero power. The temperature of LCW was measured with a temperature probe about 1 m upstream from the cavity in the cooling circuit. The resonant frequency was tracked using a simple phase locked loop.

The scaling constant, α, was measured for the scaling law: $\Delta f = \alpha\Delta T$, where $\Delta f$ and $\Delta T$ are the change in resonant frequency and the change in water temperature respectively (see Fig.3). At 91.0 ± 2.0 $^0$F, α was measured to be 8.0 kHz/K. An estimation of α, by assuming uniform expansion of cavity volume and using the linear expansion coefficient for copper, is 5.4 kHz/K. It is believed that the discrepancy is due to non-uniform cavity expansion and the presence of stainless steel plates mounted on the two end-walls of the cavity. Further study will be carried out to understand this discrepancy.

The stability of our water system is about ±0.5$^0$F. Thus, the fluctuation in resonant frequency due to coolant temperature variation is controlled to be within ±2.2 kHz.

### *RF Power Dependence of Resonant Frequency*

The designed nominal power is different for each RT-CH cavity. The highest one can go as high as 40 kW. This suggests an average power consumption of 400 W with a 1% duty factor. This will result in a significant heat load on the cavity which would cause a shift in its resonant frequency. The behavior of the cavity under high power should be studied to assure normal operation. The resonant frequency sensitivity to RF power is measured for RT-CH #2 (see Fig. 4).

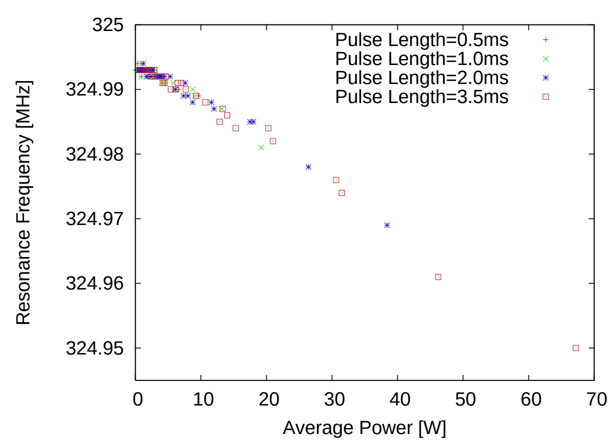

Figure 4: Cavity resonant response to RF power.

The resonant frequency of the cavity was measured for average RF power ranging from zero to about 68 W. The average RF power was controlled by adjusting the repetition rate (0.2 to 2.0 Hz), the pulse width (0.1 to 3.5 ms), and the nominal peak power (1.2 to 9.6 kW). The shift in the resonant frequency was measured to be about 43 kHz and responded linearly to the change in average power. The corresponding sensitivity is about 632 Hz/W. Notice that the change in resonant frequency does not depend upon the way in which the average power is being adjusted. Similar studies will be carried out on the rest of the RT-CH cavities.

The dynamical response of the resonant frequency to a jump in average RF power was also studied (see Fig.5). The repetition rate was set at 0.5 Hz and the nominal peak power at 8.0 kW while the pulse width was set to jump from 0.5 to 3.5 msec. This is equivalent to an average power jump from 2 to 14 Watts. The time constant of the response of the frequency was measured to be 73 sec.

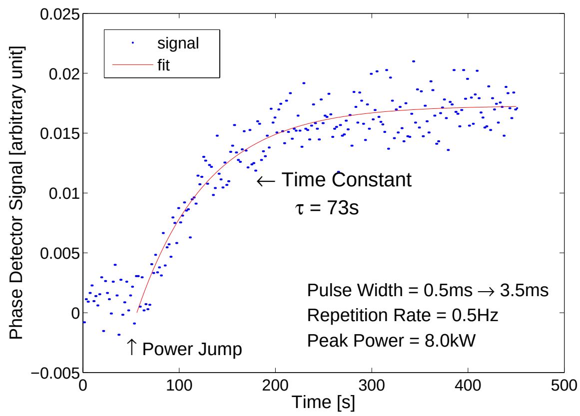

Figure 5: Dynamic measurement of cavity resonant response to RF power.

## *Plunger Tuner Test*

A pair of identical motor-driven tuners was installed on RT-CH #1. The full stroke, or the plunger active length, is about 42 mm or 106,000 motor steps. The resonant frequency of the cavity was measured by a network analyzer. With identical movement for both tuners, the tuning range was measured to be 1290.6 kHz. Resonant frequency responded linearly to the tuner position. The corresponding sensitivity is 30.7 kHz/mm or 12.2 Hz/step (see Fig. 6).

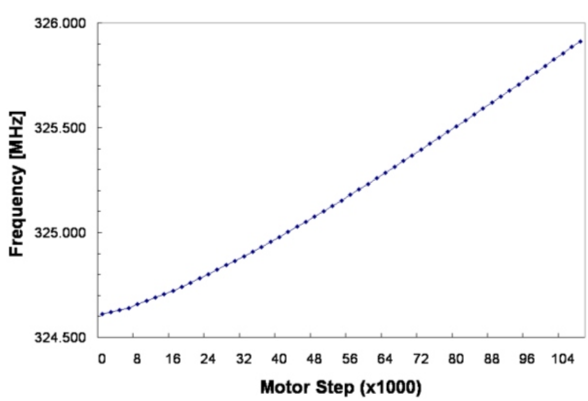

Figure 6: Cavity resonant frequency versus tuner position.

In a design revision the number of tuners is reduced to one and the full stroke of the tuner is cut by a half to 21 mm to improve the tuner's mechanical performance. The new design is sufficient to provide a reasonable tuning range.

## *RF Power Test with Vector Modulator*

Eventually these RT-CH cavities will be powered by a single klystron. To ensure control over the phase and the amplitude of individual cavities, a vector modulator (IQM) is required by each of them. A high power test of the cavity with IQM is performed (see Fig. 7).

By manipulating the drives (yellow and blue) of the IQM, the amplitude (red) of the cavity can be controlled within 13 dB. Detailed discussion on the design and performance of these IQMs can be found in this conference [5].

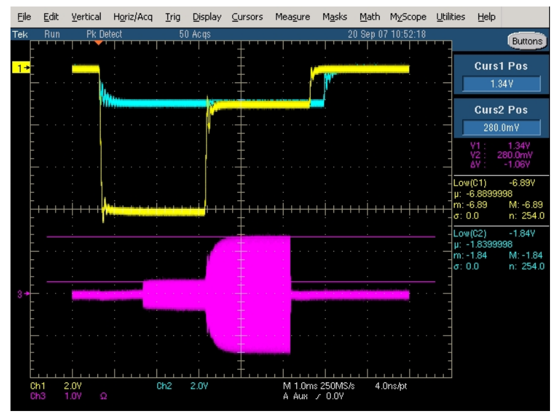

Figure 7. Amplitude control with IQM for a 6 kW 3.5 msec RF pulse. The red trace is cavity RF amplitude; the blue and the yellow are modulator bias currents.

# CONCLUSIONS

The first three of the sixteen HINS RT-CH cavities are complete and tested. These cavities have met all of the design requirements. The time needed to condition up to full power for RT-CH #2 is significantly shortened as a result of baking. Cavity sensitivity to coolant temperature, tuner position, RF power and IQM bias has been measured. These results are useful for RF control design and cavity performance improvement effort.

## ABSTRACT

The low energy part (front end) of a linac for the High Intensity Neutrino Source (HINS) project at Fermilab will use superconducting solenoids as beam focusing elements (lenses). The lenses for the conventional (room temperature) drift tube-type accelerating section of the front end require individual cryostats; in the superconducting accelerating sections, solenoids will be installed inside RF cryomodules. Some of the lenses in the conventional and superconducting section are equipped with horizontal and vertical steering dipoles. Lenses for the room temperature section are in the stage of production with certification activities ongoing at Fermilab, and a prototype lens for the superconducting section has been built and tested. Since each lens will be installed in the transport channel of the accelerator so that its magnetic axis is on the beamline, testing has also included alignment measurements.

This report summarizes design features, parameters, and test results of the focusing lenses.

## INTRODUCTION

As part of the High Intensity Neutrino Source (HINS) program at Fermilab, building a high power H⁻ RF linac is under consideration [1]. At present, main R&D efforts are concentrated on development of accelerating and transport elements for the front end of the linac. To reduce beam losses through mitigation of halo formation in the front end (see [2]), superconducting solenoids will be used as focusing lenses [3]. There are three sections of the front end, which are identified by the type of 325 MHz RF structure used for acceleration. The first section uses low-beta, room temperature Crossbar H-type (CH) structures [4]; in this section, each focusing lens is in its own cryostat. For higher energies, superconducting spoke resonators are used with several of them in one cryostat [5]; focusing lenses in these sections are mounted in the same cryostats. There exist two types of superconducting sections in the linac: SS1 and SS2; focusing lenses for these sections differ in strength.

One of the major requirements for focusing lenses in the superconducting sections of the linac is low fringe field. To limit the power loss in walls of accelerating cavities, it is desirable to keep the magnetic field on the walls below 10 μT [6].

*Work supported by the U.S. Department of Energy under contract No. DE-AC02-07CH11359.

#terechki@fnal.gov

In each section of the linac, two styles of lenses are required: with and without embedded steering dipoles for horizontal and vertical correction of beam position.

A total of 53 focusing lenses will be built for the linac (including spares). Solenoids for the CH section are in the production stage, solenoids for the SS1 section are being prototyped, and design work is ongoing for the SS2 system.

## CH SECTION FOCUSING SOLENOID

Focusing length of a solenoid-based focusing lens is given by the following expression:

$$f = \frac{8mU}{q^2 \int_{-\infty}^{+\infty} B^2 dz}$$

where ***m*** is mass, ***q*** is charge, and ***U*** is the kinetic energy of the particles in the beam. For high intensity ion beams, it is essential to have the focusing period small; this requires high magnetic field, that only can be generated by superconducting systems. Basic requirements for the focusing lens include 20 mm warm bore diameter, the squared magnetic field integral $\int B^2 dz$ of ~1.8 $T^2$-m, with an effective length less than 0.1 m (normalized to the maximum magnetic field). Steering dipoles must have an integrated strength of ~0.25 T-cm to be able to compensate for uncertainties in the solenoid magnetic axis positioning of ~0.3 mm. Due to lack of space in the beamline, the dipoles must be placed inside of some of solenoids. To solve the fringe field problem, each solenoid is made of a main coil and two bucking coils with the direction of magnetic field opposite to that of the main coil. Design of the solenoid is described in [7] and [8]. Several prototypes of the focusing solenoid were tested before serial production started. Magnetic field distribution of a solenoid with embedded steering coils in the central and the fringe area is shown in Fig. 1. Here the measured field is compared to a model prediction; the data points from both sides of the magnet are overlaid. The squared field integral at 200A is 2.5 $T^2$-m, versus the predicted value of 2.4 $T^2$-m. The maximum current in the system (quench condition) is ~240 A; the required value of 1.8 $T^2$-m can be achieved at 170 A.

The measured magnetic field in the fringe field region (outside the solenoid) is also very close to the expected. At the nominal current of 170 A, for the solenoids with the embedded steering coils, the magnetic field in the area of the accelerating cavity (~150 mm from the solenoid center) is ~0.03 T; it is ~0.01 T for the solenoids without the steering coils. Additional shielding is needed if the accelerating cavity test shows that this field is too high.

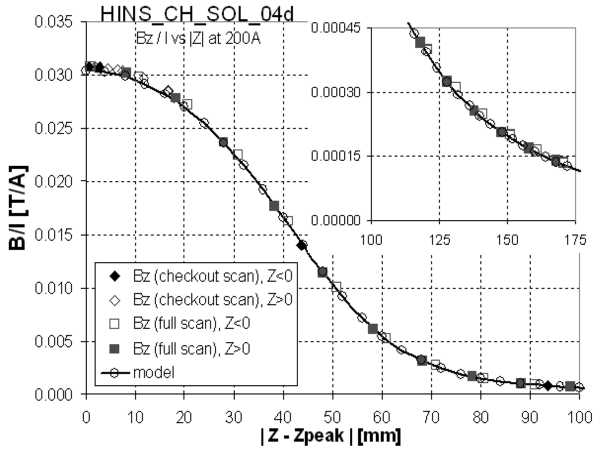

Figure 1: Comparison of measured and predicted axial magnetic field transfer function profiles for CH section solenoid at 200A in the central and fringe regions.

Each steering dipole was made by placing a one-layer winding on the surface of a G-10 cylinder. NbTi 0.8 mm strand was used for both the horizontal and vertical dipole. The steering dipole assembly is placed inside the main coil with the horizontal dipole inside the vertical one; the total radial thickness of the assembly was ~4.8 mm. The magnetic field integral ∫□□□≈ 1 T-cm was measured in both steering coils of the first production lens at 200 A. The required integrated strength of 0.25 T-cm is achieved at ~50 A.

Assembled and tested cold masses are to be placed in cryo-vessels at FNAL to form completed focusing lenses (see Fig. 2).

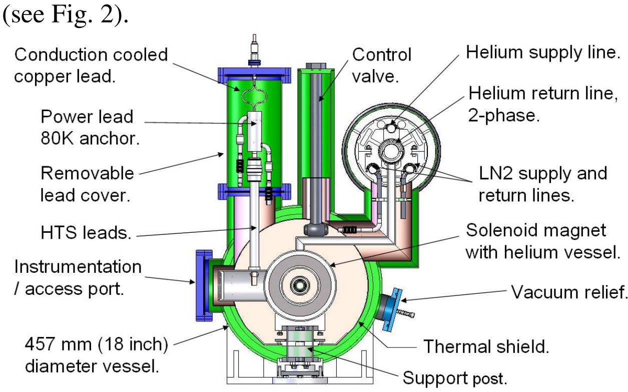

Figure 2: Cross section through CH solenoid cryostat

Description of the cryostat design can be found in [9]. All 19 cryostats in the beamline of CH section will be connected in series mechanically and in parallel cryogenically using a "header" – a pipe that contains LHe and LN2 supply and return lines. The first cryostat has been assembled with the prototype solenoid and tested to show good performance [10].

One of the most important aspects of using the solenoid-based focusing lenses is their alignment in the transport channel. During certification process at FNAL, it was found that positions of the geometric axis and the magnetic axis of a solenoid can differ by ~0.5 mm. Alignment of the lenses in the linac must be done to place the magnetic axis within ~0.25 mm of the beamline. To ensure this accuracy of alignment, the Single Stretched Wire (SSW) system is used to find the magnetic axis position relative to external fiducials [10]. This measurement is made at different stages: warm solenoid at atmospheric pressure and after pumping out the air, the solenoid cooled to 4.2 K without current, and powered solenoid at different current levels. Several cycles of these measurements were made with the first prototype lens to understand reproducibility of the magnetic axis positioning. Preliminary results show that reproducibility of the alignment is on the order of ±100 μm.

## SS SECTION FOCUSING SOLENOIDS

Main requirements for the SS1 section focusing solenoids are: 30 mm cold bore diameter, integrated focusing strength of ~3 $T^2$-m, and effective length less than 0.15 m (normalized to the maximum magnetic field). Each steering dipole must have an integrated strength higher than 0.5 T-cm. From the experience of building and testing CH section lenses, it was clear that a refined design was needed to meet the fringe field requirement. Some help comes from the fact that there is no need for individual cryostats, so the solenoid coil inner diameters could be made smaller. Nevertheless, a new steering coil design was needed to make the assembly "slim" to allow further reduction of the inner diameter of the solenoid. A new coil winding technique was developed that employed 0.3-mm NbTi strand. The reduced radial thickness of the steering dipole assembly was ~2.5 mm including the thickness of the main coil barrel; this made it possible to have identical solenoid geometry for both styles of the solenoid: with and without steering coils. Main design features of the SS-1 focusing solenoid are described in [11]. A prototype lens has been built and tested. Fig. 3 shows a comparison of the measured and predicted fringe field for the solenoid without steering coils [12].

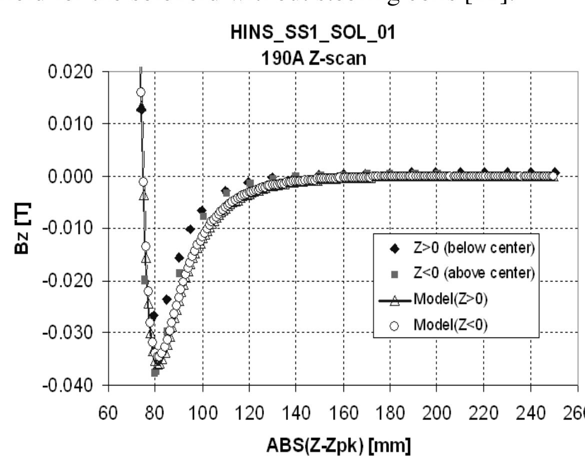

Figure 3: Predicted and measured axial magnetic field in the fringe region at 190A for SS1 prototype solenoid

Expected magnetic field on the walls of the spoke cavities is ~20 µT, and additional shielding will be needed to bring it to the level below the recommended 10 µT.

Alignment issues for the lenses in the superconducting sections of the linac are more demanding than they are in the CH section. The lenses will be installed inside RF cryomodule, and special techniques and procedures must be developed to align the lenses and follow the drift of the magnetic axis in time. An approach to solving this problem has been developed (e.g. see [13]), but specifics of the design will require a lot of work to implement a known solution or to find a new one. This part of the solenoid lens R&D is in the initial stage; a prototype cryostat is to be built to address the issue.

Design of the SS2 section focusing solenoid is similar to that of the SS1 solenoid except it is much stronger: the required squared field integral for this solenoid is 5 $T^2$-m. As a result, this solenoid stores more energy, and quench protection solution becomes more complicated in comparison with the SS1 and CH systems, that can absorb all the stored energy safely.

## SOLENOID QUENCH PROTECTION

Quench training is part of testing performed on each assembled lens. As in each focusing solenoid, a main coil and two (much) smaller bucking coils are connected in series, quenching in one of the bucking coils can result in an unacceptable temperature rise. Protection of focusing solenoids was the subject of several studies (e.g., see [14], [15], and [16]). A proper protection scheme should prevent the temperature and voltage to ground in the coils from going too high: $T_{max}$< 300 K, $V_{max}$< 300 V. Reliability of the protection dictates choosing a simple solution from many possible ones. CH and SS1 focusing solenoids appear to be self-protected; this means that if the energy stored in the system is fully dissipated by the quenching coil, the temperature and the voltage are still below the allowed limits in any part of the coil. Nevertheless, to reduce heat dissipation within LHe bath, we use an external dump resistor, that, if chosen correctly, helps to lower the voltage and temperature spikes. For solenoids of the SS2 section, using a dump resistor alone does not solve the problem. A solution to this problem is still to be found and tested.

## SUMMARY

To build a solenoid-based transport system for the front end of the HINS linac under construction at FNAL, a focusing solenoid R&D program has been initiated. The focusing lens design and fabrication technology development efforts within the R&D are close to completion. The CH series of lenses is in production with the final assembly and certification activities taking place at FNAL. Ongoing tests of SS1 prototype lenses will be followed by production in 2009. Quench protection issues for SS2 lens is under study, and design activities are in progress. A shift in the R&D is now being made towards development of adequate procedures for testing and installation of SS1 and SS2 lenses.

# STATUS OF THE LANSCE REFURBISHMENT PROJECT*

John L. Erickson, Kevin W. Jones and Michael W. Strevell
Los Alamos National Laboratory, Los Alamos, NM 87545, U.S.A.

*Abstract*

The Los Alamos Neutron Science Center (LANSCE) accelerator is an 800-MeV proton linac that drives user facilities for isotope production, proton radiography, ultra-cold neutrons, weapons neutron research and various sciences using neutron scattering. The LANSCE Refurbishment Project (LANSCE-R) is an ambitious project to refurbish key elements of the LANSCE accelerator that are becoming obsolete or nearing end-of-life. The conceptual design phase for the project is funded and underway. The 5 year, $170M (US) project will enable future decades of reliable, high-performance operation. It will replace a substantial fraction of the radio-frequency power systems (gridded tubes and klystrons) with modern systems, completely refurbish the original accelerator control and timing systems, replace obsolete diagnostic devices, and modernize other ancillary systems. An overview of the LANSCE-R project will be presented. The functional and operating requirements will be discussed, the proposed technical solutions presented, and the plan for successful project execution while meeting annual customer expectations for beam delivery will be reviewed.

## INTRODUCTION

The LANSCE User Facility accelerator is capable of simultaneously accelerating protons or negative hydrogen ions to beam powers of up to 800 kW. A beam switchyard allows tailored time-structured beams to be delivered to the five distinct experimental areas.

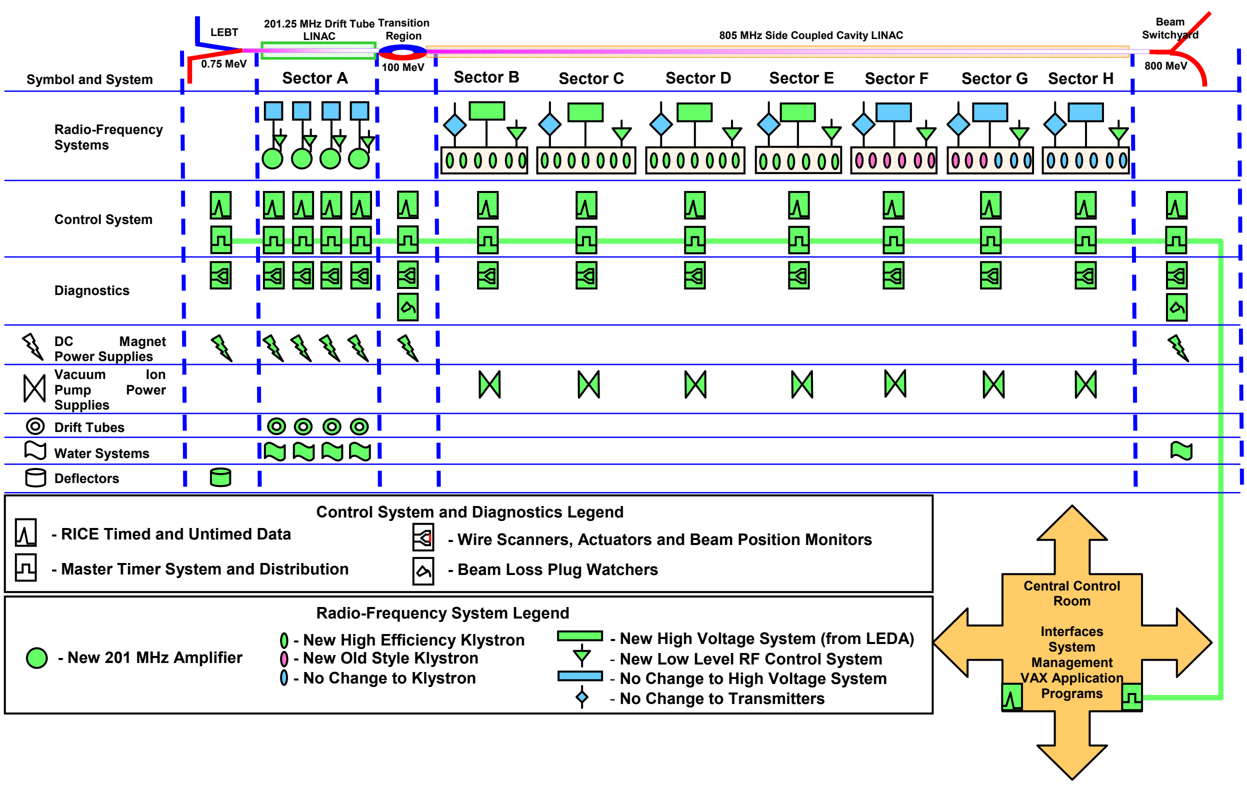

Figure 1: A summary diagram showing the scope of LANSCE-R.

## *Vision and Goals*

LANSCE produces one of the highest beam currents in the world of medium energy protons to irradiate experimental targets directly or to produce intense pulses of spallation neutrons. LANSCE performs state-of-the-art experiments in proton radiography, nuclear science, and materials science.

Our goal is to provide safe, secure, environmentally-compliant, cost-effective performance in beam delivery that meets or exceeds metrics prescribed by our customers.

*Work supported by the U. S. Department of Energy, National Nuclear Security Administration, Contract No. DE-AC52-06NA25396 – Publication Release LA-UR-08-06209

The LANSCE Refurbishment Project (LANSCE-R) ensures that the LANSCE User Facility will continue to be the premier neutron science facility at Los Alamos National Laboratory, providing NNSA with critical data in support of its Defense Programs mission. A schematic of the project scope is shown in Figure 1.

### *Assumptions*

Operation of the scientific program will continue during the refurbishment project in a tailored way to meet customer expectations to the extent possible while simultaneously implementing the refurbishment project during scheduled operational outages. Refurbishment elements will be pre-assembled, staged, and tested to the greatest extent possible prior to possible multi-shift installation evolutions.

## STRATEGIES AND PROJECTS

### *Implementation Strategies*

The overall implementation strategy is to integrate ongoing LANSCE User Facility operation with the execution of the LANSCE-R project. The operations organization for LANSCE is both well established and strong. Capital projects have a successful history of integration with the operating facility. The recent experience of integrating the construction of the Isotope Production Facility is an example of strong cooperation between a project and the operating facility.

The overall success of both LANSCE Operations and the LANSCE-R Project rests on the ability of the responsible organizations to retain and, where appropriate, develop the skilled technical staff needed to support ongoing operations, maintenance and related improvements as well as the conceptual, preliminary and final designs of LANSCE-R sub-systems, oversight of component procurement, acceptance testing, pre-installation assembly and testing, and final installation and commissioning.

The following key operational elements are essential for the integrated model to be successful:

- A commitment to schedule at least 3,000 hours of beam operation for users each fiscal year from FY2008 through FY2014 and beyond, with appropriate allocation of sole-use and beam development time.
- No more than one cold-start facility turn-on in each fiscal year.
- An appropriate distribution of extended outages of several months duration to accommodate both a modular approach to LANSCE-R sub-system installation and other operations-funded system improvements as well as appropriate cool-down times for routine maintenance on activated equipment in areas such as the Proton Storage Ring and the 1L Target.
- A disciplined approach to configuration management for accelerator and beam delivery systems to minimize return to service after short and extended outages.
- Continuous certification of the Radiation Security System to minimize the time required for resumption of production beam operation.

The following elements are essential for LANSCE-R to be successful:

- Proposed equipment and system upgrades are focused on those current LANSCE capabilities required to support Weapons Program needs.
- A design, acquisition, and assembly strategy that optimizes preparation for focused equipment installation during scheduled operational outages.
- An appropriate balance between refurbishment of the LANSCE User Facility real property and installed equipment through the Facility Infrastructure Recapitalization Program (FIRP) and refurbishment of essential accelerator sub-systems through the LANSCE-R project.
- A project execution time line that permits performance of the full scope of work in no more than five to seven years.

### *Facility and Infrastructure Projects*

Weapons Program GPP funding and the Facility Infrastructure Recapitalization Program (FIRP) have effectively been used at the LANSCE User Facility to replace Radioactive Liquid Waste handling, cooling towers, and the chilled water plant to ensure that the real property and installed equipment remain capable of supporting long term operation through 2020. These projects have been completed on schedule and within budget, with the work being carefully planned within extended accelerator maintenance outages. Additional work is needed, and replacement of electrical distribution system and certain process water systems are being undertaken in FY09.

A strong FIRP program is essential to underpin the ongoing success of LANSCE operations and the refurbishment scope planned in LANSCE-R. Out-year projects (FY09-FY11) encompass multiple electrical distribution system upgrades, process cooling water upgrades, roof replacements, and HVAC replacements.

### *LANSCE-R Preferred Scope*

The preferred scope that was included to support the Mission Need for the LANSCE-R Project will enhance cost effectiveness by system refurbishments or improvements that reduce operating costs and will improve decreasing facility reliability by replacing systems that have an impact of 15% or greater on reliability for those systems.

The full LANSCE-R project will also eliminate the following sources of operational inefficiencies that should improve operational effectiveness:

- Single-point failures with an estimated time to repair of greater than 30 days,

- Equipment that is beyond its predicted end-of-life that could severely impact facility operations,
- Obsolete equipment for which no spare parts are available,
- ES&H or code compliance issues necessary to continue safe operation.

The baseline refurbishment project consists of replacing the 201 MHz RF systems, updating about 75% of the 805 MHz RF systems, modernizing the control system, and replacing or refurbishing a variety of diagnostics and accelerator subsystems.

The RF and power supply scope includes the following:

- Magnet Power Supplies – Approximately 12 different power supply replacement projects.
- Pulsed Power – Solid State Replacement for Ground Level Deflectors
- 201 MHz RF for the Drift Tube Linac – All new 201 RF except for High Voltage
- Low Level RF – All new LLRF in the 201 MHz and 805 MHz subsystems
- 805 MHz Klystrons – 4 sectors of new high efficiency klystrons and 1.5 sectors of new old style klystrons (leaving 1.5 sectors of klystrons not replaced)
- High Voltage Power Systems – 4 sectors of new high voltage systems.

The Controls replacement scope is limited to the replacement of the control and instrumentation functions implemented by the RICE systems, DEC MicroVAX and workstation computer systems, and application software that comprise the current LANSCE Control System (LCS). The LCS provides control and data monitoring for most devices in the LINAC and for some of its associated experimental-area beam lines. The overall Control and Instrumentation scope includes the following:

- Replace Linac Beam Position Monitors and incorporate phase measurements
- Replace the Delta T system
- Replace 95 Wire scanners in the linac
- 18 IR loss monitor systems & 5 GD systems
- Replace VAXs and VAX applications
- Replace RICE systems (Remote Instrumentation Control Equipment systems)
- Replace Master Timer System.

The accelerator sub-systems scope includes:

- Cooling Water distribution and monitoring
- Vacuum system equipment and monitoring
- Linear accelerator copper structures, Drift Tubes.

The preferred scope being proposed is a self-consistent approach to maintaining reliability and addressing single point failures in the LANSCE facility that serves the NNSA/SSP Defense Programs mission. It generally assumes that the current facility capability will be maintained. LANSCE-R includes only scope to support NNSA/SSP mission research at 120 Hz and 625 µs beam gate. It only includes beam delivery elements common to pRad, WNR and Lujan Center that all have NNSA/SSP mission deliverables. It does not include refurbishment of equipment /systems from the end of the accelerator to WNR and the Lujan Center, including Line D and the PSR. In addition, LANSCE-R does not include equipment changes to support current or future H+ operations to Isotope Production or Area A/MTS. This approach is consistent with guidance received from NNSA.

## IMPLEMENTATION OF A SEVEN-YEAR PLAN FOR FY09-FY15

### *Operations Objectives for Project:*

- Operate for approximately 3,000 hours exclusive of development, documentation, and sole use operation consistent with operations in FY2008.
- Retain key staff required to perform both operations and LANSCE-R implementation at the same time.

### *LANSCE-R Current Year – FY2008-9*

- Conduct the agreed-upon scope of work for conceptual design and obtain approval of the final CD-1 Critical Decision. This will include project management, project controls, and technical writing in support of the CD-1 package development.

### *LANSCE-R Future Years – FY2010-15*

Given the funding scenario that is ultimately determined, we will manage the work to be accomplished in each annual outage (each an identified subproject) to achieve the highest priority items first within budget and funding profile constraints, while making progress on all sub-projects.

Integration of new hardware will occur during the extended outages that occur each calendar year. These will be approximately 6 months in duration and will be integrated into the operating schedule well in advance. Installation, checkout and commissioning of the first module of upgraded 201 MHz RF systems will take place in FY12 with the next two modules to follow as soon as possible after that.

Each outage will constitute a sub-project in itself that can be integrated with planned routine plant maintenance and scheduled FIRP projects. Each annual outage will include required activities with checkout and verification of interlock systems, operations manual updates, and commissioning time commensurate with extent of changes. For example, LLRF system testing requires cooling water, RF power, and control system interfaces.

Ancillary system upgrades will be planned to minimize disruption, and will begin with systems that have the least impact to gain experience and improve project estimation for more complex installations. For example, network infrastructure should be put in place and commissioned before final upgrades are made to the Master Timing system. High voltage system work for refurbishment of the 805 MHz systems should precede acquisition and installation of new or rebuilt klystrons.

# OPERATIONAL STATUS AND FUTURE PLANS FOR THE LOS ALAMOS NEUTRON SCIENCE CENTER (LANSCE)*

Kevin W. Jones and Kurt F. Schoenberg, Los Alamos National Laboratory, Los Alamos, NM 87545, U.S.A.

*Abstract*

The Los Alamos Neutron Science Center (LANSCE) continues to be a signature experimental science facility at Los Alamos National Laboratory (LANL). The 800 MeV linear proton accelerator provides multiplexed beams to five unique target stations to produce medical radioisotopes, ultra-cold neutrons, thermal and high-energy neutrons for material and nuclear science, and to conduct proton radiography of dynamic events. Recent operating experience will be reviewed and the role of an enhanced LANSCE facility in LANL's new signature facility initiative, Matter and Radiation in Extremes (MaRIE) will be discussed.

## INTRODUCTION

The Los Alamos Neutron Science Center (LANSCE) is a unique multidisciplinary facility for science and technology. The core of the facility is an 800-MeV linear accelerator system with demonstrated 1MW capability that presently accelerates up to 100kW of negative hydrogen ions with unique and highly variable timing patterns suitable for a wide variety of experimental programs. Five experimental areas form the core of the user facility. Four areas utilize the 800-MeV negative hydrogen ion beams directed by appropriate pulsed kicker systems: at the Manuel Lujan Jr. Neutron Scattering Center (Lujan Center) sixteen flight paths utilize pulsed thermal and epithermal neutrons produced at 20Hz by intense 0.29μs bursts of protons incident on a tungsten spallation target and moderated by water or liquid hydrogen; the Weapons Neutron Research Facility (WNR) provides the most intense source of high-energy neutrons in the world for neutron nuclear science and is an accepted world standard for irradiation of semiconductor electronics; the Proton Radiography Facility (pRAD) provides a unique facility for the study of shock-induced dynamic processes where shocks are driven by high explosives or projectiles; and the Ultra-Cold Neutron (UCN) facility uses a moderated solid deuterium target to generate intense pulses of ultra-cold neutrons for fundamental science research. The Isotope Production Facility (IPF) at 100 MeV utilizes a proton beam of up to 275 μA to produce proton-induced isotopes for medical imaging diagnostics and fundamental research. LANSCE continues a disciplined approach to both operations and maintenance that maintains operational performance and user satisfaction in a constrained funding environment.

*Work supported by the U. S. Department of Energy, National Nuclear Security Administration, Contract No. DE-AC52-06NA25396 – Publication Release LA-UR-08-06170

## THE LANSCE USER FACILITY

The Lujan Center provides 11 neutron scattering instruments capable of studying materials structures of diverse items such as proteins, machinery components, powders, and single crystals using both elastic and inelastic techniques. Nuclear science is supported by three flight paths, one of which is equipped with a 4π detector used to measure thermal neutron capture cross sections on unstable nuclei. This suite of instruments applies and advances neutron scattering for both defense and academic research. Beam current to the Lujan target is nominally 100μA but can be as high as 125μA depending on ion source and accelerator optimization.

The WNR facility receives beam at 40-100Hz with a variable micro-pulse spacing (typically 1.8μs) to address the needs of LANSCE Users in the areas of basic and applied nuclear science. The pulse spacing permits resolution of frame overlap in the neutron spectra. This white neutron source (Target 4) is the most intense source of high-energy (<760 MeV) neutrons worldwide and is equipped with six flight paths that determine neutron energy using time-of-flight techniques. A key flight path used principally by industry users provides a neutron spectrum essentially identical to that of cosmic-ray neutrons to permit accelerated studies of single-event-upset sensitivity for the electronics and avionics industries. A related facility (Target 2) provides direct access to proton beams with energies up to 800 MeV for studies of proton-induced reactions and target irradiations for materials testing. This target station is also equipped with five neutron flight paths.

The pRAD facility provides a unique experimental technique for studies of dynamic processes. Up to 37 pulses of protons, each with approximately $10^9$ particles per pulse, temporally spaced at appropriate intervals, are directed at a dynamic object. The scattering characteristics of each pulse are imaged by a collimator and magnetic lens system and recorded by a camera. This technique permits multi-frame radiographs of dynamic events driven by gas guns or high explosives. These radiographs permit the study of material dynamics and failure mechanisms under shock conditions.

The UCN facility accepts several full charge (~5μC) accelerator pulses separated by a period suitable for the moderation and bottling of the neutrons and compatible with average current limits, typically about 5-7 seconds. The ultra-cold neutrons are then directed through a guide to a decay volume where beta-decay parameters are measured.

The IPF irradiates source materials to produce proton-induced isotopes for applications in medical diagnostic imaging and research. Most notable is the production of $^{82}$Sr used for cardiac imaging, and other isotopes for the calibration of PET scanners. The operation of this facility is interleaved with others around the world to assure a constant supply of the necessary isotopes.

A schematic representation of the facility and its operating characteristics is given in Figure 1.

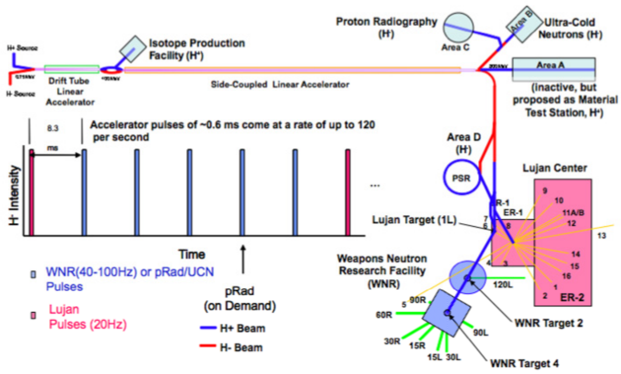

Figure 1: Schematic layout of the LANSCE User Facility

## OPERATIONS PERFORMANCE

Integrated performance for the LANSCE User Facility has been remarkably consistent since the year 2000. This is best illustrated by reliability data for the Lujan Center from 1991 to 2007 as shown in Figure 2. This represents the most complex beam delivery system including the injectors and linac, the proton storage ring, and beam transport lines.

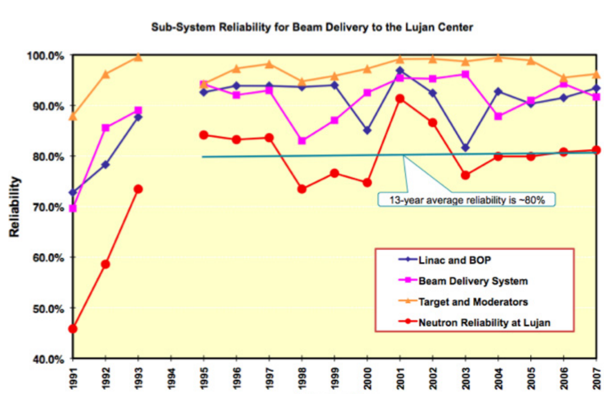

Figure 2: Sub-system reliability for beam delivery to the Lujan Center

These data illustrate that the 13-year average reliability from 1995 to 2007 is slightly over 80% which is remarkable for a facility that is now 36 years old with much of the original equipment still in service.

Operating hours from 1989 to 2007 are illustrated in Figure 3.

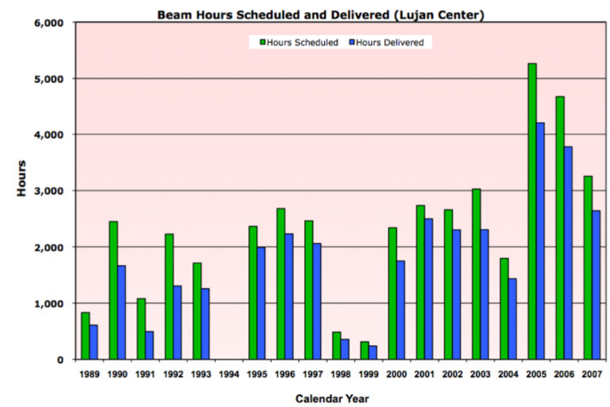

Figure 3: Operating hours for the Lujan Center illustrating recent gains.

Strong efforts have recently been made to increase the number of operating hours for the facility, but budget constraints coupled with increasing power costs dictate that future operating schedules be limited to 3,000 hours per calendar year. This operating scenario is consistent with that planned for the LANSCE Refurbishment Project discussed elsewhere at this conference [1].

Sub-system down time is recorded throughout each scheduled operating period with 1-minute resolution. Historical data allow for careful trending and allocation of scarce maintenance resources. These data have proved valuable in the definition of the scope of the LANSCE Refurbishment Project [1], and are shown in Figure 4.

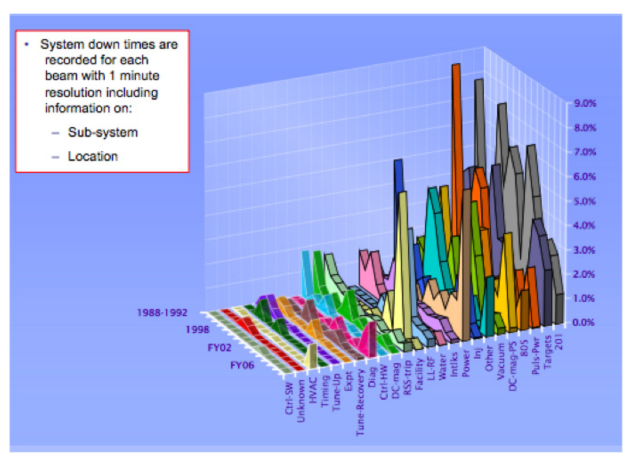

Figure 4: Historical sub-system down time for beam delivery to the Lujan Center

Average operating performance over recent years for the principal facilities at LANSCE is summarized in Table 1.

Table 1: Recent average operating performance for the principal facilities at LANSCE

| Facility | Reliability |
|---|---|
| Lujan Center | 81.6% |
| WNR Target 4 | 84.7% |
| pRAD | 89.5% |
| IPF | 83.7% |

## FUTURE PLANS

Substantial effort has been invested in the LANSCE Refurbishment Project (LANSCE-R) that is discussed elsewhere at this conference [1]. The National Nuclear Security Administration (NNSA) investment in LANSCE-R is planned to be ~$150M (US).

Another core element of facility refurbishment is replacement of electrical, water, and HVAC utilities in the linac service building. This has been done for one of the eight sectors of the accelerator, Sector B. This replacement project for the remaining 7 sectors and budgeted at $22M is planned for FY09-FY12.

Two partner organizations also plan significant investment in the facility. The DOE Office of Science/Basic Energy Sciences plans to enhance the materials science instrument suite at the Lujan Center to emphasize utilization of cold neutrons and improve compatibility with the Spallation Neutron Source at Oak Ridge National Laboratory. This will also involve a new design of the moderator suite for the target-moderator-reflector system that serves the Lujan Center. This work is underway.

The DOE Office of Nuclear Energy plans to install a Material Test Station (MTS) in the decommissioned high-power beam end-station, Area A, which in the past housed the pion and muon production targets and experimental stations for the original LAMPF nuclear physics program. Site preparation in Area A has begun and the shielding doors surrounding the production targets have successfully been opened after 15 years. The MTS will provide a target facility capable of accepting at least 800kW of proton beam power to irradiate fast-fission spectrum fuel elements for material science studies, and will be designed to accept beam powers of up to 3.6MW. The planned budget for this facility is ~$75M with construction scheduled from FY10-FY12.

Several other facility enhancements proposed by work-for-others programs are being considered. A proton interrogation test facility for remote cargo interrogation is in the conceptual design phase. This initiative would utilize single micro-pulses accelerated to 1GeV in a high-gradient superconducting afterburner accelerator for delivery down a 600m external flight path to examine prototypical cargo containers for materials of interest. This project is one of several projects at the conceptual design phase using accelerated particle beams aimed at improving national security. Other projects underway at Los Alamos also consider the use of muon beams for this purpose.

The Proton Storage Ring (PSR) beam may be utilized in different ways. Recent successful development activities have focused on modifications to the PSR to allow accumulation of stacked micro-pulses rather than the 290ns pulse intended for the Lujan Center. These stacked micropulses would be delivered to WNR Target 4 and would enhance the neutron spectrum from the white source in a region of significant interest to the neutron science program. A second concept would extract high-charge (~10μC) pulses from the PSR and deliver them to a new low-enriched sub-critical assembly where the proton burst would drive the assembly to generate a substantial neutron burst, essentially emulating a short-pulse critical assembly. This facility could replace the Short Pulse Reactor facility at Sandia National Laboratory that had been used to study neutron-induced radiation effects on materials and electronics. The estimated cost of such a facility, which is in the conceptual design stage, is ~$70M.

The Los Alamos National Laboratory is developing conceptual plans for a new signature experimental facility, MaRIE. LANSCE will form the foundation for this new facility. Plans include an increase in power capacity for the present linac from 1MW to 1.8-3.6MW for enhanced operation of the MTS. Plans also include a 35GeV high-gradient electron linac and FEL facility that will produce radiation of ~50keV for enhanced material science capabilities.

The LANSCE User Facility is the subject of resurgent interest in the spectrum of science accessible at the facility, and the future is bright.

# OPERATIONAL EXPERIENCE OF THE SNS FRONT END AND WARM LINAC

A. Aleksandrov

Oak Ridge National Laboratory, Oak Ridge, TN 37830 USA

*Abstract*

The Spallation Neutron Source accelerator complex uses set of pulsed linear accelerators of different types to accelerate beam to 1GeV. The 2.5 MeV beam from the Front End is accelerated to 86 MeV in the Drift Tube Linac, then to 185 MeV in a Coupled-Cavity Linac and finally to 1 GeV in the Superconducting Linac. In the process of the commissioning and beam power ramp up many technical systems, as well as tuning algorithms, have deviated significantly from the original design. Our understanding of beam behavior has been evolving continuously and resulted in a steady reduction of fractional beam losses in the linac. In the same time new unexpected problems have been discovered, which are still in the process of investigation. In this paper we summarize our experience up to date and report on the current directions of experimental study, simulations, and development of tuning methods.

## INTRODUCTION

The SNS Front End and warm linac consist of an $H^-$ injector, capable of producing one-ms-long pulses with 38 mA peak current, chopped with a 68% beam-on duty factor and a repetition rate of 60 Hz to produce 1.6 mA average current, an 87 MeV Drift Tube Linac (DTL), a 186 MeV Coupled Cavity Linac (CCL), and associated transport lines. After completion of the initial beam commissioning at a power level lower than the nominal, the SNS accelerator complex is gradually increasing the operating power with the goal of achieving the design parameters in 2009 [1]. Results of the initial commissioning can be found in [2], and of the initial operation experience in [3]. At the time of this writing the Front End and warm linac routinely provides beam at 40% of the design average power.

## FRONT-END PERFORMANCE

The front-end for the SNS accelerator systems is a 2.5 MeV injector consisting of the following major subsystems: an RF-driven $H^-$ source, an electrostatic low energy beam transport line (LEBT), a 402.5 MHz RFQ, a medium energy beam transport line (MEBT), a beam chopper system, and a suite of diagnostic devices. The front-end is required to produce a 2.5 MeV beam of 38 mA peak current at 6% duty factor. The 1 ms long $H^-$ macro-pulses are chopped at the revolution frequency of the accumulator ring (~1 MHz) into mini-pulses of 645 ns duration with 300 ns gaps.

### *Ion Source and LEBT*

The ion source has been capable of satisfying peak and average beam current requirements for the power ramp up goals. At the time of this writing it produces 32mA 750us pulses at 60Hz. We do not expect significant difficulties in expanding the pulse width to the design value of 1200us. Increasing peak current to the nominal 38mA is more challenging but peak current higher than 40mA in 800us pulses has been demonstrated recently in dedicated tests [4].

The RF antenna life time and the possibility of catastrophic antenna failures still remains a concern. We implemented several interlock mechanisms to prevent a possible water leak into the LEBT chamber in case of antenna failure and have not had such events for the two last run periods. An external antenna source is being developed as a long term solution and the first experimental tests have shown promising results [4].

The long standing problem of electrical breakdowns in the electrostatic LEBT has not been fully resolved yet. An improved LEBT design, which does not have glue joints and has a better isolation between the chopper electrodes and the rest of the LEBT, was installed before the last run and demonstrated significant reduction of arc related chopper failures. As a long term solution we plan to use a magnetic LEBT which is in the early stages of development.

### *Chopper Systems*

Beam chopping is performed by two separate chopper systems located in the LEBT and MEBT. The last lens in the LEBT is split into four quadrants to allow electrostatic chopping using the RFQ entrance flange as a chopper target. The LEBT chopper removes most of the beam charge during the mini-pulse gaps, and the traveling-wave MEBT chopper further cleans the gap to a level of $10^{-4}$ and reduces the rise and fall time of the mini-pulse to 10 ns. A chopper controller provides different patterns of chopped beam: “regular chopping”, “single mini-pulse”, “every n-th mini-pulse”, “blanking-off”, and “ramp up”. The chopper systems demonstrated design parameters during commissioning for the nominal chopping pattern at low average beam power. We encountered serious problems with both the LEBT and the MEBT choppers at higher beam power.

The main problem of the LEBT chopper is frequent damage to the high voltage switches by arcs in the electrostatic LEBT. Serial resistors were installed in the chopper circuitry for protection, resulting in significant increase of the chopper rise time. We change the resistor value in the range from 750 Ohm, for the case of high arcing rate, to 175 Ohm, for the case when the LEBT electrodes are well conditioned, and the arc rate is low. Even in the latter case the chopper rise time is ~80ns, which is still significantly longer than the design requirement of <50 ns. At the time of this writing we have 450 Ohm resistor installed resulting in rise/fall time in excess of 100ns as shown in Fig.1. Quite surprisingly, we are able to deliver up to 550 kW of beam power on the target with acceptable losses everywhere in the machine even with such poor chopping quality. The redesigned high voltage switch with more robust protection from the arcs is planned to be installed in January of 2009.

The MEBT chopper high voltage switches had poor reliability in early runs, and the kicker structure had to be redesigned [5]. A number of small evolutionary improvements in the high voltage electronics design resulted in significant improvement in reliability, which, together with using a new kicker, allowed using the MEBT chopper for extraction loss reduction during neutron production runs. The kick strength provided by the prototype structure of the new design is about 15% below the original design specification. Results of the kick strength measurement are shown in Fig.1. The chopper rise time of ~16 ns is still longer than the design specification. The final version of the chopper kicker, which we plan to install in January of 2009, will have a 25% stronger kick and an 8ns rise time. Figure 2 demonstrates the effect of the MEBT chopper on the ring extraction losses in one of the experiments. Just inserting the chopper target reduces losses by factor of 2 due to scraping of the vertical halo, when the chopper is on the losses are reduced by another factor of 5. In the later experiments we discovered that ion source alignment has a significant effect on the LEBT chopper efficiency. With improved alignment procedure we are able to run with negligible extraction losses even with the MEBT chopper off. We do see effects of the slow chopper rise time, most notably in bunch position and phase variation along the pulse and effective beam size increase. We have not found evidence of additional losses in the linac associated with the slow chopping.

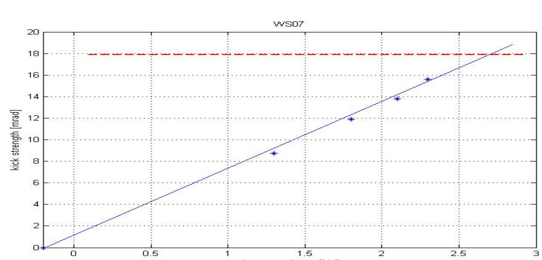

Figure 1: Chopper kicker strength vs. kicker voltage calculated from the profiles in Fig.1. Red dashed line shows the design requirements.

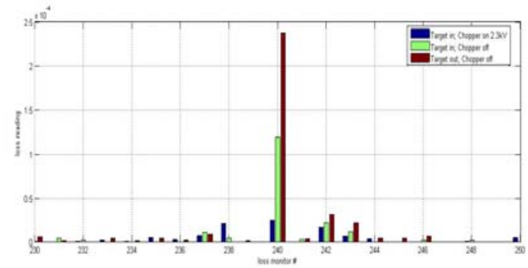

Figure 2**:** Effect of the MEBT chopper on the ring extraction losses. Bar chart is BLM readings: the brown bar– chopper is off, target is out; the green bar – chopper is off, target is in; the blue bar – chopper is on, target is in.

## DTL AND CCL PERFORMANCE

The Drift Tube Linac consists of six accelerating tanks operating at 402.5 MHz with output energy of 87 MeV. The transverse focusing is arranged in a FFODDO lattice utilizing permanent-magnet quadrupoles. Some empty drift tubes contain BPMs and dipole correctors. The Coupled Cavity Linac (CCL) consists of four 12-segment accelerating modules operating at 805 MHz with output energy of 187 MeV. The inter-segment sections contain electromagnet quadrupoles arranged in a FODO focusing lattice, BPMs, wire scanners, and Beam Shape Monitors.

The original plan for the transverse beam matching was to use profile measurements in several places along the linac. So far we have not achieved any significant progress in using wire scanner data for loss reduction. We set all quadrupole magnet strengths to the design values and manually tweak some of them within 1-2% range to minimize beam losses.

Longitudinal tuning of the linac had been routinely done using PASTA phase scan algorithm [6]. Measured longitudinal rms Twiss parameters were close to the design values and we did not observe significant beam losses in the warm linac [7]. However, with the increased average beam power we started seeing unexpectedly large losses in the Super Conducting Linac (SCL). These losses depended weakly on the transverse focusing parameters but were very sensitive to the RF phase settings of the warm linac cavities. One of the strange experimental findings was that minimum losses were achieved by shifting some of the RF phases away from the nominal set points found from the PASTA phase scans. For example, DTL6 phase had to be shifted by 6 degrees. In the process of resolving this puzzle we developed a beam based measuring technique, which allows us to measure the deviation of accelerating gradients from the design value with high accuracy. For this measurement the phase of the beam is shifted by several degrees at the entrance of a selected cavity, and the phase shift at all available BPMs downstream is recorded. The period of the resulting synchrotron oscillation inside the longitudinal separatrix depends on the accelerating field amplitude. By fitting the model to the measurements it is possible to deduce the RF amplitude errors, as illustrated by an example in Figs. 3 and 4. We found that our standard PASTA scans produced RF amplitude set points overestimated by 1-2% for each cavity. The cumulative effect of these relatively small errors led to significant deviation from the design longitudinal phase advance. After correction of the set points the minimum of the losses corresponded to the nominal set points found from the phase scans, and no DTL phase tweaking is required.

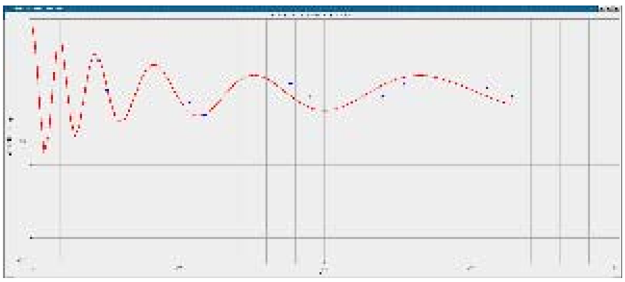

Figure 3: Synchrotron bunch oscillation in the DTL. Solid line is simulation result for the nominal cavity amplitudes; points are measured values for the case of 2.7% error of the DTL2 amplitude.

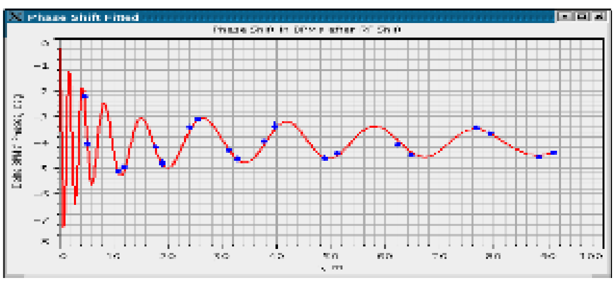

Figure 4: Synchrotron bunch oscillation in the DTL and CCL. Solid line is simulation result for the nominal cavity amplitudes; points are measured values for the case of good linac tuning.

### *Beam Loss in the Warm Linac*

There is no reduction in beam current along the linac detectable by the beam current monitors. Beam loss monitors (BLMs) based on ionization chambers are used to detect prompt radiation due to beam losses.

The integrated radiation dose recorded by the BLMs during a typical 10 day run with 400 kW beam on target is shown in Fig. 5. The result of the activation survey after 2 days of cool down period is shown in Fig. 6. There is a good correlation between the activation levels and prompt radiation doses; therefore we can use BLM data reliably in machine tuning. We associate the main hot spot in the beginning of the CCL with particles falling out of the longitudinal DTL separatrix due to large energy and/or phase deviation at the entrance. In order to fix this problem we will have to improve longitudinal beam quality in the Front End. The first step will be to increase the available RF power for the MEBT rebunchers, which is currently limited at about 75% of the nominal design level.

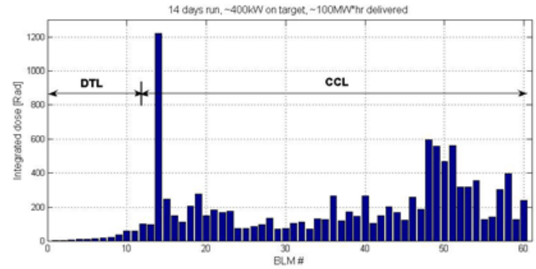

Figure 5: Measured distribution of prompt radiation due to beam loss in the warm linac.

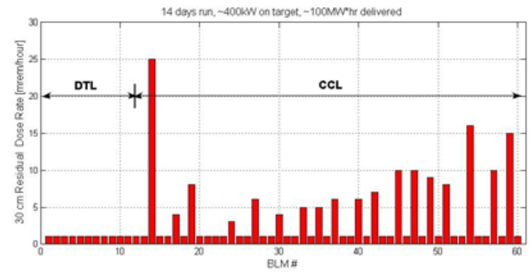

Figure 6: Measured distribution of the residual radiation in the warm linac after 36 hours of cool down period.

## CONCLUSIONS

The SNS Front End and warm linac has been successfully keeping up with the requirements of the beam power ramp up plan. We continue to refine the tuning algorithms. The most significant technical problem at the moment is inadequate chopping quality due to the electrical breakdowns in the electrostatic LEBT. Transition to a magnetic type LEBT is seen as the long term solution and various design improvements are being implemented on the existing LEBT as a temporary fix. The new MEBT chopper deflector has been successfully tested and is in use. In general, losses in the warm linac itself are well under control and should not present any limitations to increasing the average beam power to the design level. A bigger concern is losses in the downstream parts of the machine, possibly caused by the halo generated in the Front End and warm linac. This is a subject of an ongoing research.

## ACKNOWLEDGEMENT

# THE PROPOSED ISAC-III (ARIEL) LOW-ENERGY AREA AND ACCELERATOR UPGRADES

R.E. Laxdal, F. Ames, R. Baartman, M. Marchetto, M. Trinzcek, Fang Yan,
V. Zvyagintsev, TRIUMF*, Vancouver, BC, V6T2A3, Canada

*Abstract*

The ISAC-III proposal (now called ARIEL) is a ten year plan to triple the amount of radioactive ion beam (RIB) time at the facility. The plan includes the addition of two new independent target stations, a second 500 MeV proton beam line from the TRIUMF cyclotron and a new 50 MeV electron linac as a complementary driver to provide RIBs through photo-fission. A new mass-separator and low-energy beam-transport complex is foreseen to deliver the additional beams to the ISAC experimental facilities. A new linear accelerator section would provide the capability for two simultaneous accelerated RIBs to experimenters. This paper will describe the proposed installations in the low-energy transport and accelerator sections of the ISAC complex.

## INTRODUCTION

In the ISAC-I facility[1] 500 MeV protons from the cyclotron at up to 100$\mu$A impinge on one of two production targets to produce radioactive isotopes. The isotopes are ionized and the resulting beam is mass-separated and transported in the low energy beam transport (LEBT) electrostatic beamline to either the low energy experimental area or through a series of room temperature accelerating structures (RFQ, DTL) to the ISAC-I medium energy experimental area. The RFQ accelerates ions with A/q$\leq$30 to 150 keV/u and the post-stripper variable energy DTL accelerates ions with A/q$\leq$6 up to 1.8 MeV/u. The accelerated beam can also be transported to the ISAC-II Superconducting Linear Accelerator (SC-linac)[3] for further acceleration above the Coulomb barrier. An ECR charge breeder (CSB) is presently being added to extend the mass range beyond A=30.

The cyclotron provides the highest power driver beam (50 kW) of any operating ISOL based facility. Two 50 kW target stations are available to reduce the switchover time between targets. But the present scientific output is oversubscribed with more experiments requested than available beam time would allow. The aim of the ISAC-III (ARIEL) proposal is to get more RIBs on target to produce more physics. Fundamental to the plan is the eventual delivery of three simultaneous RIBs to three experimental areas. The expansion requires the addition of two new driver beams - one from a second cyclotron proton beamline and one from a new high power electron linac[2]. Two new target areas with independent separators and a flexible beam delivery system would allow simultaneous operation of three production sources. A new accelerator front end including a second charge breeder provides a second simultaneous accelerated beam capability. The TRIUMF site with the prosposed addition is shown in Fig. 1.

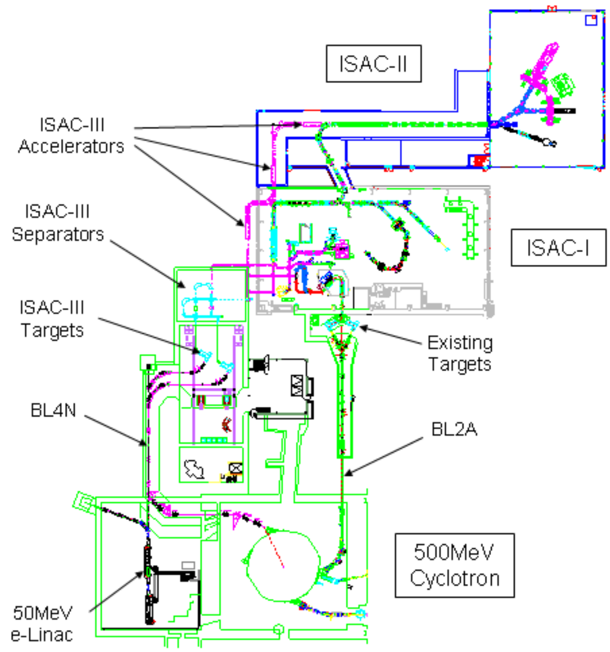

Figure 1: The TRIUMF site including the cyclotron, ISAC-I and ISAC-II and the proposed ISAC-III (ARIEL) facility. BL2A is the present proton line and the BL4N tunnel is proposed for the new ISAC-III driver beams.

## MASS-SEPARATOR SWITCHYARD

It is useful to consider a switchyard that is capable of either low resolution, medium resolution or high resolution separation schemes depending on the experiment. In general reduced resolution schemes are desired since they reduce the tuning time required. The proposed configuration is shown in Fig. 2. Here each of the two target/source units has a pre-separator and individual transport lines directing the beams to a mass-separator switchyard. The beams after separation are directed to either one of two new vertical sections VS-2 or VS-3 for delivery to the upstairs experimental area. Standard ISAC LEBT electrostatic components are used to deliver the beam to either a Medium Resolution Spectrometer (MRS) or a High Resolution Spectrometer (HRS). The medium resolution leg has a resolution of ~2500 while the high resolution leg has a resolution

* TRIUMF receives funding via a contribution agreement through the National Research Council of Canada

of ∼15000. The high resolution leg is equipped with an rf cooler to reduce the transverse emittance and energy spread of the beam before separation. The switchyard is designed with sufficient flexibility that each of the targets can pass beams through the HRS while the beam from the other target is sent to the MRS. In addition a bypass line is available so that if not required a beam with pre-separation only can be sent to the experimental area. A first stage would require only the MRS section and vertical section to transport the single new RIB beam upstairs from the first target.

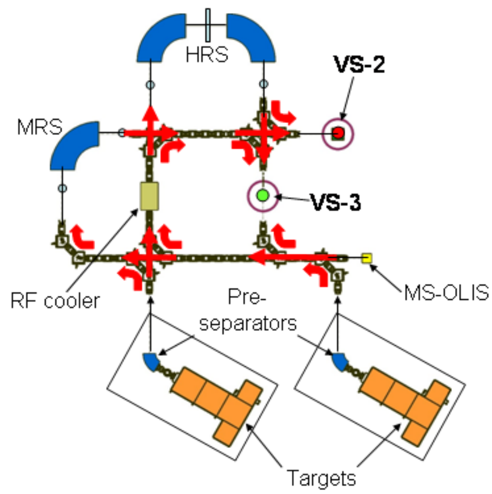

Figure 2: ISAC-III target stations and mass-separator switchyard. The red arrows indicate possible beam paths. An off-line source (MS-OLIS) is available for separator tuning.

## LOW ENERGY BEAM TRANSPORT

The LEBT is the all electrostatic transport that takes the beam at source potential (≤60 kV) from the downstairs target/separator area to the upstairs experimental floor for delivery to the low energy areas or to the accelerators. Substantial LEBT transport has already been installed in ISAC. The design of the new installation will copy the standard building blocks that comprise the present installation. The new installation is designed to provide enough flexibility that any of the target stations, existing or new, can deliver beams to any of the three experimental areas, low energy, medium energy or high energy, so that the RIB beams from each target can be optimized for a given experiment. A second path to the low energy experimental area is provided since this is where there is the largest inventory of experimental infrastructure. The ground floor LEBT for ISAC-III is shown in Fig. 3.

A second charge state booster (CSB2) is added in Stage 1 to increase the charge state of beams selected for acceleration. An extra line is added so that beams from the existing target area can also be boosted in CSB2 if preferable. A second accelerator path is available with the addition of RFQ2 positioned beside the existing ISAC RFQ1.

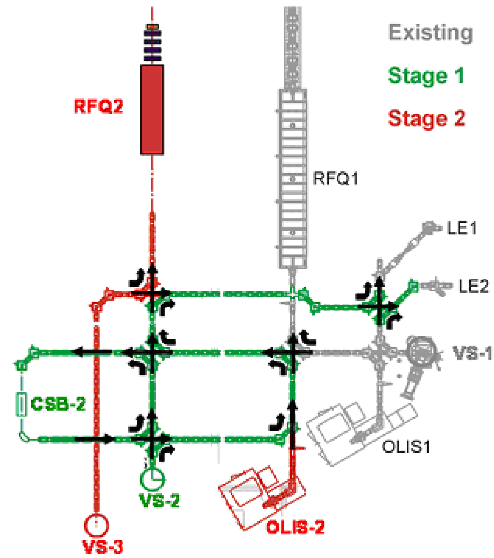

Figure 3: The new ground level LEBT (low energy beam transport) for ISAC-III. The existing section appears in grey. The first stage installation is shown in green and the second stage is shown in red. The black arrows indicate the available beam paths.

A second off line ion source (OLIS2) allows tuning of either accelerator line while delivering RIBs to the other. The LEBT vacuum normally reaches 2e-7 Torr. For transporting the higher charge states from the CSBs the vacuum will be improved to <5e-8 Torr to reduce transmission losses.

## NEW ACCELERATOR LEG

The technique of accelerating a 1+ beam through a series of stripping and acceleration steps was considered but abandoned due to the high total accelerating voltages required. Instead a second charge breeder (CSB2) will be added to boost the 1+ ions from the on-line source. The technical choice for the ISAC-III CSB2 between an EBIS or an ECRIS charge breeder will be made by 2010 after the on-line performance of CSB1 (Phoenix 14.5 GHz ECRIS) with RIB delivery can be evaluated. TRIUMF also has a working EBIS on-site with the TITAN experimental installation. CSB1 produces charge states compatible with A/q≤9 for all masses and this sets the mass specification for the second accelerator leg.

The proposed accelerator addition is shown in Fig. 4. A new RFQ compatible with accelerating ions up to A/q=9 takes the beam to 150 keV/u. A new beamline running north of the existing RFQ will provide separate paths for ISAC-I and ISAC-II accelerated beams avoiding the ISAC-DTL1 bottleneck of 2 ≤ A/q ≤6. A new medium energy transport section incorporates a switchyard that allows sending either of the RFQ1 or RFQ2 beams to either of ISAC-I or ISAC-II simultaneously. The new beamline to ISAC-II will include a room temperature drift tube linac (DTL2) to boost the energy from 0.15 MeV/u to 0.7 MeV/u for beams up to A/q=9. A new low beta cryomodule (SCA) at 106 MHz would further boost the energy to at least 1.5 MeV/u for injection into the existing SC-linac. An optional stripper could be employed between DTL2 and SCA to boost the charge state to achieve a higher final energy.

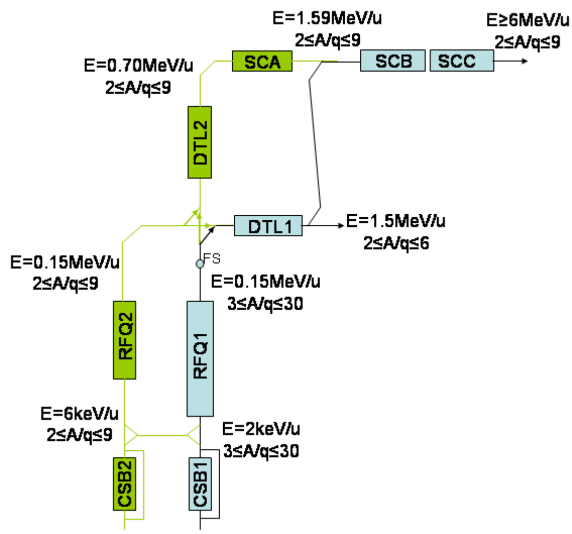

Figure 4: The existing ISAC-1 and ISAC-II accelerator chain in (blue) and the upgrade of the ISAC-III accelerator system in green.

RFQ2 is a room temperature device that accelerates beams from 6 keV/u to 150 keV/u for ions up to A/q=9. The rf structure has not yet been chosen but preliminary beam dynamics have been completed. The rf is specified at 70 MHz with $\Delta$V=1.3 MV. A length of 3.2 m is estimated.

DTL2 is presently specified as a room temperature device at 106 MHz. A four tank IH structure is chosen with magnetic triplets in between tanks for transverse focussing. Design values for number of gaps and rf parameters are shown in Table 1. The DTL is designed to accelerate at 0° synchronous phase with -60° bunching sections in the first several gaps of each tank.

Table 1: DTL2 tank design parameters.

| Tank | $N_{\text{gap}}$ | L(m) | D(m) | V(MV) | P(kW) |
|---|---|---|---|---|---|
| 1 | 10 | 0.28 | 0.92 | 0.83 | 6.1 |
| 2 | 16 | 0.55 | 0.7 | 1.66 | 10.8 |
| 3 | 18 | 0.75 | 0.7 | 2.25 | 11.9 |
| 4 | 21 | 1.04 | 0.7 | 3.13 | 14.3 |

The SCA accelerator section represents the low energy front end to the ISAC-II linac. The injection energy is 0.7 MeV/u and the section accelerates A/q values up to 9. The SCA section is comprised of one cryomodule with eight cavities and three superconducting solenoids for transverse focussing. The cavities are 70 MHz with a design geometry corresponding to $\beta_0 = 4.6\%$.

Initial beam simulations from RFQ2 to the end of the SC-Linac have been completed. The transversal RMS envelopes are shown in Fig. 5. The initial Twiss parameters for the simulation at the exit of RFQ2 are $\alpha_x = 1.3$, $\beta_x = 0.202$ (mm/mrad), $\alpha_y = -1.65$, $\beta_y = 0.283$ (mm/mrad), $\alpha_z = -0.5$, $\beta_z = 10$ (degree/%) with normalized emittances of $\epsilon_{x,y} = 0.3\pi$ mm-mrad, $\epsilon_z = 0.6\pi$ keV/u-nsec. Emittance growth of 10% and 6% are estimated for the full acceleration in the transverse and longitudinal dimensions respectively.

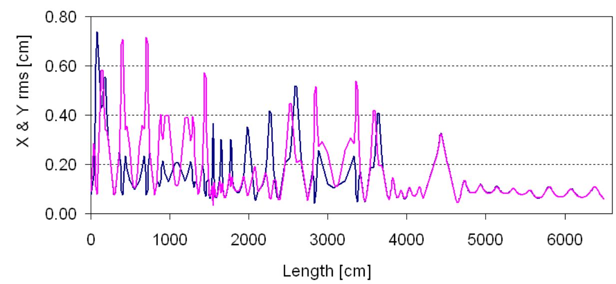

Figure 5: The x (magneta) and y (blue) beam envelopes from RFQ2 to the end of the ISAC-II SC-linac.

## STAGING

The first stage comprising the period 2010-2015 includes the additions of the e-Linac to 50 MeV, 1 mA (50 kW) capability; 25 MeV by the end of 2012, the completion of the new proton line to a capability of 500 MeV, 200$\mu$A (100 kW) by the end of 2014, one new target station with 50 kW electron/proton capability by April 2013, a new medium resolution mass separator (MRS) and low energy beam transport (LEBT) to deliver beams from the new target station to the low energy area by April 2013 and CSB2 and LEBT to allow the acceleration of beams from the new target area by the end of 2014. The second stage through 2015-2020 would include the addition of the upgrade of the e-Linac to 50 MeV, 10 mA (500 kW), a second new target station with 500 kW electron capability, an expanded low energy section with high resolution separator (HRS) allowing simultaneous beams from the two new target areas and a new accelerator front end to allow two simultaneous accelerated beams. Presently ISAC runs at ~2900 RIB hours a year. With ISAC-III this is expected to rise to 6500 by the end of 2014 with a further rise to 10700 by the end of 2019.

*Abstract*

The ISAC-II superconducting linac, operational since April 2006, adds 20 MV accelerating potential to the ISAC Radioactive Ion Beam (RIB) facility. An upgrade to the linac, in progress, calls for the addition of a further 20 MV of accelerating structure by the end of 2009. The new installation consists of twenty 141 MHz quarter wave cavities at $\beta_0$=11%. The cavities will be housed in three cryomodules with six cavities in the first two cryomodules and eight cavities in the last. A second Linde TC50 refrigerator has been installed and commissioned to provide cooling for the new installation. The design incorporates several new features as improvements to the existing cryomodules. A summary of the design and the current status of the cryomodule production and supporting infrastructure will be presented.

## INTRODUCTION

The Radioactive Ion Beam (RIB) facility, ISAC, includes an ISOL production facility and a post-accelerator for delivery of beams from 150 keV/u to beyond the Coulomb barrier.[1] The post-accelerator consists of two room temperature devices, a 35 MHz RFQ for acceleration of ions with A$\leq$30 to 150 keV/u and a 106 MHz post-stripper DTL to energies fully variable from 0.15 to 1.8 MeV/u. A superconducting heavy ion linac[2] was added in 2006 to add a further 20 MV to the ISAC beam energy. The installation known as ISAC-II is the first phase in a planned three phase installation. The Phase I linac consists of 20 bulk niobium quarter wave cavities housed in five cryomodules. Each cryomodule consists of four cavities and one superconducting solenoid arranged symmetrically along the beamline with a diagnostic box and steering magnet located between the modules at the beam waist. Routine average operating gradients of 7 MV/m corresponding to peak surface fields of 35 MV/m are achieved. Eight of the cavities (the first two cryomodules) are $\beta$=0.057 and the other twelve are $\beta$=0.071.

A second phase now in progress will see the addition of another 20 MV of accelerating potential to extend the present energy range by the end of 2009. The new installation consists of twenty 141 MHz quarter wave cavities at $\beta$=0.11. The cavities will be housed in three cryomodules with six cavities in the first two cryomodules and eight cavities in the last. The cavities and cryomodules are now in fabrication. The plan is to install the completed and tested cryomodules during an extended shutdown of ISAC-II starting in Sept. 2009. The layout of ISAC-I and ISAC-II is shown in Fig. 1.

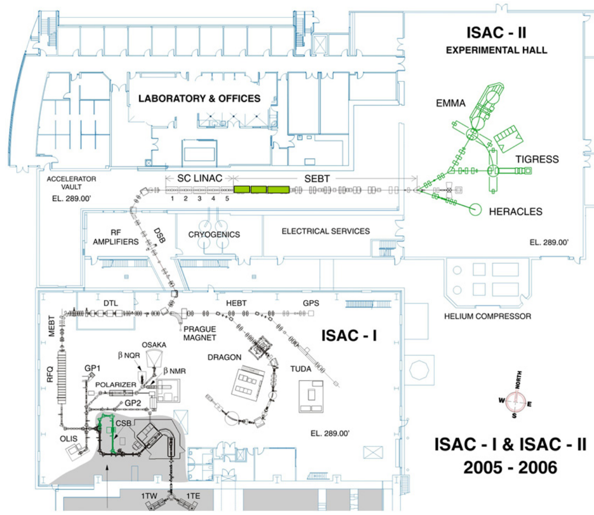

Figure 1: The layout of ISAC-I and ISAC-II. The Phase II SC-linac is highlighted.

## CRYOMODULE DESIGN AND STATUS

The Phase II cryomodules are identical in many respects compared to the Phase I cryomodules. A key design choice was to maintain the philosophy of incorporating a single vacuum space for thermal isolation and beam/rf volumes. This has been the historic choice in the low-beta community (ATLAS, INFN-Legnaro, JAERI) but recent proposed facilities in development or assembly have chosen separated vacuum systems (SARAF, SPIRAL-II, FRIB). The decision to maintain a single vacuum comes from our experience with Phase I operation of the SC-linac. We have seen very little evidence of degradation in cavity performance over the first two years of operation even after repeated thermal and venting cycles. Procedures are followed to help mitigate cavity degradation: 1. Initial cavity treatment and overall assembly using HPWR and clean conditions 2. Vacuum materials and components to be free from particulate, grease, flux and other volatiles 3. Maintain a LN2 cooled cold trap upstream and downstream of the linac to prevent volatiles migrating from the beamline into the cryomodule 4. Cryomodule venting with filtered nitrogen 5. Pumping and venting of modules at slow rates to avoid turbulences.

All cryomodules are assembled in a ‘dirty’ assembly area to check the fitting of all components. Next the assembly is completely dismantled, all parts are cleaned in

* TRIUMF receives funding via a contribution agreement through the National Research Council of Canada

an ultrasound bath, rinsed with 18 MΩ water at high pressure and dried in a clean room before assembly.

There are some differences between the Phase I and Phase II cryomodules that either address small deficiencies in the Phase I design or are required due to the longer size of the Phase II cryomodules: 1. The vacuum tanks are essentially the same with dimensional differences to accommodate the internal components. The eight cavity SCC3 has an extra set of ribs on the lid and sides to reduce vacuum deformation on the larger areas. The mounting footprint is also elongated to give more stability. 2. The cavities and solenoid are supported from a rigid strongback that is in turn supported from the tank lid by support rods. In the SCB cryomodules a three point mounting system was used to suspend the strongback. The decision here is to adopt a four point system to reduce the freedom in the movement of the cold mass. The strongback assembly is considerably more robust than in the SCB due to the increased cold mass and length. 3. In the SCB the LN2 cooling for the side shields and the coupling loop is one series circuit. In the SCC the delivery to the coupling loops is achieved with parallel channels to reduce the size of the fittings on the coupling loop. 4. The solenoid mounting system is completely modified in SCC and is based on a linked strut system to aid in alignment. 5. The helium reservoir is redesigned with thicker wall material and a purchased tee section. Bulkheads are incorporated into the weld seams to make all welds external. The service stack for the helium space is now outfitted with a 12.5 cm high spool piece with the feedthroughs and ports for all of the cryogenic and vacuum diagnostics. Provision for level sensor replacement has been added with ports on the top of the reservoir. Cables and He distribution lines are installed before final weld on each end of the reservoir. The welding is done in place of the SCB indium seals that were prone to cold leaks. 6. The mu metal thickness has been increased from 1 mm to 1.5 mm.

### *Present Status*

All three vacuum chambers and lids have been received. Mu metal has been installed on two of the vacuum chambers. The LN2 side shields panels have been fabricated and the shield box assembly is almost complete. Dirty assembly of the first cryomodule is underway. The effect of the mu metal has been characterized and reaches the specified remnant field criterion of <20mG.

## SUPERCONDUCTING CAVITIES

The cavities for Phase II are quarter wave bulk niobium with features similar to the Phase I cavities. In this case the rf frequency of 141.4 MHz (the 12th harmonic of the bunch frequency 11.8 MHz) allows to keep the same outer conductor dimension while increasing the design velocity to $\beta$=0.11. The cavity has been outfitted with a beam tube (donut) to symmetrize the transverse rf fields and improve the transit time factor. The cavity is shown in Fig. 2.

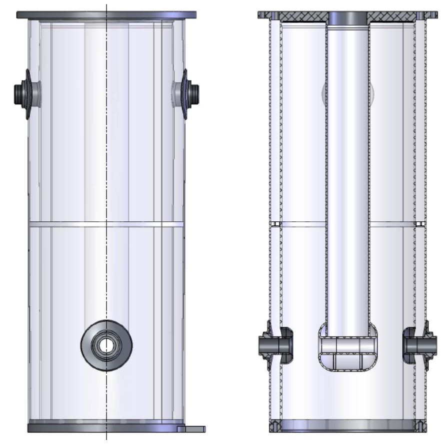

Figure 2: The 141.44MHz rf cavity for Phase II.

The cavities are being produced by Pavac Industries of Richmond BC Canada. The development included the manufacture of two full size copper models to study all of the machining, assembly, tuning and welding steps. Two Niobium cavities have been produced.[3] The cold test results of the two prototypes are shown in Fig. 3. Note that the ISAC-II specification of $E_a = 6$ MV/m at 7W ($E_p$=30 MV/m) is exceeded by a comfortable margin with average values of $E_a = 8.5$ MV/m ($E_p > 40$ MV/m). PAVAC is presently completing the first six production cavities as well as machining the rest of the parts for the remaining fourteen cavities in preparation for welding.

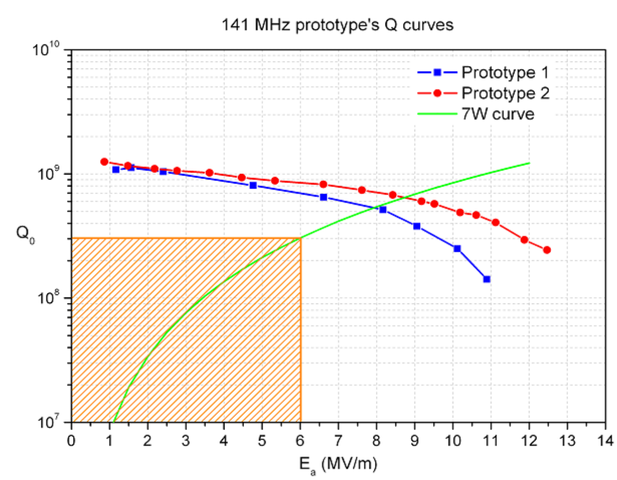

Figure 3: Characterization curves of the two 141 MHz QWR cavities.

## RF ANCILLARIES

### *Amplifiers*

As part of the upgrade of the ISAC-II superconducting linac, twenty solid state amplifiers have been ordered with QEI Corporation, NJ, USA. A prototype amplifier has been tested thoroughly prior to series production. The gain of the amplifier, the 3 dB bandwidth and output power were measured and are within the specification. Gain linearity is within $\pm 0.5$ dB and phase linearity is within $\pm 2.0$ dB for the output power range from 1 to 250 watts. The amplifier gain is measured to be $65 \pm 0.75$ dB, which is 10 dB higher than specified. The phase noise of the prototype amplifier is estimated by tests into both a dummy load and one of the prototype cavities. These measurements are compared to the same values using a tube amplifier. The solid state amplifier is significantly less noisy than the tube amplifier. For the solid state amplifier the average noise value is 0.0044° rms in the frequency range of 2-200 Hz. The average noise for the tube amplifier in the same frequency range is 0.098° rms. The integrated value of phase noise in the bandwidth of $2 - 200$ Hz was specified to be less than 0.3° rms. These amplifiers will be installed in the power supply room adjacent to the accelerator vault.

### *Mechanical Tuner*

In the Phase I system the cavities are tuned by a lever arm that pushes against a tuner plate on the bottom end of the cavity. The lever arm is actuated by a long push rod that extends to the top of the cryomodule through a bellows to a linear servo motor[4]. The system works well and provides high performance tuning for high gradient operation. The tuner motor is an expensive item and development work subsequent to the Phase I installation has resulted in a new design using a ball screw drive to replace the linear motor. The brush-less servomotor contains its own single turn absolute sine encoder. The power and encoder signals are connected through long cables to a matched digital servo-amplifier. The output shaft of the motor is connected directly to the anti-backlash internally preloaded precision ball screw nut, through a stiff bellows coupling. The anti-backlash nut is fixed rigidly to the anti-backlash liner guides that provide perfectly reproducible vertical straight-line motion resulting in a vertical position resolution of at least 0.03 $\mu$m with a positioning bandwidth of at least 30 Hz. The interface connections are designed to retrofit the SCB low beta SRF tuner rod connector design.

### *Coupling Loop*

The SCB variable coupling loop[5] uses a Teflon bearing but side loads from the LN2 cooling lines cause some stiffness in the mechanical motion at cold temperature. A redesigned coupling loop with non-magnetic cross-roller bearings and symmetric loading has greatly improved the mechanical motion and the new design is being employed in SCC.

## CRYOGENIC SYSTEM

The Phase I cryogenic system consists of a Linde TC50 cold box configured with a 79 gm/sec KAESER compressor. Helium produced in the cold box is fed to a 1000 liter dewar. The LHe is delivered to the cryomodules at 4K through vacuum jacketed LN2 cooled helium transfer lines with a slight overpressure in the dewar. The cryomodules are fed in parallel from a main supply manifold (trunk) through variable supply valves. The level in the cryomodules is used to control the opening of the supply valves. The vapour from the cryomodules is returned either in a warm return line direct to the compressor during cooldown or through a cold return line back to the cold box during normal operation.

The Phase II addition of the cryogenic system (shown in Fig.4) essentially duplicates the Phase I system. A second Linde plant has been installed identical in every respect to Phase I except that a second recovery compressor was not ordered. The system has been installed by TRIUMF and commissioned. The measured liquefaction with LN2 precool is 240 ltr/hour and the refrigeration power is 600 W. The stability of the helium pressure is within $\pm 7$ mBar.

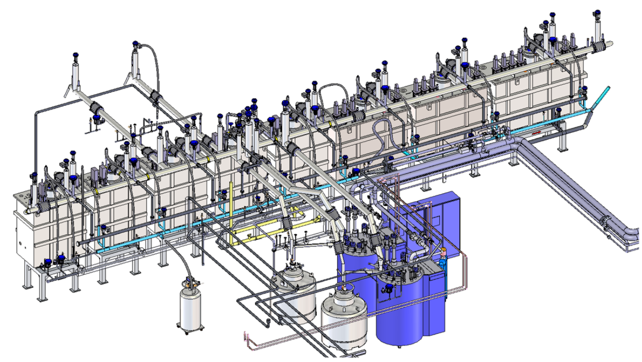

Figure 4: The cryogenics system for ISAC-II Phase I and II.

## SUMMARY

The phase II system is on schedule for completion by the end of 2009. The first six cavities are expected by the end of October. The cavities will be processed (BCP) and tested at TRIUMF before mounting into the first cryomodule for cryogenic and alignment tests. The other two cryomodules will follow with full installation by Dec. 2009.

*Abstract*

For injection into the ion trap facility HITRAP, the GSI accelerator complex has the unique possibility to provide beams of highly stripped ions and even bare nuclei up to Uranium at an energy of 4 MeV/u. The HITRAP facility comprises linear 108 MHz-structures of IH- and RFQ-type to decelerate the beams further down to 6keV/u for capturing the ions in a large penning trap for cooling purpose. The installation is completed except the RFQ.

During commissioning periods in 2007 $^{64}Ni^{28+}$ and $^{20}Ne^{10+}$ beams were used to investigate the beam optics from the experimental storage ring extraction to the HITRAP double-drift-buncher system. In 2008 the IH-structure and the downstream matching section were examined with $^{197}Au^{79+}$ beam. Comprehensive beam diagnostics were installed: Faraday cups, tubular and short capacitive pick ups, SEM grids, YAG scintillation screens, a single shot pepper pot emittance meter, and a diamond detector for bunch shape measurements. Results of the extensive measurements are presented.

## INTRODUCTION

Within the HITRAP project (Heavy Ion Trap) [1] trapped and cooled highly charged ions up to $U^{92+}$ will become available for a variety of attractive experiments in atomic physics. As presented in Fig.1 heavy ions are produced, accelerated, and stripped in the GSI accelerator complex and are stored, decelerated, and cooled in the ESR (Experimental Storage Ring) down to 4 MeV/u. After extraction from the ESR, the ions have to be further decelerated down to 6 keV/u by 108.408 MHz structures [2,3]. An IH drift tube cavity operating in the H11(0) mode reduces the ion energy to 0.5 MeV/u and a 4-rod RFQ [4] degrades it finally to 6 keV/u. Phase matching into the IH structure is prepared by a DDB (Double-Drift-Buncher combination) of λ/4-resonators whereof the second one works at 216 MHz. A third rebuncher of spiral type is located between the decelerator tanks. Finally a low power spiral type debuncher integrated into the RFQ tank at the beam exit end reduces the beam energy spread for efficient beam capturing in the super conducting penning trap. The linear decelerator as sketched in Fig. 1 is installed in the re-injection channel between ESR and SIS (Heavy Ion Synchrotron).

## STATUS OF INSTALLATIONS

Until September 2008 the HITRAP decelerator was being constructed except the RFQ tank. Magnet power

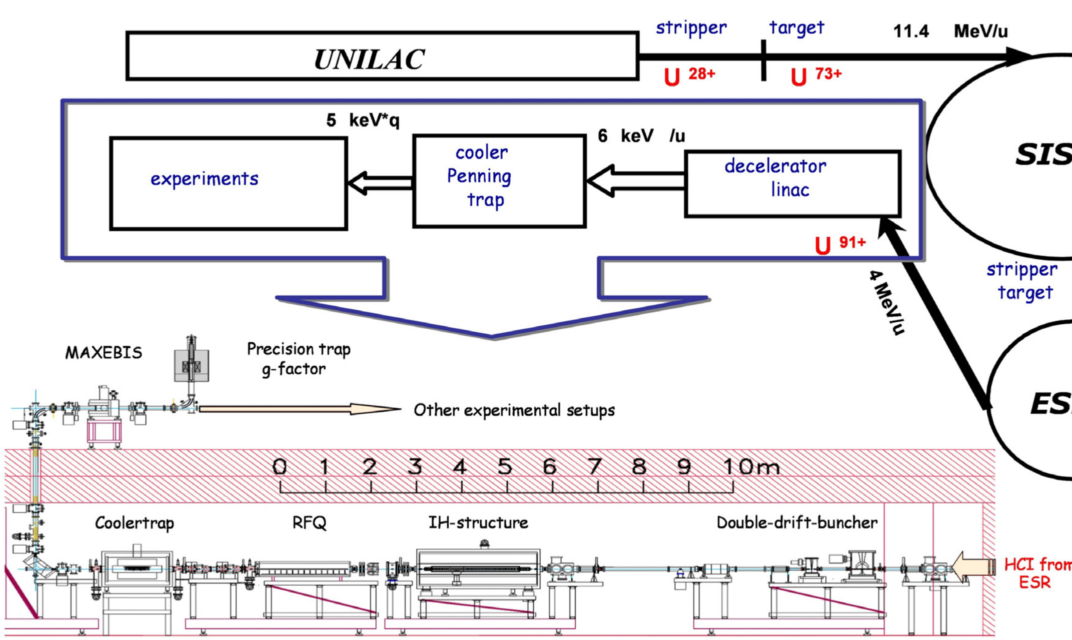

Figure 1: Production process of bare nuclei and HITRAP decelerator.

# l.dahl@gsi.de

converters and rf amplifiers are in operation as well as beam diagnostics and controls. The bunchers are fed by solid state amplifiers up to 5 kW power and could be commissioned without major problems. The decelerator cavities run by 200 kW tube amplifiers from GSI stock.

The commissioning of the IH tank [5] including bead pull measurements and rf power conditioning was done in a rather short time. Fig. 2 shows the gap voltage distribution as calculated by MWS® (Micro Wave Studio) compared to the measured one. The drop corresponds to the position of the inner quadrupole triplet lens. The deviations cause an output energy 30 keV/u higher than the 500 keV/u design value. Final adjustment of the voltage distribution will be done later by undercut tuning. The overall effective deceleration voltage is 10.5 MV.

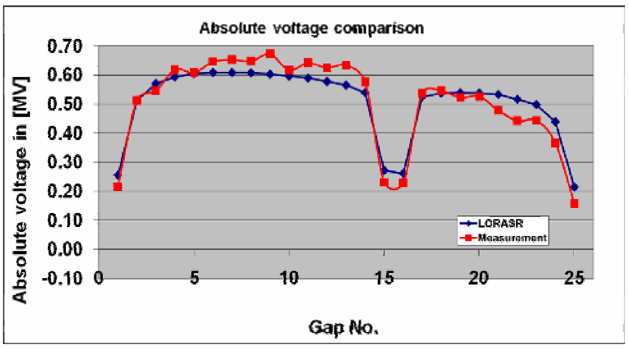

Figure 2: Measured (red) and calculated (blue) field distribution of the IH decelerator.

Table 1 shows the rf parameters of the IH structure. The measured values are very close to the calculated ones. The rf power consumption for the highest beam rigidity of mass/charge = 3 including 10 % reserve stays clearly below the limit of performance of the existing amplifiers.

Table 1: Parameters of the IH Decelerator Tank

| Parameter | layout geometry calculated | actual geometry calculated | measured |
|---|---|---|---|
| f [MHz] | 108.408 | 108.69 | 108.661 |
| Z eff [MΩ/m] | 263.3 | 264.9 | 270.2 |
| rf-power [kW] | 179.6 | 178.5 | 174.9 |
| $Q_0$ (MWS) | 21,948 | 22,163 | 22,529 |

Table 2: Measured RF Parameters of Bunchers and RFQ

| Resonator | Q | Zeff [MΩ/m] | Ueff [kV] | required rf power [kW] |
|---|---|---|---|---|
| DDB 108 MHz | 10,950 | 51.70 | 220.00 | 1.99 |
| DDB 216 MHz | 11,100 | 43.01 | 76.00 | 0.56 |
| Re-buncher 108 MHz | 5,300 | 28.60 | 105.00 | 1.92 |
| RFQ 108 MHz | 3,700 | 138.00 | 77.50 | 82.69 |
| De-buncher 108MHz | 2,700 | 15.50 | 0.40 | 0.00015 |

The RFQ tank is already placed in the HITRAP cave apart from the beam axis for high power rf conditioning. Table 2 summarizes measured properties of the bunchers and the RFQ and the resulting rf power consumption.

## COMMISSIONING MEASUREMENTS

The beam line from the ESR extraction to the HITRAP DDB section contains comprehensive beam diagnostics: Faraday cups, one tubular and two short capacitive pick-ups, three SEM grids, and four YAG scintillation screens. A single-shot pepper pot emittance meter [6] was used in the final temporary diagnostic setup containing also a diamond detector for pulse shape measurements.

In the first commissioning period in May 2007 the functionality of all components and controls was checked. The $^{64}Ni^{28+}$ beam was transported through the DDB without rf operation as an acceptance test. Operational experience showed that two additional vertical steering magnets are necessary to improve the beam transmission through a diaphragm mounted to decouple the ESR vacuum of ~$10^{-9}$ Pa from the ~$10^{-6}$ Pa in the decelerator.

During the second commissioning period in August 2007 with a $^{20}Ne^{10+}$ beam of 2 μA pulse current and 1.6 μs length the bunchers were in operation. No beam loss was measured up to the tubular pick-up behind the diaphragm. Negligible losses occurred at the narrow apertures of the buncher cavities. The capacitive pick-ups between the two bunchers and behind the second buncher generated bunch signals according to the 108 MHz operating frequency (Fig. 3).

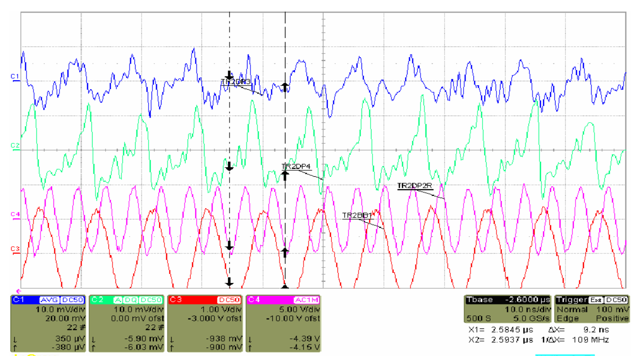

Figure 3: Top: two pick-up signals, bottom: rf signals of the 108 and 216 MHz bunchers.

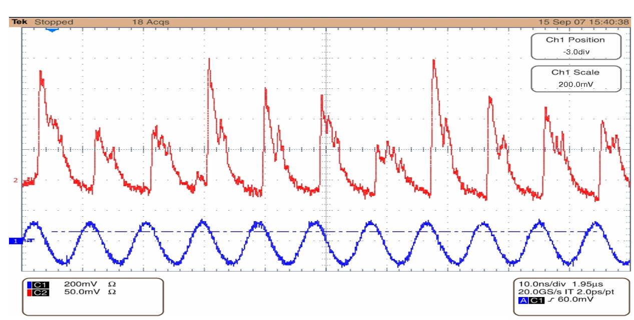

Figure 4: Top: 108 MHz bunches measured with the diamond detector, bottom: the 108 MHz reference signal.

The diamond detector turned out as an excellent diagnostic tool to optimize the bunch length. The extended fall time of the bunch signals (Fig. 4) is caused by amplifier discharge. The transverse emittance was measured by two methods, pepper pot [6] and scintillation screen combined with quadrupole variation. The results of $\varepsilon_{xrms}$ = 1.7 and $\varepsilon_{yrms}$ = 2.0 mm·mrad for 90 % of the intensity are in agreement with calculations. The successful commissioning of the DDB section allowed following up the installation of the IH tank and the matching section downstream.

For the third commissioning period in August 2008 a cooled $^{197}Au^{79+}$ beam was provided by the ESR. The investigations focused on the beam deceleration through the IH tank. Unfortunately the beam intensity at ESR extraction was only 300 nA and 200 nA at the final diagnostics station for both cases, with and without rf cavity operation. Nevertheless, using four YAG scintillation screens (Fig. 5) matching of the beam through the whole HITRAP with several narrow drift tube aperture limitations was possible comfortably.

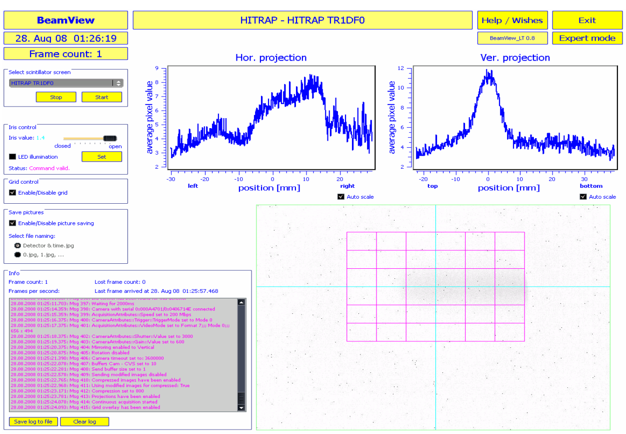

Figure 5: Screen shot of a YAG scintillation target.

The beam intensity was too low for proper capacitive pick-up signals. Therefore calibration measurements were done mainly by diamond detector signals. Fig. 6 shows typical oscilloscope signals of the tubular pick-up in front of the DDB and a Faraday cup behind the IH tank.

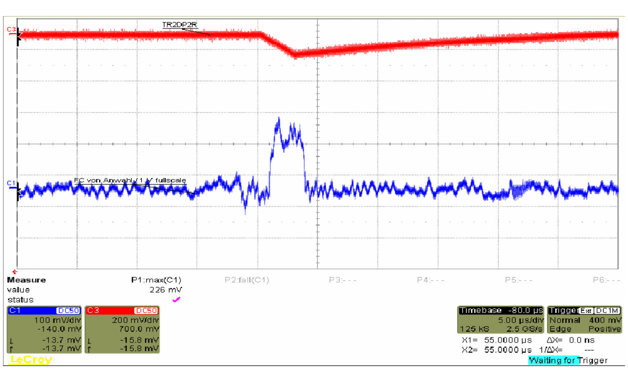

Figure 6: Top: signal of the tubular pick-up in front of the DDB, bottom: signal of a Faraday cup behind the IH tank.

In an elaborate procedure the working points of the DDB were determined by measuring the bunch width behind the IH tank. Afterwards rf power for the IH cavity was switched on and phase and amplitude settings were scanned to determine the working point of this structure. In the meantime the amplifiers of the diamond detectors were exchanged resulting in shorter fall times. Fig. 7 shows the decelerated and well shaped bunches in time distances of 9 ns for the working point settings of the DDB and IH cavity.

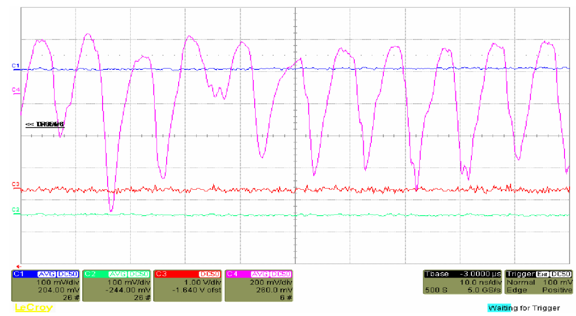

Figure 7: Inverted diamond detector signal of a 108 MHz bunch series behind the IH tank, DDB and IH switched on.

## CONCLUSIONS AND OUTLOOK

Within the three commissioning periods the technical and physical functionality of the HITRAP was proofed. No major problems occurred. Additional magnetic steerers turned out to be necessary for proper beam transport tuning. The setting was slightly modified by experience, and the working points of the rf structures were fixed. An uncertainty of the IH decelerator output energy remained. The next commissioning period in October 2008 will focus on this subject. For improved energy analysis a bending magnet and an extra scintillation screen will be installed behind the IH tank. Due to an expected higher beam intensity of the $^{64}Ni^{28+}$ beam also capacitive pick-up signals will be evaluable. The RFQ high power conditioning already began. The tank will be installed on beam axis in autumn. The final HITRAP commissioning beam time focusing on the last deceleration stage by the RFQ will take place in the first months in 2009.

Variable Energy Cyclotron Centre, 1/AF Bidhan Nagar, Kolkata 700064, India

## [illegible]

An ISOL (Isotope Separator On Line) type of RIB (Rare Ion Beam) facility is being developed at our centre. The post-acceleration scheme will consist of a Radio Frequency Quadrupole (RFQ) followed by a few IH LINAC cavities - further augumentation of energy using SC QWRs will be taken up at a later stage.

The first two IH cavities have been designed for 37.6 MHz frequency like the preceding RFQ to keep the RF defocusing smaller. Explosively bonded copper on steel has been used for the fabrication of the IH cavities and the inner components have been from of ETP grade (UNS C11000) copper. Also, we have adopted an octagonal cross-section for the cavity structure to avoid fabrication complicacies. The first and second cavity have inside lengths of 0.62 and 0.97 m respectively and the inside separation between two opposite sides of the octagon is 1.72 m.

Thermal analysis of the cavities has been carried out and cooling configurations have been optimized accordingly to control the temperature rise of the LINACs. Detailed mechanical analysis has been carried out to reduce the deflection of the LINAC components under various loads.

Design and fabrication aspects of these two cavities and results of the low power tests will be reported in this paper.

## INTRODUCTION

Rare Ion Beams (ions of $\beta$-unstable nuclei) offer many new possibilities in different branches of accelerator based research. An ISOL type of RIB facility is being developed at our centre [1]. Light ion beams ([illegible], $\alpha$) from the K=130 cyclotron will be used as a primary beam for this facility. Also an electron LINAC is being developed at present which will open up the possibility of producing RIBs using photofission route. The primary reaction products will be ionised using an on line ion source and mass separated to choose the RIB of interest from the other reaction products. The RIBs will be accelerated from 1-97.5 keV/u using a heavy ion RFQ [2, 3, 4] operating at 37.6 MHz. Further acceleration up to 1.2 MeV/u will be done using IH LINAC cavities. The first two of these cavities have been designed and fabricated. Low power tests have also been performed. Design and fabrication aspects of these two cavities and results of the low power tests will be reported in this paper.

## DESIGN REQUIREMENTS

The initial energy of the RIBs after the mass selection is 1.7 keV/u. The RIBs will be accelerated in stages - the first post-accelerator is a RFQ which accelerates up to about 98.7 keV/u at 37.6 MHz, followed by two IH cavities at the same frequency to reach 287 keV/u - all of them are designed for $q/A \geq 1/14$. This will be followed by one IH cavity designed for 75.2 MHz to reach 409.1 keV/u. There will be a charge stripper at this stage and this will be followed by three more IH cavities designed for $q/A \geq 1/7$ to reach around 1.2 MeV/u. Further acceleration using QWRs are being planned at present.

The intensity of RIBs is a prime concern as it is significantly lower than stable ion beams in most of the cases. So, the LINACs have been designed for high transmission efficiency of the ions. Many experiments require measurement of parameters at various energies and therefore the aim is to continuously vary the energy of the beam without significant loss of intensity or degradation of beam quality (spot size and energy width).

## DESIGN PRINCIPLE

The acceleration method adopted in our design consists of classical negative synchronous phase small length LINACs with transverse focusing quadrupole triplets in between the cavities. Buncher cavities will also be accomodated where need arises. The cell parameters of the LINACs have been calculated by tracking trajectory of an ion having designed values of phase and velocity by integrating its equation of motion using static electric field obtained from [illegible] code for a particular drift tube geometry – ignoring the details of the drift tube supports, ridges and cavity. With this drift tube (DT) and gap geometry, the cavity parameters have been optimised using [illegible] The detailed beam dynamics have been studied using interpolated field from [illegible] using [illegible] code. Details of this design principle has been reported elsewhere [5].

The important parameters for the first two IH cavities are shown in Table 1. The frequency of first two LINACs has been kept same as that of RFQ to keep the RF defocusing smaller for low input energy. The shunt impedance and Q-values of the table are [illegible] results and the power has been calculated for a 60% shunt impedance value. The beam energy can be veried without any significant loss of intensity or degradation of beam quality. Fig. 1 shows two possible tunes for 286.8 keV/u energy - the case for good transmission (top) and good beam quality (bottom). This has of course still room for improvement by reducing the inter-tank separation.

Table 1: Important parameters of frst two IH cavities

| Parameter | Unit | LINAC-1 | LINAC-2 |
|---|---|---|---|
| Frequency | MHz | 37.6 | 37.6 |
| q/A | | $\geq 1/14$ | $\geq 1/14$ |
| $T_{in}(\beta_{in})$ | keV/u | 98.8(1.46) | 183.6(1.98) |
| $T_{out}(\beta_{out})$ | % | 183.6(1.98) | 286.8(2.48) |
| Gaps | | 9 | 10 |
| DT ID | mm | 25 | 25 |
| DT OD | mm | 69.5 | 60 |
| Gap length | mm | 29.2 | 39.8 |
| Peak potential | kV | 101.24 | 107.5 |
| Max. field | $E_{Kil}$ | 1.4 | 1.3 |
| Sync. phase | | -24° | -25° |
| Cavity length | m | 0.618 | 0.871 |
| Accln. gradient | MV/m | 2.102 | 1.79 |
| Shunt impedance | MΩ/m | 342 | 432 |
| Q-value | | 13765 | 18963 |
| RF power | kW | 19.9 | 16.4 |

The two cavities have been fabricated using explosively bonded copper (grade ETP or UNS C11000) on steel (grade SS304L or UNS S30403 ). Also, bending of copper bonded with steel has been avoided using an octagonal cross-section of the cavity. Each of the ridges and drift tubes have been fabricated from single block of ETP grade copper.

The thermal load on the cavity has been calculated from RF analysis and used for the optimisation of cooling channels of the LINACs using adequate safety factor. A typical example of such analysis is shown in Fig. 2. In the worst case scenario, there may be a temperature rise of about 15°C at some locations within the cavity. The LINACs are subjected to loads due to atmospheric pressure, gravity and temperature distribution. The deformations may affect the alignment of the drift tubes and the end gaps of the LINACs. The thickness of the materials of the cavity and the end covers have been optimised to reduce this effect. In addition, circular reinforcements have been incorporated on the end covers and optimised to further minimise this effect. A typical simulation is shown in Fig. 3.

## FABRICATION & ALIGNMENT

The cavity has been fabricated by full penetration TIG welding of the steel plates by removing copper close to the welding joints. Adequate precautions have been taken to minimise the distortion during welding. After the fabrication, the faces of octagon on which ridges are supported have been machined to get the desired flatness, parallelism and equal distance from the centerline. Entire final machining job of the cavity with end plates have been done in a single setting of CNC machine. All inner components have also been machined using CNC. After the machining, the drift tubes were placed and their center line deviations were measured using optical theodolite with proper target fixtures. The final machining of drift tube bases were done based on the initial measurement data. The drift tubes could be aligned within an accuracy of 150 $\mu$m and the drift tube gaps have been maintained within $\pm 50$ $\mu$m. Fig. 4 shows the LINAC-1 during final assembly.

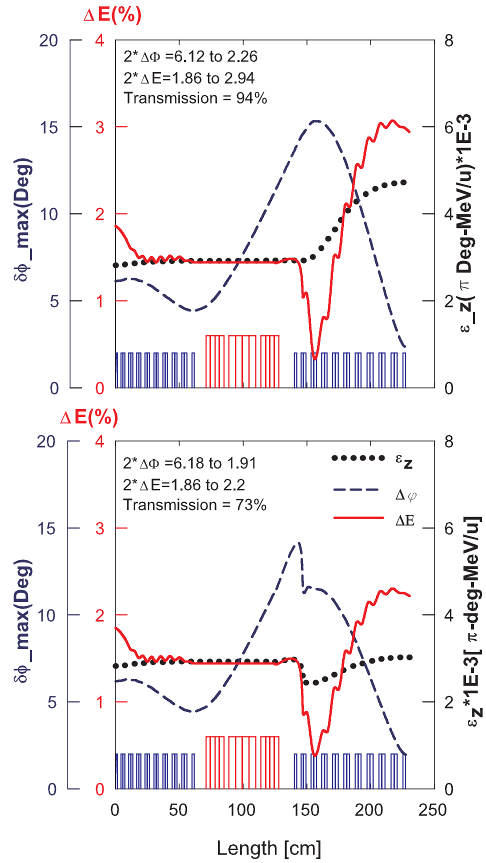

Figure 1: A typical tune through two LINAC cavities showing the variation of rms energy width, phase width and longitudinal emittance growth.

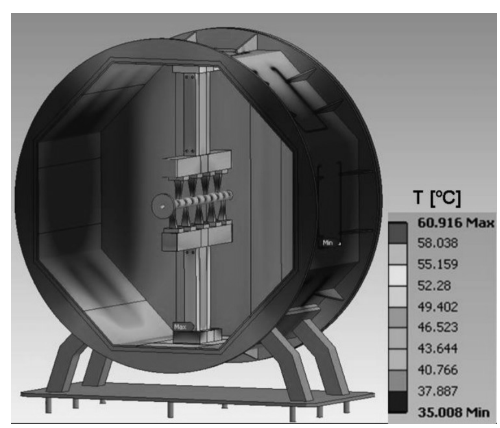

Figure 2: Temperature profile of LINAC-2 calculated using ANSYS.

Both LINAC-1 and LINAC-2 have passed the vacuum

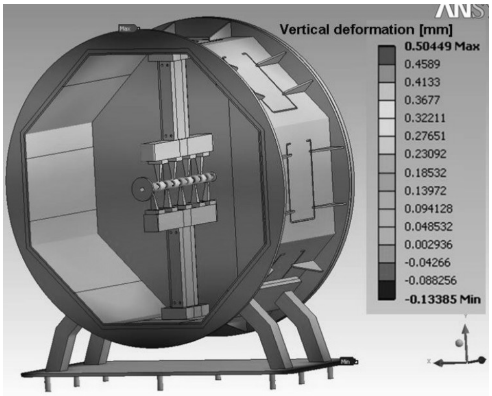

Figure 3: Structural deformation of LINAC-2 calculated using ANSYS.

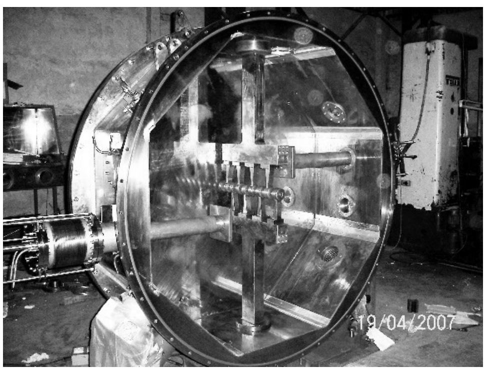

Figure 4: LINAC-1 during assembly.

performance test. Each of the LINACs with their inner components have been leak tested and no local leak could be traced up to a level of 1E-9 mbar-LPS. Both of them have been pumped using two 500 LPS turbo drag pumps after initial pumping using dry pumps. LINAC-1 reached a vacuum of 1.4E-6 mbar after about 1 week of pumping after the final cleaning. LINAC-2 reached a vacuum of 2.7E-6 mbar after about 24 Hours of pumping at manufacturer's site before the final cleaning. The performance is likely to improve significantly after the RF conditioning.

## LOW POWER TEST

Both LINAC-1 and 2 were initially assembled at manufacturers site and RF measurements were done. LINAC-1 has been throughly cleaned in our site and assembled again and RF tests have been repeated again and it is ready for putting into operation. Results of these measurements are shown in Table 2. The frequency measurements are within 0.3% of the calculated values. The measured $Q_0$ values for LINAC-1 and 2 are 59% and 35% of the calculated values. A significantly lower value of $Q_0$ for LINAC-2 is due to the facts that many of its inner components were not having the required surface finish at the time of testing and also no RF springs were used during testing. The $Q_0$ value has significantly increased to 71% of the calculated value when LINAC-1 has been assembled after through cleaning and putting RF contact at all joints. We expect similar result for LINAC-2 also.

Table 2: Important parameters of frst two IH cavities

| LINAC | Freq. [MHz] | | $Q_0$-value | |
|---|---|---|---|---|
| Number | Calc. | Meas. | Calc. | Meas. |
| 1 | 37.695 | 37.75 | 13765 | 8073 |
| 2 | 37.861 | 37.75 | 18963 | 6687 |

The electric field on the axis of LINAC-1 has been measured using bead perturbation technique. In which a dielectric bead was made to move along the drift tube axis in small steps and the frquency deviation was calculated using network analyser. Results of this measurement is shown in Fig. 5 where the □□□□□calculated field is also shown.

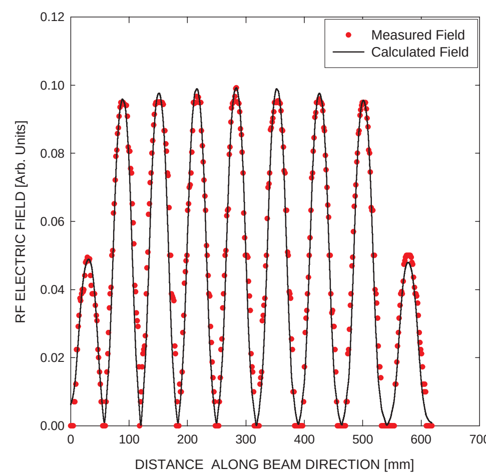

Figure 5: Results of bead perturbation measurement of LINAC-1.

*Abstract*

An ISOL type Rare Isotope Beam (RIB) Facility is being developed at VECC, Kolkata around the existing K=130 room temperature cyclotron. In the first stage, the beam energy will be about 400 keV/u using an RFQ pos-accelerator and three modules of IH-linacs. Subsequently the energy will be boosted to about 1.3 MeV/u. A separate LEBT line for material science experiments is planned. Some of the systems have already been installed and made operational. The LEBT line has been tested and stable ion beams accelerated to 29 keV/u with high efficiency in a 1.7 m RFQ. A 3.4 m RFQ and the first IH Linac tank are under installation in the post-acceleration beam line. In this contribution an overview of the present status of the facility will be presented.

## INTRODUCTION

An ISOL type RIB facility is presently under construction at VECC Kolkata [1]. The K=130 cyclotron at VECC will act as mother accelerator for this facility. A schematic layout of the facility is shown in figure 1. The 1+ radioactive ions will be produced inside a thick target integrated ion-source, injected into an on-line Electron Cyclotron Resonance Ion source (ECRIS) for high charge state ionization, mass separated and then post accelerated in a Radio Frequency Quadrupole (RFQ) Linac and IH-Linacs. The production target and ECR based charge-breeder system lead to two beam lines. The first one, a low energy beam transport (LEBT) line is already installed and presently delivers stable ion beams of 29 keV/u energy at the end of a 1.7m RFQ linac. The second, post-acceleration beam line will accelerate the beams to 1.3 MeV/u using a longer, 3.4 m RFQ and a series of IH linear accelerators. In the first stage, the beam energy will be about 400 keV/u using three modules of linacs.

## DESCRIPTION OF RIB FACILITY

### *Target Ion-Source*

The first component is the Integrated Ion source. Radioactive nuclei will be produced inside thick targets using proton and α-particle beams from the K=130 cyclotron at VECC and ionized to 1+ charge state in the integrated surface ionization source. A possibility of using a multiple target Electron Beam Plasma ion-source is also being worked out. The low energy 1+ ion beam from the first ion-source will be injected into the ECR ion source for higher charge state (n+) production in the *charge breeder*.

We have undertaken a target R&D programme as we need to develop many kinds of thick targets for our facility. Since diffusion of radioactive species out of the target increases with temperature one usually selects refractory target compounds such as oxides and carbides for the target. Target materials can be deposited on Graphite matrices (RVCF fibres) that can withstand high temperature and have sufficient porosity to allow radioactive atoms to diffuse out [2].

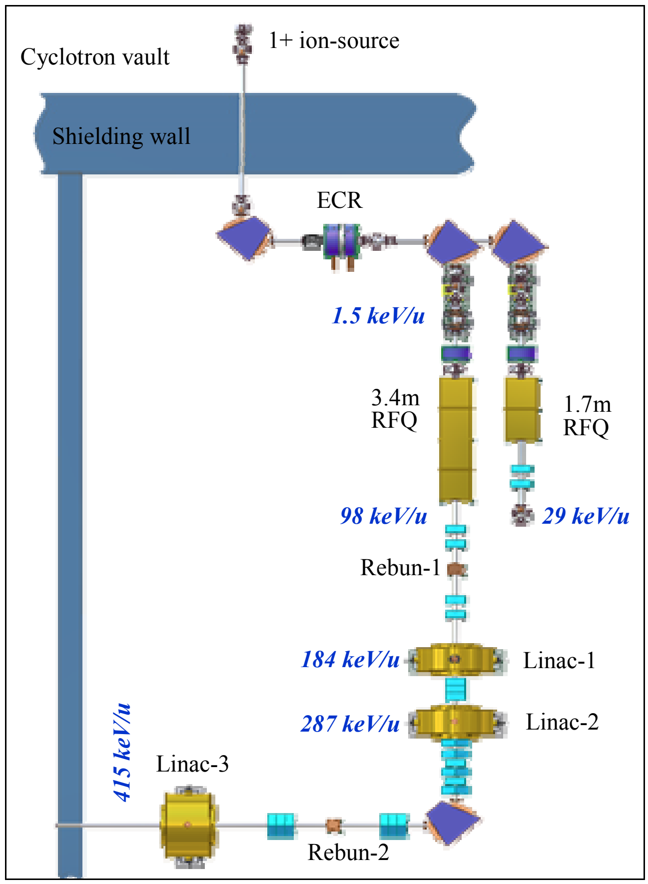

Figure 1: Layout of RIB facility.

Sintering & grain growth due to beam heating hinders the release of radioactive ions. Studies have shown that grain growth stays within limiting range if one starts with grain size of nano-metre range. Recent studies in case of ZnO have revealed that formation of a composite phase (Zinc silicate) resist the grain growth within the permissible limits even for 6 hrs heating at 1300 C[3].

*This is a VECC-DAE project

### *The Charge Breeder*

The radioactive ions have to be ionized to higher charge state with good enough efficiency in order to accelerate a wide range of RI beams. In the "two-ion source" concept the beams are ionized to 1+ charge in the integrated target-ion source and then injected into the on-line ECRIS for further ionization to higher charge state n+.

The beam transport line between the integrated target surface ionization source and the *ECRIS* incorporates a dipole, for selection of $1^+$ beam. The beam transport design ensures that the beam extent lies within the plasma region of ECR and also $1^+$ beam get properly trapped in the ECR [4]. To keep the ECR volume large we have chosen a 6.4 GHz on-line ECR ion source as the charge breeder. This ion-source has been operated for both gaseous and metallic beams. A typical spectrum for iron ions produced using the MIVOC [5] technique is shown in Fig 2. Also for heavier ions, a charge breeder with ECR operating in 10+14 GHz dual frequency mode has been designed [6].

In addition to this, new R&D on efficient & fast transport and ionisation of radioactive atoms irrespective of their chemical nature has been started. The ECRIS can be exploited as a universal $1^+$ ion-source. However, with an internal or close vicinity target the radiation damage to the permanent magnet drastically reduced the lifetime of the ion-source [7]. A possible alternative could be the Helium-jet coupled ECR ion-source with multiple thin target system (figure 3). This *universal charge breeder* option is highly attractive especially for the fission production route. Transport efficiencies of 50-60% can be obtained from the He-jet recoil method [8] for most of the elements. Assuming a typical skimmer efficiency of 50% and ionization efficiency of 50% for $1^+$ in ECR, one can expect a total transport and ionization efficiency in the range 10 – 15 % for almost all the elements.

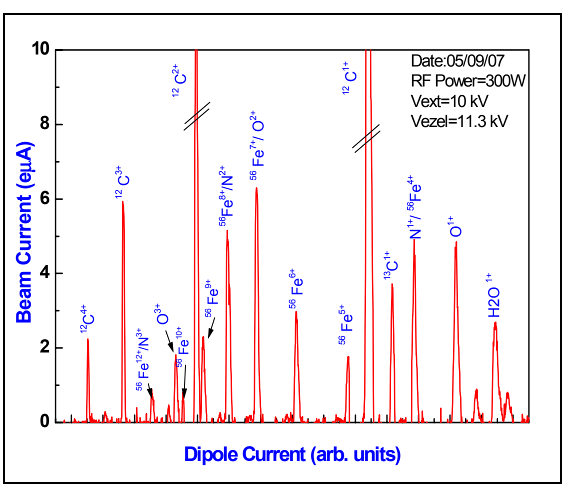

Figure 2: ECR spectrum.

### *The Heavy-Ion RFQ Linac*

Radio Frequency Quadrupole Linac would be the first post accelerator of our RIB facility. It has been designed for q/A=1/14 and input energy of 1.7 keV/u .The four-rod type RFQ is 3.4m long (vane length ~ 3.2m) and operates at the resonance frequency of 37.8 MHz. The development of RFQ has been done in phases. In the first phase we have developed a 1.7 m RFQ capable of accelerating beams up to 29 keV/u. This RFQ operates at a resonance frequency of 33.7 MHz. It has already been installed and operational since the year 2005. Transmission efficiencies of about 85% were measured for $Ar^{4+}$ and other beams like $O^{2+,3+,4+}$ and $N^{3+,4+}$ through the RFQ. The details of this RFQ and results of beam tests are reported in ref [9].

The post-acceleration RFQ is almost identical to the 1.7m RFQ but is longer to achieve higher output energy of 98 keV/u. This RFQ is also completely indigenously designed and constructed. The resonant structure including the vanes and supporting posts is made from OFHC copper and has been machined at Central Mechanical Engineering Research Institute (CMERI), Durgapur located about 200 km north of Kolkata. The top cover (cavity) has been Copper plated and built by Danfysik. A photograph of the 3.4m RFQ during installation is shown in fig. 3. In the preliminary test, beam transmission efficiency of 90% has been measured for O3+ in the RFQ. Further details about the RFQ system are presented in another contribution in Linac08 conference [10].

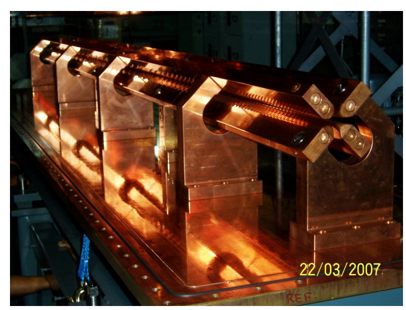

Figure 3: The 3.4m RFQ post-accelerator.

### *ECR to RFQ Beam-Line*

The beam transport line from the ECR ion-source to the RFQ consists of an Einzel lens, a 90 degree, 0.25 Tesla dipole magnet for *q/A* selection, and a solenoid magnet lens downstream of the dipole magnet to ensure proper matching of the ion-beam at the entry of the RFQ. The ion optics of this low energy transport line has been designed using the computer code TRANSPORT. The separation stage is designed for a dispersion of 1.84 cm. The magnification in the dispersive plane is -0.88. The RFQ demands converging beam in both the planes. A reasonable match could be obtained using a solenoid magnet length of 30 cm and a maximum magnetic strength of 0.65 Tesla

### *RFQ to LINAC Beam-Line*

The RFQ to LINAC-1 beam line has been designed to match the RFQ beam with the longitudinal & transverse acceptance of Linac1. A 4-gap, 37.8 MHz Re-buncher will be placed between the RFQ and Linac1 to obtain a beam of desired phase and energy width at the entry of the Linac. For transverse focusing we would be using two quadrupoles upstream and two downstream of the Re-buncher. A fortran code was written to optimize the position of Re-buncher & voltages on the drift tube. In order to recheck the results of our code we have simulated using SIMION, the time varying voltage on the drift tube of the Re-buncher and calculated the bunching property both in phase and energy, due to the applied RF voltage.

RF simulation of the Re-buncher was done using ANSYS. The height of the movable short was optimized to obtain the desired resonant frequency of 37.8 MHz. Experimentally found out value are in good agreement with calculated resonating frequency using ANSYS. The mechanical fabrication of the Re-buncher including major components such as inductive coupler, capacitive pick-up and tuner is almost complete. A photograph of the Re-buncher during assembly is shown in Fig 4.

Figure 4: The Re-buncher during assembly.

### *The IH-LINAC Post-Accelerators*

After the initial stage of acceleration in the RFQ linac the subsequent acceleration of beams will be done in LINAC tanks [11]. For these low-$\beta$ and low q/A RI beams the IH-LINAC structure is the preferred choice. In this type of structure, the LINAC cavities are excited in TE mode. Three IH-Linac cavities would accelerate the 98 keV/u beam from RFQ to about 415 keV/u. The beam energy is expected to be 184 keV/u and 287 keV/u after the first and second Linacs respectively. A photograph of the first Linac cavity is shown in Fig. 5. It is an octagonal cavity made of 25 mm thick SS304L steel cladded with 5mm thick ETP Copper. The cavity has been tested at low power. The measured frequency and Q values match reasonably well with calculated value. The axial component of the RF electric field was measured using bead perturbation technique using an insulating teflon spherical ball. The arrangement allowed us to measure frequency deviation at a step of 5 mm. The detailed design and results of Linac cavity has been presented in another contribution in Linac08 conference [12].

## SUMMARY & OUTLOOK

The status of ISOL type Rare Isotope Beam facility development at VECC Kolkata has been presented. The facility is at present delivering stable heavy-ion beams of energy 29 keV/u. Experiments can be performed at two experiment stations – one at the ECR mass separator focal point and the other at the end of the 1.7m RFQ. The longer post-accelerator RFQ is also installed and very soon the beam tests will be conducted for Linac-1.

The present RIB facility has been planned around the existing K=130 cyclotron. We are also exploring the possibility for using the photo-fission route for the production of neutron rich RI beams. For this purpose we have undertaken a programme to develop a 50 MeV, 100 kW super-conducting electron Linac. In the first phase we have received funding to construct a Horizontal Test Cryostat (HTC) cavity. Recently, a memorandum of understanding was signed between VECC and TRIUMF for the joint HTC development.

# THE ALPI SUPER-CONDUCTING ACCELERATOR UPGRADE FOR THE SPES PROJECT*

P. A. Posocco†, Consorzio RFX, Padova and INFN/LNL, Legnaro, ITALY
G. Bisoffi, A. Pisent, INFN/LNL, Legnaro, ITALY

*Abstract*

The SPES project at Laboratori Nazionali di Legnaro foresees the construction of a RIB facility based on a fission target driven by a 40 MeV proton beam. After the $^{238}$U carbide target the 1+ charged ions will be selected by a high resolution mass spectrometer, charge enhanced by a charge breeder and accelerated up to 10 MeV/A for $^{132}$Sn. The present configuration of the Legnaro super-conducting accelerator complex (PIAVE injector and ALPI main accelerator) fits the requirements for SPES post acceleration too. Nevertheless an upgrade of its performances both in overall transmission and final energy is needed and a solution which minimizes the impact on the present structures will be presented.

## INTRODUCTION

The super-conducting linac ALPI [1] is injected either by a XTU tandem or by the s-c PIAVE injector [2][3]. The linac (at the present 64 cavities and a total voltage of 48 MV) is build up in two branches connected by an achromatic and isochronous U-bend (Fig. 1). ALPI period consists in one triplet and 2 cryostats (4 cavities in each cryostat), and a diagnostic box (profile monitor and Faraday cup) in between.

The PIAVE-ALPI complex is able to accelerate beams up to A/q = 7. Higher A/q ions suffer from a too low injection energy to the medium-β cryostats, where the RF defocusing is too strong and the beam gets easily lost onto the cavity beam ports. In the last few years the average cavity accelerating field ($E_{acc}$) has been enhanced by more than a factor of two with respect to the original design value [4]. The strength of the focusing lenses on the other hand, has remained the same (20 T/m). Therefore, even for 6 < A/q < 7 it is hard to design a proper longitudinal beam dynamics such that it will not cause problems on the transverse plane. To fully exploit the available acceleration gradient, some improvements are required in the layout of both PIAVE and ALPI.

Referring to the cavity performances of Tab. 1 (expected in the next years), three subsequent upgrade scenarios may be envisaged, each one representing a step forward in the final energy (Fig. 2) and beam quality: 2009 for stable beams (funded), an intermediate and a final upgrade within the SPES project (not yet officially funded). For SPES, the Radioactive Ion Beam at 37.1 keV/A will be injected into PIAVE line upstream the SRFQs.

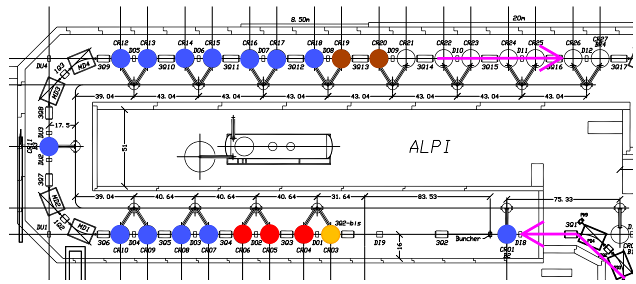

Figure 1: ALPI plan for 2009. The beam coming from PIAVE injector passes through the low-β (in orange and red), medium-β (blu) and high-β (brown) cryostats.

The beam dynamics of each scenario has been optimized for 4 < A/q < 7 thanks to several runs of PARMELA [5]: the beam behavior in the low-energy branch is highly non-linear due to the high gradients and strong Bessel components of the fields inside the cavities, therefore, in such conditions, simulation programs like Trace3D are simply ineffective.

## THE 2009 STATUS

The first ALPI cryostat (CR03) gently focuses the beam coming from PIAVE to the following cryostat. Hence, only a small acceleration is given to the beam by CRO3. The $E_{acc}$ values of the following low-energy branch cavities are

* http://www.lnl.infn.it/ spes/
† piero.antonio.posocco@lnl.infn.it

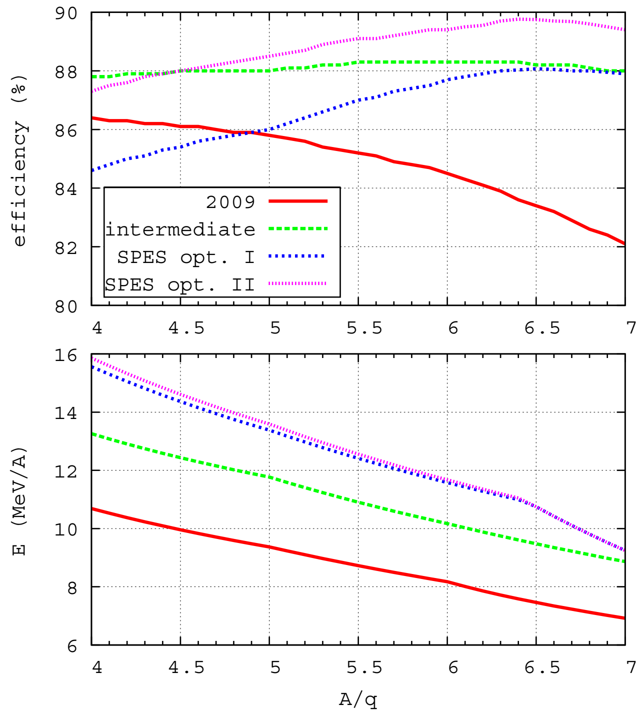

Figure 2: Accelerator efficiency and final energy for the different scenarios. The efficiency is here defined as E [MeV/A] * A/q * V$^{-1}$. For A/q ≥ 6.4 the final energy is limited by the 3 T·m max. rigidity in dipoles.

chosen as function of the A/q and the beam dynamics has been optimized for A/q = 7, where its main limit is the maximum gradient of the magnet before the last period (3Q5). For 6 < A/q < 7, the $E_{acc}$ of CR09 and CR10 are raised and the maximum field is obtained for the configuration of A/q = 6. For 5 < A/q < 6, the $E_{acc}$ is lowered by a less steep function than the linear A/q scaling, because the longitudinal match can be found by changing specific synchronous phases. For A/q = 5 the beam dynamics limit (i.e. long. phase advance and RF defocusing) is reached. Finally, for 4 < A/q < 5 $E_{acc}$ scales like A/q. Given this optimization, it results that for A/q = 4 the acceleration efficiency is at its maximum. More low-β cavities are needed in order to accelerate larger A/q in a more comfortable way.

## THE INTERMEDIATE UPGRADE

To enhance the low-β gradient, a new 80 MHz buncher is needed in front of the first ALPI period. Consequently an additional quadrupole triplet must be placed before CR03. The first period $E_{acc}$ values are scaled by A/q up to A/q = 6, whereas the remaining ALPI low-energy branch $E_{acc}$ are scaled up to A/q = 5. The acceleration is much more efficient than before and the final energies exceed 9 MeV/A. The higher beam rigidity requires the triplets to be replaced (20 T/m→30 T/m) both in the low and in the high-energy branch.

## THE FINAL UPGRADE

The present PIAVE layout (Fig. 4(a)) is very compact, with the SRFQ cryostat immediately followed by the two QWR cryostat periods with external doublet focusing. The period is kept as short as possible, especially to reduce the longitudinal phase advance. This solution presents a weak point: the lack of a separate function matching line between the two sections. In the present set-up the first cavity is used as buncher and this results in a residual longitudinal emittance increase; as a consequence, the first part of the acceleration in ALPI is troublesome and longitudinal losses cannot be avoided. Moreover, the transverse transport is such that it causes 40% vertical emittance increase (Tab. 2). Finally, the first available beam diagnostics is located only after the second QWR period.

### *New Injector Layout*

To improve the situation, a new layout (see Fig. 4(b)) of the line downstream the SRFQs is proposed.

*Bunching section.* A new low-energy n-c buncher and a quadrupole singlet must be installed. The singlet must be placed at the x-plane waist between the SRFQs and the buncher itself, in order to reverse the transverse beam divergence without affecting the quadrupole symmetry. This means that the beam dimensions are almost equal inside the cavity. After the buncher, 2PQ5 doublet focuses the beam at the first QWR cavity and the round condition should be achieved while setting the singlet field appropriately.

*New cryostats.* In the present PIAVE beam dynamics the synchronous phases are employed in a alternating "funnel" scheme, (−90| + 60| + 30| − 25) (−20| − 20| − 20| + 20) and, in order to obtain the required longitudinal acceptance, the QWRs are set to lower $E_{acc}$ values than the best achieved cavity performances. To overcome the problem, a shorter longitudinal and transverse period must be designed. A good solution is the periodic structure à la ISAC-II (TRIUMF) [6]: each cryostat houses 4 QWRs and a compact s-c solenoid (max 9 T) in the middle. Because of the dimensions of the cryostat and the solenoid, the effective longitudinal period comprises two cavities and it is half the transverse one. Hence, all the synchronous phases can be set to −30 and $E_{acc}$ ≃ 5.2 MV/m for A/q = 7 are employed. Moreover, a short space for beam diagnostics is available between the modules. This diagnostic box, combined with

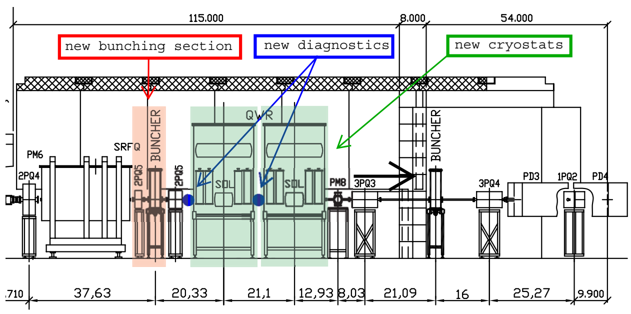
(a) Present layout.



(b) New layout.

Figure 4: PIAVE injector layout comparison.

the one placed after 2PQ5, will be used for checking the transverse match parameters and, in particular, the roundness of the beam before it enters the first cryostat. Table 2 shows the results for the new layout: the even envelopes (Fig. 3) inside the cavities do not produce the any significant emittance growth and the final energy is increased by $\sim 20\%$.

*New HEB1 location.* The n-c rebuncher HEB1 will be slightly moved downstream in order to obtain a parallel longitudinal beam transport along the bend to ALPI.

Table 2: PIAVE beam dynamics results. Emittances are in mm.mrad.

| E (MeV/A) | 0.59 | 1.24 | 1.45 | *+17%* |

### *ALPI Upgrade Options*

I. Low-β upgrade. The new period before CR03 can be filled with the two cryostats recovered from PIAVE. The last two low-β cryostats can be required to work at $E_{acc}$ = 6 MV/m up to A/q = 5. This way, the acceleration efficiency would be favorable to the heaviest ions, whereas the lightest ones would suffer from an excess of low-β cavities. However, this allows to transport the beam efficiently even if some low-β cavities were out of order.

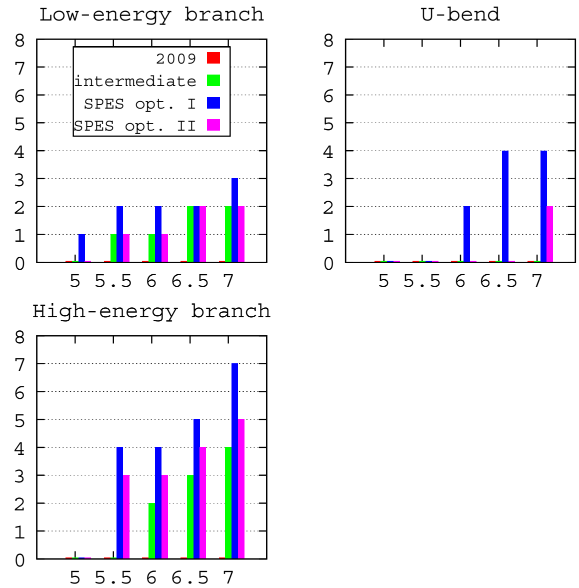

Figure 5: Number of quadrupole triplets that need to be replaced (20 T/m→30 T/m) in the various scenarios as function of A/q.

II. High-β upgrade. Alternatively, the two cryostats could be placed downstream the high-energy branch. This way, the number of cavities would be more effectively divided among the three optimum betas an the final energy for the lightest ions would be slightly enhanced.

## CONCLUSIONS

As shown in Fig. 2, in the second and third scenario the heaviest ions are accelerated in a increasingly efficient way. It is worth to point out, however, that the maximum magnetic field of the dipoles (1.6 T) in ALPI and in the extraction lines limits the performances of the SPES scenario for A/q ≥ 6.4.

SPES option I is the most demanding scenario from the point of view the magnetic quadrupole replacement (Fig. 5). The only way to keep the existing magnets in both the U-bend and the high-energy branch is to use a stripper foil, as described in [7]. As a major consequence of this, the final energies increase by 30% at the cost of a lower transmission, depending on the selected charge state probability (15 ~ 20% for the heaviest ions).

**Abstract**

The RIKEN heavy-ion linac (RILAC) has been used as an injector for the RIKEN RI-Beam Factory (RIBF) since 2006. Results of the acceleration tests of $^{48}$Ca and $^{238}$U performed recently in the RIBF are reported; we got 270 pnA of $^{48}$Ca at an energy of 114 MeV/u after the Intermediate-stage Ring Cyclotron (IRC). On the other hand, the intensity of the uranium beam is still far below the design goal. Therefore, we are planning to install a superconducting ECR ion source, which is under construction, on the high-voltage platform of the Cockcroft-Walton pre-injector. It will be possible to test this new pre-injector in April 2009. A plan to construct an alternative injector for the RIBF, consisting of an ECR ion source, an RFQ, and three DTLs, is also illustrated, which aims at independent operation of the RIBF experiments and super-heavy element synthesis.

## INTRODUCTION

The RIKEN heavy-ion linac (RILAC), which has been operated since 1981, accelerates various kinds of ions by changing the rf frequency from 18 to 38 MHz in the continuous-wave (cw) mode. The voltage gain is 16 MV in the whole frequency range, and the acceptable mass-to-charge ratio ($m/q$) of the ions ranges from 5.5 at 38 MHz to 25 at 18 MHz. The original Cockcroft-Walton pre-injector to the RILAC was replaced by an RFQ pre-injector equipped with an 18-GHz ECR ion source in 1996.

In 2001, a booster linac for the RILAC was constructed, which consists of two variable-frequency resonators and four fixed-frequency resonators; the maximum energy of the RILAC facility has been increased to 5.8 MeV/u [1]. By using the high-intensity beams from the booster, experimental study has been started for searching super-heavy elements (SHE) since 2002. The beam time provided for the SHE experiments so far has exceeded 10,000 hours. The present layout of the RILAC facility is illustrated in Fig. 1.

On the other hand, commissioning of the RI-Beam Factory (RIBF) [2] started in 2006 [3], where the RILAC is used as an injector. Results of the acceleration tests performed recently in the RIBF are given in the next section, as well as a brief introduction of the RIBF accelerators.

## RILAC AS RIBF INJECTOR

Figure 2 shows a conceptual layout of the accelerator chain of the RIBF, which consists of the RILAC injector and four booster cyclotrons (RRC, fRC, IRC and SRC) in a cascade. The fRC is exclusively used for very heavy ions such as uranium and xenon, where the rf frequency of the RILAC is fixed to 18.25 MHz and the beam energy at the exit of the SRC is 345 MeV/u. For medium-mass ions such as calcium and krypton, the fRC is skipped; it is possible to operate the accelerator chain in the variable-energy mode. There is another acceleration mode in the RIBF, where the AVF cyclotron (K70 MeV) is used as an injector for the acceleration of light ions such as deuteron and carbon.

In this year, acceleration tests were performed up to the exit of the IRC using $^{48}$Ca and $^{238}$U beams.

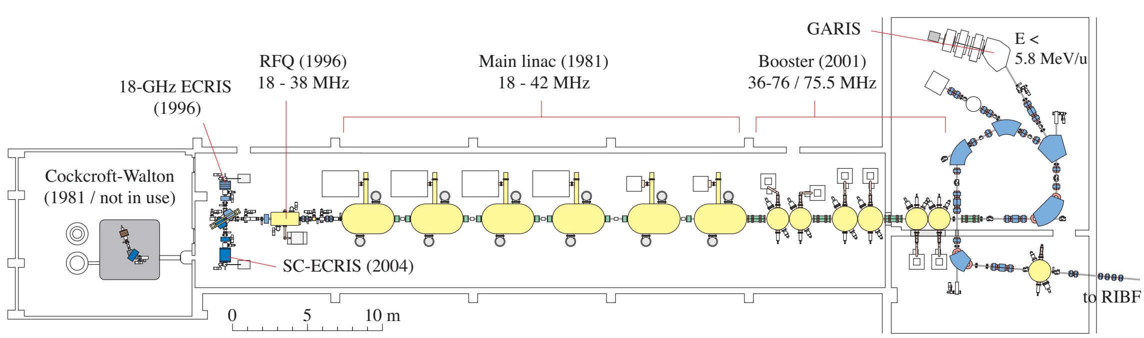

Figure 1: Plan view of the RIKEN Heavy-Ion Linac (RILAC).

† SHI Accelerator Service, Ltd.

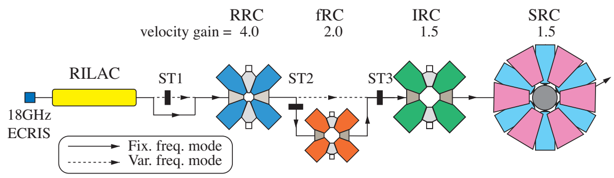

Figure 2: Conceptual layout of the accelerator chain of the RI-Beam Factory (RIBF). The RILAC injector is followed by the booster cyclotrons: RRC (RIKEN Ring Cyclotron, K540 MeV), fRC (fixed-frequency Ring Cyclotron, K570 MeV), IRC (Intermediate-stage Ring Cyclotron, K980 MeV), and SRC (Superconducting Ring Cyclotron, K2600 MeV). The charge strippers are indicated by ST1 - ST3.

## [illegible]

The acceleration test was carried out in June using the $^{48}Ca^{10+}$ ions from the 18-GHz ECR ion source. The rf frequency of the RILAC was 36.5 MHz, which corresponds to the beam energy of 114 MeV/u at the exit of the IRC.

The calcium ions were generated from a $^{48}CaO$ rod with support gas of $O_2$ in the ion source. At the extraction voltage of 16.0 kV, the beam current was 40 e$\mu$A at the first Faraday cup after the analyzing magnet. The charge state was changed into 17+ with a carbon foil of 40 $\mu$g/cm$^2$ at the beam energy of 2.7 MeV/u after passing through the RILAC . The transmission efficiency through the RILAC was 53 % and the stripping efficiency was 35 %. We used another stripper of carbon foil of 1 mg/cm$^2$ after the RRC, which fully stripped the calcium ions with an efficiency of 87 % at the energy of 46 MeV/u. Finally, we got 270 pnA at the exit of the IRC, corresponding to $1.6\times10^{12}$ pps. In the test, we used a beam attenuator of 50 % after the RILAC in order to keep the beam current below 300 pnA, which is the maximum intensity allowed by the operating license.

The rf system of the RILAC and the charge strippers were stable throughout the beam study. We are planning to accelerate the calcium beam through the SRC in November 2008.

## [illegible]

We performed the test using the $^{238}U^{35+}$ ions from the 18-GHz ECR ion source in May and July. The rf frequency of the RILAC was 18.25 MHz, corresponding to the beam energy of 114 MeV/u at the exit of the IRC.

We used a rod of metallic uranium with support gas of helium in the ion source. The beam current at the first Faraday cup was 2 e$\mu$A at the extraction voltage of 5.7 kV, and the transmission efficiency through the RILAC was 30 %. The beam was injected directly into the RRC without charge stripping. As shown in Fig. 2, the extracted beam from the RRC went through two charge strippers placed on both sides of the fRC. The final beam current at the exit of the IRC was 0.35 pnA, which corresponds to $2\times10^9$ pps.

One of the reasons for the low transmission efficiency through the RILAC comes from the mismatch of the emittance of the output beam from the ion source to the acceptance of the RFQ. We also found the vacuum pressure in the low energy part of the RILAC is not sufficient for the highly charged ions like $^{238}U^{35+}$.

During the acceleration, the rf voltage, rf phase and beam phase were measured with a monitoring system which has been newly developed based on lock-in amplifiers [4]. The measured data shows that the rf voltage and phase of the first four resonators of the RILAC sometimes moved out of the required range of $\pm0.1$ % and $\pm0.1\,^\circ$, respectively, and the beam phase in the following accelerators was influenced by these fluctuations. The origin of the variation of the rf systems is under investigation.

## NEW PRE-INJECTOR FOR RILAC

From the operational status mentioned in the previous section, it is clear that we need more beams from the ion source, especially for the uranium acceleration. To increase the intensity, we are constructing a new superconducting ECR ion source capable of the microwave frequency of 28 GHz [5]. It is designed to have as large plasma volume as 1100 cm$^3$.

The superconducting coil system of this ion source consists of six solenoids and a set of sextupole coils to make a confinement magnetic field. The maximum axial magnetic fields are 3.8 T at the rf-injection side and 2.2 T at the beam-extraction side. The inner solenoid coils are used for introducing a flat magnetic field region between the mirrors. The coils use a NbTi-copper conductor and are bath-cooled in liquid helium. The superconducting coils were already assembled and the excitation test is under progress. After the test, the assembling of the cryostat for these superconducting coils will be started. The ion source will be brought to RIKEN in December 2008.

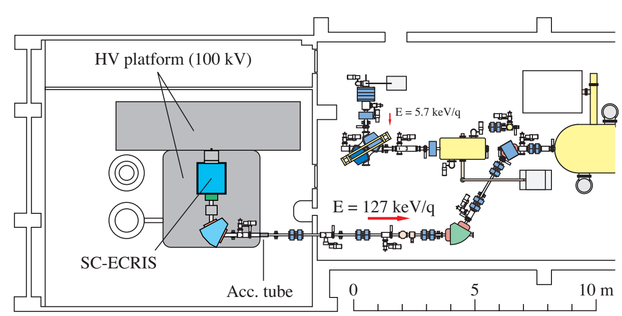

Figure 3: Configuration of the new pre-injector for the RILAC.

Low frequency operation of the RILAC at 18.25 MHz requires, however, such low extraction voltage as 5.7 kV in the $^{238}U^{35+}$ acceleration. High power beams of 5.7 kV surely grow up due to their space charge forces in the low-energy transport line. On the other hand, RILAC requires such low injection energy as 127 kV. Therefore, we decided to put the superconducting ECR ion source as well as the analyzing magnet [6] on the high-voltage terminal of the original Cockcroft-Walton pre-injector so that extracted beam from the source can be directly injected to the RILAC, skipping the RFQ , as shown in Fig. 3. We expect that the emittance growth can be suppressed in the beam transport system.

The design study of the medium-energy beam transport system is under progress, for which we plan to use recycled magnets. The original power generator of 50 kVA will be used for the devices on the platform as well as an additional power transformer of 50 kVA. We expect to start the test of the superconducting ECR ion source in April 2009.

## NEW LINAC INJECTOR FOR RIBF

The recent success in the synthesis of SHE [7] using the GARIS (gas-filled recoil ion separator) system in the RILAC facility strongly encourages us to further pursue the search for the heavier elements and to more extensively study physical and chemical properties of SHEs. This compels us to provide a longer machine time for these experiments. However, the SHE research and RIBF research conflict with each other, because both of them use the RILAC.

Therefore, a new additional injector linac to the RRC has been proposed [8], which will make it possible to conduct the SHE and RIBF research studies independently. The new injector, which will be placed in the AVF-cyclotron vault, will be used exclusively to produce primary beams of 345 MeV/u from the SRC.

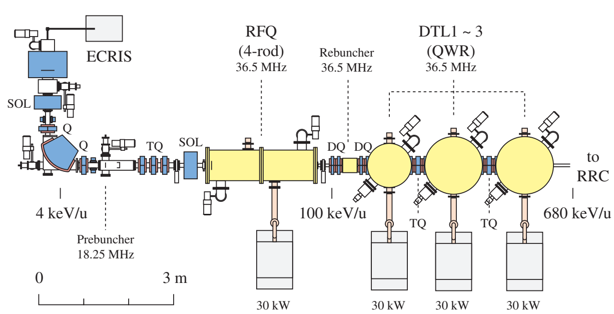

Figure 4: Schematic layout of the new injector.

The injector is designed to accelerate ions with a mass-to-charge ratio of 7, aiming at heavy ions such as $^{136}Xe^{20+}$ and $^{238}U^{35+}$, up to an energy of 680 keV/u in the cw mode. It consists of an ECR ion source, a low-energy beam transport system including a pre-buncher, an RFQ linac based on the four-rod structure, and three DTLs based on the quarter-wavelength resonator (QWR), as shown in Fig. 4. The rf resonators are supposed to be operated at a fixed rf frequency of 36.5 MHz. Strong quadrupole magnets will be placed into the beam line between the rf resonators. The output beam will be injected to the RRC without charge stripping.

In November 2007, an RFQ system including two post accelerators and their rf amplifiers was transferred to RIKEN through the courtesy of Kyoto University, as shown in Fig. 5 This RFQ system was originally developed by Nissin Electric Co., Ltd. in 1993. [9] Since the termination of its acceleration tests in the company, the RFQ system has been maintained in the Advanced Research Center for Beam Science, Kyoto University for several years.

Figure 5: Photograph of the four-rod RFQ settled in the RIBF building for high power tests.

The RFQ linac, based on a four-rod structure, accelerates heavy ions of $m/q$ = 16 up to an energy of 84 keV/u in the cw mode with an rf frequency of 33.3 MHz. When the RFQ resonator is modified so as to have a resonant frequency of 36.5 MHz, it becomes possible to accelerate ions of $m/q$ = 7 to 100 keV/u, which is the required energy in the new injector system, without changing the vane electrodes.

We plan to perform high-power tests of the RFQ resonator at the original frequency of 33.3 MHz in this year, after reassembling the rf amplifier.

*Abstract*

The methodology for a low energy spread RFQ beam dynamics design has been studied for $C^{14+}$ AMS application This paper will present a low energy spread beam dynamics and RF design for a trapezoidal IH-RFQ (abbreviated T-IH-RFQ) operating at 104MHz at Peking University. $^{14}C^{+}$ will be accelerated from 40keV to 500keV with the length of about 1.1m. The designed transmission efficiency is better than 95% and the energy spread is as low as 0.6%. Combining the beam dynamics design, a T-IH-RFQ structure was proposed, which can be cooled more easily and has better mechanical performance than traditional RFQ. The electromagnetic field distribution was simulated by CST Microwave Studio (MWS). The simulation results show such T-IH-RFQ has higher operating frequency than normal four rods RFQ and/or IH-RFQs. The specific shunt impedance and the quality factor were also compared to these RFQ structures.

## INTRODUCTION

RFQ, proposed by I.M.Kapchinsky and V.A.Teplyakov in 1970[1], has been used widely for many applications. It can focus, bunch and accelerate low energy beam, extracted from ion sources directly, over a mass range from proton to heavy ions such as uranium based on the RF electrical field of a modulated quadruple transport channel [2]. RFQ was used to $^{3}H$ Accelerator Mass Spectroscopy (AMS) firstly by LLNL in USA because of its inherent compact size [3]. RFQ based $^{14}C$ AMS application has been studying in recent years at the Institute of Heavy Ion Physics (IHIP), Peking University [4, 5]. The most critical problem is that the energy spread of full width at half magnitude (FWHM) for traditional RFQ is usually larger than 2% because of the process of adiabatic bunching and phase oscillation, which is too high for the particle identification in an AMS detector. So, ways must be found to reduce the energy spread of the output $^{14}C$ beam. The highest beam current of RFQ used for AMS $^{14}C$ facility is lower than 200μA, which is such low that the space charge effects can be ignored. Non-adiabatic bunching method should be used to make output beam energy spread low. A physical design of RFQ with 0.6% energy spread has been obtained through external bunching method by previous work at IHIP. A pre-buncher will be necessary in the injection system before RFQ to bunch beam length in the range of [-20°, 20°]. However, the bunching efficiency of a pre-buncher can only be 70~80%. As a result, the total transmission will be lower than most tandems based AMS facility even though no particle is lost in RFQ. An internal discrete bunching proposed by J.W.Staples at LBNL [6] is used to save additional RF power supply and buncher cavity. The low energy spread beam dynamics design for $^{14}C^{+}$ RFQ will be presented in this paper.

On the other hand, an IH-RFQ acceleration structure was proposed and studied. The four electrodes are supported by erect boards connected to the external cavity up and down. This new structure was named trapezoidal IH-RFQ according to its appearance. The trapezoidal IH-RFQ is easily cooled and will have good mechanical performance. Moreover, it will have higher resonant frequency than traditional IH-RFQ [7]. Simulations of the electromagnetic fields have been completed by CST Microwave Studio (MWS). RF characteristics is investigated, and geometrical parameters are optimised initially to make the shunt impedance and the quality factor as large as possible.

## BEAM DYNAMICS DESIGN

According to Staples' method, the whole RFQ beam dynamics design is divided into five sections, radial matcher, buncher section, drift section, transition section and accelerator section. The radial matcher is similar to that of four-step method developed at LANL [8], which matches DC input beam to the time-varying transverse envelope at the entrance of RFQ. The buncher section is distributed over several cells while the modulation parameter $m$ ramps from zero to a maximum and then back down to zero, which performs the function of bunching as a non-adiabatic buncher. The following several unmodulated cells make up of the drift section which allows the ideal beam bunch to form. In the transition section, the beam is accelerated slowly as the synchronous phase varies from -90º to its final value -30º. Finally, the designed energy is reached in the acceleration section. Significantly lowered longitudinal output emittance and slightly lowered transverse emittance can be obtained by this new design technique compared to previous methods, which has been proved by PARMTEQM.

* Supported by NSFC(19775009)
† Corresponding author yrlu@pku.edu.cn

There is another approach to reduce the RFQ energy spread further more, which can be shown by

$$\Delta w_{\max} = \left[2A\xi V_0 e w_s(\varphi_s \cos\varphi_s - \sin\varphi_s)\right]^{1/2} \quad (1)$$

Where $\Delta w_{\max}$ is the separatrix height that indicates the maximum beam energy spread, $\xi$ is the charge-to-mass ratio of the ion, $e$ is the charge of an electron, and $w_s$ the energy per nucleon of the synchronous particle. The formula shows that energy spread can be decreased by reducing acceleration coefficient $A$, inter-vane voltage $V_0$ and synchronous $\varphi_s$, where lower $A$ means lower $m$.

From above we can see apparently that $\varphi_s$ should be as large as possible in order to obtain low energy spread, but not be kept at -30º. On the other hand, the focus parameter $B$ should increase during the first stage of the transition section and then keep constant, whereas at the acceleration section it should decrease slowly in order to receive the constant transverse phase advance to keep the beam matched, minimize the emittance growth and related beam loss [9]. The above two aspects can be realized by MATCHDESIGN [10], a code developed at IHIP taking matching equations, equipartition condition and constant transverse beam size into account to avoid emittance growth and beam loss.

Integrating all the above points, we are capable of performing beam dynamics design in pursuit of low energy spread. The design parameters were given by MATCHDESIGN, and then the internal non-adiabatic buncher was designed by the code of J.W.Staples. On one hand $V_0$ should be as low as possible to reduce power consumption; on the other hand $V_0$ should be large enough to achieve sufficient focusing. Finally $V_0$ was chosen to be 60kV, meanwhile $m$ should be increased very slowly, otherwise particles will not be focused effectively and some of them will then be lost. The main dynamics parameters of the RFQ are plotted in figure 1 and listed in Table 1. Energy spectrum of ion beam output from this RFQ is shown as figure 2.

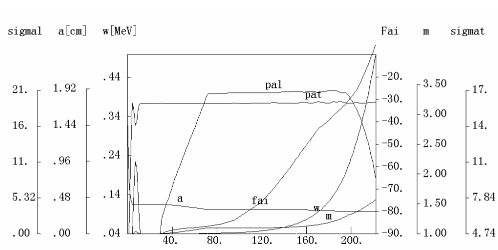

Figure 1: The main dynamics parameters (sigmal is longitudinal phase advance, sigmat is transverse phase advance, Fai is synchronous phase, a is aperture radius, w is ion kinetic energy and m is modulation respectively).

Table 1: The Main Dynamics Parameters

| | |
|---|---|
| Ion | $^{14}C$ |
| Charge number $q$ | 1 |
| Operating frequency $f$ (MHz) | 104 |
| Electrode voltage $V_0$ (kV) | 60 |
| Input energy $W_i$ (keV) | 40 |
| Output energy $W_o$ (keV) | 500 |
| Modulation $m$ | 1.0–1.57 |
| Minimum aperture radius $a$ (mm) | 2.93 |
| Maximum focusing factor $B$ | 3.44 |
| Synchronous phase $\varphi_s$ (degree) | -90 to -6 |
| Electrode length $L$ (mm) | 1091.3 |
| Transmission $T$ (%) | 97.6 |
| Energy spread (%) | 0.6 |

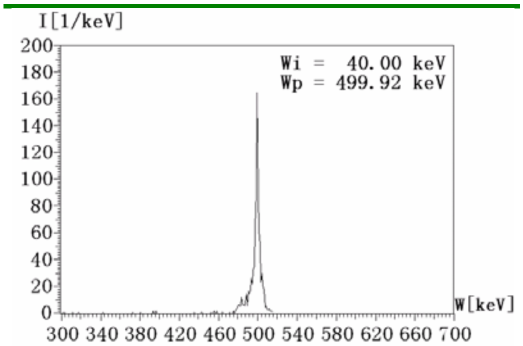

Figure 2: Output beam energy spectum.

The total length of the RFQ is about 1.1m, and further more $m$ is small to make particles be focused sufficient in the whole acceleration process and to obtain low energy spread. However, the low energy spread beam dynamics design method introduced in this paper will undoubtedly simplify the RFQ based AMS in compare to external non-adiabatic bunching. The maximum surface field is about 25MV/m, so the Kilpatrick coefficient is about 2.1 which can be accepted in the case of weak beam current. The transmission efficiency is about 97.6%, which is much better than that of external bunch design.

## RF DESIGN

A cavity model was built using MWS, given by figure 3. Intuitively, a trapezoidal IH-RFQ has great mechanical capability and will simplify the cooling system very much.

Figure 3: Model of trapezoidal IH-RFQ

The RF design includes resonance frequency, electromagnetic field distribution and RF efficiency. The field distribution illustrated that the trapezoidal IH-RFQ structure was a cavity operated at $H_{21(n)}$ mode shown in figure 4, not $H_{11(n)}$ mode like classical IH-RFQ. As a result, the trapezoidal IH-RFQ has higher resonant frequency than traditional RFQ and IH-RFQ when they have same transverse dimension. It is suitable for not only light particles such as proton and deuteron but also heavier ions such as $^{14}C^{+}$. The longitudinal field distribution un-flatness is less than 5%.

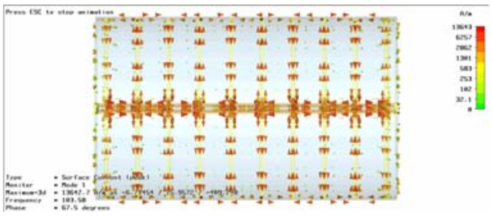

Figure 4: Current flow for T-IH-RFQ.

In order to reduce RF power loss, the specific shunt impedance and quality factor were optimized for different geometric parameters, such as shape of electrode, width and thickness of the support boards, spacing between support boards and cavity diameter. The simulated cavity frequency is a bit lower than 104MHz to keep the tuning margin, and the conductivity is set to $5.0\times10^{7}$s/m. Considering the cavity is relatively short, the whole cavity was simulated. The distance between neighbouring two support boards is almost equivalent to the amount of support boards since the total length has been confirmed by beam dynamics design. If it is large, the electrode length per module increases which leads to large capacitance, whereas a small distance means significant capacitive loading between the support boards [11]. Taking mechanical factor into account, 10 support boards were used and the distance was chosen to be 115mm. Finally, the simulated quality factor is around 5192, and the specific shunt impedance is optimized to reach about 110kΩ•m, which means the designed RF power is 36kW. The optimized structure parameters are listed in table 2.

Table 2: The Optimized Structure Parameters

| | |
|---|---|
| RF frequency $f$ (MHz) | 103.6 |
| Cavity length $L$ (mm) | 1111.3 |
| Number of support boards | 10 |
| Distance between support boards (mm) | 115 |
| Width of support boards (mm) | 112 |
| Thickness of support boards (mm) | 13.5 |
| Cavity diameter (mm) | 680 |
| Quality factor | 5192 |
| Specific shunt impedance (kΩ•m) | 110 |
| RF power (kW) | 36 |

Comparing T-IH-RFQ to traditional four rods RFQ and IH-RFQ with the same mechanical dimensions, T-IH-RFQ has the highest frequency and lowest RF shunt impedance. Their performances are shown in Table 3.

Table 3: Comparing Three Different RFQs

| | T-IH-RFQ | IH-RFQ | Four Rod RFQ |
|---|---|---|---|
| Frequency/MHz | 103.6 | 46.5 | 77.9 |
| Shunt impedance /kΩ•m | 110 | 300 | 170.9 |
| Quality Factor | 5192 | 5934 | 5077 |

Cold model cavity will not be necessary because good agreement between simulation results and the cavity measurements. The real trapezoidal IH-RFQ power cavity will be manufactured directly based on MWS design.

## CONCLUSION

Internal discrete bunching method was used to simplify the RFQ based $^{14}C$ AMS and improve the transmission. The non-adiabatic buncher section functioned as the pre-buncher before RFQ. All dynamics parameters were designed and modified repeatedly by MATCHDESIGN, the code of Staples and PARMTEQM. After a satisfying beam dynamics design was obtained, we proposed the trapezoidal IH-RFQ operating at $H_{21(n)}$ mode illustrated by MWS simulations. It has higher resonant frequency and great mechanical performance. After optimization, the quality factor and the specific shunt impedance for the trapezoidal IH-RFQ are initially satisfied.

Further optimization will be carried out for RF design mainly aimed to decrease power consumption. A trapezoidal real IH-RFQ power cavity will be constructed under the support of NSFC (19775009) and be tested next year.

*Abstract*

SFRFQ is an intermediate accelerating structure, which combines RFQ and DTL together, it can increase the accelerating efficiency at RFQ exit part by inserting gap acceleration between RFQ electrodes while providing strong focusing by RFQ focusing field. One prototype cavity has been manufactured and been used as a post accelerator of ISR RFQ to accelerate O+ from 1MeV to 1.6MeV in 1meter. A code SFRFQCODEV1.0 was developed for the beam dynamics design. The RF conditioning and full RF power test has been carried out. The intervane or gap voltage have reached 86kV at 29 kW with 1/6 duty cycle and repetition frequency 166Hz. The initial beam test results will also be presented in this paper.
PACS numbers: 29.20.Ej

## INTRODUCTION

RFQ accelerators have been widely used in many applications. Because of increasing of the beam energy, beam accelerating efficiency goes down rapidly. Actually, Longer the RFQ length is, lower kinetic energy gain per unit length is; lower the injection energy of DTL is, much higher accelerating efficiency is; more accelerating gaps at DTL entrance means stronger transverse focusing is needed for the beam. Therefore several different accelerating structures, such as SP RFQ [1] in Russia and RFD [2] in U.S.A., have been studied in last decade to improve accelerating efficiency. The novel idea of Separated Function RFQ (SFRFQ) was first proposed by the RFQ group of IHIP (Institute of Heavy Ion Physics) at Peking university[3], based on the experience of ISR-RFQ 1000 (Integral Split Ring RFQ) [4][5][6]. Initial results of electro-magnetic calculation and dynamics proved the possibility and higher RF accelerating efficiency of SFRFQ structure[7].

To verify accelerating feasibilities of the SFRFQ structure, a simulation code SFRFQCODEV1.0[8] was developed for beam dynamics design. The prototype SFRFQ cavity will be used as a post-accelerator for ISR RFQ-1000 and accelerate O+ beam with ~mA peak current from 1MeV to 1.6MeV. This paper will present the beam line setup and related experimental results.

## SFRFQ BEAMLINE SETUP

SFRFQ accelerating system consists of a 2.45GHz ECR ion source and LEBT, 1MeV ISR RFQ-1000, Magnetic Triplet, SFRFQ cavity, Analyzing Magnet and three beam Faraday cups. It is shown in Fig.1. Figure 2 shows the 2.45GHz ECR ion source and LEBT. 2.45GHz ECR ion source was made by permanent magnet. It can generate the axial magnetic field of 90~100mT in microwave discharging chamber, which is about 50mm in diameter and 50mm in length. LEBT consists of two electrostatic lenses with diameter of 80mm and 120mm respectively. The total extracted beam current can reach 5mA with extraction voltage 22kV, extraction aperture diameter of 5mm, $O_2$ gas inlet of 0.15sccm, electrostatic focusing voltage 19.6kV and 16.7kV respectively. The extracted $O^+$ ratio is about 0.6 and LEBT transmission is about 80%[9]. The beam emittance is about 0.12~0.16mm·mrad measured by Allison emmitance equipment.

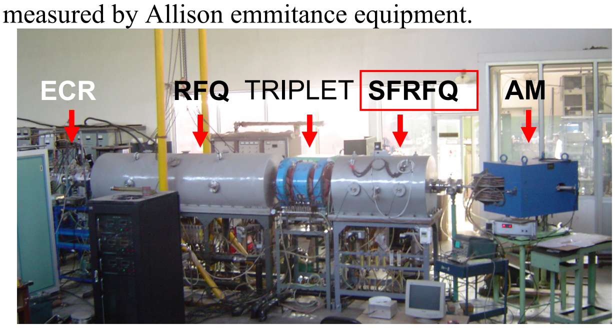

Figure 1: SFRFQ beam line setup.

The triplet has been designed to realize the beam matching in transverse. The figure 2 shows the magnetic gradient distribution along the triplet axis. It is only regret that longitudinal bunched beam length was expanded to nearly 150degree because of beam energy spread and longitudinal drifting. It asks an additional buncher to bunch the beam.

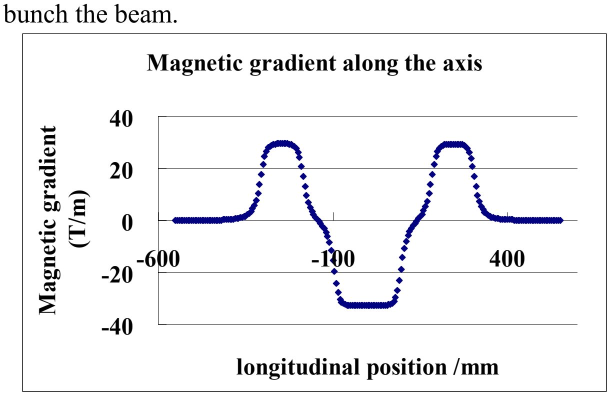

Figure 2: Magnetic gradient along the triplet axis.

The upgrade of beam test for 1MeV ISR-RFQ has been performed. The maximum output peak beam current at RFQ exit i.e. at the entrance of triplet is 2mA with sample

resistor of 1kΩ. This was shown in figure 3. The needed RF power is more than 32.5kW.

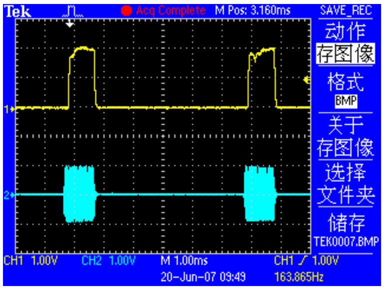

Figure 3: 2mA output peak current for 1MeV ISR RFQ with RF peak power 32.5kW, duty factor 1/6, and RFQ transmission of about 80%.

## SFRFQ AND FULL RF TEST

SFRFQ is a hybrid structure of RFQ and DTL accelerator, the inner structure is shown in figure 4. The RFQ parts are for the transversal alternating gradient focusing, gaps between diaphragms are for acceleration. As we mentioned in last section, the particles' phase are expanded to 150º in triplet drifting. The synchronous phase in SFRFQ should be set gradually from phase -87º to - 20 º (refer to figure 5). The detailed optimization for SFRFQ cavity design was referenced to[10] . In reference [10], the manufacturing tolerance for inner structure has been also studied very carefully.

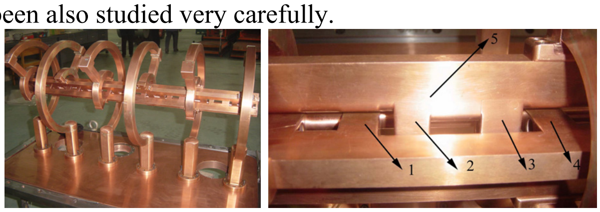

Figure 4: SFRFQ inner structure (left), 1,2,3,4 diaphragms and 5 RFQ electrodes (right).

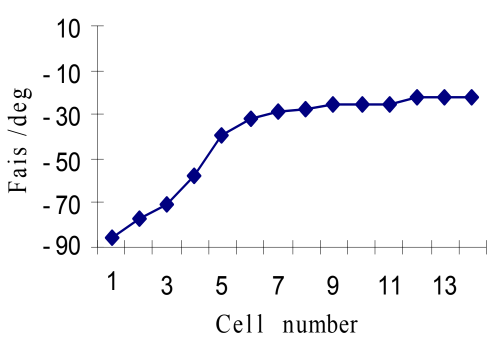

Figure 5: Synchronous phase versus cell number.

A capacitance tuner is installed on the top of tank cover. It has a frequency tuning ability from 26.42MHz to 25.95MHz when it is moved from 0 to depth of 25mm, while the unloaded quality factor goes down from 2480 to 2340. Up to now the capacitance tuner position is controlled by step motor and worked at open loop, because the cavity detuning is about 3 kHz per hour, this is easily controlled manually to decrease the influence of tuning device vibration. The electric field distribution $E^2$ along the axis was measured by bead pull measurement [10], it fits the field simulation results.

The RF systems, shown in figure 6, consist of two 30kW CW final amplifier made by FU105Z3 which is cooled by circulating distilled water. They can deliver 45kW in pulse mode operation with duty factor 1/6. Each of them includes a 20W (3-30MHz) short wave broadband preamplifier, 1kW driver made by FU100 cooled by air. The electric field gradient in the cavity is stabilized by an AGC feedback system independently. The RF system for SFRFQ cavity includes a voltage controlled phase shifter[10], it can control the RF field phase in SFRFQ cavity and keep it be synchronous with the particles. The shifted phase versus controlled voltage is shown in figure 7. The voltage standing wave ratio is less than 1.1 under the RF power test. The principal parameters for RFQ cavity can be referenced in [6], and that for SFRFQ is listed in Table 1. The RF test results are listed in Table 2. TABLE II lists the results of RF power test with the duty factor 1/6. Here $V_o$ is the intervane voltage, $\rho = \frac{V_0^2}{p} \cdot l$ is the specific shunt impedance, where $p$ and $l$ is the RF power and length of the cavity. Figure 8 gives an example of intervane voltage measurement by using high purity Ge detector. The specific shunt impedance is about 270.8kΩm.

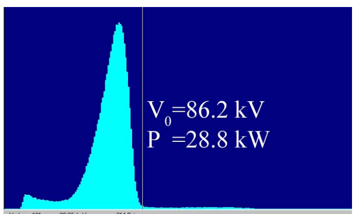

Figure 8: Roentgen spectrum at 28.8 kW RF powers.

## INITIAL BEAM TEST

Because 1MeV ISR RFQ has no frequency tuning system, RF test for total accelerating system is rather difficult at the beginning of RF conditioning. At first nearly 35kW pulse power with duty cycle of 1/6 at 166Hz repetition frequency is feed into RFQ cavity, several minutes later, and the cooling water temperature of RFQ cavity has balanced with RF feeding power. The RFQ frequency finally is kept at 26.075MHz. This is actually the working point of SFRFQ. This fits the impedance matching (figure 9) of in-coupling loop. After feeding about 20kW into SFRFQ cavity, and changing controlled voltage of phase shifter to 4.9V, setting triplet coils currents to 65A,47.5A and 65A respectively, the first beam comes at the SFRFQ exit, it is nearly about 162μA. The energy spectrum of output beam is also measured by analysing magnets. The maximum beam current is corresponding to the beam energy of 1.86MeV. It is rather higher than the designed 1.62MeV. The energy spectrum will be calibrated by nuclear reaction and beam transport will be optimized in the further experiments.

## CONCLUSION

Initial results show the SFRFQ cavity can have higher acceleration efficiency and can also stand 91kV intervane voltage. Although the output beam energy is higher than the designed value and output beam current is not yet good optimized for the final operation. The RF synchronous phase and RF power level will greatly influence the output beam current and beam energy. The triplet parameters have also great influence on the beam transport.

The authors would like to thank Prof.Dr.Klein and Prof.U.Ratzinger for their helpful discussions about H type DTL linac.

# HEAVY ION INJECTOR FOR NICA/MPD PROJECT

V.V.Kobets, A.I.Govorov, G.V.Trubnikov, E.E.Donets, E.D.Donets, A.O.Sidorin, V.A.Monchinsky, I.N.Meshkov, JINR, Dubna, Russia

*Abstract*

General goal of the NICA/MPD project under realization at JINR is to start in the coming 5÷7 years an experimental study of hot and dense strongly interacting QCD matter and search for possible manifestation of signs of the mixed phase and critical endpoint in heavy ion collisions. The Nuclotron-based Ion Collider fAcility (NICA) and the Multi Purpose Detector (MPD) are proposed for these purposes. The NICA collider is aimed to provide experiment with heavy ions like Au, Pb or U at energy up to 3.5 x 3.5 GeV/u with average luminosity of $10^{27}$ $cm^{-2} \cdot s^{-1}$ and to provide collisions of light ions in the total energy range available with the Nuclotron. New injector designed for efficient operation of the NICA facility is based on Electron String Ion Source providing short (< 10 μs) and intensive (up to 10 mA) pulses of $U^{32+}$ ions, one section of RFQ and four sections of RFQ Drift Tube Linac accelerating the ions at Z/A ≥ 0.12 up to 6.2 MeV/u of the kinetic energy. General parameters of the injector are discussed.

## INTRODUCTION

General challenge of the NICA facility is to achieve a high luminosity level of heavy ion collisions in a wide energy range starting with about 1 GeV/u. To reach this goal the NICA injection chain has to deliver a single bunch of fully stripped heavy ions ($U^{92+}$, $Pb^{82+}$ or $Au^{79+}$) at intensity of about $1 \div 1.5 \cdot 10^9$ ions [1]. The existing Nuclotron injection complex consists of HV fore-injector and Alvarez-type linac LU-20. The LU-20 accelerates the protons up to the energy of 20 MeV and ions at Z/A ≥ 0.33 up to the energy of 5 MeV/u [2]. Because of the limitation in charge to mass ration the LU-20 can not be used effectively for operation as a part of the NICA facility. Additionally, an effective stripping of the ions before injection into the Nuclotron requires their preliminary acceleration to an energy of a few hundreds of MeV/u. Therefore, realization of the NICA project presumes design and construction a heavy ion injector and intermediate booster synchrotron as new elements of the NICA collider injection chain. The injection chain optimization was started from the choice of an ion source and formulation of requirements to the linear accelerator.

## ION SOURCE AND REQUIREMENTS FOR LINAC

We have considered a few types of the heavy ion sources – namely the Laser Ion Source (LIS), the Electron Beam Ion Source (EBIS), the Electron String Ion Source (ESIS) and the Electron Cyclotron Resonance (ECR) ion source.

The LIS has limitations in the kind of ions that can be produced. Additional obstacles, such as large beam emittance due to a large energy spread, target erosion and coating of mirrors, state of the art laser requirements, and very large pulse-to-pulse fluctuations of the beam current, set one thinking seriously about development of this type of the ion source presently.

The EBIS ion source chosen as the base of the new RHIC injector [3] has parameters close to the required ones and expected for the ESIS. General disadvantage of the EBIS is very high DC power of the electron beam. So, the EBIS proposed for the new RHIC injector requires of about 300 kW DC power for the operation and maximum charge state is limited because of the electron energy limitations. At the same time, the maximum DC power of the electron beam in the ESIS is about 200 W. By contrast to the EBIS, the ESIS source can provide heavy ions in very high charge states, like $Au^{51+}$ or $U^{64+}$ at practically same intensity as $Au^{30+}$ or $U^{32+}$. The repetition frequency of ESIS operation in this mode is at the level of 1 Hz.

In view of the facts described above the decision to use the development of the ESIS as the baseline for the NICA project has been taken.

The possibility to work with ECR ion source as reserve option for the NICA facility operation is considered as well. To realize it the linac has to accelerate long heavy ions pulse generated in an ECR source for multiturn injection into the booster.

To provide optimization of the heavy ion injection chain and cover the polarized program of the NICA facility the injector-linac has to provide the following options of the operation:

- acceleration of the heavy ions at the charge state of 30+ ÷ 32+ at the intensity of $(2 \div 4) \cdot 10^9$ ions and the pulse duration of 7 μs (the ion revolution period in the booster);
- acceleration of the heavy ions like $Au^{51+}$ and $U^{64+}$ at the intensity of $(2 \div 4) \cdot 10^9$ and the pulse duration of 7 μs;
- acceleration of the heavy ions at the charge state of about 30+ ÷ 32+ at the current of 0.1 ÷ 0.2 mA and pulse duration up to 100 μs (operation with ECR source);
- acceleration of the polarized $D^-$ ions at the current up to 1 mA and the pulse duration of about 1 ms.

The first option is chosen as the baseline for realization of U-U collision experiment. The pulse of $4 \cdot 10^9$ $U^{32+}$ ions at 7 μs duration corresponds to the peak current of about

3 mA. Maximum ion current corresponds to the second option and it is about 6 mA. To provide required technical reserve the linac has to have good efficiency of the heavy ion acceleration at the current up to 10 – 15 mA.

## LINAC AND INJECTION CHAIN

The RFQ section was chosen as the initial part of the injector linear accelerator. At low ion velocity RFQ permits a continuous acceleration and perfect adiabatic conditions to produce a very good bunching efficiency (~ 100%). For the main part of the injector linac we considered four versions:
1) Alvarez-type accelerator,
2) an accelerator with the Alternative Phase Focusing (APF) [4],
2) hybrid type of the focusing proposed at GSI [5],
3) RFQ DTL developed in IHEP (Protvino) [6].

*1st version* assumes installation of an RFQ accelerator instead of the existing HV fore-injector and replacement of the drift tubes system of the LU-20 by a new one. However, in the ion energy range of a few MeV/u the peak RF power required for the Alvarez structure is about three times larger than for the structures based on H-cavities. Furthermore, the drift tube length in E-cavity structure has to be long enough to place a quadrupole lens inside it. This leads to low acceleration rate in the initial part of the structure and to decrease of the accelerator efficiency.

*2nd version*. The APF accelerator provides high acceleration rate and is simple in operation. However, its maximum ion current is below 1 mA.

*3rd version*. In the GSI type structure the strength of the transverse focusing of the APF is sufficiently increased by using quadrupole triplets located in a few large drift tubes. Such structure is used for lead ion acceleration in CERN and is planned as the main part of the new RHIC injector [3]. However, up to now such accelerators were used with ECR ion sources and their application to acceleration of a high current ion beam has been never demonstrated yet experimentally.

*The 4rd version* - the RFQ DTL, in contrast to the APF structures utilizes focusing by quadrupole components of the accelerating field and provides a strong focusing in both longitudinal and transverse planes. As result, the maximum ion beam current can reach of about 100 mA. The IHEP group (founded by one of the inventors of the RFQ accelerator Vladimir Teplyakov) has more than 30 years experience in design and construction of such structures.

Finally, *the 4d version* - RFQ DTL has been chosen as the basis for the main part of the new linac design and construction. On the basis of conceptual design of the RFQ and the RFQ DTL prepared by the IHEP group the optimization of the NICA injection chain (Fig. 1) was done. The booster maximum energy is limited by available room in the existing building and maximum magnetic field of its bending magnets. The injection chain satisfies to the requirements of the heavy ion program and provides technical reserve for the facility development.

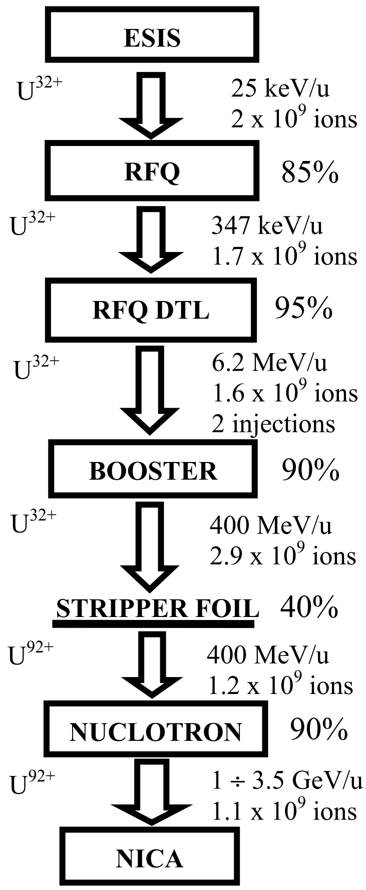

Figure 1: Injection chain of the NICA collider based on ESIS source and RFQ linac.

## STRUCTURE AND PARAMETERS OF THE INJECTOR

The injector delivers ions in wide atomic number range – from polarized deuterons to $^{238}U^{32+}$ at the energy of 6.2 MeV/u. Its total length is of 30 m. The injector will be constructed in the existing so called UFTI building (a very preliminary design is shown in the Fig. 2) in order to provide its assembly and commissioning without interruption of the Nuclotron operation.

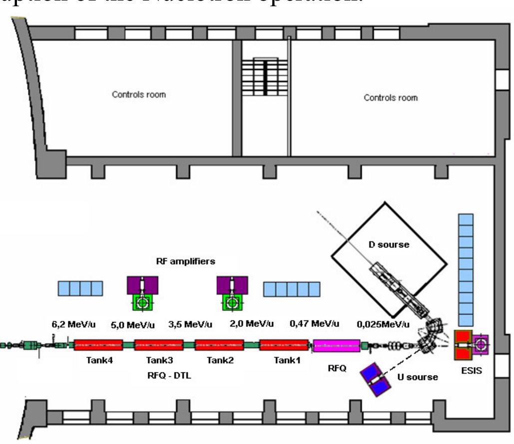

Figure 2: Injector location in the existing building.

The injector includes the following elements:
- Electron String Ion Source (ESIS);
- External uranium ion source;
- Source of polarized $D^-$ ions (POLARIS or CIPIOS);
- Low Energy Beam Transport (LEBT) to match the beam with the entrance of the linear accelerator;
- Linear accelerator consisting of the RFQ section and four sections of the RFQ DTL;
- High Energy Beam Transport (HEBT) from the exit of the linac to the injection point of the booster. This line includes also a debuncher system.

## ESIS

Electron beam ion sources (EBIS) invented at JINR [8] are used widely in many accelerator centers for production of highly charged ions. In the reflex mode of the EBIS operation the electrons do not reach electron collector after one pass through the drift space of the source. Instead they are reflected back towards the electron gun, where are reflected again near the gun cathode, travel one more to the reflector, and so on. Thus, the electrons are bouncing between the cathode and the reflector of the source and can be used for generation of highly charged ions much as a direct electron beam does.

It was found that in certain conditions the ”cloud” consisting of the multiply reflected electrons confined in a strong solenoid magnetic field exhibits properties similar to a phase transition. It leads to a stepwise increase of the confined electron plasma density in a new steady state called "the electron string". Various highly charged ion beams have been produced with the ESIS “KRION-2” constructed at JINR (Fig. 3) and used in two Nuclotron runs during recent years [9].

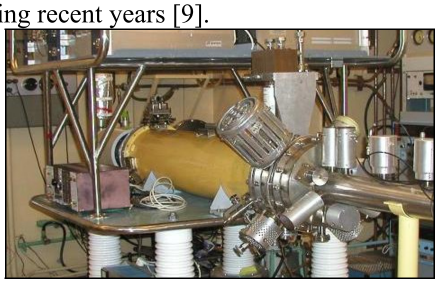

Figure 3: ESIS “KRION-2” operated at JINR.

New stand ESIS “KRION-6T” aimed to achieve parameters required for NICA (Table 1) is under construction now.

Table 1: Main Parameters of the ESIS Sources

| | “KRION-2” achieved to date | “KRION-6T” expected |
|---|---|---|
| Magnetic field, T | ≤ 3 | ≤ 6 |
| Electron energy, keV | ≤ 8 | ≤ 25 |
| Ions | $Au^{30+}$ | $Au^{32+}$ ($U^{32+}$) |
| Ionization time, s | $2 \cdot 10^{-2}$ | 0.015 |
| Work frequency, Hz | 40 | 50 |
| Number of ions per pulse (at given charge state) | $5 \cdot 10^{8}$ | $2 \cdot 10^{9}$ |
| Extraction time, μs | 8 | 6 - 8 |

## RFQ AND RFQ DTL

The RF frequency in both accelerators - the RFQ and the RFQ DTL - is equal to 75 MHz. The accelerator is designed to accelerate the beam of initial normalized rms emittance of 0.1 π·mm·mrad and the emittance growth during acceleration does not exceed two times. To avoid electron load of the cavity (cold emission) the maximum electric field at the electrode surface RFQ is chosen to be limited by the value of 350 kV/cm for RFQ DTL. The accelerator consists of the RFQ section (of the length of about 6 m) and four RFQ DTL sections (of the length of about 4.5 m, Fig. 4). The section number and length are determined by technological reasons.

The RF, water cooling, vacuum systems and the beam diagnostics along the accelerator will be designed and constructed on the basis of the IHEP long experience in the design, construction and exploitation of RFQ structures. All the elements of the linear accelerator can be fabricated in Protvino at the IHEP workshop.

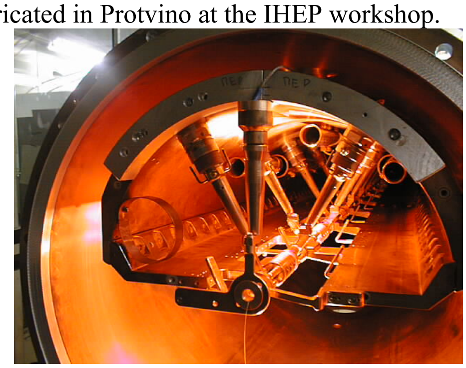

Figure 4: RFQ DTL proton linac in IHEP.

[illegible]

The High Intensity and Energy ISOLDE (HIE-ISOLDE) proposal is a major upgrade of the existing ISOLDE and REX-ISOLDE facilities with the objective of increasing the energy and the intensity of the delivered radioactive ion beam. For the energy increase a staged construction of a superconducting linac based on sputtered quarter wave cavities is foreseen downstream of the present normal conducting linac. A funded R&D program has been launched at the end of 2007 in order to prepare a full Technical Design Report covering all the issues of such linac, including cavity prototyping and testing, cryomodule design, beam dynamics and beam diagnostics. We report here on the status and planning of the R&D activities for the SCREX-ISOLDE linac.

## INTRODUCTION

Radioactive ion beam production at the ISOLDE facility at CERN is based on the ISOL (Isotope Separation On-Line) method where a max 2.8 kW proton beam, extracted at 1.4 GeV from the Proton-Syncrotron Booster (PSB), impinges upon a thick, high temperature target. The radioactive nuclei can be produced in two different target stations (GPS and HRS) via spallation, fission or fragmentation reactions. ISOLDE has been continuously developing targets and ion sources for four decades, introducing several new technologies (e.g. the resonance ionization laser ion source) so that there are now available more then 700 radioisotopes from 65 elements. These beams are accelerated to 60kV and steered to different experimental stations. In the present REX-ISOLDE facility [1] the RIBs are accelerated to higher energies with a compact Normal Conducting (NC) linac, making use of a special low energy preparatory scheme where the ion charge state is boosted so that the maximum mass to charge ratio is always $3 < A/q < 4.5$. This scheme consists of a Penning trap (REXTRAP), a charge breeder (REXEBIS) and an achromatic A/q separator of the Nier spectrometer type. The NC accelerator is designed with an accelerating voltage for a corresponding maximum A/q of 4.5 and it delivers a final energy of 3 MeV/u for $A/q < 3.5$ and 2.8 for $A/q < 4.5$. After charge breeding, the first acceleration stage is provided by a 101.28 MHz 4-rod Radio Frequency Quadrupole (RFQ) which takes the beam from an energy of 5 keV/u up to 300 keV/u. The beam is then re-bunched into the first 101.28MHz interdigital drift tube (IH) structure which increases the energy to 1.2 MeV/u. Three split ring cavities are used to give further acceleration to 2.2 MeV/u and finally a 202.56 MHz 9-gap IH cavity is used to boost and to vary the energy between $2.2 < E < 3$ MeV/u. Fig. 1 illustrate the scheme of the present linac.

The HIE-ISOLDE project contains three major parts: higher energies, improvements in beam quality and flexibility, and higher beam intensities. This requires developments in radioisotope selection, improvement in charge breeding and target-ion source development, as well as construction of the new injector for the PSB, LINAC4 [2]. The most significant improvement in the physics program [3] will come from the energy upgrade which aims at reaching a minimum energy of 10 MeV/u.

The present NC machine was developed in order to deliver beams at specific energies whilst taking advantage of the high accelerating gradient that pulsed NC IH structure could achieve. This concept is nevertheless not without some limitations: 1) limited energy variability; 2) operation restricted to pulsed mode; 3) inefficient use of the installed power when running light ions; 4) non variable longitudinal beam parameters, such as energy spread and bunch length.

To overcome the above limitations and to open the possibility of different longitudinal beam parameters, a superconducting linac based on Nb-sputtered SC Quarter Wave Resonators (QWRs) has been proposed [4]. The fact of having 2-gaps cavity independently phased assures both a very high flexibility in term of velocity acceptance and at the same time a small number of cavity types to cover the whole energy range.

## THE SUPERCONDUCTING LINAC

The superconducting linac is designed to deliver an effective accelerating voltage of at least 39.6 MV with an average synchronous phase $\phi_s$ of -20 deg. This is the minimum voltage required in order to achieve a final energy of at least 10 MeV/u with $A/q = 4.5$. Because of the steep variation of the ions velocity, at least two cavity geometries are required in order to have an efficient acceleration throughout the whole energy range. A total number of 32 cavities are needed to provide the full acceleration voltage. The geometries chosen corresponding to [illegible] ($\beta_0 = 6.3\%$) and [illegible] ($\beta_0 = 10.3\%$) "$\beta$" cavities maintain the fundamental beam frequency of 101.28 MHz and their design parameters are given in Table 1. The design accelerating gradient aims at reaching 6 MV/m with a power consumption of 7 W per low $\beta$ cavity and 10 W per high $\beta$ cavity. These values have been already achieved by the two avail-

* matteo.pasini@cern.ch

able technologies for the QWRs, namely the □□□□Nb and the □□□□□□□□cavity [5], [6].

Table 1: Cavity Design Parameters

| Cavity | Low $\beta$ | high$\beta$ |
|---|---|---|
| No. of Cells | 2 | 2 |
| f (MHz) | 101.28 | 101.28 |
| $\beta_0$ (%) | 6.3 | 10.3 |
| Design gradient $E_{\text{acc}}$(MV/m) | 6 | 6 |
| Active length (mm) | 195 | 300 |
| Inner conductor diameter (mm) | 50 | 90 |
| Mechanical length (mm) | 215 | 320 |
| Gap length (mm) | 50 | 85 |
| Beam aperture diameter (mm) | 20 | 20 |
| $U/E_{\text{acc}}{}^2$ (mJ/(MV/m)$^2$ | 73 | 207 |
| $E_{\text{pk}}/E_{\text{acc}}$ | 5.4 | 5.6 |
| $H_{\text{pk}}/E_{\text{acc}}$ (Oe/MV/m) | 80 | 100.7 |
| $R_{\text{sh}}/Q$ ($\Omega$) | 564 | 548 |
| $\Gamma = R_{\text{s}} \cdot Q_0$ ($\Omega$) | 23 | 30.6 |
| $Q_0$ for 6MV/m at 7W | $3.2 \cdot 10^8$ | $5 \cdot 10^8$ |
| TTF max | 0.85 | 0.9 |
| No. of cavities | 12 | 20 |

Because each cavity is independently phased, we can apply the maximum voltage available in each cavity so that lighter ion will reach higher final energies. Figure 2 shows a plot of the energies reached by the ions with different A/q. The focussing scheme foresees the employment of SC solenoids, which allows a higher mismatch factor tolerance with respect to standard triplet or doublet focussing scheme [7]. The low $\beta$ cavities have been grouped into two cryomodules of six cavities each, while the high $\beta$ cavities have been grouped in four cryomodules of five cavities each. Beam dynamics studies are ongoing to assess optics parameters and to optimize emittance growth control [8].

## □a□□□□□□□□□□□□□□

The Nb sputtering technology wil be used for the HIE-LINAC cavities. A distinct advantage of the sputtering technology is that, because of the dominant copper base, the cavities can be made with thick walls so to ensure high thermal conductivity and a high mechanical stability. The former guarantees an excellent thermalization of the cavity avoiding hot spots that could break the superconducting state. The latter allows substantial simplification of the tuning system. A prototype cavity is under fabrication and a detailed study for the mechanical assembly and procedures has been performed in order to avoid any copper annealing so to maintain the mechanical rigidity of the copper [9]. The established procedures allows a substantial reduction of the cost of the copper material, and critical e-beam weldings have all been tested. An important part of the cavity manufacturing is the actual sputtering of the Nb layer onto the copper base. The bias technology developed at LNL-INFN will serve as a starting point [10] but a development towards magnetron sputtering is planned. The plan foresees the completion of the copper base manufacturing by the end of October 2008, chemical treatment and Nb deposit by the end of the year. First cold tests are expected beginning 2009.

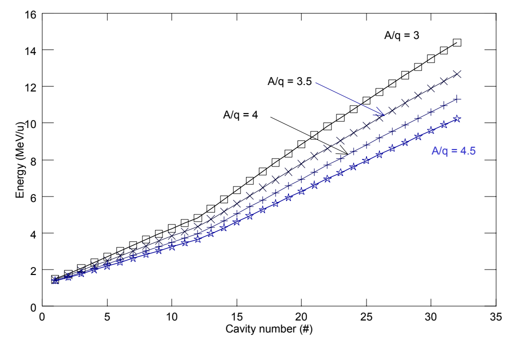

Figure 2: Beam energy as a function of the cavity number. For the $A/q = 3$ the maximum energy achieved is 14.4 MeV/u.

## □□□□□□□□□□□

The choice of having a SC solenoid as focusing element allows to reduce the intermodule distance with respect to a scheme where the focusing elements are made of warm quadrupoles. The advantage is a more compact linac, saving precious space for the experiments and simplify the longitudinal beam dynamics. The result of this scheme sets

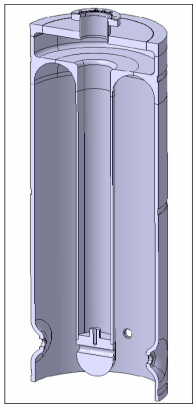

Figure 3: High $\beta$ cavity 3-D section.

several constraints on the cryomodule layout, for which a conceptual design is ongoing. An important design issue of low energy SC ion linacs is whether the beam vacuum is shared with the insulation vacuum or not. This former brings as a consequence a strict control on the fabrication and cleaning procedures, as well as the assembly. The latter brings as a consequence an additional layer of interconnection with an increased engineering complexity. Details about the conceptual design are reported in ref. [11].

### [illegible]

The cryoplant needed to supply liquid helium at 4.5 K will require an additional building - located next to the experimental hall - to house the compressor station and its cold box. We are looking at the possibility of reusing an existing refrigerator which was connected to the ALEPH magnet during the LEP operation from 1989 to 2000. The cold box was capable in 1989 to provide an isothermal refrigeration power of 630W at 4.5K plus an additional shield load of 2700 W between 55K and 75K. Fig. 4 shows a first concept design of the cryoplant. The total heat load of the system required for the complete ISOLDE energy upgrade is very close to the maximum power that the cold box can provide. Nevertheless, we have to evaluate precisely this possibility as it would allow a substantial cost saving with respect to the purchase of a new unit. The transfer line needed to supply the liquid helium is 35 m long and will be equipped with 6 [illegible] modules (one per module) to allow the isolation of each module from the common distribution line without interruption on the remaining modules.

## INSTALLATION PLAN

The first stage of the upgrade plan consists of installing two [illegible] $\beta$ cryomodules downstream the present NC linac so to reach a final energy of a least 5.5 MeV/u. The position of these two cryomodules is set to be also the final one, so that no additional removal will be required for the installation of the complete linac. Accordingly, a modular transfer line will be in place in order to accomodate the beam transport as the linac energy will increase. The position of the experimental facilities like Miniball and the planned recoil spectrometer will also be fixed at the position of the full installation. Assuming the financing is approved by mid of 2009 the first stage of the upgrade is planned to be completed in the fall 2012. The remaining high and low $\beta$ cryomodules will then be installed subsequently with the aim of completing the commissioning of the HIE-LINAC by mid 2013.

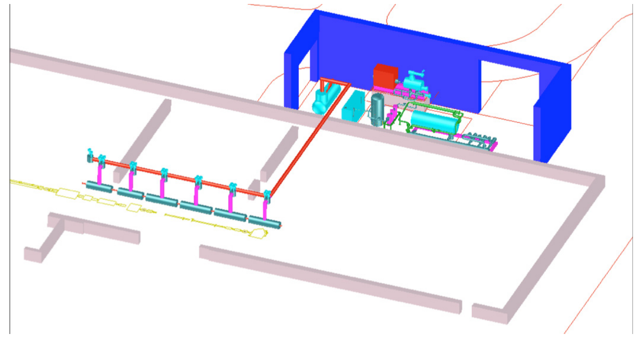

Figure 4: Cryoplant 3-D layout.

## ACKNOWLEDGEMENTS

The cavity design and the reference linac design have taken great contribution from the work performed by Enzo Palmieri and Anna Maria Porcellato of INFN-LNL. Indeed many ideas and a solid starting point have come from them.

## Abstract

For the REX-ISOLDE upgrade a superconducting linac based on 101.28 MHz Quarter Wave Resonators (QWRs) is foreseen downstream of the normal conducting (NC) linac. Currently the REX-ISOLDE linac can accelerate ions with a mass to charge ratio in the range of $3 <$ A/q $< 4.5$ up to an energy of 2.8 MeV/u. The upgrade aims to reach a minimum final beam energy of 10 MeV/u for A/q=4.5 in two main stages. The first stage consists of installing two cryomodules loaded with 10 cavities able to reach 5.5 MeV/u at the end of the present linac and the second consists of replacing part of the existing NC linac and adding further cryomodules. We report here on a beam dynamics study of the accelerator for the two installation stages.

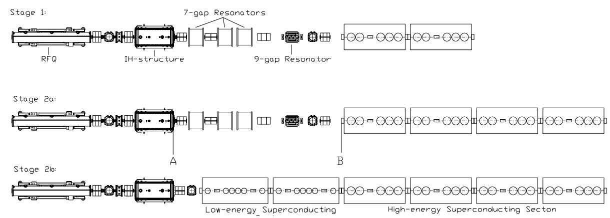

Figure 1: A Schematic of the HIE-ISOLDE linac stages. Stage 1 is shown at the top, while stage 2 can be split into two sub-stages depending on the physics priorities: the low energy cryomodules will allow the delivery of a beam with better emittance; the high energy cryomodule will enable the maximum energy to be reached.

## INTRODUCTION

The REX-ISOLDE linac for the ISOLDE Radioactive Ion Beam facility at CERN [1] consists of a normal conducting linac where the RIB gets accelerated in different stages: a 101.28 MHz 4-rod Radio Frequency Quadrupole (RFQ) takes the beam from 5 to 300 keV/u, a 101.28 MHz interdigital drift tube (IH) structure boosts the beam energy up to 1.2 MeV/u, three 101.28 MHz split ring cavities accelerate to reach 2.2 MeV/u and a final 202.56 MHz IH structure is used to vary the energy between 2.2 and 3 MeV/u. The HIE-ISOLDE project [2] looks at the overall upgrade of the facility, i.e. an increase of the final energy of the radioactive ion beam, an improvement of the beam quality and flexibility and an increase of the beam intensity. The linac upgrade will consist of a superconducting machine [3] providing 39.6 MV of effective accelerating voltage with an average synchronous phase $\phi_s$ of -20 deg. utilising 32 101.28 MHz QWRs split into two families: [illegible] and [illegible] $\beta$ cavities. The first stage of the upgrade plan consists of installing 10 high $\beta$ cavities grouped in two cryomodules downstream of the present NC linac (stage 1). The second stage will be installed in two parts. Firstly, two more high $\beta$ cryomodules will be added (stage 2a) downstream from those in stage 1 and secondly the split ring cavities and the 202.56 MHz IH cavity will be replaced with 12 low $\beta$ cavities grouped in 2 cryomodules (stage 2b). Figure 1 shows a schematic of the different installation stages. The final energy for stage 1 and stage 2 is respectively 5.5 MeV/u and 10 MeV/u for A/q=4.5.

The focusing scheme foresees the employment of 200 mm long SC solenoids, which allow a high mismatch factor tolerance with respect to a standard triplet or doublet focusing scheme [4]. This brings a significant advantage for the tuning and operation of the machine. In fact, RIBs accelerators in general make use of a [illegible] intensity stable beam as a pilot beam with an A/q ratio that is as close as possible to the A/q of the wanted RIB. This is in fact necessary, since the very low RIB's intensity is practically invisible to conventional beam instrumentation. Once the pilot beam is established, a scaling action is performed and a focusing lattice with high mismatch tolerance guarantees better beam transport in the machine after scaling, where possible beam mismatch can occur. In addition, because SC solenoids allow the intermodule distance to be minimized, the longitudinal acceptance of the linac is not reduced and multi-charge state acceleration can be performed [5]. A schematic of the two cryomodules is shown in Figure 2. With this configuration the beam diagnostics instruments are ideally positioned at the beam waist location in the inter-cryomodule region where a pair of steering magnets will also be installed.

## BEAM DYNAMICS SIMULATIONS

For the simulations of the complete HIE-LINAC (stage 2b) a 1 m long matching section with 4 quadrupoles between the first IH-structure and the first cryomodule is taken into account. It is important to keep this section as short as possible in order to minimize the longitudinal beam debunching. The input beam parameters for the simulations are constrained by the IH-cavity output beam and were calculated using TRACE3D [6]. The resonators were set to operate at a synchronous phase of -20 deg., and to increase the longitudinal phase spread capture at injection, the first resonator was phased at -40 deg. The last resonator in the first cryomodule was also re-phased, at -30 deg., in

* matteo.pasini@cern.ch

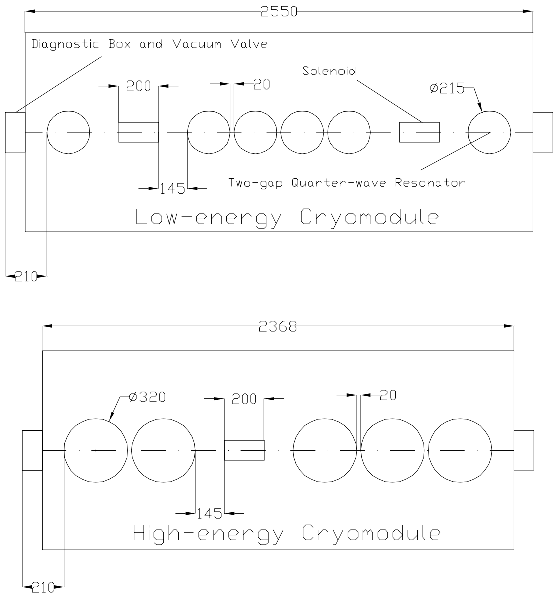

Figure 2: Schematic of the cryomodules design. On the top the low $\beta$ cryomodule and on the bottom the high $\beta$ cryomodule.

order to further decrease the longitudinal phase spread of the beam after the first cryomodule. The simulations were implemented to first-order in `LANA` [7] using a square field distribution for the cavities and solenoids and the results confirmed with `Path Manager` [8], which uses a thin-lens approximation for lattice elements. Two thousand particles were simulated and space-charge forces neglected because of the low beam intensity.

The solenoidal magnetic fields were adjusted to achieve matched beams along the HIE-LINAC. The three solenoids in the second and third cryomodules were used to match the beam across the transition region between the low and high-energy sections. Matched solutions were found for different values of the phase advance per cryomodule $\mu$ in the low-energy section and the resulting transverse emittance growth along the HIE-LINAC investigated. The source of transverse emittance growth comes essentially from the beam phase spread inside the RF gap, as can be seen from the expression for the RF defocusing impulse, $\Delta p$, acting on a single particle, and the growth can be controlled by choosing an appropriate phase advance:

$$\Delta p \propto \frac{\sin(\phi)}{\beta\gamma} r \qquad (1)$$

where $r$ is the particles radial displacement, $\phi$ is its average longitudinal phase and $\beta\gamma$ are the relativistic factors associated with its motion. From (1), a monotonic decrease in transverse emittance growth would be expected as the phase advance increases and the extent of the beam in the transverse plane shrinks, provided the spread in any of the other variables does not dominate. The results of this preliminary survey are shown in Figure 3, which shows a decrease of emittance growth with phase advance per cryomodule above 80 deg, as expected, but anomalous behaviour below 80 deg.

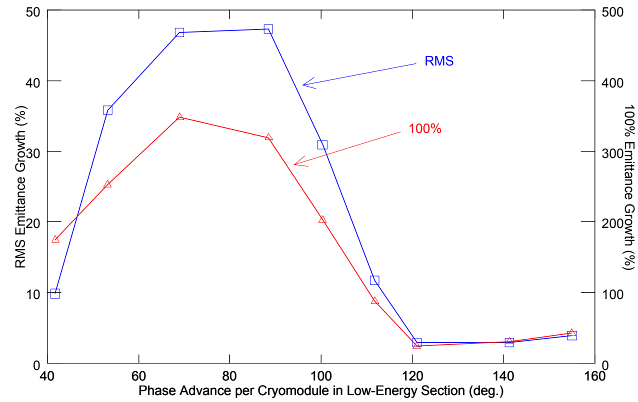

Figure 3: Final emittance growths in the HIE-LINAC with phase advance per cryomodule in the low-energy section.

The variables in Equation 1 are well controlled in the simulations and, in particular, the spread of the longitudinal phase of the beam does not vary enough to account for this anomalous behaviour at low phase advance. This anomalous behaviour was investigated by isolating the low and high-energy sections of the HIE-LINAC and simulating the behaviour of the transverse emittance growth, with phase advance, separately. The input beam parameters for the low-energy section were identical to the previous simulations but the input parameters for the high-energy section were calculated at point B in Figure 1, (i.e. 1664 mm downstream from the 9-gap). The RMS emittance behaves as expected, as shown in Figures 4 and 5, and the transverse emittance growth reduces as the transverse beam size shrinks.

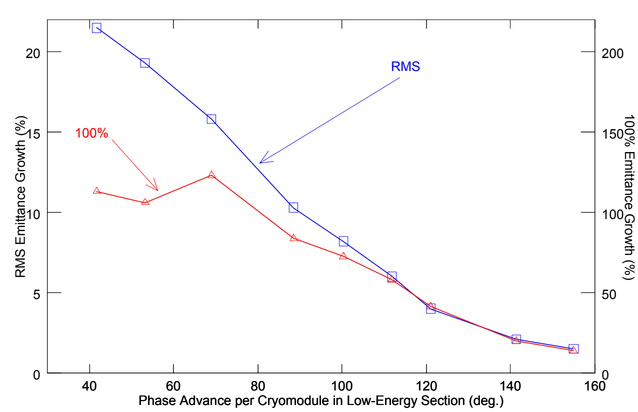

Figure 4: Emittance growth with phase advance in low-energy section.

We conclude that the anomalous behaviour in Figure 3 results from the matching region between the two sections

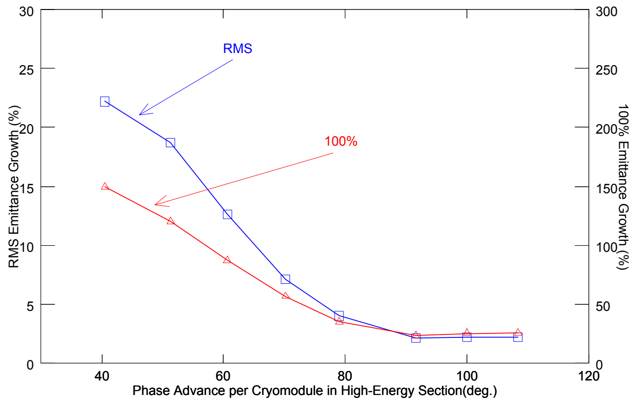

Figure 5: Emittance growth with phase advance in high-energy section.

of the HIE-LINAC. In order to confine the beam at higher phase advance, larger magnetic fields must be used in the focusing elements. We proceed with the beam dynamics study by selecting the matched solution which provides minimal emittance growth without demanding excessively high solenoidal magnetic fields.

## CONCLUSION

Due to the development of the cryomodule design, the inter-cryomodule distance, i.e. the distance from the last cavity in one cryomodule to the first cavity in the following one, was increased to 800 mm; a modification which would have little impact on the findings of our preliminary survey. Both stage 1 and stage 2 scenarios were simulated and the results of the full linac installation are shown in Fig. 6. The chosen matched solution requires 130 deg. phase advance in the first section, and 90 deg. in the second. Both the RMS transverse and longitudinal emittance grow no more than 4% throughout the HIE-LINAC, and, even with the re-phasing of the first and sixth resonators, the target energy of 10 MeV/u is reached, with A/q = 4.5.

The input and output beam parameters are listed in Table 1 for the two installation stages. The average solenoidal magnetic field in the low-energy section is 5.1 T and 7.4 T in the high-energy section.

Future study will aim to better understand the anomalous behaviour observed above. Additional simulations studying the effect of the intrinsic dipole component [9] of the QWRs and higher order effects of the focussing lattice are anticipated. These simulations will focus on field mappings for both the cavity and the solenoids.

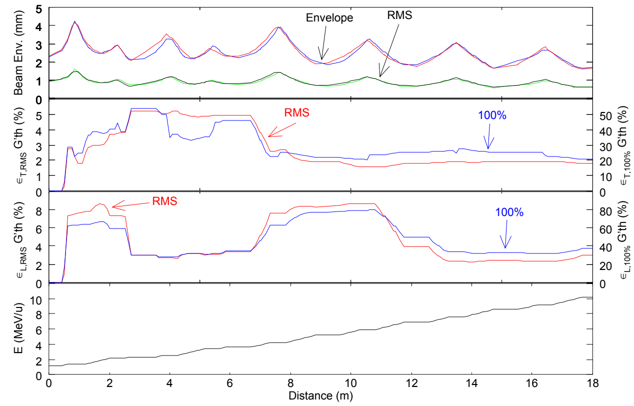

Figure 6: Beam dynamic for a simulation with phase advance of 130 and 90 deg. in the low and high-energy sections, respectively. From top to bottom: max and rms envelope, 100% and rms transverse emittance growth, 100% and rms longitudinal emittance growth, beam energy as a function of the linac length.

Table 1: Beam Parameters

| Parameter | Input | Output |
|---|---|---|
| Stage 1 | | |
| $\alpha_T$ | -0.150 | -0.165 |
| $\beta_T$ (cm/mrad) | 0.100 | 0.132 |

## ABSTRACT

The proposed Facility for Radioactive Ion Beams (FRIB) [1] will deliver up to 400 kW of any stable isotope to Rare Isotop Beam (RIB) production target. Operational efficiency could, under certain conditions, be improved by a system that can distribute the beam current, variable in a large dynamic range, to several independent targets simultaneously. A possible FRIB Beam Switchyard (BSY) utilizes an RF kicker with subsequent magnetostatic septum system to split the beam on micro-bunch to micro-bunch basis. The micro-bunches can be differentially loaded at the front-end of the Driver Linac [2]. The detailed analysis of the beam dynamics performance in the proposed BSY system is presented.

## INTRODUCTION

The effective use of the proposed FRIB facility [1] can under certain conditions be benefited by the ability to support simultaneous experiments. The stable isotope beams from the Driver Linac can be used for production of Radioactive Ion Beams (RIBs) using either Isotope Sepatation On Line (ISOL) or In-flight Particle Fragmentation methods to maximize yield of the corresponding species.

The discussed Beam Switchyard (BSY) will allow separation of the continuous stable ion beam from the Driver Linac into two independent channels on a micro-bunch by micro-bunch basis using an RF kicker followed by magnetic septum system.

The performance of this system was explored in details using three-dimensional electromagnetic fields for the RF kicker and a magnetostatic field distribution in septum magnet. As an alternative to the RF kicker, a DC septum magnet consisting of an array of thin wires and two electrodes can be used for lighter ions.

## BEAM SWITCHYARD (BSY) SYSTEM

A proposed FRIB BSY design uses an RF kicker, an alternative DC bending dipole, and a septum magnet along the beam transport channel to either split the incoming stable beam into two beam lines with 50% intensity in each branch or to supply a single target with the full beam intensity (100 %) any of two production targets. The intensity of the two branches can be varied from 0% to 50% total beam intensity independently using the additional system of differential beam loading [2]. Figure 1 shows the layout of the proposed BSY system.

To minimize beam loss, quadrupole magnets in front of the RF kicker are provided to achieve reduced horizontal beam size at the entrance of the septum magnet. Both the RF kicker and the DC dipole have the same design deflection angle of ±1.5 mrad and will be used interchangeably for either splitting the incoming beam into two segments or direct all beam into one of the following beam lines. Given the beam micro-bunch frequency of 80.5 MHz, an RF kicker frequency of 120.75 MHz is appropriate to split the beam into two segments by kicking every other bunch in opposite transverse directions. A 10 m long drift space after the initial splitting point in RF kicker is required to generate enough spatial separation to accommodate a 10 mm thick septum in the septum magnet.

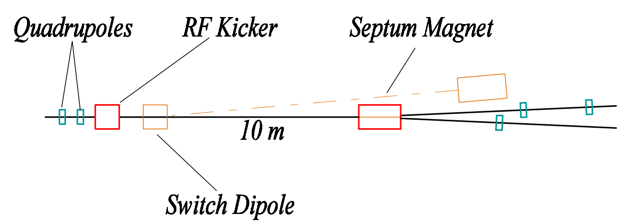

Figure 1: Layout of a proposed FRIB BSY system.

The performance of the proposed BSY system was evaluated by detailed beam dynamics simulations using the realistic three-dimensional (3D) distributions of the electromagnetic RF and magnetostatic fields in the system elements.

## RF KICKER

The electromagnetic (EM) field calculations for the RF kicker were done using the computer code MAFIA. The resonant structure of the RF kicker is shown in Figure 2 and represents a “lumped circuit” consisting of two parallel plates (capacitance) and four stems (inductors).

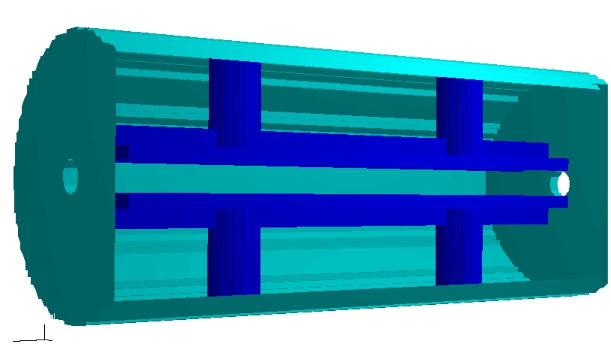

Figure 2: Three-dimensional view of the RF kicker.

The transverse electric field created between the plates deflects the beam in the direction perpendicular to the planes and parallel to the stems. Using two stems improves stiffness of the structure, simplifies cooling, and helps to equalize the longitudinal electric field

| Current density | 3000 A/cm$^2$ |
| Effective length | 1.814 m |
| Coils cross-section | 30 mm x 6 mm |

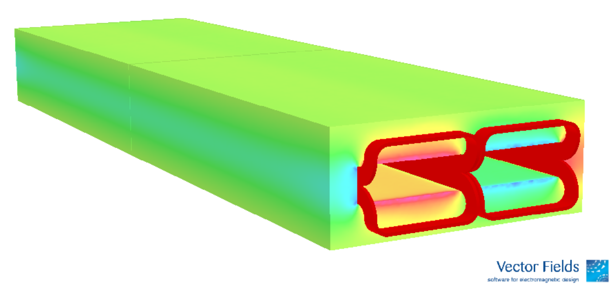

Figure 6: Three-dimensional view of the septum magnet.

## BEAM DYNAMICS SIMULATION RESULTS

Beam dynamics analysis of the proposed BSY was done using the LANA code [3]. The detailed analysis of the beam dynamics in the septum magnet was also done in parallel using the KOBRA code. The results from KOBRA and LANA were found to be in agreement within model accuracy. In all simulations, the three-dimensional electromagnetic field of the RF kicker and the magnetostatic field of septum magnet were used with the field distributions obtained from the MAFIA and OPERA computer codes respectively.

The initial beam parameters obtained from end-to-end beam simulations for the driver linac used in the BSY simulation are given in Table 3. Four quadrupole magnets before the RF kicker were used to obtain the required beam phase space at the RF kicker entrance.

Table 3: BSY Input Beam Parameters

| | | | |
|---|---|---|---|
| Energy | 400 MeV/u | $\varepsilon_Z$ | 27.6 $\pi$ ns keV/u |
| Q | 89+ | $\alpha_Z$ | 0 |
| A | 238 | $\beta_Z$ | 20.0 degree/% |
| $\varepsilon_X$ | 1.6 $\pi$ mm mrad | $\varepsilon_Y$ | 1.6 $\pi$ mm mrad |
| $\alpha_X$ | 0 | $\alpha_Y$ | 0 |
| $\beta_X$ | 1.0 | $\beta_Y$ | 1.0 |

The RF kicker is used to create an initial spatial separation between sequential (every other) bunches. To deflect every other bunch into two different trajectories, the operating frequency of the rf kicker can be any odd half-integer of the bunch frequency. The 3/2 harmonic, which corresponds to a frequency of 120.75 MHz, was chosen (see Table 1).

The septum magnet is used to further separate two beams in space. The septum magnet is placed 10 meters downstream the RF kicker where the two beams are sufficiently separated. The main beam dynamics parameters of the septum magnet are given in Table 2.

The resulting separation of the beam bunches in the bending plane for the design settings of the system parameters are summarized in the Table 4.

Table 4: Bunch Separation in the Bending Plane

| Separation | After RF kicker | Before septum | After septum |
|---|---|---|---|
| x (±) [mm] | 0.8 | 15.7 | 73.1 |
| x` (±) [mrad] | 1.53 | 1.53 | 48.5 |

From simulation, the effective emittance growth in the proposed BSY was negligible except in the bending plane. The variation of the emittance in the other planes was comparable to the simulation model accuracy. The summary of the emittance growth is given in the Table 5. The beam path inside the septum magnet is shown in Figure 7.

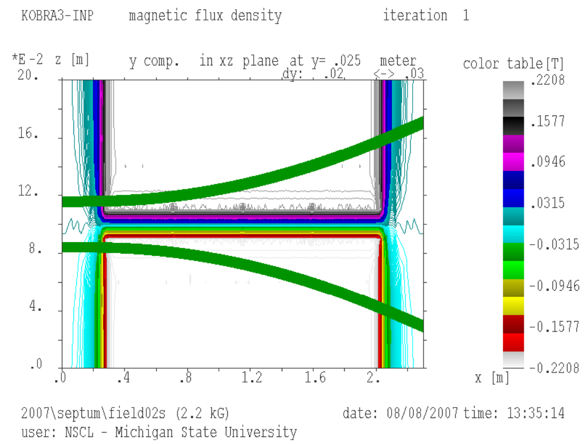

Figure 7: The path of the two separated bunches and the magnetic field distribution in the septum magnet.

The smearing of the beam due to fast amplitude variation of the RF field in the kicker (jitter) will lead to an additional emittance growth. This additional growth, however, is several times smaller than the static growth. The effect of the corresponding RF phase jitter on the final beam emittance for all three phase space projections was found to be negligible in all simulations.

## CONCLUSION

A proposed FRIB beam switchyard using an RF kicker and magnetic septum system to split the beam into two downstream beam lines on a micro-bunch by micro-bunch basis provides high quality beam on targets. It is possible to enhance the efficacy of this system by differentially loading the micro-bunches by employing a system in the Medium Energy Beam Transport system.

A dc septum system consisting of an array of thin wires and two cathodes could be used to split the beam but only for oxygen ions or lighter.

# ESTIMATES OF ENERGY FLUENCE AT THE FOCAL PLANE IN BEAMS UNDERGOING NEUTRALIZED DRIFT COMPRESSION*

J. J. Barnard, LLNL, Livermore, CA 94550, USA, P. A. Seidl, J. E. Coleman, D. Ogata, LBNL, Berkeley, CA 94720, USA, D. R. Welch, Voss Scientific Corp., Albuquerque, NM, 87108, USA

*Abstract*

We estimate the energy fluence (energy per unit area) at the focal plane of a beam undergoing neutralized drift compression and neutralized solenoidal final focus, as is being carried out in the Neutralized Drift Compression Experiment (NDCX) at LBNL. In these experiments, in order to reach high beam intensity, the beam is compressed longitudinally by ramping the beam velocity (i.e. introducing a velocity tilt) over the course of the pulse, and the beam is transversely focused in a high field solenoid just before the target. To remove the effects of space charge, the beam drifts in a plasma. The tilt introduces chromatic aberrations, with different slices of the original beam having different radii at the focal plane. The fluence can be calculated by summing the contribution from the various slices. We develop analytic formulae for the energy fluence for beams that have current profiles that are initially constant in time. We compare with envelope and particle-in-cell calculations. The expressions derived are useful for predicting how the fluence scales with accelerator and beam parameters..

## INTRODUCTION

Recently, experiments have been carried out on the Neutralized Drift Compression Experiment (NDCX) at Lawrence Berkeley National Laboratory to investigate the use of injected plasma into a final drift compression line, final focus magnet, and target chamber to eliminate the effects of space charge [1], which, in turn, allows for maximum longitudinal compression and transverse final focusing. These beams have short final pulse duration $\Delta t_f$ and small focal spot radius $r_{spot}$ (defined at $2^{1/2}$ times the rms radius, when averaged over all beam particles). Because of the possibility of creating high beam intensities in a short pulse, the beams are being used to generate so called warm dense matter (WDM) conditions [2,3]. The main figures of merit for experiments are the beam fluence (beam energy per unit area integrated over the pulse) $E$ and $\Delta t_f$, since the attainable temperature is determined by $E$ as long as $\Delta t_f$ is much shorter than the hydrodynamic timescale for expansion. In this paper, we provide an analytic estimation of $E$ which can be useful for designing experiments that maximize $E$.

In the following sections, we first describe a simplified model for a final drift and focus section. We then outline the derivation of the estimate and.compare with more detailed numerical calculations (envelope and particle in cell), and finally we describe how we have used these three approaches to help design experiments for NDCX at LBNL.

## MODEL FOR ANALYTIC ESTIMATE

We assume that after the beam is accelerated to final velocity $v_0$, and energy $qV_0$ with charge state $q$, the beam exits the accelerator with 4 rms unnormalized transverse emittance $\varepsilon$. The beam passes through an induction bunching module gap that increases the velocity of the tail to $v_t$ and decreases the velocity of the head to $v_h$. The "tilt" is defined as $\Delta \equiv (v_t-v_h)/v_0$. The beam drifts a distance $L$ to the target, longitudinally compressing as it propagates, due to the tilt. A distance $f$ from the target, when the beam has radius $r_0$ the beam enters a solenoid of strength $B_{sol}$ and length $l_{mag}$, and exits the solenoid with the envelope converging angle $r_1'$ and radius $r_1$, setting the beam onto a final trajectory that focuses onto the target with radius $r_{spot}$. (Throughout this paper, envelope radii $r$, with or without subscripts, are defined as $2^{1/2}$ times the rms radius). A plasma is assumed to fill the drift section, the final solenoid and the target chamber (that includes the distance between the target and the solenoid). We further assume that the plasma density sufficiently exceeds the beam density so that the space charge forces within the beam are negligible. This implies that each slice of the beam retains the velocity $v \equiv v_0(1+\delta)$ it obtained in the bunching gap, and so each slice will have a slightly different focal length, and hence slightly larger focal spot at the target than the focal spot of the longitudinal center of the beam ($\delta$=0). Although formal analytic solutions to the kinetic equations describing drift compression have been obtained [4], exact closed form-scaling relations for the fluence have not, as of yet, been derived.

## ANALYTIC ESTIMATE OF FLUENCE $E$

The envelope equation for the beam radius $r$ for a beam without space charge may be written: $r'' = -\frac{k_c^2}{4}r + \frac{\varepsilon^2}{r^3}$. Here $k_c = qB_{sol}/(mv)$, and prime is derivative with respect to longitudinal position $z$. Within the solenoid, the emitttance term is small relarive to the focusing term, so we may solve the envelope equation: $r_1 = r_0 \cos\frac{k_c z}{2} + \frac{2r_0'}{k_c}\sin\frac{k_c z}{2}$ . We assume that $r_0'=0$, as the change in $r'$ going through the solenoid is expected to be large. The condition that the beam comes to a focus at a distance after the magnet $f-l_{mag}$ is: $r_1' = \left(r_0/\left(f-l_{mag}\right)\right)\cos k_c l_{mag}/2 = (k_c r_0/2)\sin k_c l_{mag}/2$ . This may be expressed as: $\eta_{mag} = \theta\tan\theta/\left(1+\theta\tan\theta\right)$. Here $\eta_{mag} = l_{mag}/f$, and $\theta = k_c l_{mag}/2$. The contribution to the spot size from the emittance is thus: $r_{spot}^2\big|_{\text{emittance}} = \frac{\varepsilon^2}{r_1'^2} = \frac{\varepsilon^2 f^2}{r_0^2}F_1(\theta)$.

Here $F_1(\theta) = 1/(\cos\theta+\theta\sin\theta)^2$. For "off-momentum" slices the beam spot will be larger by the amount $dr_{spot} = r_1' df$ where the focal length is given by: $f = r_1/r_1'$ so the change in focal length for off-momentum particles is: $df = dr_1/r_1' - r_1 dr_1'/r_1'^2$. The contribution to the spot size from chromatic aberrations is thus $dr_{spot}\big|_{\text{chromatic}} = (\theta/\sin\theta) r_0\delta$. So the spot radius from both emittance and chromatic aberrations can be written:

$$r_{spot}^2(\delta) = r_{spot}^2\big|_{\text{emittance}} + dr_{spot}^2\big|_{\text{chromatic}} = \varepsilon^2 f^2 F_1(\theta)/r_0^2 + r_0^2\delta^2 F_2(\theta)$$

Here $F_2(\theta) = (\theta/\sin\theta)^2$. For the "thin lens" approximation $\theta \ll 1$, $F_1(\theta) \approx 1$ and $F_2(\theta) \approx 1$, and the "thick lens" approximation $\theta = \pi/2$, $F_1(\theta) = 4/\pi^2$ and $F_2(\theta) = \pi^2/4$. A more direct derivation of $r_{\text{spot}}(\delta)$ may be obtained by expanding the envelope equation in $\delta$ and integrating.

To calculate the central fluence $E(r=0)$, we must integrate the intensity from each slice. Since the phase space at the focus is rotated by $\sim\pi/2$ relative to the beginning of the soleonid, we expect (and assume) the spatial distribution for each slice to be close to a gaussian distribution in radius with an rms radius equal to $r_{\text{spot}}/2^{1/2}$ (for each $\delta$). This amounts to adding many different gaussians with different widths, yielding a non-gaussian distribution. The number of particles per unit area $n(r)$ at radius $r$ at the focus integrated over the pulse is thus:

$$n(r) = \int_{-l_b/2}^{l_b/2} \frac{dn(r)}{ds} ds = \int_{-\Delta/2}^{\Delta/2} \frac{dn(r)}{ds}\frac{ds}{d\delta} d\delta = \frac{l_b}{\Delta}\int_{-\Delta/2}^{\Delta/2} \frac{dn(r)}{ds} d\delta$$

Here $l_b$ is the length of the bunch before compression, and $ds$ is an element of beam along the beam length corresponding to an element of velocity tilt $d\delta$. Note that we are assuming that the velocity tilt imposed on the beam in the induction gap is linear, so that $\delta/\Delta = s/l_b$. By assumption:

$$\frac{dn(r)}{ds} = \frac{N_0/l_b}{\pi\sigma^2}\exp[-r^2/\sigma^2]$$

Here $\sigma = r_{\text{spot}}/2^{1/2}$, and $N_0$ is the total number of particles in the bunch, so that $N_0 = 2\pi\int_0^\infty dr\, r\, dn(r)/ds$. The bunch here is assumed to be constant current before bunch compression. The integral for $n(r)$ may be expressed:

$$n(r) = \frac{4N_0}{\pi f\varepsilon\Delta\sqrt{F_1(\theta)F_2(\theta)}}\int_1^{\sigma_{\max}/\sigma_{\min}} \frac{\exp[-r^2/(u^2\sigma_{\min}^2)]}{u\sqrt{u^2-1}} du$$ where

$$\sigma_{\min} = \frac{1}{\sqrt{2}}\frac{\varepsilon f\sqrt{F_1(\theta)}}{r_0} \text{ and } \sigma_{\max} = \frac{1}{\sqrt{2}}\sqrt{\frac{\varepsilon^2 f^2 F_1(\theta)}{r_0^2} + \frac{r_0^2\Delta^2 F_2(\theta)}{4}}.$$

For $r=0$, the integral may be carried out:

$$n(r=0) = \frac{4N_0}{\pi f\varepsilon\Delta\sqrt{F_1(\theta)F_2(\theta)}}\tan^{-1}\left(\frac{r_0^2\Delta\sqrt{F_2(\theta)}}{2f\varepsilon\sqrt{F_1(\theta)}}\right). \quad (1)$$

In the limit, that $\Delta$ approaches zero, the central integrated density is just that of an uncompressed emittance limited beam $n(r=0,\Delta=0) = 2N_0 r_0^2/[\pi f^2\varepsilon^2 F_1(\theta)]$. The fluence $E$ is given by $E \approx qV_0\, n(r=0)$. In figure 1, we have plotted the fluence normalized to the fluence at $\Delta=0$, as a function of the argument of the inverse tangent to show potential gains if the chromatic aberrations were corrected (as in a time dependent correction concept now under study for NDCX). For the NDCX experiments listed in Table 1 (cases b and c), the argument has a range of 4 to 16, with corresponding values of $n(r=0)/n(r=0,\Delta=0)$ ranging 0.31 to 0.092, respectively, indicating potential fluence increases of 3 to 11, respectively if chromatic aberrations are corrected.

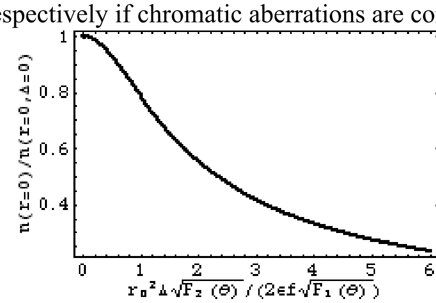

Figure 1. Fluence normalized to $\Delta=0$ fluence as function of quantity $r_0^2\Delta\, F_2(\theta)^{1/2}/[2\varepsilon f F_1(\theta)^{1/2}]$.

We may also estimate the spot radius of the integrated pulse. Integrating over all slices, the radius of the integrated pulse is given by:

$$r_{spot}^2 = \frac{\varepsilon^2 f^2}{r_0^2}F_1(\theta) + r_0^2\eta^2\Delta^2 F_2(\theta) \quad (2)$$

Here $\eta \equiv \left(\int_{-l_b/2}^{l_b/2} I(s)(\delta(s)/\Delta)^2 ds\right)^{1/2} / \left(\int_{-l_b/2}^{l_b/2} I(s) ds\right)^{1/2}$, where $I(s)$ is the current as a function of longitudinal position $s$ along the beam before drift compression, with $s=0$ corresponding to the center of the beam. For $I(s)$=constant, then $\eta = 1/12^{1/2} \approx 0.29$. (For a parabolic pulse $\eta = 1/20^{1/2} \approx 0.22$). The quantity $r_{\text{spot}}$ is minimized when $r_0$ is such that the two terms in the equation for $r_{\text{spot}}^2$ are equal, namely: $r_{0\_\text{opt}}^2 = \varepsilon f[F_1(\theta)F_2(\theta)]^{1/2}/(\eta\Delta)$ for which $r_{\text{spot\_opt}}^2 = 2\varepsilon f\eta\Delta[F_1(\theta)F_2(\theta)]^{1/2}$. Note that, although there is an optimum $r_{0\_\text{opt}}$ that minimizes the rms radius of the integrated spot $r_{\text{spot\_opt}}$[5], increasing $r_0$ increases $E$ monotonically, only saturating as the inverse tangent in eq. 2 approaches $\pi/2$. However, the area over which $E$ is large decreases as $r_0$ increases beyond $r_{0\_\text{opt}}$.

There are a number of assumptions that are built into equation (1). One assumption is that $r_0$ is constant for all $\delta$. When we rederive equation 1 replacing $r_0$ with $r_0 + \alpha L\delta$, where $\alpha$ is a constant (as can be expected from aberations from the induction bunching module), we find that the integral for $n(r=0)$ is unchanged, to lowest order in the parameter $\alpha L\delta/r_0$ as long as $\alpha L\delta/r_0 \ll 1$, with finite correction only in second order. Another assumption in the model, is that $r_0'$ is small, which usually is true relative to $r_1'$, but its impact on $r_{\text{spot}}$ has not yet been quantified analytically.

## COMPARISONS WITH NUMERICAL RESULTS

We have compared our analytic model with predictions of an envelope model and a particle in cell code LSP. The envelope model makes the same assumption as the

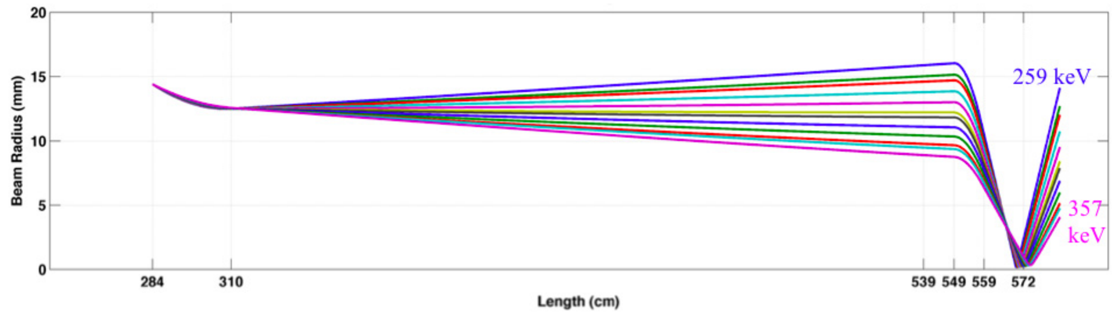

Figure 2. Calcuation of E using an envelope/slice model. Each color represents the trajectory of a different slice with different d. See text for further details.

Table 1. Comparison of *E* calculated using envelope model, LSP, and Eq. (1)

analytic model at the focal spot. Namely, take the spot radius for each slice as calculated by a numerical integration of the envelope equations, and assume a gaussian intensity profile for the slice at the target plane, summing the intensities over slices numerically. The advantage of the envelope model is that the finite $r'$ induced by the induction bunching module can be used as an initial condition at the beginning of the drift; the finite region where the beam is non-neutral can be accounted for; and so there are no assumptions about $r_0$ and $r_0'$.

The most detailed and accurate description of the drift compression and final focus is obtained using the LSP code [6,7]. LSP is a particle in cell code that includes fringe fields of the magnets and bunching module and models for calculating the plasma density and flow. The calculation includes first principle simulations of the beam through accelerator, drift, final focus, and chamber.

In figure 2, we plot an example of an envelope calculation using parameters from the NDCX experiment. The beam is 300 kV, 27 mA, singly charged potassium. The envelope calculation is initialized at $z$ = 284 cm, at the exit of the induction bunching module gap. The envelope slices are calculated assuming full space charge contribution, until the entrance to the neutralized section at $z$=310 cm. The beam propagates assuming full neutralization through the final focusing solenoid (549 < $z$ < 559 cm) to the focal plane ($z$= 572 cm).

Table 1 compares the final fluence $E$ for the numerical calculation of the envelope; LSP; and analytic model (eq. 1). The first row (a) corresponds to experiments without a final focusing solenoid. The second and third rows correspond to beamlines using a new NDCX induction bunching module, the final focusing solenoid (Bsol = 8 Tesla) and two beamline configurations: (b) with the present drift compression length ($L$=144 cm), and (c) with twice the drift compression length ($L$=288 cm) as the present setup. The two cases (b) and (c) show the effect of using a bunching module with a shorter bunch length (and relatively large tilt) with short drift length (since $L \approx l_b/\Delta$) versus using a larger bunch length and smaller tilt (and large drift length). This approximately keeps the "Volt-seconds" (roughly proportional to $\Delta\, l_b$) of the bunching module constant, which is constrained by the finite size of the induction core. As can be seen from the table the simulation yields somewhat smaller values of $E$, than the envelope results or analytic results, possibly due to imperfect neutralization, or effects of fringe fields, but the analytic calculation demonstrates the trends and scalings that can be useful for quick design estimates.

## CONCLUSION

We have estimated the energy fluence in a beam undergoing neutralized drift compression and neutralized solenoidal final focus, (eq. 1) and have compared it to envelope and particle in cell simulations. We find that the estimate is useful for understanding the general scaling of fluence on beam and accelerator parameters and for estimating system performance when alternative experiments are being considered.

# UPGRADE OF THE UNILAC HIGH CURRENT INJECTOR RFQ

A. Kolomiets, S. Minaev, ITEP, Moscow, Russia
W. Barth #, L. Dahl, H. Vormann, S. Yaramyshev, GSI, Darmstadt, Germany

*Abstract*

For the operation of the GSI-accelerator chain as an injector for the future FAIR facility a considerable increase of the heavy ion beam intensity of up to a factor of 5 at the end of the UNILAC is required. The bottleneck of the whole UNILAC is the front-end system of the High Current Injector. It is shown that the transverse RFQ-acceptance can be significantly increased while the emittance growth can be reduced. Both goals are achieved with only a moderate change of the RFQ electrode geometry; the intervane voltage raised from 125 kV to 155 kV, but keeping the design limit of the maximum field at the electrode surface. The changed resonant frequency can be compensated with a relatively small correction of the carrying rings. The beam parameters in the final focusing elements of the LEBT were optimized together with the improved design of the input radial matcher; the length of the gentle buncher section was considerably increased to provide slow and smooth bunching resulting in a reduced influence of space charge forces. DYNAMION simulation with the modified electrode design resulted in an increase of the $U^{4+}$-beam current of up to 20 emA. It is planned to start the upgrade measure in spring 2009.

## INTRODUCTION

In 1999 UNILAC passed a substantial upgrade - the Wideroe structure was replaced by the High Current Injector (HSI) [1]. The HSI consists of IH-type RFQ and two IH-DTL structures. The main goal of the upgrade project was to increase the $U^{4+}$ beam current up to 15 emA. However the measured $U^{4+}$ beam current behind the HSI never exceeded 6.5 mA. Detailed computer simulations using the DYNAMION code were performed to determine the source of beam intensity limitations [2]. The simulations were verified by beam parameters, measured during the whole period of HSI operation. The most important limitations were the following:

– lower brilliance of the injected beam in comparison with the design value;
– considerably mismatched beam at the RFQ-entrance due to the too high beam convergence required by original design;
– fast beam bunching in the RFQ gentle buncher section, leading to transverse emittance growth;
– strongly limited rf-voltage during the $U^{4+}$ operation.

As a result, a partial RFQ upgrade program took place in 2004. It was mainly directed to the improvement of the rf-performance, but also included the new design of the input radial matcher (IRM), dedicated to optimize the beam dynamics in the focusing elements in front of the RFQ and to improve the matching itself [3].

The rf-performance of the HSI-RFQ was significantly improved after replacement of the electrodes. Minor changes in the IRM lead to 15% increase of the maximum beam intensity at the RFQ output (with the same beam, coming from the ion source). More than this, the results of the numerically calculated optimization of the RFQ electrode profile was confirmed and the beam dynamics codes were approved.

The FAIR program [4] requires increased beam intensities for the UNILAC as an injector. The HSI $U^{4+}$ beam current has to be increased up to 18 mA. All previously obtained beam dynamics results confirmed that an essential RFQ electrode profile upgrade could provide for such requirements.

## DESIGN OF THE HSI RFQ PROFILE

The main conditions for the new design are:

– maximum field at electrode surface should not exceed 320 kV/cm (existing design, $U^{4+}$ -operation);
– total length of the electrodes must be exactly the same as in the existing design;
– operation frequency and other essential rf-parameters of the cavity must be kept, only minor adjustments of the resonant structure are acceptable.

It is clear, that an increase of the RFQ output beam current, keeping parameters of an injected beam, can be provided only by a corresponding increase of its transverse acceptance. The normalized transverse acceptance of the RFQ $\boldsymbol{V_k}$ can be expressed as:

$$V_k = \frac{1}{\lambda}\left(\frac{2}{m+1}\ \frac{R_0}{\rho_{\max}}\right)^2 \tag{1}$$

with $\boldsymbol{\lambda}$ - wave length, $\boldsymbol{m}$ - modulation, $\boldsymbol{R_0}$ - average distance from axis to electrode, $\boldsymbol{\rho_{max}}$ - maximum value of the normalized matched envelope. The value of $\boldsymbol{\rho_{max}}$ is defined mainly by the focusing parameter $\boldsymbol{B}$, expressed through the maximum field at the electrode surface $\boldsymbol{E_{\max}}$ :

$$B = \frac{Ze}{A}\frac{1}{E_0}\frac{E_{\max}}{\chi R_0}\lambda^2 \tag{2}$$

with $\boldsymbol{\chi}$ - field enhancement factor, $\boldsymbol{A,Z}$ - mass and charge numbers, $\boldsymbol{E_0}$ - rest energy. For flat electrodes with semicircular tips $\boldsymbol{R_e}$ it can be calculated by the formula

$$\chi = \sqrt{\frac{1}{2}\left(1+\frac{R_e}{R_0}\right)^2 + \frac{2T}{\pi}k\,R_0\,I_0\left(k\frac{R_0+R_e}{\sqrt{2}}\right)^2} \tag{3}$$

with $\boldsymbol{T}$ - transit-time factor, $\boldsymbol{k = 2\pi/\beta\lambda}$ - wave number, $\boldsymbol{\beta}$ - relative velocity of the particle, $\boldsymbol{I_0}$ - modified Bessel function [5]. It follows from the expressions above, that the only way to keep the focusing parameter $\boldsymbol{B}$ constant,

# Presenting author
W.Barth@gsi.de

while $\boldsymbol{R_0}$ increases, is to keep the $\boldsymbol{\chi R_0}$ value. The last condition can be satisfied by decreasing the $R_e/R_0$ ratio.

The electrode geometry for the existing RFQ design (dotted lines) and the new one (dashed lines) is shown in Fig.1. The bottom lines represent the electrode curvature radius $R_e$, the middle lines the average radius $R_0$ and the upper ones the $R_e/R_0$ ratio.

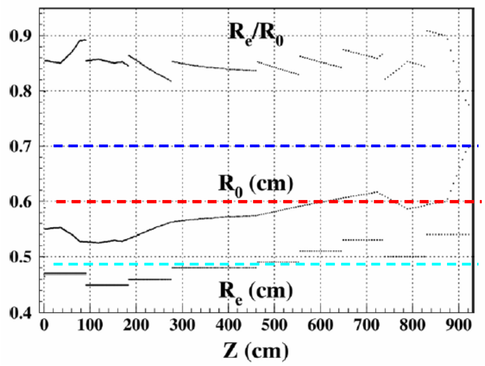

Figure 1: Electrode parameters of existing (dotted) and new (dashed) designs; the blue line represents the $\boldsymbol{R_e/R_0}$ ratio, the red line - $\boldsymbol{R_0}$ and the magenta line - $\boldsymbol{R_e}$.

The HSI-RFQ was designed with a variable $\boldsymbol{R_0}$ and $\boldsymbol{R_e}$ and with a constant voltage $\boldsymbol{U}$ along the structure. The design voltage of the existing RFQ ($\boldsymbol{U}$=125 kV) is limited by $\boldsymbol{R_0}$ near cell #100 (Fig. 1). According (2), it determines in total the relatively low acceleration rate and low focusing parameter $\boldsymbol{B}$ in the main part of the RFQ. The new electrode geometry is designed with constant $\boldsymbol{R_0}$ (6 mm) and $\boldsymbol{R_e/R_0}$ (0.7) along the whole RFQ structure. It allows to increase the voltage keeping the maximum field $\boldsymbol{E_{max}}$. The higher voltage allows to reduce the modulation in the main part of the RFQ and to optimize the beam dynamics in the gentle buncher to prevent excessive transverse emittance growth.

An increase of the high order terms in the RFQ electrical field due to the lower $\boldsymbol{R_e/R_0}$ ratio was investigated and a minor influence of this effect to the particle transmission (< 1.5%) was demonstrated.

The new RFQ-channel was designed using the DESRFQ code [6]. Modulation and synchronous phase for each RFQ-cell were chosen to provide the following conditions:

– capture of the particles into acceleration is not less then 90 %;
– separatrix is filled in the beginning of the gentle buncher as uniformly as possible;
– transverse phase advance is almost constant along the gentle buncher;
– tune depression in gentle buncher is almost equal its initial value.

The baseline design was optimized for $U^{4+}$ beam current of 20 mA and a total transverse emittance of 280 mm*mrad (unnorm.). These values were chosen on the base of the measurements in front of the RFQ (15 mA, 210 mm*mrad) assuming the same brilliance of the high current beam coming from the ion source. The main parameters of the new design are summarized in Tab. 1.

Table 1: Main RFQ Parameters

| | New | Existing |
|---|---|---|
| Voltage, kV | 155.0 | 125.0 |
| Average radius, mm | 6.0 | 5.2 ÷ 7.7 |
| Electrode width, mm | 8.4 | 9.0 ÷ 10.8 |
| Max. field, kV/cm | 312 | 318 |
| Modulation | 1.012 ÷ 1.93 | 1.001 ÷ 2.09 |
| Synch. Phase, degree | -90 ÷ -28 | -90 ÷ -34 |
| Aperture, mm | 4.1 | 5.5÷3.8÷4.8 |
| Min. transverse phase advance, rad | 0.56 | 0.45 |
| Norm. transverse acceptance, mm*mrad | 0.86 | 0.73 |
| Electrode length, mm | 9217.4 | 9217.4 |

## SIMULATION RESULTS

The beam dynamics simulations for the final RFQ design were additionally carried out with the DYNAMION code. The RFQ output beam current in dependence on the input current (15 ÷ 30 mA) is shown in Fig. 2 for the case of a constant input emittance (210 mm*mrad, green line); additionally for the input emittances increased proportionally to the beam current (210 ÷ 420 mm*mrad, red line).

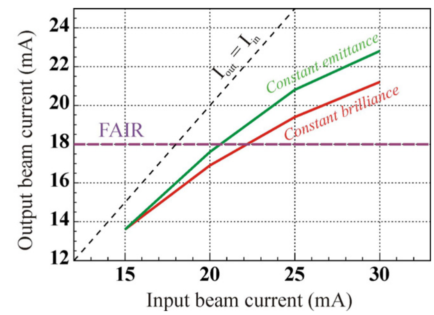

Figure 2: Simulated beam current at RFQ output in dependence on input current.

A comparison of the existing and the new RFQ channels is illustrated in Fig. 3. A beam current inside a given transverse emittance at the RFQ-output is shown for both designs. Beam dynamics simulations were done for the same beam current (25 mA) and emittance (210 mm*mrad), but with matched Twiss-parameters for each case.

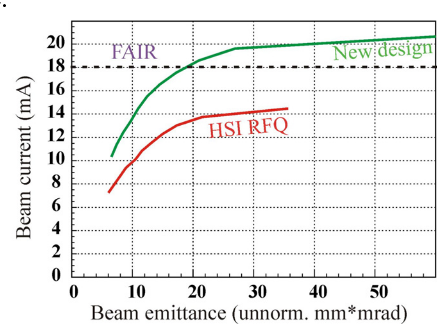

Figure 3: Beam current inside a given emittance at the RFQ-output for the existing design (red) and the new design (green).

The new RFQ design provides for more than 40% of the beam current compare to the old design. Higher beam emittance behind the new RFQ channel is formed by a few percent of the particles, while the core of the beam (20 mm*mrad) contains the required beam current.

An additional cross-check of the beam dynamics for the new RFQ was performed with the PARMTEQM code; a good coincidence of the results was demonstrated [7].

## RESONANT STRUCTURE

For improved beam dynamics the average channel aperture $R_0$ and the electrode half-width/curvature $R_e$ have been specified constant along the channel. It leads to a different capacitive load, the appearing frequency shift must be compensated by other channel parameters. For the existing IH-RFQ a frequency of 35.96 MHz was calculated, what is in good agreement with the experimentally measured value. Then the height of the electrode "shoulder" $h$ and the ring length $L$ (Fig. 4) were used as free parameters to achieve the design frequency for the new channel.

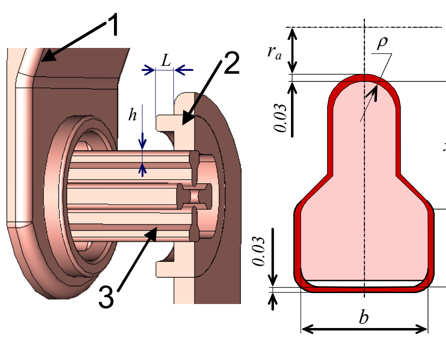

Figure 4: Regular cell of IH-RFQ structure (left) and electrode cross-section (right). 1 - stems; 2 - carrier rings; 3 - electrodes (mini-vanes).

The length of the carrier rings is the most efficient parameter for frequency adjustment, available at every cell of the structure. The frequency dependence on the length of the carrier ring edge, calculated for the structure with the modified channel, is shown in Fig. 5.

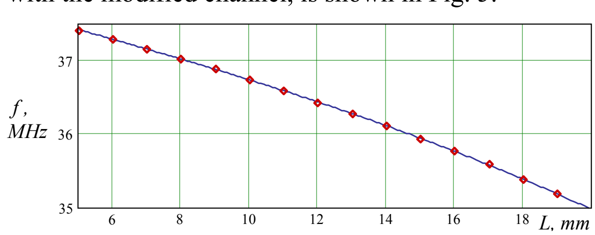

Figure 5: IH-RFQ frequency as a function of the length of the carrier ring edges.

A desired frequency of 35.96 MHz without tuners may be realized with the structure cell parameters given in the Tab. 2, while the operating frequency of 36.136 MHz will be reached with inductive tuning plungers.

Table 2: Main Dimensions of the IH-RFQ Cell

| $R_0$, mm | $R_e$, mm | b, mm | h, mm | L, mm |
|---|---|---|---|---|
| 6.0 | 4.2 | 16.0 | 7.0 | 14.8 |

In order to reduce dark current contributions [3], the electrode surface has to be covered by a 0.03 mm layer of electrolytic copper (Fig. 4, right). The electrodynamics simulations for the final geometry showed that additional 10 micrometers of copper layer lead to a frequency shift of about 0.023 MHz, which is comparable to the effect of one plunger. The frequency sensitivity to the radial displacement of the electrode is considerably less (0.0006 MHz/μm).

## CONCLUSION

The new electrode profile for the HSI-RFQ was designed with higher transverse acceptance and phase advance, keeping the maximum field at the electrode surface of the recently operating machine. The new design of the Input Radial Matcher allows for an improved beam matching to the RFQ by means of the LEBT quadrupole lenses. Beam dynamics in the beginning of the gentle buncher was optimized to provide for rapid and uniform (as possible) separatrix filling. To avoid an excessive rf-defocusing and a significant space charge influence, the modulation and the synchronous phase in the gentle buncher increase considerably slower compare to the existing RFQ-design. The maximum modulation in the main RFQ part is also reduced.

The shift of the resonant frequency of the cavity with increased average radius and reduced electrode thickness can be compensated with minor changes of the topology of the mini-vane and the connecting ring.

Beam dynamics in the new channel were studied with the DYNAMION code. It could be shown, that the beam intensity at the HSI-RFQ output (18 mA of $U^{4+}$ ions), required for the FAIR program, can be reached.

## ACKNOWLEDGMENTS

Authors would like to express sincere acknowledgments to our colleagues from the IAP Frankfurt, Prof. U. Ratzinger, Prof. A. Schempp and Dr. R. Tiede for fruitful discussions and supporting simulations [8].

# THE NEW EBIS RFQ FOR BNL

M. Vossberg, J. Schmidt, B. Hofmann, A. Schempp, C. Zhang, IAP, Univ. Frankfurt, Germany
J. Alessi, D. Raparia, L. Snydstrup, BNL, Upton NY, U.S.A.

*Abstract*

A new RFQ is being built as a part of the new EBIS-Linac at BNL. The RFQ accepts highly charged ions from the EBIS ion source with energy of 17 keV/u and ion currents of up to 10 mA. The operation frequency will be 100.625 MHz. The design had been optimized to get a rather short structure with $L_{RFQ} = 3.1$ m with moderate electrode voltages of $U_Q = 70$ kV. The resonant insert has a cooled base plate and solid stems and vane-electrodes. The mechanical design is very stiff, with a precise base-structure. The top lid along the RFQ allows installation, alignment, inspection and maintenance.
After the mechanical alignment of the electrodes the longitudinal electrode voltage distribution will be adjusted with tuning plates between the stems. The properties of the RFQ, the results of the tuning and the status of the project will be discussed.

## INTRODUCTION

Availability for beams for high energy heavy ion physics is limited by the properties and performance of the accelerator chain especially the low energy part, where beam intensities and emittances are set.

At RHIC the injector consists of a Tandem whose beam is transported to the AGS. The limitations of that injector, a combination of a dc, low beam current heavy ion machine, a long transport line with a typical pulsed proton high energy machine are obvious. Starting with negative ions, the mass range is also limited.

Plans for a new injector making use of the new developments of ion sources as well as rf-linacs have been discussed for a number of years. Now that modern injector scheme is being set up at BNL, which will lead to more reliable operation and improved capability especially for the RHIC and NSRL programs [1].

The EBIS ion source is perfectly matched to the operation pattern with its pulsed beam of highly charged ions. The RFQ accepts a low energy heavy ion beam, and bunches and accelerates it with high efficiency and low emittance growth [2]. The IH structure has been applied for heavy ion machines e.g. at GSI and CERN which have demonstrated operation with very high gradients resulting in a very efficient compact ion injector for a Synchrotron [3,4].

Figure 1 shows a layout of the new heavy ion injector linac with total length of appr. 12 m, which will provide ions with 2 MeV/u for a mass to charge ratio of up to A/q = 6.25.

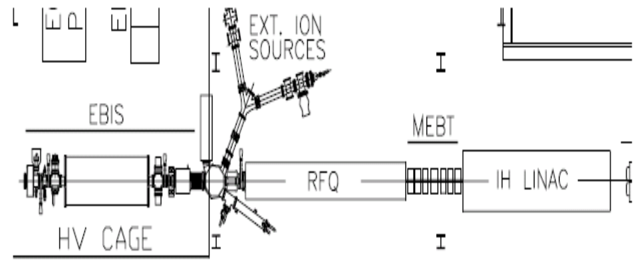

Figure 1: Layout of the EBIS Linac at BNL.

## RFQ

The RFQ for the new EBIS-linac at BNL accepts highly charged ions from the EBIS ion source with energy of 17 keV/u and ion currents of up tp 10 mA. The operation frequency will be 100.625 MHz.

### *Beam Dynamics*

The beam dynamics design does an adiabatic variation of the RFQ parameters to shape, bunch and accelerate the beam [5]. We optimized the design to get a rather short structure with $L_{RFQ} = 3.1$ m with moderate electrode voltage of $U_Q = 70$ kV.

Table 1: RFQ Beam Dynamics Design Parameters

| | |
|---|---|
| Frequency | 100.625 MHz |
| Input energy | 17 keV/u |
| Output energy | 0.3 MeV/u |
| Mass to charge ratio | 6.25 |
| Beam current | 10 mA |
| Outp trans. emitt rms norm. 90% | < 0.38 π mm mrad |
| Output long. emittance 90% | < 220 deg keV/u |
| Transmission | 98% |
| Electrode voltage | 70 kV |
| RFQ length | 3.1 m |
| Cell number | 189 |
| Aperture min - max | 2.96-5.25 mm |

Results of particle dynamics simulations show the RFQ output transmission and emittances for different beam input emittances and currents show low emittance growth and very high transmission also for I = 10 mA

*Work supported by the US Department of Energy and the National Aeronautic and Space Administration.

Table 2: RFQ Beam Emittances

| $\varepsilon_{in}^{trans.,un., real}$ [π mm-rad] | Transm. [%] | $\varepsilon_{out}^{z, rms}$ [MeV-deg] 100% | $\varepsilon_{out}^{xy, rms}$ [π mm mrad] 100/90% |
|---|---|---|---|
| 0.05790 I=0 | 99.2 | 0.284 | 0.064 / 0.0271 |
| 0.08685 I=10 | 96.7 | 0.243 | 0.09 / 0.038 |
| 0.11580 I=0 | 98.4 | 0.27 | 0.126 / 0.053 |
| 0.11580 I=10 | 98.7 | 0.33 | 0.15 / 0.060 |

Beam dynamics simulations have been done with Parmteqm Vers. 3.07. This allows applying a Crandall-Output cell with low divergence of the beam. The final design has good emittances in both axial and radial direction, a very high transmission.

The beam dynamics design is very flexible; it allows rather large variations of the input beam parameters and has good output beam quality.

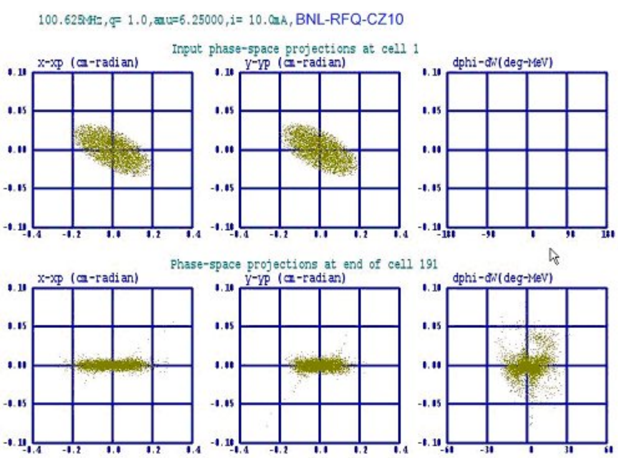

Figure 2: RFQ emittances for I = 10 mA.

## *4-Rod-RFQ-Structure*

The 4-Rod-RFQ consists of a chain of λ/2 resonators which are operated in π-0-mode, to have opposite voltage on the adjacent electrodes and constant voltage along the RFQ. It is possible to describe the basic cell of the 4-Rod-RFQ as a capacitively loaded line, at which the electrodes are the capacity and the stems the inductivity resp. the short line.

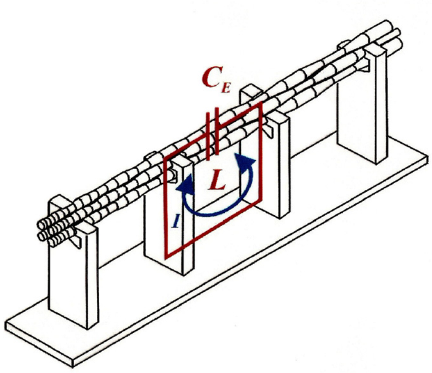

Figure 3: Basic cell of the 4-Rod RFQ structure.

Table 3: 4 Rod Structure Parameters

| | |
|---|---|
| 4-Rod-RFQ | 100.625 MHz |
| Tank diameter | 350 mm |
| Tank length | 3100mm |
| Beam axis height | 147 mm |
| Stem number | 20 |
| Stem distance / thickness | 158 mm / 10mm |
| Aperture | 5.2-2.96 mm |
| Modulation factor | 1-1.99 |

Based on MWS-simulations and experimental results of similar RFQs the structure power for the EBIS-RFQ is $P_S$ = 105 kW. Two inductive tuners will perturb the field in the plane between the stems. The 3-1/8" power line will be fed in by a central coupling loop.

The RFQ-cavity is made out of a 5 cm thick wall tube, copper plated, with inner diameter of 350 mm. The resonant insert has a cooled base plate and solid stems and sloped-electrodes. The support stand structure is 70 cm wide and allows horizontal adjustment.

The mechanical design is very stiff, avoids much welding for stress free, precise basic structure and by the use of the top lid allows rather easy installation, alignment, inspection and maintenance.

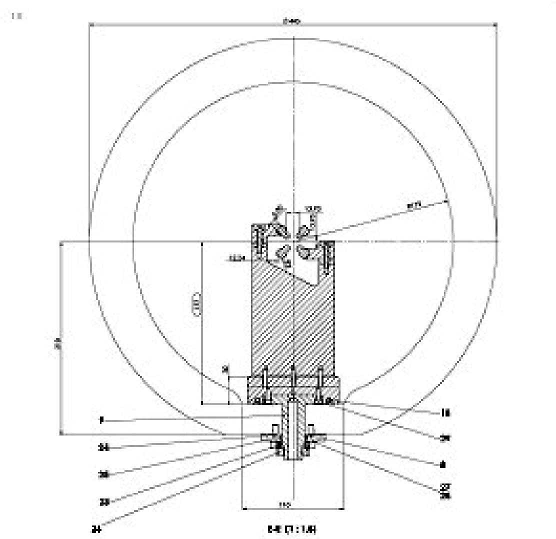

Figure 4: BNL 4-Rod RFQ Cross section.

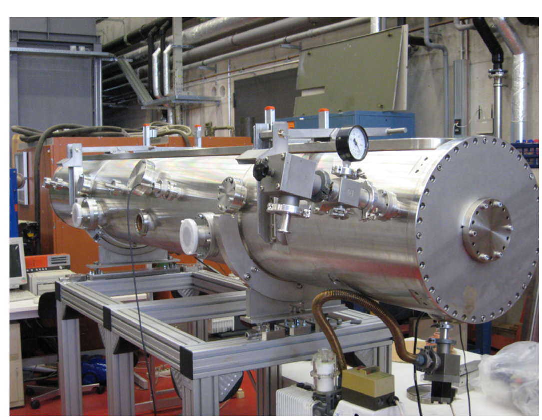

Figure 5: BNL 4-Rod RFQ set up.

### *Mechanical Alignment and Tuning*

The first step for the mechanical alignment is to mount the stems onto the base plate and insert this set-up into the cavity. For alignment in the tank, measurements of the distance between the backsides of the electrode bridge heads and the minima of the aperture are needed. This is done with a Tesla meter in vertical and horizontal plane. Afterwards the electrodes are attached on the stems in the tank. To align them silver plated shims with a size of 4mm up to 6mm are fixed between the electrodes and the stems. They can easily be changed in order to adapt the proper vertical position. To align the electrodes horizontal we can change their position by shifting them. The top flange of the tank serves as reference for these measurements. Our measurement equipment for the alignment in the tank is the FARO Gage plus meter with which we can quantify distances of planes easily. The results of measurement show, that the positions is better than ±0,03 mm.

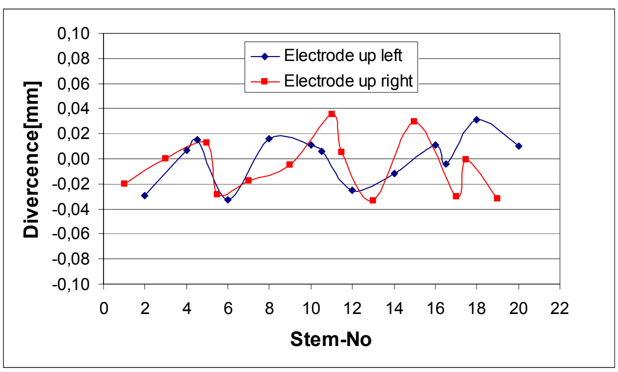

Figure 6: Results of Alignment.

A constant voltage on the electrodes of the RFQ is required for correct operation according to the beam dynamics design. For electrodes with no modulation and constant capacity a simulation of the whole structure was done. In structures with length design of 3,1 meters, the voltage difference from the mean voltage ranges between +11,8 % and -5,4 %. To balance this unflatness, tuning plates are inserted between the stems. They will change the local eigenfrequency of about 15 kHz per mm and correct the voltage differences, what is measured with a network analyzer. So each tuning plate is positioned at an individual height. As results of our tuning the quadrupole voltage (flatness) is better than ± 2 %.

Table 4: Position of Tuningplates in the BNL-RFQ

| Cell No. | Height | Cell No. | Height |
|---|---|---|---|
| 1 | 48.4 mm | 12 | 23.3 mm |
| 7 | 36 mm | 13 | 38.3 mm |
| 8 | 30 mm | 19 | 44.2 mm |

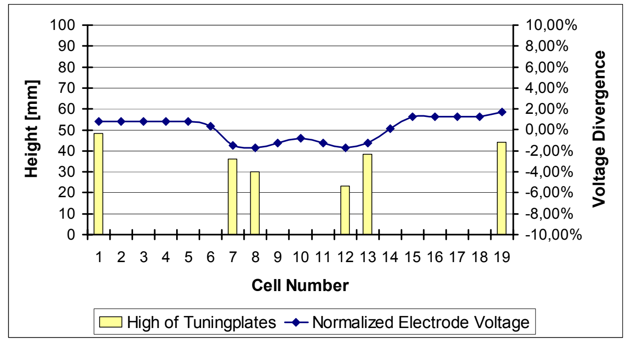

Figure 7: Results of Tuning.

The tuning plates change not only the local eigenfrequency but also the general one. For the precise adjustment of the resonance frequency, two inductive piston tuners are used. They enhance the resonance frequency up to 0.4 MHz dependent to the depth of the tuner.

## STATUS

The resonant structure is inserted into the cavity. We have done the alignment with a precede of ±0.03 mm and the flatness is better than ±2 %. Leak tests have been done and the EBIS- RFQ will be prepared for transport to BNL in the week before LINAC 08.

# HEAVY ION RADIO-FREQUENCY QUADRUPOLE LINAC FOR VEC-RIB FACILITY

Siddhartha Dechoudhury, Vaishali Naik, Arup Bandyopadhyay, Manas Mondal, Hemendra Kumar Pandey, Tapatee Kundu Roy,Dirtha Sanyal, Debasis Bhowmick, Alok Chakrabarti

Variable Energy Cyclotron Centre,1/AF Bidhan Nagar, Kolkata 700 064, India

*Abstract*

Post acceleration of ion beams would be done in Radio Frequency Quadrupole (RFQ) LINAC for the upcoming Radioactive Ion Beam (RIB) facility at Variable Energy Cyclotron Centre (VECC), India. A 33.7 Mhz RFQ capable of accelerating stable as well as RI beams of q/A≥1/16 to about 30 keV/u has already been constructed and operational since September 2005. This has been installed in a dedicated beam line for doing material science experiments. Another 3.4 m long RFQ resonating at 37.8 Mhz and capable of accelerating heavy ion beams upto 98 keV/u have been fabricated which is to be installed in the beam-line for the VEC-RIB facility. The physical parameters, rf test along with the measurements of accelerated beams from RFQ would be presented.

## DESIGN OF RFQ

We plan to accelerate beams with mass ranging up to A=150 in the VEC-RIB facility[1]. The radioactive atoms would be ionized in Electron Cyclotron resonance ion source(ECRIS) operating in "High B-mode". The ions would be then subsequently mass separated and accelerated in RFQ and Linac tanks[2]. ECRIS in principle would be able to deliver beams of around $15^+$ for uranium even in the on-line mode .Thus q/A≥ 1/14 seems to be a judicious choice for our RFQ. Normalized emmittance of ion beam has been taken to be 0.05 π cm mrad. Characteristic radius of 0.71 mm for the RFQ ensured a good transmission of the RI beams through the RFQ. The four-rod type structure have extended vanes supported on posts similar to the structure developed by Fujisawa[3]. The rods are placed at an angle of $45^o$ with respect to conventional horizontal and vertical axes.

The beam dynamics simulation has been done using GENRFQ and PARMTEQ code. Optimization of different physical parameters was done keeping in mind the goal to achieve the desired acceleration with minimum vane length and maximum transmission efficiency. Initially the RFQ was decided to design for input beam of energy of 1keV/u and input bunch width of $\pm 42^o$ and final energy of 86 keV/u[4]. The RFQ was designed to resonate at frequency of 35 MHz. A half scale cold model was fabricated for RF measurements. The results show good agreement with the simulation using MAFIA. In the next stage we have designed and fabricated 33.7 MHz RFQ delivering beam of 29 keV/u to be installed in the dedicated beam line for material science experiments . As the first post accelerator, using the experience and expertise gathered with 33.7 MHz RFQ final 3.4 m RFQ accelerating RIB's to 98 keV/u have been fabricated.

## 33.7 MHz RFQ

### *Design Parameters*

The RFQ is designed for an input dc beam of 1.38 keV/u, *q/A*=1/ 16, and resonant frequency of 33.7 MHz. The intervane voltage has been chosen to be 45.9 kV, which is about 1.12 times the Kilpatric limit for cw operation. With the interelectrode potential of 45.9 kV the calculated output energy comes out to be 29.06 keV/u for a vane length of 1.552 m. The radial matching section consists of 6 rf cells, and a total of 119 cells are needed to reach the energy. The synchronous phase in the acceleration section is chosen to be −30°. The calculated transmission efficiency is 95.8% for a beam current of 1 mA. The optimized physical parameters are shown in Fig.1. Energy width of the beam at the exit of RFQ is ± 0.67 keV/u.

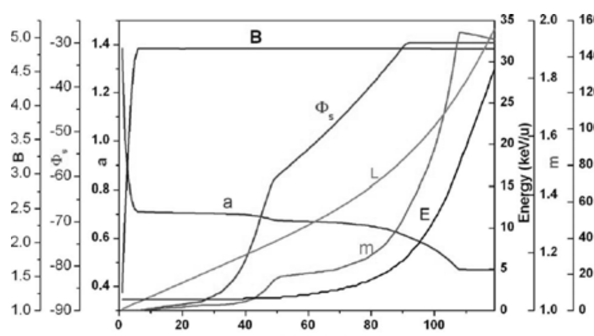

Figure 1: Optimised physical parameters variation along length of 33.7 MHz RFQ.

### *RF Analysis*

MAFIA estimates resonant frequency, *Q*, and *Rp* values for the structure with unmodulated electrodes of the same characteristic radius to be 35 MHz, 9830, and 174 kΩ respectively. The measured resonating frequency is 33.7 MHz. The Q value measured using pick ups under 99% power reflection method is 5200.The tuning range of the tuner has been measured to be 100 KHz.

### *Beam Energy Measurement*

Low energy beam transport line from ECRIS to RFQ consists of einzel lens,$90^o$dipole for q/A selection and solenoid as matching element. The separation stage is designed for a dispersion of 1.84 cm. The ions are extracted from ECRIS at 1.38 keV/u. In the downstream of RFQ a QQD configuration has been installed for energy measurement. The quadrupole and dipole magnet strengths are calculated using TRANSPORT for RFQ beam energy of 29.06 keV/u, as theoretically predicted by PARMTEQ. The 5.4 m long beamline is designed for dispersion of 1.9 cm. The magnetic strengths of the quadrupoles and the dipole magnet are tuned so as to achieve maximum beam current on the Faraday cup (with electron suppression) placed upstream of the dipole after the RFQ. The beam tests have been carried out using oxygen ($^{16}O^{2+}$, $^{16}O^{3+}$, $^{16}O^{4+}$), nitrogen ($^{14}N^{3+}$, $^{14}N^{4+}$), and argon ($^{40}Ar^{4+}$).Typical transmission efficiency for most of the beams is 85% & 80% respectively for un analyzed and analyzed beam[5]. A plot of beam current measured on Faraday cup before RFQ as a function of vane voltage measured pickup voltage, proportional to vane voltage is shown in Fig.2.The transmission falls drastically when the vane voltage is reduced to a value lower than roughly 86.6% of the voltage corresponding to maximum transmission, as expected for the chosen synchronous phase of −30°.

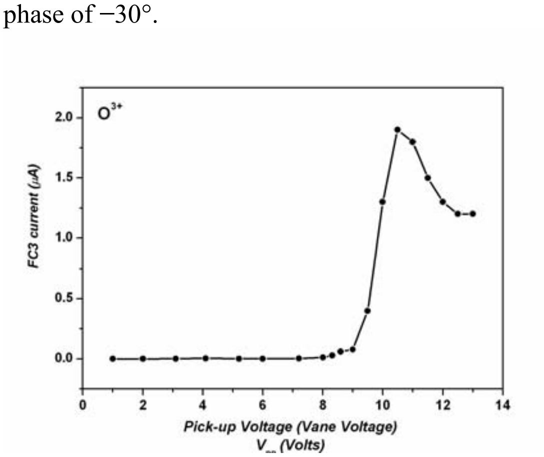

Figure 2: Variation of beam current with vane voltage for $^{16}O^{3+}$ beam.

## 37.8 MHz RFQ

### *Design Parameters*

The RFQ has been designed for DC beams with input energy of 1.7 keV/u. The vane voltage of 53.7 kV accelerates the beam to energy of 98 keV/u over a length of 3.12m. This voltage is around 1.12 times of Killpatric Voltage of 47.65 kV. RFQ consists of 6 radial matching sections (RMS) and in all 147 cells. The potential formulation in the RMS is similar to that proposed by Yamada [6], where the focusing strength (B) obeys a sinusoidal variation over the length of RMS. The calculated efficiency for 1mA beam comes out to be ~96% The variation of the optimized physical parameters along the length of RFQ is shown in Fig 3.The minimum aperture radius is 4.1mm while the maximum modulation parameter is 1.388. Energy width of the output beam through the RFQ is around ± 0.3% of the final energy. Output beam distribution as calculated by PARMTEQ, both in longitudinal & transverse phase space is shown in Fig 4.

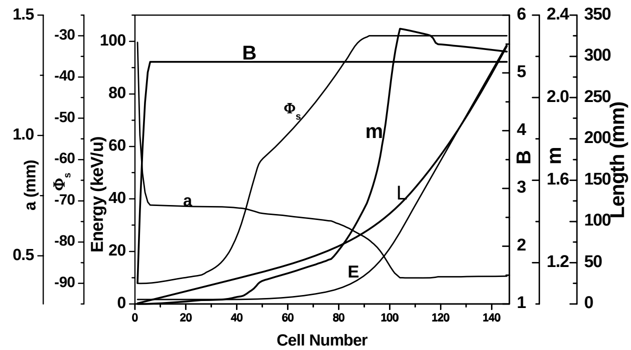

Figure 3: Variation of optimised physical parameters along the length of RFQ.

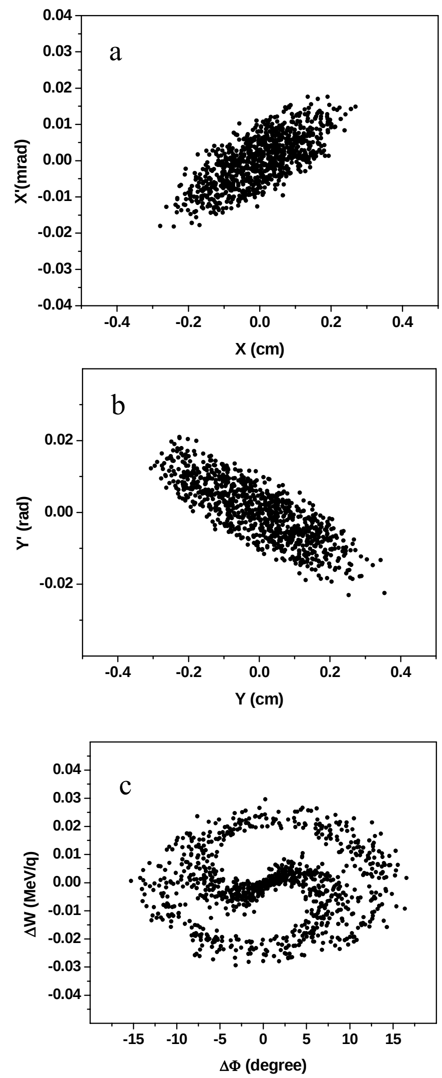

Figure 4: Longitudinal and transverse beam distribution at the exit of RFQ.

### *RF Analysis*

The RF structure design was done using the code ANSYS. The resonant frequency, Q and $R_p$ value simulated with unmodulated vanes having same characteristic radius are 37 MHz, 9763 and 78 kΩ respectively. Estimated power loss for 53.7 kV is around 18 kW. The resonance frequency is measured to be 37.8 MHz which is about 2% higher than simulated from ANSYS. The Q-value (Unloaded) measured using two pick-up loops under more than 98% reflection of power (-56 dB) is about 3705 (fig 5). The shunt impedance Rp was measured using both capacitance variation method (fig 6) and input admittance variance method. From both the methods Rp value comes out to be 53.65 KΩ and 53.9 KΩ which are about 68% of the calculated value.

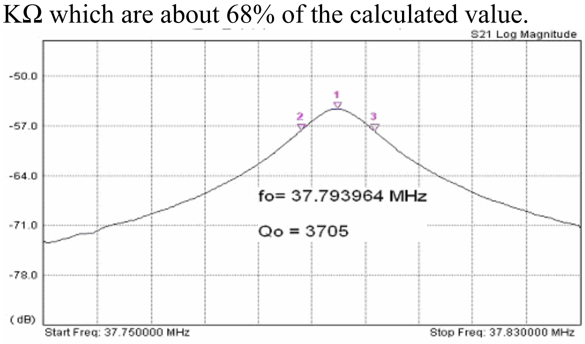

Figure 5: Unloaded Q value measurement using pick-up probes.

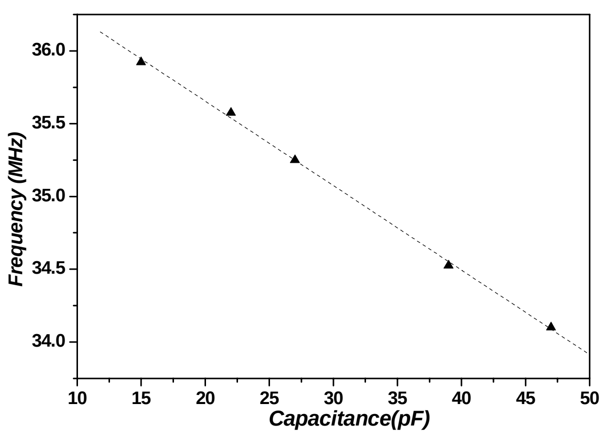

Figure 6: Rp/Q value measurement using capacitance variation method.

### *Beam Transmission Efficiency*

The acceleration performance of RFQ has been measured with O(5+) beam extracted from ECRIS at 1.7 keV/u. After selection through 90 degree dipole magnet the solenoid is tuned in order to match the beam with RFQ. The ion optics has been calculated using TRANSPORT code. The strength of both the Dipole magnet and solenoid has been tuned accordingly. The transmission efficiency has been measured by taking the ratio of currents for faraday cups placed upstream and downstream of RFQ. Unanalysed efficiency is close to 90% for $O(^{5+})$ beam.

## Discussion

33.7 MHz RFQ have been successfully built and we are able to accelerate beam to 29keV/u with high enough efficiency through it. We have also succeeded in accelerating heavy ions such as $Fe^{5+}$ through the RFQ for material science experiments. 3.4 m long RFQ have already been installed in the beam-line for accelerating heavy ion RI beams to 98 keV/u.Beam line after RFQ is in process of installation. A QQD configuration will be installed to assess the analysed beam transmission efficiency, in due course of time.

## Acknowledgement

The authors would like to acknowledge Osamu Kamigaito, Akira Goto, and Yashushige Yano from RIKEN Accelerator Research Facility, Japan, for their help during design and development of the RFQ. Authors would like to thank the teams of CMERI and SAMEER for their valuable technical support in this work.

# THE IFMIF-EVEDA RFQ: BEAM DYNAMICS DESIGN

M. Comunian, A. Pisent INFN/LNL, Legnaro (PD) Italy, E. Fagotti (Consorzio RFX, Padova)

*Abstract*

The IFMIF-EVEDA (Engineering Validation and Engineering Design Activities) project foresees the construction of a high intensity deuteron accelerator up to 9 MeV, with the characteristics required for the actual IFMIF facility. The linac will be installed in Rokkasho, and INFN is in charge of the construction of a 5 MeV, 125 mA, deuteron RFQ operating at 175 MHz. In this article the beam dynamics design of this challenging RFQ is described, namely the design, the main outcomes in terms of beam particles physics, and finally the study of mechanical and rf field error tolerances. The RFQ design method has been aimed to the optimization of the voltage and R0 law along the RFQ, the accurate tuning of the maximum surface field and the enlargement of the acceptance in the final part of the structure. As a result this RFQ is characterized by a length shorter than in all previous design, very low losses (especially at higher energy) and small RF power dissipation[1][2][3].

## RFQ PARAMETERS AND DESIGN

The IFMIF EVEDA RFQ specification and the main design parameters are listed in Table 1.

Table 1: IFMIF RFQ Parameters

| | | |
|---|---|---|
| Particles | D+ | |
| Frequency | 175 | MHz |
| Input Current | 130 | mA |
| RMS Input tr. emittance | 0.25 | N.mmmrad |
| Input/Output Energy | 0.1/5 | MeV |
| Max Surface Field (1.82 Kp) | 25.6 | MV/m |
| Length L | 9.78 | m (5.7 λ) |
| Voltage Min/Max | 79/132 | kV |
| Total Power with margins | 1.6 | MW |
| Mean aperture $R_0$(min/max) | 4.1 / 7.1 | mm |
| Trans. (WaterBag÷Gauss)* | 99.1÷95.7 | % |
| Power Loss(WaterBag÷Gauss)* | 253÷1007 | Watts |
| RMS Output Long. Emittance* | 0.197 | MeVdeg |
| RMS Output Tr. Emittance* | 0.26 | N.mmmrad |

*Average of 10 Toutatis runs with $10^6$ particles.

The design of such high current RFQ is very challenging due to the necessity to limit deuteron losses, keeping in particular extremely low the losses in the high energy part. The aim is to minimize the neutron production and the consequent activation of the RFQ structure.

Due to the high space charge effect at low energy. The value of input energy has been chosen of 0.1 MeV to maintain the value of maximum transverse current up to 200 mA until the end of Gentle Buncher;, this large margin guarantees small losses along the buncher formation process.

All the RFQ simulations here reported has been made by using the CEA code "Toutatis" [4].

### *Transverse Parameters Characterization*

The IFMIF EVEDA RFQ beam dynamics study was aimed at minimizing beam losses at high energy, reducing the RFQ length and power consumption. The main parameters are plotted in fig. 1, the focusing force "B" at the beginning of RFQ is about 7, i.e. a very high value to compensate the high space charge force and keep the beam in a linear force fields. It is not possible to ramp the value of "B" in the shaper because we get a larger beam size and due to that same losses in the gentle buncher process. The normalized transverse acceptance of the RFQ in smooth approximation is defined by:

$$Acc = \frac{a^2\sigma_{T0}}{2\lambda}\sqrt{\left(1-\frac{B}{4\pi^2}\right)^3 / \left(1+\frac{B}{4\pi^2}\right)}$$

with λ the wavelength *a* small aperture,$\sigma_{T0}$ phase advance at zero current and "B" the focusing factor expressed by:

$$B = \frac{qV}{mc^2}\frac{\lambda^2}{R_0^{\,2}} \quad and \quad \sigma^2_{T0} = \Delta_{RF} + \frac{B^2}{8\pi^2}$$

The variation of acceptance and "B" is therefore strictly connect to voltage and average aperture $R_0$ along the RFQ. For that reason a closed-form and continuous up to the 2$^{nd}$ derivative voltage law V(z) and $R_0$(z) was used.

$$V(z) = V_1 + (V_2 - V_1)\left(\frac{1}{2} + \frac{15}{8}\left(-\sin(\Delta z_{12}) - \frac{1}{3}\sin(3\Delta z_{12}) + \frac{1}{5}\sin(5\Delta z_{12})\right)\right)$$

$$R_0(z) = R_{01} + (R_{02} - R_{01})\left(\frac{1}{2} + \frac{15}{8}\left(-\sin(\Delta z_{34}) - \frac{1}{3}\sin(3\Delta z_{34}) + \frac{1}{5}\sin(5\Delta z_{34})\right)\right)$$

$$with \quad \Delta z_{12} = \frac{\pi}{6} - \frac{\pi(z-z_1)}{3(z_2-z_1)} \quad and \quad \Delta z_{34} = \frac{\pi}{6} - \frac{\pi(z-z_3)}{3(z_4-z_3)}$$

In this way it is possible to increase the voltage in a smooth way in the accelerator part and to have continuous variation of the phase advance per meter along the RFQ. The R0 and the voltage V are ramped after the Gentle Buncher, the V is increased for 4.4 meters instead the R0 are changed for 4.5 meters to reduce the surface fields and smoothing the phase advance change rate. The final value of the voltage $V_2$ is limited by the total available RF power, the final value of R0 allows to avoid the resonance $\sigma_T = \sigma_L$.

In the final 3 meters of accelerator almost all the parameters are kept constant. It's done to avoid small losses and to limit the part of the RFQ where the full 3D machining modulation is needed.

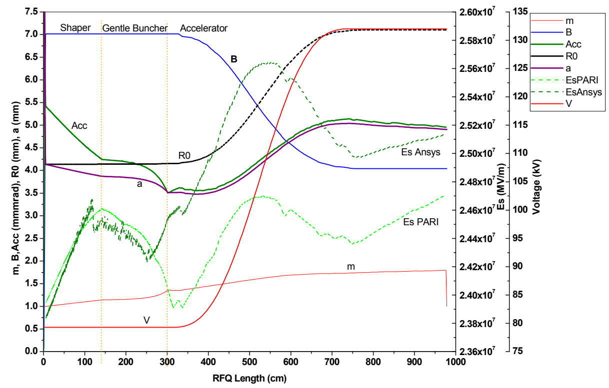

Figure 1: Modulation, Focusing factor B, Acceptance, Mean aperture "R0", minimum aperture "a", Surface Fields "Es" and voltage profile along the RFQ.

The ratio of V/R0 also is limited by the surface fields Es. The increase of R0 and "a" produce the increase of acceptance. The ratio of ρ/R0 is kept constant at 0.75 to reduce the surface fields, at the price of higher multipoles components. The modulation law chosen was the "2TERM" type, allows to manage successfully the non linearities.

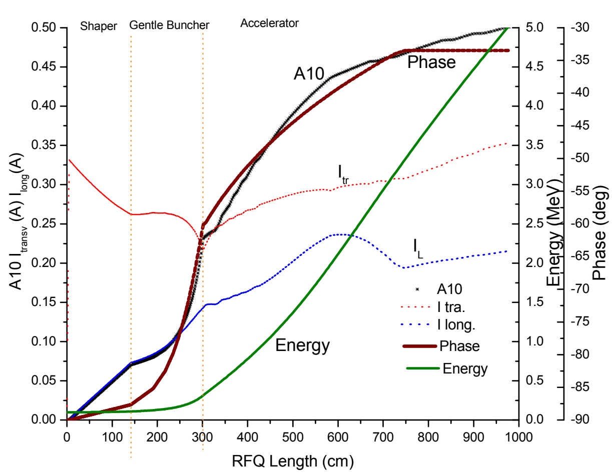

Figure 2: Energy, Acceleration coefficient A10, Synchronous phase, Current Limit Transverse and Longitudinal along the RFQ.

## *Longitudinal Parameters Characterization*

Due to the strong longitudinal space charge phenomena during the separatrix formation, also with the presence of filamentations, the shaper section of the RFQ is very long, about 1.4 meters, this guarantees with an relative high number of cells, the high longitudinal beam capture. The bunching process is so done in as smooth as possible way to capture as much as possible particles. The particles capture indicate by RFQuick was 100% in a large range of GB energy but with the multiparticles tests the real useful zone in energy was very small, so the selected GB final energy was 0.31 MeV, and at the end of GB the synchronous phase is -60 deg, this is the maximum phase possible keeping in account the longitudinal current limit. In the accelerator part the synchronous phase is increased linearly, respect to the cell, from -60 to -33.5 deg, if it is increase more rapidly part of the beam go out of the separatrix. The energy gain per meter in the accelerator part is about 0.7 MeV/m. The plot of Fig. 3 show the final phase space with a gaussian input beam distribution, very few particles on 106 are making longitudinal halo.

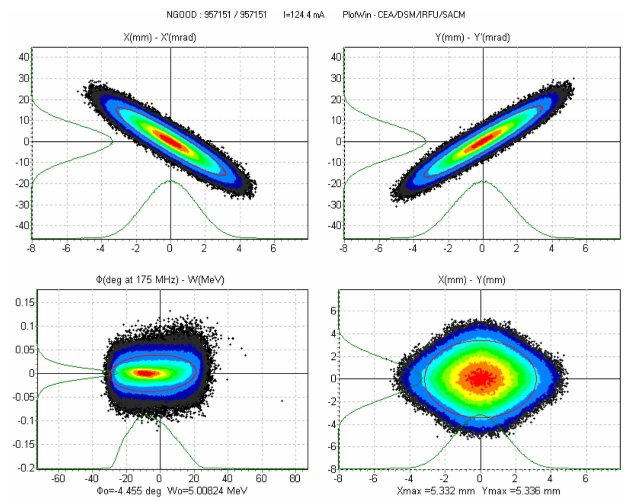

Figure 3: Phase Space at RFQ output with input Gaussian beam distribution of 130 mA, ε=0.25 RMS N. mm mrad.

## ERRORS STUDIES

### *Alignment Between Modules*

The RFQ structure will be made by fundamental elements 550 mm long; such elements are either brazed of flanged with a short longitudinal discontinuity. For that reason a study of tranverse misalignment at transition is mandatory. Vanes shape with an error on profile value $x_p(z)$ were generated, according to:

$$xp(z) = xp_0(z) \pm r\Delta X \quad with \quad -1 \le r \le 1$$

where $\Delta X$ is the maximum vane error amplitude considered and the random value "r" is regenerated for each element (Fig. 4). This procedure are made with 10 different RFQs, to accumulate statistics, and with a range from 0 to 100 μm of $\Delta X$ (Fig.5). It appears to be possible to handle errors on segmented RFQ in the order of ±50 μm, without a too large impact on transmission and power beam losses.

Due the huge numbers of runs to do, the errors study has been made by using Toutatis on a Linux cluster with about 20 nodes.

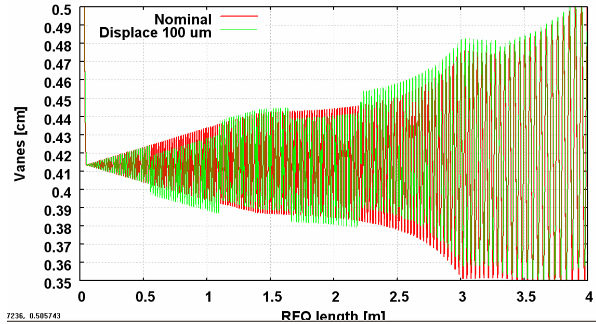

Figure 4: Vanes profile nominal and segmented in 550 mm pieces, along the first 4 meters of RFQ.

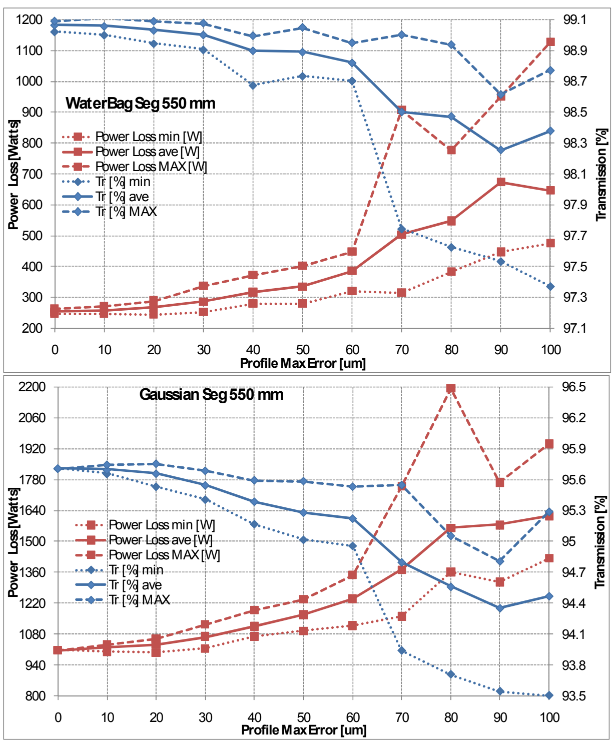

Figure 5: Transmission and Power loss due to the segmentations applied with gaussian and waterbag input beam distribution.

## *Voltage Tilt*

To study the RF errors a tilt on voltage respect to the nominal value has been generated, (fig. 6), corresponding to a non null component of the first perturbing quadrupole.

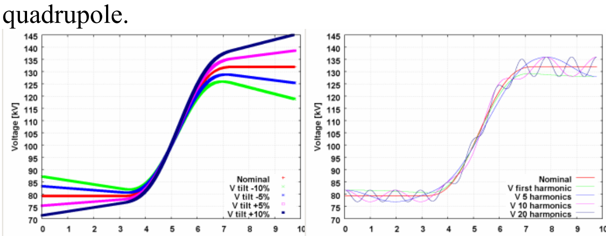

Figure 6: Tilted Voltage profile and harmonics profiled Voltage along the rfq.

The results of tilted voltage are in fig. 7, a positive tilt means a lower value of voltage at RFQ beginning. The power loss remains below 1.6 kW for very large range of values of tilted voltage.

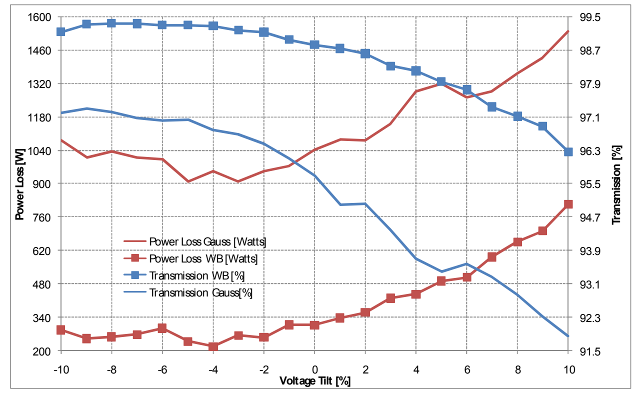

Figure 7: Voltage tilts effects on Transmission and Power loss with gaussian and waterbag input beam distribution.

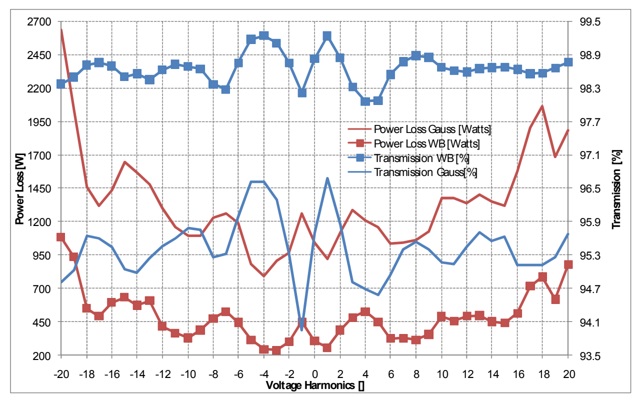

Figure 8: Voltage harmonics effects on transmission and power loss with gaussian and waterbag input beam distribution.

## *Residual Voltage Error*

We have then simulated the residual voltage error after RFQ tuning by introducing higher order harmonics according to:

$$V_r(z) = V_0(z) + \mathrm{sgn}(n)\cdot\Delta V\cdot\cos(n\cdot\frac{\pi}{2}\cdot z / L_{rfq})$$

where $n$ is integer and $\Delta V$=3% of the nominal voltage (Fig. 6). The results show very little dependence from the applied voltage harmonics. From the results on tilted voltage and harmonics analysis it seems to be possible to handle a maximum error of ±3% on voltage (Fig. 8).

# RF DESIGN OF THE IFMIF-EVEDA RFQ

F. Grespan, A. Palmieri, A. Pisent INFN/LNL, Legnaro (PD) Italy

*Abstract*

The RFQ of IFMIF-EVEDA project is characterized by very challenging specifications, with 125 mA of deuteron current accelerated up to 5 MeV. Upon beam dynamics studies, it has been chosen a law for the variation of $R_0$ and voltage along the structure; this law provides a significant reduction in terms of structure length, beam losses and rf power consumption. Starting from these outcomes, the rf study of the RFQ, aimed at determining the optimum design of the cavity shape, was performed. The stabilization issues were also addressed, through the analysis of the RFQ sensitivity to geometrical errors, by means of perturbative theory-based algorithms developed for this purpose . Moreover the determination of the main 3D details of the structure was also carried out. In this article the results of the rf studies concerning the above-mentioned topics are outlined.

## RFQ PARAMETERS AND CAVITY DESIGN

The main RFQ parameters are listed in Table 1, and the 3D layout in Figure 1.

Table 1: IFMIF RFQ Input Design Parameters

| | | |
|---|---|---|
| Particles | D+ | |
| Frequency | 175 | MHz |
| Input Current | 130 | mA |
| Energy (in-out) | 0.1-5 | MeV |
| Max Surface Field | 25.2 | MV/m (1.8 Kp) |
| Length L | 9.78 | m |
| Voltage min/max | 79/132 | kV |
| Mean aperture $R_0$ | 4.1 / 7.1 | mm |
| Pole tip radius ρ | 3.08/5.33 | mm |

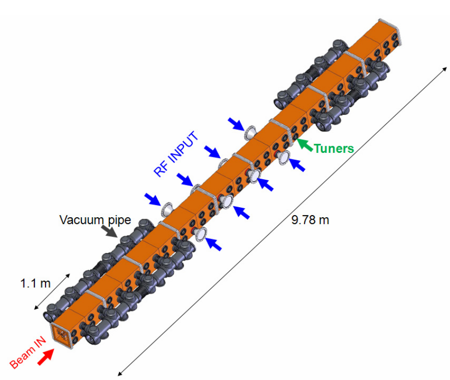

Figure 1: IFMIF RFQ schematic layout.

The IFMIF EVEDA RFQ beam dynamics study[1] was aimed at minimizing beam losses at high energy, reducing the RFQ length and power consumption. A closed-form and continuous up to the 2nd derivative voltage law V(z) was used. In this way it is possible to increase the voltage smoothly along the accelerator part and to have continuous cut-off frequency variations.

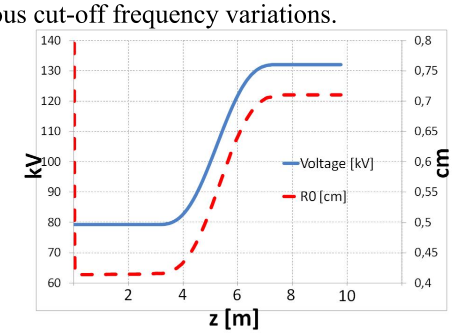

Figure 2: Mean aperture and voltage profile along the RFQ.

The goal of the cavity design was the optimization of the transverse section in order to match the local cut-off frequency with respect to local $TE_{21}$ cut-off frequency f(z) variation due both to voltage and aperture variation, by varying the Vane Base Width 2·W1 along the RFQ with the usage of the RFQFISH routine. The minimum W value (1 cm) was chosen in order to allow cooling channel positioning and the maximum W1 value (1.5 cm) to avoid mechanical oscillations during machining. The upper flat surfaces H1 and H2 (9 cm) allow the positioning of tuners and RF couplers (Fig.3). Moreover the choice of the section was also dictated by the fact that a “square” shape of the RFQ cross-section allows, for a given frequency and $R_0$, a better volume/surface ratio and a subsequent Q improvement (about 10%) with respect to a “triangular” shape.

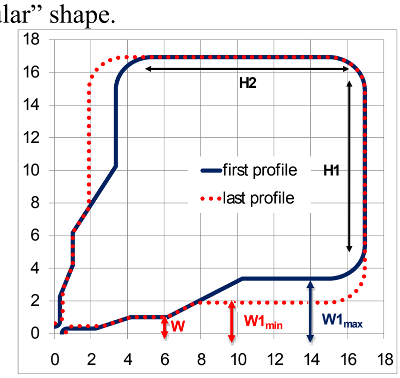

Figure 3: The variable shape of the RFQ section.

The main parameters obtained from the SUPERFISH optimization are summarized in Table 2.

Table 2: SUPERFISH Results

| | | |
|---|---|---|
| $Q_0$ (SF) (z=0-z=L) | 15100-16700 | |
| 2D Power (SF) | 450 | kW |
| Stored Energy | 6.6 | J |
| Max H field (z=0-z=L) | 3000-4500 | A/m |
| Max. Power Density (z=0-z=L) | 1.6-3.1 | W/cm$^2$ |
| Total power $P_d$ | 1.345 | MW |

The $P_d$ is related to the 2D power calculated by SUPERFISH, $P_{SF}$, by means of the relationship

$$P_d = P_{SF}\alpha_{3D}\alpha_v + P_b$$

where $\alpha_{3D}$=1.3 (for 3D losses), $P_b$ is the beam power at 130 mA and $\alpha_v$ = 1.21 ( = 1.1$^2$) for Voltage enhancement The sensitivity with respect to geometrical errors was addressed both numerically and analytically, and it was found that the maximum [minimum] sensitivity $\chi$ is located in the initial [final] section of the RFQ, where $\Delta f/\Delta R_0$=11.8 MHz/mm [7.5 MHz/mm].

## FIELD STABILIZATION ISSUES

Geometrical errors in the RFQ section produce perturbations on the nominal voltage profile $U_0(z)$ via capacitance perturbations. General beam dynamics considerations prescribe that $|\Delta U(z)/U_0(z)|< 0.01$ and $|U_{qd1,qd2}(z)/U_0(z)|$<0.02 [2] where $\Delta U(z)$ and $U_{qd1,qd2}(z)$ are the voltage perturbations due to upper quadrupole modes and the two kinds of dipole modes respectively. In order to reach such goal, it is necessary to use a system of $N_T$ slug tuners per quadrant of radius $a$ and depth $h$ variable in the interval [0, $h_{max}$]. Each tuner can vary the resonant frequency of the RFQ of an amount equal to $\Delta f_t = \chi_t h$ $\chi_t$ being the tuner sensitivity related to the magnetic field on the upper RFQ wall. The idea is that the tuning range (the frequency interval that can spanned by the tuners) $\Delta f_{TR} = 2N_T\chi_t h_{\max}$ should be able to correct for frequency shifts induced by geometrical error $\Delta f_q$ with appropriate margin, that is $\Delta f_{TR} = k\Delta f_q$ with k>1. If $f_c$ is the average cut-off frequency of the RFQ and $f_0$ is the operating frequency, the tuning range is symmetric around $f_0$, in the sense that $\Delta f_{TR}=f_0- f_c$. If all tuners, couplers and vacuum ports are placed along, say, H1 surface, then the number of tuners is determined by the space constraints Looking at the structure of IFMIF RFQ (Figure 1), there are $N_T$=22 longitudinal locations per quadrant available for tuners. However, $N_T$ can be increased to 24 or 27, by placing the tuners in H2 surface and all the other ancillaries along H1 (see Figure 3), thus permitting the tuners to be periodically spaced. In the following the effectiveness of tuning will be discussed by comparing the case of coupled and uncoupled RFQs in terms of tuning range required, with the coupling element is located at L/2. For simplicity let us assume that the RFQ is uniform with $R_0$=4.1 mm, a=45 mm and $\chi_t$= 800 Hz/mm. In order to understand better the meaning of the tuning range, let us suppose to have a geometric perturbation $\Delta R_0$=0.04 mm if 0<z<L/2 and $\Delta R_0$=0 mm otherwise and equal in all the four quadrants. ($\Delta U(z)\neq 0$, $U_{qd1,qd2}(z)=0$). For this kind of perturbation, we have a local frequency variation equal to 500 kHz. The corresponding $\Delta U(z)/U_0(z)$ functions for the case of coupled and uncoupled RFQ are shown in Figure 5. Now, let us suppose that our tuning system is rated for $\Delta f_{TR} = 1MHz$ corresponding to $h_{max}$=28.6 mm and k=2. It is possible to show that, in this case, the voltage variation can be reduced to ±1.5% in one tuning step without exploiting the whole tuners depth capability, both for coupled and uncoupled RFQ's (Figures 4 and 5).

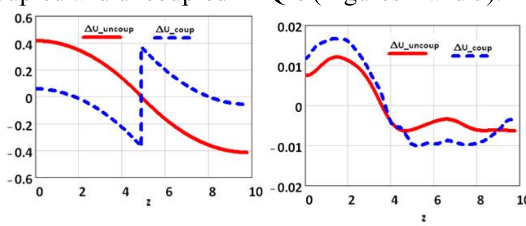

Figure 4: The $\Delta U/U_0$ function before (left) and after (right) one tuning step.

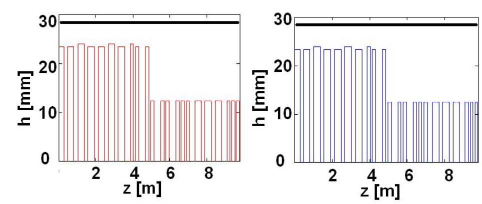

Figure 5: The tuner depths needed for the uncoupled (left) and coupled (right) case vs. tuner locations.

The situation is different if the tuning range is such that k=1. In fact, in this case, the tuning range is halved, and therefore all tuner depths saturate to $h_{max}$=14.3 mm in the first half of the RFQ and the voltage variation does not reduce less than 7.5% for the coupled case and 8.8 % for the uncoupled case. In conclusion, for our L/λ ratio, the usage of a coupling element does not reduce significantly the tuning range needed and the chosen tuning range seems to be effective to contrast perturbations also with an unsegmented structure. This is somewhat in agreement with the fact that the SNS RFQ (which is only 15% shorter than IFMIF RFQ in terms of L/λ) does not use any coupling cell.

As for the dipoles, the minimum sensitivity to dipole errors vs. boundary conditions for coupled and uncoupled structures is substantially the same. This can be shown by comparing in both cases the minimum value of the quantity $h_{dip}$ as a function of the voltage slope $s_a$= $U'_{qd1,d2}(0)/U_{qd1,d2}(0)$ (boundary condition) at the beginning of the RFQ [6]. Such quantity is defined as the maximum value with respect to z and $z_0$ of

$U_{qd1,d2}(z)/U_0(z)$ in the case of a delta capacitance perturbation located in z=$z_0$ (Figure 6).

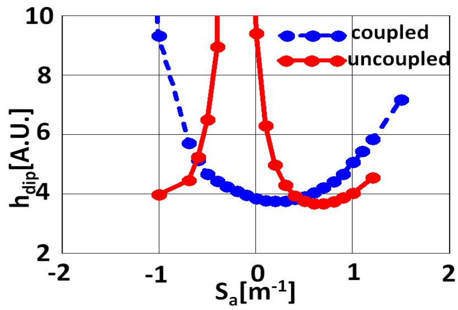

Figure 6: $h_{dip}$ comparison for IFMIF RFQ.

The tuning system effectiveness will be experimentally tested on a real-scale aluminium model of the RFQ, which will allow also the possibility of introducing a coupling element in between.

## 3D MODELING OF THE RFQ AND RELATED HFSS SIMULATIONS

The study of the 3D details of the RFQ, performed with the code HFSS v. 11.1 was concentrated mainly on the following aspects: voltage law validation, end cell design and study of the vacuum grid. In the following the power densities are calculated by using the $\alpha_{3D}\alpha_v$ margins defined before.

The validation of the voltage law was made by comparing the magnitude of the electric fields in a point ($X_0$, $Y_0$) = (1cm, 1 cm) along the symmetry axis of the quadrant given by SUPERFISH and HFSS. The agreement between the two field profiles is within 4% and the Q value calculated by HFSS is equal to 15400. Moreover, it was also possible to calculate the value of the longitudinal surface currents that are non vanishing, since the voltage profile is not constant. This component intercepts discontinuities due to modularity of RFQ, but its value (~4 A/m ) is negligible respect to the transverse component (~2000 A/m).

The design of the end cells was accomplished too, by determining the dimensions of the vane undercuts that assure the achievement of the proper boundary conditions at the RFQ extremities. For such structure, the power density was checked in view of the 3D thermo-structural calculation. In Figure 7 the geometry of the matched Low Energy undercut is shown, as well as the power density profile.

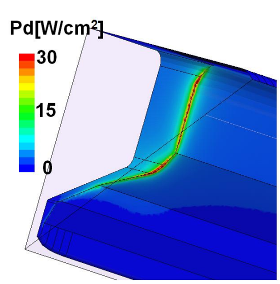

Figure 7: Power density profile along the end-cell.

As for the vacuum grids, they introduce a discontinuity in the upper wall of the RFQ, that creates a frequency shift and an enhancement in current density. In order to understand the amount of such effects, simulations on a 27.5 cm RFQ slice were performed for the grid model of Figure 8, in which the slit distance δ was varied. The results are summarized in Table 3 and Figure 9.

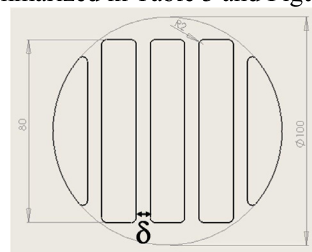

Figure 8: The vacuum grid model.

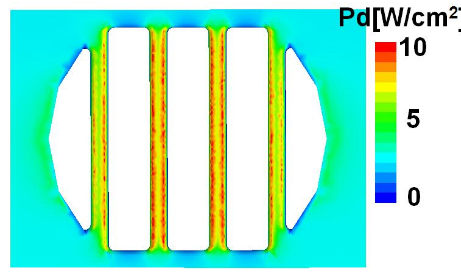

Figure 9: Power density in the vacuum grid for δ=6.5 mm.

Table 3: Vacuum Grid Main Parameters

| case | δ[mm] | f[MHz] | Pd grid [W] |
|---|---|---|---|
| nominal | No grid | 174.375 | 153 (on the flat surface to be occupied by the grid) |
| 1 | 6.25 | 174.245 | 186 |
| 2 | 7.25 | 174.267 | 187 |
| 3 | 8.25 | 174.289 | 188 |
| 4 | 9.25 | 174.312 | 179 |

The Q drop due to the vacuum grid keeps under 1% and the power density enhancement due to the grid is about 3 with respect to the flush wall. The validation of the current layout of the grid will be given upon thermal simulations whose input data are the above calculated power densities.

## Abstract

The Legnaro National Laboratory (LNL) is building the 30 mA, 5 MeV front end injector for the production of intense neutron fluxes for interdisciplinary application. This injector comprises a proton source, a low energy beam transport line (LEBT), a radio frequency quadrupole (RFQ) and a beam transport line designed to provide a 150 kW beam to the beryllium target used as neutron converter. The RFQ, developed within TRASCO project for ADS application, is designed to operate cw at 352.2 MHz. The structure is made of OFE copper and is fully brazed. The RFQ is built in 6 modules, each approximately 1.2 meter long. This paper covers the mechanical fabrication, the brazing results and acceptance tests for the various modules.

## INTRODUCTION

The high intensity RFQ under construction at LNL, developed within TRASCO project[1] for ADS study, will be devoted to the application of Boron Neutron Capture Therapy (BNCT) for the treatment of skin melanoma[2]. The main RFQ nominal parameters are listed in Table 1.

Table 1: Main RFQ parameters

| Parameter | Value | Unit |
|---|---|---|
| Energy In/Out | 0.08/5 | MeV |
| Frequency | 352.2 | MHz |
| Proton Current (CW) | 30 | mA |
| Emit. t. rms.n. in/out | 0.20/0.21 | mm-mrad |
| Emit. l. rms. | 0.19 | MeV-deg |
| RFQ length | 7.13 | m (8.4 λ) |
| Intervane Voltage | 68 | KV (1.8 Kilp.) |
| Transmission (Waterbag) | 98.5 | % |
| Q (70% of SF result) | 7000 | |
| Beam Loading | 0.148 | MW |
| RF Power dissipation | 0.847 | MW |

The RFQ consists of three electromagnetic segments 2.4 meters long resonantly coupled via two coupling cells in order to reduce sensitivity to machining errors. Each module consists of two 1.2 meters long modules, which are the basic construction units.

In order to accelerate the 30 mA CW proton beam up to 5 MeV, the maximum amount of power expected to be delivered to the RFQ is about 995 kW (148 kW beam power + 847 kW dissipated power). The possibility of a ten percent voltage increase respect to the nominal is considered in the dissipated power value. The power is generated by one klystron and supplied to the RFQ by a WR2300 waveguide system. Due to the fact that each RF coupler is rated for a maximum of 140 kW[3], the RF power is split in eight ways via magic-Tee dividers. An artistic view of the integration of the RF distribution, vacuum system and support is presented in Fig.1.

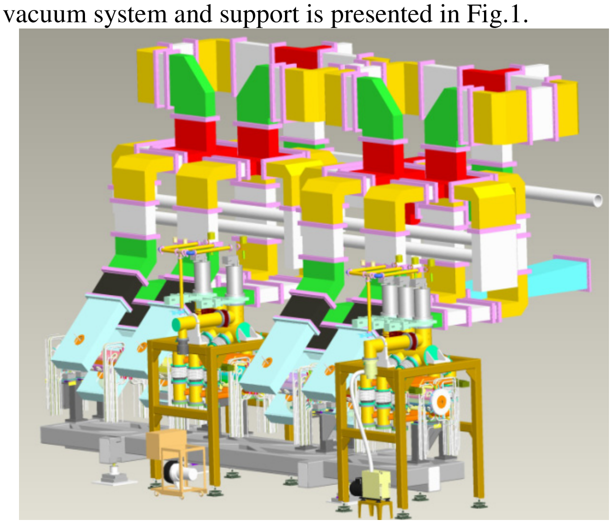

Figure 1: Integration of RFQ with ancillaries.

## MECHANICAL FABRICATION AND BRAZING

Each module, built in OFE copper, is made of four main parts. The head flanges between modules and the rectangular vacuum flanges are made of SS (LN316). To reduce the number of brazing joints, the longitudinal cooling passages are deep-hole drilled from one side and closed with brazed plugs on the flat surfaces of the RFQ module (opposite to the coupling or end cells). Moreover, the vacuum grids with their cooling channels are directly machined on the copper bulk.

Two brazing steps occur. In the first the four main parts are brazed in horizontal position in a horizontal vacuum furnace, as well as the OFE plugs for the cooling channels. The brazing alloy is Ag68CuPd-807/810 (57.3% at., 38,4% at., 4.3% at.) and the brazing temperature is 815°C. After first brazing, housings for the head flanges and the flat end surfaces (where the cooling channel plugs are located) are machined. In the second brazing cycle the head SS flanges, the inlet and outlet cooling water SS tubes, the SS supports for vacuum ports flanges and the SS flanges for couplers are brazed in vertical position in a vertical vacuum furnace. The brazing alloy is Ag72Cu-779 (40% at.) and the brazing temperature is 785ºC.

Maximum temperature of the OFE copper stabilization cycle before finishing turned out to be extremely important to avoid deformation after brazing. For the first two modules this temperature was 250ºC. After brazing both the modules showed a two hundreds microns longitudinal bending (banana shape). Moreover the module 2 presented an important displacement in one transversal direction that entailed the opening of eight more tuner holes for frequency recovery. Relaxation of stress induced during machining was identified as the main effect in comparison with the deformations due to the brazing heat treatment.

Consequently machining procedure changed. For the remaining modules a full annealing at 600 °C preceded finishing. In addition finishing was as soft as possible in order to minimize induced stress. The success of the new procedure was evident after the brazing of the third module (Fig.2). Banana shape and transversal movements generated by brazing heat treatment turned out to maintain nominal tolerances (±20 µm). Almost the same results were obtained after brazing of RFQ4 and RFQ5.

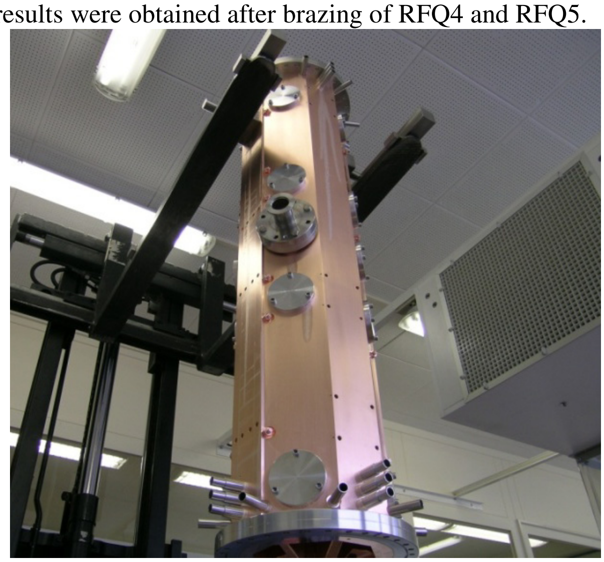

Figure 2: Module 3 after vertical brazing.

Some minor problems characterized the brazing of module 3 and 4. Module 3 experienced a vacuum leak after vertical brazing. Leak was caused by a bad nickelization process of the head SS flanges. A repairing brazing was attempted before summer without success. This will force to remove the head flanges and to repeat the vertical brazing with new nickelized flanges. Regarding RFQ4, the water channel plugs experienced some problem of brazing alloy flow. Plugs with not visible brazing alloy were removed and re-brazed in the vertical brazing last week. RFQ6 is currently under first brazing.

The plan for the next future foresees the brazing completion before the end of the year.

## ACCEPTANCE TESTS

RF and mechanical measurements allow checking the correctness of each fabrication step.

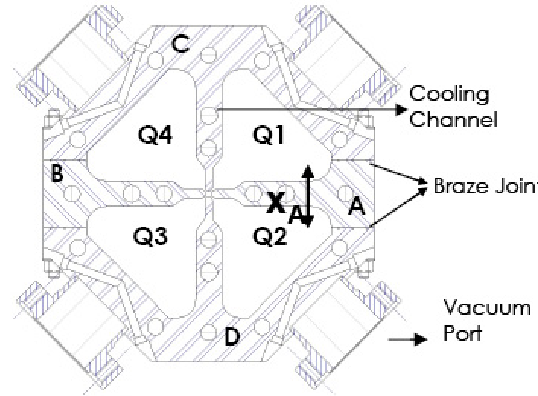

Figure 3: Nomenclature for electrodes and quadrants.

With reference to Fig.3, let $\Delta x$ be the extra thicknesses of the electrodes A and B, with respect to their nominal values $\Delta y$ the amount of extraction of the electrodes A and B with respect to their nominal position. The initial values of such parameters are $\Delta x$=50µm and $\Delta y$=0µm. The first measurement step foresees the determination of the quadrupole and dipole frequency {fQ, fD1, fD2} in such configuration and with tuners set at the nominal penetration. Then $\Delta y$ is varied by means of the application of calibrated spacers and a new set of {fQ, fD1, fD2} is found. The knowledge of these two sets permits us to determine the values of $\Delta x^*$and $\Delta y^*$ that fulfil the conditions fQ= 352.2 MHz and fD1=fD2 within the precision limits of the spacers and of the milling machine (±10µm). Then the thickness $\Delta x^*$ is removed from the electrodes A and B and the definitive spacers are applied. With this configuration the tuning operations (based on bead-pulling measurements) are performed up to the achievement of an overall ±5% longitudinal uniformity of the electric fields in all quadrants.

The modules RFQ2 to RFQ6 successfully underwent such characterization before 1st brazing step with the values for $\Delta x^*$ and $\Delta y^*$ presented in Table.2. Concerning RFQ1 the $\Delta y$ tuning was not yet introduced; as a result the quadrupole mode was tuned, but the two dipoles were splitted by about 2 MHz.

For RFQ1 and RFQ2 the entire set of RF measurements (including bead pulling) was repeated at CERN immediately before brazing. The reproducibility found allowed to skip this step for the following modules.

After brazing, a set of mechanical measurements is foreseen in order to check the effect of brazing upon some important parameters, namely the reference plane distance (directly related to $R_0$) and the width of the coupling gap. Then the tuning procedure is repeated up to the achievement of the above-mentioned specifications.

Table 2: Pre-braze setting for the RFQ modules.

| Module | $\Delta x^*$[µm] | $\Delta y^*$[µm] |
|---|---|---|
| RFQ2 | 70 | 20 |
| RFQ3 | 50 | 50 |
| RFQ4 | 70 | 50 |
| RFQ5 | 65 | 40 |
| RFQ6 | 60 | 15 |

To date modules up to RFQ3 underwent such characterization, with somewhat different outcomes. As for RFQ2 a quadrupole frequency increase of 700 kHz and a ± 20% dipole content on the operational mode were observed after brazing. Such a unexpected voltage variation, related to the abnormal bending discussed in the previous paragraph, could not be completely recovered with standard tuners. Therefore eight additional holes for tuners (four in Quadrant 1 and four in Quadrant 4) were machined and the required voltage flatness was recovered. As for the other modules, the RF measurement and tuning procedure was carried out without any particular problem.

## RF MEASUREMENTS ON THE 1ST RFQ SEGMENT (RFQ1+RFQ2)

The first RFQ segment was mounted at LNL for low power RF and vacuum tests (Fig.4). Prior to the vertical assembling of the two modules, the beam axis of each RFQ was characterized, and the necessary reference planes and pins were machined.

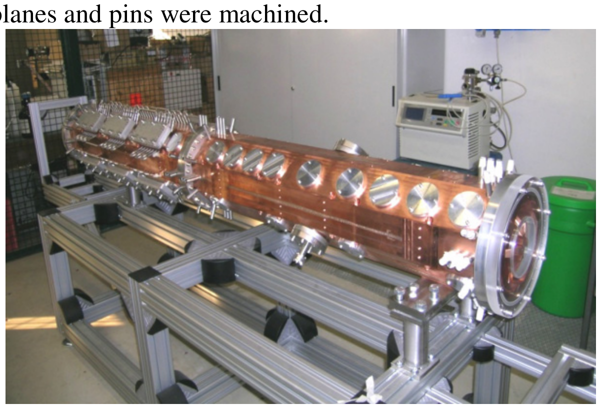

Figure 4: The 1st RFQ segment mounted at LNL.

In order to allow a complete RF characterization, the segment was equipped on low and high energy sides with two aluminum Tunable End Cells (Fig.5) equipped with variable dipole stabilizing rods (DSR). The RF measurements were performed in steps: first the optimum length and transverse position of DSRs that guaranteed the maximum dipole-free region (about ±7 MHz) around the operating mode were determined: the optimum DSR length are equal to Then, the boundary conditions for the $TE_{210}$ mode were tuned by inserting the octagon in the RFQ volume.

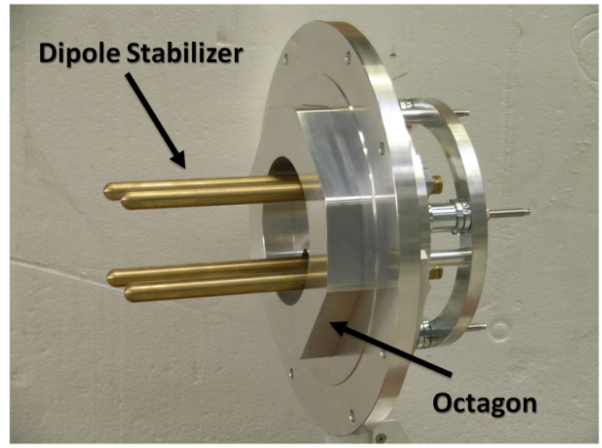

Figure 5: The Tunable End Cell.

Finally the bead pull measurements and the tuning operations (based on an on-purpose developed algorithms making use on the RFQ modal expansion) were performed. The effectiveness of the tuning algorithms is shown in the following two figures, where the voltage perturbations due to upper quadrupole modes and the two kinds of dipole modes □(□)/□$_0$ and □$_{□□1,□□2}$(□)/□$_0$ are shown before and after tuning (Fig. 6 and 7).

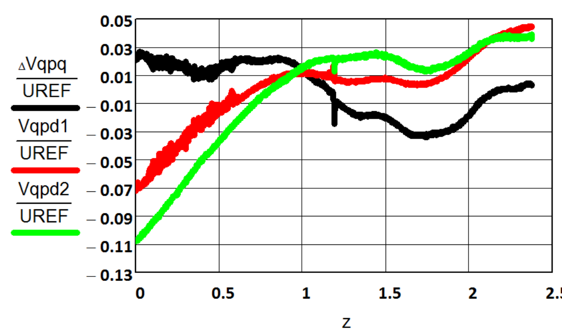

Figure 6: Perturbative quadrupole (black) and dipole (red and green) components before tuning.

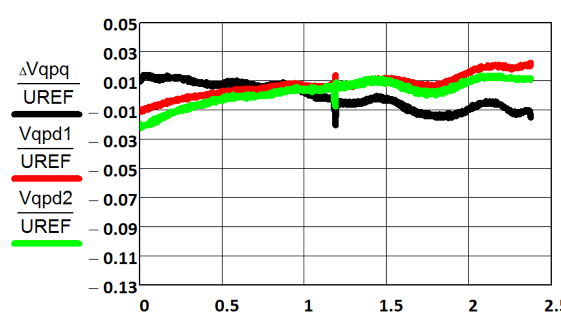

Figure 7: Perturbative quadrupole (black) and dipole (red and green) components after tuning.

# DESIGN OF A 2-BEAM TYPE IH-RFQ LINAC FOR HIGH INTENSE HEAVY ION BEAM ACCELERATIONS IN LOW ENERGY REGION

Takuya Ishibashi#, Noriyosu Hayashizaki, Toshiyuki Hattori,
Research Laboratory for Nuclear Research, Tokyo Institute of Technology, Tokyo, Japan

*Abstract*

For generating high intense ion beams from a linear accelerator (linac) stably, it is necessary to suppress the defocusing force between the charged particles. The defocusing force is extremely strong in low energy and high intense beams. Therefore, high intense ion beam acceleration in the low energy region is one of the most difficult conditions to achieve. One of the solutions is to suppress the defocusing force by dividing the high intense beam into several beams. Thus, a multibeam IH type Radio Frequency Quadrupole (IH-RFQ) linac has been proposed for the low energy and high intense beam acceleration. In particular, we have been developing a 2-beam type IH-RFQ cavity as a prototype of the multibeam type IH-RFQ.

## INTRODUCTION

High intense ion beam acceleration in the low energy region is one of the most difficult conditions to achieve due to the space charge effect. As a solution for this problem, an idea has been proposed to divide a single, high intense beam into several beams, and merge these beams into a single high intense beam with higher energy. Toward this end, an accelerator technology for a heavy ion inertial confinement fusion driver has been studied [1-3].

There is a HIBLIC in Japan that serves as a conceptual design of the inertial confinement fusion reactor [1]. The design requires 16 RFQ linacs for the first acceleration stage because the maximum output current limit is estimated to be 35 mA in the conventional RFQ linac. In this case, a beam is accelerated in a cavity conventionally. Thus, if several beams can be accelerated in a cavity towards a cascade acceleration, this method would be better than the existing systems in terms of space and cost economy.

Therefore, multibeam type linacs, which consist of several beam channels in one cavity, have been studied. For instance, a multibeam type RFQ linac with an IH structure was proposed at GSI in Germany [4]. However, there have been no previous cases in which the actual machine was manufactured. Consequently, we have developed an IH-RFQ linac with two beam channels in one cavity as a prototype for the multibeam type linac.

## DESIGN AND PARAMETERS

The external appearance of the 2-beam type IH-RFQ cavity is shown in Fig. 1, which consists of two sets of quadrupole electrodes. The RF electromagnetic field is stimulated by the $TE_{111}$ mode as well as the IH cavity. The RFQ electric field is generated by four rods installed in each of the stems taking the polarity into consideration. We adopted a structure separated into three parts, a main frame and two semi cylinders, for ease in fabrication and modification of the electrodes.

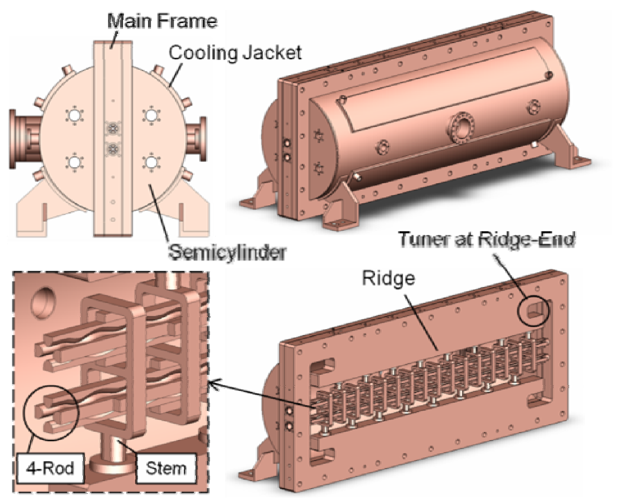

Figure 1: External appearance of the 2-beam type IH-RFQ.

The RFQ cavity can replace a resonance circuit equivalently, and the four gaps between the quadrupole electrodes in the RFQ are represented as the electrical capacitance in the resonance circuit. The resonance frequency is proportional to $(LC)^{-0.5}$. $L$ and $C$ are inductance and electrical capacitance in the cavity respectively. The electrical capacitance of the 2-beam type IH-RFQ cavity increases compared to the single beam type because the 2-beam type structure has two sets of quadrupole electrodes. This allows a comparatively low frequency to be achieved within a small cavity diameter. The cuts at the end of the ridge adjust the resonance frequency by changing the area of the magnetic flux surface and the inductance in the cavity.

Acceleration properties of the 2-beam type and the single beam type IH-RFQ linac were simulated [5]. The results demonstrated that the cavity diameter and length of the 2-beam type cavity are more compact than those of the single beam type cavity. The transmission of the 2-beam type cavity is 34% larger than that of the single beam type cavity, which has double the cross section of the beam channel in the 2-beam type. However, the beams from the multibeam type cavity need to be merged because the total emittance of the several output beams is too large for most applications to handle. There is a

# ishibashi.t.aa@m.titech.ac.jp

possibility that a portion of the ion beams are lost due to beam funneling, so beam funneling technology with efficiency is required for multibeam acceleration.

The accelerated particles were set to q/A≥1/6, and $C^{2+}$ beams will be accelerated in the test of this linac. The resonance frequency in this cavity is 46.2 MHz in MW-Studio calculation. The input energy is 5 keV/u considering beam dynamics simulations and the voltage at which the beam will be extracted from an ion source. Taking into consideration the maximum output of the RF power source, the wall loss is saved less than about 80 kW including beam loading. A Kilpatrick factor of the maximum field at inter-rod is 1.8 which is the ratio of electric field to the Kilpatrick criterion.

Table 1 shows the main parameters for the 2-beam type IH-RFQ linac. The computer code RFQUICK was used to generate the cell parameters for the PARMTEQM calculation [6]. The RFQUICK is suitable for the design of RFQ linacs whose output beam currents exceed 10 mA. The computer code PARMTEQM was used to simulate the beam dynamics in the RFQ. The electromagnetic simulation software MW-Studio was used to calculate the resonance frequency, the Q value and the wall loss of the cavity.

Table 1: Main Parameters for the 2-beam Type IH-RFQ

| | |
|---|---|
| Chargh to mass ratio (q/A) | 1/6 |
| Input energy (keV/u) | 5 |
| Output energy (keV/u) | 60 |
| Resonance frequency (calculated by MW-Studio) (MHz) | 46.2 |
| Rod-tip type | $0.75r_0$ |
| Modulation type | Standard |
| Average bore radius, $r_0$ (cm) | 0.76 |
| Minimum bore radius, $a_{min}$ (cm) | 0.41 |
| Cavature radious of rod-tip (cm) | 0.57 |
| Focusing strength, $B$ | 8.754 |
| Defocusing strength (at exit of the gentle buncher section), $\|\Delta\|$ | 0.216 |
| Synchronous phase, $\phi_s$ (degree) | -90 → -30 |
| Rod length (cm) | 148.12 |
| Total number of cells | 104 |
| Cavity length (cm) | 150 |
| Cavity diameter (cm) | 49.2 |
| Maximum field at inter-rod (Kilpat.) | 1.8 |
| Q value (calculated by MW-Studio) | 7500 |
| Wall loss (at normalized inter-rod voltage, 80% Q) (kW) | 25 |

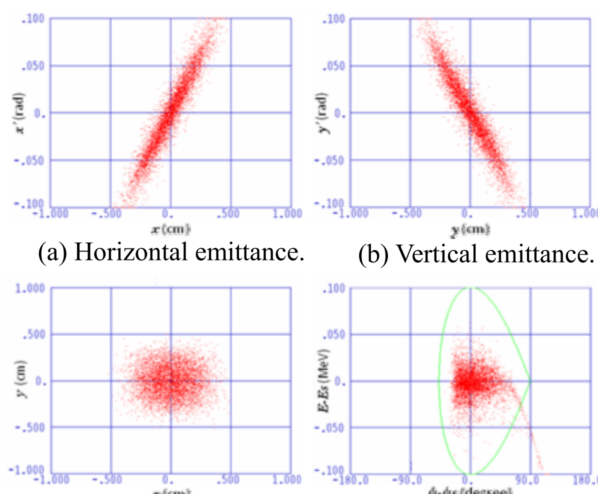
## BEAM DYNAMICS SIMULATION

Table 2 shows the parameters of the input beam for the beam dynamics simulations. $\alpha_t$ and $\beta_t$ refer to twiss parameters, and $\varepsilon_t$ refers to the emittance at the transverse direction. The parameters were determined under the assumption that a laser ion source with a direct plasma injection scheme would be adopted as the injection system for the linac [7]. The particle distribution of the 4-D waterbag exhibits a uniform phase and a random energy spread [6].

Table 2: Parameters of the Input Beam for the Beam Dynamics Simulation

| | |
|---|---|
| Beam current (mA) | 60 |
| Number of particles | 10000 |
| $\alpha_t$ | 3.4 |
| $\beta_t$ (cm/rad) | 12.7 |
| $\varepsilon_t$ (π mm.mrad, RMS, normarized) | 0.1 |
| Distribution | 4-D waterbag |
| phase | uniform |
| energy | 5keV/u, random |

Figure 2 shows the output beam profile at the end of the 4-rod. The emittance and the twiss parameters at the end of the rods are shown in Table 3. When a beam current of 60 mA from an ion source is injected into a beam channel, the 2-beam type IH-RFQ linac accelerates an output current of 43.6 mA per beam channel. As a result, when the total beam current of 120 mA is injected into the two beam channels, the total output current from the cavity will be 87.2 mA.



(a) Horizontal emittance. (b) Vertical emittance.

(c) Particle distribution on the real plane. (d) Longitudinal emittance.

Figure 2: Beam profile at the end of the 4-rod.

Table 3: Parameters of the Output Beam from a Beam Channel

| | |
|---|---|
| Transmission (%) | 72.7 |
| Output current (mA) | 43.6 |
| $\alpha_x$ | 1.8 |
| $\beta_x$ (cm/rad) | 14.8 |
| $\varepsilon_x$ (π mm.mrad, RMS, normarized) | 0.25 |
| $\alpha_y$ | -1.6 |
| $\beta_y$ (cm/rad) | 10.5 |
| $\varepsilon_y$ (π mm.mrad, RMS, normarized) | 0.23 |
| $\alpha_z$ | 0.69 |
| $\beta_z$ (degree/MeV) | 1473 |
| $\varepsilon_z$ (π MeV.degree, RMS, normarized) | 0.33 |

The output current against the input current in this design is shown in Fig. 3. The output current saturates when the input beam current reaches 120 mA and above. Figure 4 shows the output current against the Kilpatrick factor at the inter-rod. The output current can rise to about 8% by increasing from 1.8 to 2.2 Kilpatrick factor.

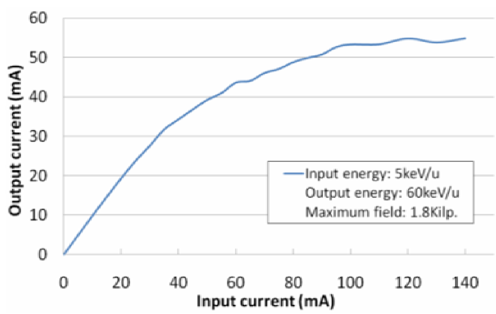


Figure 3: Output current versus the input current per beam channel.

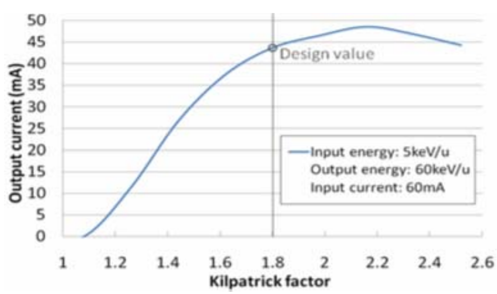

Figure 4: Output current per beam channel versus Kilpatrick factor.

## RF MEASUREMENT

As shown in Fig. 5., the actual machine of the 2-beam type IH-RFQ cavity was manufactured, and the low power RF property of the cavity in room air was measured by using a network analyzer (E5070B made by Agilent Technologies, Inc.). At the time of the measurement, the room air temperature, the cavity temperature and the humidity were 31.2°C, 30.4°C and 51.5% respectively. The $S_{21}$ parameter in $TE_{111}$ mode is shown in Fig. 6. The resonance frequency and the Q value were about 46.99MHz and about 5900 respectively.

Figure 5: Low power RF measurement of the 2-beam type IH-RFQ cavity.

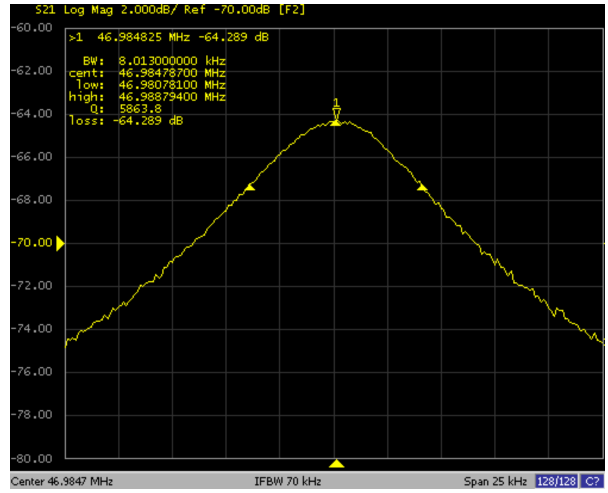

Figure 6: $S_{21}$ parameter in $TE_{111}$ mode.

The Q value in the real cavity goes down to about 80% from the calculated value because electrical contacts and surface roughness of the elements in the cavity are less than perfect. In the case of a 2-beam type RFQ with a π-0 mode structure, the Q value in the real cavity was 2000-3000 [8]. This indicates that the 2-beam type IH-RFQ is more power-efficient than the type with the π-0 mode structure because the power loss per RF cycle in the cavity is in inverse proportion to the Q value.

## CONCLUSION

We have studied a multibeam type IH-RFQ linac that is a practical and efficient method to accelerate high intense and low energy ion beams and developed a 2-beam type as the prototype. The actual machine of the 2-beam type IH-RFQ has been manufactured, and the RF property has been measured.

The results of the beam dynamics simulations demonstrated that the total output current from the 2-beam type IH-RFQ linac is 87.2 mA to yield a total input current of 120 mA in q/A=1/6 particle acceleration. The output current from the 2-beam type IH-RFQ can exceed that from the conventional RFQ.

*Abstract*

The first stage of acceleration in Linac4, the new 160 MeV CERN H$^-$ injector, is a 352 MHz, 3-m long Radiofrequency Quadrupole (RFQ) Accelerator. The RFQ will capture a 70 mA, 45 keV beam from the RF source and accelerate it to 3 MeV, an energy suitable for chopping and injecting the beam in a conventional Drift Tube Linac. Although the RFQ will be initially operated at low duty cycle (0.1%), its design is compatible with higher duty cycle (10%) as the front-end for a possible high-intensity upgrade of the CERN linac facility.

The RFQ will be of brazed-copper construction and will be built and assembled at CERN. Beam dynamics design allows for a compact structure made of a single resonant unit. Field symmetry is ensured by fixed tuners placed along the structure. In this paper we present the RF and mechanical design, the beam dynamics and the sensitivity to fabrication and to RF errors.

## INTRODUCTION

In Linac4 an RFQ is required to capture the beam extracted from the H$^-$ ion source and accelerate it to an energy suitable for injection in the following DTL [1]. This energy must also be compatible with the operation of a chopper line, used to create a microstructure in the beam pulse. The initial Linac4 plans considered using the RFQ developed and built by CEA and IN2P3, for their IPHI project [2].

The possibility to adopt a lighter design, by reducing the injection energy and adopting a different acceleration profile, made CERN decide in 2007 to build a dedicated RFQ, which could profit from the tools and experience developed at CEA within the IPHI and SPIRAL2 projects, thus reducing the R&D cost and time. Besides, CERN has recently brazed the RFQ for the TRASCO project and therefore has contributed to the related mechanical design and gained access to this manufacturing experience [3].

## BEAM DYNAMICS CONSIDERATIONS

The RFQ must initially be able to operate in Linac4 to fill the PS Booster, delivering beam pulses of 400 µs at 1.1 Hz, and, at a later stage, to fill a Superconducting Proton Linac (SPL) operated as LHC injector (1.2 ms, 2 Hz). In case a high intensity beam programme would be approved, the option is left open to operate with 400 µs, 50 Hz pulses. These different requirements represent an additional complication to the design. The specification parameters are listed in Table 1.

Table 1: Main Design Specification for the Linac4 RFQ, with rms Values of Emittance in the Two Planes

| Linac4 RFQ Parameter | Min | Max | Units |
|---|---|---|---|
| Beam energy | 3.0 | 3.0 | MeV |
| Operating frequency | 352.2 | | MHz |
| Peak beam current (pulse) | 10 | 80 | mA |
| RF duty cycle | 0.08 | 7.5 | % |
| Transverse emittance (in) | 0.20 | 0.35 | π mm mrad |
| Longitudinal emittance (out) | 0.11 | 0.20 | π deg MeV |

The decision to designing a dedicated RFQ came after the chopper line elements had already been procured and assembly plans made. The output beam parameters of the new RFQ have to be similar to the IPHI ones or at least compatible with the existing chopper line. Other constraints on the design are the requirement to limit the RF power to 0.8 MW peak, corresponding to a single LEP klystron with a sufficient safety margin, and to keep the RFQ length around 3 m. This allows dividing the RFQ into 3 segments of 1 meter while keeping the overall length at 3.5 λ, thus allowing the direct coupling of the three RFQ sections without using coupling cells between sections.

The results of the redesign is a compact RFQ (3 m vs 6 m of IPHI) with an intra-vane voltage of 78 kV and a peak surface field of 34 MV/m (1.84 times the Kilpatrick limit). The main design parameters are shown in Figure 1.

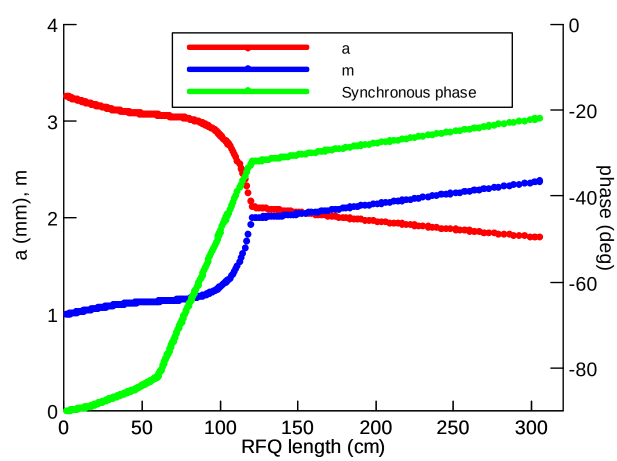

Figure 1: Graph of the synchronous phase, with the RFQ aperture a and modulation parameter m.

The considerable reduction in length was made possible by the lower injection energy, a higher focusing factor and a compromise on the current limit (80 mA vs. 100 mA). The beam quality for the nominal current is equivalent to that of the 6 m long IPHI RFQ. The value for the peak surface field appears acceptable as it is reached over a short section and the RFQ is not meant to work in CW mode.

The minimum value for the aperture a is 0.18 cm and the maximum modulation factor m is 2.38.The main beam parameters, evaluated for 70 mA of beam current, are summarized in Table 2.

Table 2: Summary of the Main Beam Dynamics Parameters for the Linac4 RFQ (rms Values of Emittance)

| RFQ Beam Parameter | Value | Units |
|---|---|---|
| Beam input energy | 0.045 | MeV |
| Beam output energy | 3.0 | MeV |
| Nominal beam current | 70 | mA |
| Average aperture $r_0$ | 0.33 | cm |
| Ratio $\rho/ r_0$ | 0.85 | |
| Focusing parameter | 5.77 | |
| Input emittance (norm) | 0.25 | $\pi$ mm mrad |
| Acceptance at zero current | 1.7 | $\pi$ mm mrad |
| Longitudinal emittance (out) | 0.13 | $\pi$ deg MeV |
| Transmission | 95 | % |
| Transverse emittance growth | 0 | % |

## RF DESIGN

The RFQ cavity design has been driven by the aim of keeping the design as simple as the project requirements could allow.

The 2D section of the RFQ cavity has been kept constant over the full RFQ length, in order to simplify the mechanical fabrication. The intra-vane voltage is also constant at 78 kV and the tuning of the accelerating field profile is left to 12 tuners per quadrant distributed over the accelerator length. Table 3 shows the 2-dimensional electrical parameters for the quadrupole cut-off frequency mode, i.e. without tuner and end-cell contributions.

Table 3: RFQ Electrical Parameters (2D Simulation)

| RFQ Electrical Parameter | Value | Units |
|---|---|---|
| Vane voltage | 78.27 | kV |
| Quality factor (unloaded) | 10269 | - |
| Stored energy | 0.372 | J/m |
| Dissipated power | 78.738 | kW/m |
| Magnetic field (max) | 5444 | A/m |

The design of a short RFQ has helped in minimizing the RF power requirements from the klystron and one klystron should be sufficient to drive the RFQ in all conditions. This also allows the use of a single input RF coupling port: an iris coupled ridged waveguide connecting the WR2300 reduced height RF window to the RFQ cavity.

The impact of the vane modulation on the cut-off frequency of the transmission line modes has been studied by means of 3D simulations, showing a frequency reduction of 0.208 MHz for the quadrupole mode and of 3.871 MHz for the fundamental dipole mode when the modulation is taken into account.

The frequency separation between the accelerating quadrupole mode and the adjacent dipole modes is about 5 MHz, which should guarantee sufficient stability during operation in all conditions. The study for the tuning of the end cells has shown that dipole rods are not required to displace the dipole modes which are closer to the accelerating mode due to the favourable length of this design. The proper tuning of the end-cells should guarantee a voltage error in the RFQ not exceeding ±1 %.

First simulations have shown that eight cooling channels should be sufficient to allow temperature stabilization of the RFQ cavity, because of the limited dissipated power in pulsed mode. The dynamic tuning strategy is based on two cooling circuits, one using four channels drilled inside the vane pole tips and the other using four channels in the RFQ body. The dynamic tuning of the RFQ cavity is obtained by regulating the water temperature difference between the two circuits.

Thirty-two fixed tuners (80 mm diameter) plus the RF and the dummy RF ports will allow achieving a flat electrical field for the quadrupole accelerating mode. The nominal tuner position has been set at 15 mm inside the cavity to allow linear frequency variations as a function of the tuner penetration. The total peak power dissipated in the tuners will be less than 100 kW.

## MECHANICAL DESIGN

The RFQ cavity is made of three sections, each one-meter long, directly coupled. Each of the three sections results from the assembly of two major vanes and two minor vanes. A CAD picture of the RFQ is shown in Figure 2.

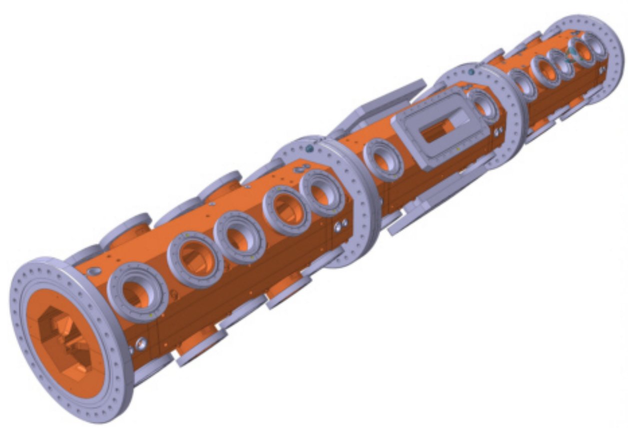

Figure 2: Linac4 RFQ.

The structure is equipped with a total of thirty-two circular apertures, 82 mm diameter, to host the fixed tuners; four rectangular apertures have been designed in the central section for the RF input(s). The first and last section holds eight circular apertures that have been designed to host the vacuum pumping ports. The design of the vacuum system takes into account that the main gas load is coming from the LEBT gas injection used for neutralization and is estimated at 1.1 $10^{-3}$ mbar l/s, whereas the gas load from outgassing is only 1.5 $10^{-5}$ mbar l/s. By using eight diode ion pumps and four turbo molecular pumps the effective pumping speed of 2700 l/s is obtained, which allows to keep the dynamic vacuum level of the RFQ in the range of $10^{-7}$ mbar.

The vane modulation is achieved by a milling machine using a wheel shaped cutting tool. The assembly of the RFQ cavity will be performed by means of a two-step brazing procedure that has been developed at CERN during the fabrication of the IPHI and TRASCO RFQs [4].

The first assembly step of the four poles is made by brazing in the horizontal position, at 825 °C, which allows a uniform diffusion of the brazing material, by capillary action. The second assembly step, performed in a vertical oven at 790 °C, brings the stainless steel flanges and end-flanges onto the RFQ cavity.

The OFE copper used for fabrication has been submitted to a severe 3D forging, in order to obtain the maximum of homogeneity in the raw material. A detailed procedure, alternating machining phases to thermal annealing cycles has been established in order to stabilize the material and avoid deformations and possible displacements of the vanes, especially on the occasion of the first brazing step.

The machining and assembly tolerances have been defined following an error study simulation campaign, which showed that the beam dynamics design adopted is relatively insensitive to errors. The most important contributions come from section tilts and electromagnetic field errors. The set of errors considered is summarized in Table 4, while Table 5 shows how such errors affect the beam dynamics.

Table 4: RFQ Mechanical and Field Tolerances

| **Linac4 RFQ Tolerances** | **Value** | **Units** |
|---|---|---|
| Machining error | ± 20 | μm |
| Vane modulation error | ± 20 | μm |
| Vane tilt over 1 m | ± 100 | μm |
| Vane positioning error (displacement h+V) | ± 30 | μm |
| Vane thickness error | ± 10 | μm |
| Contiguous section gap | 100 ± 15 | μm |
| Section tilt over 1 m | ± 30 | μm |
| Klystron error | ± 1 | % |

Table 5: Beam Degradation Due to Mechanical and Field Errors

| | Losses % | EmitX % | EmitY % | EmitZ % |
|---|---|---|---|---|
| Average | 1.674 | 2.034 | 2.146 | 3.497 |
| Min | -0.940 | -1.839 | -1.573 | -3.442 |
| Max | 5.098 | 6.813 | 6.508 | 17.107 |
| StDev | 0.940 | 1.337 | 1.239 | 3.093 |

## ORGANISATION, STATUS AND PLANNING OF THE PROJECT

The RFQ project has been organized in two work packages: the first is responsible for establishing the general design (beam dynamics, RF design, thermal loads) and performing the RF measurements, tuning and final commissioning, while the second is in charge of the mechanical design and of the fabrication (raw material procurement, machining, assembly). The first work package relies on the contribution from CEA for the RF design, the thermo-mechanical calculations, the RF measurements and the final tuning.

The general design is now complete and execution drawings are being prepared. The 3D forged copper has been purchased and delivered; first machining tests have started at the CERN workshop. The start of the machining of the first section is expected before the end of 2008.

The Linac4 RFQ is expected to become available earlier than needed for Linac4 installation. It will be installed in a dedicated 3 MeV Test Stand to test the beam dynamics of the Linac4 low energy end [5]. Since all emittance increase and beam degradation occurs before 3 MeV, three aspects of beam dynamics must be carefully studied: the space charge control at low energy, the beam chopping and re-matching to the DTL and the beam matching to the RFQ in the presence of neutralization. Studies cannot be performed any more once the front end has taken its place in the Linac4 tunnel. The 3 MeV Test Stand is already in an advanced stage of preparation, the klystron and the prototype modulator that will be used for feeding RFQ have already been tested. The ion source is presently being assembled and the LEBT and chopper lines are in the installation phase. The RFQ schedule is shown in Figure 3.

The Linac4 RFQ will accelerate beam at the Test Stand during 2010 and the first half of 2011. In order to achieve this goal, the RFQ construction has to be completed in the first months of 2010.

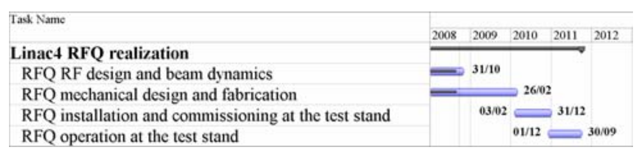

Figure 3: Linac4 RFQ project schedule.

*Abstract*

Fermilab is designing and building the HINS front-end test facility. The HINS proton linear accelerator consists of a normal-conducting and a superconducting section. The normal-conducting (warm) section is composed of an ion source, a 2.5 MeV radio frequency quadrupole (RFQ), a medium energy beam transport, and 16 normal-conducting crossbar H-type cavities that accelerate the beam to 10 MeV. Production of 325MHz 4-vane RFQ is recently completed. This paper presents the design concepts for this RFQ, the mechanical design and tuning results. Issues that arose during manufacturing of the RFQ will be discussed and specific corrective modifications will be explained. The preliminary results of initial testing of RFQ at the test facility will be presented and comparisons with the former simulations will also be discussed.

## INTRODUCTION

Within the framework of the High Intensity Neutrino Source (HINS) program at FNAL, we plan to build and operate a portion of the Front End (up to energies of 90 MeV) as a technical feasibility proof of the proposal. A detailed description of the project and the current status is given in [1]. In the Front End test stand a four vane 325 MHz Radio Frequency Quadrupole (RFQ) will be used for bunching the beam and accelerating it from 50 keV to 2.5 MeV.

The technical specifications for the RFQ were developed by ANL/FNAL collaboration and are presented in Table 1.

Table 1. Initial Specifications for the RFQ Design

| | |
|---|---|
| Input energy | 50 keV |
| Output energy | 2.5 MeV |
| Frequency, MHz | 325 |
| Accelerating beam current, mA | 40 |
| Peak surface field, kV/cm | <330 |
| Acceleration efficiency,% | >95 |
| Pulsed power losses in copper, kW | <450 |
| Duty factor, % | 1 |
| Total length of vanes | 302.428 cm |
| Average bore radius | 3.4 mm |
| Input rms transverse emittance, normalized π mm mrad | 0.25 |
| Transverse emittance growth factor | <1.1 |
| Longitudinal rms emittance, π keV deg | <150 |
| Separation between operating and nearest dipole modes | >4 MHz |

*This work was supported by the U.S. Department of Energy under contract number DE-AC02-76CH03000.
#gromanov@fnal.gov.

In this collaborative effort ANL was responsible for complete beam dynamic design resulting in a vane tip modulation table for machining. RF design with computational support from FNAL, mechanical design and manufacturing, preliminary tuning were delivered by AccSys Technology, Inc. Serious issues arose during manufacturing of the RFQ that prevented proper preliminary tuning. Intensive study has been undertaken to address the problem and specific corrective modifications have been done. Final RF measurements and testing of recently arrived RFQ have been performed by FNAL. The preliminary results of initial testing of RFQ at the test facility are presented.

## DESIGN FEATURES

Similar to many other linear accelerators, the HINS proton accelerator requires an RFQ for initial acceleration and formation of the bunched beam structure. The HINS RFQ will operate at 325 MHz. The initially projected acceleration of ~40 mA pulsed current is considered a relatively moderate problem in the physics design of the RFQ. The design of the RFQ, MEBT and whole proton accelerator lattice has been iterated several times to satisfy more advanced RFQ beam specifications. Particularly, the longitudinal phase space beam emittance must be halo free to avoid excessive beam loss in the high energy section of the accelerator. As a part of this approach, axial-symmetric beam was requested at the RFQ output.

For RFQs longer than ~3l rf wavelengths, it is difficult to stabilize the operating field and damp field errors. To address this problem, modern RFQ designs include p-mode stabilizing loops (PISLs) [2]. PISLs complicate the resonator design and increase its cost; therefore we proposed to minimize the length of the RFQ resonator to allow using the end-wall dipole mode tuners for field

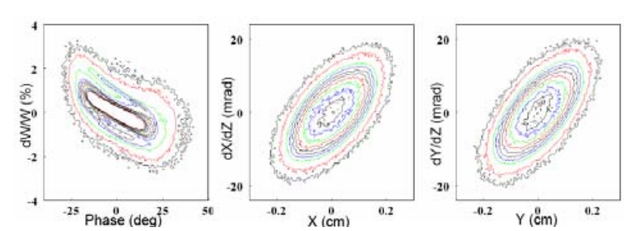

Figure 1: Phase space plots of accelerated beam. The outmost isoline contains 100%, the next one contains 99%.

stabilization that were successfully applied to several RFQs.

For the beam dynamics design, the RFQ is divided into three main sections: an input radial matcher, a main modulated vane section where bunching and acceleration occur, and an output radial matcher. The emittance and profile of the beam exiting the RFQ obtained from TRACK simulation of $10^6$ particles are shown in Fig. 1

The complete beam dynamics design, resulting in a vane tip modulation table for machining, is described in [3].

## RFQ MECHANICAL DESIGN

The RFQ resonator was fabricated using AccSys patented Univane technology [4]. The four identical univanes were each fabricated from solid copper billets (Fig. 2). The univanes are bolted together (Fig. 3) and can be disassembled and re-assembled to facilitate repairs, surface cleaning etc, if necessary. This mechanical design feature turned out to be very useful.

Figure 2: CMM measurements of the univane at SLAC.

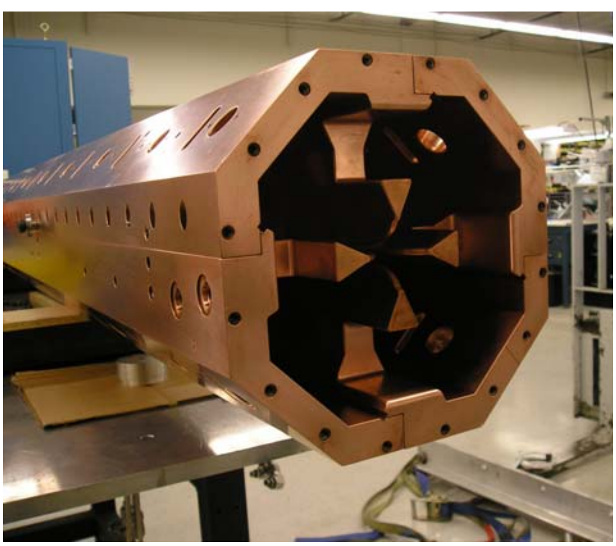

Figure 3: Assembled RFQ resonator. Output end.

Twelve cooling water passages were gun-drilled through the full length of the structure. The cooling passages near vane tips are isolated from passages in outer part of the body to allow RFQ resonant frequency control by adjusting the differential water temperature between the two circuits. The RFQ resonant frequency may also be adjusted using a moveable slug tuner located at the midpoint of the cavity.

Two 3 1/8 inch RF drive loops are used to keep the RF losses in the loops low and also to allow the coupling to be easily adjusted. To operationally monitor and control field distribution in the RFQ, 12 pick-up electrodes (3 per quadrant) are provided. Tuning of the structure at assembly is achieved by means of 64 fixed slug type tuners (16 per quadrant at evenly distributed locations).

Since RFQ resonator cavity does not serve as a vacuum chamber, it is placed in a stainless steel vacuum chamber with vacuum feedthroughs for the RF drive loops, the water cooling and RF pick-up loops (see Fig. 4). Two ports are located on the bottom for mounting vacuum pumps to maintain an operating pressure in the chamber less than $1x10^{-8}$ Torr.

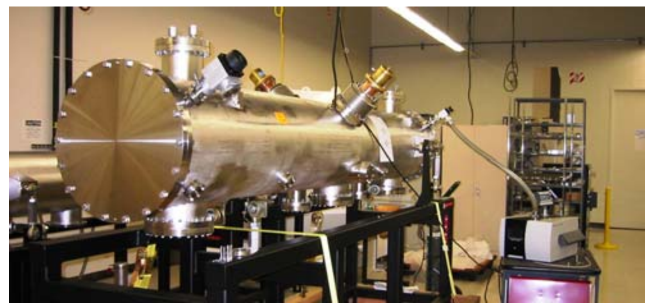

Figure 4: RFQ in the vacuum chamber.

## DESIGN CORRECTIONS AND TUNING

During the initial tuning of the RFQ it turned out impossible to correct (flatten) the resonator's quadrupole field without exceeding the nominal operating frequency by 2-3 MHz. The quadrupole field measurements showed an extreme tilt of field distribution along the resonator, approx. 80%. This was beyond the range of normal correction (i.e. end tuners and slugs) and indicated a fundamental geometry error in the RFQ.

Extensive numerical simulations of the RF properties of the RFQ were performed at FNAL with the use of MWS and HFSS to understand the problem and find a solution [5, 6, and 7]. It was determined that the main problem was the result of a mis-tuned output matcher. The output radial matcher is designed to form axially symmetric beam exiting the RFQ, and because of this special function it is different than the input radial matcher. An error in the final dimensions of the matcher was not realized before univane machining and the resultant matcher local frequency went too high. Simulations indicated that fixing the problem without affecting fields in the matching area meant disassembly and re-machining of the univanes (see Fig. 5).

Also during simulations it became understood that there is an additional distortion of the quadrupole field distribution due to the local frequency variation along the RFQ associated with very specific vane tip modulation. This frequency variation was a potentially serious problem as well, but could be avoided by proper assembly and tuning. This meant reducing the bore radius by 50-70 microns using shims of appropriate thickness (see Fig. 6).

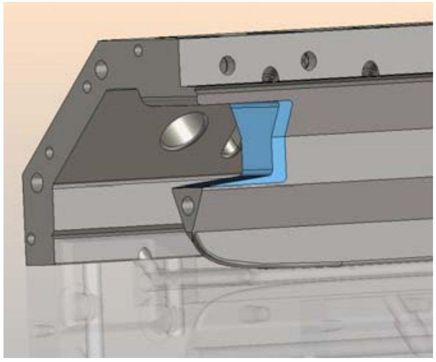

Figure 5: The blue volume has been removed during the univanes re-machining to tune output matcher.

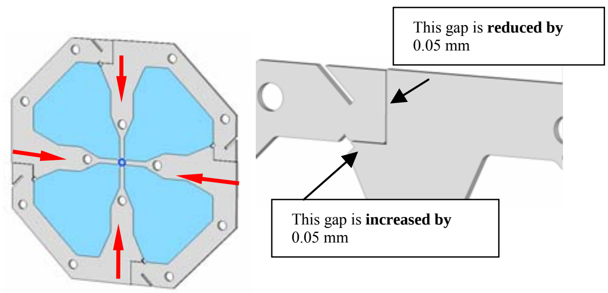

Figure 6: The shims of appropriate thickness reduced bore radius by 50 microns.

After all recommended corrections were done, the tuning went smoothly and RFQ met all design requirements. Fig. 7 shows the evolution of the field distribution. Overall final flatness of field distribution is in ±2% interval.

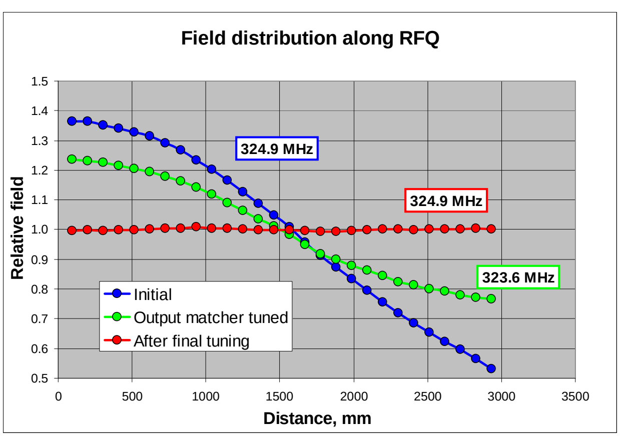

Figure 7: Measurements of field distribution along RFQ resonator at different stages of tuning (average over four quadrants).

Frequency spectra measured at room temperature of 22°C and air filled cavity are given in MHz in Table 2.

Table 2

| Mode | Q | D1 | D2 |
|---|---|---|---|
| 0 | 324.942 | 313.249 | 312.731 |
| 1 | 328.693 | 319.226 | 319.594 |
| 2 | 339.837 | 330.378 | 330.608 |
| 3 | 357.102 | 348.062 | 347.797 |

Nearest dipole modes are located symmetrically in respect to operating frequency with separation more than 5 MHz. Measured unloaded quality factor was Q=9650 compare to the simulated figure of 10750.

## TESTING

The RFQ was delivered to Fermilab this month. Receiving inspections, alignment measurements, and final cold tests are now under way prior to high power RF conditioning expected to commence in October 2008.

The HINS 325 MHz RF power system is operational and ready for the RFQ. A proton ion source and low energy beam transport line is installed and waiting. Following RF conditioning, the source and RFQ will be coupled. The first 2.5 MeV beam is expected by December this year.

## CONCLUSIONS

The HINS RFQ has been fabricated and has passed all mechanical and low power RF tests. The excellent agreement between comprehensive numerical simulations and the RFQ structure's behavior in response to re-machining and during final assembly and tuning offers confidence that the RFQ will perform as designed with beam.

# COMPLETE RF DESIGN OF THE HINS RFQ WITH CST MWS AND HFSS*

G. Romanov[#], A.Lunin, Fermilab, Batavia, IL 60510, USA.

*Abstract*

Similar to many other linear accelerators, the High Intensity Neutron Source requires an RFQ for initial acceleration and formation of the bunched beam structure. The RFQ design includes two main tasks: a) the beam dynamics design resulting in a vane tip modulation table for machining and b) the resonator electromagnetic design resulting in the final dimensions of the resonator. The focus of this paper is on the second task. We report complete and detailed RF modeling on the HINS RFQ resonator using simulating codes CST Microwave Studio (MWS) and Ansoft High Frequency Structure Simulator (HFSS). All details of the resonator such as input and output radial matchers, the end cut-backs etc have been precisely determined. Finally in the first time a full size RFQ model with modulated vane tips and all tuners installed has been built, and a complete simulation of RFQ tuning has been performed. Comparison of the simulation results with experimental measurements demonstrated excellent agreement.

## INTRODUCTION

Within the framework of the High Intensity Neutrino Source (HINS) program at FNAL, we plan to build and operate a portion of the Front End (up to energy of 62 MeV) as a technical feasibility proof of the proposal. A detailed description of the project and the current status is given in [1]. In the Front End test stand a four vane 325 MHz Radio Frequency Quadrupole (RFQ) will be used for bunching the beam and accelerating it from 50 keV to 2.5 MeV.

The complete beam dynamics design, resulted in a vane tip modulation table for machining, is described in [2]. The mechanical design concepts for this RFQ, tuning results, manufacturing of the RFQ in industry and the preliminary results of initial testing of RFQ at the Front End test stand are discussed in [3].

The electromagnetic design of RFQ resonators is rather complicated and requires essentially three-dimensional modeling. That, and also an additional complication with RF tuning because of some blunder made in the mechanical design of RFQ, urged us to develop a full length 3D RFQ model for simulation. Modern three-dimensional electromagnetic codes are now available and successfully used for RFQ design [4, 5, and 6]. This paper focuses exclusively on the computational technique of electromagnetic design. We report complete and detailed RF modeling on the HINS RFQ resonator using simulating codes CST Microwave Studio (MWS) and Ansoft High Frequency Structure Simulator (HFSS).

## RFQ MODEL FOR ELECTROMAGNETIC SIMULATION

The basic parameters of the RFQ are given in table 1.

Table 1

| | |
|---|---|
| Input energy | 50 keV |
| Output energy | 2.5 MeV |
| Frequency | 325 MHz |
| Total length of vanes | 302.428 cm |
| Average bore radius | 3.4 mm |

The RFQ design has several features that have been taken into account during electromagnetic simulations.

Instead of π-mode stabilizing loops (PISLs) usual for RFQs longer than ~3λ, where λ is the rf wavelength [7], FNAL's RFQ design uses the end-wall tuners - field stabilizers simpler than PISLs [8]. This method requires a precise knowledge of dipole mode spectrum, so simulating full length RFQ with end-wall tuners installed was needed.

Modulation of the vanes in the regular accelerating section of the RFQ is shown in Fig. 1. A variable modulation changes capacitive loading and therefore local frequency along RFQ as also reported elsewhere [4, 9, and 10]. In our RFQ the local frequency variation due to the modulation is significant, so the vane tip modulation has been included in the model.

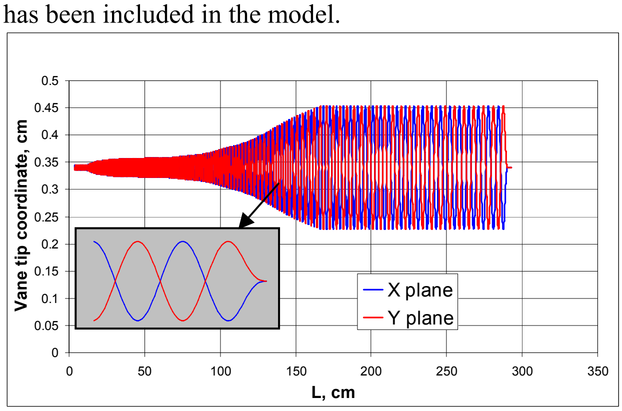

Figure 1: Vane tip modulation along RFQ. Radial matchers are excluded.

The output radial matcher is designed to form axially symmetric beam exiting the RFQ, and because of this special function it is different than the input radial matcher. Fig. 2 shows profile of the output radial matcher and imposed profile of the input matcher to compare with. The RFQ ends (cutbacks) can be tuned in simulations individually, but their combined effect on field flatness must be evaluated. Besides the end-wall tuners have different tuning range and sensitivity for input and output ends of the RFQ. So again, for proper RFQ end design a full length model had to be considered.

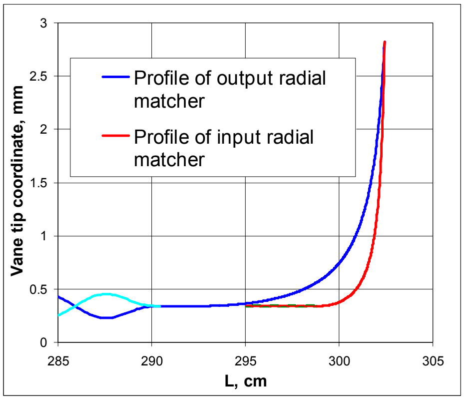

Figure 2: The Radial Matcher Profiles.

The basis of the 3D RF model prepared for simulation was a solid engineering model built in SolidWorks and stored in SAT format. The SAT file was then imported into CST Microwave Studio. CST MWS has its own well developed tools to work with solid models and to heal imported objects, so the RF model was completely prepared directly in MWS environment.

## PERIODS OF RFQ

Many basic RFQ parameters can be obtained and defined with 2D approach. CST MWS and HFSS are entirely 3D codes, but RFQ “slices” with thickness of one mesh step were effectively used to define the basic RFQ parameters. Some RF features like PISLs and slug tuners can be studied with periods of RFQ [6]. The period of RFQ defined by the slug tuner spacing was simulated to evaluate slug tuning sensitivity. Also magnetic field distortion around slug tuners was investigated since the bumps created by the tuners were visible at the bead pull axis which was close to the tuners.

The specific vane tip modulation (see Fig. 1) attracted attention as a possible reason of the local frequency variation. To check whether the vane tip modulation affects local resonant frequency, one accelerating period with modulated vane tips (see Fig. 3) has been simulated. The frequency of the model was found to be 324.7 MHz, while the frequency of the same model with identical average bore radius and no modulation was 323.5 MHz. The difference of 1.2 MHz is significant for such a long RFQ and must be taken into account.

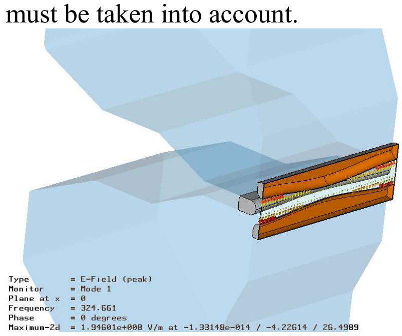

Figure 3: A model of accelerating period #267.

## RFQ END TUNING

Field flatness is always one of the most important tasks for RFQ tuning. This parameter is very sensitive (especially in long RFQs) to proper vane terminations. The RFQ ends are supposed to be tuned by appropriate geometry and dimensions of undercuts and the errors are usually hard to fix.

In the RF 3D model the end-wall tuners were set to a default value of 25.4 mm of penetration as it was during the initial RF measurements. The tuning slugs were flush with the inner wall of the RFQ cavity, so the slugs were not included in RF model for the vane end tuning. Each RFQ end can be tuned separately, so applying appropriate boundary conditions we used 1/8 of the full model, which is equivalent to full length RFQ with two input or two output ends. Actually the model can be of any length for this tuning, but we prefer to use field flatness as a tuning criterion which is more sensitive for longer cavity. If a local frequency is used as a tuning criterion, a reasonably short model should be used for higher sensitivity.

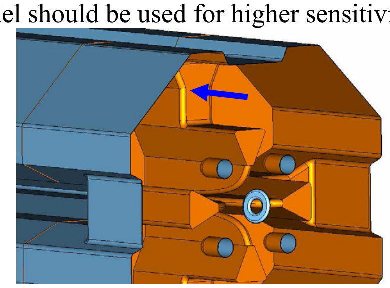

Figure 4: A model of RFQ output end. The back wall (marked by arrow) is moved for tuning.

After main dimensions of cut-backs have been found, the back wall as the most influential parameter was being moved inward (i.e. “removing” of material) for fine tuning (Fig. 4). We monitored the electric field distribution of quadrupole mode along RFQ at 4 mm and 45° off the axis (in the gap between tips). The field distribution changes with cut-back variation as it is shown in Fig. 5, and it gets flat at optimal cut-back of 65.6 mm.

## COMPLETE SIMULATION

Initially the full length model was used to obtain realistic spectrum of quadrupole and dipole modes with end-wall tuners installed, since the exact mode spacing is a key for field stabilization in the RFQ. Then it was realized that the vane tip modulation cannot be ignored, and this feature has been added to the full length model.

The attempts to perform the simulation of the full model with MWS were not successful. It was decided to transfer the problem into HFSS. Using powerful MWS modeler the vane tip modulation was prepared in faceted representation of shape that is more appropriate for triangulated surface meshing in HFSS (see Fig. 6).

The model parameters were set in accordance with actual initial RFQ settings during RF measurement just after final assembly [11]. Fig. 7 shows the field distributions as simulated with and without vane modulation in comparison to the previous actual

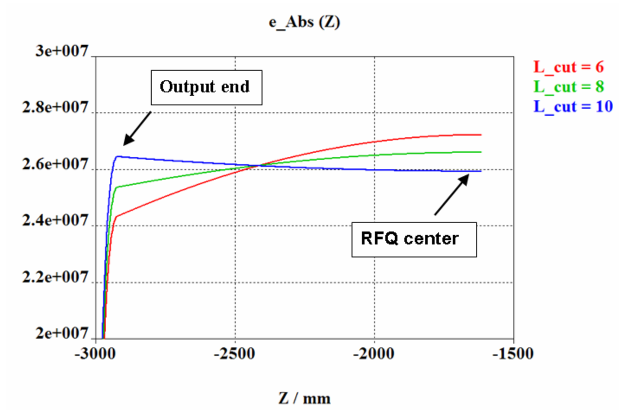

Figure 5: Field distribution with varying cut-back depths.

measurements. With the vane tip modulation included in the model, the simulation reproduces the measurements with high accuracy, including both total field distribution tilt and sinus-like shape. Therefore, the theory that the vane tip modulation is responsible for the additional field distribution distortion is supported. Without modulation, the field tilt in the simulation is due only to the detuned output matcher.

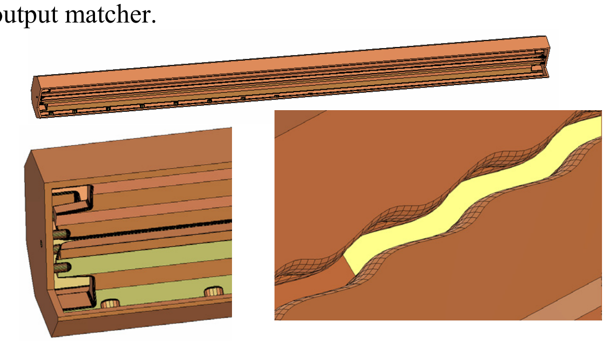

Figure 6: Full length RFQ model with vane tip modulation, radial end matchers, end-wall tuners and slug tuners.

To check final RFQ tuning in simulation, the output matcher cut-back dimensions in the solid model were set to the specified values and slug tuners were introduced. Skipping intermediate simulations of the tuning process with slug tuners, the result is summarized in Fig. 9.

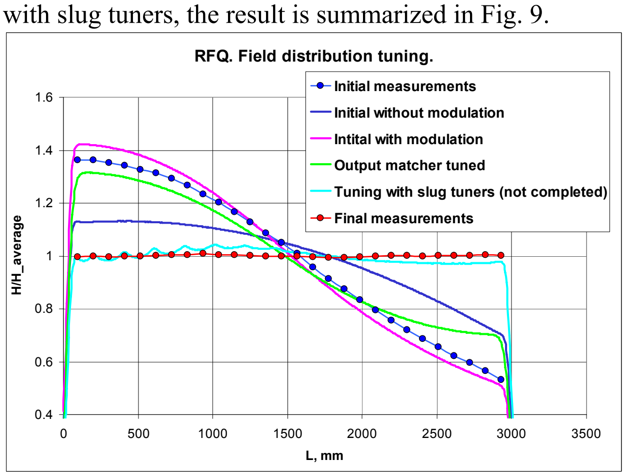

Figure 7: Evolution of field distribution. Lines – simulations, points – measurements. Due to the axial symmetry H-field distributions for only one quadrant are shown.

The slug tuners can only increase the local and overall frequency. After field flattening in the simulation, the RFQ frequency was well above required value of 325 MHz. To decrease the initial frequency of the resonator a reduction of the average bore radius by 50-70 µm was recommended after test simulations.

The results of simulations and the recommendations were taken into account during the final vane machining, RFQ assembly and tuning [4].

## CONCLUSIONS

In the first time a full size RFQ model with modulated vane tips and all tuners installed has been built, and a complete simulation of RFQ tuning has been performed. Results of this complete simulation are in excellent agreement with the measurements made on the RFQ during initial assembly and tuning. All recommendation and predictions were proven correct by the final tuning results.

This work is an important step toward entirely computational RF modeling on RFQ structures.

# SIMULATION OF MULTIPACTING IN HINS ACCELERATING STRUCTURES WITH CST PARTICLE STUDIO*

G. Romanov #, Fermilab, Batavia, IL 60510

*Abstract*

Recently high power tests of the room temperature cross-bar H-type resonators (CH resonators) and high gradient tests of a superconducting single spoke resonator (SSR) have been performed under the High Intensity Neutrino Source (HINS) project at Fermilab. The resonators have shown a tendency of having multipacting at various levels of input power and therefore longer processing time. To provide insights for the problem, detailed numerical simulations of multipacting for these resonators have become necessary. New generation of accelerating structures like superconducting spoke resonators and room temperature CH resonators need a full 3D treatment. Simulations and study of multipacting in the resonators have been carried out using CST Particle Studio. The problematic regions and power levels have been identified for both types of resonators. This presentation will give the result of simulations and comparison with experimental data.

## INTRODUCTION

Within the framework of the High Intensity Neutrino Source (HINS) program, we plan to build and operate a portion of the Front End (up to energy of 62 MeV) as a technical feasibility proof of the proposal. A detailed description of the project and the current status is given in [1]. The Front End of HINS, operating at 325 MHz, uses a mixture of warm copper structures and superconducting spoke resonators. After a standard RFQ [2], room-temperature crossbar H-type resonators are used to accelerate the beam from 2.5 to 10 MeV [3]. The use of short normal conducting resonators up to ~10 MeV reduces the number of different types of SC cavities and provides adiabatic beam matching. Three types of superconducting spoke resonators are used to accelerate protons from 10 MeV to 400 MeV [4].

Recently high power tests of the room temperature cross-bar H-type resonators (CH resonators) and high gradient tests of a superconducting single spoke resonator (SSR) have been performed [5,6]. The resonators have shown a tendency of having multipacting at various levels of input power and therefore longer processing time. To provide insights for the problem, detailed numerical simulations of multipacting for these resonators have become necessary. Simulations and study of multipacting in the resonators have been carried out using CST Particle Studio. Since CST PS is probably the first commercial code that can simulate realistic electron multiplication, the result of study is useful also as the code benchmarking.

## MODEL PREPARATION

A general approach for mulipacting simulation was developed a while ago and it can be mapped to the three steps. These steps are performed in every case, with variations in execution, strategies for detailed implementation and numerical methods. The first step is the definition of the geometry and the calculation of the RF and static fields in this geometry. In a second step, a motion of large number of particles is tracked in the structure. And in a third and final step a multipacting behavior in the collection of particle tracking data is identified [7]. In CST PS, all three steps are smoothly integrated in one code.

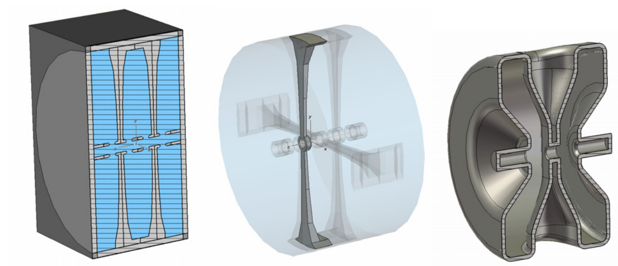

Figure 1: RT CH model consisting of background PEC, cavity components and vacuum filling is on the left. In the center a separate half of spoke is shown. Model of single spoke superconducting cavity SSR is on the right.

RF design for all HINS cavities was done with CST MicroWave Studio. The standard “vacuum” solid models from MWS can not be used “as is” in PS and additional manipulations are needed. First of all, the models before importing into PS from MWS had to be converted to more realistic models with metal walls (or developed from scratch). This is because the secondary emission properties in PS can be assigned to metal surface only, and PS does not recognize Perfect Electric Conductor background as a metal surface. Besides creating a model with metallic walls it is recommended to fill it with vacuum and make background of PEC as shown in Fig.1. This eliminates parasitic mode simulation outside a cavity. Usually several locations are suspicious as MP ones, so it is useful to build a cavity model consisting of separate parts and provide them with independent initial particle sources. It helps to evaluate MP on different surfaces independently.

The prepared models were imported first into MWS for field calculations (it is preferable because MWS has more

*This work was supported by the U.S. Department of Energy under contract number DE-AC02-76CH03000.

#gromanov@fnal.gov.

advanced eigenmode solvers than PS), and then into PS for particle tracking.

In this study the Furman probabilistic model of secondary emission for copper was used with default PS parameters. Usually 50 generations of secondary electrons were tracked and maximum of secondaries per hit was 1.5-2.5. The particle sources provided the simulations with primary electrons uniformly distributed over source area and uniformly distributed over the energy range of 0-4 eV. Number of primary electrons per source was from 200 to 5000. Unfortunately there is no possibility to distribute primary electrons in time, so all initial electrons were launched simultaneously at the same phase of RF field.

## MULTIPACTING IN CH RESONATORS

The goal of MP simulations is to find a location of multipacting activity in a cavity and determine the RF power levels or zones where MP conditions are fulfilled. After analyzing field pattern and trying particle sources on different surfaces, a location of stable multipacting activity in RT CH was found in area shown in Fig.2.

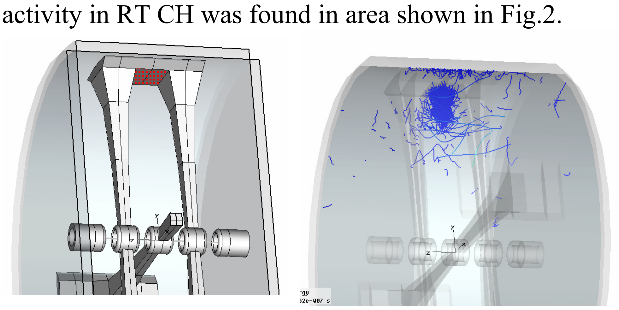

Figure 2: Initial electron source and particle trajectories in CH1 after 40 RF periods (crashed particles are not shown).

PS evaluates particle number in a cavity volume vs time, which is a natural parameter to indicate and verify electron multiplication (see Fig.3).

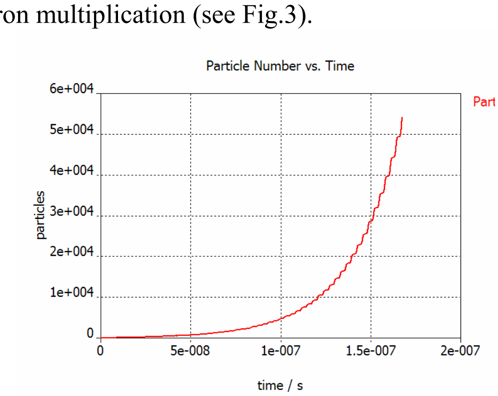

Figure 3: Exponential growth of particle number in a cavity when MP conditions are fulfilled.

PS stores information on emission and collision for every separately defined surface. This data allows to calculate integral secondary emission yield defined as <SEY>=(Total Number of Secondaries)/(Total Number of Hits) and evaluate MP probability, its intensity and zones for each separate surface. Simulations for all RT CH cavities have been performed and shown essentially similar MP behavior. Typical curves <SEY> vs input power are shown in Fig. 4.

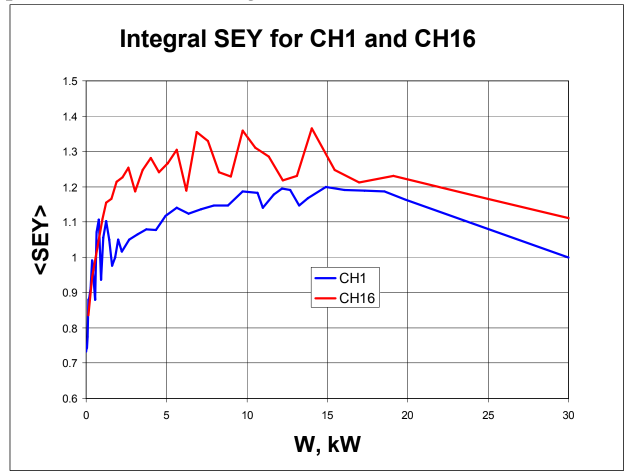

Figure 4: Results of the MP simulations in CH1 and CH16.

Single trajectory simulations show that multipacting is of 5-6 order, and therefore the MP can not be very powerful. It can exist only due to the specific field “trap” for electrons plus flat surface between spokes. In practice it takes time to process a CH resonator first time through 2-10 kW barrier, but eventually MP disappears [5].

## MULTIPACTING IN SSR1

Multipacting seems to be a common problem for low beta SC spoke cavities. Once a particular case of multipacting was simulated in a single spoke cavity [8], but existence of several levels of MP and its broad band character were not explained.

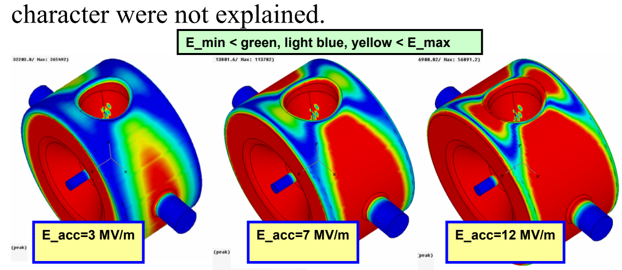

Figure 5: Electric surface field distribution at different accelerating gradients.

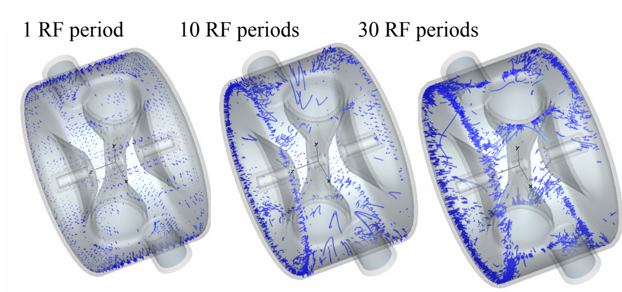

Figure 6: Development of multipacting in time at accelerating gradient of 7 MV/m.

To understand locations of multipacting in SSR1 the upper and lower limits of RF electric field, where MP can exist, were defined in accordance with [9]. Corresponding areas, where electrons can gain right incident energy, are shown at different accelerating gradients in Fig.5. These areas are just approximate locations of potential MP because only surface field is considered. But since MP is a near surface process it is an accurate approximation.

In Fig.6 development of multipacting in the cavity is shown. Uniformly distributed initial electrons were launched from cylindrical surface of the cavity. After 30 RF periods the MP concentration reproduced the surface field pattern. So, the surface field distribution predicts correctly probable locations of multipacting, and one can conclude that MP should migrate from one area to another with accelerating gradient increase.

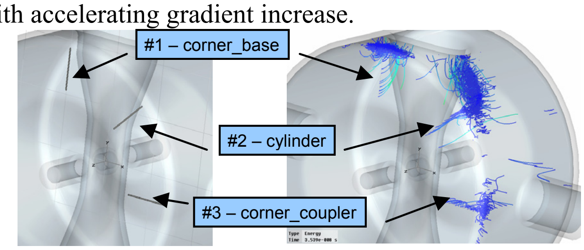

Figure 7: The initial electron sources in different locations.

To evaluate MP in different locations and track the MP migration around the cavity three sources of initial electrons were introduced (Fig.7). Each source allows studying MP in particular area. Simulations were performed for all sources simultaneously and the trick was to stop simulation before MP spreads over the cavity. Then the integral secondary emission yield can be calculated for each source separately.

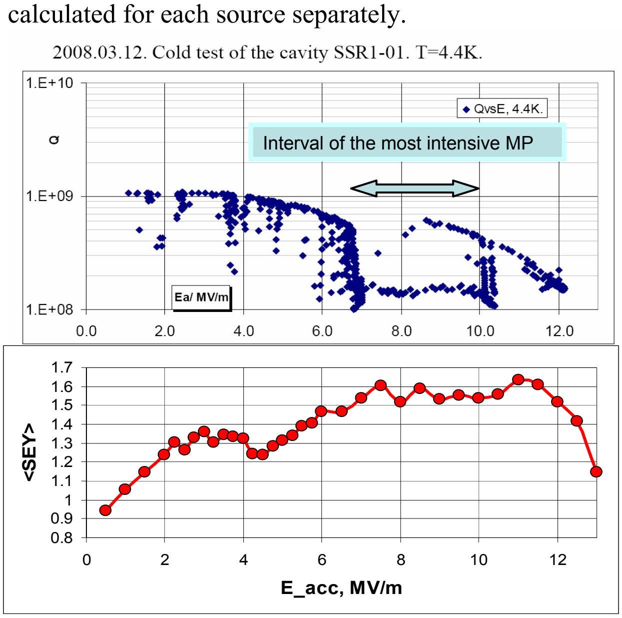

Figure 8: Comparison with experiment.

The simulations confirmed that the most intensive spot of multipacting migrates from location to location with accelerating gradient increase. While moving to the new areas the spot sees “fresh” unconditioned parts of surface and this explains the broad interval of mulipacting. The spatial stability of MP is poor, so rather high re-emision coefficient (>1.7) is required to sustain the process. The intensity of multipacting drops when areas with favorable for MP conditions start shrinking due to high fields (see Fig.5).

Combined <SEY> for all three sources is plotted in Fig.8 along with quality factor Q measurements made during first high gradient test of SSR1 cavity [6]. The drops of Q correspond to the MP levels and zones. The simulations correctly indicate that MP zones.

## CONCLUSIONS

The multipacting in CH resonators and SSRs is a broadband phenomenon. There are not many chances to rid of it by reshaping the problem spots because it is related to the operating field distribution and basic geometry. Fortunately, the MP is not persistent and very powerful in both cases due to the mentioned above reasons, so the effect is no show stopper, but just annoying for operation/start-up.

CST PS proved to be a good tool for MP study. To make it more effective a development of tracking in real time, distributing of primary electrons over RF phases and more advanced evaluation of particle data to identify multipacting, is recommended.

*Abstract*

Direct injection scheme was proposed in 2000 at RIKEN in Japan. The first beam test was done at Tokyo Institute of Technology using a $CO_2$ laser and an 80 MHz 4 vane RFQ in 2001, and further development continued in RIKEN. In 2006, all the experimental equipments were moved to BNL and a new development program was started. We report on our recent activities at BNL including the use of a frozen gas target for the laser source, low charge state ion beam production and a newly developed laser irradiation system.

## INTRODUCTION

A laser ion source (LIS) is a leading candidate of heavy ion sources for providing intense highly charged beams for high-energy accelerators. The laser power can be deposited within a tiny area of the target material's surface and the evaporation process starts. Successively the evaporated gas absorbs the laser power and becomes plasma. Since the large laser power goes into a very limited volume, huge amount of the highly charged ions are produced. An emission from a table top small laser easily produce more than$10^{12}$ W/cm$^2$ on a target surface and the total induced current reaches more than a few hundred A.

We have studied LIS since 2000. We proposed direct plasma injection scheme which enables high current heavy ion beam acceleration. More than 60 mA of carbon [1] and aluminum beam accelerations by an RFQ were demonstrated. We have also examined several laser systems and many targets species [2]. Using the measured plasma data, almost any desired species can be used for the LIS except helium gas.

In 2006, our group moved from RIKEN, Japan to BNL, USA with all the experimental equipments and we started a new development program in BNL. In this report, we briefly introduce our current activities related LIS and DPIS.

## LASER EMISSION CONTROL

The laser emission control is important to gain good ion beam stability. We are currently using a tabletop Nd-YAG laser system, Thales-SAGA 230/10. When we started to use this laser, we were suffered by laser leakages. The laser consists of two laser cavities, a master oscillator and a power amplifier, and a Q-switch is installed at the oscillator to make a short pulse. The Q-switch controls a polarization and adjusts laser-firing timing. The laser media is pumped by flash lamps. A typical emission of the flash lamps is indicated as red curve in Fig. 1. The flash lamp emission lasts more than 200 μs and the Q-switch selects certain timing for releasing the pumped energy to maximize laser emission power.

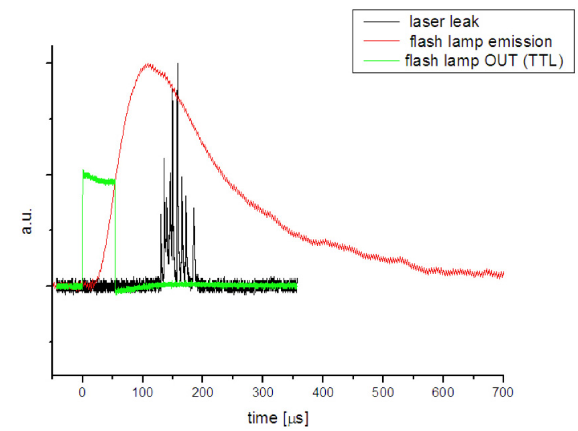

Figure 1: Flash lamp timing and laser leakage.

The laser emission pulse width is typically 6 ~ 9 ns. The flash lamps are always operated at 10 Hz for good stability and the laser emission is only controlled by the Q-switch. While the Q-switch is off position, the laser should not be emitted. However even Q-switch is turned off, very week laser emission exists. This leakage could not be sensed by a power meter. We observed the leakage by directly seeing the light from the plasma using an IR viewer. The leaking laser energy is very small but is enough to make plasmas and can damage the surface of the target since the leaked energy is concentrated onto a pinpoint by a focusing mirror. To avoid the pre-damage of the target due to the laser leakage, we installed a fast mechanical shutter in the laser path to the ion source. The shutter closes or opens within several ms and this speed is adequate to choose any desired laser pulses because the flash lamps are blinking at 10 Hz. So that the laser shots caused only by the Q-switch are transported to the ion source. Un-desired laser leakages from the un-fired blinking of the flash lamps are blocked. The ion beam stability was dramatically improved. However the laser shutter is not enough to eliminate the negative effects completely. Again in Fig. 1, you see the black plot which shows the time structure of the laser leakage when the Q-switch closed. The leakage still exists even in the same fired laser pulse. The Q-witch timing is usually selected to maximize the laser emitting power and typically around 180 μs behind the flash lamp control signal triggered.

*Work supported by U.S. DOE and RIKEN

However as it is shown in the figure, before 180 μs, the leakage starts. The leakage in a single laser pulse is weak and we cannot observe any foot print on the target surface, however this small leakage just before the main pulse of the laser shot has enormous effect to the plasma heating condition. Let us note that this leakage is not considered as "pre-lasing," since this is usually too weak and cannot be detected while you are measuring the main laser pulse. Therefore the Q-switch timing should be selected before the leakage starts or after the leakage ends. Base on our experience, it is suggested to wait for more than several μs past after the leakage ends for the Q-switch timing. The behavior of the laser leakage depends on the type of Q-switch. The careful timing settings are required for the good ion beam stability. The further investigations of the performance of the Q-switch and its timing are presently performed.

## FROZEN TARGET

Although LIS had only used solid target materials, we started to induce plasma from rare gaseous. The idea is quite simple. We used a cryo-cooler head, Sumitomo RDK-408D2, to condense gases and the solidified targets were tested in BNL. Ar and Ne were successfully used to provide intense beams. We also tried hydrogen, but the cooling power or a heat shield was not enough and could not get stable beams. Figure 2 shows the detected charge states from the Ar experiment.

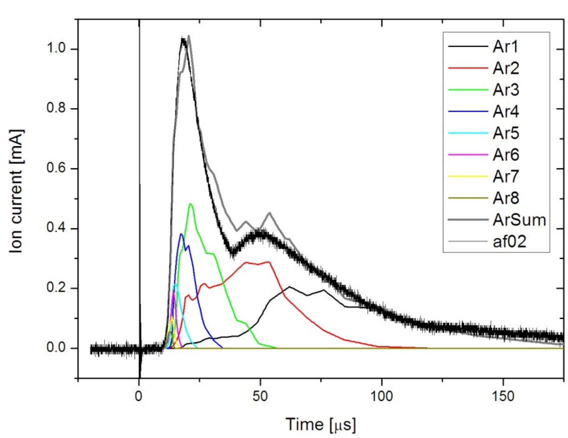

Figure 2: Analyzed Ar plasma. The currents are measured at 2.4 m from the target. The aperture size of the Faraday cup was 10 mm in diameter. The laser was set to 1200 mJ with a second harmonic crystal (532 nm). The applied laser power density on the target was about $5x10^9$ W/cm$^2$.

The cryo head could be cooled down to 4.5 K that temperature was low enough for almost any gases except helium. At the beginning of the experiment, the gases were fed by a thin plastic pipe, less than 1 mm in diameter, to spray directly to the target surface however this structure was not necessary. The gas could be fed into the vacuum chamber without the nozzle and the pressure was controlled not to exceed $10^{-4}$ Pa. The residual gas was mostly the fed molecules and those were caught by the cold surface automatically. The cold surface was coated by several layers of the molecules and those were enough to provide the desired plasmas. Once laser was shot, the surface became clean and the surrounding area was also flashed by the conducted heat. The accumulated layers always started on the fresh cold surface and were in same condition for every laser shot. The reproducibility was quite good. On the other hand, rapid cycle was not applicable and more than a few seconds were needed as an interval. To increase the repetition rate, a differential pumping system will be required. We plan to accelerate the rare gas atoms by an RFQ in the near future.

## LOW CHARGE STATE BEAMS

By controlling the laser power density on the target, a charge states distribution can be shifted. We are studying low charge ion beam production from the LIS. Generally lower laser power density is better to produce low charge state beam, however there is a threshold value of the density to make a plasma. We tested many materials and most of the material have almost same thresholds which are about $10^8$ W/cm$^2$. Only carbon graphite showed higher threshold.

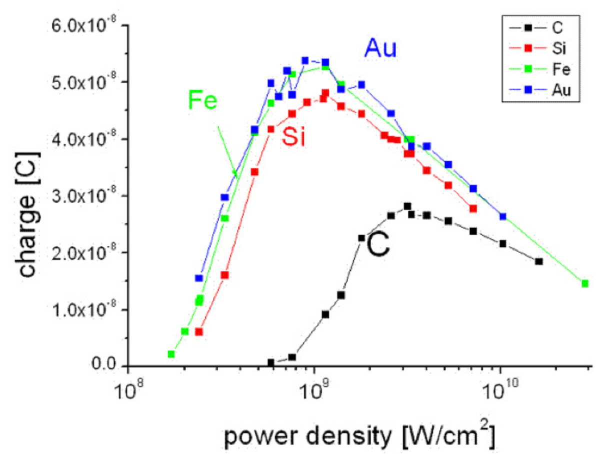

Figure 3: The measured total charges. The laser power density was controlled by changing the position of the focusing lens. The lower density also implies a larger exposure area.

By measuring the velocity distribution of the plasma, the initial plasma temperature was estimated and the obtained temperature was consistent with the first ionization energy of the atoms except the carbon case. We can provide intense low charged ions to the RFQ with the DPIS. This is suitable approach for "heavy ion inertial fusion." Unfortunately we do not have an adequate RFQ to capture the very low charge to mass ratio particles. In the next step we plan to inject the $Au^{1+}$ beam to our existing 100 MHz RFQ to examine just the transverse motion of the beam.

The low charge state beam from the LIS has another superior advantage. We measured the emittance of the extracted beam and the obtained values were dominated by an emittance measurement system [4]. The plasma was produced under the high temperature condition but it is adiabatically expanded before the ion extraction process. This means the extracted beam is cold and it might be useful for other applications.

## IMPROVED DPIS-LIS

The mechanical structure of the ion source is also developing. To accelerate many kinds of species, the plasma drift length is adjustable in our newly designed DPIS chamber. The plasma drift length is the distance between the target surface and the extraction point where is the entrance of the RFQ linac. The dense plasma is diluted while it travels over the drift length and becomes a required density at the extraction point. To obtain good matching condition of the extracted beam to the acceptance of the RFQ, the length needs to be optimized for a desired current, species and charge states. Our recent study indicated that more than 200 mA of carbon 6+ beam can be matched into the acceptance of the existing RFQ. Also the position of the final focusing element can be adjusted. We had used concave mirrors as final focusing element, however a focused image of the laser light on the target were elliptical. To avoid this effect, a convex lens will be used instead of the concave mirror. The focal distance was shortened from 100 mm to 50 mm and the laser power density can be increased. Unlike ion beam optics, there is a diffraction limit for the laser light as the minimum spot size, however we still expect a reasonable improvement. Figure 4 shows the new ion source vacuum chamber which is being constructed in BNL. We also developed a winding system to roll a plastic tape which protect the final focusing lens from the plasma exposure.

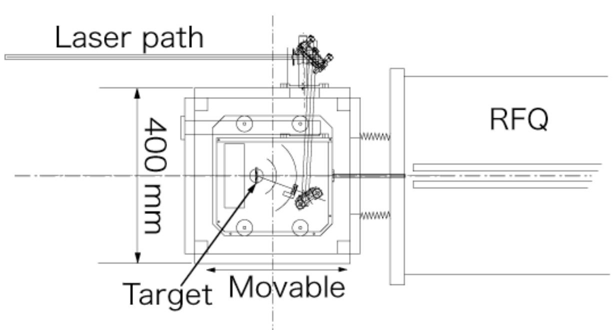

Figure 4: New DPIS set-up.

## RFQ

The existing RFQ was designed and fabricated in 2003 [5]. Due to a limitation of a radiation safety regulation in a facility where the beam commissioning was carried out. The output energy was restricted to 100 keV/u, however the acceleration is achieved within the first 1.42 m of the RFQ. The rest of the RFQ length is 0.5 m and this secsion has un-modulated vanes. In the un-modulated section, only transverse confinement force exists and consequently longitudinal bunch structure is completely lost.

In BNL, this RFQ is already connected to a 300 kW RF power amplifier and the high power test was done. At 220 kW RF power input, X-ray emission was measured as 120 μrem/h at the tank surface near the RF coupler. Now we are waiting for an approval for the beam operation in BNL. Using newly optimized condition, carbon beam will be produced and accelerated in next month.

The RFQ has 4 rod structure and the resonator including vanes can be replaceable. The next version of the resonator was already fabricated. The basic parameters of the existing resonator and the new one are listed in Table 1.

Table 1: Basic Parameters of the DPIS RFQ

| | Type I | Type II |
|---|---|---|
| Design beam | $C^{4+}$ 100 mA | $Ag^{15+}$ 15 mA |
| Frequency | 100 MHz | 100 MHz |
| Duty factor | 0.1 % | 0.1 % |
| Inter vane voltage | 120 kV | 73 kV |
| Injection energy | 20 keV/u | 8.3 keV/u |
| Output energy | 100 keV/u | 270 keV/u |
| Cell number | 118 | 143 |

## SUMMARY AND PLAN

As mentioned above, the intensive plasma extraction studies were done in BNL. The feasibility of the frozen gas target was also proved. Many small but important improvements were adopted in the new ion source chamber. A higher current and higher quality beam is expected using the DPIS in BNL.

## ACKNOWLEDGEMENT

We thank all the collaborators and friends in BNL, RIKEN, JAEA, KEK, TITech, NIRS and IAP-Frankfurt.

# DESIGN STUDY OF A DPIS INJECTOR FOR A HEAVY ION FFAG *

M. Okamura#, D. Raparia, BNL, Upton, NY 11973, U.S.A.
K. Ishibashi, Y. Yonemura, T. Kanesue, Kyushu University, Ito, Fukuoka 819-0395, Japan

*Abstract*

A new heavy ion injector linac is proposed for providing heavy ion beams to a fixed field alternating gradient (FFAG) accelerator in Kyushu University. A combination of the new intense laser source based injector and the FFAG will be able to accelerate high current ion beams with 100 Hz of a repetition rate. The planned average current reaches 7 µA with carbon 6+ beam.

## A NEW INTENSE PULSED ACCELERATOR

To obtain large beam power within a limited space, cyclotrons have been chosen since they provide CW beams even with relatively small peak beam current. In this report, we propose a new approach to utilize comparatively large beam power using a laser ion source and a FFAG synchrotron accelerator.

Generally a synchrotron can have larger peak current than cyclotron has, however most of the time is occupied for ramping up and down the bending magnets in the operation and the beam pulse width is very limited. To increase the total beam power, it is effective to have high repetition rate. The maximum repetition rate is about 1 to 25 Hz for normal conducting synchrotrons [1]. Recently FFAG accelerators are being focused as high repetition synchrotrons and some FFAGs have already been built by KEK and Kyoto University groups both lead by Y. Mori [2]. It has been proved to operate it at 100 Hz in KEK and possibly it will run at 1 KHz. Also FFAG has large transverse acceptance and is expected to deliver large current.

A laser ion source (LIS) has an advantage to induce a powerful pulsed beam and can operate at high repetition rate which is restricted by a driver laser system. A typical flash lamp pumped solid laser can reach 100 Hz and a LED pumped laser easily achieves above 1 kHz operation with good stability. Hence both a laser source and a FFAG are operational at same high frequency range. Since a LIS can provide large current, beam losses in a transport line which connects from the ion source to a first stage accelerator, typically RFQ, was always tough issue. To overcome this difficulty caused by space charge effect, direct plasma injection scheme (DPIS) has been studied. Using the DPIS, several tens of mA heavy ion beams have been accelerated effortlessly in an RFQ [3]. A rapid cycle LIS with DPIS and a high current heavy ion RFQ suit a FFAG well to boost the beam power.

In Kyushu University, a new facility called "Center for accelerator and beam applied science" is established [4]. A new building was already constructed to accommodate a FFAG accelerator which was originally designed and constructed in KEK as a prototype 150 MeV FFAG. The installation of the FFAG to the new building is in progress. A small proton cyclotron will be used as an injector in the first stage and in the next stage we plan to install a new injector system to provide heavy ions for various application including medical, engineering studies and educational activities. A photo of the FFAG and its design parameters are shown in Fig. 1 and Table 1.

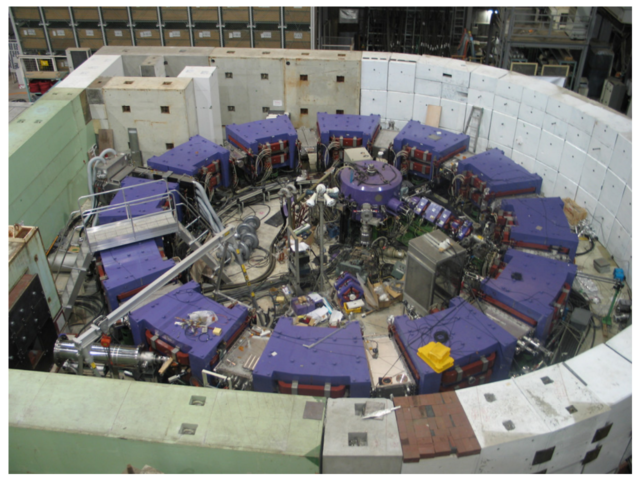

Figure 1: 150 MeV FFAG in KEK.

Table 1: Design Parameters of 150 MeV FFAG

| | |
|---|---|
| Energy | 10 – 125 MeV (proton)<br>2.5 – 31 MeV/u ($C^{6+}$) |
| Type of magnet | Triplet radial (DFD) |
| Number of cell | 12 |
| Average radius | 4.47 – 5.20 m |
| Magnetic field | Focus: 1.63 T<br>Defocus: 0.78 T |
| Revolution Frequency | 1.5 – 4.2 MHz (proton)<br>0.78 – 2.3 MHz ($C^{6+}$) |
| Repetition rate | 100 Hz (2 RF cavities) |

The proposed heavy ion injector will accelerate fully stripped ion beams up to 2.5 MeV/u with the highest available current which will be induced by a conventional table top laser system with the DPIS.

## LASER ION SOURCE

### *Beam Pulse Width*

The harmonic number of the FFAG ring is one and revolution period at the injection energy is 1.28 µs. With single turn injection scenario, the required beam pulse

*Work supported by U. S. DOE
#okamura@bnl.gov

width is about 1.2 - 1.3 μs with adiabatic beam capturing which can build up the distributed beam over the 360 degree of the injection RF cycle. Using the DPIS, we can provide sufficient number of particles with the short period. In this case, we can assume the acceleration RF phase of the FFAG at the beam injection. If the Separatrix occupies 150 degree of phase acceptance, the required beam pulse width is 0.53 μs. The LIS was designed to produce slightly longer than 0.53 μs of the pulse duration.

### *Laser System*

We assumed a flush lamp driven Nd-YAG laser as a driver since it is commercially available and has good stability (typically a few %). To provide fully stripped ions from light to medium species efficiently, more than 1 J per shot of the laser energy is recommended. To obtain 100 Hz operation, it may need to have multiple oscillators. Table 2 shows the planned laser parameters for the injector.

Table 2: Laser Parameters for FFAG LIS

| | |
|---|---|
| Media | Nd - YAG |
| Wave length | 1064 nm |
| Oscillator | 2 stages (multiple) |
| Pulse width | 5 - 7 ns (Q switched) |
| Energy | 1.5 J |
| Repetition rate | 100 Hz |

### *Induced Ions from the DPIS Geometry*

A LIS consists of a laser, a target material and extraction electrodes. Particularly in the DPIS, RFQ vanes are used as negative electrodes of the extraction system. The positive electrode, plasma target and the space between them are all biased to high voltage which corresponds to the injection energy of the RFQ. Firstly a plasma induced by a laser shot on the target. The plasma is started to expand and is ionized during laser irradiation, typically in several ns. After ionization, the plasma keeps expanding like a cloud and the gravity center of the cloud moves perpendicular to the target surface. All these processes appear in the enclosed space by a high voltage cage. At the beam extraction point, the ion beam begins when the head of the plasma cloud reaches and ends when the tail passes. The moving velocity of the plasma and its distribution are determined by a laser power density on the target. However we have the minimum laser power density since fully stripped ions, like $C^{6+}$ is required. The laser power density should be more than $10^{12}$ W/cm$^2$. To optimize the beam pulse width, the drift length is adjusted around 0.5 m. The expected peak current of the $C^{6+}$ beam reaches about 300 mA assuming the positive extraction hole of 8 mm in diameter.

### *Expected Beam Characteristics*

Assuming the irradiation condition, we measured charge states distributions from a carbon graphite target in BNL. Thales – SAGA 230/10 laser system was used and the laser energy was set to 1.5 J. A convex mirror were placed 100 mm from the target surface. The incident angle to the target was 15 degree off from the perpendicular line. Figure 2 shows the expected charge distribution and the currents converted from the measured data. The pulse length of $C^{6+}$ beam was 0.63 μs (above 10% of the peak value). The experimental setup was same as described in ref. [5].

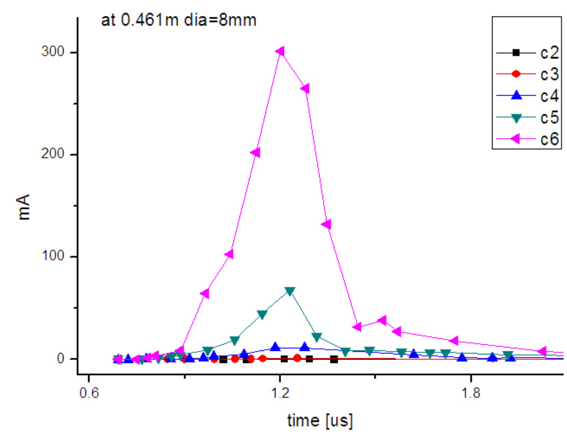

Figure 2: Re-constructed currents based on the measurements.

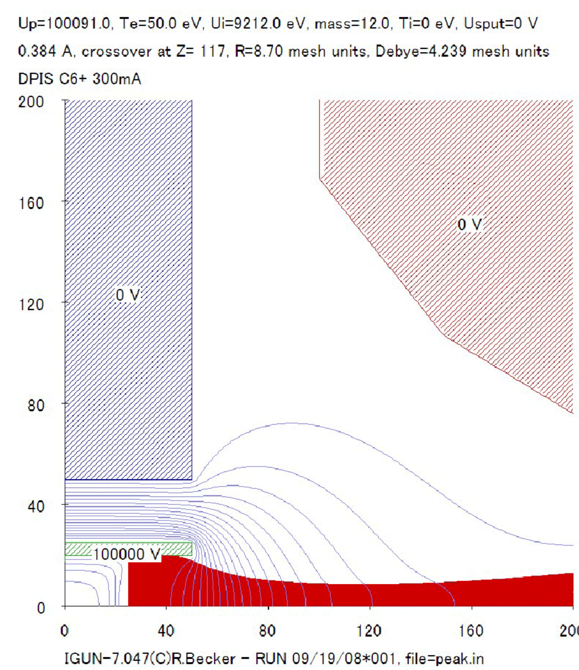

Figure 3: Beam extraction simulation by IGUN.

The beam extraction condition of $C^{6+}$ beam with small fractions of other charge states was simulated by using IGUN [6]. The applied bias voltage is 100 kV to obtain a matched condition of the extraction. Table 3 shows the Twiss parameters of the predicted beams at the peak current. The study of other species production is in progress.

Table 3: The Simulated Extracted Beams

| | Current (mA) | ε rms (mm mrad) | α | β (mm/rad) | γ (rad/mm) |
|---|---|---|---|---|---|
| $C^{4+}$ | 11.9 | 35.7 | 1.16 | 63.7 | 0.0369 |
| $C^{5+}$ | 62.1 | 35.5 | 1.16 | 63.7 | 0.0368 |
| $C^{6+}$ | 300 | 35.5 | 1.16 | 63.7 | 0.0368 |

## RFQ

The RFQ was designed to be fit into the inside of the FFAG ring. By adopting the DPIS, the ion source part can be made very compact. The plasma drift length is about 0.5 m and the entire source part needs around 0.7 m in length. The injection energy was given by the plasma extraction condition as 100 kV (50 keV/u). The kilpatrik limit factor (14.7 MV/m at 200 MHz) was set to 2.3 supposing a vane tip curvature equals to the average bore radius. Since the required beam pulse length is short and the probability of RF break down will be small even adopting a high bravery factor. Also by controlling the multpole components in the field, a smaller vane tip curvature can be applied and the electric field strength can be reduced. The operation RF frequency was chosen as 200 MHz due to an availability of an existing RF amplifier. The design parameters of the RFQ are summarized in Table 4.

Table 4: DPIS RFQ for FFAG

| | |
|---|---|
| Energy | 0.05 – 2.5 MeV/u |
| Cell number | 215 |
| Vane length | 4.28 m |
| Frequency | 200 MHz |
| Inter-vane voltage | 140 kV |
| Average bore radius | 5.0 mm |
| $m_{max.}$ | 2.25 |
| $a_{min.}$ | 2.9 mm |

The power consumption was estimated as 580 kW by scaling from an existing 4-rod DPIS RFQ. The beam pulse is much shorter than the RF build up time, so that the duty factor of the RFQ is determined by a Q value of the cavity. Assuming 5000 of the Q value, the duty factor is about 2.5 %. Since the beam pulse is only 0.5 µs, the effect of the beam loading will be negligible. The tracking simulations in the RFQ were done by using PARMTEQ [7] and Pteq-HI [8]. In the Pteq-HI calculation, three charge state ions, $C^{4+}$, $C^{5+}$ and $C^{6+}$, were tracked simultaneously. The peak currents shown in Table 3 as the input beam condition resulted 205 mA of the accelerated $C^{6+}$ current. The beam spread in the longitudinal phase space is shown in Fig. 4.

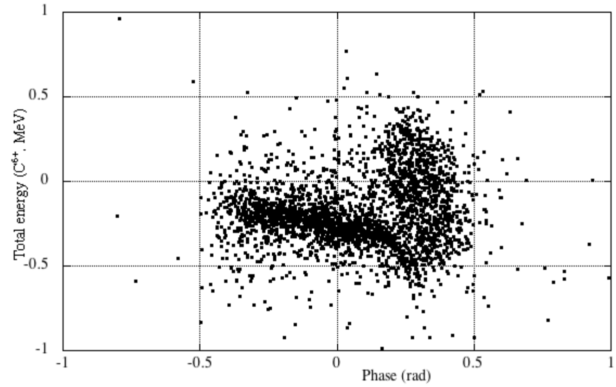

Figure 4: Simulated $C^{6+}$ output beam in longitudinal phase space.

The simulation based on the above discussion predicted that the RFQ provides average current of 8 µA to the FFAG.

## CONCLUSION

A new injector using DPIS was designed to accelerate $C^{6+}$ beam with a 200 MHz RFQ. The laser ion source will provide 300 mA $C^{6+}$ beam and the RFQ will provide 186 mA at peak. If we assume 10 % and 5 % beam losses at the beam injection and extraction of the FFAG The average output current will be 7 µA. The total beam power will be 400 W. Let us note that we adopted 100 Hz as the repetition rate of the entire accelerator system in the discussion, however it can be increased up to 1 KHz by modifying the RF system of the FFAG and the laser system.

# COMMISSIONING OF THE NEW GSI-CHARGE STATE SEPARATOR SYSTEM FOR HIGH CURRENT HEAVY ION BEAMS

W. Barth, L. Dahl, L. Groening, P. Gerhard, S. Mickat, M. Kaiser
Gesellschaft für Schwerionenforschung, D-64291 Darmstadt, Germany

*Abstract*

A dedicated charge separator system has been installed in the transfer line to the GSI synchrotron SIS18, replacing charge separation with a single 11 degree dipole magnet after a 25 m beam transport section. This was not adequate to meet the requirements during high current operation for FAIR: it only allows for charge state separation of low intensity and low emittance beams. With the new compact charge separator system emittance blow up and undesired beam losses for high intensity beam operation will be avoided. Additionally, a new beam diagnostics test bench is integrated to measure beam parameters (ion current, beam profile, beam position, transversal emittance, bunch structure and beam energy) for the injection into the SIS 18 in parallel to the routine operation in the transfer line. Results of commissioning with high intensity argon beams as well as with an uranium beam will be reported. We acknowledge the support of the EU-Research Infrastructure Activity under the FP6 "Construction of infrastructure for the FAIR-project" (co.-number 515876).

## INTRODUCTION

In the transfer line (TK) to the GSI synchrotron SIS 18 the beam is stripped to higher charge states in a carbon foil, if high final energies from the SIS 18 are required. The TK is operated at 3 Hz pulse to pulse mode at maximum, with beams of different ion species and intensities, with or without stripping. A high current $U^{28+}$-beam of 15 emA (FAIR requirement) has a power of 1.5 MW (≤300μs pulse length). After stripping, undesired charge states with 85 % of the beam power must be separated and dumped. A newly developed stripper foil (with enlarged width) is loaded with 3 % of the beam power. To avoid evaporation in a single beam pulse, the beam is rapidly swept over its width of 55 mm. The UNILAC delivers beam emittances in the range of 5 to 20 μm, depending on the beam current. Emittance growth in the TK is caused by small angle scattering in the stripper foil, and by space charge forces, mainly in the section between the stripper and the charge separator (see Fig. 1). To minimize emittance growth, a narrow, vertically elongated beam spot (4 mm · 20 mm) is prepared, and the distance to the separator is kept as short as possible. [1]

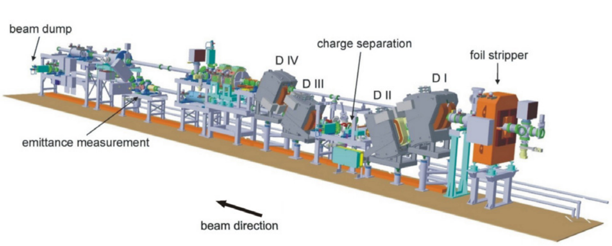

Figure 1: New charge state separator system integrated in the TK comprising the foil stripper, the four 35°-Dipole magnets (DI - DIV), and a beam diagnostics bench.

## THE NEW CHARGE STATE SEPARATOR SETUP

The vertical magnetic bending system of the new charge state separator system consists of four 1.6 T-dipole magnets providing high resolution and a field homogeneity ≥ 99.97 %. Each of the four 35° H-type dipole magnets (D I - D IV) has a bending radius of 1.1 m. The first two dipoles have the same vertical and horizontal aperture, as well as D III and D IV. Rogowski profiles at the beam entrance and the beam exit assure independence of the magnetic flux density (up to 1.6 T) from the effective magnetic length. The gyration number of each coil is chosen to make use of three equal power supplies (650 A/380 V); the last two dipole magnets (with reduced gap height) are operated in a serial mode. All coils are equipped with correction coils to compensate remaining fields. [2] With a beam diagnostic bench behind D III high current beam measurements are accomplished to prepare for the injection of high intensity heavy ion beams into the synchrotron. Besides ion current the beam profile and position, the emittance, the beam energy and the bunch structure can be measured. Additionally, beam focusing using a quadrupole duplet and the correction of beam positions is provided in the 12 m diagnostic line. [3]

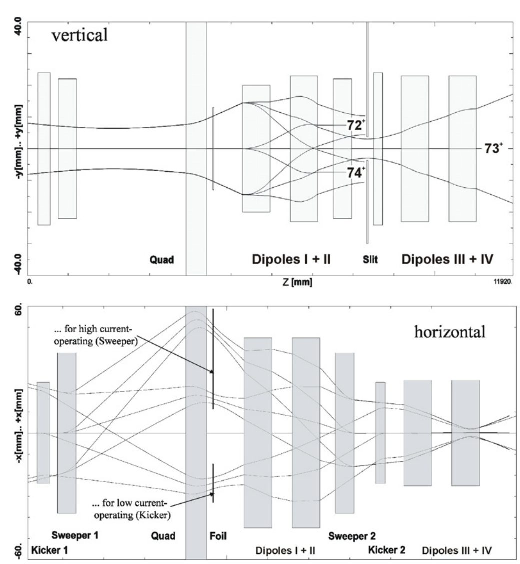

Figure 2: Beam dynamics layout of the new charge state separator system.

## BEAM DYNAMICS LAYOUT

Beam envelopes [3] are shown in Fig. 2. Well focused beams, passing the stripper in horizontal off-axis positions, are bend back by a quadrupole magnet into the horizontally 90 mm wide gaps of the first two dipoles of the analysing system. The beams are realigned to the ion optical axis in a sweeper or a kicker magnet, respectively. In the vertical plane, the rather wide, divergent beam striking the stripper is charge states separated by the first magnet. Simultaneously, it is focused by the magnets upstream pole face rotation angle of -20° onto the analysing slit. Ions from neighbouring charge states hit the jaws of the slit and even the magnet chambers. These components were designed for a high thermal surface load and low radiation activation. The charge resolution q/Δq is about 100. The slot width is 10 mm; the dispersion in this point is 7.5 mm/%. The dispersion of the complete system is zero.

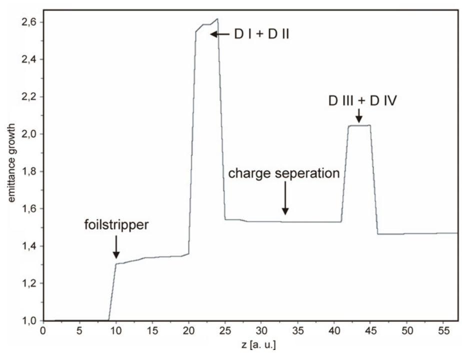

Figure 3: Vertical emittance growth in the charge separator.

PARMILA Transport simulations were performed to investigate the influence of space charge effects on the beam dynamics layout. As shown in Fig. 3 the vertical rms emittance increases by 50 %. Besides small angle scattering in the stripper foil, the emittance growth in vertical as well as in horizontal plane is caused by coulomb interactions.

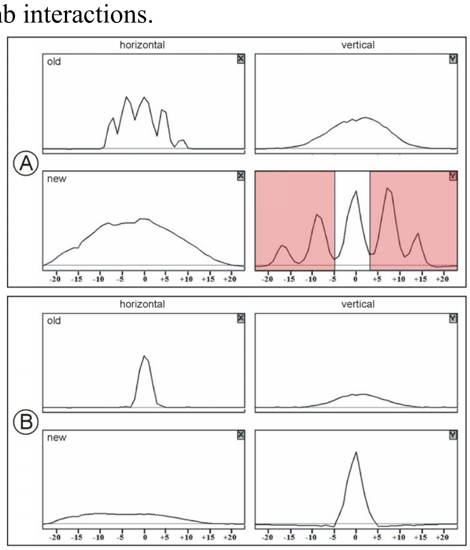

Figure 4: Measured uranium beam profiles with opened (A) and closed (B) separation slits.

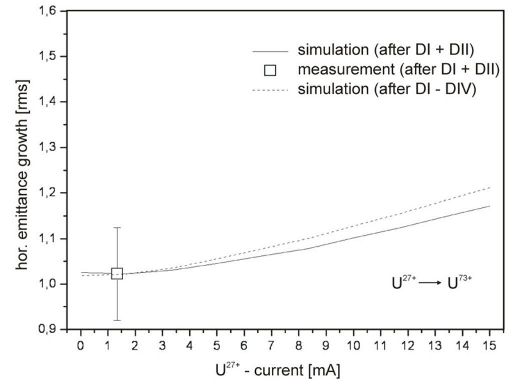

Figure 5: PARMILA Transport beam simulations for different uranium beam intensities; emittance growth measured for low and medium intensities.

## COMMISSIONING RESULTS

After mounting the magnetic charge state separator and the beam diagnostics bench in the TK (December 2007), commissioning of all subsystems and components was performed until January 2008, followed by a three weeks period of beam commissioning with a high intensity $^{40}Ar^{11+}$ beam (7 emA) and a $^{238}U^{27+}$ beam with a beam intensity of up to 2 emA. The uranium beam was used to investigate the separation capabilities of the system. Fig. 4 shows the measured uranium beam profile inside the charge separator and at the position of former charge separation. For the new charge separator an improved charge resolution (factor of 2) is clearly visible, especially when the separation slits are closed.

The simulated horizontal rms emittance growth is presented in Fig. 5. Behind D II as well as behind the whole charge separator system the maximum growth factor is less than 20 % (for 15 emA). Emittance growth for low intensities is confirmed by measurements with a 1.5 emA $U^{27+}$-beam. High and low current argon beam emittance measurements were performed along the whole transfer line. As an example Fig. 6 shows measured transverse beam emittances behind D II. For the high current case the emittance is significantly increased in both transverse planes (65 % horizontally, 30 % vertically). When the beam is passing D III and D IV the dispersion becomes zero – the measured transverse emittance decreases significantly.

The space charge induced emittance growth is reduced to less than 10 % horizontally and less than 20 % vertically. The total horizontal normalized rms emittance was measured with 0.22 mm*mrad, meeting the FAIR-requirements. The beam transmission in the charge state separator system and the adjacent beam transport lines to the emittance measurement devices is close to 100 %.

Table 1: Measured $^{40}AR^{18+}$-beam Emittances (90 %)

| ($4 \cdot \varepsilon_{rms}$ [µm]) | high current | | low current | |
|---|---|---|---|---|
| | hor. | vert. | hor. | vert. |
| behind D II | 9,0 | 17,6 | 6,9 | 7,1 |
| SIS injection | 5,5 | 8,1 | 5,9 | 5,6 |

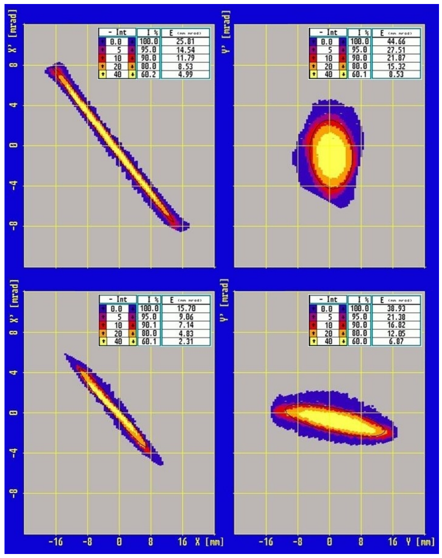

Figure 6: High (top) and low (bottom) current argon beam emittance behind D II.

Emittance measurements for low and high intensity argon beams were also performed for different stripper foil thicknesses. The equilibrium charge state distribution is reached for 400 μg/cm². For this reason space charge induced emittance growth for high current argon beams hitting thicker targets is much higher as for the 200 μg/cm² stripper foil. The 600 μg/cm² foil is sufficient for the operation with heavy ions; e.g. $U^{73+}$ is stripped with high efficiency (15 %). For the argon beam additional emittance growth is measured, while the stripping efficiency stays constant. As simulated with the PARMILA Transport code the horizontal emittance growth is below 50 % for low and high current, while the vertical emittance increases by 70 %. In both transverse planes the space charge dominated beam transport from the stripper foil downstream to the first dipole magnet (D I), where charge separation reduces the space charge forces, increases the emittance area significantly.

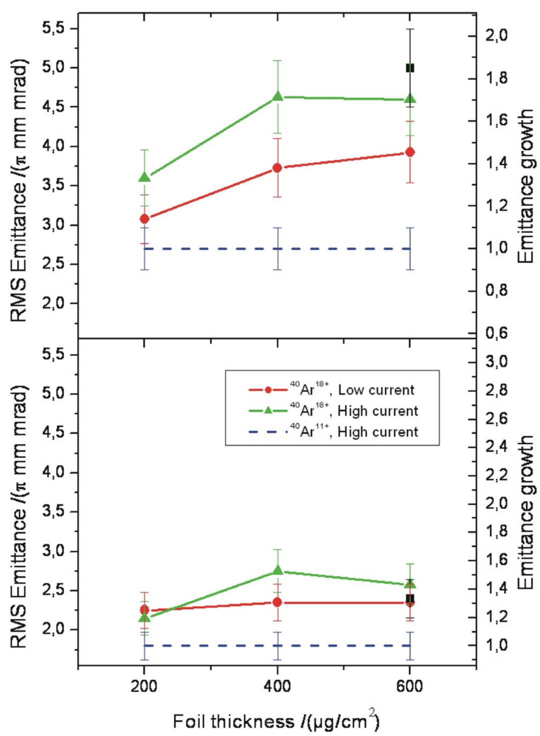

Figure 7: High and low intensity argon emittance measure-ments for different stripper foil thicknesses in horizontal (bottom) and vertical (top) plane; additionally measure-ments with $U^{73+}$ (600 μg/cm²) are shown in black.

## SUMMARY

The new charge separator system was installed in the transfer line to the GSI SIS 18 in December 2007. After commissioning of all components, beam commissioning was performed successfully with a medium intensity uranium beam and a high intensity argon beam. The measured beam transmission is close to 100 % for low and high current operation. For the high current heavy ion beam operation newly developed stripper foils of extended size are in use. The sweeper operation was tested with a high intensity argon beam as well as with an uranium beam. In general emittance growth is not induced by the sweeper devices. The stripping efficiency measured with the charge separator as a spectrometer is as expected. The improved charge separation capability was confirmed for heavy ions as well as for high current operation. Simulated and measured emittance growth effects for low current operation are caused by small angle straggling. Additionally, the vertical emittance inside the charge state separator is increased by disper-sion. Space charge forces act in the short drift length between stripper foil and charge separation in D I only – the space charge influenced emittance growth is 10 % (hor.) resp. 20 % (vert.). The measured high current emittance potentially meets the requirement defined by the FAIR project [4]. We acknowledge the support of GSI expert divisions involved in the charge separator project.

# QUADRUPOLE MAGNET DEVELOPMENT FOR 132 MEV DTL OF CSNS

Yi Cheng, Xuejun Yin, Zhirui Sun, Keyun Gong, Shinian Fu
[1]IHEP, Institute of High Energy Physics, Chinese Academy of Sciences, Beijing 100049, China

*Abstract*

In the China Spallation Neutron Source (CSNS) linac, a conventional 324 MHz drift-tube linac (DTL) accelerating an H- ion beam from 3 MeV to 132 MeV has been designed with 1.05% duty, consisting of 7 tanks with a total length of approximately 59.6 m. Currently, R&D work has focused on the first module of Tank 1, which will have 29 drift-tubes (DT) each housing an electro-magnet quadrupole (EMQ). Some EMQs with SAKAE coil have been fabricated and are under rigorous magnetic measurements by means of Hall probe (HP), single stretched wire (SSW), rotating coil (RC) in order to verify the design specifications and fabrication technology. Magnetic measurements on the EMQs with iron cores made from the electrical-discharge machining (EDM) and the stacking method will be compared and discussed. Work has been implemented to reduce the alignment discrepancies between the geometric center of the DT and magnetic center of EMQ to within +/- 50 µm.

## INTRODUCTION

Currently, a prototype cavity of the 1st module of Tank 1, of the 132MeV drift tube linac (DTL) for the proton linear accelerator for the CSNS has been constructed. A frequency of 324 MHz and a duty factor of 1.05% have been chosen for the RF structures. The design of the DTL was presented in reference [1]. Alongside with the construction of the DTL RF cavity, R&D work has also focused on the drift-tubes (DT) and the electro-magnet quadrupoles (EMQ). Presently, six EMQs with J-PARC type SAKAE coils [2] have been fabricated and are under rigorous magnetic measurements that includes the Hall probe (HP), single stretched wire (SSW) and rotating coil (RC) measurements, to verify the EMQ design specifications and fabrication technology and capabilities in the Institute of High Energy Physics (IHEP), Beijing. The design parameters for the EMQs and DTL Tank-1 are listed in Table 1.

Table 1: Design Parameters for EMQ and DTL Tank-1

| EMQ | | Tank 1 of DTL | |
|---|---|---|---|
| Parameter name | Parameter values | Parameter name | Parameter values |
| Beam aperture[mm] | 15 | Output energy [MeV] | 21.76 |
| Core outer diameter[mm] | 59 | Length [m] | 7.99 |
| Core length[mm] | 35 | Number of DTs | 61 |
| Magnetic field gradient[T/m] | 75 | RF power for each cell[MW] | 1.41 |
| Magnetic field effective length[mm] | 40.96 | Total RF power[MW] | 1.97 |
| Maximum excitation current[A] | 530 | Accelerating field strength[MV/m] | 2.2-3.1 |
| Field integral, *GL*[T] | 3.07 | | |
| Coil resistance [mΩ] | 9.08 | | |

## THE ELECTRO-MAGNET QUADRUPOLES (EMQ)

The six EMQ-magnets constructed consists of 3 EMQs with their iron cores made using the Stamped-Stacking Method (SSM), and 3 EMQs with their iron cores made using the Electrical Discharge Machining (EDM). DQ1#DW is the only EMQ that has its water gasket installed as shown in Figure 1.The results of the magnetic measurements for both EDM-made and SSM-made iron core EMQs will be presented, in order to illustrate their magnetic parameters' similarities and differences.

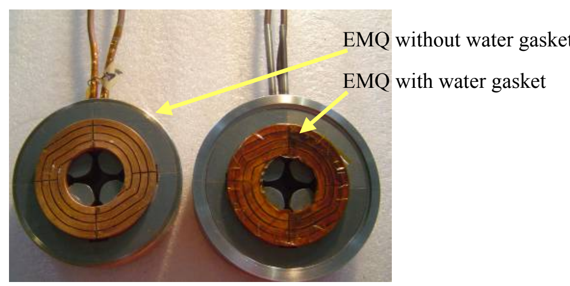

Figure 1: Photos of EMQ.

## MAGNET MEASUREMENTS

### *Hall Measurements*

From the HP measurement, the magnetic field profile along the beam-axis of the EMQ can be obtained at different x and y transverse positions. A typical result from the HP measurement is shown Figure 2.

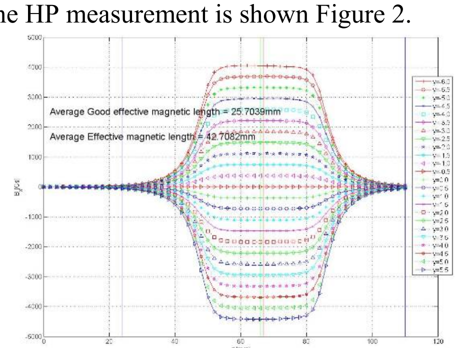

Figure 2: Typical HP measurement result on an EMQ.

The average effective magnetic length, $\overline{L_{eff}}$ , is computed by taking the average of all the effective magnetic length obtained from each profile along the transverse x or y direction. The good effective magnetic length is the region where only field strengths are within 5% from the maximum field strength. The magnetic field profiles obtained from all the EMQs are smooth within the good field region. The averaged effective magnetic length is about 42.64mm. No significant difference in magnetic length was observed between iron cores made from SSM and EDM.

Next, the field gradient distribution of the EMQs was investigated. The gradient value was then evaluated using the expression below:

$$g_{meas} = \frac{A_{i+1} - A_i}{d_{i+1} - d_i} \quad (1)$$

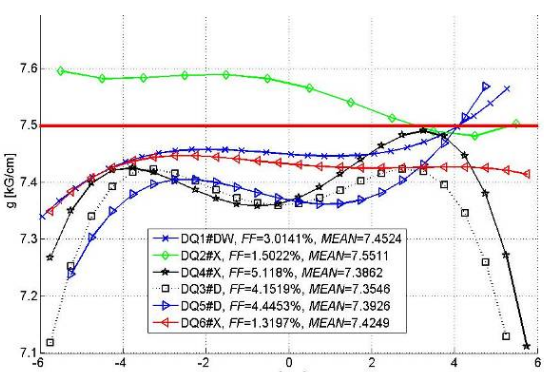
where $A$ and $d$ can be either $Bx$ and $y$ or $By$ and $x$ respectively, and the subscripts i stands for the i-th position along x or y axis respectively for $By$ or $Bx$.

The flatness of the gradient distribution was calculated by implementing the idea of field flatness from [3],

$$FF = \frac{g_{\max} - g_{\min}}{\frac{1}{N}\sum_{i=1}^{N} g_i} \text{ x } 100\% \quad (2)$$

where $FF$ is the flatness percentage; $g_{\max}$ and $g_{\min}$ are the maximum and minimum gradient respectively; denominator of $FF$ is the mean gradient. The required field flatness for the gradient distribution in the transverse direction is $FF \leq 1\%$.

Figure 3 shows some of the results obtained from evaluating all the gradient profile of the magnets. A decision was made to implement upper and lower limits to eliminate data which were considered to be incorrect due to measurement errors. The limits were implemented to be 5% from the mean of each profile. Data points within the limits are taken into consideration to replot the gradient profiles of all magnets and evaluate the flatness of the profiles.



Data Set 1 (Average *FF*: 3.26%)

Figure 3: Example of field gradient distribution along x-axis.

As shown in Figure 3, the field gradient distribution is not entirely constant or smooth along the transverse direction for all EMQs. The *FF* for most of the EMQs are higher than 1%, which is not acceptable.

The reasons for poor field flatness in the transverse field gradient profile are speculative. One can argue that there is high systematic error contribution due to mechanical misalignments and measured data acquisition. There is a need to accumulate the systematic errors of the measuring probe and probe positioning errors in order to verify such suspicions. Furthermore, repeatability of the HP measurement results should be investigated in order to eliminate or understand the systematic errors as suspected.

One other important difference between the EDM-made and SSM-made iron cores is that, the EDM-made laminations are short-circuited at the magnet pole tip. Since the EMQs will be supplied with pulse currents, the EDM-made laminations will not be suitable for this operation mode because eddy-currents will be significant and will affect the performance of the EMQs.

## *SSW Measurement Results*

The SSW measurement results on all the EMQs are presented in this section. The measurements are performed within a range of ±5mm in the x- and y-axis from the magnetic field center.

Table 3: Quadrupole Magnetic Field Center Deviation from Mechanical Center on Each EMQ

| | Magnet names | Δx [mm] | Δy [mm] | $\theta_{role}$ [mrad] |
|---|---|---|---|---|
| SSM-made Iron Core | DQ1#DW | -0.270 | 0.300 | -0.403 |
| | DQ3#D | 0.500 | 0.080 | 0.897 |
| | DQ5#D | 0.610 | 0.260 | 1.233 |
| EDM-made Iron core | DQ2#X | 0.200 | 0.025 | -0.074 |
| | DQ4#X | 0.060 | 0.158 | -0.165 |
| | DQ6#X | 0.255 | -0.205 | -0.537 |

The mechanical center was determined by aligning the wire via motors to the optical alignment instruments. The magnetic center of quadrupole mode was measured by the SSW measurement. From Table 3, it suggests that the deviation between the mechanical center and magnetic field center are significantly large, where the largest deviation is 0.61mm. This indicates that the drift tube housing must have at least 0.65mm of material to machine in order to reduce the deviation within ±50μm. This requirement is achievable.

Currently, it is believed that poor mechanical reference points contributed to the mechanical misalignment of the EMQ, and hence the large deviation between mechanical center and magnetic field center. Mechanical assembly details and measurements have to be reviewed to further verify the above suspicions and to make proper improvements.

To determine the operating current, $I_o$, for each EMQ, the required field integral, $GL = G \text{ x } L_{eff}$, has to be determined for each EMQ using their individually measured $L_{eff}$. With the required $GL$ value, the required $I_o$ can be determined from the excitation curve of the EMQs.

Table 4: Field Integral for Magnets

| | SSM-made Iron Core | | | EDM-made Iron core | | |
|---|---|---|---|---|---|---|
| Magnet names | DQ1#DW | DQ3#D | DQ5#D | DQ2#X | DQ4#X | DQ6#X |
| $L_{eff}$ [mm] | 42.42 | 42.72 | 42.64 | 42.78 | 42.40 | 42.87 |
| Field integral *GL* [T] | 3.18 | 3.20 | 3.20 | 3.21 | 3.18 | 3.21 |

Table 4 tabulates the $L_{eff}$ results obtained from HP measurements, and their corresponding *GL* value that must be achieved to meet the required G, which will be used to determine the magnets' $I_o$ from the excitation curves.

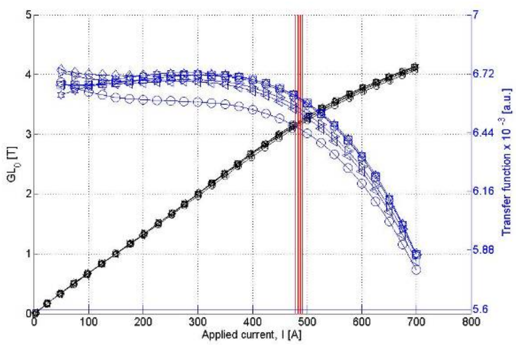


Figure 5: Quadrupole excitation curve.

Figure 5 shows the excitation curves and transfer function coefficient curves for all EMQs, curve-fitted with a polynomial of the 6th degree. It is worth noting that, the curves for EMQs with EDM-made and SSM-made iron cores are similar. Furthermore, the EMQs with EDM-made iron cores seemed to need a lower $I_o$ value to achieve the required *GL*.

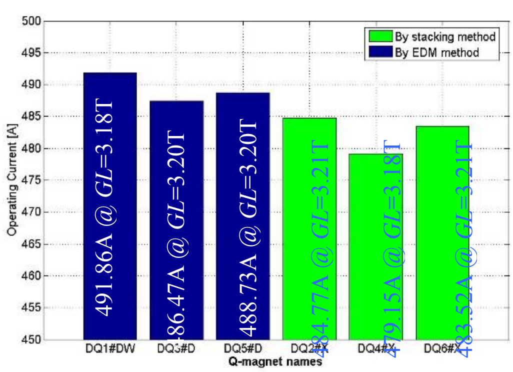

Figure 6: Operating current required for EMQs.

Figure 6 shows a bar chart of the operating current required for the EMQs. It indicates that the EMQs with EDM-made iron cores requires less current to achieve their corresponding *GL* value in order to meet the gradient specification. So, one advantage from using EDM-made iron cores is the reduction of electrical supply cost to operate such an EMQ.

## DEVELOPMENT OF RC MEASUREMENT SYSTEM

The RC system has been developed, as shown in Figure 7, which includes a harmonic coil and a measurement stand. One EMQ is put onto the driving stand which can be adjusted along the x and y in the horizontal plane. The driving axis where the harmonic coil connected with can be moved vertically, so the harmonic coil can be push into the magnet aperture. A stepper motor and an angular encoder are connected with the driving axis in series. As the coil rotates inside the magnet aperture, the integral field, field harmonic contents and the magnetic center are measured at the same time. By carefully adjusting the EMQ position relative to the harmonic coil, the normalized magnitude of the dipole component can be reduced to less than $6 \times 10^{-4}$, and the magnetic center adjusted to within ±3μm. Figure 7 shows a screenshot for the software interface and the measurement results.

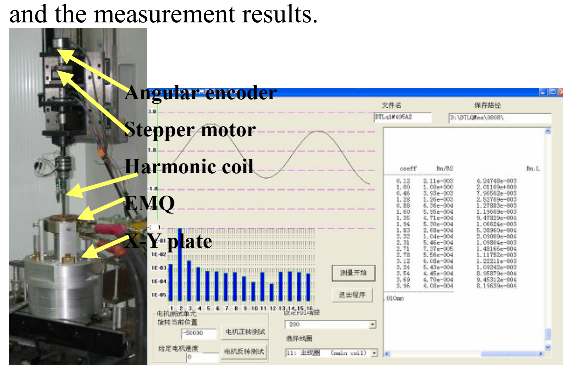

Figure 7: Harmonic measurement system and shot of measurement results.

## CONCLUSIONS

Six EMQs for the eventual DTL test cavity has been manufactured and tested for its assembly reliability in IHEP. Current results suggest that many mechanical fine tuning has to be done. A review in the manufacturing process of the EMQ should be underway. Magnet measurement systems for the sole-purpose to develop these EMQs are within completion. The SSM-made iron core EMQs will be used.

## ACKNOWLEDGEMENTS

We would like to acknowledge C. T. Shi, C. Yuan, L. Li, B. G. Yin, Q. L Peng and Z. Zhang of the Magnet Group for their assistance and help in magnet measurements, and Z. Z. Zhang and his fellow technicians for their continuing effort in producing the EMQs.

# DTL TANK DEVELOPMENT OF 132 MeV LINAC FOR CSNS

Zhirui Sun, Xuejun Yin, Keyun Gong, Jun Peng, Shinian Fu
IHEP, Institute of High Energy Physics, Beijing 100049, China

*Abstract*

A conventional 324 MHz DTL has been designed for China Spallation Neutron Source (CSNS) to accelerate $H^-$ ion beam from 3MeV to 81MeV and up to 132MeV in its second phase. There are 7 tanks in the 132MeV DTL and currently the R&D of the first tank is under progress. In the design, tank-1 has a tilt field distribution partial for obtaining the most effective energy gain and keeping the low Kilpatrick parameter. This tank is under fabrication and the manufacture technique was verified by the measurement results. Concerning of the difficulty of tuning a partial tilt field distribution, the complex RF measuring and tuning procedure is introduced.

## INTRODUCTION

China Spallation Neutron Source (CSNS) mainly consists of an $H^-$ linac and a rapid cycling synchrotron of 1.6GeV[1]. The DTL linac are designed in two phases, with energy of 81MeV for phase I and 132MeV for phase II. R&D program for some key technologies involves a prototype of the first unit of the DTL tank, which is the most difficult section in the whole DTL linac. A 3-meter module covers an energy range from 3MeV to 8.9MeV. The tilt field is designed in this module with an electrical field from 2.2MV/m to 3.1MV/m. The electrical field will keep 3.1MV/m after tilt part through whole DTL tank. Concerning the difficulty in tuning this kind of RF field, a procedure for measuring and tuning the tank is designed. In this paper, we will introduce the progress of module tank fabrication and RF tuning procedure.

## DTL CAVITY DESIGN

The main parameters of the CSNS DTL are listed in Table 1. There are four tanks for phase I and additional three tanks for phase II. The first tank is composed of three short module tanks, and the first module tank is under manufacturing.

Table 1: DTL main parameters

| | CSNS-I | CSNS-II |
|---|---|---|
| Input Energy (MeV) | 3 | 3 |
| Output Energy（MeV） | 81 | 132 |
| Chopping rate （%） | 50 | 50 |
| Average I（μA） | 75 | 150 |
| Pulse Current（mA） | 15 | 30 |
| RF frequency (MHz) | 324 | 324 |
| Repetition frequency(Hz) | 25 | 25 |
| Duty factor（%） | 1.05 | 1.05 |

Mechanical parameters for this unit are listed in Table 2. In the drift tube, the electromagnetic quadrupole (EMQ) is used to supply a gradient 75T/m focusing strength in maximum. The focusing periods are designed as the FD lattice and each drift tube contains one quadrupole.

Table 2: The parameters of first module tank

| | |
|---|---|
| Tank length (m) | 2.85 |
| Energy range (MeV) | 3-8.88 |
| Average $E_0$ (MV/m) | 2.2 ~ 3.1 |
| Synchronous phase (deg) | -30 ~ -25 |
| Tube face angle (deg) | 0 ~ 9 ~ 14 |
| Tank inner diameter(mm) | 566.27 |
| Cells number | 29 |
| No. of Slug tuners | 4 |
| Bore radius (mm) | 6 |
| DT diameter (mm) | 148 |

## TANK MANUFACTURE

The tank body was made of carbon steel with a copper inner surface. To develop the technology, we tried various approaches with some short test tanks. At the beginning, an explosive bonding technology was tested. A thin copper plate was tightly bonded with a steel tank in the inner surface. Since the tank had many ports and holes for vacuum and for holding drift tubes, here the bonding condition was not as good as the inner surface, resulting in vacuum leakage at some ports. Then we turned to adopt the technology of the Periodic Reverse (PR) copper electroforming method. It has been successful for both inner surface and all ports/holes. Figure1 shows the 2.8m tank module after electroforming. The inner copper surface was polished and the ports are now under fine machining for high accuracy and high flatness. There are twelve straight water cooling channel embedded into tank out-wall. Size of the channel is 26mm×13mm. The tank end plate is separated into two parts for water cooling with opposite water flow direction. Water channels on the end plate are shown in Figure 2.

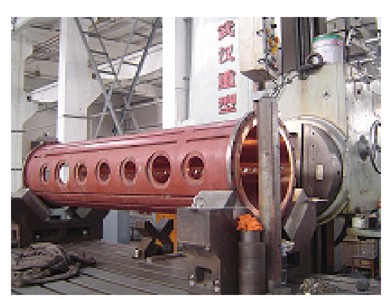

Figure 1: The first module tank is under fine machining after copper electroform.

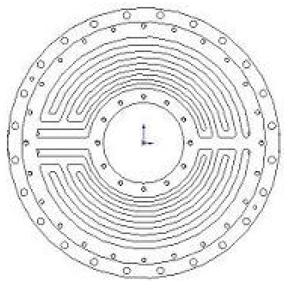

Figure 2: Water channels inside of end plate.

Elements in the first module tank are consist of 28 drift tubes with stems, 14 post couplers, 4 slug tuners, 3 vacuum ports, 1 vacuum detecting port, 4 pickups, 1 viewing window and 29 quadrupoles. There are 29 physical cells in this module tank. The downstream ending plate is made of aluminium as a dummying end plate and thus there is no magnet in the half drift tube. Concerning the permanent magnets hardly have a good uniformity, all the quadrupoles in DTL are electromagnetic quadrupole. The magnets cores have the same thickness of 34mm and the same gradient of 75T/m. The magnet coil is the SAKAE type made by electroforming method which was used in J-PARK DTL linac[2]. Figure 3 shows the magnet inside with the half copper drift tube.

Figure 3: Magnet with SAKAE coil inside the drift tube.

Some field measurements have been carried out with six model magnets in IHEP. The effective length, magnet field gradient in transverse plane, B-H curve and magnet field centre were measured and analyzed. Detailed results can be found in another paper in this conference[3].

The magnet installed into drift tube has a concentric tolerance of less than 50μm error. The mechanical centre is fixed by a set of supporting structure on the rotating coil measurement system. Then beam pipe and outer diameter of the drift tube are machined in accordance with the magnetic centre which is defined as the position with a minimum dipole component. The supporting structure is shown in Figure 4.

## OFC DRIFT TUBE MANUFACTURE

The drift tube of DTL for CSNS is made of oxygen free copper (OFC). The advance is there is no electroplating after electron beam welding (EBW) of the two halves of a drift tube, and the surface machining demands only one time according to the mechanical centre fixed from magnetic measurement, saving a lot of time in mass production.

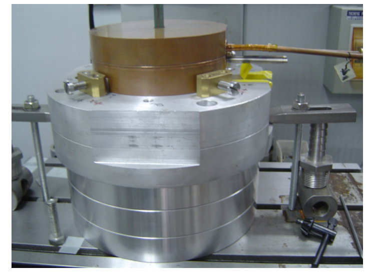

Figure 4: Supporting structure for rotating coil measurement.

In fact, a stainless steel drift tube was constructed in the early R&D stage. The welding deformation was more than 1mm, which was thought bigger than expected. Then we tried to manufacture drift tube with OFC. By using OFC drift tube, the deformation in EBW is 0.4mm, and this error will be corrected by fine machining after welding.

However the major concern is its intensity of OFC drift tube in comparison with stainless steel one. We have done two experiments to check the intensity of OFC drift tube. The first is to check the deformation of the drift tube surface under a giving high air pressure inside the welded drift tube, as shown in Figure 5. The result was 0.02mm deformation when the air pressure was increased from 0 to 1.5kg/cm$^2$, while it recovered back to 0 when no air pressure was applied. The second is to check deformation of the total length of the stem with an additional hanging load for a long time, as shown in Figure 6. The result was 0.01mm length change with a 150kg hanging load for 23 hours, while it became 0 when taking away the load. These tests demonstrate the intensity of OFC is high enough for our design.

Figure 5: Deformation check of an OFC drift tube under a high air pressure.

Figure 6: DT Deformation test with a hanging heavy load.

## DESIGN OF THE ELECTRICAL FIELD

In the analysis of tilt field design of the first tank, the accelerating field distribution generated by MDTFISH code is different with the design data[4]. Figure 7 shows the difference between these two fields. This difference will cause beam property completely different with the design, especially beam loss. In order to recover the electrical field as designed, a cell gap adjustment in special position is adopted. The modified field becomes nearly the same as the designed field, as plotted in Figure 8, but on the other hand it causes the beam synchronous phase in adjusted cells different with the design. As a result, the beam energy is 0.2% lower than the design value in simulation.

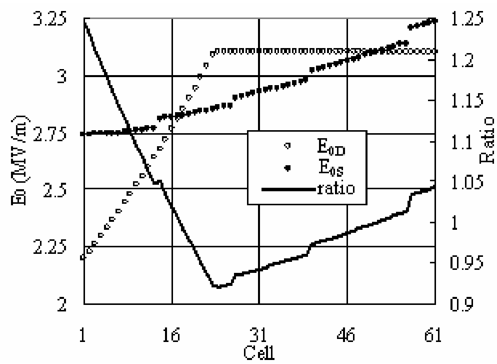

Figure 7: The code generated field before adjusting

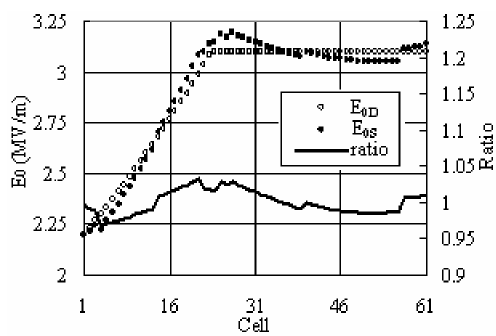

Figure 8: The code generated field after adjusting.

## RF TUNING DESIGN

In the RF tuning of DTL for CSNS, the field is required to be no more than 1% different from the design one. There are several procedures on RF tuning for that goal. First, separate the perturbation of slug tuners and post couplers. Second, adjust the slug tuners by calculating the transfer matrix for field modification. Third, check the sensitivity of RF field in a 5% tilt field. And last, check the effects of the movable tuners both on field tilt and on field flatness.

According these procedures, the RF tuning of DTL is designed for three aims: resonant frequency, flatness and field sensitivity. The most concerned issue is how to get the designed field distribution for both tilt field section and flat field section. While the sensitivity in different sections, including movable tuners effect on tilt part, is also under thorough detecting.

In the tank 1 there are 12 fixed tuners and 2 movable tuners, as shown in the Fig 10. All the 14 slug tuners have a 150mm diameter and 10mm corner radius. The maximum penetrating depth is 100mm. Frequency adjustment is designed as ±1MHz.

**1. Frequency tuning** The designed field is complicated, so the tuning of post couplers is separated from frequency tuning with slug tuners. The frequency shift caused by the insertion of the post couplers is 486.34 kHz in simulation. Here the simulated post couplers are fixed in length and have no tip angle. In the frequency tuning, post couplers are all pulled out. The slug tuners penetrate into tank with different length to obtain the required field distribution as designed at the resonant frequency. And the position changes of slug tuners for ±5% are recorded to check the sensitivity afterwards.

**2. Flatness tuning** When the frequency is proper and field is flat, post couplers are inserted in a same length and same tip angle. According to the frequency shift and field perturbation, the post couplers are tuned in several groups with different length. Flatness tuning is an iterating process between resonant frequency and designed flatness approach.

**3. Sensitivity tuning** The sensitivity is judged by 2 points. Firstly, 5% field change introduced from fixed tuners has a perturbation on designed field. Rotate the post couplers angle until the perturbation has no effect on field distribution. Secondly, check the waveform by bead pulling system to ensure the RF field as designed. After the post couplers adjustment, movable tuners perturbation is measured with 1% field variation.

For the RF tuning of DTL for CSNS, the target field distribution is different from any other design. So the RF tuning, especially the flatness and sensitivity, is more difficult. After the module tank is manufactured, more experiment will be conducted to check the design.

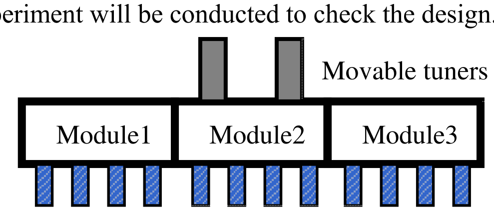

Figure 9: Tuner distribution on the first DTL tank

## ACKNOWLEDGEMENTS

We are grateful to K. Hasegawa and F. Naito of J-PARC for their great support. Many discussions with them are instructive for our work.

# DRIFT TUBE LINAC DESIGN AND PROTOTYPING FOR THE CERN LINAC4

S. Ramberger, N. Alharbi, P. Bourquin, Y. Cuvet, F. Gerigk, A.M. Lombardi, E. Sargsyan, M. Vretenar, CERN, Geneva, Switzerland, A. Pisent, INFN/LNL, Legnaro, Italy

## Abstract

The Drift Tube Linac (DTL) for the new linear accelerator Linac4 at CERN will accelerate H⁻-ion beams of up to 40 mA average pulse current from 3 to 50 MeV. It is designed to operate at 352.2 MHz and at duty cycles of up to 10 %, if required by future physics programmes. The accelerating field is 3.2 MV/m over the entire length. Permanent magnet quadrupoles (PMQs) are used as focusing elements. The 3 DTL cavities consist of 2, 4 and 4 section of about 1.8 m each, are equipped with 35, 41 and 29 drift tubes respectively, and are stabilized with post-couplers. Several new features have been incorporated in the basic design. The electro-magnetic design has been refined in order to reduce peak field levels in critical areas. The mechanical design aims at reducing the complexity of the mechanical structure and of the adjustment procedure. Drift tubes and holders on the tanks that are machined to tight tolerances do not require adjustment mechanisms like screws or bellows for drift tube positioning. A scaled cold model, an assembly model and a full-scale prototype of the first half section have been constructed to validate the design principles. The results of metrological and RF tests are presented.

## INTRODUCTION

The Linac4 DTL will accelerate H⁻-ion beams of up to 40 mA average pulse current from 3 MeV to 50 MeV in 3 accelerating cavities over a length of 18.7 m. The RF cavities operating at 352.2 MHz and at duty cycles of up to 10% are 520 mm in diameter with drift tubes of 90 mm diameter and 20 mm beam aperture.

The drift tubes are equipped with permanent magnet quadrupoles (PMQ) with an FFDD lattice in cavity 1 and an FD lattice in cavity 2 and 3. PMQs have the advantage of small size at medium magnetic gradients without the need for current supply wires or power converters. To ease matching for beam currents below nominal, electro-magnetic quadrupoles are placed in each of the intertank sections. Latest design parameters are shown in Table 1.

## ELECTRO-MAGNETIC DESIGN

The electro-magnetic design aims at an acceleration with high constant average field $E_0$ of 3.2 MV/m over all gaps with a high effective shunt impedance per unit length $ZT^2$. While it is a typical DTL concept to ramp $E_0$ in the first cavity in order to adiabatically capture the beam longitudinally [1], the choice of high constant $E_0$ aims at maximizing the energy acceptance to the incoming beam and leads to a more compact design [2].

Table 1: DTL Cavity Parameters

| Parameter | Cavity 1 / 2 / 3 |
|---|---|
| Cells per cavity | 36 / 42 / 30 |
| Maximum surface field | 1.6 / 1.4 / 1.3 Kilp |
| Synchronous phase | -30 to -20 / -20 / -20 deg |
| RF peak power per cavity | 0.95 / 1.92 / 1.85 MW |
| RF beam / peak power | 1.88 MW / 4.7 MW |
| Focusing scheme | FFDD / FD / FD |
| Quadrupole length | 45 / 80 / 80 mm |
| Number of sections | 2 / 4 / 4 |
| Length per cavity | 3.63 / 7.38 / 7.25 m |

A particular advantage of ramping $E_0$ are lower peak fields at lower beam energies where earlier designs showed increased breakdowns [3]. Several parameters might be of influence: comparably large surfaces of flat opposing faces on consecutive drift tubes, more outgassing due to larger overall surfaces including the cavity end-wall, an incoming beam with a higher number of stray particles, magnetic fields close to surfaces of shorter drift tubes.

Recent studies for muon cooling where strong accelerating and magnetic fields have to be combined, emphasize the importance of the latter [4]. The PMQs that will be used for the DTL design have a peak magnetic surface field of 0.5 T which in the shortest drift tubes falls close to the area of peak electric fields.

In order to reduce breakdown probability in the first cells, the peak electric field therefore has been reduced by 30% by increasing the gap length. The cells are tuned by the face angle. At longer drift tubes the peak electric field can be ramped to values that allow for optimum effective shunt impedance (Fig. 1). In this way, the same advantage of lower peak fields in the first cells is achieved as when ramping $E_0$.

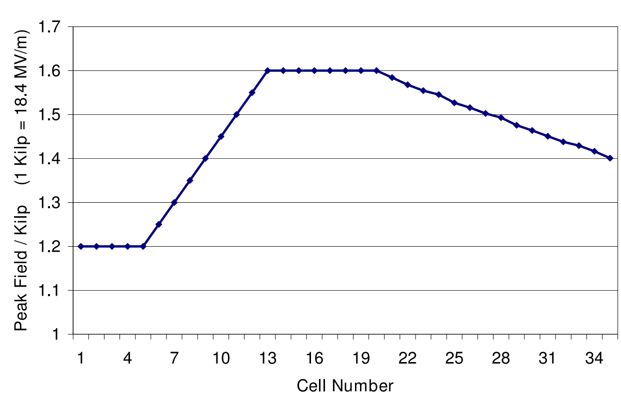

Figure 1: The peak field is reduced in the first cells.

The minimum gap length increases by 40 % from about 8.5 mm to 11.9 mm. As a further advantage also longitudinal mechanical tolerances increase by the same relative amount. The consequences on the effectiveness of the structure remain low. Energy gain in the first cells decreases by 4.1% but only 1% in beam energy over the first cavity is lost.

## ALIGNMENT TOLERANCES

The required alignment tolerances were defined by error studies on beam dynamics [5]. Limits for transversal and rotational positioning of quadrupoles are tight (Table 2). The longitudinal magnet position is less critical.

Table 2: Alignment Tolerances Between Drift Tubes

| Error Type | Max. Amplitude |
|---|---|
| Transverse horiz. & vert. (x,y) | ±0.1 mm |
| Magnet rotation, all axes | ±3 mrad |

The tolerances are tight but following advances in machining quality, they are considered feasible without any further adjustment mechanism. In consequence, all critical parts have to undergo metrology before assembly. Considerable advantage of this strategy is that the assembly becomes straightforward and that positioning cannot degrade by accidental movement of screws. It is worth noting that on other DTLs like the Linac2 at CERN, the drift tube positions have never been corrected after their first alignment even though the design had foreseen this explicitly [6].

## MECHANICAL DTL STRUCTURE

The DTL cavities consist of a steel cavity, an aluminium girder, drift tubes assembled from pre-machined copper pieces, and accessories for mounting drift tubes in girders as well as for tuning, stabilization, support, vacuum pumping and alignment of the structures (Fig. 2).

The cavities are made from 50 mm thick mild steel cylinders that provide the rigidity to achieve the required tolerances when placed on supports. The cavity is segmented into 2 sections in the first cavity, and 4 sections in the second and third cavity that are aligned with precisely machined rings after assembly of each section. Mild steel is the material of choice due to its thermal conductivity, mechanical strength, and comparably low price [1].

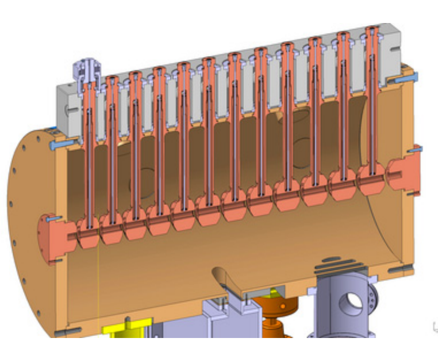

Figure 2: DTL prototype cut along the beam axis.

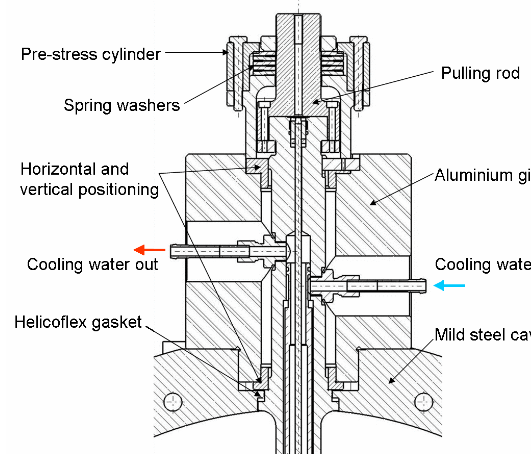

Figure 3: Drift tube mount assembly.

The steel cylinders of about 1.8 m length are precision machined in order to correctly position rectangular aluminium girders on top. The girders are pre-machined for each drift tube and stainless steel rings are inserted into the openings from above and below. The steel rings are remachined for precise drift tube positioning.

## DRIFT TUBE MOUNT ASSEMBLY

The completed girder is placed on the steel cylinder and provides the reference for drift tube mounting (Fig. 3). The horizontal position of the drift tube is defined via the lever arm between upper and lower steel rings whereas the vertical position is given by the stop position on the lower ring.

At the top, the copper drift tube is extended by a stainless steel pulling rod as the length of the drift tube shaft that can be installed in the cavity is limited by the diameter of the cavity. The Helicoflex® gasket rests on a stop on the drift tube and provides for vacuum tightness and RF continuity towards the copper plated mild steel cavity. Spring washers at the top of the drift tube provide the required force via a nut to compress the Helicoflex® gaskets.

For the installation of the spring washers a pre-compression socket is assembled in advance with the lower support socket. This pre-assembly is placed over the pulling rod and rests on the upper stainless steel ring. The nut is placed on the extension rod and just locked on the spring washers. The pre-compression cylinder is released in a way that the compression force is transferred uniformly to the drift tube through the nut and the extension rod.

## MANUFACTURING PROCEDURE

The manufacturing procedure for drift tubes is critical in order to reach the required high precision at assembly:

- Machining of drift tube parts with main references
- Assembly of drift tube with stem by e-beam welding
- Vacuum test of cooling circuit
- Final machining of magnet holder and references
- Insertion of PMQ

- Closure of drift tube by e-beam welding
- Metrology

After assembly of each cavity section, the position of drift tubes to reference surfaces is checked by a laser tracker.

## THE PROTOTYPES

A full-scale pre-prototype with two drift tubes has been built to test the mount assembly. Laser tracker measurements compared to dimensional metrology data show that the vertical positioning is within 0.01 mm. The horizontal positioning is within 0.1 mm longitudinally and within 0.05 mm transversally with respect to the cylinder axis.

Currently a full-scale prototype of a half section with 12 drift tubes without PMQs is being constructed at CERN (Fig.4). The purpose is to gain a small representative statistic sample on drift tube mechanics and to test technologies such as copper plating, e-beam welding, vacuum sealing, as well as tuning, stabilization, and operation at high RF power. At a later stage, few drift tubes with PMQs will be installed. All the prototype component machining has been provided by INFN/LNL, a contribution in view of a possible application for a radioactive ion beam facility driver in the SPES project [7].

A scaled cold model has been manufactured in order to study stabilization with post-couplers considered to be critical because of the drift tube to tank distance of $1.01\ \lambda/4$ and the 1 in 3 post-coupler scheme in the first cavity [8]. The model could be easily stabilized. Figure 5 compares bead-pull measurements with and without post-couplers after detuning by shifting the half drift tubes at either end.

## CONCLUSIONS

The DTL design for the Linac4 at CERN incorporates new features in a basic design: Peak fields are ramped in the first cavity in order to reduce probability for breakdown

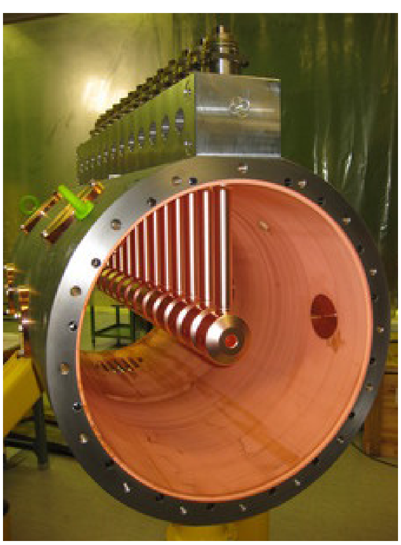

Figure 4: DTL prototype in the assembly stage.

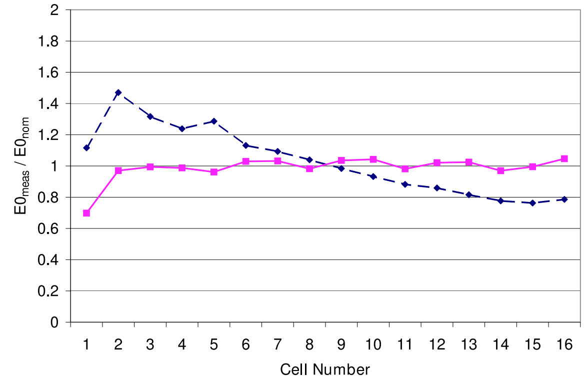

Figure 5: Accelerating voltage per cell in the cold model without (dashed) and with post-couplers (continuous).

while the accelerating field $E_0$ is kept constant over the whole structure. A new mounting mechanism is described that does not require any adjustment after assembly. Both features aim at a robust and reliable construction and operation. First results of metrological and RF tests demonstrate the current progress of prototyping.

## ACKNOWLEDGEMENT

Construction of the prototypes relies on the CERN central workshops for assembly and finishing technologies. The cold model has been financed and manufactured by KACST, Riad, Saudi Arabia.

We acknowledge the support of the European Community-Research Infrastructure Activity under the FP6 “Structuring the European Research Area” programme (CARE, contract number RII3-CT-2003-506395).

# DEVELOPMENT OF INVESTIGATIONS ON THE MILAC HEAVY ION LINEAR ACCELERATOR

V.O.Bomko, O.F.Dyachenko, O.M.Yegorov, A.P.Kobets#, M.S.Lesnykh, K.V.Pavlii, Z.Ye.Ptukhina, V.M.Reshetnikov, S.S.Tishkin, O.V.Zabotin, B.V.Zajtsev, B.M.Zinchenko, V.G.Zhuravlev, National Science Center "Kharkov Institute of Physics and Technology", Kharkov, Ukraine

*Abstract*

On the Kharkov heavy ion linear accelerator MILAC works are carried out with heavy ion beams accelerated to 8.5 MeV/u, and development of new methods for acceleration and investigations on modernization of accelerating structures [1].

## MILAC LINEAR ACCELERATOR

The Kharkov ***multicharge ion linear accelerator*** (MILAC) is a unique physical and technology complex that consists the first prestripping section PSS-15 (Fig. 1, p. 2), second prestripping section PSS-4 (Fig. 1, p. 5), main section MS-5 (Fig. 1, p. 3) and the system of the ion irradiation (Fig. 1, p. 8). The structural scheme of the accelerator is given in the Fig.1.

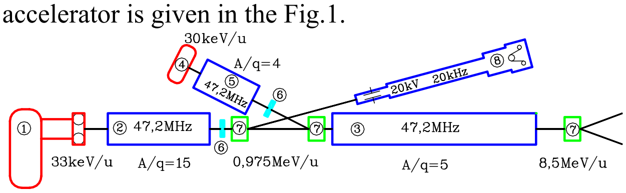

Figure 1: The structural scheme of the MILAC.

At the main and two pre-stripping sections of the MILAC linear accelerator the accelerating DTL structure on the H-wave of interdigital type (IH-structure). was applied [2].

The characteristic feature of the main section MS-5 (Fig. 1, p. 3) is its electrodynamic characteristics. An effective method was developed for adjusting the cells of the accelerating structure using additional current-carrying rods located at an angle to the supporting rod (Fig.2).

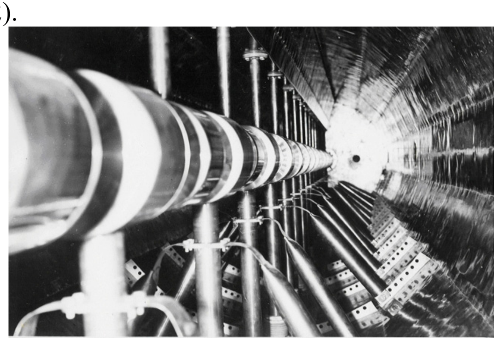

Figure 2: Accelerating structure MS-5.

This method of adjusting the inductive accelerating cell parameters allowed formation of a uniform accelerating field distribution along the structure. From one hand, this allowed to increase significantly the acceleration rate, and from the other, to form the paths of the uniform filed distribution of the controllable extension which gives a possibility to obtain the beams of intermediate energies [3]. Additionally, a method was developed for adjusting the field distribution using the ending resonance adjusting device, which represent quarter wave oscillators; on the side of the oscillator facing the side wall of the cavity a control piston is placed which can move in longitudinal direction. Such systems are installed on the input and output ends of the cavity.

The main section MS-5 11 m in length with 42 drift tubes, of which 21 contain magnetic quadrupoles gives a possibility to accelerate ions with A/q≤5 from 0.975 to 8.5 MeV/u. Total acceleration rate in the prestripping section is 3.2 MeV/m.

Second pre-stripping section PSS-4 (Fig. 1, p. 5) for accelerating only light ions with A/q≤4 from 30 keV/u to 1 MeV/u is developed. In this new section irregular interdigital (IH) accelerating structure with beam focusing by radiofrequency field (alternating phase focusing with stepped changing the synchronous phase along the focusing period) are used. After stripping this beam will be output on the acceleration line of the main MILAC section (Fig. 1, p. 3) and accelerated up to 8.5 MeV/u.

The problem of adjustment accelerating structure PSS-4 was especially difficult in connection with the non-uniform of lengths of cells mention above in structure of the focusing periods and increasing character of distribution of an accelerating field along the accelerator. Therefore it was required to apply a combination of various tuning methods The new effective inductance-capacitor tuning devices (contrivance) as rods located on the drift tube side, opposite to their holders are developed [4]. At the certain design the exact local tuning of cells is possible for carrying out not only selection of contrivance length, but also by change of a corner of their disposition concerning an axis of drift tube holders (Fig.3.).

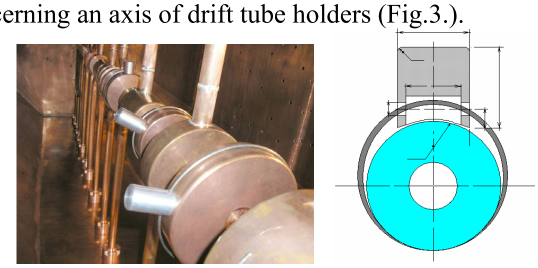

Figure 3: Accelerating structure PSS-4 with contrivance.

The high efficiency such inductance-capacitor tuning system allows to receive required electro-dynamic characteristics of accelerating structure at an identical small diameter of drift tubes, that considerably simplifies

#kobets@kipt.kharkov.ua

their design, reduces a radiating background around of the accelerator and prevents occurrence of the multypaction high-frequency discharges.

## INVESTIGATIONS ON MILAC

Introduction on MILAC linear accelerator IH accelerating structures of various modifications considerably expand a scientific and applied range of researches. Experimental investigations with heavy ions beams for obtaining track-etched membranes, production of unique radionuclides, developments of proton and ion therapy, studying of radiating characteristics of constructional materials of nuclear power, research processes of fusion-fission superheavy nucleus and other problems of nuclear physics are carried out.

### *Track-Etched Membranes*

Presently, on MILAC experimental investigations on irradiation the polymer films with heavy ion beams with the aim of obtaining track-etched membranes [5]. In the MILAC prestripping section triple-charge $Ar_{40}^{3+}$ ions were accelerated to the energy of 1 MeV/u with the intensity of $10^{10}$ particles/s; PETF films 6 – 10 μm thick were irradiated, and after subsequent physical and chemical treatment it was possible to obtain experimental samples of track-etched membranes with through pores from 2 to 0.05 μm in diameter (Fig.4).

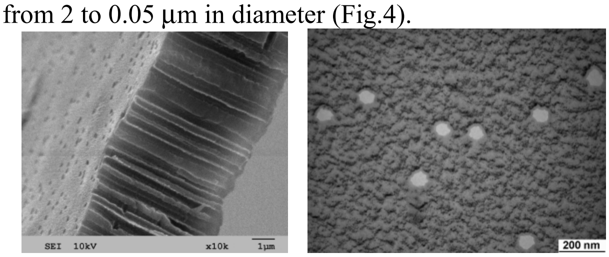

Figure 4: Pores at the cross section and the surface track-etched membrane.

To provide uniform track distribution in the polymer film with the specified density and orientation a system for ion irradiation of polymer film with horizontal beam scanning with the frequency of 20 kHz and sinusoidal voltage up to 20 kV was developed.

### *Radiation Investigations on Structural Materials*

In connection with the forthcoming termination of the design service life of some energetic blocks at nuclear power plants in Ukraine it is necessary to develop a scientific and engineering substantiation for extending the operating lives of NPP units. The use of accelerated charged particles allows one to imitate quite completely the processes involved by radiation effects in the reactor cores under steady-state and transient operating conditions.

In experiments the ions of helium, neon and argon are accelerated at the accelerator MILAC in the two prestripping sections PSS-15 and PSS-4 to energy of 1 MeV/nucleon and in the main section MS-5 to energy of 8.5 MeV/nucleon. Thus, it is possible to imitate the process of irradiation with heavy ions of fuel element materials and other structural materials used in energetic blocks.

For investigations on the mechanical characteristics of structural materials a complex of experimental devices was developed. It is designed to study the creep, stress relaxation and active straining of samples after irradiation with accelerated ions.

A device permitting to study the creep, stress relaxation, active straining and dimension stability directly in the process of irradiation with accelerated ions was designed. In Fig.5 given are the schematic presentation and the photograph of the experimental device for investigations of plastic properties of structural materials exposed to the ion beam.

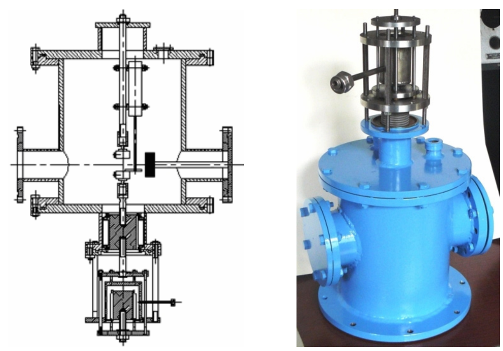

Figure 5: Chamber for investigations of plastic properties of structural materials exposed to the ion beam.

Using the developed methods and experimental devices at the accelerator MILAC it will be possible to investigate the structural materials directly in the process of irradiation with heavy ions, as well as, after irradiation.

### *Development of Investigations on the Nuclear Fusion of Heavy Particles*

At present, 1.5 tens of supeheavy elements are obtained, but there are no direct reactions to produce, for example, a stable isotope of the element-114 with an atomic number 298 for lack of neutrons.

To produce new superheavy elements and to study their properties in the field of the assumed stability island it is necessary to develop new experimental techniques. For arrangement of experiments on studying the reactions of deep inelastic transfers during interactions of heavy ions, with a maximum yield of interesting isotopes, the choice of an initial target-beam isotope combination and kinetic beam energy is a determining factor. The most realistic description of the process of nuclear fusion is proposed in the concept of a double nuclear system. Basing on this system a series of models are constructed being successfully applied in the description of the processes of fusion-quasi-fission of heavy nuclei.

We have calculated the number of protons and neutrons in the fragments of the double nuclear system and considered possible variants of transitions which are controlled by the potential energy and are determined by its minimum value. The dynamics of transitions in the reaction of isotopes *Fe*, *Ni* and *Co with* $^{238}U$ for ±n, ±p, ±(n+p) allowed transitions is calculated. With a correct choice of the target-beam isotope configuration, taking into account the nucleon emission and excitation energy changing, there is a probability to direct the reaction into the channel of nucleon transfer for production of superheavy nuclei.

Using the accelerator MILAC it is planned to accelerate the ions of iron, cobalt, nickel, copper and zinc to the energy of 8.5 MeV/nucleon. In experiments the target of uranium, bismuth, lead and other heavy metals will be used. When carrying out experiments on the study of the reactions of deep inelastic transfers there is a need for heavy ion accelerators with controlled beam energy. The team of specialists working at the accelerator MILAC facility has a wide theoretical and experimental experience in smooth variation of ion energy, including the beam ion energy of the main section MS-5 [3].

## *Radionuclides for PET Diagnostic*

For investigation with PET it is important to choose a radionuclide having a low maximum energy of $\beta^+$-particles which provides high resolution of the image. $^{18}$F having the maximum energy of $\beta^+$-particles of 635 keV is the best among the other radionuclides. Ideally, average period of life of radionuclides should be of the same order as the time necessary for investigating

$^{18}$F is relatively long living among short living isotopes ($T_{1/2}$=109.7 minutes) which radiopharmaceutical preparation takes the main part in the development of positron-emission tomography. PET investigations requires from 1 to 4 hours for scanning from the moment of the admission of the preparation.

Production of considerable amount of fluorine-18 (about 1 curie per an hour) at linear accelerator MILAC is possible with $^{18}O(p,n)^{18}F$ and $^{16}O(\alpha,pn)^{18}F$ reactions with energies 8.5 and 34 MeV for protons and helium ions, respectively. In the Fig. 6. the function for excitation of $^{16}O(\alpha,pn)^{18}F$ reaction is shown. It is easily seen that at the energy of 34 MeV it has the maximum.

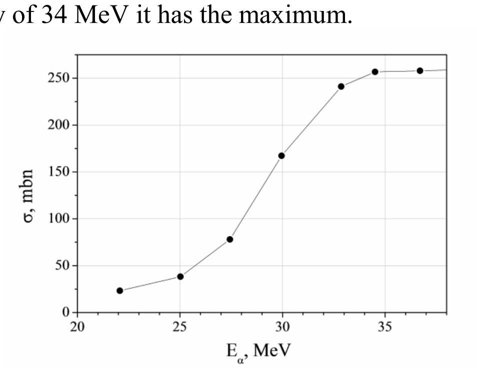

Figure 6: The function for excitation of $^{16}O(\alpha, pn)^{18}F$.

After start prestripping section PSS-4 on linear accelerator MILAC acceleration of ions of helium up to energy 34 MeV at an average intensity of helium ion beam up to 10 μA is planned.

A system for target irradiation was created; in the targets nuclear reactions run. Production process of $^{18}$F radioactive fluorine from $CeO_2$ oxide respectively to the nuclear reaction $^{16}O(\alpha, pn)^{18}F$ was studied.

## *Ion Therapy*

In Ukraine medical centers of proton and ion therapy are not at all. The oncological disease and mortality rate in our country is highest throughout Europe and the survival rate is lower by a factor of 2.5 then in other countries. Widespread investigations demonstrated that the best method of overcoming the tumor resistivity is the use of a close-ionizing radiation with linear energy losses of 50÷100 KeV/μm. Practical results revealed a high efficiency of radiation treatment with carbon ions. In many cases the effective treatment is ensured by the combined use of proton and ion beams. Therefore, the most complete center of radiotheraphy should provide the radiation treatment by carbon ions and protons.

After starting the new prestripping section PSS-4 at the linear accelerator MILAC it will be possible to accelerate protons to energy of 8.5 MeV, helium ions to energy of 34 MeV and carbon ions to energy of 102 MeV. For further acceleration of above mentioned ions it is necessary to construct a synchrotron having 20 m in diameter. Then ions could be accelerated to the controlled energy from 50 to 400 MeV/nucleon being necessary for the ray therapeutics. Establishing of the center of radiotherapy has a reason, as it is located near the accelerator MILAC of the research institute of medical radiotheraphy possessing a necessary therapeutic base and highly qualified personnel having a great experience in treatment of oncological patients by surgical, chemotherapeutical and radiation methods.

# LINAC OPERATIONS AT FERMILAB

L. Allen, FNAL, Box 500, Batavia, IL 60510 USA

The Fermilab Linac has been delivering unprecedented amounts of beam for HEP. The addition of Main Injector, three high intensity high repetition rate experiments and the 120 GeV Fixed Target Programs have increased the repetition rates from 0.33Hz. to a maximum of 7.5 Hz. and it is expected to increase further. The intensity accelerated by the Booster is 5 E12 protons per pulse. The effects on radiation levels and operational reliability and developments helping both to cope with the higher rates and make the beam more useful to Booster will be discussed.

## THE PROBLEM

As the demand for higher booster intensity and repetition rate began to ramp up, the Booster was operating at about 65% efficiency. Because the Linac discards the first ten μsec of beam it needed to accelerate almost 1 E13 H- ions per pulse. Today after many improvements to the Linac and Booster, booster efficiency is 90% and only 7.7 E12 per pulse are required from Linac.

## IMPROVEMENTS

In the late 1990's Milorad Popovic [1] accurately modeled the high energy linac quadruples. Using this data he was able to make significant reductions in losses. The match to the Booster was also improved.

In 2001 an experiment [2] was performed measuring the effect of linac beam current on booster efficiency. At that time the Linac normally accelerated 50ma. and injected 11 turns into the Booster. During the experiment, linac beam current was reduced to 30ma. and The Booster was tuned with up to 20 turns injected. The Booster operated at the same or better efficiency at the lower current. As a result, linac beam current was reduced to 40 ma. and as a result of further booster improvements to 36 ma.

As a result of these improvements, linac beam losses have decreased dramatically. The parameter D7LMSM is the sum of all the loss monitors in the RF area. In 2000 D7LMSM was >20. The improvements noted plus constant tuning has reduced the total losses to the 10 to 12 region for the H- ion source and less than ten for the I- ion source.

To get a better measurement of the linac energy on a day to day basis a device called the Velocity Meter [3] has been installed in the 400 MeV Line. By measuring the beam phase between two Griffin [4] detectors it measures flight. While it is not calibrated in energy, it does alert one to energy changes. Before this monitor was installed it was impossible to determine if an energy drift was causing booster efficiency to decline.

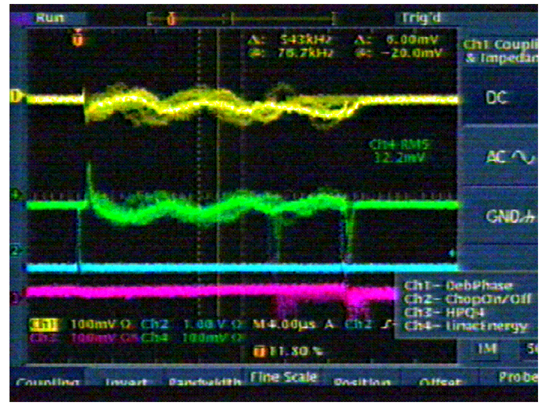

Figure 1: Velocity meter scope traces.

The output signal (in green) viewed on an oscilloscope can detect an energy swing during the pulse or an overall energy shift. The computer reads this parameter and automatically changes the RF phase in the final RF module to correct the energy. Using this method has stabilized the linac energy and made booster tuning more repeatable.

A Bunch Length Monitor [5] was also installed in the 400 MeV Line. It has been empirically determined that booster needs this device to read less than .85 nsec. for good operation. Linac has been tuned so that it averages approximately .83 nsec. The low energy buncher. medium energy buncher and the phase difference between the Low Energy Linac(LE Linac) and High Energy Linac(HE Linac) are the most common adjustments to control this.

## CONTINUING PROBLEMS

Looking at the trace in Fig. 1 one notices an oscillation. The oscillation is at approximately 130 kHz and is a real energy effect. We can see this in the HE Linac RF phase and at times in the gradient. There is a program underway, lead by Ken Quinn, to locate and repair the source of this oscillation.

There is a slow drift of some parameter in the LE Linac. The signature of this drift indicates that it is RF related. The gradients have independent readings but intertank phase does not. The drift does not appear to be the gradient because the independent readings do not change at the same time. The lack of independent readings has made looking at phase difficult. The fix is to vary the phase of LE Tank 5. This both changes the output energy of the LE Linac and the phase difference between the LE Linac and the HE Linac.

As mentioned earlier the Linac discards the first 10μsec. of beam each pulse. This is the time it takes for the feedback systems in the LE Linac to settle in. During this time the beam is unreliable and dumped. This beam usually has slightly higher losses than the later beam sent to booster and should not be necessary. The HE Linac settles in about two µsec.

To address the LE RF drift and the 10 µsec. throwaway there is a program ongoing to replace the LE Linac LLRF System [6,7]. The new system replaces the current Intertank Phase Error reading with a phase measurement between the cavity and reference line. This will provide proper read-backs and control of the amplitude and phase of the RF. It will hold the accelerating gradient to within .3 percent and the phase being held to less than .3 deg. and settle in two µsec. The effect of this will be to eliminate the LE Linac RF drift and cut the 10 µsec. of beam thrown away to two µsec. These improvements improve linac stability and losses.

## RELIABILITY

Overall linac reliability has decreased over the last few years. Before the upgrade in 1993 uptime was 98%. So far in 2008 it is 95.6%, in 2007 it averaged 94.8%. Over the period of Run II from 2001 to 2005 it was 97%. From June, 2006 through August, 2008 it was 95%.

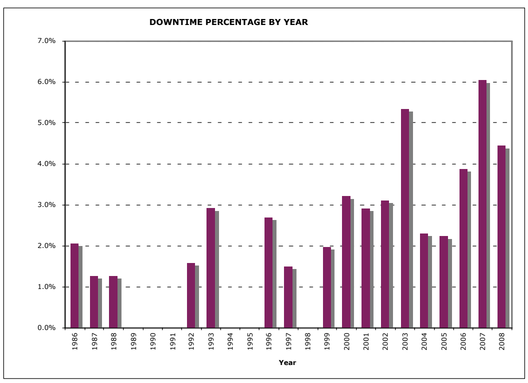

Figure 2: Linac downtime percentage by year.

In the time period of 2001 through 2005 there were 1160 hours of downtime or 3.03% of the total scheduled time from 6621 entries. In the period from June 2006 through August of 2008 there are 908.5 hours or 5.035% on 4986 entries.

Table 1: Percent of Downtime By Major Subsystem.

| | 2001-2005 | 2006-2008 |
|---|---|---|
| **LRF TOTAL** | 36.78% | 38.77% |
| **KRF TOT.** | 32.92% | 19.55% |
| **PREAC** | 8.38% | 10.78% |
| **MISC. TOT.** | 19.27% | 28.34% |
| **SAFETY** | 1.10% | 1.17% |
| **CONTROLS** | 1.45% | 1.39% |

Table 1 shows the distribution of downtime by major subsystem. The differences are small between the 2001-2005 and 2006-2008 time periods. There are however more incidents of longer duration in the 2006-2008 time period. There were an average of 131 events per month from 2001 to 2005, while the average for 2006 to 2008 is 191.

There are several reasons for the decrease in reliability. Components are aging and require more maintenance. The retirement of a the last technician who was here from the beginning The decrease in the lifetime of some components coupled with Fermilab's policy of not scheduling regular maintenance periods.

The water flow meters for the Klystron RF Systems are an example of aging components. They operated without major problems for several years, but are now sticking and causing the systems to trip. Each trip causes from 2 to 5 minutes of downtime.. A program to replace them has been going on for some time with limited success.

In the period around 2001 to 2003 the lifetimes of the 7835 triodes decreased dramatically. There was a time when the lifetime was less than the time needed to build or rebuild them. Fermilab had to borrow tubes from other laboratories to continue operating. The manufacturer, Burle Industries, has made great strides in modernization and quality control. As a result, average lifetimes have increased but there is still a wide spread in tube lifetime. While not back to the pre 2000 levels, the last few years have shown an upward trend.

The policy of not scheduling maintenance periods also contributes to lower linac reliability. While this maintenance policy does work for the laboratory as a whole, there are so many users that the Booster must be broken for Linac to get maintenance time. The result is that the Linac has trouble stretching problems until a maintenance period.

Most linac downtimes are less than two minutes. Since June, 2006 downtimes of two minutes or less account for 61.25% of the total entries. Events lasting 14 minutes or less account for 90% of the total number of downtime entries. Forty six percent of the total downtime results from entries of less than 2 hours. Some serious problems do not always result in one long downtime but can be many short ones.

A recent example of this type of problem was a long series of Klystron Charging Supply Trips. The downtime from each was generally less than four minutes. The frequency started out low, one or two trips per day, and ramped up to as many as nine per day. The problem took almost six months to get to the point of being noticeable. It turned out that the temperature in the charging supply was to low causing the ignitron to self-fire. The total cost was 39.2 hours down on 1096 incidents.

## SUMMARY

The Fermilab Linac has been made to run in a way that makes it possible for the Booster to operate very efficiently. These improvements are mostly the result of diagnostics developed by the Booster Group. Using these diagnostics, both in automatic loops and manual tuning, has stabilized the Linac. The underlying problems are still there but we now have solutions in progress and are close to being able to implement them.

# RE-PHASING OF THE ISAC SUPERCONDUCTING LINAC WITH COMPUTED VALUES

M. Marchetto, R.E. Laxdal, Fang Yan TRIUMF, Vancouver, BC V6T2A3, Canada

## Abstract

The ISAC superconducting linac is a fully operational machine that routinely provides beam to experiments. The linac consists of twenty superconducting independently phased cavities housed in five cryomodules. The initial tune is done manually aided by MATLAB routines to phase the linac and set the correct optics. From the initial tune we calculate the gradient at which each cavity operates based on the energy gain, the transit time factor and the geometry of the cavity itself. Then in the event of a gradient change of one or more cavities we can calculate the RF phase shift of each downstream cavity using the initial gradients, the known geometry of the entire linac and assuming linearity of the RF controls. This possibility has been investigated and we have demonstrated that the calculated phase shift can be implemented automatically thus avoiding a complete retune of the machine. In this paper we will present the calculations and the results of the online tests.

## INTRODUCTION

The ISAC facility at TRIUMF (Fig. 1) has at present the most intense driver available for ISOL based radioactive ion beams (RIB) production. The RIBs can be delivered to three experimental areas; one using the beam at source potential (60 kV), the other two using post accelerated beam.

In the ISAC I facility the beam is accelerated through a chain composed of an RFQ injector followed by an IH drift tube linac (DTL). The DTL is design as an energy variable machine [1] being able to deliver all the energies ranging between 150 keV/u and 1.8 MeV/u. The DTL injects also the beam in the ISAC II linac at 1.5 MeV/u.

In the ISAC II facility the beam is accelerated by means of a superconducting (SC) linac operating at 106.08 MHz [3]. The present installation of the SC linac is composed of five cryomodules each housing four superconducting cavities and one superconducting solenoid. The cavity voltages are set to operate each at a fixed power of 7W, for a total of ∼20MV of acceleration. The twenty cavities are independently phased at -25° synchronous phase in sequence starting from the first one. The number of cavities turned on determines the final energy. The tuning time for the SC linac can be as long as four hours although tuning algorithms are being developed to reduce this time. The ISAC II linac is going to be upgraded by the end of 2009 adding twenty more cavities housed in three cryomodules [2]. In this case there is an increased motivation to look for more tuning aids.

In order to maximize the integrated beam at the experiment it is essential to reduce the downtime as much as possible. One possible source of downtime is the retuning of

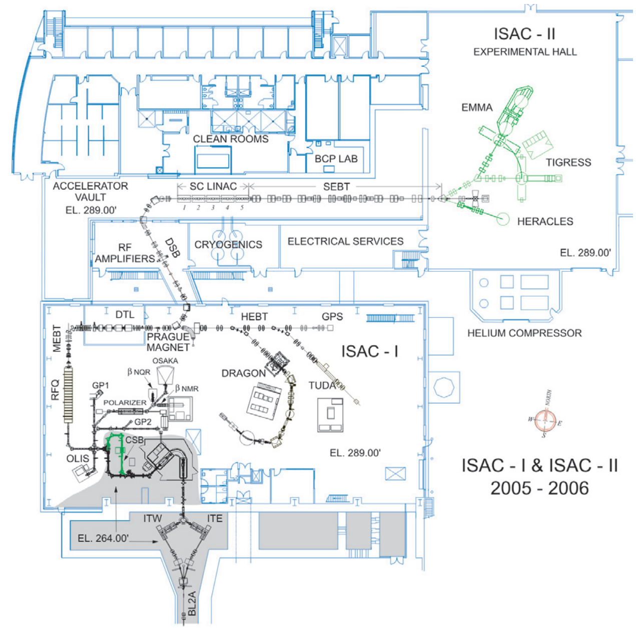

Figure 1: Overview of the ISAC facility at TRIUMF. The ISAC II linac is superconducting while in ISAC I they (RFQ and DTL) are normal conducting.

the superconducting linac in case one cavity (or more) experiences a drop of the accelerating gradient. In this paper we call this generic event a cavity failure without specifying the cause. In this case it is possible to recalculate the difference in time of flight and hence the shift of the RF phase for each cavity downstream of the faulty one. In order to calculate the phase shifts we need to know the geometry of the linac, the transit time factor of the cavities and the accelerating gradients. The transit time factor is known from radio frequency simulations of the cavity geometry. The geometry of the linac is also known by design. The operating gradients of each cavity are calculated based on the energy gain measured from the initial tuning of the linac.

## ONLINE MEASUREMENT

In order to validate the calculated values of the rephasing routine the first cavity is turned off and online RF phases are manually reset for the nineteen cavities downstream. Four separate runs are completed using different ion beams, meaning also that the energy gain after each cavity is different from one run to another due to different A/Q. These four series together with their original phase setting give the online phase shift for cavity one off. Fig. 2 represents the calculated time of flights (TOF) before and after cavity one failure for a $^{22}Ne^{4+}$ beam. In the same figure the calculated phase shift, relative to the TOFs, are plotted as well as the measured (online) phase shift for the same type of ion. The comparison of the calculated versus the online values shows a discrepancy in some cases of more than ten degrees.

These discrepancies between the online (measured) and the calculated values are the phase errors of the calculated values themselves. The discrepancy data of the four runs are binned and the distribution of the binned phase errors is represented in Fig. 3; it has $\sigma$=6.5 deg.

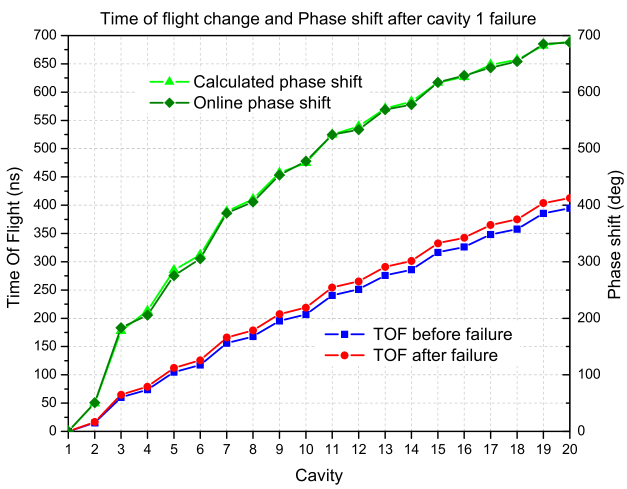

Figure 2: The plot represents the time of flights (TOF) before and after the failure for a $^{22}Ne^{4+}$ beam. The relative phase shifts are also plotted together with the online measured phase shifts.

We can identify three possible sources of error for the discrepancy. First of all the distances between cavities have some systematic error. Second, the gradient of the cavities is calculated through the energy gain, and the measurement of the energy is affected by a random error. These two errors contribute to the error of the calculated values. In addition the rephasing routine assumes the cavity has no dimension meaning the acceleration happens instantly at the center of the cavity. Third, the phasing method we use [4], by cosine fitting the energy gain versus the RF phase curve, has also a random error estimated to be $\pm 3°$. This last error affects the phases set manually. Both series of phases (manual set and calculated) contain some uncertainties meaning none of them are the absolute RF phases. Nevertheless the online measurements can be considered as the actual values for the phasing the linac.

## BEAM SIMULATION

In order to analyse the effect of the random phase error we simulate the longitudinal emittance growth for different cases. The phase errors distribution produced by the calculated values (see Fig. 3) is then associated to an emittance growth. The emittance growth is also compared with

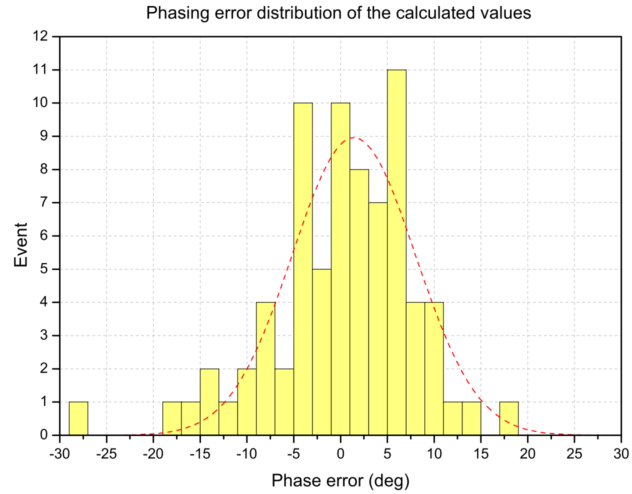

Figure 3: The plot shows the distribution of the phase error we commit when we use the rephasing calculated values. The distribution $\sigma$=6.5 deg.

the acceptance of the linac. Both the emittance growth and the acceptance are estimated via simulation done with the LANA code [5].

The beam dynamics of the ISAC linacs are simulated using the LANA code. The LANA models of our linacs well match the online measurements at the machines. We therefore use this code model to characterized the SC linac in terms of emittance growth and acceptance of the linac. The ion we simulate has A=3, Q=1 and $E_{in}$=1.5 MeV/u.

### [illegible]

The longitudinal emittance of the injected beam we use for the simulation is 1.5 $\pi$ keV/u·ns (this emittance is the design one, the measured emittance of the real beam is around 1 $\pi$ keV/u·ns).

The error we commit in the RF phase setting of the twenty cavities is assumed to be random with normal distribution centered around the synchronous phase we want to set, for us being -25°. In the simulations we consider four different distributions with $\sigma$ values of 2.5°,5°,10° and 15° centered around -25°. For each distribution we run 300 seeds (each seed corresponding to a LANA simulation run) of twenty RF phase. For each seed we record the final emittance and the final energy. For each distribution we then collect the final longitudinal emittance distribution and the final energy distribution.

The energy distribution can be fitted with a gaussian curve and therefore characterize the spread of the final energy in terms of $\sigma$ .

The longitudinal emittance distribution is instead asymmetric with a minimum value represented by the initial longitudinal emittance. In this case we calculate the rms value to characterize each error distribution.

The final results are plotted in Fig. 4. The longitudinal emittance growth is normalized to the initial emittance. In the graph it can be noticed that at 0° spread, meaning no error in the set up of the RF phase, the emittance slightly grows to a value of 1.04.

For $\sigma$=6.5 deg the emittance growth factor is ∼1.4.

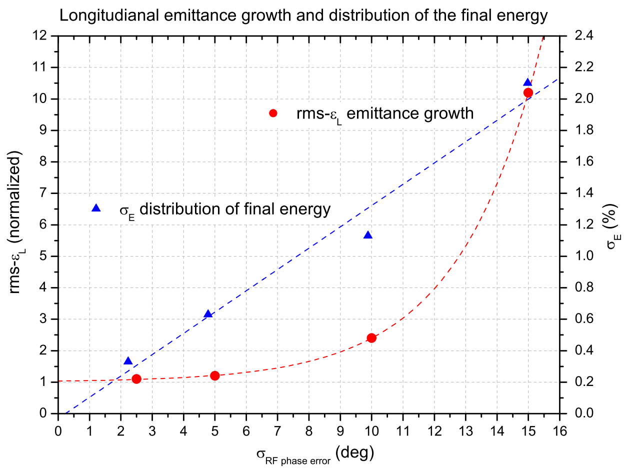

Figure 4: A plot of the longitudinal emittance growth and the spread of the final energy as a function of the RF phase error spread. The longitudinal emittance growth is normalized to the initial emittance.

## [illegible]

An estimate of the acceptance of the linac can be simulated by injecting a beam with a large longitudinal emittance and noting those particles that are transmitted to the end. The surviving particles are then mapped back to the original distribution.

The initial beam distribution for the simulation runs is uniformly distributed over 360 degree with a ±15% energy spread. The cavity accelerating gradient is set to 6MV/m.

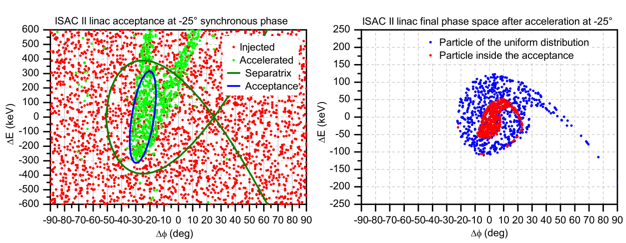

Figure 5: (Right) The red and green dots represent the injected and the accelerated particle of the initial phase space. The drawn ellipse is the acceptance. (Left) The phase space after acceleration at -25° synchronous phase. The final energy is 20.31 MeV. The red dots represent the accelerated particles inside the acceptance.

The acceptance is the maximum emittance that can be accelerated through the linac without loss. The acceptance is estimated fitting an ellipse to the initial reconstructed phase space. The acceptance and final phase space for -25° synchronous phase are represented respectively in Fig. 5.

The estimated acceptance at -25° synchronous phase is 22 $\pi$ keV/u·ns. For comparison we recall that the measured longitudinal emittance of the injected beam is ∼1 $\pi$ keV/u·ns. At -10° the estimated acceptance is 6 $\pi$ keV/u·ns.

## CONCLUSION

Based on the estimated emittance growth (see Fig. 4) we expect to have less than 50% emittance growth when using the calculated phase shift of the rephasing routine. This means that if ∼1 $\pi$ keV/u·ns emittance is injected, a ∼1.5 $\pi$ keV/u·ns emittance is expected at the exit of the linac. This longitudinal emittance is more than one order of magnitude lower with respect to the acceptance of the linac at -25°. The analysis shows that even though the rephasing values are affected by an error it is acceptable to rephase the linac in case of cavity failures. The first beam test using $^{22}Ne^{4+}$ successfully demonstrated the utility of the rephasing routine.

# THE SPIRAL 2 SUPERCONDUCTING LINAC

R. Ferdinand, T. Junquera, SPIRAL2/GANIL Caen
P. Bosland, PE Bernaudin CEA Saclay
H. Saugnac, G. Olry IPN Orsay
Y. Gómez-Martínez LPSC Grenoble

*Abstract*

The SPIRAL 2 superconducting linac is composed of 2 cryomodule families, basically one of low beta, called Cryomodule A, and one of high beta, called Cryomodule B. The low beta family is composed of 12 single cavity cryomodules. The high energy section is composed of 7 cryomodules hosting 2 cavities each. According to beam dynamics calculations all the cavities will operate at 88 MHz: one family at $\beta$=0.07, and one at $\beta$=0.12. The design goal for the accelerating field Eacc of the SPIRAL 2 QWRs is 6.5 MV/m. The configuration, cavities and cryomodule tests and status are described.

## INTRODUCTION

The GANIL's SPIRAL 2 Project [1] aims at delivering high intensities of rare isotope beams by adopting the best production method for each respective radioactive beam. The unstable beams will be produced by the ISOL "Isotope Separation On-Line" method via a converter, or by direct irradiation of fissile material.

The driver will accelerate protons (0.15 to 5 mA – 33 MeV), deuterons (0.15 to 5 mA – 40 MeV) and heavy ions (up to 1 mA, Q/A=1/3 14.5 MeV/u to 1/6 8.5 MeV/A). It consists of high performance ECR sources, a RFQ, and the superconducting light/heavy ion linac. The driver is also asked to provide all the energies from 2 MeV/u to the maximum designed value.

Figure 1 : SPIRAL2 superconducting linac – 2 QuaterWave Resonator (QWR) families.

The superconducting linac is composed of cryomodules type A developed by CEA-Saclay, and cryomodules type B developed by IPN-Orsay. Both types of cavities will be equipped with the same power coupler specified for a maximum power into the cavity of 12.8 kW@6.5MV/m, which is developed in a third laboratory, LPSC-Grenoble. The coupler must handle 100% reflected power at maximum incident power.

All the components of the series (cavities and cryomodules) will be fabricated in the industries. Couplers conditioning, cavities chemical treatments, HPR rinsing in clean room, assembly, and RF tests of the cavities in vertical cryostat and RF power tests of the cryomodules will be made in the respective 3 labs.

## CRYOMODULES A - $\beta$=0.07

Details of the cavity and cryomodule design were described in [2,3].

The cavity tuner works by cavity deformation perpendicularly to the beam axis. This design saves room in the beam axis direction. The cavity mechanical design was optimized in order to reach a full tuning range of ±25 kHz at 4 K, without plastic deformation of the niobium cavity.

Figure 2 : Cavity A with MLI and B in clean room.

Each cavity A will be feed by 5 to 10 kW solid state RF amplifier [4]. The first cavities of this low beta section working at low accelerating field (≈ 0.49 MV/m, 0.5 kW) will require less power than the last cavities of the section.

At present, one cavity prototype and a qualifying cavity have been tested in vertical cryostat. Whereas the prototype reached the specifications, the qualifying cavity performances were not as good as expected. The maximum accelerating field, 11 MV/m, was much higher that needed, but the $Q_0$ value was a factor 10 below the acceptable value, about 2 $10^8$ (see Figure 3).

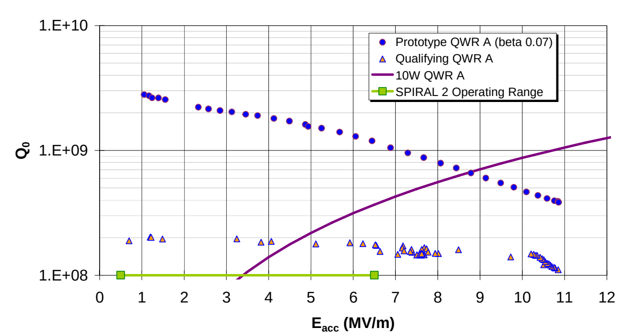

Figure 3: prototype and qualifying QWR A cavity in vertical cryostat.

Several tests were performed to localise the dissipating defects without success. We could determine that this defect is not located at the cavity extremities, at the maximum $B_{peak}$ region, or at the dismountable bottom plate. It may be located at middle height of the cavity. At about 11 MV/m the cavity dissipates more than 100 W. Fortunately small gradients are required at the beginning of the LINAC, and the dissipations can be kept bellow the 10 W limit ($E_{acc} < 4.5$ MV/m).

As consequences of these low performances, the different tests induced delays, and a new call for tender was restarted for the series of the cavities, inducing more delays. The new procedure asks for 2 new cavities with 2 different manufacturers, ZANON and SDMS. A stop point exists after the cavity welding and before the helium tank welding for tests. The 2 manufacturers allow us to speed up the process while being confident on the cavity design. The remaining series cavities of this order will then be manufactured with one or both companies. These 2 first cavities are expected in February 2009. The last cavities are expected in September 2010.

The qualification cryomodule has been assembled with the faulty cavity. Because of the small size of the Saclay clean room, the clean assembly took place in two phases. At first the HPR was performed at Saclay and all components prepared for clean assembly. Secondly, the cavity and associated components, where mounted in the vacuum tank in the large clean room at CERN.

A severe vacuum leak occurred during assembling and prevented us to perform the RF power tests as expected. Only low level RF measurements and cryogenic analyses could be made. The measured static consumption of the cold mass @ 4K of the cryostat is about 7 W, within the expected value. 21 W is dissipated on the copper screen at 77 K. The valve box, cryogenic lines and cryomodule dissipate about 25 W @ 4 K, little more than expected.

Figure 4: qualification type A cryomodule ($\beta$=0.07).

Preliminary analyses of the microphonics were performed. The resonance of the stem oscillation was observed at 39 Hz as expected, and vibrations generated by the pumping systems were detected around 100 Hz. Further analysis is still needed to determine if the microphonics observed are dangerous or not and to confirm if a damping system is required.

At present the qualification cryomodule is being dismounted. It will be remounted using the IPN-Orsay SUPRATECH clean room, now available.

The RF power tests with the cryomodule in the accelerator configuration are expected in November this year.

The call for tender of the cryostat series is ongoing. The order should take place late in December this year or January 2009. The test of the last assembled cryomodule A is scheduled in March 2011.

## CRYOMODULES B - $\beta$=0.12

A first “qualifying” cryomodule has been manufactured and tested with success in early 2008. The serial production of the 6 remaining cryomodules is under way.

Figure 5 : qualification type B cryomodule (2×$\beta$=0.12).

### *Resonators*

At present time, one prototype, 2 pre-series cavities and one series cavity has been tested. The first qualification resonator equipped with its Titanium helium tank has been tested in vertical cryostat in May 2007, the second one had a vacuum leak revealed by the chemical treatment and is lost.

The ACCEL Company is manufacturing the cavities series. Three series cavities are in hand at present time. The first one has some mechanical default but was tested with excellent result. The ACCEL Company improved the mechanical manufacturing of the two other ones. They are under chemical treatment and will be tested very soon. A stop point was decided in order to validate the design with a complete set of cavities. The company will then be able to finish the manufacturing. The remaining resonators should all be in hand before the end of 2009.

The first qualification cavity, and the first series cavity named “Erentrude” on the curve Figure 7, showed good electro-magnetic performances. Another good sign is that we observe a slight improvement from the prototype to the first series production. Design gives $E_s/E_{acc}$ = 5.51 and $B_s/E_{acc}$ = 10.19 mT/MV/m, for a $\beta\times\lambda$ accelerating length of 0.41 mm). Despite modification of the electric field area shape, multipacting barriers, identical to the ones observed on the prototype, are measured. One barrier (around 1.3 MV/m) can be easily processed while two or more barriers at very low field (between 30 and 80 kV/m) cannot. These barriers were observed at about the same fields on the 2 cavity types (A and B).

The cavity cold tuning is performed using superconducting plungers inserted on the top of the cavity inside the magnetic volume [5].

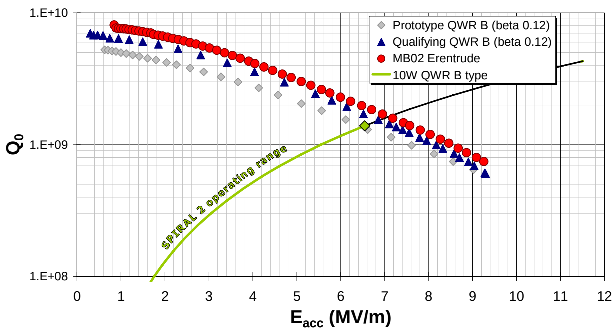

Figure 7 : $Q_0$ curve of the first type B cavities.

### *Cryostat*

The call for tender of the cryostats is started. The offer will be analysed and the contract should be signed by the end of the year.

The qualification cryomodule was first used to validate the design. As the second qualifying cavity was not useable it was tested with the prototype cavity with an antenna at the critical coupling ($\beta$=1) and with the first qualifying equipped with a power coupler. In this configuration, 8 MV/m was reach in the cryomodule. The specified main performances was achieved, Eacc = 6.5 MV/m with a dissipated power < 10 W @ 6.5 MV/m, without magnetic shielding. The static dissipation was 13 W for 11 W specified, with possibilities for improvements. Good results were obtained with the power coupler, the 10 kW solid state amplifiers [4], microphonics and the cold tuning system mentioned above. Very interesting pollution tests were performed to validate the surrounding warm sections of the cryomodules [6] and the possible use of interceptive diagnostics close to the cavities. The low field multipactor problem was solved with the use of the power coupler. See details in [7].

The cryostat has been disassembled; the cavities cleaned are under re-assembly in the final configuration with the terrestrial magnetic shielding. It will be tested in November this year, focusing on microphonics, alignment repeatability, digital low level RF and usability of the power amplifier at low power.

## COUPLERS

The RF couplers have to provide 12.8 kW CW power to the cavities at 88.05 MHz for the design goal accelerating field of 6.5 MV/m [8].

The coupler has a fixed coaxial antenna with a disc-shape ceramic (6 mm thickness). The coupling will be fixed, and the RF system will have to manage some reflected power. Coupler prototypes have been tested (head to head) up to 40 kW CW with good results.

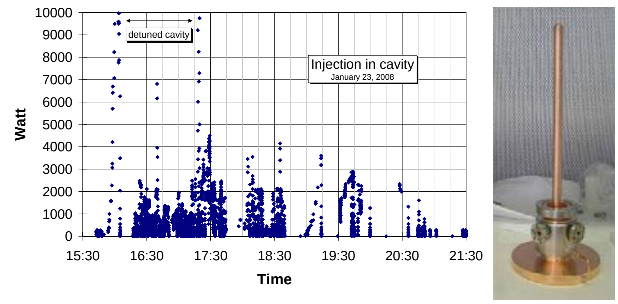

Figure 6 : Power test with the cryomodule.

The transport of three qualification couplers showed some weakness and the design has been recently improved. RF simulations, mechanical and thermal simulations were carried out.

As previously describe, the full power RF test was performed using the B type cryomodule (see Figure 6). The coupler was warm and cold conditioned, we observed some low level multipactor, as with the critical coupling, but we had no difficulties to pass them.

The tender of the series was won by the SCT Company in France. The kick off meeting of the series the production was in September this year. The completion of this production is foreseen in 2010.

## CONCLUSION

The different teams of each laboratory involved in this project are now preparing the industrialization. Installation in the linac tunnel is foreseen in 2011.

# EXPERIENCE WITH STRIPPING CARBON FOILS IN ALPI SUPER-CONDUCTING ACCELERATOR

P. A. Posocco*, Consorzio RFX, Padova, and INFN/LNL, Legnaro, ITALY
D. Carlucci, A. Pisent, M. Poggi, INFN/LNL, Legnaro, ITALY

*Abstract*

The super-conducting linac ALPI, injected either by a XTU tandem or by the s-c RFQ of PIAVE, is composed by 3 cryostats of bulk-Nb cavities ($\beta_o$ = 0.056) and 13 cryostats of Nb-sputtered-on-Cu cavities ($\beta_o$ = 0.11 and $\beta_o$ = 0.13), for a total of 64 cavities and an equivalent voltage of 35 MV. The linac is build up in two branches connected by an achromatic and isochronous U-bend. In January 2007 a stripping station equipped with carbon foils of different thickness was placed after 6 cryostats, before the U-bend, to test the feasibility of acceleration and transport of a charge enhanced beam. The study was performed with 4 different beams (Ca, Ar, Zr and Xe) and a complete data analysis has been carried out.

## INTRODUCTION

ALPI (Acceleratore Lineare Per Ioni) [1] is a super-conducting linac running since 1995 at LNL, Legnaro. The structure of this booster (see Fig. 1) is comprised of two branches (low and high-energy branch) connected by an achromatic and isochronous U-bend. There are three families of cavities, 12 $\beta_o$ = 0.056 of bulk Nb, 44 $\beta_o$ = 0.11 and 8 $\beta_o$ = 0.13 of Nb-sputtered-on-Cu, 4 cavities in each cryostat. At present the low-$\beta$ cryostats reach an average accelerating field of 3.5 MV/m, the medium-$\beta$ 4.2 MV/m and the high-$\beta$ 5.5 MV/m, resulting in a total available voltage of 48 MV [2]. The effective voltage reaches $\sim$ 35 MV due to a careful beam dynamics optimization.

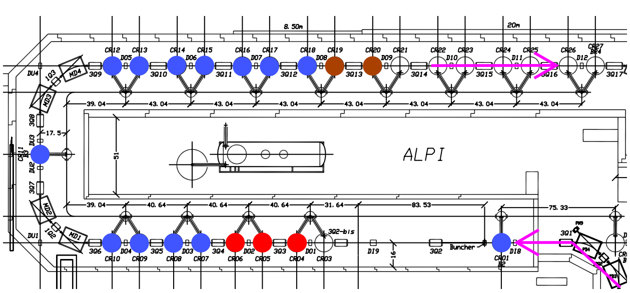

Figure 1: ALPI plan. The beam coming from PIAVE injector passes through the low-β (in red), medium-β (blu) and high-β (brown) cryostats.

The linac period is made by one triplet and 2 cryostats with a diagnostics box (profile monitor and Faraday cup) in between. In January 2007 it was decided to place a stripper station in the center of the low-energy branch period, at the both transverse and longitudinal focal point in order to reduce undesired emittance growths. Hence, the diagnostics box DO4 was modified to held the device.

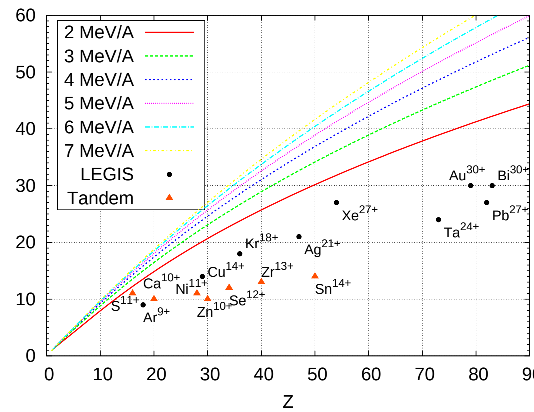

Figure 2: Most probable charge state from stripper as function of Z and energy compared to some examples of available ions out of LNL Tandem injector or foreseen for the new LEGnaro ecrIS (LEGIS).

The position along the accelerator was chosen to optimize the overall energy gain: the energy before the stripping is about 3 MeV/A, enough to enhance the charge state by 50% for the medium/high mass ions (see Fig. 2), and the remaining accelerating voltage is 2/3 of the total voltage. This means that the final energy of the stripped beam is 20 $\sim$ 30% higher than the unstripped one.

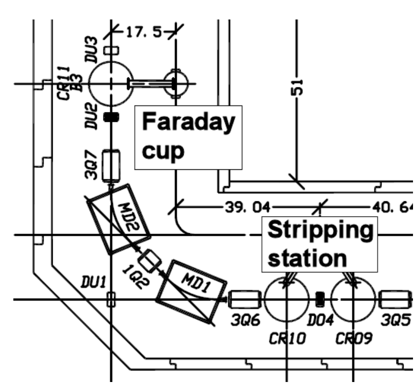

Figure 3: ALPI layout around the stripper station. The beam focalized in the diagnostic box D04 is stripped and then selected by the two dipoles MD1 and MD2.

Figure 4: Stripping probability as function of the target thickness. Semi-empirical formulas predictions are added as comparison. The data are normalized on the beam current before stripping.

## EXPERIMENTAL SET-UP

The stripper station foresees a carousel equipped with a hundred stripper foil of various thickness values (5-10-20-50 µg/cm$^2$) preceded by a collimator, which ensures a proper beam focusing at the foil plane. The system is remote-controlled via PC. Downstream the stripper station the beam is focalized by 3Q6 triplet and bent by MD1 and MD2, whose magnetic field is measured by a Tesla-meter with a precision of $1/10^6$. The beam passes through 3Q7 triplet (set to off) and is then monitored relatively to its position and current in the diagnostics box DU2, in the middle of the U-bend. This way, the first half of the U-bend acts as a spectrometer. The overall scheme is shown in Fig. 3.

The procedure consists in recording dipole field and current of both the collimated unstripped beam and of the different stripped charge states, which are selected by the dipoles. The procedure is repeated for the different foil thicknesses.

## STRIPPING DATA ANALYSIS

If $N(q)$ is the number of ions having charge state $q$ after being stripped, the charge state fraction is defined by $P(q) = N(q)/\sum_q N(q)$. Figure 4 shows the evolution of the charge state fractions for $^{90}$Zr, $^{48}$Ca (from Tandem) and $^{136}$Xe, $^{36}$Ar (from PIAVE) as a function of the carbon target thickness $t$. As the thickness is increased, the $P(q)$ curve moves towards higher charge states. The equilibrium thickness $t_\infty$ is reached when the average charge state $\bar{q} = \sum_q P(q)$ stops raising.

The $\bar{q}$ as function of $t$ (Fig. 5) can be fitted by

$$\bar{q}(t) = q_0 + (\bar{q}_\infty - q_0)\ e^{-\frac{t}{k}}, \tag{1}$$

where $q_0$ is the charge of the beam before stripping and $\bar{q}_\infty$ is the most probable charge state for $t_\infty$. This formula, already used in [3], is misleading because the beam loses part of its energy as it passes through the foil, resulting in a drop of $\bar{q}$ for $t >> t_\infty$. Nevertheless, for low thickness it is very useful and it is easy to get the $\bar{q}_\infty$. From the fit it possible to obtain an estimate of the $t_\infty$ as well. Assuming that $t_\infty \simeq 5\ k$, the results are reported in Tab. 1.

Equilibrium distributions may be approximately represented by a normal distribution,

$$P(q) = \frac{1}{d\sqrt{2\pi}} \exp\left(-\frac{(q-\bar{q}_\infty)^2}{2d^2}\right)$$

with $d^2 = \sum_q (q-\bar{q}_\infty)^2 P(q) - 1/12$.

A large collection of data from stripping experiments was analyzed by H. D. Betz in [4]. In particular he summarizes all the semi-empirical formulas for $\bar{q}_\infty$ and $d$ published up to that time, listing them by stripper material, Z of the ions and energy range. Among those, only two fit the conditions for the present experiment (Carbon foils, medium/high Z, E ∼ 3 MeV/A): Dmitriev and Nikolaev (D&N) and Baron and Delaunay (B&D). The predictions by these formulas (Tab. 1) match both the maximum $\bar{q}$ found in the data distributions and the $\bar{q}_\infty$ from the fit.

Concerning the beam energy loss through the stripper, the data in Fig. 6 are linearly fitted by

$$\Delta\mathrm{E}(t) = \delta\mathrm{E} + \Delta\mathrm{E}/\Delta\mathrm{x} \cdot t, \quad (2)$$

where ΔE/Δx is the stopping power and δE is the error on the beam energy before stripping (see Tab. 1). For all the four beams, the former perfectly matches the value calculated via SRIM program [5]. On the contrary, the latter is not compatible with zero: a systematic error was clearly committed in the energy measurement, probably due to a slight misalignment of the beam line. The problem will be investigated promptly.

## CONCLUSIONS

- $^{136}$Xe$^{34+}$ was easily transported to the experiment: the final energy reached 1.1 GeV (8.1 MeV/A), 20% more of the energy of the unstripped beam (923 MeV). The beam current on target was greater than 1 pnA, but the transmission in the ALPI high-energy branch was limited to 50%, probably due to an unexpected longitudinal emittance growth. A better control over the longitudinal focusing at the foil plane is therefore mandatory.

- $^{90}$Zr$^{28+}$ was transported only up to half of the high-energy branch. Due to the low current of the selected charge state (< 1 pnA), the cavity setting was extremely difficult and the right synchronous phase setting could not be guaranteed.

Table 1: Data analysis. The equilibrium thickness is in [µg/cm$^2$], energy in [MeV/A] and the stopping power in [keV/µg/cm$^2$].

| | $^{136}$Xe$^{23+}$ | $^{90}$Zr$^{13+}$ | $^{36}$Ar$^{8+}$ | $^{48}$Ca$^{9+}$ |
|---|---|---|---|---|
| E | 2.475 | 2.614 | 3.206 | 3.487 |
| max $\bar{q}$ | 33.9 ± 0.4 | 27.9 ± 0.7 | 15.0 ± 0.4 | 16.9 ± 0.3 |
| D&N | 35.8 | 28.5 | 15.0 | 16.7 |
| B&D | 34.5 | 27.9 | 15.3 | 17.0 |
| $\bar{q}_\infty$ | 33.9 | 27.9 ± 0.7 | 14.8 ± 0.1 | 16.6 ± 0.2 |
| $t_\infty$ | 24 | 13 ± 3 | 9 ± 3 | 15 ± 3 |
| ΔE/Δx | 78.8 | 62 ± 6 | 18 ± 3 | 22 ± 6 |
| SRIM | 82.9 | 58.1 | 19.4 | 22.7 |
| δE (‰) | 8.6 | 4.6 ± 0.8 | 7.7 ± 0.5 | 2.1 ± 1.5 |

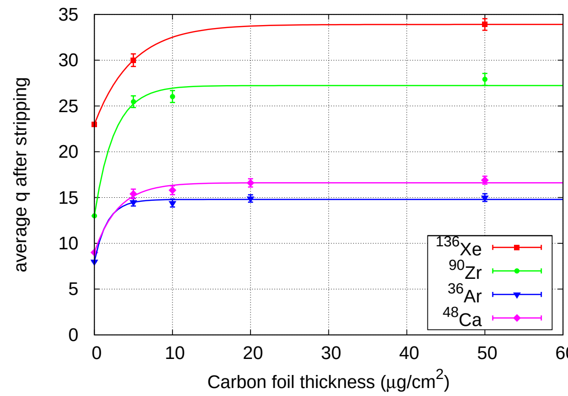

Figure 5: Beam average charge $\bar{q} = \sum_q P(q)$ as a function of target thickness. Fit by Eq. 1.

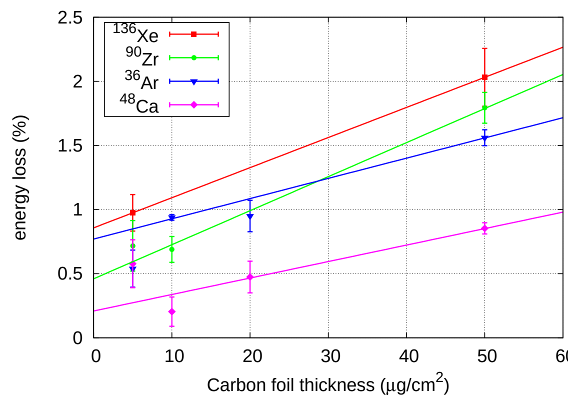

Figure 6: Beam energy loss as a function of the target thickness. Fit by Eq. 2.

- $^{36}$Ar$^{15+}$ was transported to the experiment with some troubles due the failure of the last cryostat before the stripper station. The final energy reached 450 MeV, whereas the energy without stripping was 300 MeV. The lack of the four cavities did not allow to focus longitudinally the beam at the foil plain and the transmission of the high-energy branch was extremely low (20%).

- $^{48}$Ca$^{17+}$ was not transported since the current was too low for the synchronous phase setting.

The acceleration was successful only for the beams coming from PIAVE thanks to the high current provided by the ECRIS ion source. The low-energy branch beam dynamics must be carefully optimized to obtain a strong longitudinal focusing at the foil plane.

# PLANS FOR A SUPERCONDUCTING H$^-$ LINAC (SPL) AT CERN

O. Brunner, S. Calatroni, E. Ciapala, R. Garoby, F. Gerigk , A.M. Lombardi, R. Losito, V. Parma, C. Rossi, J. Tuckmantel, M. Vretenar, W. Weingarten, CERN, Geneva, Switzerland

*Abstract*

As part of the upgrade of the LHC injector complex at CERN, the construction of a 4 GeV Superconducting Proton Linac (the SPL, in fact an H$^-$ accelerator) is planned to begin in 2012. Depending upon physics requests, it should be upgradeable to 5 GeV and multi-MW beam power at a later stage. The construction of Linac4, its low energy front end, has started at the beginning of 2008. A full project proposal with a cost estimate for the low power version of the SPL aimed at improving LHC performance has to be ready for mid-2011. As a first step towards that goal, essential machine parameters like RF frequency, cooling temperature and accelerating gradient have recently been revisited and plans have been drawn for designing and testing critical components.

## INTRODUCTION

The foreseen upgrade of the LHC injector complex [1] will entail the construction of PS2, a new 50 GeV synchrotron and of the SPL as its injector. The SPS will not be replaced, but it will be significantly upgraded. The layout of these new accelerators on the CERN site has been decided [2] and Linac4 [3], the SPL front-end, is being built at its final location (Fig. 1).

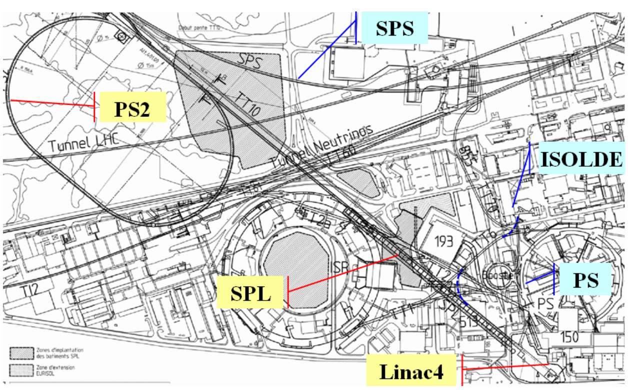

Figure 1: Layout of the new injector complex.

The flexibility and the potential of evolution of the SPL will make it an important asset for physics in the future [4]. As injector of PS2, only a 4 GeV low power version of the SPL is needed ("the "LP-SPL"). For a neutrino facility, the LP-SPL would have to be upgraded to 5 GeV and 4 MW of beam power, and accompanied with an accumulator and a compression ring to meet the required time structure of the beam [5]. For a Radioactive Ion Beam Facility of the next generation [6], a similar beam power would also be required at 2.5 GeV. A summary of the specifications of the accelerator in its different possible phases of implementation is given in Table 1.

As a first step in the preparation for the project proposal to be submitted to the CERN Council by mid-2011, the choice of the basic parameters of the SPL [7] has been revisited during the past months in view of optimizing synergy with the worldwide development effort on superconducting accelerating structures cavities. The RF frequency was therefore reconsidered, as well as the cooling temperature of the superconducting cavities and the foreseeable accelerating gradients [8, 9, 10].

Table 1: Main Characteristics of the Successive Phases of Realization of the SPL

| | LP-SPL | SPL (5 GeV) | SPL (2.5 GeV) |
|---|---|---|---|
| Users | PS2 ISOLDE | + ν facility | + RIB facility |
| T [GeV] | 4 | 5 | 2.5 |
| $P_{beam}$ [MW] | 0.2 | 4 | 4 |

| $T_{pulse}$ [ms] | 1.2 | 0.4 | 0.8 |

## DESIGN OPTIONS

The RF frequency of 352 MHz has been selected for Linac4, because it is very well matched for use in the low energy front end of a proton linac and because of the large inventory of RF hardware available at that frequency since the decommissioning of LEP. Hence only harmonics of 352 MHz can be considered for acceleration after Linac4 (160 MeV). The three design options which have been compared [9] (Table 2) were especially aimed at analysing the interest of 1408 MHz which is close to the frequency used in the ILC and X-FEL projects.

An updated survey of recent experimental results, confirmed the 2006 conclusion [7, 10] that the maximum accelerating gradient of bulk Niobium cavities only depends on geometry ($\beta_{geometrical}$) and on the quality of the surface treatment techniques, and not on the RF frequency. It is therefore assumed when comparing the length of the different options that the superconducting elliptical cavities operate at an accelerating gradient corresponding to the same peak surface field of 50 MV/m, as in a β=1 cavity with an accelerating gradient of 25 MV/m. Their characteristics are given in Table 3.

The "Nominal" option in Table 2 is a slightly improved version of the SPL design published in 2006 [7]. It uses only 2 types of 5 cell elliptical cavities and has a length of 439 m.

Table 2: SPL Design Options

| | Nominal | High frequency | Hybrid |
|---|---|---|---|
| Frequency [MHz] | 704 | 1408 | 352/1408 |
| Type of cavities | elliptical | elliptical | spoke/elliptical |
| $\beta_{geometrical}$ | 0.65/0.92 | 0.6/0.76/0.94 | 0.67/0.8/0.94 |
| Number of cells/cavity | 5/5 | 7/9/9 | 4/5/9 |
| Input energies/section [MeV] | 160/581 | 160/357/884 | 160/392/758 |
| Accelerating gradient* [MV/m] | 19.4/24.2 | 18.1/21.7/24.2 | 8.5/9.5/24.2 |
| Number of cavities/focusing period | 3/8 | 2/4/8 | 3/4/8 |
| Number of cavities | 42/200 | 30/40/208 | 27/24/216 |
| Total number of cavities | 242 | 278 | 267 |
| Length of sc linac | 439 | 499 | 485 |

* Normalized for elliptical cavities to a peak surface field of 50 MV/m.

Table 3: Estimated Characteristics of SC Cavities

| f [MHz] | $\beta_{geometric}$ | R/Q [Ω] | $Q_0$ [$10^9$] @4.5/2 K | $E_{acc}$ [MV/m] |
|---|---|---|---|---|
| 704 | 0.65 | 285 | 0.3/5.8 | 19.4 |
| 704 | 0.92 | 501 | 0.4/7.7 | 24.2 |
| 1408 | 0.60 | 441 | 0.1/2.3 | 18.1 |
| 1408 | 0.76 | 671 | 0.12/2.5 | 21.7 |
| 1408 | 0.94 | 931 | 0.15/3.2 | 24.2 |

In the “High frequency” option, 1408 MHz elliptical cavities are used immediately after Linac4. To preserve comparable real-estate gradient, cavities with more cells must be used, which reduces their energy range and forces to have three different types. Moreover, the accelerator length has to be 60 m longer because of the longer matching section needed by the x4 frequency jump.

In the “Hybrid” option, the transition to 1408 MHz is done at 758 MeV only, using spoke cavities operating at 352 MHz immediately after Linac4. Two different types of Spoke and one type of elliptical cavities are needed. The total length remains 46 m longer than in the nominal case.

## ANALYSIS

### *Beam Dynamics*

Similar design principles are used in all options, using similar focusing periods and avoiding space charge resonances by keeping an approximately constant ratio between transverse and longitudinal phase advances. Beam dynamics performance is compared in terms of r.m.s. emittance growth and sensitivity to RF field errors.

Transverse emittance growth is small in all cases [between 1.5 (5.3) and 5.6 (8.2) % for $\varepsilon_X$ (resp. $\varepsilon_Y$)], with a slight advantage for the “hybrid” option. The situation is more contrasted in the longitudinal phase plane where the “high frequency” option is clearly worse (12 % blow-up instead of 6.8 % and 2.5 % in the “nominal” and “hybrid” cases). This is confirmed by the analysis of the effect of RF field errors and energy/phase jitter of the Linac4 beam, 4.2 % of the simulation runs showing particle loss with the “high frequency” option.

### *Impact of Frequency on Cavity Parameters*

The characteristic impedance R/Q of a one cell elliptical cavity with a given geometry is independent of its resonant frequency f. The impedance per unit of length is then proportional to f.

The stored energy, for the same accelerating gradient, scales like the volume as $1/f^3$. Hence the energy stored in a 1408 MHz multi-cell cavity is ¼ of the energy stored in a 704 MHz cavity of the same length (and less cells). Since SPL cavities are pulsed, filling them with RF field uses four times more wall-plug power at 704 MHz.

For longitudinal High Order Modes (HOM), similar reasoning shows that the short range wake-field is 4 times larger in a 1408 MHz multi-cell cavity. The impedance for long range longitudinal wake-fields is between 8 and 16 times larger, depending upon the mode. The impedance for transverse long range dipole modes is between 8 and 32 times larger, resulting in a reduction by the same factor of the threshold for the onset of beam break-up.

In the case of real/imperfect structures, the production scatter in the individual cell frequencies and end-cell correction for the fundamental mode disturbs the HOM field profiles. This makes their coupling and hence their damping more uncertain by a factor 2 to 4 in the 1408 MHz case.

### *Impact of Frequency on RF Hardware*

RF equipment is more compact at higher frequency, which increases the difficulty to dissipate the heat generated at ~10 % duty cycle. 1 MW class hybrids and amplitude & phase modulators will be especially challenging to design at 1408 MHz. For klystrons, manufacturers have clearly expressed their reluctance for similar reasons.

### *Cryogenics Issues*

The design of the SPL cryomodule will re-use as much as possible of the state-of-the-art development made for the ILC. Static cryogenic losses are minimized using a long cryomodule with a high packing factor and containing the helium supply and return pipes. The pumping return line is also a structural element securing the alignment of the cavities and magnets. It is however impossible to duplicate exactly the ILC device because of the 1.7 % slope of the SPL (ILC: 0.6 %), and because of the 10 times higher duty factor of the SPL which imposes new designs for the RF and HOM couplers.

The quality factor $Q_0$ estimated [9] at the indicated gradient for the different types of superconducting elliptical cavities is shown in Table 3. It is more than 20 times larger at 2 K than at 4.5 K, independently of frequency, and more than 2.5 times higher at 704 than at 1408 MHz. Taking these estimates and static loads [7] into account, the equivalent cryogenic load of the 5 GeV-4 MW SPL for the "nominal" and high frequency" options is given in Table 4. Electrical power consumption imposes clearly to operate cavities at much lower temperature than 4.5 K.

Table 4 also shows the power required by RF which is ~9 MW larger at 704 MHz because of the larger stored energy in the cavities (see above).

Table 4: Cryogenic load and electrical consumption of the 5 GeV/4 MW SPL

| Option [see Table 2] | $T_{cryo}$ [K] | $Q_{eq\ @\ 4.5\ K}$ [kW] | $P_{el}$ (cryo) [MW] | $P_{el}$ (RF) [MW] |
|---|---|---|---|---|
| "Nominal" | 2 | 20.8 | 5.2 | 25.5 |
| "Nominal" | 4.5 | 95.4 | 23.9 | 25.5 |
| "High frequency" | 2 | 18.3 | 4.6 | 16.3 |
| "High frequency" | 4.5 | 81.9 | 20.5 | 16.3 |

### *Achievable Gradient*

The performance of cavities recently built for SNS and at DESY has been analysed [10]. For a yield of 90 %, the maximum achievable equivalent gradient in β=1 cavities is between 16 MV/m (SNS) and 23 MV/m (DESY). Higher gradients like the 25 MV/m presently assumed in the SPL can only be achieved after reprocessing a large number of cavities and/or with an improved surface treatment (electro-polishing). It is therefore important to design and build SPL-type superconducting cavities in the near future to arrive at a realistic estimate.

## CONCLUSION AND PLANS

The main advantage of the "high frequency" option is its smaller power consumption which may be balanced against its longer length and larger number of cavities and cavity types with respect to the "normal" option. For a high power proton accelerator where beam losses have to be minimized, it suffers however from less tolerance to energy/phase jitter of the Linac4 front end. Moreover, the high power RF components that it requires are much more difficult to design/build/buy. The "hybrid" option suffers from the same drawbacks, plus the need to develop an additional family of cavities (spokes). 704 MHz is hence confirmed as the correct choice for the frequency and ~2 K for the cooling temperature of the SPL. Although valuable for the LP-SPL, these choices are mandatory for the foreseen high power/ high duty cycle extensions.

The accelerating gradient that can be expected with a reasonable yield deserves further investigation.

The main goals of the next 3 years will hence be to:

- optimize the overall design of the SPL,
- build and test 704 MHz superconducting cavities to better estimate the achievable accelerating gradient,
- design and test a solution for stabilization of the field in pulsed mode,
- progress in the development of an $H^-$ ion source,
- design, assemble and characterize a complete high energy cryomodule.

# THE STATUS OF THE MSU RE-ACCELERATOR (ReA3)*

X. Wu[†], C. Compton, S. Chouhan, M. Doleans, W. Hartung, D. Lawton,
G. Machicoane, F. Marti, P. Miller, J. Ottarson, M. Portillo, R. C. York, A. Zeller and Q. Zhao
National Superconducting Cyclotron Laboratory, Michigan State University, E. Lansing, MI 48824, U.S.A.

Abstract

The Re-accelerator ReA3 [1] being developed at the Michigan State University is a major component of a novel system proposed to first stop the high energy Rare Isotope Beams (RIBs) created using Coupled Cyclotron Facility (CCF) by the in-flight particle fragmentation method in a helium filled gas system, then increase their charge state with an Electron Beam Ion Trap (EBIT) charge breeder, and finally re-accelerate them to 3 MeV/u to provide opportunities for an experimental program ranging from low-energy Coulomb excitation to transfer reaction studies of astrophysical reactions. The accelerator system consists of a Low Energy Beam Transport (LEBT) with an external multi-harmonic buncher, a radio frequency quadrupole (RFQ), a superconducting linac, and a High Energy Beam Transport (HEBT). The superconducting linac will use quarter-wave resonators with $\beta_{opt}$ of 0.041 and 0.085 for acceleration and superconducting solenoid magnets for transverse focusing. The paper will discuss the recent progress of R&D and beam dynamics studies for ReA3.

## INTRODUCTION

Isotope Separation On-line (ISOL) and Projectile Fragmentation (PF) are the two methods used to produce high quality RIBs for the nuclear science. Since 1989, the NSCL has been using the PF method with great success to produce fast RIBs for nuclear structure and nuclear reaction experiments, especially after the completion of the CCF and the A1900 Fragment Separator in 2001. For ReA3, RIBs from the EBIT will have an initial energy of 12 keV/u and an initial emittance of 0.6 $\pi$ mm-mrad. The ReA3 is required to accelerate RIBs with charge-to-mass ratios (Q/A) ranging from 0.2 to 0.4 and to achieve a final energy ranging from 0.3 to 3 MeV/u. The nuclear astrophysics experimental program requires the beam bunch width and the energy spread for the RIBs on the experiment target within 1 ns and 1 keV/u, respectively, which corresponding to a small longitudinal emittance of ~0.25 $\pi$ keV/u-ns. The ReA3 accelerator system consists of four segments: a Low Energy Beam Transport (LEBT) system to transport, bunch and match the RIBs from the EBIT to the RFQ, an RFQ for initial beam acceleration and focusing, a superconducting linac system for RIBs acceleration to the desired energy, and a High Energy Beam Transport (HEBT) system to deliver the RIBs to an experimental area with the required beam parameters. The entire ReA3 accelerator system will be located on a balcony in the NSCL high bay area.

## LEBT

The ReA3 LEBT will transport, bunch and match RIBs from the EBIT into RFQ. An electrostatic triple Bender is implemented in the LEBT in order to allow a stable ion source (SIS) on a high voltage platform to deliver $^4He^{1+}$ beam into the RFQ for SC linac tuning and diagnostics calibrations. It is also capable to deliver RIBs from the EBIT directly to a low energy experiment area as well as accept RIBs from a possible 2nd EBIT in the future upgrade. Figure 1 shows the layout of the ReA3 LEBT. Electrostatic quadrupoles and a solenoid magnet are used to provide transverse focusing for both RIBs and stable beam. In addition, there are four beam diagnostics stations in the LEBT for proper beam transverse and longitudinal matching into the RFQ. To achieve a small longitudinal emittance, an external Multi-Harmonic Buncher (MHB) is used in the LEBT, which has been constructed and tested at MSU recently [2].

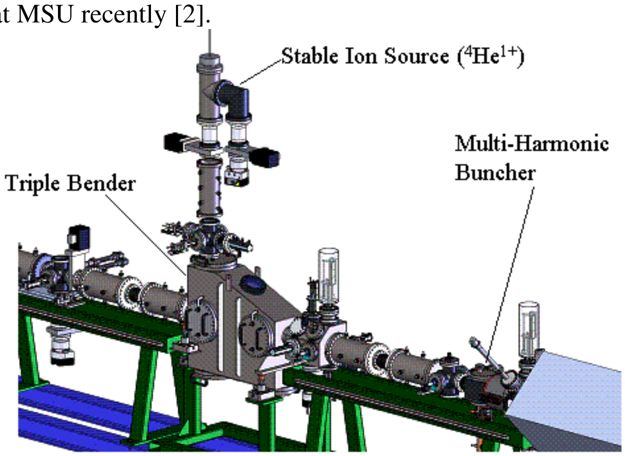

Figure 1: The layout of the ReA3 LEBT.

Figure 2 shows the structure of the triple bender. It consists of three 75° spherical benders and two 15° parallel plate kickers. The spherical bender has a bend radius of 250 mm and a gap of 80 mm. For a maximum initial accelerating voltage of 60 kV, potentials of ±19.2 kV are required to bend beam by 75°. The parallel plate kicker has a gap of 120 mm, and requires potentials of ±9.3 kV to deflect beam by ±15°. Herzog shunt plates grounded to the vacuum chamber are used for limiting the fringe electric fields at the entrance and exit of the electrodes. A gap of 12 mm separates the shunt plates and the electrodes. COSY INFINITY [3] and SIMION [4] were used for beam simulations and optimizations of the shape of the electrodes and the shunt plates.

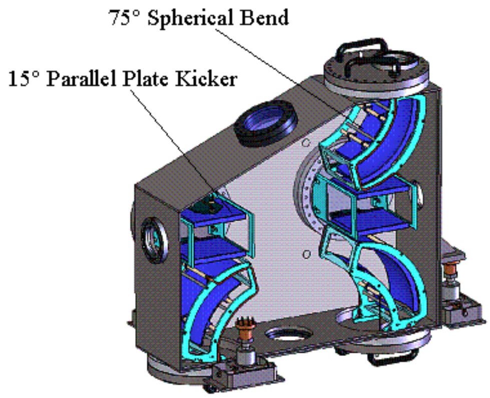

Figure 2: The structure of the triple bender in LEBT.

The beam simulations for RIBs from the EBIT and the $^{4}He^{1+}$ beam from the stable ion source were performed and results show both were well matched transversely and longitudinally into the RFQ. Figure 3 shows the beam envelopes in the LEBT. The triple bender was active only for the stable beam.

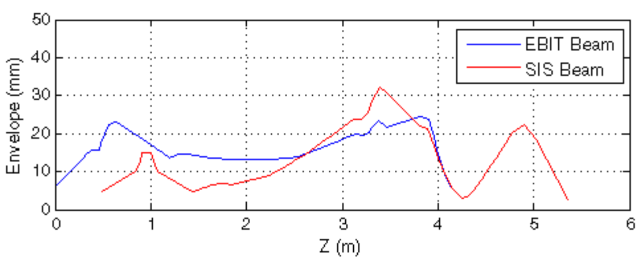

Figure 3: Beam envelopes in the LEBT for RIBs from the EBIT and He beam from the stable ion source.

## RFQ

The ReA3 RFQ [5] will accelerate RIBs from 12 keV/u to 600 keV/u with a Q/A ratio of 0.2 to 0.4. The 4-rod structure, CW, room temperature RFQ is currently under design and construction at Frankfurt University [6]. Table 1 lists the main parameters of the RFQ. Together with the external MHB in the LEBT, the ReA3 RFQ will achieve a 90% longitudinal emittance of ~0.29 π keV/u-ns in order to meet the beam requirement for ReA3. The transmission efficiency of the RFQ is about 82%. The RFQ will have an Aluminum tank and improved cooling channels. The delivery of the RFQ, and initial RF and beam tests are expected in 2009.

Table 1: Main RFQ Parameters

| | |
|---|---|
| Frequency (MHz) | 80.5 |
| Length (m) | 3.5 |
| Mid-cell radial aperture (mm) | 7.3 |
| Vane tip radius (mm) | 6.0 |
| Inter-vane voltage (kV) | 86.2 |
| Peak field ($\square_{kilpatrick}$) | 1.6 |
| Peak electric field (MV/m) | 16.7 |

## SUPERCONDUCTING LINAC

The ReA3 superconducting linac will provide the acceleration or deceleration of the RIBs from RFQ output energy of 600 keV/u to the desired final energies ranging from 0.3 to 3 MeV/u on target. The SC linac consists of a total of three cryomodules with fifteen 80.5 MHz λ/4 SRF cavities. Eight superconducting solenoid magnets inside cryomodules will provide the transverse focusing. Each solenoid will have two dipole coils to provide alignment error corrections. Figures 4 and 5 show the structures of the λ/4 SRF cavities and the layout of cryomodules of the ReA3 SC linac. Four beam diagnostics stations located in the warm region between cryomodules will be used for beam and SC linac tuning.

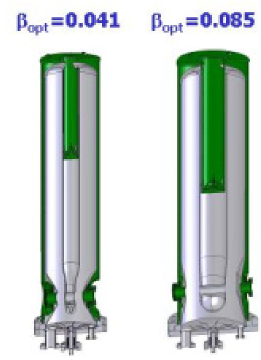

Figure 4: λ/4 SRF cavities used in ReA3 SC linac.

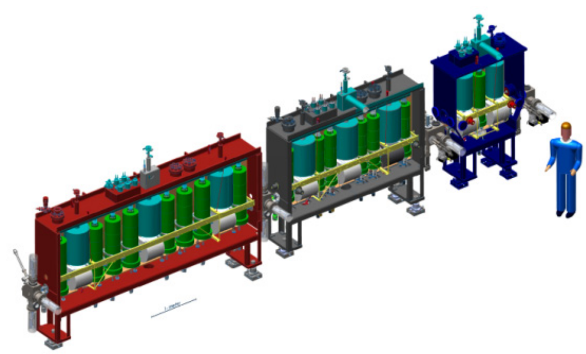

Figure 5: The layout of the cryomodules of the ReA3 SC Linac.

Both λ/4 SRF cavities have been prototyped and tested at MSU, and the RF test results show both cavities exceeding the design field levels by a comfortable margin. A prototype cryomodule consisting of a 80.5 MHz $\beta_{opt}$ = 0.085 λ/4 cavity and a 322 MHz $\beta_{opt}$ = 0.285 λ/2 cavity, with helium vessels made of titanium, was fabricated and tested at the NSCL recently. The superconducting focusing magnets inside the cryomodule consist of a 9 T solenoid with an integrated steering dipole and a 31 T/m quadrupole. In addition, a coaxial probe-type rf fundamental power coupler for both λ/4 SRF cavities and a prototype niobium tuning plate for $\beta_{opt}$ = 0.041 cavity been designed, fabricated and tested at MSU. The detailed test results for the prototype cryomudule, tuner and power coupler will be discussed in separate papers [7, 8].

## HEBT

The REA3 HEBT will transport RIBs from the SC linac to the experiment area. Figure 6 shows the layout of the proposed HEBT for ReA3. Two achromatic bending sections were used to bring RIBs from the mezzanine floor to the ground floor while limit the beam emittance growth. A cryomodule with a single λ/4 SRF cavity with $\beta_{opt}$ = 0.041located between the achromatic bending sections was used to rotate the beam longitudinal phase space, minimizing the final beam energy spread in order to achieve the required beam bunch width and the energy spread for the RIBs on the experiment target within 1 ns and 1 keV/u.

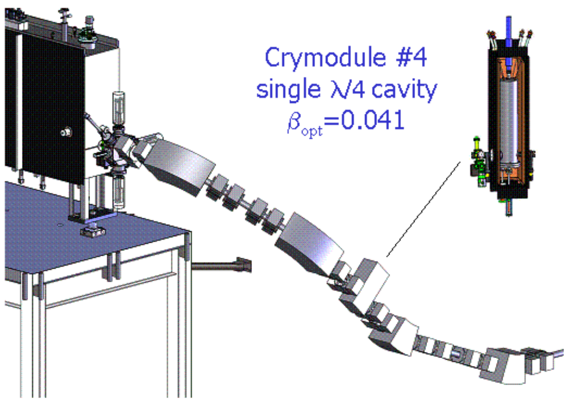

Figure 6: The layout of the ReA3 HEBT.

The beam envelope in the SC linac and HEBT for RIBs accelerated to 3 MeV/u with a Q/A of 0.25 is shown in Figure 7. Beam simulations show that the performance for the RIBs decelerated to ~300 keV/u was similar. About ~88% of beam on target was found to be within the required bunch width and energy spread.

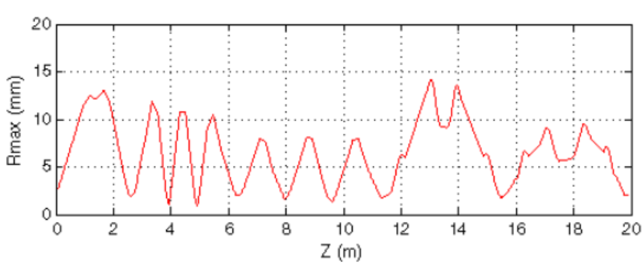

Figure 7: Beam envelope in the SC linac and HEBT.

## BEAM DIAGNOSTICS

Many of the beam diagnostic devices for ReA3 are similar to those in use at the ISAC-II accelerator at TRIUMF [9, 10]. They are deployed in various combinations at four diagnostic stations in the LEBT, and the other four in the SC linac section. Because of intensity requirements, many of the devices are usable only with a stable ion beam from either the stable ion source in the LEBT or the EBIT. The preliminary tuning of the RFQ and SC linac will be performed using such a stable beam of the same charge-to-mass as the RIBs.

A movable slit plate containing a vertical and a horizontal slit can be scanned through the beam to provide transverse beam profiles using the beam current registered on the Faraday cup behind it. A phosphor viewer plate is used in diagnostics stations in the LEBT to display the beam cross section. A series of grids for attenuation of the beam current may be inserted if needed to control the stable ion beam intensity. There is provision for installing an emittance rig in one of the diagnostics stations in the LEBT. A 2-dimensional Allison type scanner similar to those used in the CCP injection line will be used for initial beam studies for ReA3.

Downstream from the MHB in the LEBT, there are up to 5 diagnostics stations where a high-resolution timing detector [9] can be used to characterize the longitudinal phase space distribution of the beam and to measure the beam velocity. The beam particles release secondary electrons from a biased coaxial wire inside a metal cylinder, some of which are detected by a multi-channel plate behind a hole in the cylinder wall. The time structure of the beam is directly indicated by the time distribution of the electrons. In addition, up to four scattered particle monitors [10] based on Si heavy ion detectors measuring the energy of elastically scattered beam from a thin gold foil.

# LINAC FRONT-END UPGRADE AT THE CANCER THERAPY FACILITY HIT

M. Maier[#], W. Barth, B. Schlitt, A. Orzychevkaya, H. Vormann, S. Yaramyshev

GSI, Darmstadt, Germany

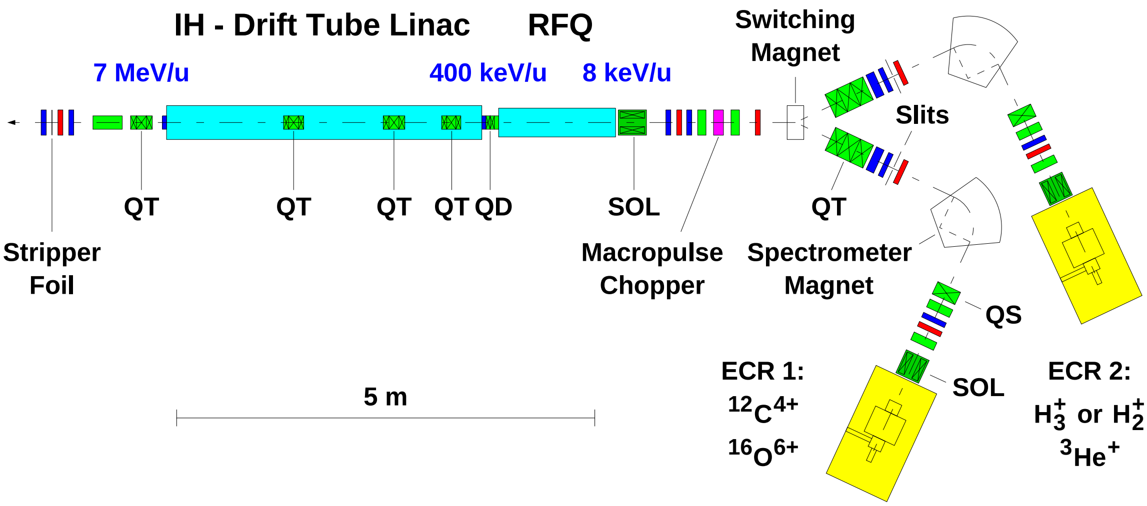

Figure 1: Layout of the Injector Linac [1]. QS = Quadrupole singulet, QT = Quadrupole triplet, SOL = solenoid, magnetic focusing and steering magnets (green), profile grids and the tantalum screen (red), and the beam current monitors (blue).

*Abstract*

A clinical facility for cancer therapy using energetic proton and ion beams (C, He and O) has been installed at the Radiologische Universitätsklinik in Heidelberg, Germany [1]. It consists of two ECR ion sources, a 7 MeV/u linac injector, and a 6.5 Tm synchrotron to accelerate the ions up to 430 MeV/u. The linac [2] comprises a 400 keV/u RFQ [3] and a 7 MeV/u IH-DTL [4] operating at 216.8 MHz and has been commissioned successfully in 2006 [5]. Yet the overall achieved transmission through the injector linac did not ecxeed 30 % due to a mismatch of the beam at the RFQ entrance. Thus a detailed upgrade programm has been started to exchange the RFQ with a new radial matcher design, to correct the missalignment and to optimize beam transport to the IH-DTL. The aim is to achive a sufficient overall linac transmission above 60%. Since August 2008 the new RFQ is at a test setup in Risø, Danmark. There a test bench comprising a full ion source and LEBT setup to commission the RFQ has been installed by Danfysik.

## INTRODUCTION

The commissioning of the injector Linac [5] shown in Figure 1 was performed in three consecutive steps for the LEBT, the RFQ, and the IH-DTL.

Because of the low transmission (~30 %) achieved for the injector Linac an upgrade program was initiated in 2007. The timeline of the commissioning and the upgrade program is given in Table 1.

## LINAC FRONT-END UPGRADE

As a result of the Linac commissioning and excessive beam dynamics simulations the reasons for the low RFQ transmission were found to be:

- The poor performance of the ion sources,
- field errors of the Solenoid matching the beam to the RFQ,
- RFQ input radial matcher section and
- the deformed electrodes due to mechanical stress on the tank.

As first the Solenoid matching the beam to the RFQ has been exchanged and the result is shown in Figure 3.

During this solenoid exchange a measurement campaign was performed to obtain sufficient data for optimization of the input radial matcher design.

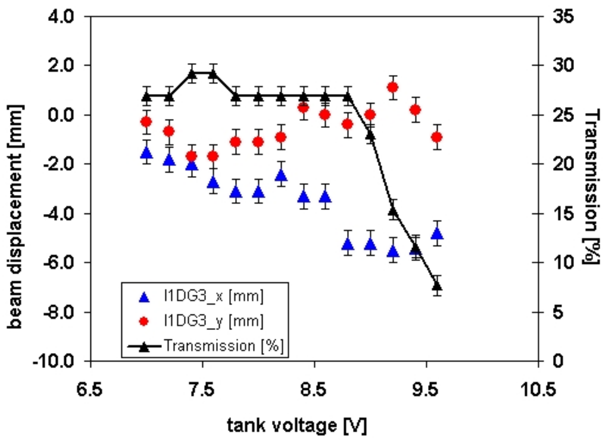

Figure 2: Transmission and beam displacement of the RFQ measured during commissioning in 2006.

Yet, because of unstable conditions of the ion sources this data could not be used. Instead, from the emittance measurements of the commissioning in 2006 a particle distribution was generated (Figure 4) and used for simulation with the simulation code Dynamion [6].

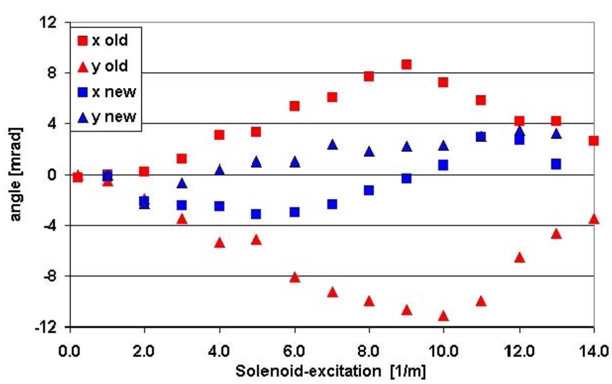

Figure 3: Steering of the beam behind the old and new Solenoids depending on their field strengths.

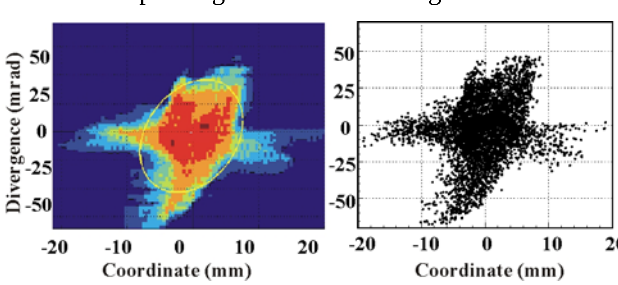

Figure 4: Measured $^{12}C^{4+}$ emittance at the RFQ entrance (left) and generated particle distribution to be used for simulation.

This distribution was transformed backwards through the solenoid. By varying the field strength in the transformations forward it was found that it is not the total emittance but the mismatch of the Twiss-parameters that leads to the beam losses. The possible improvement changing the input radial matcher is shown in Figure 5.

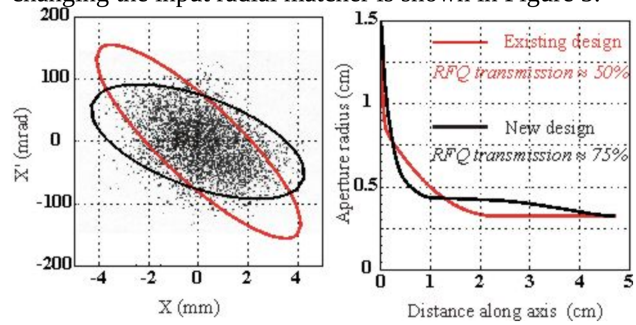

Figure 5: Dynamion simulation of the transmission improvement through the old and the new input radial matcher design using the particle distributions generated from the measured emittances (Figure 4).

During commissioning the alignment of the electrodes has been checked and a strong bending due to mechanical stress on the structure was found. A measurement of this deformation is shown in Figure 6 for the CNAO RFQ [7], a copy of the HIT RFQ. This deformation most likely happened during the alignment procedure and is of the same order of magnitude for both RFQs. A new stiffened tank design with thicker walls (6 mm instead of 4 mm), extra supports and 3 instead of 4 fixation points should solve this problem for the new RFQ design.

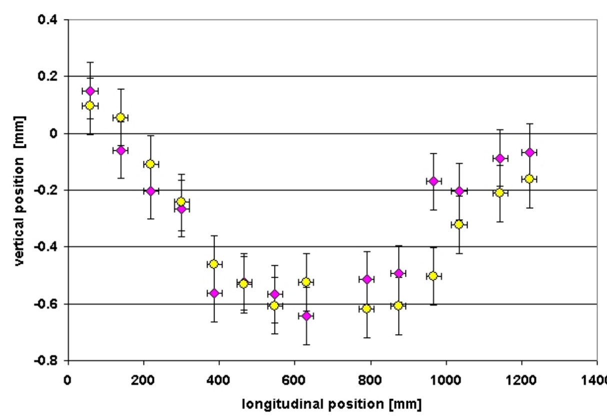

Figure 6: Vertical deformation of the CNAO RFQ electrodes measured on the upper and lower rods for a fixed (red) and loosened (yellow) tank.

Before the electrodes for the new design of the RFQ were machined, test pieces have been prepared to check the machining procedures for their feasibility. After the whole RFQ has been assembled, aligned and RF tuned it was shipped to a test setup of Danfysik in Risø, Denmark. This type of RFQ has an integrated rebuncher section (Figure 8) which has to be adjusted in a first commissioning step as described in [8]. The adjustment of the rebuncher voltage, which is a necessary prerequisite to commission the RFQ, has highest priority.

Besides an investigation of the high energy end of the RFQ is foreseen. The data obtained during commissioning in 2006 indicates that there might be particle losses also in the rebuncher section.

Figure 7: Final test piece of the RFQ radial matcher section to check the production procedures.

Beam losses definitely occurred in the doublet following the RFQ. Yet this fact does not allow for simulating the data further back as at this point all information about the transversal beam properties are lost.

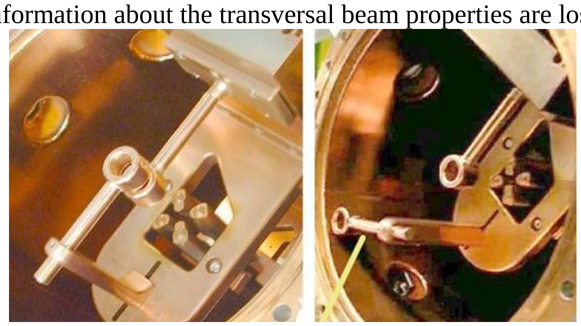

Figure 8: Rebuncher structure as mounted for operation (left) and in a dummy position to measure the output energy of the RFQ itself (right).

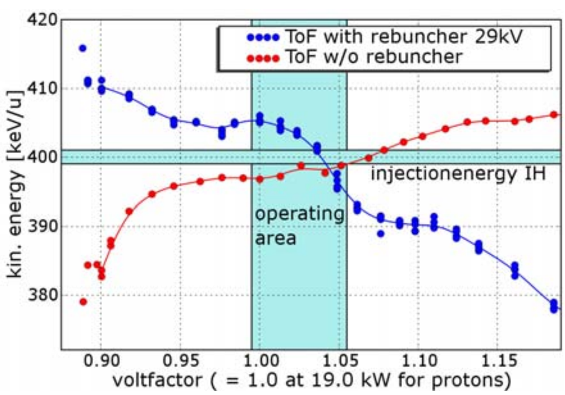

Figure 9: Measurement to adjust the rebuncher gap voltage [6].

The measurement campaign in Risø has started in September 2008 and for the first part the test bench shown in Figure 10 is equipped with three pickups a profile grid and an end cup for electron suppression. With this equipment the first energy scan without the rebuncher section shown in Figure 11 could be obtained.
Presently the rebuncher is adjusted to the design position continuing the beam energy measurements. After the rebuncher setting is fixed it is foreseen to change the test bench setup to allow for beam current and emittance measurements. Due to narrow apertures in front of the pickups it is not possible to do so with the provided setup for energy measurements.

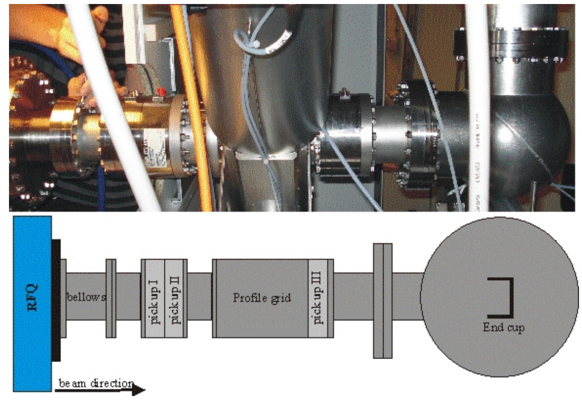

Figure 10: A photo of the diagnostics test bench as currently installed at Risø for RFQ energy measurements (top) and a schematic drawing (bottom).

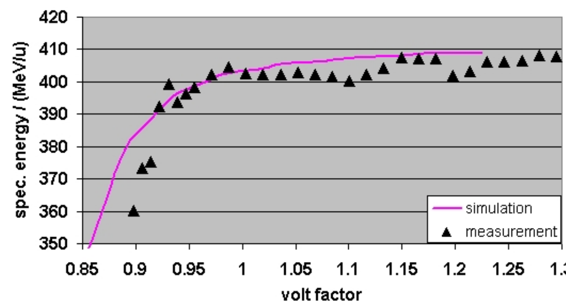

Figure 11: The RFQ energy scan with the rebuncher in the dummy position (blue) and the theory curve (red).

The planed second setup will consist of a beam current monitor, an emittance scanner and an end cup.

## OUTLOOK

After the commissioning of the RFQ at the test bench in Risø in autumn 2008 it will be shipped to Heidelberg and included in the system during the first available shutdown period. A significant improvement in the overall Linac transmission up to 60% is expected.

## ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the fruitful collaboration with the Heidelberg Ion therapy HIT and IAP Frankfurt as well as towards the companies NTG, Danfysik and Siemens for their contribution.

*Abstract*

We succeeded to accelerate more than 18mA of $C^{6+}$ ions with Direct Plasma Injection Scheme (DPIS) of YAG laser in 2004. We believe that these techniques are quite effective for pulse accelerator complexes (linac and synchrotron) such as heavy ion cancer therapy. We study a new hybrid single cavity $C^{6+}$ linac for heavy ion cancer therapy. This hybrid linac, combined with radio frequency quadrupole (4rod-RFQ) electrodes and drift tube electrodes into a single cavity, is able to downsize the linac system and reduce the peripheral device. High intensity beam of $C^{6+}$ by DPIS have many advantage for the synchrotron of heavy ion cancer therapy. We will present the design procedures of this hybrid linac, which is base on a three-dimensional electromagnetic field simulation.

## INTRODUCTION

In order to verify DPIS, accelerator test was carried out using Tokyo Institute of Technology (Titech) RFQ heavy ion linear accelerator and $CO_2$ laser heavy-ion source in 2001. The accelerated carbon beam obtained 9.2mA of $C^{4+}$ was much higher than designed currents. [1-4 ] To confirm the capability of the DPIS, we designed and fabricated a new RFQ linac to accommodate 100mA of carbon beam collaboration The Institute of Physical and Chemical Research and Frankfurt University. We succeeded to accelerate very intense carbon ions with the DPIS in 2004. The peak current reached more than 60mA of $C^{4+}$ and 18mA of $C^{6+}$ by CO2 and YAG laser, respectively [5-9]. Fig. 1 shows photographs of Titech RFQ linac and 100 mA Test RFQ linac. We believe that these techniques are quite effective for pulse accelerator complexes such as linear accelerator and synchrotron. The accelerator complexes are heavy ion cancer therapy and heavy ion inertial fusion.

We are studying a new hybrid single cavity linac [10] for Boron Neutron Capture Therapy. This hybrid linac, combined with radio frequency quadrupole electrodes and drift tube electrodes into an interdigital-H (IH) type single cavity, is able to downsize the linac system and reduce the peripheral device. From these matters, we propose a small Hybrid Single Cavity (HSC) linac for injector of heavy ion cancer therapy.

## ND-YAG LASE ION SOURCE

A Nd-YAG laser with a wavelength of 1060nm is used for this ion source. The pulse duration is 15ns(FWHM) and its energy is 400mJ. Fig.2 shows charge state distribution of Carbon ion with about 400mJ. Fig.3 shows laser power dependence of charge state distribution of Carbon ion. From these data, $C^{6+}$ ions were produced 40%. $C^{6+}$ ion beam have pulse width of about 2 $\mu$ s and about 200mA at injection point of 4 rod of RFQ.

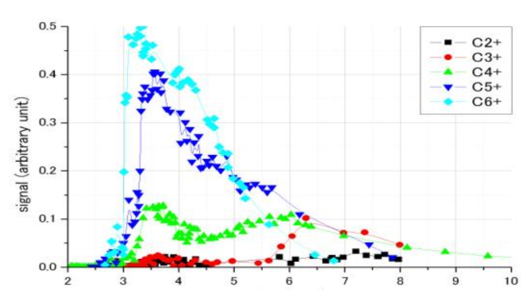

Figure 2: Charge state distribution of the Carbon ion with about 400mJ of YAG laser.

## DESIGN AND PARAMETERS

The accelerated particles are set to $C^{6+}$ more than 10 mA ( more than $2\times10^{10}$ particles/pulse) with YAG laser ion source. The operation frequency in this linac is 80 MHz. The HSC linac accelerate from 25keV/amu up to 2MeV/amu, see Table 1.

Table 1: Main parameters of $C^{6+}$ HSC Linac.

| | RFQ | BTL | DT |
|---|---|---|---|
| Accelerate particle | | $C^{6+}$ | |
| Input energy (keV/u) | 25 | 160 | 160 |
| Output energy(keV/u) | 160 | 160 | 2000 |
| Cavity diameters(cm) | 40 | 80 | 80 |
| Cavity length (cm) | 104 | 35 | 134 |
| Cavity total length(cm) | | 273 | |
| Operation power (kW) | | lower 80 | |
| Beam bore radius(mm) | 5 | 12 | 7 |
| Cell number | 160 | (10) | 15 |
| Beam focusing | RFQ | TQM | APF |
| Beam current | | 10 mA | |

The computer code RFQUICK was used to generate the cell parameters for the PARMTEQM calculation [11]. The computer code PARMTEQM was used to simulate the beam dynamics in the RFQ section. Drift tube structure section was calculated by computer code PARMIRA. Beam maching of RFQ and Dorift tube section were calculated by computer code Trace-3D.

The 3D electromagnetic simulation software MW-Studio [12] was used to calculate the resonance frequency, the electric field, the Q value and the wall loss of the cavity.

## DESIGN AND CAVITY SIMULATION

The electric field distribution of the HSC(IH) cavity must be constant through out the beam line. However the electric field of the inner IH cavity is increased towards the beam injection side. Because, capacitances of the RFQ section are larger than that of DT section. To adjust this unequal field distribution, we improved the IH cavity geometry. First, in order to modify the cavity diameter at the DT section, the field distribution was spread along the beam output side. Secondly, as the End Ridge Tuner (ERT) length was adjusted, the cavity was made to adopt a constant resonance frequency along the cavity. The electric-field strength was investigated by means of field simulations. Adjustments of realizing cavity at the ERT length were performed. Fig.4 shows modified cavity diameter and End Ridge Tuner.

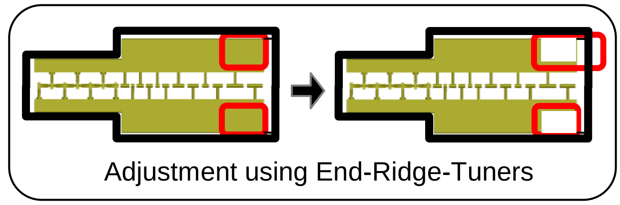

Figure 4: Modified cavity diameter and End Ridge Tuner.

The more the diameter of DT section was increased, the more the frequency of both sides were approached, and electric field was excited from input side to output side when inside diameter was 80-90cm. We calculated the electric field distribution from 280 to 360mm at 20mm intervals of ERT at the exit of the cavity. The optimum electric-field distribution was obtained with ERT length of 320mm as shown in Fig.5,6,7.

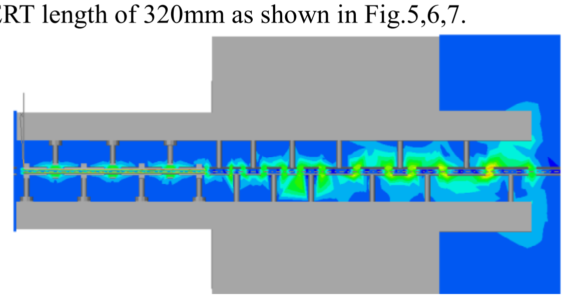

Figure 5: $C^{6+}$ HSC linac cross section and electric field.

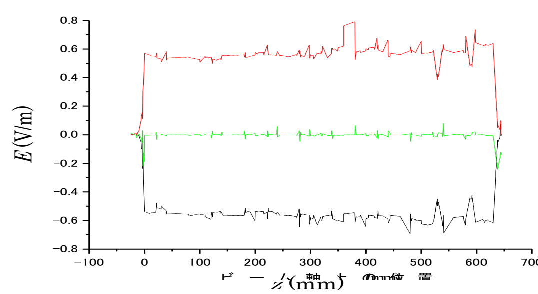

Figure 6: Electric-field distribution of RFQ section.

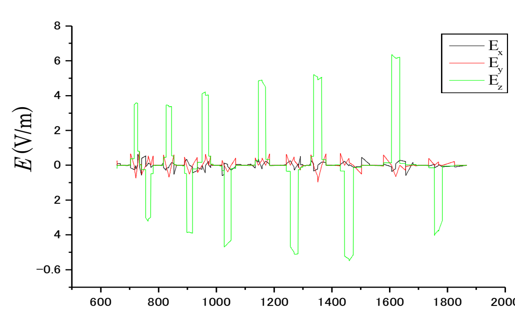

Figure 7: Electric-field distribution of DT section.

## ELECTRIC-FIELD BETWEEN RFQ AND DT SECTION

In the HSC linac, electric-field distribution in the gap region between the back-end of the 4-rod(RFQ) and injection side of DT region must be considered as shown in Fig.8-A. This electric-field have a negative effect on the acceleration beam as shown in Fig.9-A. We studied an improved electrode of drift-tube shape in which three quadrupole magnets, was inserted into this gap as shown in Fig.8-B. The electrode was able to reduce the excitation of the electric-field at the gap between 4 rods and drift tube as shown in Fig.9-B.

## HEAVY ION SYNCHROTRON OF CANCER THERAPY

DPIS techniques are quite effective for pulse accelerator complexes (linac and synchrotron) such as heavy ion cancer therapy. High intensity beam of $C^{6+}$ by DPIS have many advantage for synchrotron.

A) Effects of $C^{6+}$ ion injection

1.Striper foil system is not necessary by $C^{6+}$ ion injection. 2.Emittance growth is decrease by decrease of energy loss and energy straggling. 3.Injection energy of synchrotron is decrease to 2-3 MeV/u by no decrease of ions. 4.Operation of synchrotron is easy with no change of energy that is happened by decrease of stripper foil thickness.

B) Effects of one turn by injection of high intensity $C^{6+}$

1. Mulch turns injection system is not necessary by more than $10^9$ ions of $C^{6+}$. 2. Magnets (bending magnet, quadrupole magnet and sextapole magnet) of synchrotron are compacted by small size beam of one turn injection.

The heavy ion synchrotron is compact and use low electric power. Therefore facility of heavy ion cancer therapy will be able to smaller than present size.

## CONCLUSION

We study a new hybrid single cavity (HSC) $C^{6+}$ linac with DPIS for heavy ion cancer therapy. This HSC linac accelerate $C^{6+}$ ion from 25keV/amu up to 2MeV/amu.

Electromagnetic simulation of the cavity was done by MW-Studio. Acceleration cavity is 40cm (RFQ section) and 80cm (DT section) in diameter and 273cm in length. The operation frequency is 80MHz. Acceleration current is 10mA of $C^{6+}$ ( $2x10^{10}$particles/pulse). For this beam intensity of $C^{6+}$, The heavy ion synchrotron is compact and use low electric power. Therefore facility of heavy ion cancer therapy will be able to smaller than present size.

*Abstract*

Energy spread compression scheme for laser-produced ions by phase rotation with the use of an RF electric field synchronized to the pulse laser has been proved in principle for rather lower energies up to ~2 MeV. Its extension to higher energy around 200 MeV has been investigated with multi-gap structure assuming higher frequency of L-Band (~1.3 GHz). RF defocusing effect worried about at lower energy was found to be manageable at such a higher energy if the laser-produced-protons are well treated just after production at the target

## INTRODUCTION

Based on recent rapid development of high-power short-pulse laser with the use of Chirped Pulse Amplification, laser-produced ion beam has been proposed to be utilized as an injection beam of a medical synchrotron for cancer therapy replacing the RF linac as shown in Fig.1 [1]. For that purpose, however, the characteristics of laser-produced ion beam are not well suited. The energy spread of the laser-produced ion beam has been almost 100 % without a rather sophisticated treatment of the production target [2] or additional radial focusing scheme [3], which seems not to be suitable for operation by a tolerable repetition (~1 Hz) with good reproducibility as is required from medical use.

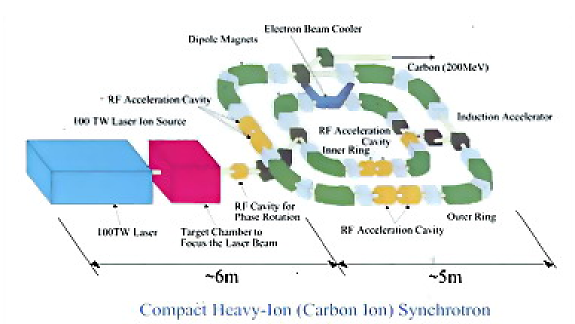

Figure 1: Layout of a medical synchrotron for cancer therapy replacing an injector linac by laser-produced ion beam.

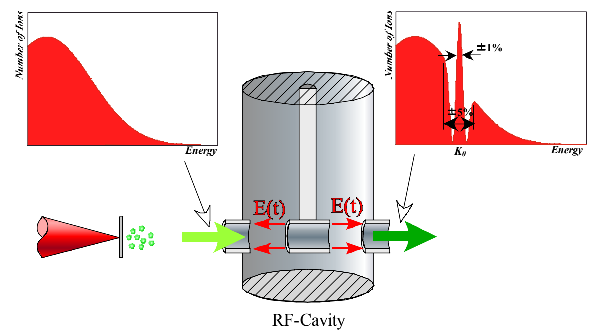

Figure 2: Illustration of the phase rotation principle.

In order to manage such a situation, a phase rotation scheme of the laser-produced ion beam with the use of an RF electric field synchronized to the pulse laser has been proposed [1]. In Fig.2, a basic concept of the phase rotation of phase rotation is illustrated. Utilizing the phase difference caused by the speed difference among ions with different energies, faster and slower ions are decelerated and accelerated, respectively in order to be put together into a central peak. Such an idea of energy spread compression of laser-produced ions by phase rotation has already been experimentally demonstrated with use of a rather smaller peak power (~10 TW) pulse laser, J-LITEX [4, 5]. Recent experiments with use of higher peak power (~100TW) laser, J-KAREN, has extended the energy of laser-produced proton up to ~4 MeV and also given us the information on the radial focusing/defocusing of such protons by the RF electric field created with the phase rotation cavity [6]. In the present paper, capability of multi-gap structure cavity for phase rotation has been considered for the case of

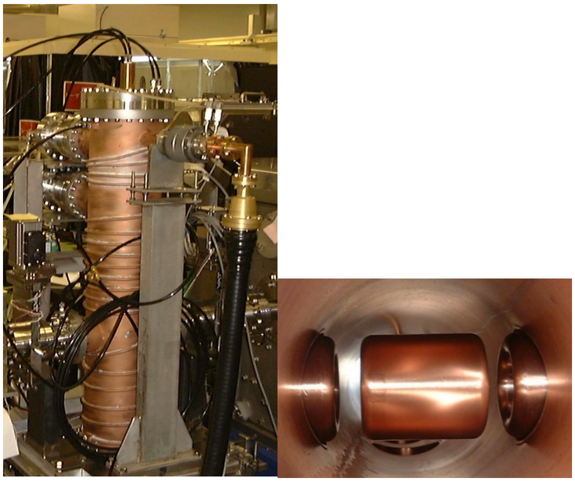

Figure 3: Fabricated two gap resonator for phase rotation of an injection beam for synchrotron with lower energy (~2 MeV).

extension to the higher energy (~200 MeV) applicable to cancer therapy directly. In the process, not only energy compression, but also radial oscillation amplitude is taken into account.

## PHASE ROTATION FOR INJECTION BEAM

For the scheme to utilize the laser-induced proton beam as the injection beam of a synchrotron to replace an injector linac, a two gap resonator with quarter wave-length as shown in Fig. 3 has been fabricated [4]. The main parameters of the cavity are listed up in table 1. The cavity is designed to enable phase rotation of the ion beam with the kinetic energy of up to 2 MeV/u for such ions as $^{12}C^{6+}$ with a charge to mass ratio of 1/2 [1].

### *Creation of Energy Peak*

The first phase rotation experiment with the use of J-KAREN has been performed with the set up as shown in Fig. 4. Due to the limited available time of J-KAREN, the energy spectrum of the laser-produced protons has been measured by their time of flight between production target and TOF detector, which, however, has been found to give a correct spectrum only for the case of without phase rotation, because due to energy change by the electric field of phase rotation cavity, time of flight of proton does not uniquely corresponds to its energy. So as to obtain correct energy spectrum of phase

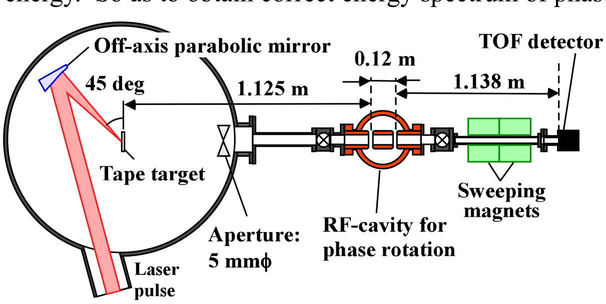

Figure 4: Experimental setup of proton-beam production and its phase rotation with the use of J-KAREN.

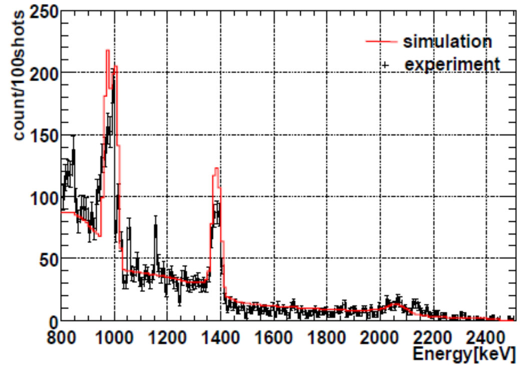

Figure 5: Energy spectrum of phase rotated laser-produced proton beam detected by a Thomson parabola. Clear peak creation has been observed at ~1.0MeV and ~1.4 MeV.

rotated protons, the next experiment with J-KAREN was performed by replacing TOF detector in Fig. 4 by a Thomson Parabola using CR39, which can give us correct energy information of detected protons. In Fig. 5, clear energy peaks formed by phase rotation are shown around 1.0 and 1.4 MeV [5]. It is shown that these peak positions coincide with the ones expected from simulation, which also coincide with the ones observed by the TOF method [6].

### *Radial Focusing Effect*

Through the experiments of phase rotation of proton beam produced by J-KAREN utilizing a two gap cavity above mentioned, radial focusing and defocusing effects as shown in Fig. 6 is observed Images of the mesh set 387 mm downstream from the production target were observed by CR39 detectors set at the positions 0.491 m down stream from the second gap of the phase rotation cavity (1.736 m downstream from the target). With

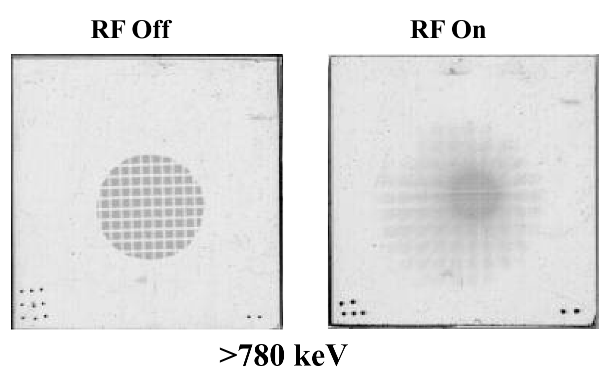

Figure 6: Observed radial focusing/defocusing effects on laser-produced protons by the electric fields of the phase rotation cavity located 1.125 m down stream from the production target. Images of the mesh set 387 mm downstream from the production target observed by CR39 detectors at the positions 1.736 m are shown for both cases with and without RF voltage of the phase rotation cavity.

application of phase rotation voltage, focusing and defocusing effects in radial motion are observed corresponding to various phases applied for protons with various energies. This is considered to be due to curved structure of the applied electric field at the phase rotation cavity, which results in the radial components of the electric field.

## MULTI-GAP STRUICTURE FOR HIGHER ENERGIES

The scheme to utilize the laser-produced protons by application of phase rotation and electron beam cooling as an injection beam of a synchrotron for cancer therapy [1] has been proved in principle up to now [4,5]. It, however, is considered a little bit complex compared with a scheme to produce directly a beam with the desired energy for cancer therapy by laser ion production and the latter scheme is eagerly pursuit although the energy attained with direct production by laser-plasma interaction is rather limited (~ 4 MeV) at the moment.

Even for proton beam, the desired energy for cancer therapy is rather high as >180 MeV for human body treatment and ~70 MeV for eye treatment. Extension of the energy of laser-produced ion has been under elaborate investigation all over the world to respond the urgent needs for wide spread use of effective cancer therapy. In addition to the increase of the attained ion energy, improvement of the characteristics of the laser-produced ion with good energy resolution and good reproducibility is one of the most important items to be investigated. For such a purpose, we have proposed to extend our previous two gap resonator to a multi-gap structure in order to increase the applicable energy to higher value without causing spark problem at the RF cavity. Expecting rapid increase of laser-produced protons, we have investigated the capability of applying the phase rotation scheme to laser-produced ions with such a higher energy (~200 MeV) as can directly be applied for cancer therapy.

### *Selection of RF Frequency*

As the RF frequency of the two gap resonator for phase rotation, we have adopted the same frequency as the source laser (~ 80 MHz) [4]. As the sparking limit of the RF electric field is proportional to square root of the frequency, it is preferable to select as high frequency as possible from this point of view, which, however, needs to be compromised with the practical aspects of hardware construction. Considering the easiness of synchronization between the RF electric field and the pulse laser together with the above requirement, we have selected the frequency of the integral (16 times) multiples of the source frequency of the pulse laser, [80.6 MHz (83.7 MHz)], in the L-Band [1290 MHz (1339 MHz)].

### *Multi-Gap Structure*

For the reference design of phase rotation of laser-produced proton to be directly applicable for cancer therapy, its energy is assumed at 200 MeV. In case we want to collect protons in the energy region of ±5% of this energy, maximum needed energy correction at a single passage through the resonator is 10 MeV. It seems to be well applicable by 12 cell resonator considering the so-called “Kilpatric limit” [7]. For the frequency ~1.3 GHz, the distance between the centres of adjacent two gaps is to be 130 mm if 200 MeV proton is assumed to pass through with the same phase. The energy compression is expected for the passage with the phase where the RF voltage is increasing, while the RF defocusing is anticipated with this phase. So as to suppress this radial defocusing, a scheme to utilize alternating phases at successive gaps has been proposed for lower energy [6]. Such radial focusing/defocusing effect, however, was found to be less dominant at the higher energy as -200 MeV from the computer simulation and it is considered to be manageable if enough focusing action has been applied before phase rotation. So it is possible to utilize every gap with the phase to compress the energy spread. Thus, the length of the phase rotation multi-gap cavity is expected to be around 1.5 m, which seems to be well compact for real medical applications.

## SUMMARY

With the use of multi-gap cavity with the frequency of L-Band (~1.3 GHz), energy peak creation by phase rotation is also expected for higher energy as ~200 MeV.

# THE FEASIBILITY OF LOW-ENERGY ELECTRONUCLEAR POWER PLANT

Yu.A. Svistunov, M.F. Vorogushin (D.V. Efremov Institune, 196641, St.Petersburg, Russia),
I.V. Kudinovich (A.N. Krylov Shipbuilding Research Institute, 196158, Moskovskoye Shosse, 44, St.Petersburg, Russia)

*Abstract*

There are examined prospects and challengers associated with the development of low-energy electronuclear power plant eliminating any possibility of uncontrolled chain fission reaction through fission in subcritical reactor with an additional neutron source. The neutron source is anticipated to be a heavy-element target irradiated with a beam of protons accelerated to several hundreds of mega-electron-volts. The intensity of external neutron source for an electronuclear reactor rated under 200-400 MW may be much less than for greater ones, and that allows reducing accelerator performances to limits that are already run in the world industry. Potential applications of such electronuclear plants include municipal, industrial and other electricity, and heat supply utilities in remote areas. The same engineering philosophy may be used on solving of the nuclear waste transmutation problem.

## INTRODUCTION

Thermal power $N_T$ which is picked out in active zone of a subcritical reactor with an outer neutron source and effective multiplying factor $K_{ef}$ is determined by formula

$$N_t = \frac{I_p n_0}{e} \cdot \frac{K_\infty}{1-K_{ef}} \cdot \frac{E_f}{\nu} \quad (1)$$

where $E_f$ - energy which is picked out under fussion of one fuel nucleus; $\upsilon$ - average number of neutrons from one act of fission; $K_\infty$ - multiplying factor of infinite reactor; $I_p$ - average current of accelerator; $n_0$ - number of neutrons which are produced by one particle after interaction with target. It is supposed now that for save of nuclear safety $K_{ef}$ must be not more than 0.98. During the active zone campaign $K_{ef}$ can decrease due to change of the fuel isotope composition (fuel burning out, toxic effect etc.) One expect $K_{ef}$ will decrease to 0.95 for fast neutron reactor. Results of modeling of active zones of gas-cooled reactor with multiplying target and $K_{ef}$ =0.96 give release of thermal power 200 MW for intensity of outer source $4.2\cdot 10^{17}$ n/s. This intensity may be achieved for $I_p$ =5mA and yield of neutron $n_0$ =13. Such yield neutrons can obtain from (UN+W) target under proton energy $E_p$ =200-400 MeV. 200 MeV spread depend on incompleteness of experimental data, possibilities to use $K_{ef}$ >0.96, cascade zone etc. There is consider proton linac as outer source of neutrons. Alternative variant is to use cyclotron as energy amplifier. Among contemporary cyclotrons PSI (or such type cyclotron) may provide 1 MW beam and required conversion "proton-neutron". But cost of such machine and weight will be well higher than 200-400 MeV, 5 mA proton linac. On the other hand cyclotron with energy 400 MeV and 5 mA current could consider as alternative of rf linac for stationary nuclear power station. Conclusions of workshop [1] show that at present creation of 5 mA cyclotron has more problems than creation of rf linac with the same current.

## LINEAR ACCELERATOR

A probable scheme of such proton linac is given on fig.1 It includes: RF volume source, LEBT, 4-vane spatially-homogeneous strong focusing structure (RFQ), alternating phase focusing structure (APF DTL), coupled cavity linac structure (CCL). APF DTL structure is IH-cavity with thick holders turned on right angle in each following sell and magnetic lenses in drift tubes [2].

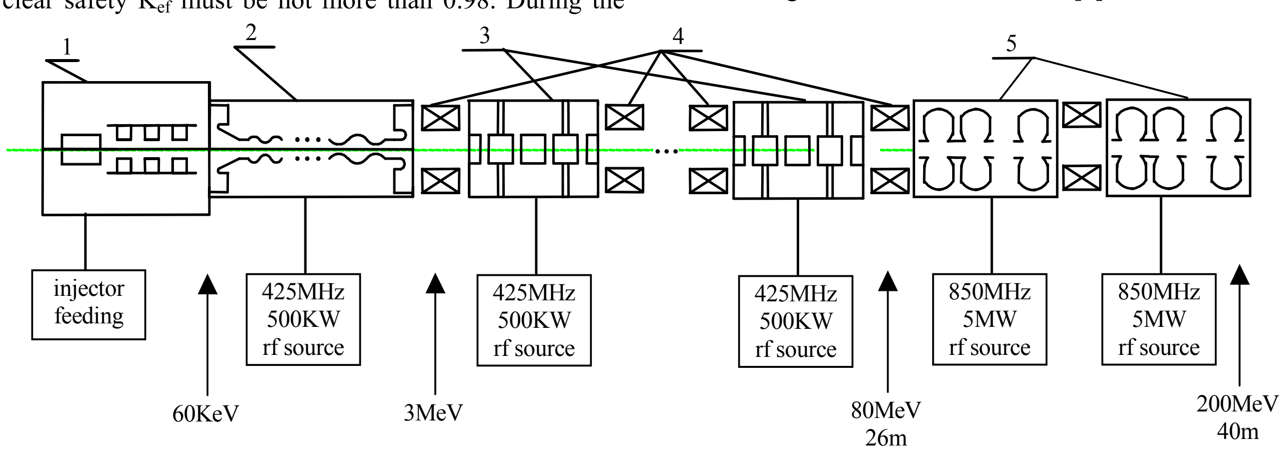

Figure 1: Layout of linac. 1 - ion source and LEBT 2 - spatially-homogeneous strong focusing structure (RFQ) 3 - alternating phase focusing structure (APF DTL) 4 - coupled cavity linac structure (CCL) 5 - focus lenses

Main parameters of linac are given in table 1.

Table 1: Main Parameters of Linac

| | |
|---|---|
| Output energy, MeV | 200-400 |
| Average current, mA | 5 |
| Duty Factor, % | 10 |
| Possible frequency range of RFQ and DTL, MHz | 402.5-433 |
| Beam power, MW | 1-2 |
| Working frequency of CCL, MHz | 805-866 |
| Number of RFQ | 1 |
| Number of APF DTL resonators | 20 |
| Number of CCL module | 4 |

Presented parameters are based on achievements of accelerator technologies of the last twenty five years [3], [4], [5].

## HIGH TEMPERATURE GAS-COOLED REACTOR

To compensate decreasing of $K_{ef}$ during long reactor working one need increase accelerator current. Therefore it is expediently reactor with hard spectrum of neutrons to use for LEEPP where diapason of $K_{ef}$ change much less than the same in thermal neutron reactors. There is considered high-temperature gas-cooled fast neutron reactor (HTGCR) [6] as reactor of LEEP. Gaseous heat-carrier captures neutrons weakly therefore fuel reproduction is improved and change of reactivity is lowered in fast neutron reactors. So that risk of inlet of positive reactivity because of heat-carrier lost is absent. Helium is chosen as heat-carrier of gas-cooled reactor of LEEPP since helium has best thermal properties than other than other gaseous heat-carriers. Advantages of helium are chemical inertness preventing corrosion of constructional materials and absence of activation under action of neutron irradiation. It raises radioactive safety of LEEPP. HTGCR design of LEEPP is shown on fig. 2. Active zone of LEEPP reactor may be created on base of elements developed for ship HTGCR. Active zone consists of cylindrical heat assemblings (diameter 42 mm) with ball-shaped elements of HRA. Heat releasing elements (HRE) (diameter 2-4 mm) include fuel core from mononitrid of uranium covered by tangsten. HRE take place in inside HRA as backfill in ring gap between two coaxial pipes of niobium. Cooling of HRE is released by transversal stream of helium via ball-shape backfill. Reactor of thermal power 200 MW active zone sizes are: outer diameter 1.6 m, height 1.5 m. These sizes are determined by energy intensity 70 $MW/m^3$. It proves safe elimination of heat from active zone. Results of modeling show that in active zone with multiplying target (UN+W) (diameter 0.4 m) power heat releasing 200 MW may be achieved for $K_{ef}$ 0.96 and source intensity $4.2\cdot10^{17}$ n/s.

## NEUTRON-PRODUCING TARGET

In this report one proposes design of target with tubular irradiated elements (fig.3). Three of coaxially-located shells form vessel. Inner carrier shell, connected with ion transport channel, is insulated from heat-carrier and has good vacuum. Target is cooled by heat-carrier of reactor - helium. Middle and outer shells of vessel prove circulation of cooling heat-carrier in the target. The middle shell has holes inside surface which are connected with inner pipe of suitable irradiated elements via adapter. Radial clearances between shells are used as collectors of heat carrier which are cooling neutron-producing target.

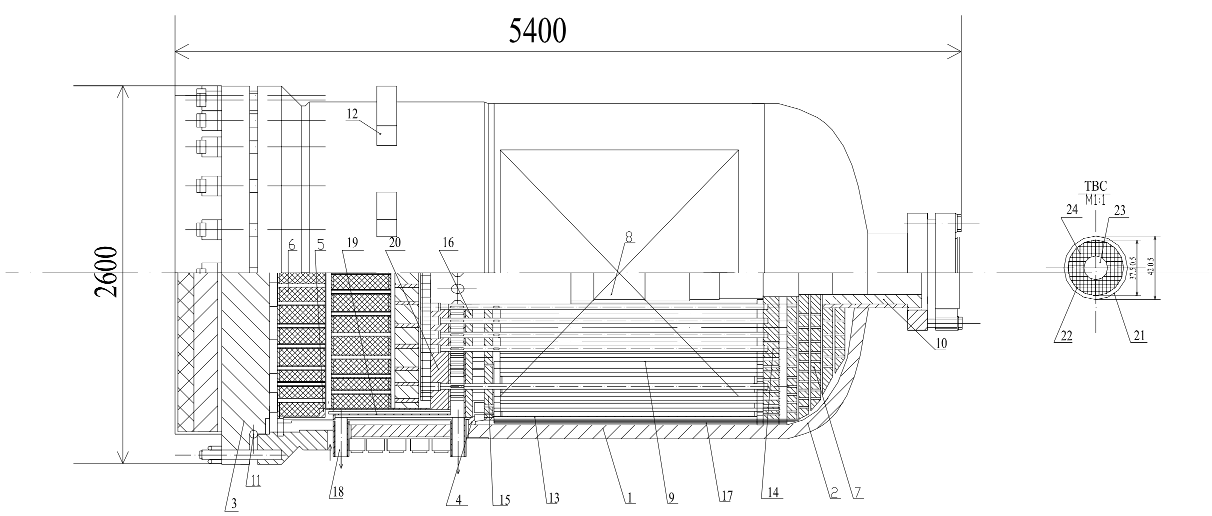

Figure 2: Design of high-temperature gas-cooled reactor. 1 - vessel 2 - bottom 3 - cap 4 - holder of active zone 5 - holder of heat releasing assembling (HRA) 6 - upper shield plug 7 - edge-joint screens 8 - neutron-producing target 9 - active zone 10 - cooled socket for target strengthening 11 - tubular thickening 12 - elements of strengthening of bio-protection 13 - carrying shell 14 - bottom bearing plate 15 - intermediate plate 16 - dividing plate 17 - sidelong screen 18 - sockets "pipe in pipe" type 19 - shell of HRA holder 20 - upper plate of HRA holder 21, 22, 23 - tube of HRA 24 - ball-shaped elements of HRA

Each tubular irradiated element consists of two coaxial pipes with thin walls.

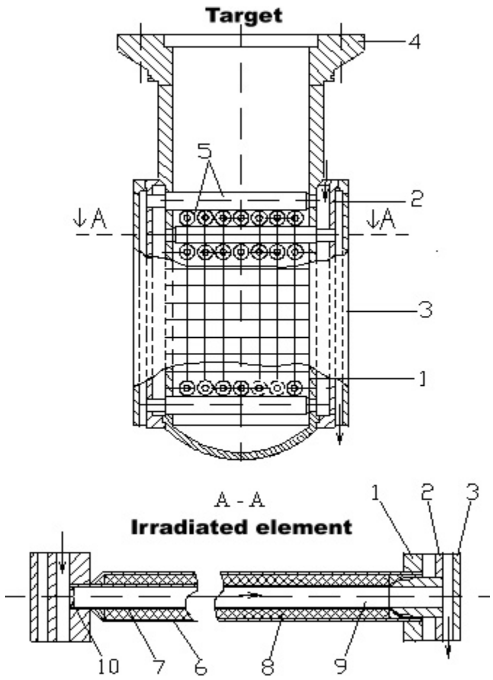

Figure 3: Neutron-producing target. 1, 2, 3 - shells of vessel, forming channel of heat carrier 4 - ion supply channel 5 - irradiated elements of target 6, 7 - shells of irradiated element 8 - neutron-producing material 9 - heat-carriers channel 10 - choke element

Between walls is placed neutron producing material. Such structure of irradiated element allows to use neutron-producing substance in different form (tablets, powder etc.) and to decrease requirements to radiative and heat resistance. It is proposed uranium compound UN to use as neutron-producing material. It is heat-resistance and multiplying target allows to obtain heat power in activ zone 1.5 times as much as unmultiplying one. Experimental data of neutron yields from targets of finite sizes presented in publications have essential distinctions. Modeling of neutron yield from UN 60 cm diameter target for 400 MeV protons gives more than 20 n/p.

## CONCLUSION. DESIGN LEEPP

Scheme of principle placement of basic equipment is given on fig. 4. It is possible to place installation in protected container with diameter 10 m and length 25 m. It is according to sizes of atomicship's compartments. linac and power equipment of LEEPP are placed in same enclosed space to reduce length of protected container. Longitudinal size of linac may be reduced under 180° turn of accelerator tract. Turbocompressor with start system, power turbine, heat-exchanger and main electric generator are forming rigid construction. they are placed inside power vessel connected with reactor. Foundation of construction is attached to protected container's vessel. Linac is placed on foundation which is integral whole construction. It help to prevent deformations of beam tract due to vibrations of mechanical equipment of LEEPP. Blocks of linac RF system may be placed in special chambers protected from radiation. It proves possibility of their servicing under working LEEPP.

# CW PROTON LINAC FOR THE BNCT APPLICATION

Donald A. Swenson, Linac Systems, LLC, Albuquerque, NM

*Abstract*

A 2.5-MeV, 20-mA, cw, proton linac for the Boron Neutron Capture Therapy medical application is under construction at Linac Systems. The system consists of a 25-keV microwave ion source, a solenoid lens based low energy beam transport system, a 0.75-MeV RFQ linac, a 2.5-MeV RFI linac, and the necessary service systems. Because of the superb low energy capabilities of the RFI structure, the RFQ linac need only go to 0.75 MeV, resulting in a cavity dissipation of 74 kW for the RFQ section. Because of the high rf efficiency of the RFI structure, the cavity dissipation is only 35 kW for the RFI section. Extensive thermal studies have been made to accommodate these cw heat load. The beam power is 50 kW. The rf power system is designed for an average power output of 200 kW. The RFQ and RFI sections are coupled into a single resonant unit by a quarter-wave-stub resonant coupler. The combination is driven at a single point in the RFQ structure. The total length of the linac is 2.84 meters.

## INTRODUCTION

There are very few cw linacs in the world. Our proprietary linac structures offer the best chance to realize a commercially viable cw linac product. Features of our patented Rf Focused Interdigital (RFI) linac structure make it practical to consider cw linac systems for applications requiring very high average beam intensities. BNCT and Isotope Production are two such medical application. Solid state materials modification is another such application.

A 2.5-MeV, 20-mA, cw, proton linac for the Boron Neutron Capture Therapy (BNCT) medical application is under construction at Linac Systems. The system consists of a 25-keV microwave ion source, a solenoid lens based low energy beam transport (LEBT) system, a 0.75-MeV RFQ linac, a 2.5-MeV RFI linac, and the necessary service systems. This 2.84-m linac system is shown in Fig. 1.

The largest engineering challenge for cw operation is the removal of the heat generated by the cw operation. To mitigate this problem, we have performed extensive thermal management studies on the critical parts of the system. The highest power density in the RFQ linac structure is the RFQ bar supporting strut. The highest power density in the RFI structure is the main drift tube support stem.

Because of the superb low energy capabilities of the RFI structure, the RFQ linac need only go to 0.75 MeV, resulting in a cavity dissipation of only 65 kW (30% beyond theoretical) for the RFQ section. Because of the high rf efficiency of the RFI structure, the cavity dissipation for the RFI section is only 35 kW (30% beyond theoretical). The beam power is 50 kW. The

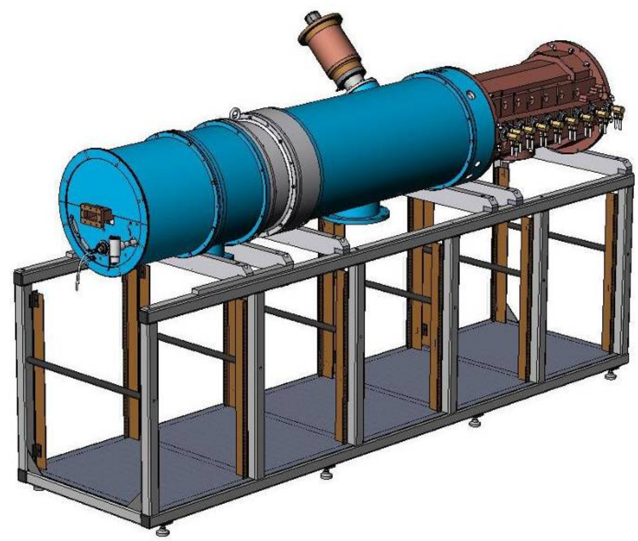

Figure 1: Cw proton linac.

total rf power required is 150 kW. The two linac structures are resonantly coupled, providing a single drive point for the combination. The details of this coupler are presented in another paper at this conference[1].

Abundant quantities of epithermal neutrons are produced when the 50 kW, 2.5-MeV proton beam falls on a solid lithium target, which is under design and fabrication at Linac Systems. The details of this target are presented in another paper at this conference[2].

## THE INJECTION SYSTEM

The first section of this accelerator is an ion source and low-energy beam transport (LEBT) system. The ion source is a microwave ion source which produces a 25-keV, 30-mA, dc, proton beam with low emittance and high proton fraction. A drawing of the injection system is shown in Fig. 2. The total distance from the ion source to the RFQ is 540 mm.

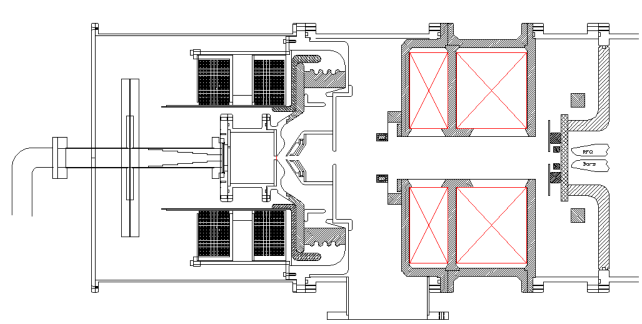

Figure 2: Injection system.

The focusing element in the LEBT is a novel dual-solenoid magnet utilizing two separate tape-wound, edge-cooled coils. The upstream coil produces 25,000 Amp-turns for a current of 85 A. The downstream coil produces twice the Amp-turns for the same current. An x,y steering magnet is suspended a few centimeters in front of the solenoid.

## THE RFQ LINAC

The next section of this accelerator is the RFQ linac, which accelerates the beam from the ion source energy of 25 keV to an output energy of 0.75 MeV, in a length of 1.04 m. The RFQ a four-bar RFQ of the Radial Strut design, where the individual bars are supported by radial struts emanating from the walls of the cavity with four-pole symmetry. A significant advantage of the Radial Strut design is that the rf dipole mode is 6 MHz above the quadrupole mode and does not present a problem with rf field stability.

The rf efficiency of the RFQ is expressed in terms of a transverse shunt impedance, $Z_{TR}$ (MΩ-m), defined as $V^2/P_L$, where V is the bar-to-bar voltage and $P_L$ is the rf power per unit length in the structure. The shunt impedance of the radial strut design is 0.12 MΩ/m, about twice the value of conventional four-bar RFQs.

## THE RFI LINAC

The Rf-Focused Interdigital (RFI) linac structure represents an effective combination of the interdigital (Wideröe) linac structure and the rf electric quadrupole focusing used in the Radio Frequency Quadrupole (RFQ) and Rf-Focused Drift tube (RFD) linac structures. This linac structure is three to four times more efficient and three times smaller in diameter than the conventional Drift Tube Linac (DTL) structure in the energy range from 0.75 to 6 MeV. It is ten times more efficient than the RFQ linac structure in the 0.75 to 6 MeV range.

In the RFI structure, when the accelerated particles enter the drift tube, the electric fields are near their maximum. When the accelerated particles are three quarters of the way through the drift tube, the electric fields are zero and changing sign. As a result, the focusing action must be pushed upstream to lie as close to the leading edge of the drift tube as possible, leaving the latter portion of the drift tube solely as a drift action (no focusing, no acceleration). Hence, the drift tubes of the RFI linac structure are asymmetrical, consisting of a minor piece and a major piece.

The rf focusing is introduced into the RFI linac structure by configuring the drift tubes as two independent pieces operating at different electrical potentials as determined by the rf fields of the linac structure. Each piece supports two fingers pointed inwards towards the opposite end of the drift tube forming a four-finger geometry, which produces an rf quadrupole field along the axis of the linac for focusing the beam.

The assembly and alignment procedure goes as follows. After the tank and stems are fabricated, the stems (major and minor) are installed in their hard socket prior to attachment of the major and minor drift tube bodies. Socket for the drift tube bodies are precision machined into the major and minor stems using an extended wire EDM facility that can span the entire length of the tank (≤750mm). In this way, the relative alignment of the drift tube bodies is very good. Following this EDM process, the stems are removed, the drift tube bodies are soldered into their sockets and the stems are re-installed. A picture of this multi-cell structure is shown in Fig. 3.

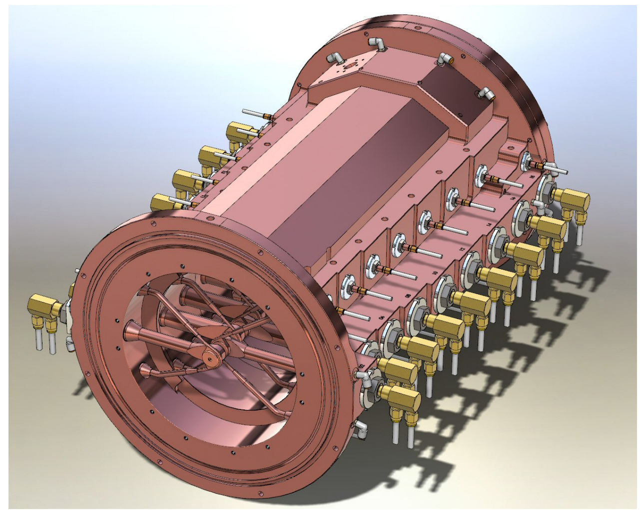

Figure 3: Multi-cell RFI linac structure.

Our first RFI structure was built as a series of unit cells, each containing a major drift tube body mounted on a supporting stem and a minor drift tube body mounted on a supporting stem[1]. Alignment shoulders on each cell provided cell-to-cell alignment. The drift tube alignment was achieved by machining sockets in the major and minor stems for the major and minor drift tube parts, relative to the alignment shoulders, by a precision wire EDM process.

Our present fabrication scheme results in multi-cell RFI tank sections. In this scheme, the tank sections are precision machined with "hard socket" for all major and minor stems. The basic requirement on the hard socket is that the stem location be reproducible – that is, that the stem can be removed and replaced to the same location with considerable precision (~25 microns).

## RF POWER SYSTEM

The rf power system is designed to produce a cw power of 200 kW at 200 MHz, and consists of a Low Level Rf chassis, a Solid State Amplifier, an Intermediate Power Amplifiers, and a Final Power Amplifier. The rf systems are designed and built by JP Accelerator Works, Inc.

## POWER AND COOLING REQUIREMENTS

The short, 0.75-MeV RFQ linac structure and the very efficient RFI linac structure present a manageable power and cooling requirement for this cw linac system.

The total structure power for the RFQ linac structure is 65 kW. Seventy percent of this power (45.5 kW) is dissipated in the bar/strut assemblies. There are a total of 20 parallel cooling circuits, implying about 2.3 kW per cooling circuit. The majority of this power is in the struts, where we employ a conical spiral cooling path for heat transfer. In all, the RFQ is cooled by 30 parallel cooling circuits. Some cooling circuits are shown in Fig. 4.

The total structure power for the RFI structure is 35 kW. This power is evenly split between the cavity wall and the drift tube stems. The highest power dissipation is in the 18 major drift tube stems, where the power per stem is about 0.8 kW. Each of these stems is cooled by a parallel cooling circuit. In all, the RFI is cooled by 52 parallel cooling circuits. Some cooling circuits are shown in Fig. 5.

## CW TEST CAVITY TESTS

The two most difficult components of this linac system to cool are the RFQ strut and the RFI main stem. Both of these components were tested in a Test Cavity set up for this purpose. To expose the main stem to its design level of dissipation required 1162 W of rf power in the Test Cavity. We chose to supply this power as 116.2 kW of power at a 1% duty factor. To expose the strut to its design level of dissipation required 5932 W of rf power. We chose to supply this power as 118.64 kW of power at a 5% duty factor. Both components survived the tests with no sign of damage.

## THERMAL CALCULATIONS

Both linac structures are cooled by multiple, parallel, cooling circuits between supply and return manifolds as seen in Figs. 4 and 5. Thermal and flow dynamics calculations were made on all typical cooling circuits. Pressures like 20 psi and flow velocities like 3 m/s keep the temperature rise in the coolant to less than 8 C.

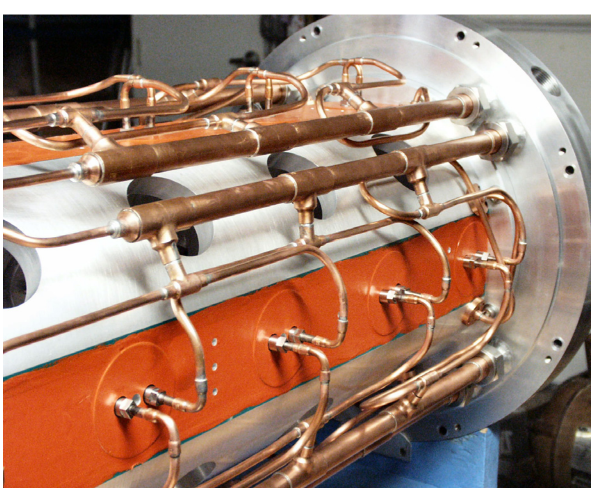

Figure 4: RFQ cooling circuits.

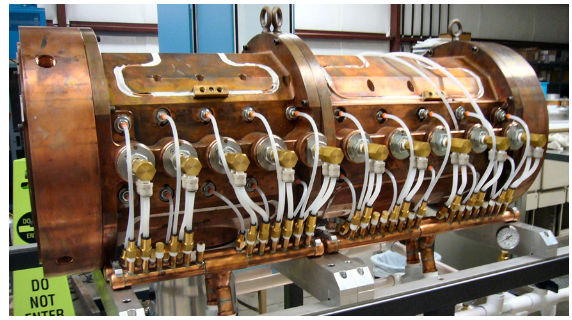

Figure 5: RFI cooling circuits.

# HIGH-POWER LITHIUM TARGET FOR ACCELERATOR-BASED BNCT

Carl Willis*, John Lenz, Donald Swenson, Linac Systems LLC, Albuquerque, NM 87109, USA

*Abstract*

A water-cooled conical target for producing neutrons via the $^{7}Li(p,n)^{7}Be$ reaction at 2.5 MeV is under development at Linac Systems. The target is intended to accept an expanded 50-kW beam from an rf linac, and is predicted to meet the intensity requirements for practical accelerator-based boron neutron capture therapy (BNCT) in concert with Linac Systems' CW RFI linac[1]. Lithium metal targets present well-known physical and mechanical challenges at high beam power density that are addressed in our design. CFD modelling indicates that the peak lithium temperature can be held below 150°C with a water flow rate near 80 kg $min^{-1}$ and corresponding pressure drop of 170 kPa. The target prototype has been fabricated and is undergoing thermal-hydraulic testing using an electron beam at the Plasma Materials Test Facility, Sandia National Laboratories.

## INTRODUCTION

The $^{7}Li(p,n)^{7}Be$ reaction on lithium metal, at energies in the range of 1.9-3.0 MeV, has desirable properties as a potential source of neutrons for BNCT. Yield is high, typically reported in the range of $8\text{-}9 \times 10^{14}$ n $A^{-1}$ $s^{-1}$ at 2.5 MeV. Neutron energy is low; at 2.5 MeV, the flux-weighted mean neutron energy is only 330 keV.

Despite nuclear advantages, lithium presents thermal challenges in a high-power-density target. The solid is preferable on account of the corrosive and mobile nature of the liquid, but its 180°C melting point necessitates careful cooling. Recent experimental attempts at using solid lithium in targets have elucidated other difficulties. Taskaev[2] operated a 10-cm-diameter planar copper-backed lithium target with a 25-kW beam, finding that blistering of the copper substrate by beam-implanted hydrogen limited target lifetime to under a day.

Linac Systems is developing a unique solid lithium target for a 2.5-MeV, 20-mA beam. In this paper we focus on the target prototype mechanical design and some results of experiment and modelling pertaining to the thermal hydraulics of the heat removal system.

## TARGET DESIGN AND FABRICATION

### *Design Criteria and CFD Modelling*

Several basic functional requirements for our target were stipulated to guide the design:

- The proton beam is an 8-cm-diameter stationary (i.e. not rastered or rotated), magnetically-expanded, "waterbag" distribution produced by an rf linac.
- Peak surface temperature must not exceed 150°C to keep lithium layer solid (including safety margin).
- Liquid water coolant will be used with inlet temperature of 20-30°C, outlet pressure of 101 kPa.
- Symmetry of target system about the beam axis is desirable to simplify neutron dosimetry and treatment planning calculations.

The concept born from these requirements consists of a 10-cm diameter conical heat exchanger with water channels on the exterior that mates with a coolant manifold. This concept is illustrated in Figure 1.

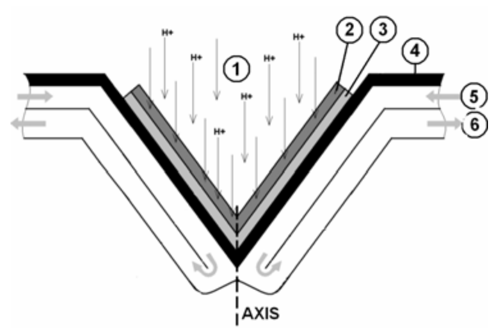

Figure 1: Protons (1) strike a 50-μm lithium metal layer (2) that is deposited on a Pd anti-blistering substrate (3), supported by a channelized conical heat exchanger (4). Coolant (5) flows through a conical-annular duct that encompasses the channels of the heat exchanger; reverses at the apex; returns via an outer conical-annular duct, and exits (6).

Design of the channelized heat exchanger was carried out with the aid of the CFD packages FLUENT, CFDesign, and COSMOS FloWorks. Simulations examined the effects of channel dimensions, number of channels, heat exchanger material, and apex-region geometry upon the coolant flow, pressure drop, and pumping power needed to meet the target surface temperature requirement. Initial studies focused on designs with straight tangential channels, but we determined that helical channels would offer superior performance (Figure 2). Copper was selected as the only viable heat exchanger material. In simulations comparing identical aluminium and copper heat exchangers, copper conferred a ~40°C target temperature improvement over aluminium for given coolant flow rates.

Modelling concluded with the acceptance of a copper heat exchanger design with 20 2-mm helical channels. According to the FloWorks models, this design will hold the target surface temperature below 150 °C by means of 80 kg $min^{-1}$ of water flow with 170 kPa pressure drop. Such a requirement is easily met with a small centrifugal pump.

*Willis.219@osu.edu

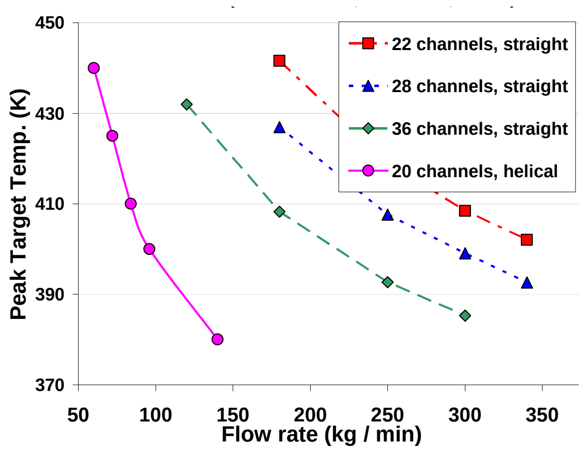

Figure 2: Predicted maximum target temperature as a function of coolant flow for various copper heat exchangers. Maximum design temperature is 420K.

Our proposed antidote to the blistering problem is a ~10-µm substrate of electroplated palladium interposed between the lithium and the heat exchanger, of sufficient thickness to encompass the Bragg peak of the beam and dissipate hydrogen either by storage or diffusion. Palladium electroplating on copper is routine. Lithium readily alloys with palladium[3], indicating that adherence is likely to be good, but raising the possibility of destructive solid phase changes.

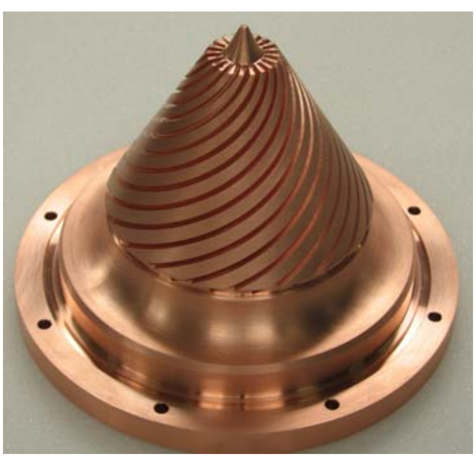

Figure 3: Channelized heat exchanger.

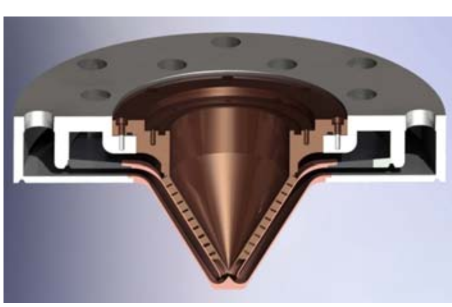

Figure 4: Manifold with target heat exchanger installed.

### Prototype Fabrication

A prototype target heat exchanger (Figure 3) and manifold (Figure 4) were constructed to experimentally validate our CFD thermal-hydraulic predictions.

The conical heat exchanger is OFE copper, while the manifold is mostly aluminium that has been electroless-nickel-plated internally to prevent galvanic corrosion. Components in the apex region of the manifold, where coolant flow is rapid and potentially erosive, are solid copper joined to the plated aluminium with low-temperature silver solder. These joints have so far proven reliable. Water enters and exits the manifold through 16 3/4-inch (1.9 cm) pipe fittings in the upstream face.

## EXPERIMENTS AND RESULTS

The prototype BNCT target has undergone limited electron-beam thermal testing with the 50-kW EB-60 electron gun at the Plasma Materials Test Facility, Sandia National Laboratories, Albuquerque, and further testing is planned. The capabilities of this unique user facility are described in detail by Youchison[4]. Linac Systems has used a homemade flow loop for preliminary hydraulic testing at its own laboratory.

### Preliminary Hydraulic Testing

A test cooling loop at Linac Systems is based upon a small centrifugal pump (Chemflo-1, MP Pumps, Inc.), transit-time ultrasonic flow meter, pressure transducers, and data-logging computer. The target and manifold were connected to this loop to produce pressure-vs.-flow data that is in good agreement with the FloWorks predictions (Figure 5).

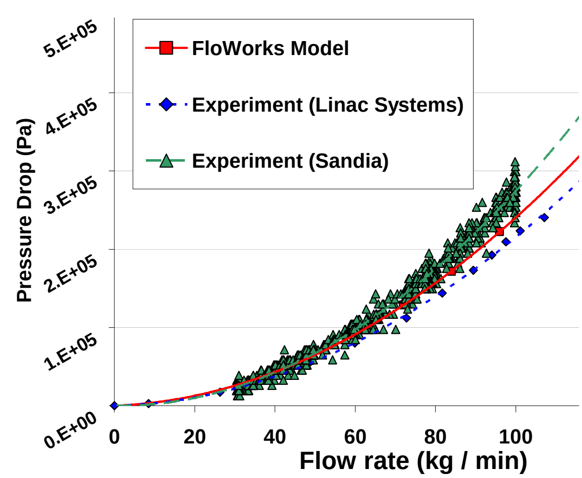

Figure 5: Pressure-flow characteristics of 20-helical-channel heat exchanger, with both CFD and experimental results. Design flow is 80 kg $min^{-1}$.

### PMTF Experiment

Manifold, target, and associated plumbing have been placed in the PMTF EB-60 vacuum chamber for testing. In this facility, a 20-keV electron gun scans a raster pattern representing the intended “waterbag” power density distribution onto the conical target surface. According to plan, two series of data will be collected: surface temperature as a function of beam power with fixed coolant flow rate; and temperature as a function of flow rate for fixed beam power. Water from a high-purity loop is used to cool the target. Absorbed power measurements are made by calorimetry on this coolant, the inlet and outlet feedthroughs being fitted with platinum RTDs.

Target surface thermographs are collected using IR cameras observing the target through ZnSe viewports. To account for the emissivity of the surface and calibrate the cameras, thermocouples are mounted in a section of the target wall.

Thus far, results from e-beam testing have been limited by some practical difficulties: a leaky weld on the manifold, and an apparent inability to produce more than 10 kW from the EB-60 gun. Alternatively, the latter observation may suggest problems with calorimetry, since the electron gun power supplies indicated that up to 30 kW has been developed.

Figures 6 and 7 show an example thermograph and radial temperature profile, respectively, of the target surface. Conditions in that experiment were 9.3 kW absorbed power, 36.7 kg min$^{-1}$ coolant flow.

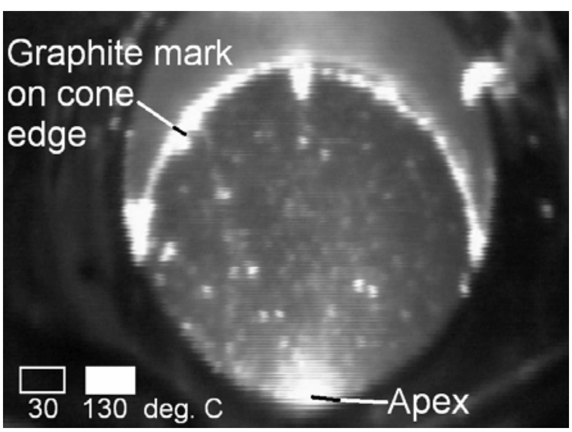

Figure 6: Thermograph of target surface.

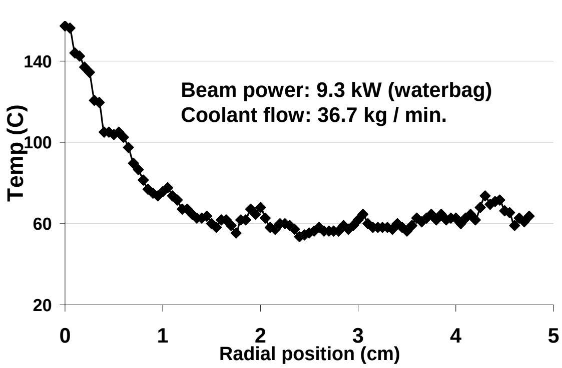

Figure 7: Target surface temperature vs. position.

## CONCLUSIONS

Electron-beam heating is an attractive tool to validate CFD models of high-power accelerator targets, particularly those whose operation would be associated with significant hazards to personnel and equipment. Linac Systems' experience with e-beam heating at PMTF is only in the incipient phase and there may be limits to the utility of the technique. These include variations in surface emissivity during testing; inaccurate power-density distributions on the concave conical surface resulting from electron scattering; or simply the inability of the PMTF guns to deliver required beam power (which so far has remained below 10 kW). We are also sceptical of the calorimetry at PMTF in our tests to date. More work needs to be done to allow us to trust thermal data from e-beam heating.

Pressure-flow characteristics of the target heat exchanger match CFD predictions. We were concerned that the fast (~ 10 m s$^{-1}$), turning flows in the apex region would be prone to cavitation, but after an estimated 10 hours of exposure to high-flow testing—including flow rates 20% higher than the estimated requirement—the target and manifold components show no signs of erosion.

In the present work we have focused on the heat removal problem. Of course many other aspects of design must be considered before a high-power lithium target for BNCT can enter clinical service, including neutronics, shielding, and the target preparation and replacement procedures. We hope to publish detail on our work in these areas soon.

## ACKNOWLEDGEMENTS

The authors are grateful for the assistance of Dennis Youchison and his staff at PMTF, Sandia National Laboratories; and the mechanical design contributions of David Sattler on this project. Carl Willis acknowledges the USDOE NE Graduate Fellowship for prior support of his work, and thanks his faculty advisors at Ohio State University for their guidance.

# BENT SOLENOID TUNING SIMULATIONS FOR THE COMET BEAMLINE.*

A. Kurup, Imperial College London, UK / FNAL, Batavia, USA

*Abstract*

The COMET experiment beamline uses bent superconducting solenoids for the muon transport and the spectrometer used to analyse the decay electrons from stopped muons. The bent solenoid includes not just a solenoid field but also a vertical dipole field. It is therefore important to have the ability to tune the field distribution. However, since the field distribution is mainly determined by the geometry it is difficult to adjust once the solenoids have been constructed. A cost effective method to provide tuning capability of the field distribution of the bent solenoids is proposed and the results of simulations presented.

## INTRODUCTION

The COMET [1] experiment aims to investigate COherent Muon to Electron Transitions by nuclear capture. This requires having a very precisely controlled muon momentum spectrum on a target that will stop the muons and the electron momentum spectrum produced by coherent $\mu \rightarrow e$ transitions needs to be accurately measured. The COMET experiment utilises bent solenoids for the muon transport and the electron spectrometer. However, helical trajectories in a curved solenoid drift in the vertical direction. In order to compensate for this vertical drift an additional dipole field in the vertical direction is applied. In the COMET design this is done in a cost effective way by tilting the solenoids. The downside to using this method is that the relative magnitude of the vertical dipole field component is given by the geometry, which is fixed after the solenoid has been manufactured. It may be necessary to tune the magnitude of the vertical dipole component after manufacture to correct for manufacturing tolerances and thermal contraction due to cooling the magnets to superconducting operating temperatures.

This paper investigates the possibility of having some control over the vertical dipole component by powering alternate solenoids with a different current. The simulations presented aim to demonstrate whether this method could provide the ability to control the momentum distribution, vertical dispersion and composition of the beam at the stopping target. For these simulations, only the muon transport has been considered and only the simple scenario where all solenoids in the bent transport channel have identical geometries and only two different power supplies are used.

* This work has been supported by The Royal Society as a joint project between Imperial College London and Osaka University. The author would also like to thank the members of the COMET collaboration for all their help.

## G4BEAMLINE FIELD DISTRIBUTION

Initial simulations were done using G4Beamline [2] by taking the existing baseline design of the COMET beamline. The geometry was altered to include the tilt of the solenoids but all other parameters were kept the same. Figure 1 shows the model that was simulated and Fig. 2 shows the tilt of the solenoids, which is $1.43°$. All the solenoids

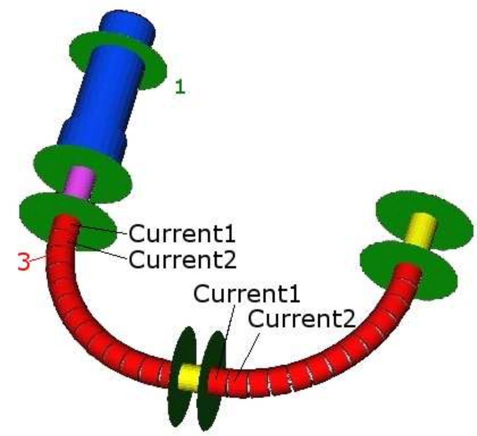

Figure 1: G4Beamline model of the muon transport channel. The blue solenoids are the pion capture channel, the red solenoids are the bent, tilted solenoids for pion decay and muon transport and the final yellow solenoids end just before the stopping target. The virtual detector (green circle) labelled 1 shows the position of the pion production target. Alternate solenoids in the transport channel (in red) were powered with a different current. Field measurements were made at the centre of the solenoid labelled 3.

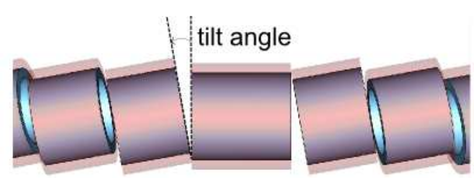

Figure 2: Drawing of the bent, tilted muon transport channel of the COMET beamline showing the tilt used to produced the vertical dipole field. The tilt angle shown here is exaggerated as the angle used in the simulations is $1.43°$.

in the G4Beamline simulations are ideal solenoids composed of infinitely-thin current sheets. Four different scenarios for powering the bent, tilted solenoids were investigated, see Table 1.

Table 1: Values for Current1 and Current2 used in the simulations. Current1 was applied to every other solenoid starting with the first one and Current2 was applied to the other solenoids, see Fig. 1.

| | **Current1 (A)** | **Current2 (A)** |
|---|---|---|
| 1 | 631890 | 631890 |
| 2 | 758268 | 758268 |
| 3 | 631890 | 1263780 |
| 4 | 631890 | 315945 |

Figure 3 shows the $B_x$, $B_y$ and $B_z$ field components at the centre of the third solenoid (labelled 3 in Fig. 1) for the different powering schemes. The $z$ direction is parallel to the axis of each solenoid and the $x$ axis is in the plane of the bend. As can be seen, by supplying alternate solenoids with a different current it is possible to adjust, to some extent, the vertical dipole component (i.e. $B_y$) independently.

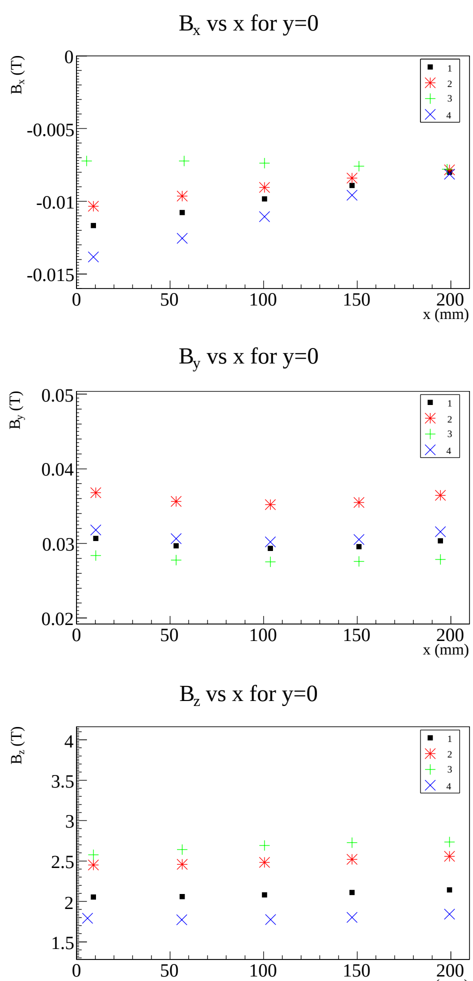

Figure 3: Results of the G4Beamline simulation. The plots show the $B_x$,$B_y$ and $B_z$ components as a function of x for the different powering schemes described in Table 1.

## EM STUDIO FIELD DISTRIBUTION

To obtain a more accurate field distribution of the beamline, a 3-D magnetostatic simulation using EM Studio [3] was done. The geometry was kept the same as in the G4Beamline simulations. Preliminary designs of the superconducting solenoids have a non-magnetic steel wall inside the coils and an iron yoke outside. To obtain a comparison with the G4Bemaline model the iron yoke was not considered and the permeability of the steel was set to 1.

Figure 4 shows the $B_x$, $B_y$ and $B_z$ field distributions, for the same location as in the G4Beamline simulation, for the same four current scenarios listed in Table 1. The

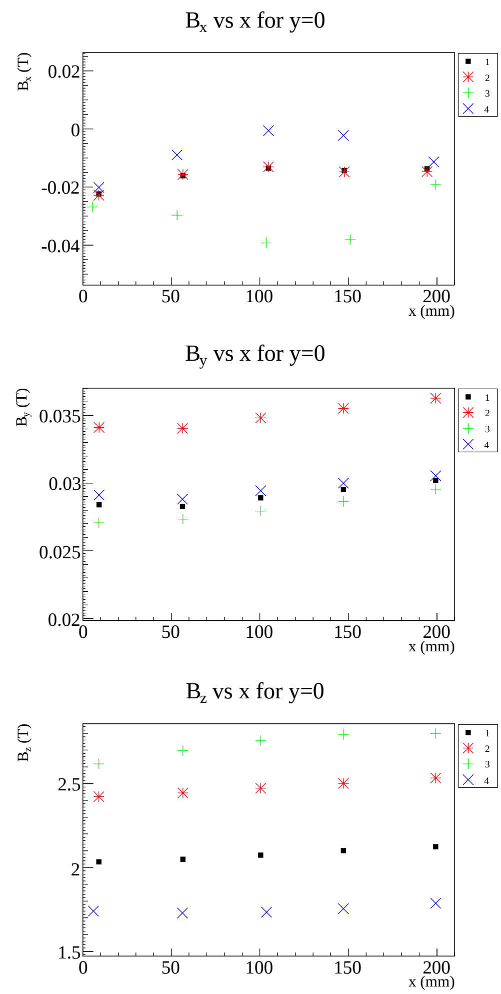

Figure 4: Results of the EM Studio simulation. The plots show the $B_x$,$B_y$ and $B_z$ components as a function of x for the different powering schemes described in Table 1.

$B_y$ and $B_z$ components show good agreement with the G4Beamline simulation but the $B_x$ component shows significant differences, though the absolute magnitude of the differences are small. This is likely due to the way in which fringe fields are considered in G4Beamline. However, the fact that the $B_x$ component in the EM Studio simulations does not follow the same trend as in the G4Beamline simulations will complicate tuning the beam transported by the channel.

## PARTICLE TRACKING

To understand the effect of altering the field in the solenoids, some preliminary tracking studies have been done using the G4Beamline model of the muon transport channel. Initially, a simple muon beam was tracked through $90°$ of the bent solenoid. The input beam contained on-axis, parallel muons with a momentum range of 10–150 $MeV/c$. Figure 5 shows the momentum distribution as a function of the vertical position after the muons were tracked through half of the bent solenoid. This figure shows that it is possible to affect the vertical dispersion produced by the transport channel by powering alternate solenoids with a different current.

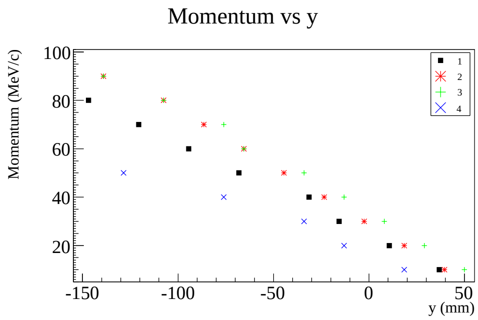

Figure 5: Momentum as a function of vertical position for an on-axis,parallel muon beam with a momentum range of 10–150 $MeV$.

Since the COMET experiment requires a very low background rate it is important to track particles using a realistic beam to determine to composition of the beam at the stopping target. An input beam produced by a MARS [4] simulation of 8 $GeV/c$ protons on a graphite target was tracked through the whole G4Beamline model. Figure 6 shows the momentum distribution of muons and Table 2 shows the composition of the beam at the stopping target for the different current scenarios.

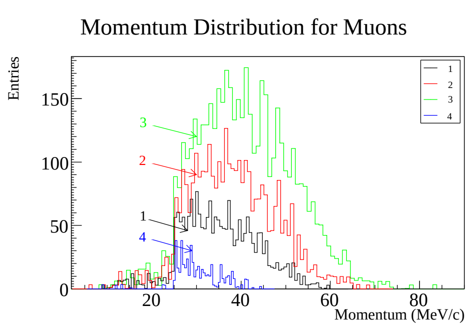

Figure 6: Momentum distribution of muons at the end of the muon transport channel for the different scenarios.

Table 2: Fractional beam composition at the stopping target for the four different scenarios.

| | $\mu^-$ | $\mu^+$ | $e^-$ | $e^+$ | $\pi^-$ | $\pi^+$ | $p^+$ |
|---|---|---|---|---|---|---|---|
| 1 | 0.89 | 0.02 | 0.055 | 0.030 | 0 | 0 | 0.0024 |
| 2 | 0.89 | 0.011 | 0.072 | 0.029 | 0 | 0 | 0.001 |
| 3 | 0.91 | 0.014 | 0.063 | 0.009 | 0 | 0 | 0.0006 |
| 4 | 0.96 | 0.027 | 0 | 0 | 0.018 | 0 | 0 |

Although it is possible to affect the momentum distribution of muons at the stopping target by powering alternate solenoids with a different current, the change in the muon yield is quite significant. This may be detrimental if tuning the solenoid requires reducing the current.

## CONCLUSIONS

By powering alternate solenoids with a different power supply it is possible to independently control the vertical dipole component of the bent, tilted solenoids. The simulations using EM Studio show deviations of the $B_x$ component compared to the G4Beamline solenoid model. To make the model more accurate it will be necessary to include the iron yoke. The effect of this on the transport of particles will need to be investigated. Thus, tracking with a field map from the EM Studio simulations is essential.

It is also important to study the mechanical forces applied to the support structure of the solenoid as having significantly different currents in adjacent solenoids may put significant additional stress on the support structure.

As the next step, it will be useful to study the effect of thermal contraction on an optimised version of the muon transport channel, tuning of the momentum spectrum to obtain the best yield and apply this method to the electron spectrometer to allow tuning of the momentum selection.

# STATUS OF MICE: THE INTERNATIONAL MUON IONIZATION COOLING EXPERIMENT

Dazhang Huang#, Daniel M. Kaplan, IIT, Chicago, IL 60616 USA
Michael S. Zisman, LBNL, Berkeley, CA 94720 USA

*Abstract*

A key unanswered question in particle physics is why the universe consists only of matter. It is believed that CP violation in the lepton sector is the answer. The best tool to find this is a muon-based neutrino factory. Muons can also be used for an energy-frontier collider that would fit on an existing laboratory site. Since muons are produced as a tertiary beam, their phase space and energy spread are large and must be reduced (cooled) to create a usable beam. Ionization cooling, comprising momentum loss in material followed by RF reacceleration, is the only suitable technique. A transverse cooling channel is merely a linac with absorbing material in the beam path. To demonstrate an understanding of the physics and technology issues, MICE will test a section of cooling channel exposed to a muon beam derived from the ISIS synchrotron at RAL. The muon beam line is now installed and commissioning is under way. Fabrication of cooling-channel components and the required detector systems has begun. A successful demonstration will go a long way toward proving the value of muon beams for future accelerator-based particle physics experiments.

## INTRODUCTION

Muon ionization cooling is the only practical method for preparing high-brilliance beams needed for a neutrino factory or muon collider. It reduces the transverse phase space of muons sufficiently to permit subsequent acceleration and storage in a practical acceleration system. This key enabling technology will be demonstrated experimentally for the first time in the Muon Ionization Cooling Experiment (MICE).

MICE is an experimental program to establish the feasibility and performance of ionization cooling. The approach is to measure precisely the emittance of 140–240 MeV/c muon beams both before and after an ionization-cooling cell. Implementing such a system will tell us about the subtleties of fabrication of the required components and, after comparing our results with detailed simulation predictions, will provide a validated tool for designing and optimizing the performance of a future neutrino factory and/or muon collider cooling channel.

The experiment is currently under construction at the Rutherford Appleton Laboratory (RAL) in the UK.

## MICE BEAM LINE AND SCHEDULE

The secondary muon beam line at RAL's ISIS synchrotron is being built to meet the needs of MICE. The line will provide muon beams in the range of 140–240 MeV/c momentum, with normalized transverse emittance values in the range of 1–10 π mm-rad. The muon beam will be momentum-selected and transported to the MICE apparatus (see Fig. 1). Particle identification ensures better than 99.9% muon purity. Via magnet settings and a Pb diffuser of adjustable thickness, the transverse emittance of the input muon beam can be tuned. The input 6D emittance is measured [1] in a magnetic spectrometer comprising a five-station scintillating-fiber tracker mounted within a 4 T superconducting (SC) solenoid. The tracker determines $x$, $x'$, $y$, $y'$, and particle energy. The time-of-flight (TOF) counters measure the sixth phase space coordinate, $t$. The cooling cell consists of low-$Z$ absorbers and normal conducting (NC) RF cavities, along with SC coils to provide strong focusing for the beam. The final emittance is measured in a second spectrometer system identical to the first one. Electrons from muon decay are eliminated from the data by calorimetry.

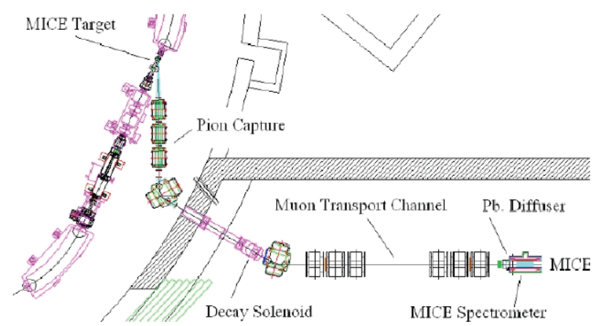

Figure 1: MICE beam line at ISIS, with two bending magnets and three quadrupole triplets.

The most important part of MICE is the cooling cell (see Fig. 2). It comprises three absorber–focus-coil (AFC) modules [2,3] and two RF–coupling-coil (RFCC) modules [4] (Fig. 3). Each hydrogen absorber contains about 20 L of liquid and is enclosed within a pair of room-temperature safety windows (Fig. 4) [5].

A pair of focus coils is employed to focus the muon beam, which results in a low equilibrium emittance for the channel. While hydrogen is best, for emittance far from equilibrium, a more practical absorption medium may be LiH, or Be. MICE is therefore designed to test both liquid and solid absorbers over a range of beta-function values. Critical hydrogen system issues are:

1. safety
2. use of the thinnest possible metal containment windows
3. hydrogen storage

A commercial metal-hydride storage system will be tested at RAL.

# huangd@iit.edu

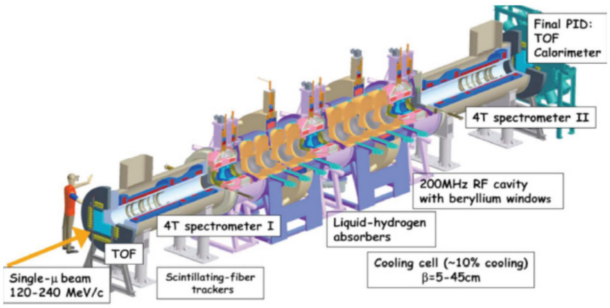

Figure 2: Cutaway view of the MICE cooling channel.

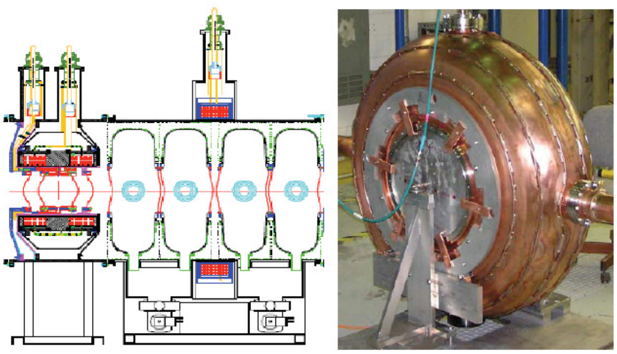

Figure 3: (left) Schematic diagram of AFC module connected to RFCC module, with cavities closed by curved Be windows; (right) a photo of the 201 MHz prototype cavity.

Since the beam to be cooled is large, the RF frequency must be low; due to the focusing magnetic field, NC cavities must be used to restore the energy lost in cooling. The eight 201 MHz RF acceleration cavities are very similar to the prototype cavity being tested in the MuCool Test Area (MTA) at Fermilab, and each will have Be windows on the beam apertures to close the cavity electro-magnetically. This is acceptable in a muon channel since the muons only interact weakly with material in their path. Compared with an open-cell cavity design, this method greatly improves the accelerating gradient of the cavity and is able to achieve ~18 MV/m in the 201 MHz cavity and ~40 MV/m in an 805 MHz ¼-scale prototype cavity with no magnetic field.

Although conceptually simple, both ionization cooling and its experimental verification pose challenges:

1. Operation of high-gradient (≈16 MV/m), low-frequency (201 MHz) RF cavities in strong (1–3 T) magnetic fields.
2. Safe designs employing substantial amounts of $LH_2$ near potential ignition sources.
3. The small effect (≈10%) of an affordable cooling device that leads to the goal of $10^{-3}$ emittance precision, requiring single-particle measurements rather than standard beam instrumentation.

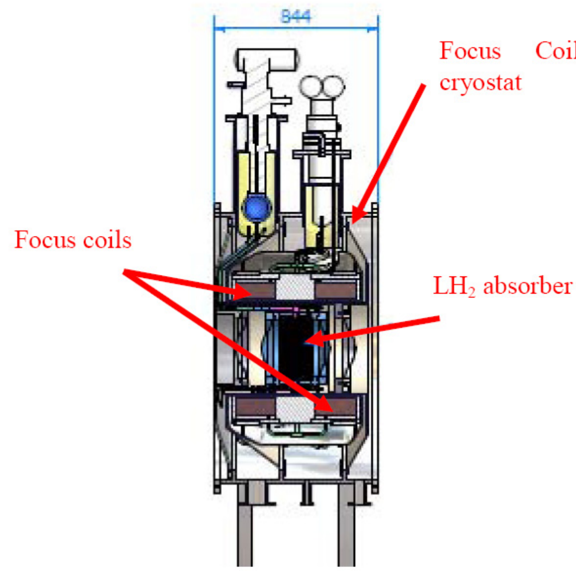

Figure 4: Side view of absorber–focus-coil module.

The staging of MICE (Fig. 5) allows careful calibration at each step and also reflects funding realities. Beam characterization and data acquisition have begun. Measurements of particle momenta and emittance will be possible once the first spectrometer solenoid is available. In Step III, up- and downstream emittance measurements will be precisely compared, which allows a precise determination of biases and testing of the required correction procedures. Step V will test "repeatable" cooling, in which the momentum lost in the absorbers is restored in the RF cavities. Step VI will test the full cooling cell.

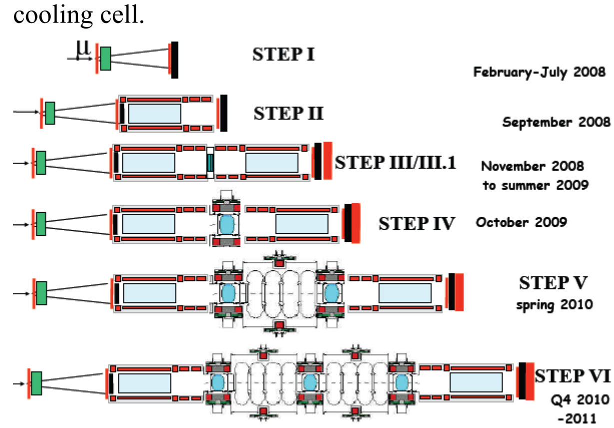

Figure 5: The planned stages of MICE.

## CURRENT STATUS

The beam line is now operational. The pions from a small, movable Ti target grazing the ISIS proton beam during its 2 ms flattop are captured by a quadrupole triplet and momentum-selected by a dipole magnet. Muons from pions decaying within a 5 T solenoid of 5 m length and 12 cm bore are momentum-selected in a second dipole at a momentum about half that of the pions. Two aerogel

Cherenkov counters and TOF0 (Fig. 6) are placed between quadrupole triplets 2 and 3. Three two-layer scintillator-hodoscope TOF stations each provide 50 ps resolution.

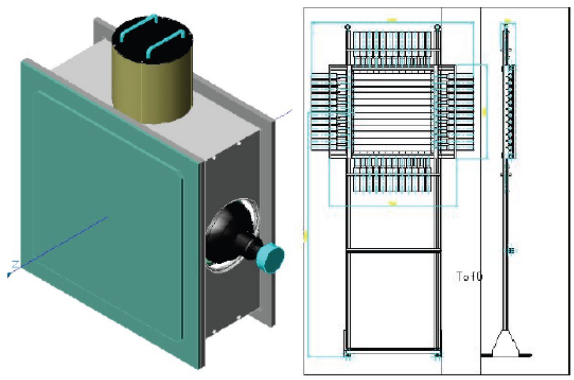

Figure 6: MICE upstream (Cherenkov and TOF) particle ID detectors.

The 2-m-long spectrometer solenoids (Fig. 7) will provide 4 T over a 1-m-long, 20-cm-radius tracking volume. Two end coils ensure <1% field non-uniformity and two matching coils at one end match optics in and out of the cooling cell. The magnets are on order for late-2008 delivery. This will be followed by field measurement and installation at RAL. Magnet sensors will monitor the field. Scintillating-fiber tracker 1 is completed and undergoing cosmic-ray testing and tracker 2 is in final assembly.

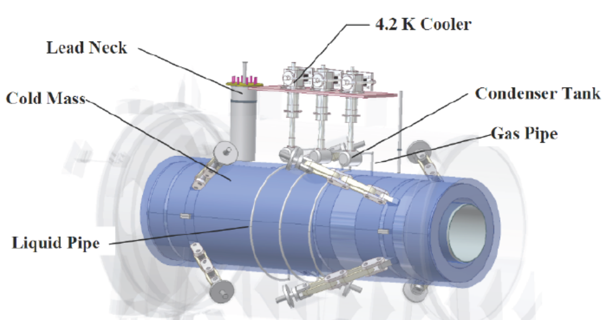

Figure 7: Schematic of spectrometer solenoid.

Downstream particle ID comprises TOF2 and a calorimeter to distinguish muons from decay electrons. A Pb–scintillating-fiber sandwich layer precedes a ≈1 $m^3$, fully sensitive, segmented scintillator block. The sandwich layer degrades electrons; the scintillator block precisely measures muon range. Prototypes have been tested and assembly of final detectors is in progress.

Currently, a CERN-refurbished 4 MW RF power source plus two 2-MW RF sources donated by LBNL give 8 MW in total, allowing 23 MeV of acceleration in MICE Step VI. The coupling coils are being constructed at the Institute of Cryogenics and Superconductivity Technology (ICST) of the Harbin Institute of Technology in China, in collaboration with LBNL. Crucial high-magnetic-field cavity tests await delivery of the first coupling coil.

MICE will run at ≈ 1 Hz and record up to 600 muons in each 1 ms beam burst. RF amplitude and phase, absorber mass, and other parameters must be precisely known for comparison with predictions and simulations. State-of-the-art instrumentation will monitor and record the relevant parameters.

MICE beam line commissioning started in February, 2008. The production rates of various particles, such as protons and pions, have been measured and particle identification has been made by means of Cherenkov light and time-of-flight measurements. Some representative results are given in Fig. 8, which demonstrates particle identification of both protons and pions.

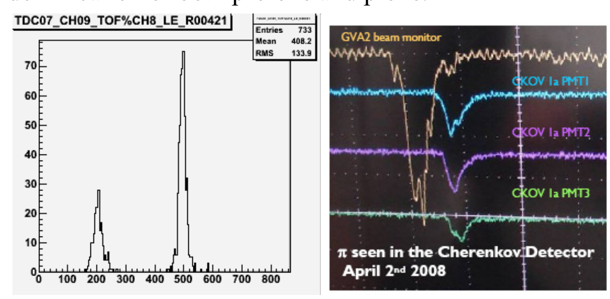

Figure 8: Representative MICE results. (left) Pions and protons separated through the time-of-flight with 414 MeV/c proton momentum at the first bending magnet; the left peak is pions, and the right peak is protons. (right) Cherenkov photomultiplier tube signals in coincidence with pulses from the second scintillating paddle indicating the passage of pions [6].

*Abstract*

Dielectric loaded wakefield structures are being developed to be used as high gradient accelerator components. The high current electron beam at the Argonne Wakefield Accelerator Facility (AWA) was used to excite wakefields in cylindrical dielectric loaded wakefield structures in the frequency range of 8 to 14 GHz, with pulse duration of a few nanoseconds. Short electron bunches (13 ps FWHM) of up to 86 nC drove these wakefields, and accelerating fields as high as 100 MV/m were reached. Similar structures were used to extract RF power from the electron beam; however, in this case they were traveling-wave structures, driven by electron bunch trains of up to 16 bunches. RF pulses of up to 40 MW were measured at the output coupler of these structures. The AWA electron beam was also used to drive the cavity modes in a metallic standing-wave structure designed and built by SLAC / KEK (originally meant to be powered by a klystron).

## INTRODUCTION

The Argonne Wakefield Accelerator Facility (AWA) is dedicated to the study of electron beam physics and the development of accelerating structures based on electron beam driven wakefields [1]. In order to carry out these studies, the facility employs a photocathode RF gun capable of generating electron beams with high bunch charges and short bunch lengths (up to 100 nC with a bunch length of 13 ps FWHM). This high intensity beam is used to excite wakefields in the structures under investigation. The wakefield structures presently under development are dielectric loaded cylindrical waveguides with operating frequencies between 8 and 14 GHz.

The facility is also used to investigate the generation and propagation of high brightness electron beams, and to develop novel electron beam diagnostics.

The AWA electron beam is also used in laboratory-based astrophysics experiments; namely, measurements of microwave Cherenkov radiation and beam induced fluorescence of air [2].

## AWA FACILITY

The AWA high intensity electron beam is generated by a photocathode RF gun, operating at 1.3 GHz. This one-and-a-half cell gun typically runs with 12 MW of input power, which generates an 80 MV/m electric field on its Magnesium cathode surface. A 1.3 GHz linac structure increases the electron beam energy, from the 8 MeV produced by the RF gun, to 15 MeV. The charge of the electron bunches can be easily varied from 1 to 100 nC, with bunch lengths of 2 mm rms, and normalized emittances of 30 to 200 $\pi$ mm mrad.

The AWA laser system consists of a Spectra Physics Tsunami oscillator followed by a Spitfire regenerative amplifier and two Ti:Sapphire amplifiers (TSA 50). It produces 1.5 mJ pulses at 248 nm, with a pulse length of 2 to 8 ps FWHM and a repetition rate of up to 10 pps. A final KrF Excimer amplifier is optionally used to increase the energy per pulse to 15 mJ. The generation of electron bunch trains (presently up to 16 bunches) requires each laser pulse to be divided by means of beam splitters into a laser pulse train.

## HIGH GRADIENT WAKEFIELD GENERATION

We have recently built and tested four dielectric loaded wakefield structures. Each one consists of a cylindrical dielectric tube inserted into a cylindrical copper waveguide. The dielectric material is either a ceramic known as cordierite, or quartz. The insertion of metallic end-pieces with a cut-off frequency above the operating frequency, makes these devices operate as standing-wave structures. A weakly coupled field probe (-60 dB) near the outer diameter of the dielectric cylinders serves to monitor the wakefields generated by the driving electron bunches, and to verify the absence of electric breakdown. Table 1 shows some parameters of four wakefield structures tested.

Table 1: Parameters of Standing-Wave Structures

| SW Structure | # 1 | # 2 | # 3 | # 4 |
|---|---|---|---|---|
| Material | Cordierite | Cordierite | Cordierite | Quartz |
| Dielectric constant | 4.76 | 4.76 | 4.76 | 3.75 |
| Freq. of TM01n | 14.1 GHz | 14.1 GHz | 9.4 GHz | 8.6 GHz |
| Inner radius | 5 mm | 5 mm | 2.75 mm | 1.9 mm |
| Outer radius | 7.49 mm | 7.49 mm | 7.49 mm | 7.49 mm |
| Length | 102 mm | 23 mm | 28 mm | 25.4 mm |
| Maximum charge | 46 nC | 86 nC | 86 nC | 75 nC |
| Maximum gradient | 21 MV/m | 43 MV/m | 78 MV/m | 100 MV/m |

*Work supported by the U.S. Department of Energy under contract No. DE-AC02-06CH11357.
#conde@anl.gov

Table 1 also lists the maximum bunch charge that traversed each structure, and the accelerating gradient generated in the structure by its passage. These values of gradient result from numerical calculations with the software MAFIA, using the known parameters of the structures and of the electron bunches. The amplitude of the field probe signals are not a reliable way to measure the field gradients, because the calibration of the probe cannot be made accurately enough for the different modes supported by the structures. Thus, the field probe signals are used solely to monitor possible electric breakdown events in the structures.

The field probe signal can be sent directly to a high bandwidth oscilloscope (Tektronix TDS-6154C; 15 GHz bandwidth). Figure 1 shows this signal and its FFT, as seen when electron bunches propagate through structure #4. Due to the field probe geometry, its signal is basically proportional to the radial electric field present at the tip of the probe. A comparison of the FFT of the signal with numerical simulations allows the different peaks to be identified with the various modes supported by the structure.

## POWER EXTRACTOR FOR TWO-BEAM-ACCELERATION

The development of the necessary components for two-beam-acceleration experiments is being pursued. Thus, we recently tested a decelerating structure, which has an RF power output coupler as an integral part of the structure. The drive beam of a two-beam-accelerator (TBA) would traverse this so-called power extractor, and the generated RF power would then be coupled out of the decelerator and into the accelerating structure.

This power extractor was installed on the AWA drive beamline, and a calibrated bi-directional RF coupler was connected to its output coupler, to enable the measurement of the RF power generated by the beam.

Single electron bunches were initially put through this structure, generating short RF pulses (about 2 ns FWHM) with a frequency spectrum centered at 7.8 GHz. A maximum peak power of 30 MW was generated by electron bunches of 66 nC. Subsequently, bunch trains consisting of 16 electron bunches were used to generate longer RF pulses; these electron bunches were either spaced by six RF periods of the 7.8 GHz wakefield (one RF period of the 1.3 GHz RF gun), or by twelve periods of the 7.8 GHz wakefield (two RF periods of the 1.3 GHz RF gun). Due to the finite group velocity of the RF packets in the structure, the superposition of the RF fields of the individual bunches involves fewer bunches when they are spaced further part. Figure 2 shows a series of oscilloscope traces from the bi-directional coupler signal, for an increasing number of electron bunches, each separated by six RF periods. Obviously, the larger number of bunches generate longer RF pulses, with narrower frequency spectra. Figure 3 shows the bi-directional coupler signal generated by bunch trains in which the bunches are separated by twelve RF periods. In this case, longer RF pulses are generated, but due to the effective superposition of fewer pulses, the amplitude of the RF pulse is smaller, for a given bunch charge.

The highest power generated by this structure was 44 MW, of which 40 MW were actually coupled out, the difference being accounted for by losses in the output coupler. This was achieved with four electron bunches spaced by six RF periods, with a total charge of 107 nC; in this case the pulse length was approximately 4 ns FWHM.

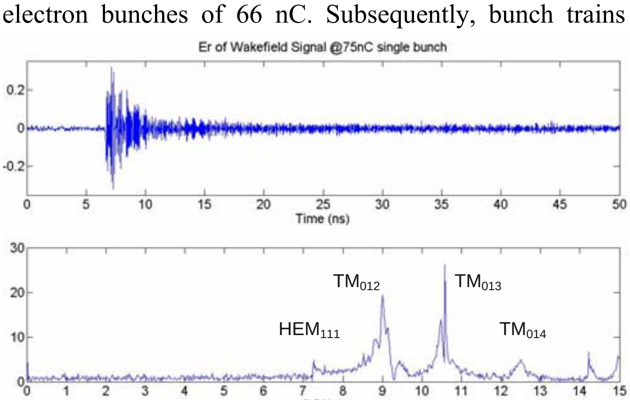

Figure 1: Measurement of the radial electric field driven by a 75 nC electron bunch, using the field probe on Structure 4: (a) temporal profile of the radial electric field; (b) the FFT of the signal.

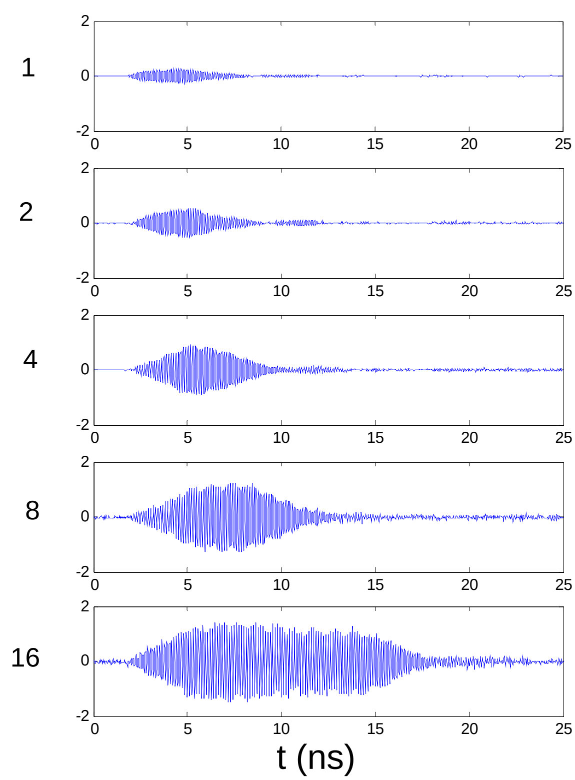

Figure 2: Oscilloscope traces showing the RF pulses sampled by the bi-directional coupler. The number on the left side of the plots indicates the number of electron bunches that propagated through the power extractor.

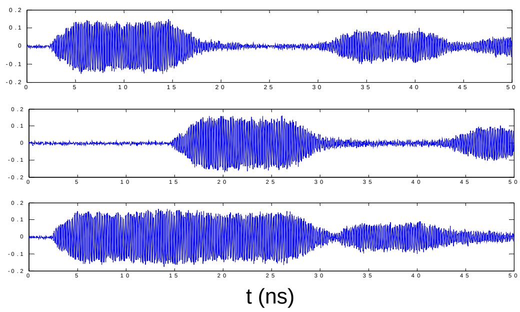

Figure 3: Oscilloscope traces showing the RF pulses sampled by the bi-directional coupler: (a) eight bunches spaced by twelve RF periods; (b) later set of eight bunches spaced by twelve RF periods; (c) sixteen bunches spaced by twelve RF periods.

## SLAC / KEK STRUCTURE

Recently, we have performed an experiment at AWA using a metallic iris loaded standing wave X-band structure developed by SLAC and KEK, which was originally meant to be powered by a klystron. The structure, installed in the AWA drive beamline, is shown in Fig. 4. A bidirectional coupler at the coupling port allows the measurement of the wakefields excited by the passage of the drive electron bunch (Fig. 5). The estimated peak wakefield generated is about 50 MV/m for a bunch charge of 80 nC. Also from the figure, a loaded quality factor Q of about 5500 can be estimated. Figure 6 shows the peak electric field measured at the bidirectional coupler as a function of the drive bunch charge; the deviation from the initial linear dependence is due to the slight bunch lengthening that occurs as the bunch charge is increased. One could increase the gradient to much higher levels by using a multiple bunch drive beam. We believe this is an effective way to test properties of high gradient structures, including the excitation of higher order modes.

## NEXT STEPS

In the immediate future, the development of dielectric loaded structures will proceed, as well as the testing of more X-band metallic structures driven as wakefield devices: a photonic band-gap structure and more iris loaded standing wave structure (built by SLAC / KEK). A

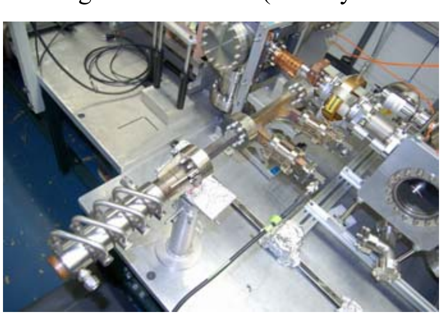

Figure 4: SLAC / KEK X-band structure installed at the AWA beamline.

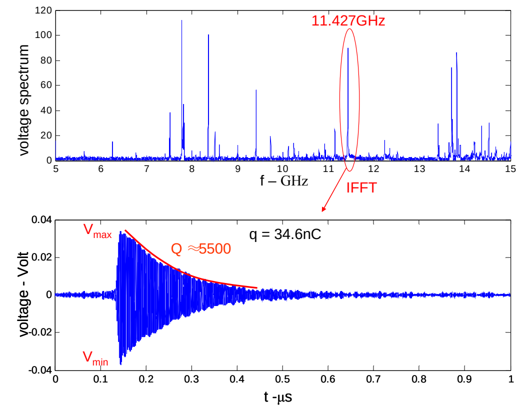

Figure 5: Wakefields observed at bidirectional coupler: (a) FFT of voltage signal; (b) IFFT of 11.4 GHz component only.

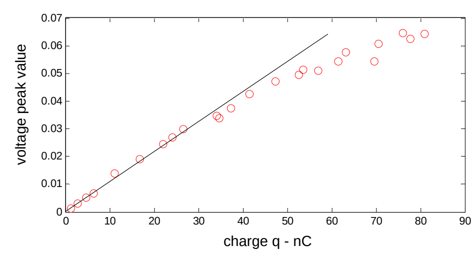

Figure 6: Peak electric field measured at the bidirectional coupler as a function of the drive bunch charge.

new RF power station, now under fabrication, with an additional 30 MW L-band klystron (on loan from LANL – many thanks!) will greatly increase the capabilities of the AWA facility, by increasing the drive beam energy and enabling experiments with smaller diameter structures. This additional RF power will also allow the operation of a second RF gun, now under fabrication, which will provide the witness beam to directly probe the generated wakefields. The development of a Cesium Telluride photocathode fabrication chamber, now in its final stages, will enable the generation of longer electron bunch trains, with high charge per bunch, which will produce longer wakefield RF pulses with even higher amplitude. The goal is to reach gradients on the order of 0.5 GV/m, and to be able to generate RF pulses with GW power level.

*Abstract*

In the plasma wakefield accelerator (PWFA), high quality accelerated electron bunches can be produced by injecting a witness bunch behind a single drive bunch or a train of N bunches. To operate at large gradient the plasma density must be in the $10^{17}$/cc range, corresponding to a typical bunch separation of the order of the plasma wavelength or ~100$\mu$m. We have demonstrated that such a subpicosecond temporal bunch structure can be produced using a mask to selectively spoil the emittance of temporal slices of the bunch*. The bunches spacing, as well as their length can be tailored by designing the mask and choosing the beam parameters at the mask location. The number of bunches is varied by using an adjustable width energy limiting slit. The bunches spacing is measured with coherent transition radiation interferometry. Experimental results will be presented and compared to simulations of the bunch train formation process with the particle tracking code ELEGANT.

# BEAM DYNAMICS SIMULATIONS FOR A 15 MEV SUPERCONDUCTING ELECTRON LINAC COUPLED TO A DC PHOTO-INJECTOR

D. Guilhem, J-L. Lemaire, S. Pichon
CEA, Département de Physique théorique et Appliquée
Bruyères Le Châtel, 91297 Arpajon, Cedex, France

## Abstract

A 15 MeV accelerator scheme based on a DC photo-injector and a RF superconducting linac has been proposed as a new facility for radiography applications.

The beam operating condition is a limited number of bunches up to twenty electron micro-pulses of 100 ps time duration and 200 nC bunch charge at 352 MHz repetition rate.

The overall beam dynamics simulation process based on LANL POISSON-SUPERFISH and PARMELA codes, is presented and the results will be reviewed.

## INTRODUCTION

A new versatile scheme based on well-tested technologies has been studied in the purpose to produce flash X-ray pulses from very intense electron beams impinging a high Z material target [1].

This machine consists to a DC photo-injector coupled to a RF superconducting accelerator. A final beam transport allows tight beam focusing on the target. Electrons bunches are emitted from a photocathode driven by a 266 nm wavelength laser and extracted up to the_energy of 2.5 MeV in a DC gun. The beam is accelerated in a 352 MHz RF-cavity to a final energy of 15MeV (Fig. 1). Among several applications, one requires a total accelerated charge of 1μC. In this scope, we studied two beam distributions in time: either ten electron bunches carrying 100 nC each (pulse time duration of 28 ns) or five electron bunches carrying 200 nC each (pulse time duration 13 ns).

Beam dynamics have been computed using a simulation chain based on LANL codes POISSON-SUPERFISH [2] and PARMELA [2]. The optimizations of the photo-injector beam transport and the final focusing on the target are presented. The results for the whole machine simulation are reviewed for the two different configurations.

## BEAM DYNAMICS CHART

Our beam dynamics study is based on the LANL POISSON-SUPERFISH and PARMELA codes. We have linked them together through a graphical interactive interface which was developed specifically for this use (Fig. 2). POISSON-SUPERFISH first computes electromagnetic field maps of the photo-injector, the RF cavity and final focusing. These results are used as input data in PARMELA to calculate the beam dynamics along the machine. We have developed coupling and post processing tools compatible with CEA-PLOTWIN software (*.plt) [3] which allows powerful, interactive and friendly viewing of the beam behaviour.

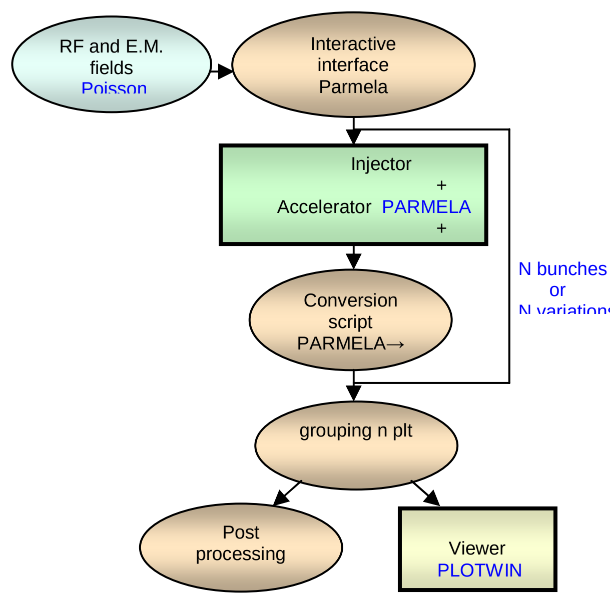

Figure 2: Beam dynamics simulation chart.

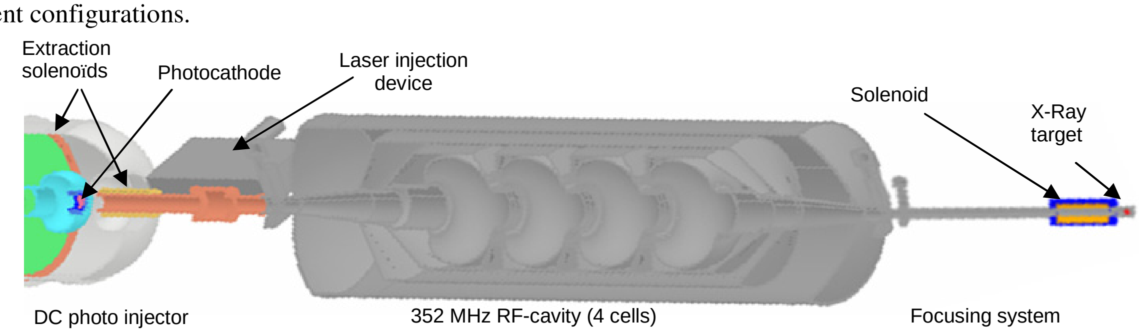

Figure 1: Scheme for the 15MeV RF proposed machine.

For identical beam input conditions, comparisons with other codes (MAGIC, PARTRAN) and experimental validations have been carried out in order to validate this beam simulation scheme.

## PHOTO-INJECTOR OPTIMIZATION

The photo-injector [4] delivers to the linac the required 2.5 MeV pulsed e-beam with the smallest achievable emittance. Every bunch is emitted at 352 MHz and has an initial uniform transverse distribution as well as a 100 ps FHWH time Gaussian distribution.
The photocathode shape, the electrode geometry and the focusing lens contribute to the beam quality (Fig. 3). A cathode recess and the magnetostatic focusing system have been optimized to deal with the space charge effect at the emission and during extraction.

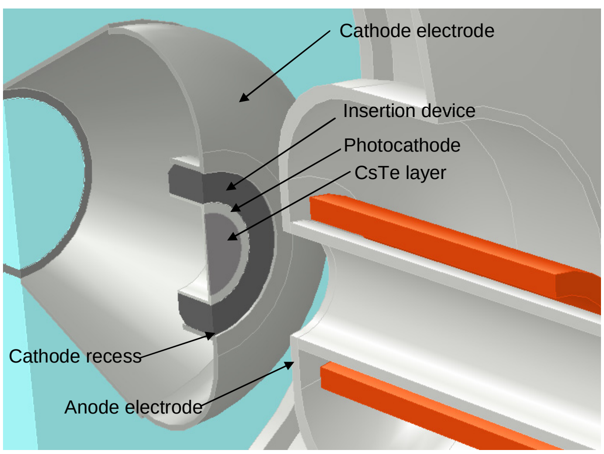

Figure 3: Cathode electrode with photocathode structure.

### [illegible]

The emitive surface of the photocathode has a 40 mm diameter $Cs_2Te$ deposit layered on a 50 mm diameter molybdenum substrate. The photocathode assembly is mechanically inserted by remote handling under ultra high vacuum.

We have performed beam dynamics simulations for different cathode recess values. The cathode recess locally curves the electric field lines. This effect induces a transverse electric field component which contributes to transverse focusing. Since the electron beam is early focused at emission, the space charge is under better control and nonlinear effects are limited.

The beam dynamics has been optimized to provide a parallel beam at the linac entrance (Fig. 4). The best beam transport (lowest emittance) is obtained for a 4 mm length cathode recess. The net gain in emittance is close to 30%.

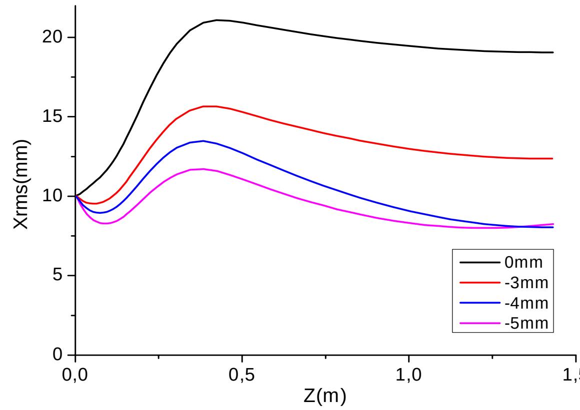

Figure 4: RMS beam envelope for different cathode recess.

### [illegible]

The magnetostatic focusing at extraction is based on a solenoid lens. Two options were considered. The first one is made of a main solenoid surrounding the anode vacuum tube and a bucking coil at the cathode surrounding the vacuum vessel. Initial momentum condition is then nil and increase in emittance is limited. The second option consists to a single solenoid which has been magnetically shielded. This last solution produces a stronger magnetic field localized in a restricted volume and acts as a short magnetic lens (solenoids must be considered as long magnetic lenses). In addition, no need for a bucking coil is required in this case. Tune is consequently eased.

Former results (Fig. 5) showed that the solenoid location along the beam axis is a critical parameter. After optimization of the two options, the second one (shielded coil) leads to a decrease of the beam emittance by about 10%.

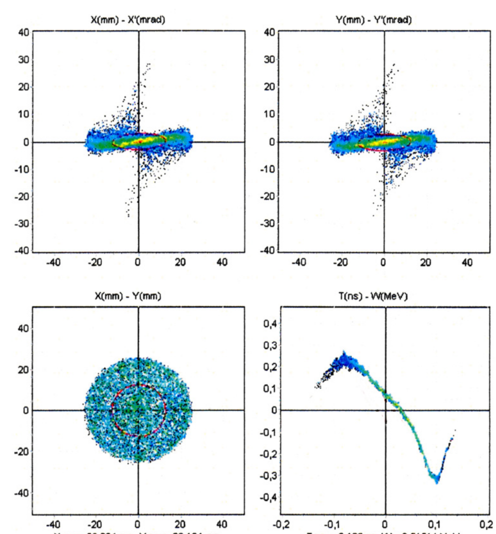

Figure 5: Phase space diagrams with the optimized shielded coil at the linac entrance.

## SIMULATION RESULTS OF THE WHOLE ACCELERATOR MACHINE

Beam dynamics of the whole accelerator machine has been carried out thanks to the simulation chain described above. The optimized values of the photo-injector are used. The linac RF cavity phase is tuned to provide the lowest RMS beam energy spread. The final focusing system is adjusted to provide the smallest spot on the target. Two different bunch configurations have been studied: 5 bunches of 200nC/bunch and 10 bunches of 100nC/bunch. Differences between these configurations are essentially the total beam duration from 13 ns to 28 ns, the space charge effects and the beam loading in the RF cavity.

The beam envelopes and the phase space diagrams on the target are shown on the figures below (Figs. 6-8).

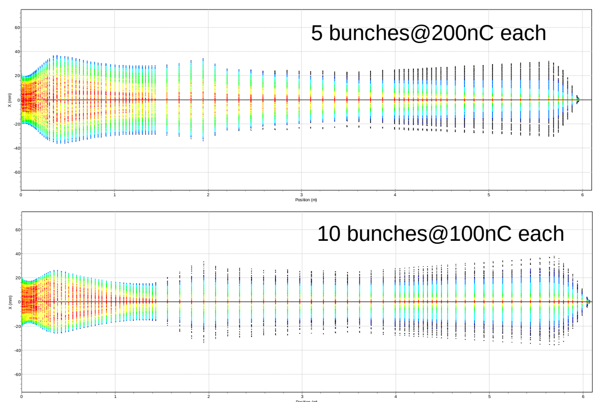

Figure 6: RMS beam envelope for the two configurations.

Although the number of bunches and charge per bunch are very different, the simulations for the two accelerated beam configurations give very close results (difference of only 5% on the spot size). The larger energy spread due to the beam loading of the 10 bunches train configuration carrying 100 nC each is balanced by the higher space charge effect of the 5 bunches train configuration carrying 200 nC each.

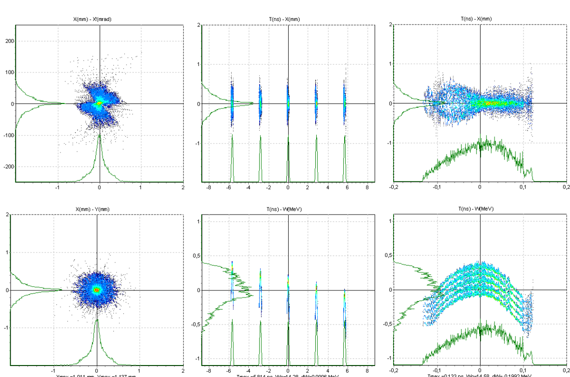

Figure 7: Phase space diagrams on the target for the 5 bunches@200nC per bunch configuration.

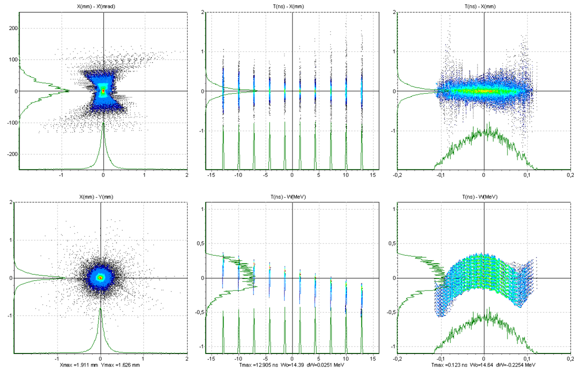

Figure 8: Phase space diagrams on the target for the 10 bunches@100 nC per bunch configuration.

The 5 bunches train configuration @200nC leads to faster radiographic imaging (13 ns) at same spot size and dose. In addition, the total length of the high voltage generator part of the photo-injector is shorter allowing a more compact overall radiographic facility.

## CONCLUSION

Beam dynamics simulations for a new X-ray radiographic project have been performed with an interactive, fast and accurate chain simulation codes based on POISSON- SUPERFISH and PARMELA .

Photo-injector beam transport calculations have showed that a single shielded solenoid achieves best beam qualities (10% reduction in beam emittance) than the usual focusing configuration using long solenoid and bucking coil. Thanks to a cathode recess, the early space charge effect is limited in the photo-injector. In consequence the beam emittance is lowered by 30% for a 4 mm optimized cathode recess.

The whole machine simulations for a 1μC total charge beam have been carried out for two beam configurations: 5 bunches of 200 nC each and 10 bunches of 100 nC. Quite similar beam characteristics are obtained on the target. Spot size and dose are the same. The 5 bunches train configuration @200nC allows faster radiographic imaging (13 ns). The total length of the high voltage generator part of the photo-injector is also shorter allowing a more compact radiographic facility.

# BEAM DYNAMICS AND ERROR STUDIES OF THE SPIRAL2 DRIVER ACCELERATOR

P. Bertrand, GANIL, Caen, France
J-L. Biarrotte, L. Perrot, CNRS / IPN Orsay, France
D. Uriot, CEA Saclay, France.

*Abstract*

After a detailed design study phase (2003-2004), the SPIRAL2 project at GANIL (Caen, France) was officially approved in May 2005, and is now in its phase of construction, with a project group including the participation of many French laboratories (CEA,CNRS) and international partners. The SPIRAL2 facility is composed of a multi-beam driver accelerator (5mA 40MeV deuterons, 5mA 33Mev protons, 1mA 14.5MeV/u heavy ions), a dedicated building for the production of Radioactive Ion Beams, the existing cyclotron CIME for the post acceleration of the RIBs, and new experimental areas. In this paper we focus on the beam dynamics and error studies dedicated to the SPIRAL2 accelerator part of the project, from the ECR sources to the High Energy Beam Lines which have been recently updated.

## INTRODUCTION

The SPIRAL2 facility is now in its construction phase with huge progress for many parts of the machine as explained in [1]. In parallel, many beam dynamics calculations have been performed in order to extend the possibilities of the accelerator, and to take into account new demands of experimental physics.

As indicated table 1, the Spiral2 accelerator will deliver a huge variety of beams, at various intensities and energies, which constitutes a great challenge.

Table 1: Beam Specifications

| beam | P+ | D+ | ions | ions |
|---|---|---|---|---|
| Q/A | 1 | 1/2 | 1/3 | 1/6 |
| Max. I (mA) | 5 | 5 | 1 | 1 |
| Min. output W (Mev/A) | 2 | 2 | 2 | 2 |
| Max output W (Mev/A) | 33 | 20 | 14.5 | 8 |
| CW Max. beam power (kW) | 165 | 200 | 44 | 48 |

Our beam dynamics reference program is the well known TRACEWIN code [2]. It allows us to simulate the machine from the source to the final target, with a huge number of pseudo-particles. All the simulations can use 3D electromagnetic maps of magnets and cavities which are presently under construction, and the beam optimization uses the set of diagnostics which will be effectively used in the real machine. Moreover we project to incorporate (part of) TRACEWIN into the control system as an essential component of the tuning process.

## SPIRAL2 INJECTOR

### *LEBT Lines and RFQ*

The beam dynamics of the LEBT has been explained in detail in [3] and there is no recent modification. However we have investigated in detail the behaviour of the beam for various estimated values of the space charge compensation: this aspect is crucial when we manage the duty cycle and keep perfect bunches with a combination of ECR source, slow chopper and RFQ pulsations.

The 88 MHz 4-vane RFQ accepts charge/mass ratio between 1 and 1/3, and is designed for a very high transmission, in particular in the case of Deuterons at full intensity. We have checked that the 99% transmission was kept with or without space charge.

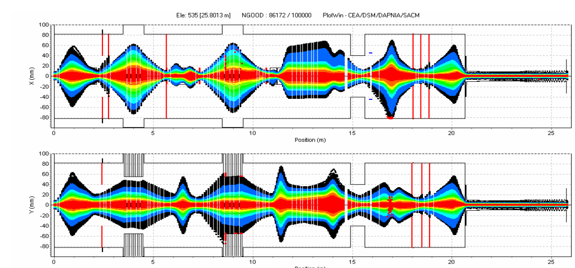

Figure 1: LEBT transport and RFQ acceleration for 1mA 1/3 heavy ions.

### *MEBT Line*

The SPIRAL2 MEBT (Fig. 2) is a complex 8 meters transfer line with the following fundamental functions:

- Transverse/longitudinal matching into the linac
- Fast chopping system and associated beam stop
- Drift for a future connexion of a q/A=1/6 injector
- Movable slits for halo elimination.

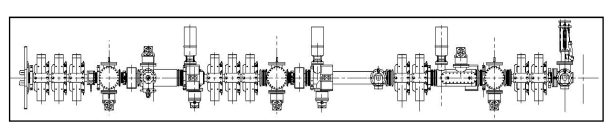

Figure 2: SPIRAL2 MEBT design.

The MEBT beam energy is fixed to 0.75 Mev/u, which corresponds to 7.5 kW for 5mA D+. Beam dynamics have been performed for all types of ions, using particle distributions from LEBTs and the RFQ, using quadrupole and rebuncher 3D maps and with linac matching (fig.3).

Calculations with use of the fast chopper have been performed in parallel with the development of the device.

We have checked that using a static magnetic deviator combined with an RF electric wave did not generate a significant emittance growth (Fig. 4).

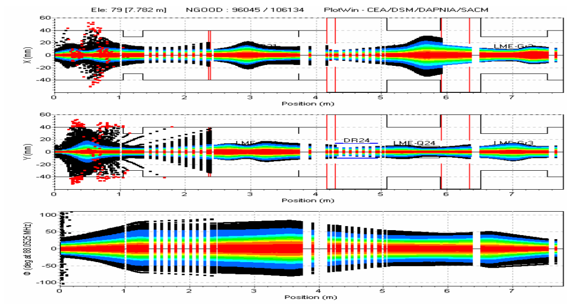

Figure 3: LME nominal (x,y, $\phi$) optics for 5mA D+ beam.

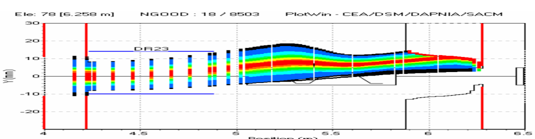

Figure 4: LME fast chopper and beam stopper (7.5 kW).

## SUPER-CONDUCTIONG LINAC

The SPIRAL2 linear accelerator [4] is composed of 2 families of 88 MHz SC QWR cavities ($\beta_0$=0.07, $\beta_0$=0.12), which permits the acceleration of all ions and energies mentioned in table 1. Between each cryomodule, beam focusing is performed by means of 2 warm quadrupoles with short vacuum/diagnostics boxes in between.

### *Linac Tuning*

Thanks to the regular geometry of the linac, it is possible to put the quadrupole strengths in such a way to obtain a continuous phase advance per meter and a continuous transverse focusing channel. We match the beam to the Linac by adjusting the 2 last MEBT quadrupoles and the first Linac doublet (Fig. 5).

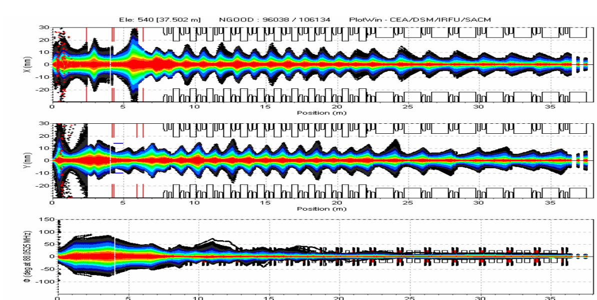

Figure 5: 5 mA $D^+$ nominal (x,y,$\phi$) optics in MEBT and the linac (40 Mev at exit).

The control of the transverse beam matching in the periodic sections is done by using the quadrupolar moment of the Beam Position Monitors. The non interceptive BPMs are located inside the first quadrupole of each lattice, where envelopes are different in x and y. The longitudinal matching is tuned by applying a similar method based on the adjustment of the 3 MEBT re-bunchers, in association with beam phase length diagnostics located in the first Linac periods.

### *Output Energy Tuning*

Physics requirements impose the Linac output energy to be adjustable between 2 and 20 MeV/u, with the beam kept bunched (<0.5ns) at target in some cases. In the low energy cases, the $\beta_0$=0.07 cavities are tuned to obtain 2 MeV/u, while $\beta_0$=0.12 cavities are off except one or two, in order to keep the beam bunched at the linac exit.

### *Error Studies*

The TRACEWIN code can pilot a heterogeneous collection of computers including PCs and clusters. We use this feature to simulate more than 1400 linacs with $10^6$ macro-particles for each one, and study very precisely the losses occurring in the full linac, following the Extreme Value Theory detailed in [5]. For each linac the procedure is the following: the parameters are initialized with theoretical perfect values. A set of random "*static errors*" is applied: cavity/quads misalignments, amplitude errors due to tuning or machining imperfections... and the standard corrections scheme is performed, typically the beam centring with steerers associated with BMPs, beam size adjustment with envelope measurement and quads. In a second step, a set of random "*dynamic errors*" is applied: RF jitter, mechanical vibrations, diagnostic noises or errors…Finally the simulation with $10^6$ particles is done from the output ECR source to the linac exit, using a Gaussian initial beam distribution. Most of elements are simulated using a 3D electromagnetic field maps. Then, statistical information concerning emittance growth, centroid behaviour and losses are available. In the case of 5mA 40MeV $D^+$, average Linac-integrated losses are 0.2W, with 0.26W deviation (Fig. 6).

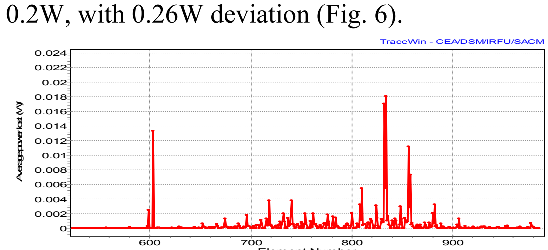

Figure 6: Average beam loss distribution for $D^+$.

## HEBT LINES

HEBT have been recently updated, according to the evolution of physics demands and implantation of buildings and experimental areas:

The "red" production cave (separate building) is dedicated to the production of radioactive nuclides using D+ beam, neutron converter and UCx target production. RIBs will be used in a low energy hall (DESIR) or/and accelerated with the existing CIME cyclotron.

The Super Separator Spectrometer (S3) is dedicated to experiments using heavy ion beams from LINAC (super-heavy and very-heavy nuclei, spectroscopy at and beyond the drip-line, isomers and ground state properties…)

Neutrons For Science hall (NFS) is dedicated to cross-section measurements (TOF or irradiation techniques) and fundamental physics. It concerns transmutation of nuclear waste, design of future fission and fusion reactors, nuclear medicine and tests and development of new detectors.

SRI facility is dedicated to atomic physics research.

HEBT lines are designed with a limited number of repeated structures:

- Matching sections composed of 4 quadrupoles, used at Linac exit, for the beam dump, and at the entrance of each experimental room,
- Triplet sections for transport, with repetitive transverse waists and periodic envelopes,
- Achromatic double deviations for beam distribution and protection of targets against energy fluctuations.

HEBT beam dynamics scheme is such that we have always the same radial envelopes, up to a homothety, according to the type of beam and the final energy (fig. 7). In some cases, very short bunch time lengths are needed on target (<0.5 ns for $S^3$and NFS). We will use a set of 2 SC cavities (probably $\beta_0$=0.07) installed between triplet sections, where the beam diameter is minimum. The SPIRAL2 beam dump is located in the straight line of the LINAC. For safety and radioprotection reasons, beam dump entrance is located around 6meters from the last matching quadrupole. An optimized beam-dump geometry profile limits the power deposition density to 400W/cm² and permits a 200kW beam (5mA $D^+$, 40MeV), although we will always limit the duty cycle to around 5% during the tuning of the accelerator.

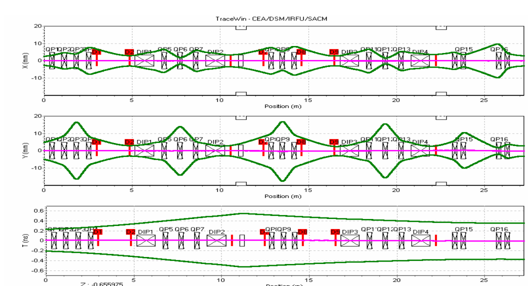

Figure 7: 5rms HEBT envelopes of Q/A=1/3 1mA ion beam at 14.5MeV/u between linac and $S^3$.

Ideally, HEBT beam error and beam loss studies must be done for all beam lines, all species and for minimum and maximum energies. By decreasing artificially the beam tube diameter, the worst case appears to be the 33MeV protons beam: beam losses are located in the middle of triplet sections, where the vertical envelope is maximal, and also at the output of the re-buncher. (Fig.7).

Recent activation calculations confirm that dose rate obtained with stainless steel vacuum chamber would be higher than with aluminium, for deuterons or even protons. Moreover, the decrease after beam put off is much favourable in the case of aluminium. In order to permits hands-on maintenance and reduce exposure, we are looking carefully at the best compromise in term of beam tube diameter and material, collimators and beam loss monitors along the HEBT lines.

## OPERATION MODES

It is fundamental to protect the machine from thermal and activation problems during the tuning as well as at full nominal beam power. The best way is certainly to dispose of a dedicate software/hardware which gives successive authorizations to increase the beam power, depending upon the part of the machine we consider.

However in the case of SPIRAL2, the problem is very complex, because it also depends of the type of accelerated beam (D+, p+…) and of the required final energy. Moreover we have many possible paths for the beam (2 ECR sources, many experimental halls…) and we must distinguish various types of targets (with or without neutron convertor in the red cave for example…)

In order to have a clear idea of what we are doing during the tuning and avoid dangerous mistakes, we propose to introduce a "tuning mode 3D-Matrix", with 3 axis corresponding to the following basic modes:

- The "beam-type mode", corresponding to the type of beam we want to accelerate,
- The "machine-path mode", corresponding to the path of the beam and the intermediate beam stop or final target we consider,
- The "beam-power mode", corresponding to a maximum authorized beam power at a given step.

Once the 3D (sparse) matrix obtained is filled according to the relevant combinations, and given a beam type at a given final energy, we can extract the corresponding 2D matrix automatically and determine the succession of safe steps to increase the beam power along the machine.

## CONCLUSION

Beam dynamics calculations for the SPIRAL2 driver accelerator have been performed on various aspects, with results giving more and more confidence in the machine capability to ensure a safe and flexible beam operation. Further studies are on-going, especially concerning the final definition of the HEBT lines, the management of operation modes, and the role to be played by the TRACEWIN code into the control-command process of the real machine.

# BEAM DYNAMICS SIMULATION OF THE LOW ENERGY BEAM TRANSPORT LINE FOR IFMIF/EVEDA

N. Chauvin*, O. Delferrière, R. Duperrier, R. Gobin, P.A.P. Nghiem, D. Uriot,
CEA, IRFU, F-91191 Gif-sur-Yvette, France.

*Abstract*

The purpose of the IFMIF-EVEDA (International Fusion Materials Irradiation Facility-Engineering Validation and Engineering Design Activities) demonstrator is to accelerate a 125 mA cw deuteron beam up to 9 MeV. Therefore, the project requires that the ion source and the low energy beam transport (LEBT) line deliver a 140 mA cw deuteron beam with an energy of 100 keV and an emittance of 0.25 $\pi$.mm.mrad (rms normalized) at the entrance of the RFQ. The deuteron beam is extracted from a 2.45 GHz ECR source based on the SILHI design. A LEBT with a two solenoids focusing system is foreseen to transport and adapt the beam for the RFQ injection. In order to validate the LEBT design, intensive beam dynamics simulations have been carried out using a parallel implementation of a particle-in-cell 3D code which takes into account the space charge compensation of the beam induced by the ionization of the residual gas. The simulations results (in particular from the emittance growth point of view) performed under several conditions of gas species or gas pressure in the beam line are presented.

## INTRODUCTION

The International Fusion Materials Irradiation Facility (IFMIF) will produce a high flux ($10^{18}$n.m$^{-2}$.s$^{-1}$) of 14 MeV neutron dedicated to characterization and study of candidate materials for future fusion reactors. A solution based on two high power cw accelerator drivers, each delivering a 125 mA deuteron beam at 40 MeV to a liquid lithium target, is foreseen [1].

In the first phase of IFMIF, called EVEDA (Engineering Validation and Engineering Design Activities), a 125 mA cw/9 MeV deuteron demonstrator accelerator will be constructed, tested and operated at Rokkasho-mura, in Japan [2]. This accelerator is composed by an ECR (Electron Cyclotron Resonance) ion source, a low energy beam transport (LEBT) line, a RFQ (100 keV to 5 MeV) [3], a matching section, a superconducting Half Wave Resonator cavities section (5 MeV to 9 MeV), and a high energy beam line equiped with diagnostic plate and a beam dump. This paper will focused on the LEBT section of the EVEDA project.

The purpose of the LEBT is to transport the 140 mA/100 keV deuteron beam extracted from the ECR source to the RFQ. In order to design the LEBT parameters and to optimize the beam injection in the RFQ, beam dynamics simulations have been performed.

* Nicolas.Chauvin@cea.fr

## LOW ENERGY BEAM LINE LAYOUT

### *ECR Ion Source and Extraction System*

The beam intensity and reliability required for the IFMIF project have lead to the choice of an ECR ion source to produce the deuteron beam. The IFMIF source, based on the SILHI design, will operate at 2.45 GHz [4]. The extraction system has been optimized to increase the total beam intensity from 150 mA to 175 mA in order to meet the 140 mA $D^+$ requirements, as $D_2^+$ and $D_3^+$ are also produced in the ECR source. The extraction energy has also been increased from 95 keV to 100 keV, and a four electrode system has been calculated to minimize the $D^+$ divergence. In order to decrease the risk of high voltage breakdown, the maximum of the extraction electric field has been kept around 100 kV/cm.

Table 1: Beams Parameters after the Extraction System

| Extracted Species | Intensity (mA) | Emittance ($\pi$ mm.mrad) |
|---|---|---|
| $D^+$ | 141 | 0.064 |
| $D_2^+$ | 26.5 | 0.043 |
| $D_3^+$ | 8.8 | 0.042 |

The particle distributions after the source are derived from their tracking through the extraction system. Those beam distributions, of which main parameters are summarized in table 1, have been taken as inputs for the LEBT simulations. More precisely, the simulations start with a part of source extraction system, computed with AXCEL-INP [5], in order to get relevant boundary condition.

### *Low Energy Beam Transport Line*

The optics for the LEBT is based on a dual solenoids system. The 3D magnetic field maps of the solenoids (pole length: 300 mm), computed by finite elements method, have been included in the simulations.

The total length of the beam line, from the plasma electrode to the RFQ entrance is 2.05 m (see Fig.1). A pumping system and beam diagnostics as movable Faraday cup and emittance measurement could be inserted between the two solenoids. A regulating valve is also foreseen in order to inject a controlled flux of a specific gas in the beam line.

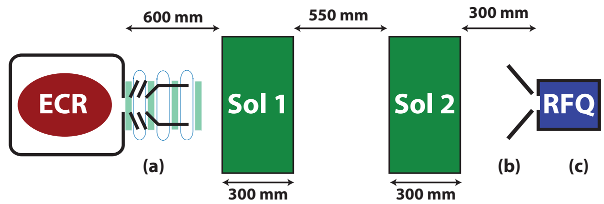

Figure 1: Scheme of the IFMIF-EVEDA LEBT. (a): ECR extraction system - (b): RFQ injection cone - (c): first RFQ segment.

## SIMULATION AND OPTIMIZATION

### Codes Used

For this work, three different numerical codes have been employed.

First, the modeling of the extraction system of the ECR source has been done with a commercial code, called AXCEL-INP.

In order to achieve realistic beam transport simulations in the 100 keV energy range and with such a high intensity, it is necessary to take into account the space charge compensation of the beam on the residual gas. For that, a 3D particle-in-cell (PIC), called SOLMAXP, has been recently developed at CEA/Saclay and has been employed for this work. The basics of this code are briefly described in the next section.

Finally, the optimization of the LEBT optics parameters for the beam injection in the RFQ has been performed with TraceWin [6].

### SOLMAXP: A 3D PIC Code

In this code, the motion of the macro-particle (each of them carrying an equal fraction of the overall beam intensity) is integrated on a time step basis. The simulation region is divided into a 3D grid. At each time step, the following procedure is done:

- weighting of the position of the particle to assign a charge density on the grid nodes.
- calculation of the potential and electric field from the charge density, by solving the Poisson equation.
- weighting of the forces (from the **B** and **E** self-generated fields and external fields) at the position of the particles.
- calculation of the new velocity and the position of the particles by integration of the equation of motion.
- simulation of collisions (ionization and neutralization) between particles, with the help of a Monte-Carlo algorithm.

This procedure is repeated until the emittance at the end of the LEBT has reached its steady-state.

### Optimization Method

A first calculation is made with TraceWin, considering around 70 % of space charge neutralization, to find the beam transport and focalization that met the required Twiss parameters for the injection in the RFQ. In our case, the goal is to find magnetic field values applied by the two solenoids of the LEBT.

Then, a calculation is made with SOLMAXP, with the beam line parameters found with TraceWin. SOLMAXP is run until the steady-state of the space charge compensation is reached. The code outputs are the particle distribution (ions, electrons, neutral atoms) and the electric field map derived from the potential created by the space charge along the beam line. A projection of a space charge potential map is represented in Fig. 2.

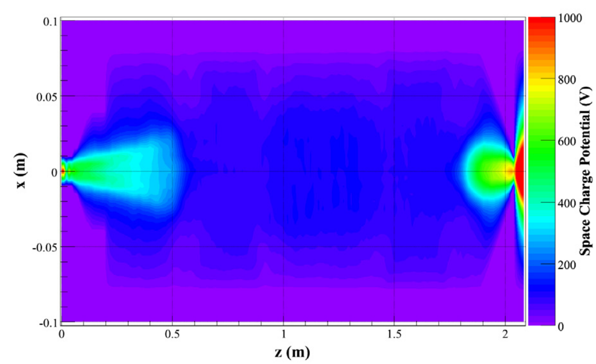

Figure 2: Two dimension projection in (z0x) plane of a space charge potential map.

For the TraceWin calculation, this space charge electric field map is then superimposed to those of the beam line elements. So, the RFQ injection optimization is now performed with space charge compensation through the LEBT. During that TraceWin optimization process, the optics parameters are modified and consequently, the space charge compensation should vary, because of the new particle distribution. Thus, another simulation has to be done with SOLMAXP.

After a few steps of that back and forth process between the two codes, the convergence toward the optimized solution is reached.

## SIMULATION RESULTS

One of the most critical beam parameter in the IFMIF LEBT, is the emittance growth. The emittance values presented in the following section are derived from the particle distributions calculated with SOLMAXP.

### Gas Pressure

Previous measurements performed with the SILHI source and LEBT [7] showed that beam emittance can be improved by injecting some gas in the beam line. Furthermore, this improvement seems to depend strongly on the gas species.

Preliminary simulations were done, with a shorter and simplified beam line, for pressure values of deuteron gas of $4\times10^{-4}$ hPa and $4\times10^{-5}$ hPa. The results showed clearly that with the higher pressure, the obtained emittance is 45% lower.

But, in the IFMIF LEBT, the pressure has to be kept around several $10^{-5}$ hPa to minimize the high voltage breakdowns and ion losses on neutral gas. Then, we chose a total pressure value of $5\times10^{-5}$ hPa. Nevertheless, according to reference [7], a lower emittance could be obtained by adding a heavier gas like krypton in the beam line.

Assuming that the residual $D_2$ gas contibution to the total pressure in the beam line is $10^{-5}$ hPa, two simulations were done by adding a partial pressure ($4\times10^{-5}$) of either $D_2$ or krypton, all the other parameters remaining constant. The results are presented in table 2.

Table 2: Simulations Results for Two Gas Species Injected.

| $D_2$ partial pressure (hPa) | Kr partial pressure (hPa) | Final Emittance ($\pi$ mm.mrad) |
|---|---|---|
| $5\times10^{-5}$ | 0 | 0.41 |
| $1\times10^{-5}$ | $4\times10^{-5}$ | 0.31 |

These simulation results confirm that the emittance is lowered with kryton injection, as it has been observed experimentally. Then, we can recommend that some krypton has to be injected in the IFMIF LEBT.

Finally, we have to consider the loss rate due to the $D^+$ beam neutralization by the gases. With these pressure conditions, the loss rate is around 2.4%.

### *Focalization*

In the preliminary optimization process, it has been determined that the Twiss parameters required for the beam injection in the RFQ could be reached with two different beam focalization types: with or without a beam waist between the two solenoids (respectively called “strong” and “weak” focalization).

Simulations have been performed for these two cases, with a gas pressure of $5\times10^{-5}$ hPa ($D_2$ and Kr). Fig. 3 shows the emittance results.

This results shows that the “weak” focalization should be adopted for the IFMIF LEBT in order to get a final emittance value of $0.31\pi$ mm.mrad. The magnetic field values on the two solenoids are respectively 0.36 T and 0.4 T

### *Space charge compensation steady-state*

The simulations with SOLMAXP make possible to determine when the space charge compensation steady-state is reached. This information can be useful for an operation in pulsed mode, during the commissioning phase, for example. In this case, the pulsed mode has to be representative of the cw mode from the space charge compensation point of view.

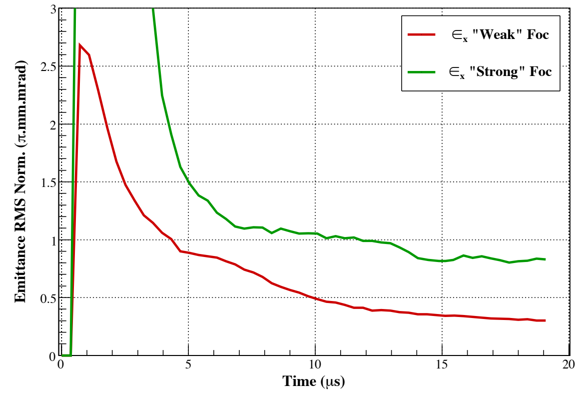

Figure 3: Emittance evolution as a function of time, for the two type focalisation conditions. The simulation starts at time t=0.

From Fig 3, one can deduce that the space charge compensation steady-state is reached after around 15 $\mu$s.

## CONCLUSIONS AND PERSPECTIVES

The beam dynamics simulations for the IFMIF LEBT have been achieved with a 3D PIC code developed at CEA/Saclay to compute the space charge compensation of the beam by the ionization of the residual gas.

The calculated beam emittance value at the end of the LEBT is still higher than the RFQ requirements. However, the optimization process, in order to adapt the beam for its injection in the RFQ is currently in progress. The preliminary results are promising and further optimization may lead to a lower beam emittance value than the current one. Otherwise, the final beam emittance can also be lowered by increasing slightly the krypton pressure in the beam line or by reducing the distance between the two solenoids.

*Abstract*

One major system of IFMIF (International Fusion Materials Irradiation Facility) is its accelerator facility, consisting of two 175 MHz CW accelerators, each accelerating a deuteron beam of 125 mA to the energy of 40 MeV. This high power beam, 10 MW, induces challenging issues that lead to plan a first phase called EVEDA (Engineering Validation and Engineering Design Activity), where only the portion up to 9 MeV of one accelerator will be constructed and tested. For these accelerators, the Parameter Design phase is about to be completed. Particular efforts have been dedicated to minimise the space charge effect that can strongly increase the beam size via the halo, and the losses that can prohibit the requested hand-on maintenance. This paper presents the status of these studies.

## INTRODUCTION

In the future Fusion Demonstration Reactor (DEMO), the materials surrounding the plasma will be submitted to a very intense neutron flux, so that their atoms can be displaced up to hundreds of times more than with those of present fusion materials. In order to test and qualify the material behaviour under such severe irradiations, the International Fusion Materials Irradiation Facility (IFMIF) is planned, with the purpose of delivering an intense neutron flux, generated by the impact of an accelerated deuteron beam on a liquid lithium target. One major system of IFMIF is its accelerator facility, consisting of two 175 MHz CW accelerators, each accelerating a deuteron beam of 125 mA to the energy of 40 MeV. The total power delivered at the target is 10 MW. One important challenging specification of these accelerators is therefore their very high intensity, which must nevertheless be reconciled with the requested hands-on maintenance imperative. That is why a first phase called Engineering Validation and Engineering Design Activity (EVEDA) is now starting, where a prototype accelerator will be constructed and tested, consisting of only the portion up to 9 MeV of one IFMIF accelerator. For these accelerators, the parameter design and beam dynamics simulations are now well engaged. Two topics have been particularly scrutinised: characterisation and minimisation of the space-charge effect, very critical in the low energy part, and of the losses, very critical in the high energy part. Different solutions have been studied, and the choices between them are either done or underway. In this paper, after having given the general layout, the status of those studies is presented for each accelerator section.

## LAYOUT & CHALLENGING ISSUES

The layout and general parameters of IFMIF and EVEDA accelerators are given in Fig.1. D+ particles are extracted from the ion source at 100 keV, then properly focused by the LEBT in order to be injected into the RFQ where they are bunched and accelerated to 5 MeV. The MEBT matches the RFQ output beam in transverse and longitudinal to that required by the superconducting HWR-Linac. Composed of 4 cryomodules housing solenoids and accelerating cavities, the Linac accelerates particles to the final energy of 40 MeV, where the HEBT transports the beam to the lithium target while giving it the required dimensions and homogeneity. For the prototype accelerator, only the first cryomodule will be constructed, and a special HEBT sends the resulting 9 MeV beam with the right dimensions to a beam dump, while allowing to measure its characteristics.

For Beam dynamics studies, the TraceWin package code(including PARTRAN and TOUTATIS) [1] is used as the common code between the different sections, where multiparticle trackings are performed under a strong space charge regime. Given the very high

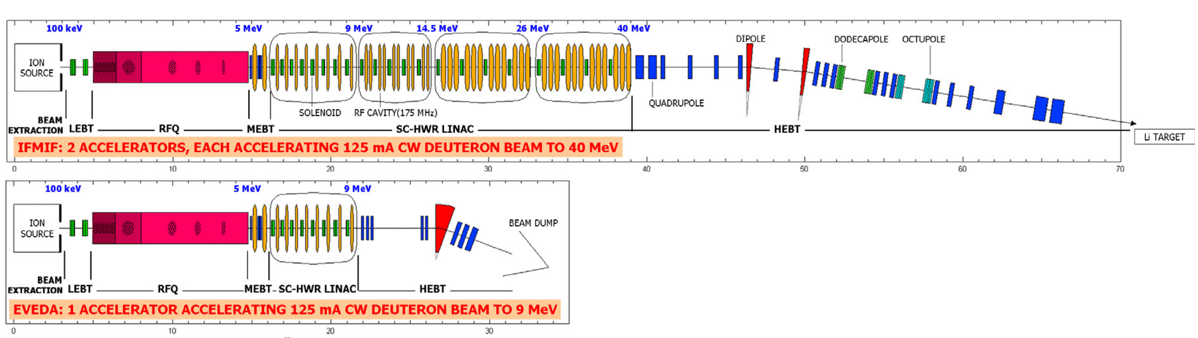

Figure1: General layout of the IFMIF-EVEDA accelerators.

intensity involved, any linear calculation is even useless. Indeed, space charge forces always overtake magnetic forces. The tune depression parameter is 0.4-0.5 in the RFQ, and 0.2-0.5 in the HWR-Linac. It results a high compactness for the accelerator so that available space for beam equipments and diagnostics has been dramatically reduced.

The high intensity impacts also strongly on beam losses considerations. To allow hands-on maintenance, losses should not exceed 1W/m for particles at energies beyond 5 MeV. Table 1 lists the beam power at different positions along the accelerator and the corresponding beam fraction per meter allowed to be lost. We can see that it concerns a really tiny part of the beam. Let us consider for example the 23 m long HWR-Linac. If we adopt an accepted loss average current of 100 nA/m, it means that, no more than 2 $10^{-5}$ of the beam can be lost for the whole Linac. This demonstrates how carefully should be considered the beam loss problem for IFMIF. In particular, beam dynamics studies must be made with $10^6$ macroparticles downstream the LEBT, and total losses of more than two dozens of macroparticles should be avoided. Losses in case of errors, tunings or accidents should also be precisely examined.

Table 1: Beam Energy, Beam Power and Allowed loss/m (Beam Fraction or Current) at Different Locations

| End of | Energy (MeV) | Power (MW) | Allowed loss (fraction/m) | Allowed loss (nA/m) |
|---|---|---|---|---|
| RFQ | 5.0 | 0.625 | 1.6 $10^{-6}$ | 200 |
| 1$^{rst}$ Cryo | 9.0 | 1.125 | 9.0 $10^{-7}$ | 100 |
| 2$^{nd}$ Cryo | 14.5 | 1.813 | 5.5 $10^{-7}$ | 70 |
| 3$^{rd}$ Cryo | 26.0 | 3.250 | 3.1 $10^{-7}$ | 38 |
| 4$^{th}$ Cryo | 40.0 | 5.000 | 2.0 $10^{-7}$ | 25 |

## BEAM EXTRACTION

The beam extraction system is designed following that of the SILHI source [2]. To extract a higher flux from the ion source, the diameter of the plasma electrode hole is enlarged from 10 to 12 mm. To reduce the space charge effects, the overall length of extraction electrodes has been shortened by reducing their number from 5 to 4. Their spacing has been adjusted to keep a maximum electric field not exceeding too much 100 kV/cm. As a result, the extracted beam emittance is 0.06 $\pi$mm.mrad (normalised RMS), at the current of 140 mA (D+) in anticipation of some losses in the low energy sections. The beam distribution is not Gaussian. The density is rather flat, except on a thin part near the edge where it is higher. This is due to the beam size, in the very first extraction steps, which spreads into non linear focusing zones so that the external part is folded toward interior. For a same emittance, this distribution is more compact than a Gaussian one and should not be unfavourable.

## LEBT

In this low energy section, the strong space charge is partially compensated by residual gas electrons. A fine calculation of the resulting space charge potential is thus necessary, and it has been performed with a home made code [3], taken into account the ionisation and the dynamics of ions and electrons. It has been found with this code that the space charge is better compensated within a quadrupole than within a solenoid. But for this line, quadrupoles induce more emittance growth because the distance source-quadrupole is so huge that a bigger beam enveloppe is induced than with solenoids that focus in both planes at the same time. For solutions with two solenoids, it has also been noted that a strong focusing scheme (with a waist in between them) leads to a stronger emittance growth. Finally, a configuration with 2 solenoids has been adopted in the weak focusing scheme. The 2.1m total length can admit various technical equipments and diagnostics, of which an emittance measurement. No beam loss occurs in this section, excepting the neutralisation induced by the addition of Krypton gas aiming at producing a more linear space charge. Nevertheless, the output emittance is higher than expected. This value can be lowered as first further optimisations have shown. Otherwise, either higher Krypton pressure has to be added, or the distance between the solenoids has to be reduced. The matching of the output beam to the RFQ channel is being performed by means of the TraceWin code.

## RFQ

From this section, calculations begin to be made with $10^6$ macroparticles, and losses should begin to be carefully managed. For that, the design [4] has adopted a "2TERM" geometry type combined with a strong electric focusing to produce extremely linear transverse fields around the beam. At the end of the Gentle Buncher, about the first third of the RFQ, an abrupt decrease of the aperture is intended to loose out-of-energy particles that are not bunched, in order to prevent them from being accelerated to higher energy. On the contrary, in the last third of the RFQ all parameters are let unchanged to avoid losses at an energy approaching 5 MeV. Therefore, losses are concentrated in the first part and concern mainly particles at low energy around 100 keV. Notice that only 3 particles out of $10^6$ with energies between 3.5 and 4.5 MeV are not bunched and will be lost in the next sections. These calculations have been made with the PARMTEQM code [5], cross-checked with the TOUTATIS code. The overall transmission of the 9.78 m long RFQ depends on the beam current, emittance, and distribution type at input. We can remember that for 130 mA, 0.25 $\pi$mm.mrad at input, the transmission is 95.7 % for a Gaussian distribution, and 99.1% for a Waterbag one. The emittance growth is insignificant because here the tiny lengths of focusing lattices forbid any space charge manifestation.

## MEBT

This section has been re-designed from the initial IFMIF Conceptual Design Report, in order to reach a more realistic 1.36 m long section, in which can be now installed essential beam diagnostics along with 3 quadrupoles and 2 buncher cavities. These last elements must have enough focalisation strength in transverse and longitudinal to be capable to match the beam from a very short focusing lattice (cm) of the RFQ to a much longer one (m) of the HWR-Linac.

## HWR-LINAC

The design of the superconducting HWR-Linac has been performed under many constraints of energy, length, RF power, feasibility, and more particularly of emittance growth and beam losses [6]. The beam dimensions, in transverse as well as in longitudinal, have to be kept as small and regular as possible along the 22.8 m long Linac. To further improve the transition between consecutive cryomodules, the lattice lengths in each cryomodule have been progressively made longer. But these considerations about 3RMS beam size are not enough. A precise examination of the beam halo is necessary to prevent particle losses. For that, the very external fringe of the beam has to be considered. We arrive then to a solution where there is no loss over $10^6$ macroparticles, and where the contour line encircling 100% of particles occupies 60-80% of the aperture, with a comfortable room in longitudinal acceptance. This result remains to be further improved. On the other hand, the emittance growth is not negligible; it reaches 50%, of which 40% occurs at the MEBT and the first meter of the first cryomodule.

The aim now is to keep this no-loss result in the presence of errors which remain to be simulated. While errors of the HWR-Linac alone could be not critical, errors combined from the ion source down to the accelerator end could enhance losses. Re-tuning of the Linac could be necessary in real operation. The point is that the above described tuning allowing to avoid losses is based on the knowledge of beam sizes. But in order to limit emittance and halo growths, focusing lattices need to be the shortest possible, and thus no place is available for beam size measurements. Therefore this question of managing losses in the real machine has to be addressed and simulated.

A possible solution that can help is the use of quadrupoles instead of solenoids. Thanks to the now different horizontal-vertical sizes, and provided that Beam Position Monitors can be installed inside the quadrupoles, difference of squared transverse sizes can be measured, and would be useful to match the beam [7]. That is why a Linac configuration with quadrupoles has also been simulated, and it gives equivalent results than with solenoids. The choice of the final configuration will depend on current feasibility studies of SC quadrupoles with BPM inside.

## HEBT-EVEDA

For the prototype accelerator, the HEBT line transports the 9 MeV beam output from the first Linac cryomodule to a beam dump [8]. At this point, the beam is expanded at optimised size and divergence in order to spread the energy deposition. Another goal is to allow beam characterisation by a 3m long diagnostic plate. Given the high space-charge regime, the beam is very quickly debunched, and the use of a buncher is necessary for any longitudinal measurement. For the same reason, the transverse emittance measurement by varying quadrupole strengths is no longer possible by linear calculations. A minimisation code remains to be made, calling the multiparticle TraceWin code. For the moment, we have verified that variations of horizontal and vertical beam sizes by a factor of 6 and 3 are possible without any loss. Simulations along the 10m long HEBT have also shown that 100% of the beam occupies 50-70% of the aperture.

## HEBT-IFMIF

For the IFMIF accelerator, the HEBT line has to guide the 5 MW beam to the target with precise specified dimensions and homogeneity. Until now, only a feasibility study has verified that with the beam output from the above HWR-Linac, it is possible to obtain roughly a beam footprint of 5x20 cm as required, with relatively hard edges and good homogeneity. All that with a ~40m long line containing quadrupoles, octupoles and dodecapoles. But it seems that results are very sensitive to the input beam. More detailed studies remain to be done.

## CONCLUSIONS

The design and simulations of the IFMIF-EVEDA accelerators are challenging due to its very high beam power. A true competition between focusing and space-charge forces has to be managed. A detailed examination of each particle loss is necessary to allow the required hands-on maintenance. This paper has summarised the status of these studies, by pointing out the specific hot topics for each section, and the choices made or to be made to solve them.

# BEAM DYNAMICS SIMULATIONS OF SUB-PS ELECTRON BUNCH PRODUCED IN A PHOTO-INJECTOR

R. Roux
LAL, bâtiment 200, Université Paris-Sud, 91898 Orsay, France.

*Abstract*

A growing number of experiments require low emittance ultra-short electron bunches in the 100 fs range (rms value) for the production of coherent light or the injection into a plasma for laser-plasma acceleration. Especially in the last case it is highly desirable to have a compact accelerator; hence a strong experimental activity is carried out to get such a beam directly from a photo-injector. We have performed beam dynamic simulations using the PARMELA code to study the performances of the alphaX photo-injector installed in the University of Strathclyde in UK*. This RF gun is aimed to produce electron bunches which have 100 pC of bunch charge, 100 fs bunch length and 1 π mmmrad transverse emittance. We will show the results of systematic parametric studies as a function of charge and laser pulse duration as well as the natural evolution of the beam phase space as a function of the distance from the photo-cathode.

## INTRODUCTION

Up to now the preferred way to get very short bunch is to use a magnetic chicane but this could lead to a degradation of the emittance due to the emission of coherent synchrotron radiation. Moreover it is difficult to make a compact beamline in such a scheme. Some experiments as alphaX [1] in the University of Strathclyde strive to produce X ray in the SASE [2] regime with a very short accelerator which the length is roughly 7 meters. The idea is to inject a very short electron bunch coming from a photo-injector into a laser-plasma [3] accelerating cell to bring it at 1 GeV over few millimeters instead of ≈ 30 m in classical linear accelerators. In order to get an efficient acceleration in the plasma, the specification on the bunch length must be absolutely fulfilled. So the purpose of this study is to investigate the behaviour of sub-ps electron bunches directly issued from the photo-injector using numerical simulations.

## PARMELA SIMULATIONS

PARMELA is a well-known code used for beam dynamics in linacs which takes into account the space charge force effect. It was created by Los Alamos National Laboratory and modified at LAL by B. Mouton to include, for instance, the photo-injectors.

*We acknowledge the support of the European Community-New and Emerging Science and Technology Activity under the FP6 "Structuring the European Research Area" programme (project EuroLEAP, contract number 028514).

### *AlphaX Photo-injector*

The alphaX photo-injector is made of 2.5 cells at 3 GHz resonant frequency. This gun designed at the Eindhoven University of Technology [4] exhibits two noticeable features. First, the shape of irises is elliptical because, according to the RF simulations, the surface electrical field is reduced by a factor 2 with respect to the more usual cylindrical shape. So one hopes to operate the gun at gradient higher than 100 MV/m without electrical breakdowns. Secondly the RF power is sent to the gun via a coaxial "doorknob" antenna in a coupler at the output of the gun. In this way the gun keeps a perfect cylindrical symmetry in order to avoid possible degradation of the emittance rising in non-symmetric coupling.

Simulations in PARMELA are performed with the electrical field of alphaX calculated with the 2D RF code SUPERFISH. Results are shown in table 1 for 6000 macro-particles used in the simulation.

Table 1: Results of PARMELA simulations at the output of the gun, input parameters are (rms value): Q = 100 pC, laser has a Gaussian profile, radius = 1.4 mm cut at 10 mm and pulse duration = 100 fs cut at 500 fs. The peak electrical field is 92 MV/m and the phase is chosen to optimise the energy gain, rms value.

| | |
|---|---|
| Beam radius (mm) | 3.1 |
| Bunch length (fs) | 206 |
| Energy (MeV) | 6.2 |
| Normalized Emittance (πmmmrad) | 4.2 |
| Energy spread (%) | 0.172 |

In this case the specifications are not fulfilled, the emittance being 4 times higher and the bunch length 2 times bigger. About the emittance there is a way to significantly reduce the effect of the space charge forces thanks to a uniform transverse profile instead of a Gaussian shape for the laser. The same technique can be applied along the longitudinal axis. But before to show the results of the improvements with a square distribution, one may wonder about the validity of these calculations. Indeed most of simulations are usually performed with electron bunches which the length is in the picosecond range.

### *Test of PARMELA*

Up to now there are no measurements of sub-ps bunches produced directly from the gun to compare with PARMELA simulations. But it is possible to check if the results of PARMELA are at least in agreement with the physics of charged beam. For instance the scaling of the emittance as a function of the bunch charge depends on the space charge forces. Normally the repulsive force applying on each electron is proportional to the total charge. In figure 1 we tested this scaling law for 2 bunch lengths, 10 ps and 100 fs.

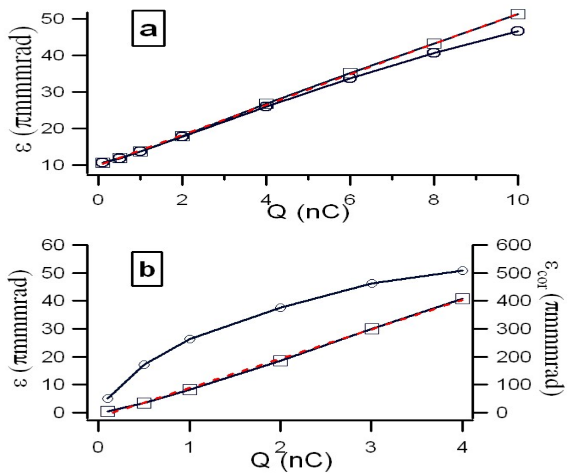

Figure 1: normalized emittance as a function of the total charge. In a), the laser pulse duration is 10 ps; in b), it is 100 fs. Lines with circle are raw PARMELA results, lines with squares are corrected data and dashed red line is a linear fit. In the case of b), the value of the corrected data is reported on the right axis.

In the case of the long bunches, 10 ps, the growth of the emittance becomes non-linear for charges above 4 nC and this change even occurs below 1 nC for the 100 fs bunches. This is due to the fact that the space charge force is proportional to the electronic density. So when it becomes stronger, the bunch length increases leading to a reduction of the space charge force and therefore the emittance growth is slowed down. To remove this effect, we multiplied the emittance by a corrective factor which is the ratio of the bunch length at the output of the gun over the bunch length at zero charge. The corrected data fit perfectly with a linear law for fs bunches as well as for ps bunches. So PARMELA seems to be still reliable for short bunches and we can look for better performances with 100 fs bunches.

## EMITTANCE OPTIMISATION

It is now usual to make a flat shape of the laser distribution in order to decrease the space charge forces. After optimisation, the best parameters for the laser are: in transverse plane, $\sigma_r$ = 4 mm, $r_{max}$ = 1.2 mm and no change in the longitudinal axis, results are given in table 2. The emittance is reduced by 33 % with respect to the case of the laser with a Gaussian profile (table 1). However it was impossible to find a set of longitudinal laser parameters which allows one to further decrease the emittance. It is a first visible difference with respect to the ps bunches where using also a flat longitudinal pulse leads to a supplementary reduction of the emittance.

Table 2: Results of PARMELA simulations for Q = 100 pC in rms value (6000 macro-particles) for a laser flat transverse profile and 2 accelerating fields.

| | 92 MV/m | 120 MV/m |
|---|---|---|
| Beam radius (mm) | 1.6 | 1.5 |
| Bunch length (fs) | 283 | 196 |
| Energy (MeV) | 6.2 | 8 |
| Normalized Emittance (πmmmrad) | 2.8 | 2.4 |
| Energy spread (%) | 0.43 | 0.32 |

Moreover the bunch length and the energy spread are enhanced while it should be the opposite. One way to overcome these difficulties is to increase the accelerating gradient. But it seems to profit mainly to the bunch length which is reduced of 30 % while it is only 14 % for the emittance. Of course only the experiment can tell if the gun can be operated at such high gradient with a good stability. So unless to relax the specification on the bunch length it seems difficult to get the 1 πmmmrad for 100 pC and 100 fs bunch length.

## LONGITUDINAL DYNAMICS

For some applications the bunch length is a parameter of a paramount importance and one must investigate how evolves a bunch with a length of 100 fs.

### *Natural Behavior*

Plotting the evolution of the bunch length as a function of the longitudinal distance, a special feature of the short bunches appears, as illustrated in figure 2.

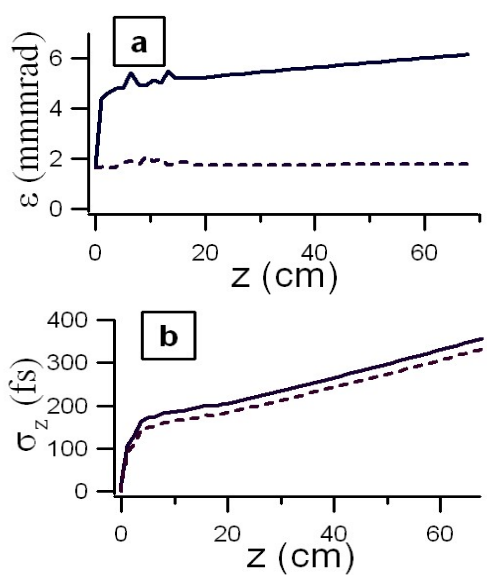

Figure 2: a), emittance as a function of the longitudinal distance z; b), bunch length as a function of z. Plain line is the simulation taking into account the space charge forces, dashed line is without space charge. Parameters of the simulations are the same as used in table 1 except number of macro-particles, 1000 in this case.

In the drift space after the gun, there is a slow increase of the emittance while the bunch is lengthened by a factor 2. In the case of the emittance it is clearly the consequence of the space charge forces. At the opposite the major part of the bunch lengthening even occurs without the inclusion of the space charge forces. The latter give a very weak contribution to the bunch length. This bunch lengthening was already investigated by previous studies [5] with the GPT code and is a pure geometrical effect. External electrons have higher divergence with respect to electrons on axis. Therefore they follow a longer path than electrons in the centre of the bunch and accumulate a time lag which means they go to the tail of the bunch. With longer bunch, 10 ps, a drift of the external electrons of 0.1 ps is completely absorbed in the overall bunch.

### *Behavior with Vertical Focussing*

To transport the electron beam or to focus it for an experiment, the use of a solenoid or quadrupole is unavoidable. Usually the longitudinal dynamic is not coupled to the transverse motion, except in a dipole. But for fs bunches it is not true anymore. We performed a simulation with a quadrupole focussing in the horizontal plane, results are shown in figure 3.

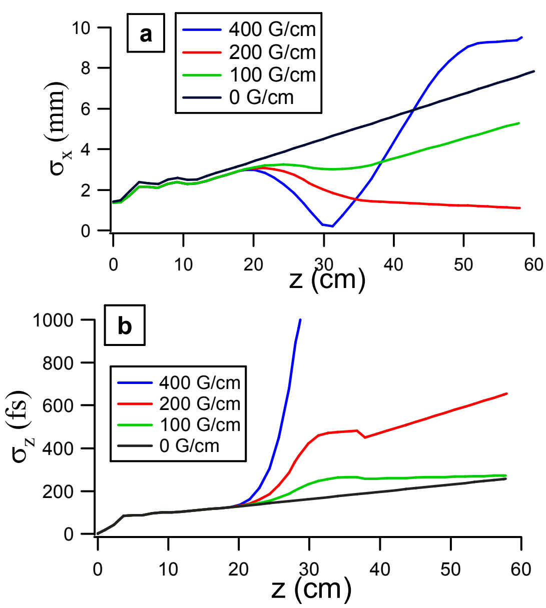

Figure 3: simulations without space charge, same parameters for the laser (see table 1), a horizontal quadrupole is placed at z = 20 cm; in a), horizontal sizes (rms) and in b) the bunch lengths (rms) for several values of the quadrupole gradient.

When one tries to focus the electron beam, the bunch length quickly increases. When the beam passes through the quadrupole, external electrons have a longer path to go to the focus point with respect to the on axis electron. It is a critical issue because if it is really required to focus the beam at a size below 0.2 mm (to inject in a capillary for instance) the bunch length inflates, from 130 fs up to 4 ps, 40 cm after the gun. Simulations performed with a solenoid give the same results as the quadrupole ones. So every time the beam is transported or focused with magnets the bunch length strongly increases.

The only way to compensate this bunch lengthening is to use a curved photo-cathode [6] made in such a way that external electrons are emitted in first with respect to on axis electrons.

### *With a Laser at Non-zero Incidence*

Usually in the simulations, one neglects the angle of incidence of the laser onto the photo-cathode because it is very small, ≈ 3° in our case. In figure 4 is reported the result of a simulation with an incident angle of 3° and compared with the case at normal incidence.

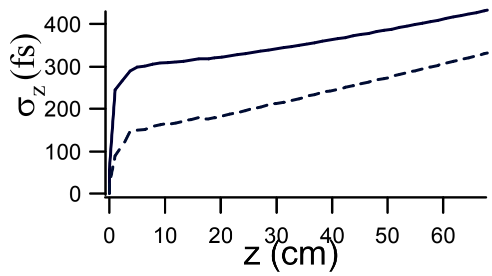

Figure 4: bunch length as a function of the longitudinal distance. The parameters of the simulations are those used in table 1; plain line: angle of laser incidence is 3°, dashed line: normal incidence on the photo-cathode.

The result is rather clear: for femtosecond bunches one must not neglect the angle of incidence anymore. Even with only 3° it induces a bunch lengthening of 120 fs.

## CONCLUSION

A study of femtosecond bunches based on PARMELA simulations has been performed which shows that the handling of such beam produced from a photo-injector is rather difficult. External electrons have a longer path to travel than the core electron; a drift space or magnets used to transport or focus the beam induce inevitably a bunch lengthening. The minimization of the emittance thanks to a flat transverse profile of the laser is obtained at the expense of a degradation of the bunch length and energy spread.

*Abstract*

Transverse emittance growth along the Alvarez DTL section is a major concern with respect to the preservation of beam quality of high current beams at the GSI UNILAC. In order to define measures to reduce this growth appropriate tools to simulate the beam dynamics are indispensable. This paper is on benchmarking of three beam dynamics simulation codes, i.e. DYNAMION, PARMILA and PARTRAN against systematic measurements of beam emittance growth for different machine settings. Experimental set-ups, data reduction, the preparation of the simulations, and the evaluation of the simulations will be described. It was found that the mean value of final horizontal and vertical rms-emittance can be reproduced well by the codes.

## INTRODUCTION

In the last decades many beam dynamics computer codes were developed [1] in order to simulate emittance growth along a linac. Several benchmarking studies among codes have been performed [2, 3, 4] generally assuming idealized conditions as initial Gaussian distributions, equal transverse emittances, matched injection into a periodic lattice, and small longitudinal emittance with respect to the rf-bucket size. In case of an operating linac most likely non of these conditions is met. To apply simulation codes to a realistic environment a benchmark activity was started aiming at the simulations of beam emittance measurements performed at a DTL entrance and exit, respectively. The studies were performed at the GSI UNILAC [5]. For the simulations three different codes were used: DYNAMION [6], PARMILA (V 2.32) [7], and PARTRAN [8]. A more detailed description of the campaign is given in [9].

## EXPERIMENT SET-UP AND PROCEDURE

Intense beams are provided by MEVVA, MUCIS, or CHORDIS sources at low charge states with the energy of 2.2 keV/u. An RFQ followed by two IH-cavities (HSI section) accelerates the ions to 1.4 MeV/u using an rf-frequency of 36 MHz. A subsequent gas-stripper increases the average charge state of the ion beam. Final acceleration to 11.4 MeV/u is done in the Alvarez DTL section operated at 108 MHz. The increase of rf-frequency by a factor of three requires a dedicated matching section preceding the DTL. It comprises a 36 MHz buncher for longitudinal bunch compression, a 108 MHz buncher for final bunch rotation, a quadrupole doublet for transverse compression, and a quadrupole triplet for final transverse beam matching.

The Alvarez DTL comprises five independent rf-tanks. Transverse beam focusing is performed by quadrupoles in the F-D-D-F mode. Each drift tube houses one quadrupole. The periodicity of the lattice is interrupted by four intertank sections, where D-F-D focusing is applied. Acceleration is done -30° from crest in the first three tanks and -25° from crest in the last two tanks.

Figure 1 presents the schematic set-up of the experiments. Beam current transformers are placed in front of

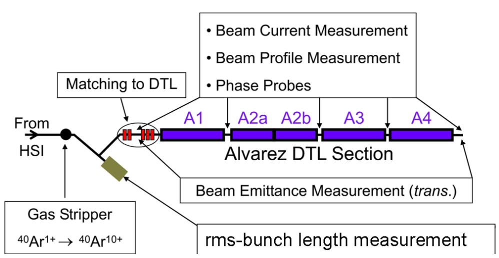

Figure 1: Schematic set-up of the experiments.

and behind the DTL as well as horizontal and vertical slit/grid emittance measurement devices. The total accuracy of each rms-emittance measurement including its evaluation is estimated to be 10%. A set-up to measure the longitudinal rms-bunch length is available in front of the DTL [10]. It measures the time of impact of a single ion on a foil. This time is related to a 36 MHz master oscillator. The resolution is 0.3° (36 MHz).

The HSI was set to obtain 7.1 mA of $^{40}Ar^{10+}$ in front of the DTL being space charge equivalent to the UNILAC design beam of 15 mA of $^{238}U^{28+}$. Horizontal and vertical phase space distributions were measured in front of the DTL. The longitudinal rms-bunch length was measured at the entrance to the DTL. The DTL quadrupoles were set to zero current transverse phase advances $\sigma_o$ ranging from 35° to 90° in steps of 5°. Due to space charge the phase advances in all three dimensions were depressed. The transverse depression reached from 21% (90°) to 43% (35°). Afterwards the quadrupoles and bunchers preceding the DTL were set to obtain full transmission and to minimize low energy tails of the beam. For each value of $\sigma_o$ horizontal and vertical beam emittances were measured at the exit of the DTL with a resolution of 0.8 mm in space and 0.5 mrad in angle.

Each emittance measurement delivers a two dimensional matrix of discrete slit-positions and discrete angles. The data are processed by the measurement & evaluation program PROEMI [11]. Fractional emittances can be extracted as well since in practical cases it is beneficial to focus on the "inner" 95% of the particles. The emittance containing a given percentage $p$ of the full distribution is extracted as follows: (i) The sum $\sum_{100}$ of all pixel contents is calculated. (ii) The pixels are sorted by their content starting from the largest one. (iii) Starting from the largest content the sum of all pixel contents is built as long as this sum is less or equal to the percentage $p$ of $\sum_{100}$. (iv) Those pixels that contributed to the sum are considered for the rms-evaluation. Simulation deliver a set of six dimensional particle coordinates. This ensemble is projected onto a pixel-grid having the same characteristics as the slit/grid device used for the measurements. The grid is read by the measurement evaluation program PROEMI such that data reduction was done in the same way as for measured data.

## INPUT FOR SIMULATIONS

From the transverse emittances measured in front of the DTL normalized 100%-rms-emittances of 0.12 and 0.23 mm mrad were evaluated horizontally and vertically, respectively. Measuring the rms-bunch length in front of the DTL a value of 25 mm was found corresponding to a phase spread of 20° at 36 MHz.

The reconstruction of the initial distribution is done in two steps. First the 100%-rms-Twiss parameters are determined. In the second step the type of distribution is reconstructed. The transverse rms-measurements and the longitudinal rms-measurements on the initial distribution, done at different locations along the beam line (Fig. 2), had to be combined.

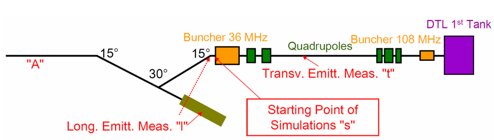

Figure 2: Reference points used for reconstruction of the initial phase space distribution.

This was achieved by attaching to the transverse rms-parameters measured at location "t" such longitudinal rms-parameters that result in the measured rms-bunch length measured at location "l", after rms-tracking the distribution from "t" to "s". The tracking implies the assumption that the virtual transport from "l" to "s" can be approximated by a simple drift including space charge. The length of this drift is given by the difference of the distances ("A", "l") and ("A", "s"), i.e. 0.4 m. Additionally, the recombined distribution must result in longitudinally matched injection into the DTL in accordance with the measurements. Eventual longitudinal mismatch could have been observed experimentally by transmission loss and the occurance of low energy tails.

The reconstruction of the type of distribution is based on evaluation of the brilliance curve, i.e. the fractional rms-emittance as function of the fraction (Fig. 3). Different

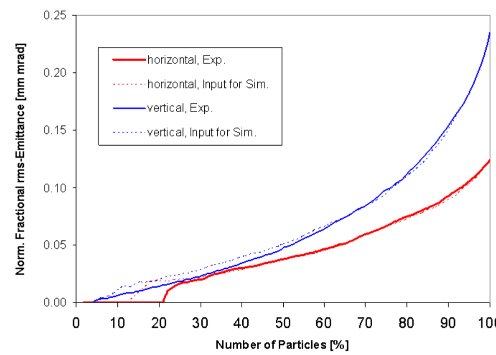

Figure 3: Brilliance curves of the phase space distribution in front of the DTL. Bold: from measurement; dashed: from initial distribution for simulations

amounts of halo have been found in the two transverse planes as indicated by the horizontal and vertical curvatures. For proper modelling of the initial distribution, both curvatures must be reproduced. This was achieved by using a distribution function as

$$f(R) \;=\; \frac{a}{2.5\cdot 10^{-4}\,+\,R^{10}},\quad R\leq 1 \qquad (1)$$

and $f(R)$=0 for $R > 0$ with

$$R^2 \;=\; X^2+X'^2+Y^{1.2}+Y'^{1.2}+\Phi^2+(\delta P/P)^2\,, \quad (2)$$

where $a$ is the normalization constant and the constant in the demoninator results from the cut off condition at $R$ = 1. By defining the radius $R$ using different powers for different sub phase spaces the halos within the planes could be modelled. Since for the longitudinal phase space distribution no measurement but on the rms-bunch length is available, a Gaussian distribution cut at $4\sigma$ is assumed. This can be achieved by setting the respective powers in the definition of $R$ to a value of 2.

## COMPARISON OF RESULTS

For all phase advances full beam transmission was observed through the DTL in the experiment. The codes revealed losses of about 2%. Figure 4 displays final horizontal phase space distributions at the DTL output as obtained from measurements and from simulations for three different values of $\sigma_o$. The simulated final distributions look quite similar. Simulations could reproduce the wings attached to the core measured at highest phase advances. But the codes did not show the asymmetric distributions measured at lowest phase advances. Final 95%-rms-emittances

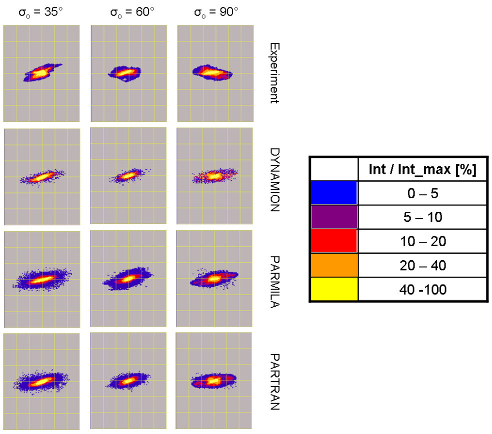

Figure 4: Top to buttom: horizontal phase space distributions at the DTL exit. Left: $\sigma_o$ = 35°; centre: $\sigma_o$ = 60°; right: $\sigma_o$ = 90°. The scaling is $\pm$ 24 mm (horizontal axis) and $\pm$ 24 mrad (vertical axis), respectively.

are presented in Fig. 5 to Fig. 7 as function of the transverse phase advance $\sigma_o$. The measurements and the simulations revealed lowest emittances at $\sigma_o \approx 60°$. In general good agreement among the codes was found. However, the codes slightly underestimate the emittance growth. This is reasonable since the codes assume a machine without errors causing additional growth [12].

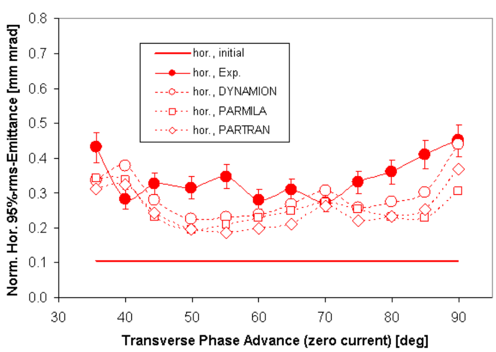

Figure 5: Horizontal 95%-rms-emittance at the end of the DTL as function of $\sigma_o$.

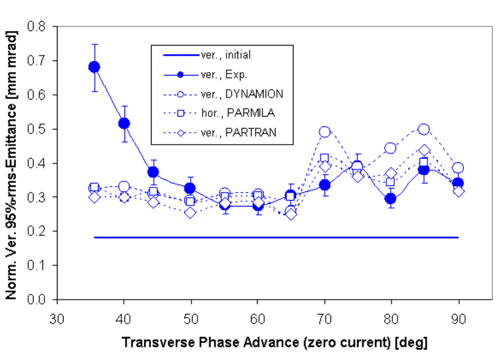

Figure 6: Vertical 95%-rms-emittance at the end of the DTL as function of $\sigma_o$.

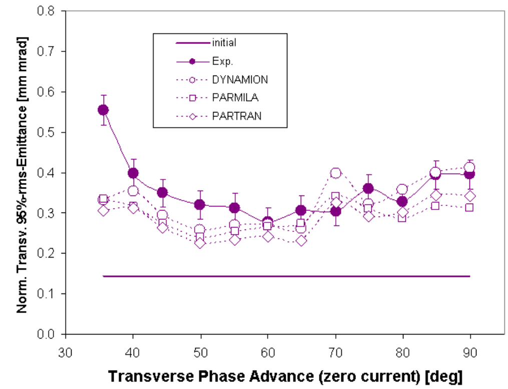

Figure 7: Mean value of horizontal and vertical 95%-rms-emittance at the end of the DTL as function of $\sigma_o$.

## Abstract

The design process and the operation of particle accelerator machines can advantageously be assisted by fast online beam dynamics simulations because of its flexible parameter variation combined with nearly simultaneous solution responses providing a detailed insight into the actual machine status. Based on the moment approach a fast tracking code named V-Code has been implemented at TEMF. At the Superconducting DArmstädter LINear ACcelerator S-DALINAC the V-Code is used during the design process of the injector for the new 100 keV polarized electron source but is also supposed to be employed at the control system. For these purposes an implementation of fringe field alpha magnets is mandatory. In this paper a summary of issues regarding the implementation complemented with simulation results will be provided.

## INTRODUCTION

At the Superconducting DArmstädter LINear ACcelerator (S-DALINAC) a new 100 keV polarized electron source is currently being installed. Therefore, a new low energy injection concept has to be designed. The most important components of the injector are a polarized electron source, an alpha magnet and a Wien filter used for spin rotation together with various beam forming elements. The polarized electrons extracted vertically from a photo cathode are bent into the horizontal injector beam line with the help of an alpha magnet. Unlike a classical alpha magnet designed as a half quadrupole given for example in [1], the hyperbolic poles of the installed alpha magnet are supplemented by a dipole like extension in order to achieve a 90° bending angle. In Fig. 1 a schematic computational model of the realized alpha magnet is visualized. Within the V-Code simulation tool the beam line is represented as a consecutive alignment of separate independent beam line elements. This procedure allows to simulate even a very long beam line with minimum requirements to the computer memory. In order to be able to simulate the hole injector an implementation of alpha magnets was missing so far.

## NUMERICAL MODEL

The V-Code simulation tool is based on the moment approach to beam dynamics. Instead of using the particle distribution itself this method applies a discrete set of moments of the particle distribution. The time evolution of each moment can be deduced from the VLASOV equation when suitable initial conditions are given and all essential external forces are known. These forces are given by the LORENTZ equation in combination with the distribution of electric and magnetic fields obtained during a preprocessing step.
The required three-dimensional field distribution in the immediate vicinity of the particle trajectory can be reconstructed from extracted one-dimensional field components by means of a TAYLOR series expansion. This allows to considerably reduce the size of the required field data inside a specific beam line element.
A precise description of the numerical model is given in [2]. Details about its implementation in V-Code are published for example in [3] and [4].

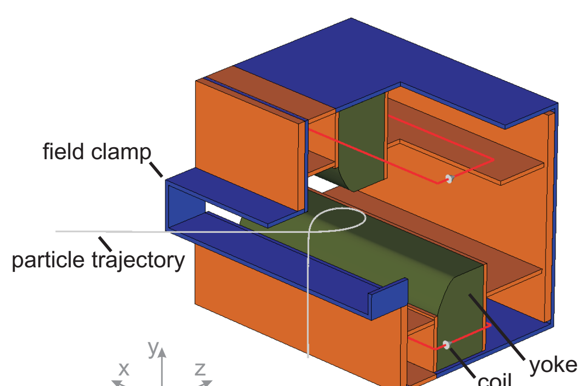

Figure 1: Schematic computational model of an $\alpha$-magnet including the excitation coils and the high permeable yoke. For visualization reasons the upper corner of the housing and the yoke have been cut away. Additionally, a typical particle trajectory is specified as a reference path.

### [illegible]

The particle tracking in external magnetic fields requires the detailed knowledge of the local field distribution which can be determined for example with the magnetostatic solver included in the CST Design Environment. From the precise field data one can extract the necessary multipole components and provide those information in a very efficient manner for further usage. In V-Code the full field can be reconstructed and evaluated particularly in the vicinity of the bunch trajectory. Due to the layout of the magnet it is sufficient to evaluate the field along the longitudinal axis z while it is assumed to be constant in transversal direction. In Fig. 3 the important vertical component of the magnetic flux density is displayed.

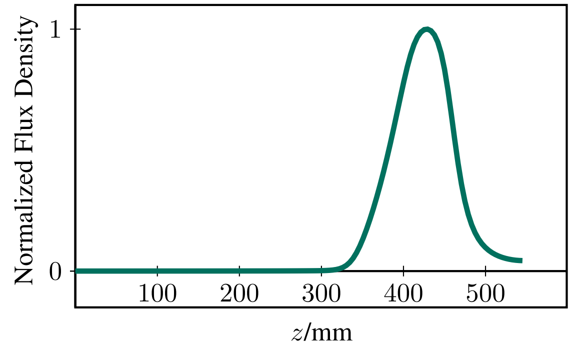

Figure 3: Vertical component of the magnetic flux density inside the $\alpha$-magnet normalized to the absolute maximum. Geometric details are specified in Fig. 1.

### [illegible]

In order to determine the components which have to be considered in the multipole expansion, one can analyze the tangential field component on concentric circles of different radii along the longitudinal axis of the alpha magnet. In Fig. 2 the calculated multipole coefficients are shown in logarithmic scale. From the plot one can see that the sextupole part forms the most eminent disturbance to the dipole field. Since the magnitudes of all higher order multipoles are at least two orders of magnitude smaller than the dominant dipole component even for the pessimistic evaluation radius $r = 6$ mm we neglect all multipole parts except the dipole field in the following.

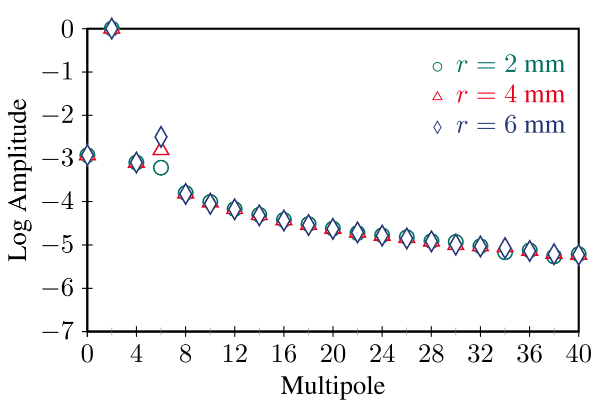

Figure 2: Normalized multipole moments of the magnetic flux density evaluated on concentric circles of different radii in the center of the $\alpha$-magnet.

### [illegible]

Within the V-Code simulation tool the entire beam line is represented as a straight line directed along the z axis. This requires for a beam line element like the alpha magnet the definition of a curved reference path, determining the nominal length inside the beam line. A suitable reference path can be attained for example by tracking a single particle with proper initial conditions in the provided magnetic field.

## IMPLEMENTATION

For accuracy reasons it is not advisable to calculate and visualize the bunch evolution in the same successively rotated coordinate system. A more accurate proceeding avoiding the accumulation of errors due to rotation is illustrated in Fig 4. At the beginning a coordinate transformation is performed to align the global primed coordinate system with the unprimed system in which the field components are reconstructed and the bunch evolution is calculated. The simulated bunch parameters are plotted in the visualization pane relative to the reference path using the double primed coordinate system. For this purpose the normal projection from the actual bunch position $(z_1, x_1)$ onto the reference path $(z_s, x_s)$ and a local coordinate transformation for the first and second order moments is performed. At the end a final transformation from the unprimed to the triple primed coordinate system is necessary in order to orient the global system along the subsequent beam line.

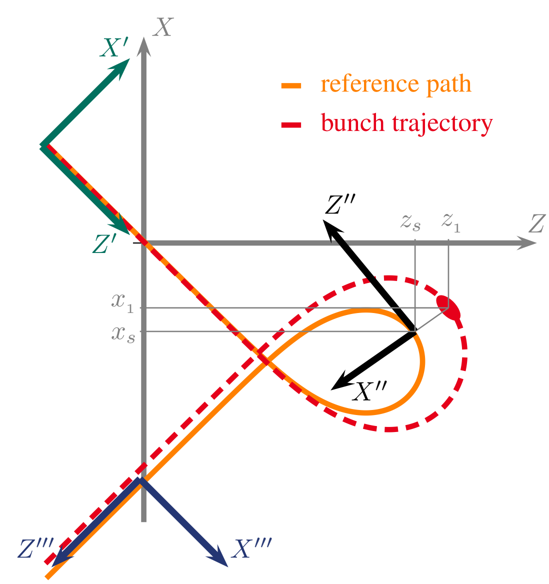

Figure 4: Typical projected bunch trajectory together with the predefined reference path for the $\alpha$-magnet setup specified in Fig. 1.

## SIMULATION

In order to study the applicability of the preprocessing steps and the implementation of the proposed scheme the simulation results from V-Code are compared to simulation results obtained with a reference tracking code based on the so called Boris algorithm [6] as well as results extracted from the particle tracker integrated in the CST Design Environment.

In Fig. 5 and Fig. 6 the evolution of the center of mass of a nearly point-like bunch equipped with a vertical offset of 1 mm from the reference path is tracked with V-Code and is compared to trajectories of individual particles calculated with the Boris algorithm and with the CST particle tracker.

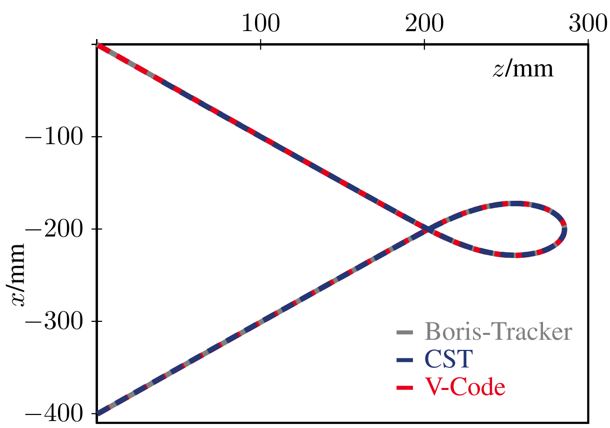

Figure 5: Simulation of the horizontal evolution of two individual particles with 1 mm vertical offset from the symmetry plane within the $\alpha$-magnet.

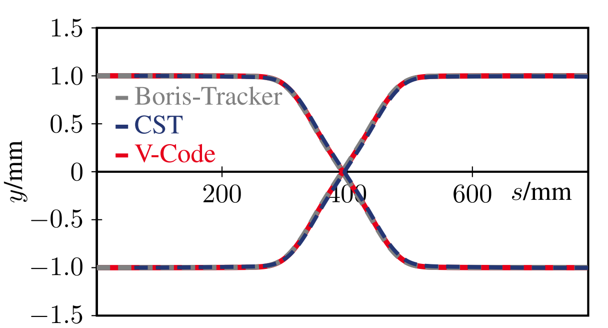

Figure 6: Simulation of the vertical evolution of two single particles with 1 mm vertical offset from the symmetry plane within the $\alpha$-magnet.

In Fig. 7 and Fig. 8 the focusing behavior inside the alpha magnet is illustrated. From the CST Design Environment the bunch dimensions were obtained by tracking a bunch of particles through the build-in particle monitors placed orthogonal to the reference path inside the alpha magnet. In V-Code the horizontal and vertical bunch dimensions are calculated from the global coordinates by means of coordinate transformations as explained in the previous section. In all tracking routines space charge effects are neglected.

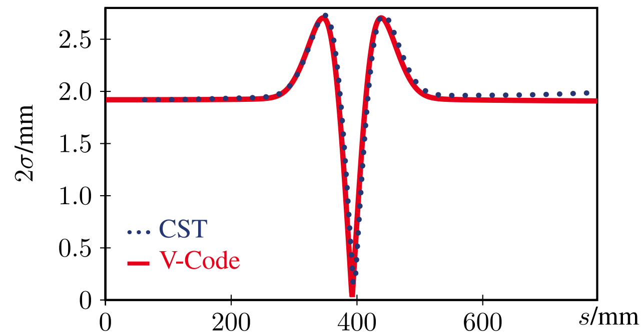

Figure 7: Simulation of the horizontal focusing behavior within the $\alpha$-magnet.

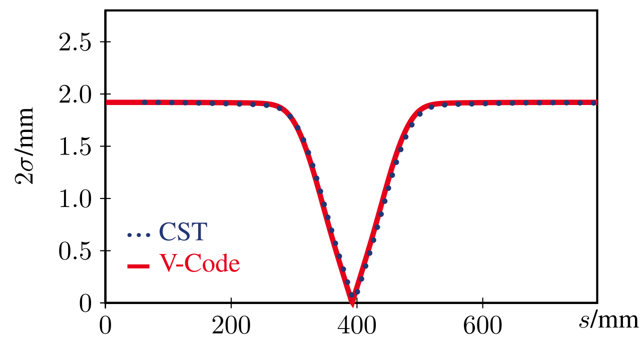

Figure 8: Simulation of the vertical focusing behavior within the $\alpha$-magnet.

The provided charts show that the center of mass as well as the transversal beam dynamics are precisely modeled in the new beam line element in V-Code.

# BEAM DYNAMICS STUDIES ON THE EURISOL DRIVER ACCELERATOR

A. Facco, A. Balabin, R. Paparella, D. Zenere, INFN-Laboratori Nazionali di Legnaro, Padova, Italy; D. Berkovits, J. Rodnizki, SOREQ, Yavne, Israel; J. L. Biarrotte, S. Bousson, A. Ponton, IPN Orsay, France; R. Duperrier, D. Uriot, CEA/Saclay, France; V. Zvyagintsev, TRIUMF, Vancouver, Canada

*Abstract*

A 1 GeV, 5 mA cw superconducting proton/$H^-$ linac, with the capability of supplying cw primary beam to up to four targets simultaneously by means of a new beam splitting scheme, is under study in the framework of the EURISOL DS project which aims to produce an engineering-oriented design of a next generation European Radioactive beam facility. The EURISOL driver accelerator would be able to accelerate also a 100 μA, $^3$He beam up to 2.2 GeV, and a 5 mA deuteron beam up to 264 MeV. The linac characteristics and the status of the beam dynamics studies will be presented.

## INTRODUCTION

The EURISOL-DS project [1] aims at the design of a last generation Radioactive Ion Beam (RIB) facility for nuclear physics experiments, based on the ISOL method, to be constructed in Europe [2]. This facility is based on a 1 GeV, 5 mA primary proton beam feeding 4 RIB production targets. One of them (the high power target) will include a 4 MW neutron converter, able to receive most of the beam power and to create an intense neutron flux to the RIB target. The three remaining ones will accept a proton beam up to 100 kW for RIB production through direct reactions. The radioactive ions will be then extracted from the sources, selected and post-accelerated to the required energy (up to 150 MeV/A) by means of a superconducting linac.

One of the main requirements for the driver accelerator is the possibility of feeding more than one target in parallel, possibly in cw mode with finely tunable intensity to avoid destructive thermal shocks. No apparatus was available for this operation when the EURISOL-DS study started.

New requirements for the Driver, proposed after the first year of studies by the Beam Intensity Calculations Task group with the aim of opening new lines of experiments, are the possibility of delivering to the direct targets a 2 GeV, 100 μA $^3$He beam, and to a new target station a 250 MeV, 5 mA deuteron beam. This could be accomplished with a rather limited effort taking advantage of the structure of the EURISOL Driver, based on short, independently phased cavities, which allows a rather wide beam velocity acceptance.

## EURISOL DRIVER LAYOUT

The EURISOL Driver is a superconducting (SC) linac that includes 5 different sections: Injector, Low-β section, medium-β section, high-β section and CW Beam Splitter (Fig. 2). The lengths of the injector and of the SC part are 12 m and 247 m, respectively, while the 4-way beam splitting section is 55 m long. An additional extraction sector is located at the beginning of the high-β section, giving a beam line for 264 MeV deuterons. All cryostats are planned to work at 4.5K.

### *Injector*

The injector design is rather similar to the SARAF one [3], with modifications required by the different beam types (Fig. 1). Two ion sources are used. The first one is a TRIUMF-type multicusp $H^-$ source [4], located in the straight LEBT line. The second one is an ECR source for production of Deuterons (5 mA) and doubly charged $^3$He (0.1 mA) beams, located in the 90° LEBT branch to allow A/q selection. The minimum beam parameters at the sources output are listed in Table 1.

Table 1: LEBT Input Beams Specifications

| beam | $H^-$ | $^3He^{++}$ | $D^+$ |
|---|---|---|---|
| E (keV/A) | 20 | 20 | 20 |
| I (mA) | 6 | 0.2 | 6 |
| $\varepsilon_x$, $\varepsilon_y$ (π mm mrad rms norm.) | 0.125 | 0.125 | 0.1 |

The LEBT includes 6 solenoids and one dipole. An electron trap is foreseen at the RFQ injection.

The 176 MHz RFQ, resembling the SARAF one, is 3.8 m long and must be able to operate in cw mode. It allows acceleration up to 1.5 MeV/A, requiring a maximum power of 300 kW for acceleration of the Deuteron beam.

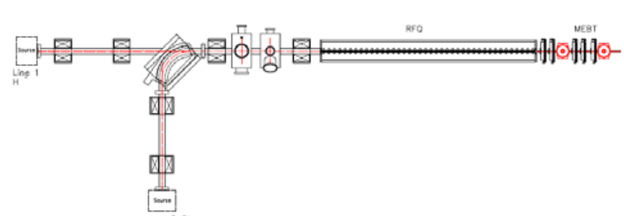

Figure 1: Injector RFQ and MEBT schematic layout.

Little emittance growth and relatively small size and cost are its main characteristics, at the price of a not spectacular transmission (92% accelerated beam for $H^-$ and 95 % for D and $^3$He). However, this appears to be fully acceptable for our application. The transmitted, but not accelerated RFQ particles (about 3%) are lost in the MEBT which is used to match the RFQ beam to the superconducting linac in order to prevent halo formation. The MEBT includes 5 quadrupole magnets and 2 normal conducting HWR bunchers.

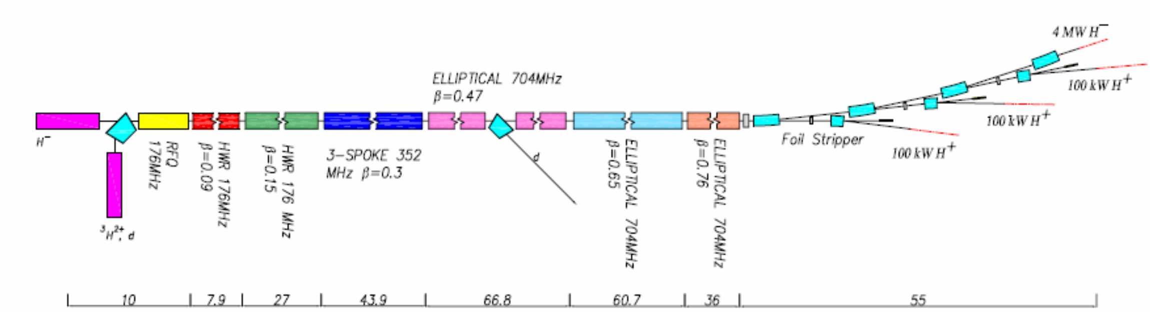

Figure 2: EURISOL Driver schematic layout (not in scale) and length of the different sections.

### *Low-β Section*

The low-β section consists of 9 cryostats, containing 8 176 MHz Half-Wave resonators (HWRs) each.

The required resonators are of 2 types, with $\beta_0$=0.09 and 0.15, working at the conservative gradient of 4.5 and 5.5 MV/m, respectively. They are being developed in the EURISOL Task 8 framework [5]. SARAF resonators [6] might also be adapted to this linac. The HWR geometry was chosen because it is steering free. In the first two cryostats every resonator is alternated with one superconducting solenoid; from the third cryostat on, there is one solenoid every two HWRs. The beam vacuum and the vacuum required for thermal insulation are in common to minimize cost. Until now, the most performing low-β heavy ion linacs in operation working at similar or lower rf frequency, are of this type.

### *Medium-β Section*

The medium-β section is based on 36, 352 MHz triple-spoke resonators, also developed in the EURISOL Task 8 framework, with β=0.3 and a specified gradient of 8 MV/m [7]. The architecture has been optimized with the GenLinWin code [8]. The cryostats contain three resonators each, and in this case, as usual for this rf frequency value, the beam vacuum and the insulating vacuum are separated. Transverse focusing is provided by conventional quadrupole doublets. The matching between the low- and the medium-β sections is achieved by replacing the first medium-β doublet with a triplet.

### *High-β Section*

The high-β section is based on 112, 5-cells elliptical cavities with 3 different optimum β of 0.47, 0.65 and 0.76. These β have been optimized to minimize the length of the linac with the GenLinWin code. The cavities are of the type developed in previous projects and the specified gradients of 12, 18 and 18 MV/m, respectively, were chosen, taking into account the experimental results of the on-line SNS cavities [9]. Transverse focusing is done by conventional quadrupole doublets. In the first subsection, one of the cryostats is replaced by a dipole magnet which allows the deuteron beam extraction at 264 MeV.

## THE 1 GeV, CW BEAM SPLITTER

A unique peculiarity of the EURISOL driver is its possibility of delivering parallel cw proton beams to different targets with low losses [10]. This is achieved by using a $H^-$ primary beam (up to 5 MW), neutralizing part of it (up to 100 kW) by magnetic stripping, and then displacing the unneutralized $H^-$ ions to a different beam line by means of a dipole magnet (Fig. 3). When the two beams are sufficiently separated, the neutral one is transformed into a proton beam by means of a stripper foil. From here on, the H- and H+ beams can be transported independently. The 100 kW limit of the extracted beam is dictated by the present RIB direct target technology. The beam losses, mainly due to the stripper foil efficiency, can be limited to a few tens of Watts and collected by a small beam dump. The splitting operation can be repeated by adding more splitting sections, providing multiple cw beams.

A critical component of the system is the special magnetic neutralizer, a simple and unconventional chicane made of 3 short dipoles that can provide partial neutralization without affecting the primary beam emittance and without producing unwanted $H^+$ ions. Since the neutralization rate is determined by the magnetic field intensity, it is possible to raise slowly the field (thus the secondary beam current) to avoid thermal shocks in the direct RIB targets.

## BEAM DYNAMICS

The linac beam dynamics was studied using the TRACEWIN code developed at CEA Saclay [8]. The transport of all the beams ($H^-$, $D^+$ and $^3He^{++}$) was simulated from the exit of the ion source to the target (except for D which was stopped at its extraction point) with macroparticles. All the cavities and the solenoids have been simulated with their computed EM field maps.

We chose to use conservative specifications for the linac components (cavity gradients, magnet fields) in order to achieve a reliable design without depending on future technological breakthroughs. We kept the transverse and longitudinal phase advance per period below 90° along the linac, and carefully tried to avoid parametric resonances. The continuity of the phase advance per meter has been also an important criterion in

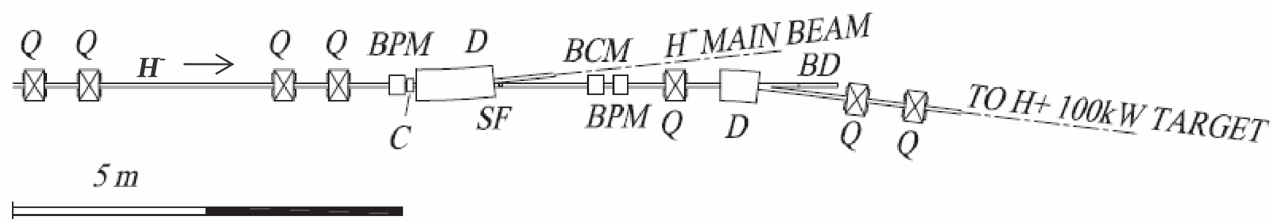

Figure 3: CW beam splitter layout (1 section). The main $H^-$ beam (coming from left) is partially neutralized in a small magnetic chicane (C). In the first bending magnet (D), the main $H^-$ beam is guided to the next splitter section, while the $H^0$ particles move straight to the stripper foil (SF), to be stripped into $H^+$ and then transported to the target. Q=quadrupole magnet; BD=beam dump; BCM=beam current monitor; BPM=beam profile monitor.

order to simplify the matching at transition. This point is especially relevant to transport different beam currents in a common linac. The frequency jump from 352 to 704 MHz was managed according to the technique described in [11] in order to avoid a longitudinal bottleneck just before the high energy section. Beam losses could be confined below 1.5 MeV, before entering the superconducting linac.

A special effort was required for transporting the 5 mA $H^-$ beam in the low-β section, where cryostats with different structure introduce discontinuities in the lattice. However, the final layout could allow transport with satisfactory acceptance and emittance growth for all beams (Tab. 2, Fig. 4 and 5). Studies performed in an earlier version of the HWR section showed a moderate (25%), further increase in emittance growth after introduction of errors in the lattice [12]. Error study for the whole accelerator will begin in autumn 2008.

Table 2: Source-to-target rms Emittance Growth for Each Beam (Longitudinal: from RFQ Output to Linac End)

| beam | $H^-$ | $^3He^{++}$ | $D^+$ |
|---|---|---|---|
| Tr. emittance growth (%) | 75 | 20 | 80 |
| Lg. emittance growth (%) | 43 | 12 | 0 |

## CONCLUSIONS

The EURISOL Driver design has achieved its beam dynamics specifications. The linac, which is only based on the RF superconducting technology above 1.5 MeV/A, is able to accelerate 5mA beams to 1GeV/q (for 1 ≤ A/q ≤1.5) and to 264 MeV (for A/q ≤2). A novel splitting scheme allows to distribute the primary $H^-$ output beam in 4 parallel cw beams which can be used independently in different beam lines.

# TRANSVERSE BEAM MATCHING AND ORBIT CORRECTIONS AT J-PARC LINAC

H. Sako#, A. Ueno, T. Ohkawa, Y. Kondo, T. Morishita, JAEA, Tokai, Japan
M. Ikegami, H. Akikawa, KEK, Tsukuba, Japan

## [illegible]

In high intensity $H^-$ beam of J-PARC LINAC, precise control of transverse beam dynamics is extremely important to suppress beam loss. Transverse matching has been performed at several matching sections in LINAC, which consist of knob quadruple magnets (QM's) and wire scanners (WS's) for profile measurements. Mismatch factors of less than 5% have been achieved. Matching of Twiss parameters and dispersion at the RCS injection point has been also done with quadruple magnets at L3BT injection region with beam profiles measured with WS's and also multi-wire profile monitors (MWPM's) at RCS. Orbit corrections along the whole LINAC have been done with steering dipole magnets in the upstream of beam position monitors (BPM's). Orbit deviations were suppressed within 1mm in the whole LINAC.

## TRANSVERSE MATCHING

The strategy of the LINAC transverse matching is as follows;

1. At MEBT1, we fit transverse and longitudinal Twiss parameters and emittance at the MEBT1 entrance.
2. Then, using the beam parameters, an initial QM field pattern at matching sections through LINAC and electric field and phase settings of Buncher 1 and 2 at MEBT1 is calculated requiring matching conditions with a model (TRACE3D).
3. Applying the calculated settings to QM's and Bunchers, we measure beam profiles from most upstream (MEBT1) to most downstream (L3BT injection section) in turn at each matching section. At sections after MEBT1 QM field is corrected to fulfil matching conditions.

The LINAC has 7 matching sections, each of which consists of 4 or more upstream QM's and 4 or more downstream WS's. At MEBT1, only fitting of initial beam parameters is done. At RCS injection section, special matching procedure is performed which is described later. At the rest of matching sections; SDTL entrance, MEBT2, L3BT straight, L3BT arc, L3BT collimator sections, lattices are periodic at each WS position; where the following common procedure has been applied.

1. Fit the XAL online model [2, 3] to measured horizontal and vertical beam widths at 4 WS's by varying ($\alpha_x$, $\alpha_y$, $\beta_x$, $\beta_y$, $\varepsilon_x$, $\varepsilon_y$) at an upstream position from the QM's. The fit is done with a response matrix calculated with the model.
2. Corrections of 4 QM field are calculated to require that $\alpha_x$, $\alpha_y$, $\beta_x$, $\beta_y$ agree at each WS. The calculation is done by applying the response matrix calculated with XAL [2].
3. The above procedures 1 and 2 are iteratively applied until convergence.

In MEBT1, Procedure 1 is replaced by 1';

1'. In addition to transverse parameter ($\alpha_x$, $\alpha_y$, $\beta_x$, $\beta_y$, $\varepsilon_x$, $\varepsilon_y$), longitudinal parameters ($\alpha_z$, $\beta_z$, $\varepsilon_z$) are varied to fit simultaneously beam widths at 4 WS's at MEBT1 and transverse emittance and Twiss parameters measured at a double-slit emittance monitor at MEBT1 bend line [4].

In L3BT injection section, Procedure 2 is replaced by;

2'. QM's after the collimator section (L3BT QM62-79) are used to tune transverse Twiss parameters and dispersion at the RCS injection point of the charge exchange foil.

These procedures are done with a newly developed application called "matcher" [2].

## [illegible]

Measured emittance is shown in Fig. 1 at 5 mA and 30 mA at all sections. At 5 mA, measured 1 σ emittance at 5 mA is 0.17 πmm-mrad and 0.25 πmm-mrad at 30 mA.

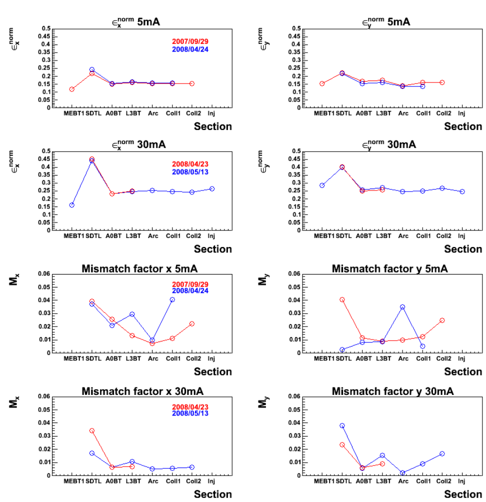

Figure 1: Normalized 1 σ emittance at 5mA (first row) and 30 mA (second row) in horizontal (left) and vertical (right) directions. Mismatch factors at 5 mA (third row) and 30 mA (forth row) in horizontal (left) and vertical directions (right).

Red and blue lines show matching results at two different periods, which proves good reproducibility of the matching procedure. Emittance growth at the SDTL entrance has been observed 5 mA and more enhanced at 30 mA. Mismatch factors of less than 5% have been achieved at 5 mA and 30 mA.

Figure 2 shows fit of beam widths measured from L3BT straight section to L3BT collimator sections to XAL. The XAL model without emittance growth describes very well the data at L3BT.

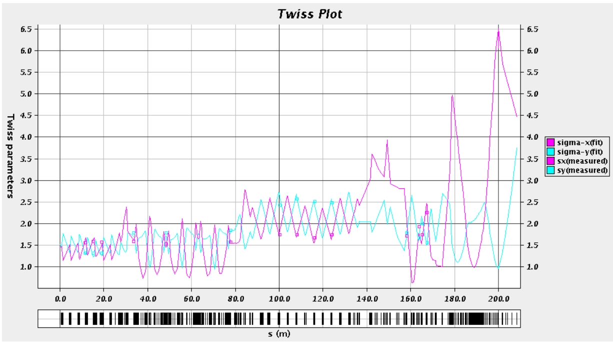

Figure 2: Horizontal (pink) and vertical (blue) 1 σ beam widths [mm] at L3BT fit to XAL model at 30 mA.

## [illegible]

The main goal of this section is to determine transverse and longitudinal beam parameters. Using above method 1', we have fit beam widths at WS's in the straight line, and emittance and Twiss parameters at the emittance monitor at the bend line.

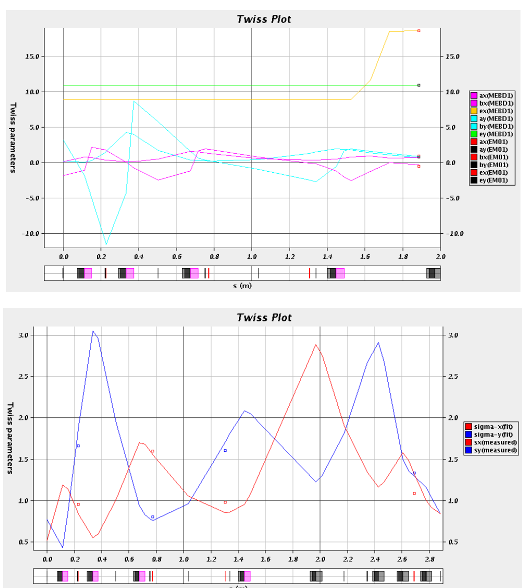

Figure 3: Top: measured transverse emittance and Twiss parameters with the double-slit emittance monitor at MEBT1 bend line. Bottom: measured profile widths with wire scanners at MEBT1. The curves show simultaneous fit with entrance transverse and longitudinal emittance and Twiss parameters.

Reasonable fit has been obtained as shown in Fig. 3. The resulting 5 σ longitudinal emittance at 5 mA and 30 mA is 582 and 477 π deg-keV. The values are similar to preliminary PARMTEQM calculations [7] of 550 and 410 π deg-keV.

## [illegible]

This section tunes Twiss parameters and dispersions at the RCS injection point. The following three sets of beam parameters and QM configurations have been set and measured;

1. "Matched" setting where ($\alpha_x$, $\alpha_y$, $\beta_x$, $\beta_y$) are matched with those of RCS circulating beam.
2. "Dispersion matched" setting where [illegible] and [illegible] at the foil.
3. "Half-matched" setting" which is a default setting with Twiss parameters and dispersions between "Matched" and "Dispersion matched" settings.

Figure 4 shows results of "Half-matched" configuration and fit to the XAL model, which shows beam parameters can be actually controlled by LINAC QM's.

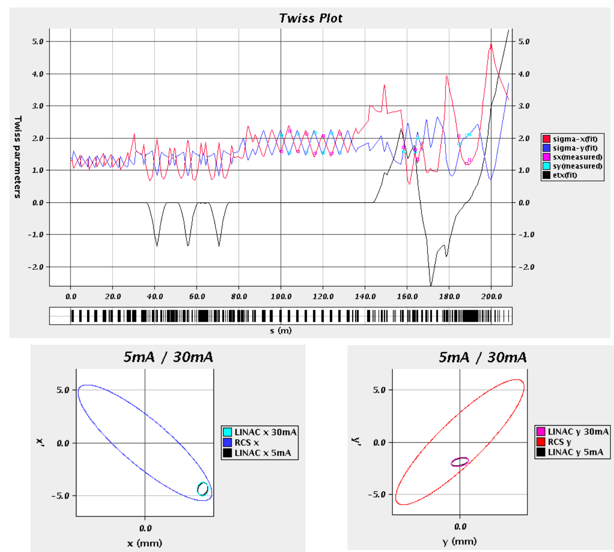

Figure 4: Top: Horizontal (red line) and vertical (blue line) envelopes fit to profile widths (points) and dispersions (m) (black line) calculated by the model at different sets of QM field for "Half-matched" setting at 5 mA. Bottom: Horizontal (left) and vertical (right) phase ellipses of LINAC beam at the injection point at 5 mA and 30 mA with "Half-matched" setting compared to RCS phase ellipse.

# EMITTANCE GROWTH AT SDTL AND COMPARISON WITH IMPACT

In order to understand the observed evolution of emittance from MEBT1 to SDTL exit, we have compared the data with IMPACT simulation [6] at 30 mA. The initial particle phase space distributions are Gaussian with initial Twiss parameters and emittance from the measured values at MEBT1. Figure 5 shows comparison of measured profiles at the second WS in MEBT1, the first WS in SDTL entrance, and the third WS at the MEBT2 section with IMPACT. Another distributions with $\alpha_x$, and $\alpha_y$ deviated by ~25% to make mismatch by ~30% at the DTL1 entrance are also simulated. In that case, IMPACT does not deviate from measured profile data very much. IMPACT in both cases apparently underestimates the beam width at the SDTL entrance, and fails to create tails at the SDTL exit.

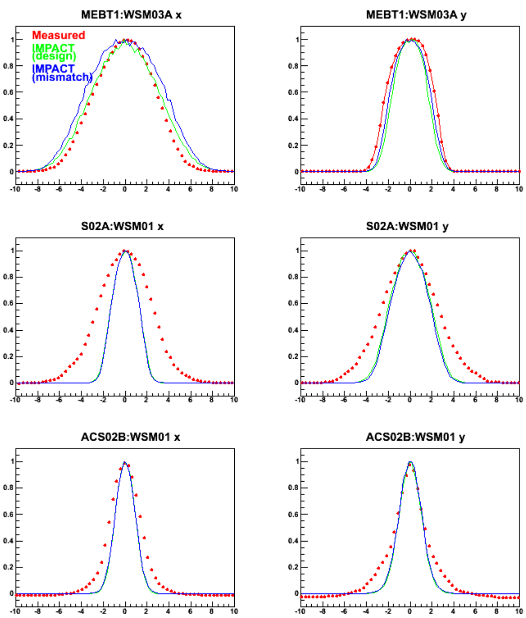

Figure 5: Horizontal (left) and vertical (right) beam profiles at MEBT1 (top), SDTL entrance (middle), and SDTL exit (bottom). Red dots show measured data with WS's. Blue lines show IMPACT calculations with the initial beam parameters from fit at MEBT1. Green lines show IMPACT calculations mismatched at the entrance of DTL1 by deviating initial Twiss parameters

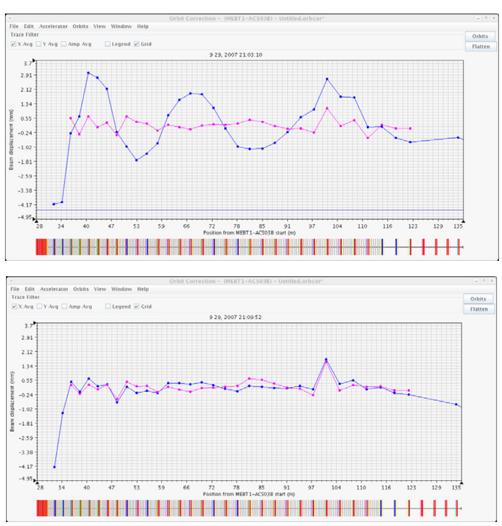

Figure 6: Horizontal orbit positions as a function of a distance at SDTL before correction (top) and after correction (bottom). Blue lines show measured beam positions, and pink lines show predicted positions.

## ORBIT CORRECTIONS

Orbit corrections are performed for good beam transport and beam loss suppression. Main sources of orbit deviations are alignment errors of magnets, and magnetic and electric field errors. Beam positions are measured with beam position monitors (BPM's), and orbits are corrected with dipole steering magnets. The corrections are calculated with XAL in the application "orbitcorrect" as shown in Fig. 6 [5]. Orbit references and steering field patterns are saved, and orbit corrections are started with the restored field patterns and the orbit references. After the corrections, the orbit deviations are suppressed within 1 mm. The dipole field patterns have been stable at different runs.

## CONCLUSIONS

Procedures of transverse matching in the whole LINAC have been established. At MEBT1, longitudinal and transverse initial beam parameters have been obtained. From SDTL to L3BT collimator sections, mismatch factors less than 5% have been achieved with good reproducibility. Twiss parameters at the RCS injection point have been controlled by QM's at LINAC. Emittance enhancement has been observed at SDTL entrance, and profile tails have been developed after SDTL. They are not reproduced by IMPACT by causing mismatch by varying initial transverse Twiss parameters in the constraint of profile data at MEBT. This problem is not critical for beam loss and emittance enhancement. However, to solve this problem it is necessary to improve precision of geometry, magnetic and electric field at MEBT1, DTL and SDTL. Orbit corrections have been successfully performed with orbit deviation within 1 mm.

# DEVELOPMENT OF MODULATING PERMANENT MAGNET SEXTUPOLE LENS FOR FOCUSING OF PULSED COLD NEUTRONS*

Masako Yamada, Yoshihisa Iwashita, Masahiro Ichikawa, Hiromu Tongu, Hiroshi Fujisawa (ICR, Kyoto University, Uji Kyoto Japan), Hirohiko M. Shimizu, Takashi Ino, Kenji Mishima, Kaoru Taketani, Takahiro Morishima, Suguru Mutou, Tamaki Yoshioka (KEK, Ibaraki Japan), Takayuki Oku, Kenji Sakai, Takenao Shinohara, Jun-ichi Suzuki (JAEA, Ibaraki, Japan), Katsuya Hirota, Yoshie Otake, Hiromi Sato (RIKEN, Wako, Saitama), Yoshichika Seki (Kyoto University, Kyoto), Sinsuke Kawasaki, Hidetoshi Otono, Sachio Komamiya (The University of Tokyo), Satoru Yamashita, Yoshio Kamiya (ICEPP, Tokyo), Peter Geltenbort (ILL, Grenoble, France)

*Abstract*

Cold neutron beams can be focused by a strong sextupole magnetic field. A permanent magnet sextupole lens whose focusing strength can be synchronously modulated at the rate of pulsed cold neutron beams is under development. This device should keep the focal point for pulsed neutron beams whose wavelength spreads as a function of time of flight. This kind of device improves the utilization of valuable neutrons and saves experiment time and costs. It will raise linac based small neutron sources as a good counter part to large powerful neutron facilities. Experimental results that were obtained at Institute Laue-Langevin (ILL) are also described.

## INTRODUCTION

Neutron beams are well known as powerful probes for both material science and fundamental physics. The applicable research field, however, is limited by the low intensity of the neutron beams. Meanwhile, the efficiency of a neutron beam has recently been much improved by techniques such as neutron optics [1-6], time of flight (TOF) method, and so on.

Among such neutron optics devices, a magnetic lens can focus neutron beams on such targets as samples and/or detectors by using interaction between the neutron's magnetic dipole moment and the sextupole field. When we apply the TOF method to pulsed neutrons for increasing the efficiency of each experiment, the wavelength range to be covered is in the order of a few times. The time dependence of the wavelength λ is proportional to $t$ (time of flight of a neutron). Then we should modulate the field gradient proportional to $t^{-2}$ in order to keep the focal length $Z_f$ fixed independent of $\lambda$. With these aspects, we are developing a modulating permanent magnet sextupole lens (PMSx) for focusing of pulsed neutron beams with chromatic aberration suppressed. The sextupole lens is composed of permanent magnets (NdBFe) because they can generate a strong magnetic field within limited space.

This lens increases the intensity of neutron beams on a target to reduce an experiment time with sufficient count rate and to increase the spatial resolution. Then neutron probe applications can be widely extended, for example, even the linac-based small neutron source now under development becomes practical.

## FOCUSING OF PULSED NEUTRONS BY SEXTUPOLE MAGNET

The origin of the focusing force is the interaction between neutron's magnetic dipole moment and the external magnetic field [7-9]. A sextupole component of magnetic field B can be written as:

$$|B| = G'/2\left(x^2 + y^2\right) \qquad (1)$$

where $G'$ is a positive value indicating the strength of the gradient of magnetic field. In the sextupole field, neutrons feel the thrusting force proportional to the distance from the magnetic centre and their equation of motion is a simple harmonic oscillator described as

$$\frac{d^2x}{dt^2} = -\omega^2 x,\quad \frac{d^2y}{dt^2} = -\omega^2 y,\quad \frac{d^2z}{dt^2} = 0 \qquad (2)$$

where $\omega^2 = G'\alpha$, $\alpha = |\mu_n/m_n| = 5.77$ m$^2$ s$^{-2}$ T$^{-1}$, $\mu_n$ is magnetic dipole moment and $m_n$ is the mass of neutron, in case the neutron spin is parallel to the local magnetic field [7-8]. When the ambient magnetic field is strong and changes slow enough (adiabatic condition), the spin direction follows the magnetic field direction. Because the magnetic dipole moment of the neutron is connected to the spin, the polarity of the force changes in accordance

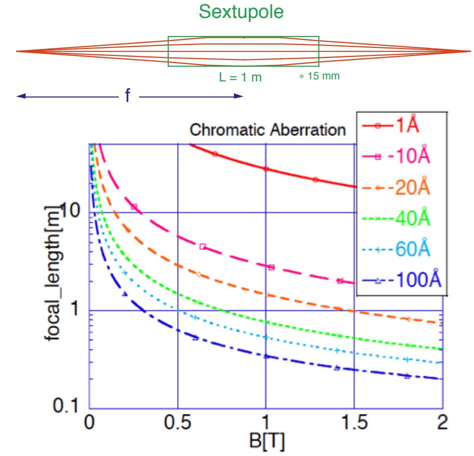

Figure 1: Focusing of neutrons by sextupole magnet and chromatic aberration.

*Work partially supported by the Ministry of Education, Science, Sports and Culture, Grant-in-Aid for Scientific Research (A), 18204023(2006) and 19GS0210.

with the spin polarity. The focal point is described as

$$Z_f = Z_m + \frac{h}{\omega m_n \lambda} \cot\left(\frac{\omega m_n \lambda}{h} Z_m\right). \tag{3}$$

When $\lambda$ is close to zero, Eq. 5 can be rewritten as

$$Z_f = \frac{2}{3} Z_m + \frac{1}{Z_m G \alpha}\left(\frac{h}{m_n \lambda}\right)^2, \tag{4}$$

where $h$ is Plank constant. The focal length of the magnetic lens depends on the wavelength (momentum) of the neutrons and field gradient (Fig. 1). For pulsed neutrons, we can apply the Time of Flight method for effective use of valuable neutrons. In that case, we need to modulate the field gradient according to the wavelength change in time. In order to keep the focal length constant independent of the $\lambda$ proportional to t, in other words, to suppress the chromatic aberration, we need to follow the relation:

$$G' \propto \lambda^{-2} \propto t^{-2}. \tag{5}$$

## FABRICATION OF THE PROTOTYPE

We have fabricated a prototype of magnetic lens using permanent magnets as mentioned before (see Fig. 2). In order to adjust the strength, the magnet is divided into two nested co-axial rings, where the inner ring is fixed and the outer ring can be rotated (see Fig. 3). Synchronizing the modulation with neutron beam pulse suppresses the chromatic aberration. Strictly speaking, the modulation is not proportional to $t^{-2}$ but sinusoidal. But we can use a part of the descending slope.

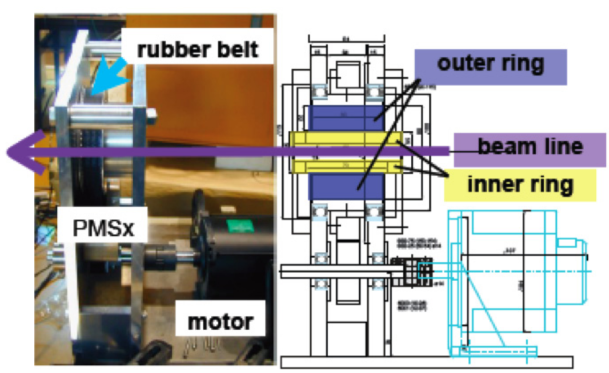

Figure 2: The overview and cross section of the prototype of PMSx

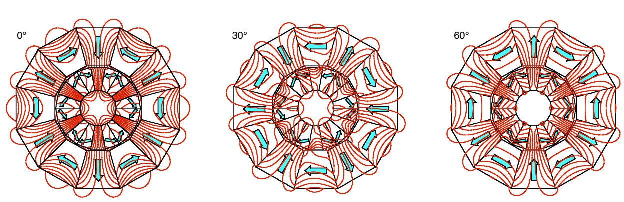

Figure 3: Sextupole with two-nested ring structure. (a) maximum strength position where the outer ring is in phase with inner ring (b) 30° rotated (c) minimum strength position where the outer ring is out of phase (60°). The arrows indicate the easy axes of the magnet pieces. The pieces without arrows are made of soft magnet material.

The magnet has Extended Halbach configuration, where one of the soft magnetic materials, Permendur, is used as pole material to generate stronger field [10]. The outer ring is composed of 12 magnet pieces and the inner ring is composed of 12 magnet pieces and 6 Permendur ones (18 pieces total). The magnetic field changes three times in one revolution of the outer ring. The diameter of the bore is 15mm, the repetition rate of the magnetic field modulation is 25Hz (the same as J-PARC), and the magnet length is 66mm. The strongest magnetic field (rotation angle is determined as 0º) measured by single axis tesla meter (Group-3 DTM151) at the surface of poles showed 1.65 T, $G = 5.69 \times 10^4$ [T/m$^2$], and the focal length is calculated to be about 0.5m for $\lambda$=40Å, which is a practical value (see Fig. 4).

The temperature rise during the operation has been reduced [11] and is under improvement further beyond.

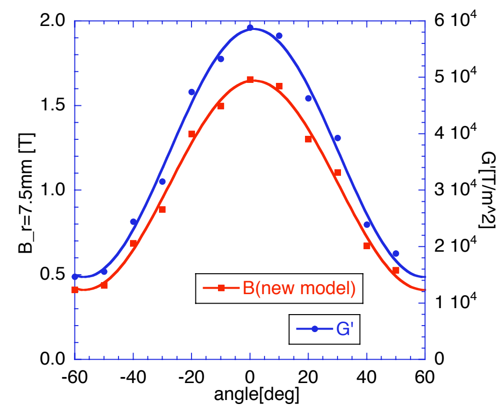

Figure 4: The measured magnetic field modulation and derived its field gradient.

## EXPERIMENTS WITH VCN

We carried out experiments on focusing of pulsed VCN with TOF method in PF2 beam line at ILL. In this experiments, we fixed the outer ring rotation angle at 0º, 31.7º and 60º (see Fig. 4). The setup is shown in Fig. 5. The disc-chopper (see Fig. 5 right) chops the continuous neutron beams to be pulsed, around 20~60Å in their wavelengths. The detector has time resolution and 2D spatial resolution, which is composed of a scintillation screen and 2D-PMT. The polarising super mirror selects neutrons with parallel spins to the magnetic field, thus only the images of focused neutrons are detected. After the ø1mm slit, in order to satisfy the adiabatic condition as mentioned at Eq. (2), we placed two dipoles to keep the polarization. The magnetic field from the mirror to the PMSx was not less than 15G. We obtained the wavelengths (momentum, energy) from their time of flight when neutrons are focused by PMSx, and compared with the field gradient.

The results are shown in Fig. 6 and Table 1. The results are consistent with the calculation. We confirmed that neutrons are focused depending on the strength of magnetic field. However, the timing offset ($t_0$) is not considered in this analysis. We plan to determine the $t_0$ pre-

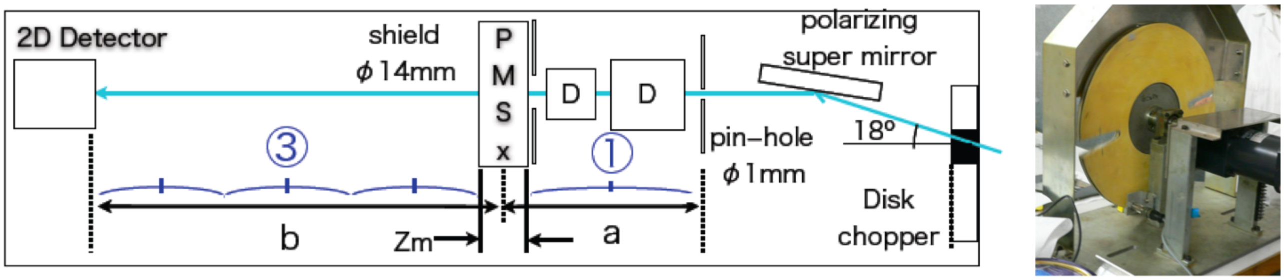

Figure 5: (left): The set up of experiments: a=720mm, b=2140mm, then $Z_f$=540mm. (right): The disk-chopper making the VCN beam pulsed.

Table 1: the results compared with calculation

| angle [deg] | B(r=7.5mm) [T] | $G'\times10^4$ $[T/m^2]$ | λ[Å] (calc.) | λ[Å] (meas.) |
|---|---|---|---|---|
| 0 | 1.65 | 5.88 | 38 | 39 |
| 31.7 | 0.89 | 3.15 | 49 | 50 |
| 60 | 0.41 | 1.48 | 75 | out of focus |

cisely soon. It should be mentioned that we might see the effect of gravity from the vertical movements of the centre (see Fig. 6 - right).

## FUTURE PROSPECTS

We are going to develop a practical PMSx this year. Firstly, we will have the pole sliced thinner and annealed for less eddy currents and hysteresis losses, while keeping the strength of the magnetic field as good as possible. Secondly, we are going to incorporate a technique for smooth rotation of the outer ring such as a torque canceller.

The first application of this device would be Small Angle Neutron Scattering (SANS) for material science. Dr. Bleuel has carried out some focusing-SANS experiments with our PMSx after our experiments [12]. The idea of PMSx can be extended widely when we use the time harmonics. It will ease the adjustment of time variation of the focusing strength.

# MULTIPACTING SIMULATION IN RF STRUCTURES

M.A.Gusarova, V.I.Kaminsky, S.V.Kutsaev, M.V.Lalayan, N.P.Sobenin, MEPhI, Moscow, Russia
L.V.Kravchuk, S.G.Tarasov, INR, Moscow, Russia

*Abstract*

A new computer code for 3D simulation of multipacting phenomenon in radio frequency (RF) structures is developed. Simulation results in various RF devices are compared with theoretical calculations and experimental measurements.

## INTRODUCTION

Design of accelerating cavities, input power couplers and other RF devices for the charged particle accelerators should provide the conditions of multipactor discharge elimination or suppression. The multipactor effect is a phenomenon in radio frequency (RF) devices (cavities, waveguides and others), where, under certain conditions, secondary electron emission in resonance with an alternating electric field leads to exponential electron multiplication, possibly damaging and even destroying the RF device.

Currently, there are three general approaches for suppressing multipactor discharge: conditioning of the components by the discharge, coatings and other surface treatments, and geometrical modifications. Proper design and geometry choice are the most powerful methods for multipactor suppression. Geometry modification results in electromagnetic field pattern changes. Latter leads to electrons trajectories distortion that breaks resonant conditions for multipactor discharge.

The code MultP–M is a tool that allows the analysis of multipacting in fully 3 dimensional RF structures and the modification for multipactor suppression

## MULTP-M

The main window MultP-M is presented on Fig. 1. The code was programmed using Object Pascal in Delphi environment.

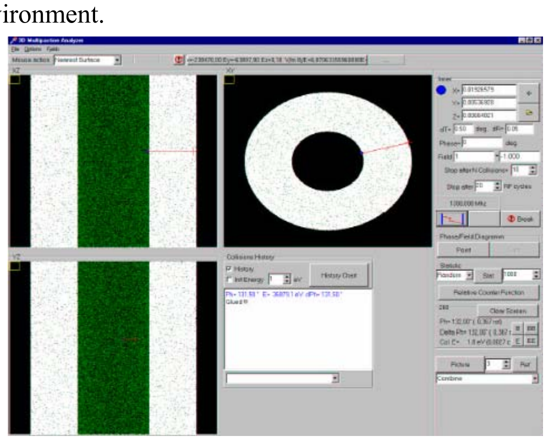

Figure 1: The main window. Example: single trajectory in a coax cavity.

MultP–M is the succeeding code for MultP [1, 2]. The latter was upgraded to get more functionality.

The code MultP–M is a tool that allows the analysis of multipacting in fully 3-dimensional RF structures. It solves the non-relativistic equation of motion of electrons in time harmonic rf fields. MultP–M does not contain a field solver, but it provides an interface to import the field-map from a text-file. The external field solver must be able to export field-maps to text-files, and it is strongly recommended that it uses a conformal mesh (mesh-points coincide with the boundary). MultP-M takes into account the RF device operation mode and allows simulation both for standing and traveling waves.

The resulting trajectories can be analyses by means of electron counter function and various statistics (statistics - particle counter, statistics - impact energy distribution, statistics - distribution of impact phases, statistics - the collision counter, statistics - finding trajectories with more than n impacts). All parameters used in the calculation (field level ranges, SEY, initial energy of electron, electron emission phases, initial number of particles, minimal collision, frequency, and limitation of number of field periods for calculation) are assigned by user.

The final decision whether multipacting is possible or not is up to the user.

### *Testing of MultP-M*

As the test several narrow rectangular waveguides were simulated. For the narrow rectangular waveguides it is possible to do the theoretical estimation of the electric field strength threshold providing the conditions to multipactor discharge (equation 1). Resonance sizes of discharge gaps h(k) can be calculated using expression (2).

$$E_0 = \frac{\omega}{e}\sqrt{\frac{W_1 m}{2}} \quad (1) \qquad h^{(k)} = \frac{eE_0 k\pi}{m\omega^2} \quad (2)$$

Here h - distance between the wide walls of waveguide, k - multipactor order, $W_1$ - energy of primary electron providing SEY > 1. These equations are rather simple and leave out the electron's initial phase and velocity spread.

Two rectangular waveguides were studied namely copper waveguides of 70x3.5 mm and 70x2.1 mm operated on 1.3 GHz.

Fig. 2 illustrates direct modeling results for 70x3.5 mm waveguide presented in two cross sections in xy and yz planes. The region subject to multipactor electrons burst is marked with dark blue.

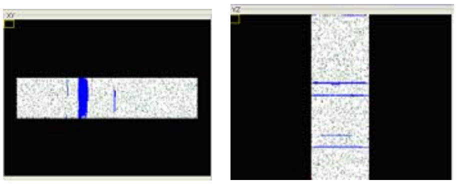

Figure 2: Multipactor discharge region in narrow rectangular waveguide.

The results of theoretical calculation of electrical field strength threshold and simulation done by MultP–M code are summarized in table 1.

Table 1: The Results of Theoretical Calculation of Electrical Field Strength Threshold and Simulation Done by MultP–M.

| Narrow waveguide (normal conducting, Cu) 70×3.5 mm | | |
|---|---|---|
| | Theoretical calculations | MultP–M |
| Field strength, kV/m | 450 | 448 |
| Order of the multipacting | 5 | 5 |
| Narrow waveguide (normal conducting, Cu) 70×2.1 mm | | |
| | Theoretical calculations | MultP–M |
| Field strength, kV/m | 450 | 447 |
| Order of the multipacting | 3 | 3 |

It is seen that the results are in good agreement within ±3 kV/m. This divergence can be caused by constant secondary electron emission yield value for impact energy 200 eV, used for analytical calculation, whereas the entire yield on energy dependence was used in numeric simulation.

## EXAMPLES SIMULATION

In order to illustrate MultP-M usage let us consider accelerating cavity (standing wave mode) and ceramic window (traveling wave mode) analysis

### *RF Cavity*

The superconducting accelerating cavity for Energy Recovery Linac [3] is good choice to illustrate multipactor simulation in standing wave device. Its model made in MultP-M is shown on Fig. 3.

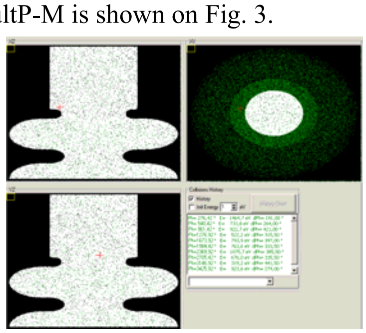

Figure 3: Cavity model in MultP-M.

Electromagnetic field distribution used for simulation had values defined for Nx=100 $N_y$=100 $N_z$=300 nodes. Electron energy providing SEY>1 was 50 to 1500 eV. Simulation made for 1000 initial particles. The results of simulation done by MultP–M are presented on Fig. 4 – 6.

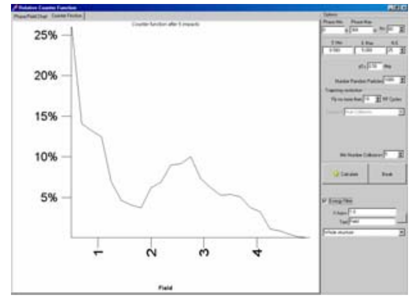

Figure 4: MultP-M, Electron Counter Function; (1= 11.635 MV/m).

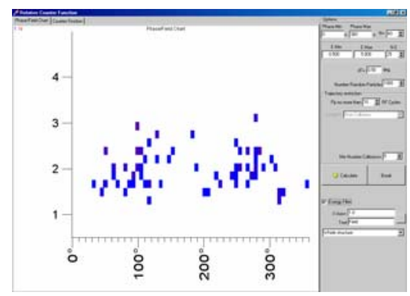

Figure 5: MultP-M, Phase/Field Diagram; (1= 11.635 MV/m).

From simulation results namely Electron Counter Function and Phase/Field diagram presented on Fig. 4. It is seen that about 10% of the primary particles remain in the structure for the field strength ~ of 21 - 36 MV/m (normalized value 1.8 – 3.1). Impact energy distribution study for this field strength range showed that electrons impact energy corresponds to SEY value exceeding one.

Electron trajectories thorough analysis showed the resonant conditions exist in rounded interconnection area between cell and drift tube. These trajectories are shown on Fig. 6 exist for electric field strength on axis ranging from 22 to 36 MV/m.

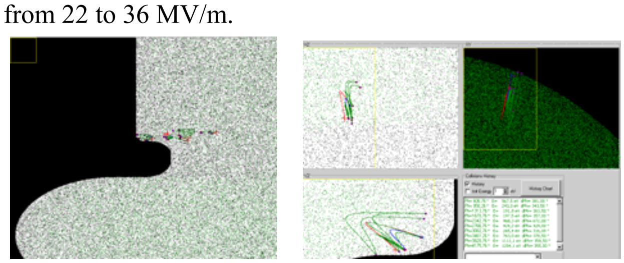

Figure 6: Resonance electron trajectories.

Summarizing the results described above one could conclude that this structure is subject to multipactor discharge on drift tube to cell interconnection region. Multipactor is most possible to occur for on-axis electric field strength range 22–36 MV/m. This result obtained using MultP-M code agrees with published data [3].

## *Ceramic RF-windows*

Ceramic vacuum windows are traveling wave operating devices. It is to be noted that usually there are at least two different materials featuring diverse SEY values used in design. In order to simulate multipactor in this case MultP-M allows assigning different properties for all materials used in single model.

Some results of Energy Recovery Linac [4] RF-coupler cold window simulation using MultP-M code are presented below. The cold window model used for simulations included the ceramics, upstream coaxial line from warm window (D=62 mm, d=28.8 mm) and the downstream one to cavity (D=62 mm, d=22.8 mm).

Fig.7 - 8 illustrates the direct modeling results for multipactor discharge at 100 and 700 kW transmitted power.

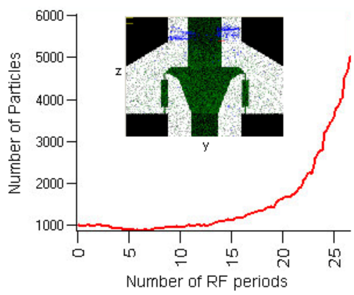

Figure 7: Statistical simulation results for ceramic window operated at 100kW.

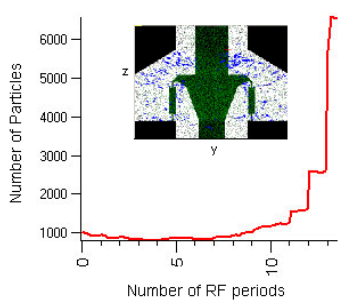

Figure 8: Statistical simulation results for ceramic window operated at 700 kW.

The statistical simulations were made using 1000 initial particles of 1eV energy. Secondary electron emission yield for metal was equal to 3 and for the ceramics was 6. Electromagnetic fields were obtained using Microwave studio run for model with 30.000 nodes. The area where multipactor occurs is marked with dark (blue) fill.

The simulation results showed that the multipactor could occur when power > 50kW. It is seen, that for low power less than 200 kW the dangerous areas located close to coaxial waveguides Fig. 7 whereas the discharge in the ceramics vicinity could occur for higher power Fig. 8.

## CONCLUSIONS

MultP–M code is a convenient tool designed for multipactor discharge simulations in RF devices of a complicated 3D shape. The results obtained using MultP-M code are agree with theoretical and experimental data. MultP–M makes the modification, optimization and design available for RF components used in the charged particle accelerators.

*Abstract*

An investigation of input coupler asymmetry influence on electron beam dynamics in energy recovery linacs (ERL) with superconducting cavities was carried out. There were several types of input power couplers – coaxial and waveguide, asymmetric and symmetric considered. Using numerical simulation the electromagnetic fields distribution in accelerating cavity with input coupler was found and transverse deflecting impulse was calculated. RTMTRACE code was adapted for beam dynamics modeling.

## INTRODUCTION

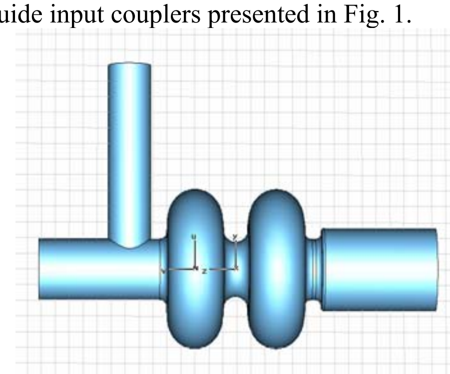
Choice of asymmetric geometry for RF-power input coupler for accelerator leads to transverse components of EM-field on the beam axis, which are responsible for a transverse impulse deflecting particles from the axis and making the beam emittance grow. To estimate the influence of the current effect on beam dynamics a notion of the beam kick is introduced. Numerically it is characterized by a ratio of Lorenz force integral normalized by charge and integral of longitudinal accelerating component of EM-field. Integration is made along the trajectory of the beam center. One must also take into account transit-time factor.

$$kick = \frac{V_t}{V_{acc}} = \frac{\int \left(E_y + eH_x\right)dx}{\int E_z dz} \qquad (1)$$

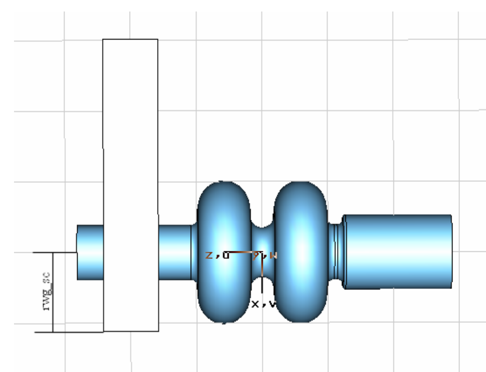
Calculation of beam emittance change due to field asymmetry in the beam region can be performed by analytical formula, which is given in [1]. More precise results can be obtained by modeling of beam dynamics, i.e. by solving motion equations for all beam particles in the field distribution obtained. RTMTRACE software was used for that task. It was originally designed for electron beam dynamics simulation in microtron [2]. Further developments made it possible to use RTMTRACE for calculation of other accelerating structures. One has to provide EM-field calculated using external software and exported to file in a special format for dynamics modeling. Also, to calculate structures considered below initial program was modified and compiled to produce an executable file.

## COAXIAL INPUT COUPLER

Calculations were made for structures with coaxial and waveguide input couplers presented in Fig. 1.



a



b

Figure 1: Coaxial and waveguide input couplers.

Calculation for a structure with a single coaxial input coupler (Fig.1, a) was performed to compare results with those given in [1]. During field calculation manual mesh optimization was performed in order to increase the number of mesh nodes in the beam region. Finally mesh with 160000 elements was used for field calculation, 10000 nodes corresponded to the beam region. Fig.2 presents the components of EM-fields in asymmetric coaxial input coupler calculated for perfect electric wall set as boundary condition. Similar calculations were made for a perfect magnetic wall.

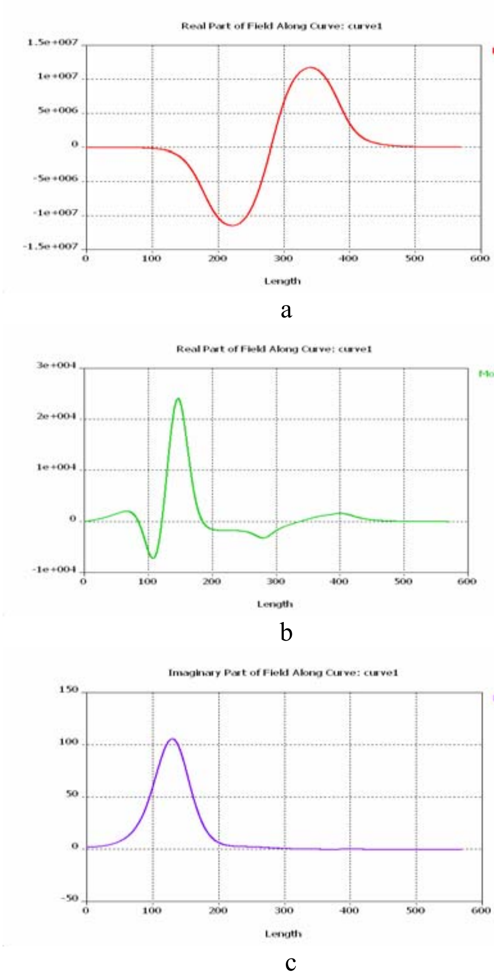


Figure 2: Longitudinal (a), transverse (b) components of electric field and transverse component of магmagnetic field (c) on structure axis for electric wall boundary condition.

Table 1 gives values of peak electric and magnetic field components values, obtained by calculation with two boundary conditions (E-wall and H-wall). In order to determine kick in two-cell buncher of ERL by using these data normalization was made to get effective accelerating voltage in the cavity equal to 1 MV. The kick calculation method gave kick = 0.0014 – 0.0018i. The following parameters of ERL injector were used: operating frequency is 1.3 GHz, initial beam energy 4 MeV, accelerating voltage 1 MV, beam current 0.1 A, charge 77 pC, transverse beam radius $\sigma_{x,y}$=2 mm, beam length $\sigma_я$=0.6 mm, and initial emittance $\varepsilon_0$=1 mm*mrad. Beam emittance growth calculated by the analytical formula [1] for kick value obtained was 12% for one of the five accelerating cavities. The difference from the result of 20% given in [1] can be explained by mesh effects, and by different software used to compute fields.

Beam dynamics modeling by RTMTRACE in cavity with the single coaxial input coupler was done for two various electron bunches. Results are given in Table 2.

Table 1: EM-Field Components Peak Values on Beam Axis

| Component | Peak value | |
|---|---|---|
| | E-wall | H-wall |
| $E_z$ [V/m] | $1.1\cdot10^7$ | $1.1\cdot10^7$ |
| $E_y$ [V/м] | $2.6\cdot10^4$ | $5.6\cdot10^4$ |
| $c\cdot B_x$ [V/m] | $4.0\cdot10^4$ | $4.0\cdot10^4$ |

Table 2: Electron Beam Dynamics Modeling Results

| Bunch | q [pC] | $\varepsilon_0$ [mm·mrad] | $\sigma_z$ [mm] | $\sigma_{x,y}$ [mm] | emittance growth, % |
|---|---|---|---|---|---|
| 1 | 77 | 1 | 0.6 | 2 | 5 |
| 2 | 8 | 0.1 | 0.6 | 0.6 | 12 |

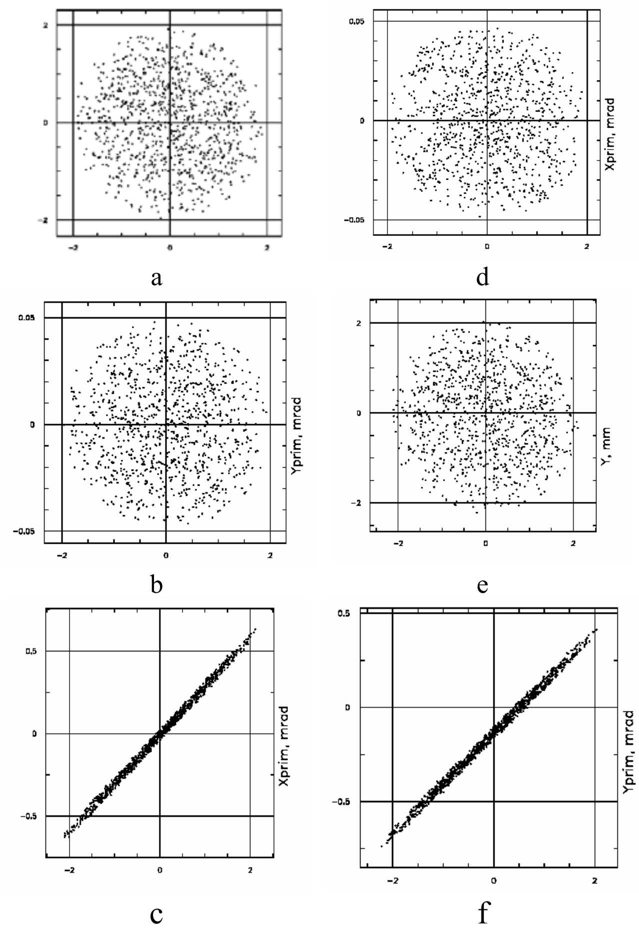

Figure 3: Beam parameters before (a – cross-section, b – phase plane x-xp, c– phase plane y-yp) and after passing the accelerator (d– cross-section, e – phase plane x-xp, f – phase plane y-yp).

Beam characteristics obtained using RTMTRACE before and after passing the accelerator are presented on Fig.3. Here are some other output parameters of beam dynamics modeling: energy spread – 6.23%, maximum particle deflection – 2.25 mm from axis, bunch length – 1.05º.

Structure with symmetric coaxial input coupler was also used to determine beam dynamics with RTMTRACE. Two cases given in Table 2 were considered. For either case the emittance growth did not exceed 4%.

## WAVEGUIDE INPUT COUPLER

Waveguide input coupler, shown in Fig. 1, b is proposed as a good alternative to coaxial coupler if geometric asymmetry does not lead to considerable transverse components values of EM-field in the beam region. Analysis of the structure using MWS showed that on-axis field distribution is strongly affected by the length of short-circuited waveguide, which is noted as *rwg_sc* in Fig. 1, b. Table 3 gives values for peak fields on structure axis for two values of *rwg_sc* – 111 mm and 145 mm.

Table 3: Peak Field Values on Structure Axis with Various Lengths of Rectangular Waveguide

| Boundary | Parameter | | |
|---|---|---|---|
| | $E_z$ [V/m] | $E_y$ [V/m] (min./max) | $cB_x$ [V/m] |
| | Peak value, for rwg_sc = 110 mm | | |
| E-wall | $1.15\cdot10^7$ | $(3.6/4.1)\cdot10^3$ | $1.6\cdot10^4$ |
| H-wall | $1.15\cdot10^7$ | $(3.1/3.8)\cdot10^5$ | $1.4\cdot10^6$ |
| | Peak value, for rwg_sc = 145 mm | | |
| E- wall | $1.15\cdot10^7$ | $(1.4/1.6)10^3$ | $6.4\cdot10^3$ |
| H- wall | $1.15\cdot10^7$ | $(7.0/8.0)\cdot10^3$ | $3.1\cdot10^4$ |

In both cases the estimation of beam emittance growth was made for the bunch (see Table 2) center being in phase with the accelerating wave. The following values were obtained for kick and emittance growth: for rwg_sc = 110 mm кick = 0.0638 – 0,0241i and emittance growth is 154%; for rwg_sc = 145 mm kick = 0.0009 – 0.0006i and emittance growth is 3.8%.

For rwg_sc = 145 mm the transverse components are considerably lower. Obviously, smaller waveguide length leads to a local field perturbation.

## CONCLUSIONS

The results obtained are evaluative; the calculations did not take into account transverse dependence of electromagnetic fields. However, the following conclusions can be made:

the asymmetric structure with coaxial input coupler cannot provide low beam emittance growth;

the asymmetric structure with waveguide rectangular input coupler with some size optimization can provide quite low emittance growth (3,8%).

*Abstract*

Calculations of neutron production in metallic targets bombarded by protons with energies up to 1 GeV in framework of GEANT-4 are presented. Calculations of neutron production in targets of large size, dependencies of neutron yields on target dimensions and spatial distribution of energy deposited in the target, intended for working out ADS targets with multiplying blankets are also presented.

## INTRODUCTION

Accelerator driven systems (ADS) as powerful spallation sources of neutrons can find their application in nuclear power engineering for transmutation of long-living radioactive waste, production of new elements and substances with fission capability and for power generation. In hybrid reactor also called energy amplifier (EA) - fission reaction takes place in sub-critical reactor while the necessary density of neutron flux is provided by the spallation neutron source.

Costs, dimensions and weights as well as power consumption of accelerators required in a large extend depend on the output power of EA. Installations with high (about 1GW) power output for their operation require beams of protons accelerated up to the energies of 1GeV and higher with intensities of hundreds of mA. Beams of charged particles with mentioned characteristics one can get only using unique expensive accelerator machines. However EA of 200-400MW output require substantially lower intensities of neutron sources. This fact allows one to make use of accelerators producing beams of several hundred MeV and few mA current which can be copiously produced by industrial means.

In our work on the basis of calculations performed within GEANT-4 framework (v.9.1) we present neutron yield for different metal targets (Cu,Fe,Ta,W, Pb) bombarded by proton beam with energies from 300 MeV up to 1 GeV and spatial distribution of heat deposited in target.

GEANT-4 (v.9.1) developed by CERN is a program package (a set of C++ libraries) designed for modelling particle interactions with matter on the Monte-Carlo basis [1]. GEANT-4 can be used with different types of projectiles, materials and geometry of targets (detectors) and user is free to choose models for physical processes involved according to the task, which he is working at.

In our calculations we take into account electromagnetic processes, i.e. multiple scatterings off nuclei and ionization losses of charged particles, together with nuclear processes. For modelling of high-energy hadron—nucleus interactions we choose Bertini intranuclear cascade model for the very first cascade stage of interaction (approx. $10^{-23}$ s). Excited nucleus formed after this first stage rather emits hadrons (cascade-exciton and evaporation models are used respectively for pre-equilibrium and equilibrium states of excited nucleus) or breaks up instantly (multifragmentation or Fermi break-up for light nuclei). Interaction of neutrons having energies lower than 20 MeV with matter is described by parameterization-driven models based on ENDF/B-IV neutron cross section libraries.

Interaction of particles with matter within GEANT-4 is modelled on step-by step basis, at each step characteristics of generated track can be extracted and processed. To obtain our results we process up to 10000 of primary proton tracks.

Computation error was determined according to root mean square deviation (RMS) of the quantity of interest, determined using same set of values for the quantity obtained by Monte-Carlo. That is, for $N$ events and RMS value of $D$ computation error on 3σ level for quantity $X$ can be determined according to central limit theorem as

$$\Delta X = 3D / \sqrt{N} \qquad (1)$$

Table 1 represents comparison of experimental data on neutron yields from target bombarded by protons with GEANT-4 computations.

Table 1: Average Neutron Yield m from Cylindrical Lead Targets per 1 Proton

| Target dimensions D×L cm | $E_p$, MeV | *m*, n/p GEANT-4 | *m*, n/p experimental data | Reference (experimental data ) |
|---|---|---|---|---|
| 10.0×60 | 17 | 3.65±0.52 | 3.13±0.06 | [2] |
| 10.2×61 | 70 | 7.53±0.80 | 8.0±0.4 | [3] |

| | 60 | 24.63±1.38 | 20.3±1.1 | [5] |

Comparison of GEANT-4 evolved quantities confirms a possibility to apply the toolkit for practical calculations of targets for ADS.

## NEUTRON GENERATION IN TARGET

Neutron yield from the target depends on parameters of the charged particles beam, target composition and dimensions. Bombardment by high-energy particles produces a hadron-electromagnetic cascade in target matter. Accelerated primaries induce fission of atomic nuclei and creation of secondary particles which in their turn can also induce fission and create new generations of particles (protons, neutrons, mesons and γ-quanta). High-energy particles can induce fission not only of those nuclei for which fission can be induced by low-energy neutrons (e.g. uranium) but also of other heavy elements (e.g. tantalum, lead, tungsten). The latter ones can be used as the neutron-producing material of the target.

In Fig. 1 we present total number of neutrons produced in different metal targets as a function of the incident primary proton energy. Calculations are performed for infinite targets.

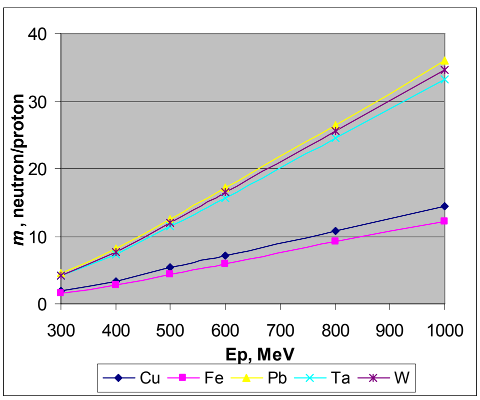

Figure 1: Total number of neutrons produced in infinite target.

Yields of neutrons (number of neurons which escape from the target) for finite targets depend on both beam characteristics and target dimensions. When dimensions are small a substantial part of secondary particles capable to induce fission with additional neutron production escapes form the target without interaction. At the same time in large target neutron radiative capture plays an important role.

For cylindrical target an optimal diameter with respect to neutron yield corresponds to few (2-3) characteristic inelastic interaction lengths $\lambda_{in}$. Due to anisotropy in particle production for inelastic proton scatterings in the lab frame (most of particles are produced in forward direction), the target length $L$ should be somewhat larger than its radius, at the same time value of $L$ has minor effect on the neutron multiplicity provided $L>D>\lambda_{in}$. Substantial part of neutrons escapes through the front butt-end of the target block, so neutron yield is maximal for comparatively small deepening of the beam injection point $z_0 \approx 0.3\lambda_{in}$.

In Table 2 we present calculated values for optimal dimensions of cylindrical target, Fig. 2 represents maximum neutron yields for them obtained via GEANT-4.

Table 2: Optimal Dimensions of Cylindrical Target

| Material | D, sm | L,sm | Beam injection point, $z_0$ ,sm |
|---|---|---|---|
| Fe | 40 | 50 | 5 |
| Cu | 30 | 50 | 5 |
| Ta | 20 | 50 | 2.5 |
| W | 20 | 50 | 2.5 |
| Pb | 40 | 50 | 7.5 |

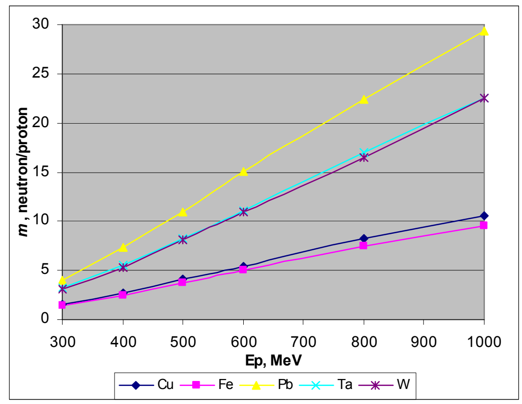

Figure 2: Maximal neutron yields for cylindrical targets. Target dimensions according to Table 2.

Energy spectrum of the neutrons obtained by electronuclear method is close to the fission spectrum. Specific energy spent for a single neutron production first drops with growth of beam energy $E_p$ and stays approximately constant afterwards (see Fig. 3).

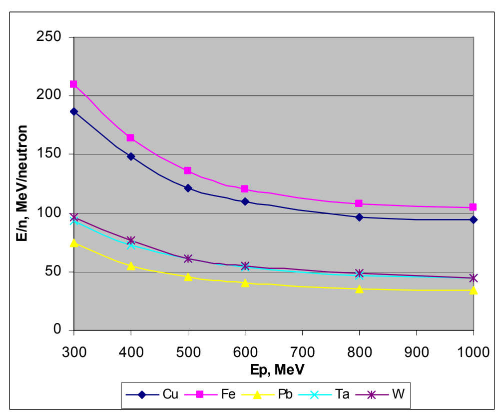

Figure.3: Specific energy spent for a single neutron yield. Target dimensions according to Table 2.

Power capacity of sub-critical reactor ($N_T$) with external neutron source spatial distribution similar to fission neutron one (reference external neutron source) is evaluated as

$$N_T = S_0 \cdot \frac{k_{eff}}{1-k_{eff}} \cdot \frac{1}{\nu} \cdot E_f \qquad (2)$$

where $S_0$- intensity of reference external neutron source, $k_{eff} < 1$ – multiplication factor, ν – mean number of neutrons per fission , $E_f$ – energy released per fission.

From (2) it follows that for a subcritical reactor with 200 MW power output and $k_{eff}$ =0.98 that ensures critical safety the needed intensity of the neutron source is $S_0=4.2\cdot10^{17}$n/s. It is possible to reduce intensity of external neutron source locating one in the center of core and hence decrease neutron leakage. In case of cylindrical core the intensity of central neutron source ($S$) may be twice lower than reference source intensity ($S_0$).

Intensity of the electronuclear neutron source

$$S = \frac{I_p m_0}{e} \qquad (3)$$

with $I_p$ standing for an average current of accelerator, $m_0$ – average neutron yield out of the target per single accelerated beam particle, $e$ – charge of the accelerated particle.

Intensity $S=2.1\cdot10^{17}$n/s can be reached for 5mA accelerator current if the yield is about $m_0 = 6.5$ neutrons per one primary accelerated particle. Our calculations (fig.2) show that the corresponding neutron yields can be reached for proton beam energies larger than 400 MeV for Pb target and larger than 450 MeV for Ta and W targets.

## HEAT DEPOSITION IN TARGET

To determine temperature field in the target and for calculations of cooling system one should possess data on a heat deposition in target bombarded by charged particle beam. Heat deposition in target is due to ionization losses of charged particles, (electromagnetic interaction of charged particles with material), inelastic interaction of cascade hadrons (neutrons, protons, $\pi$-mesons) with nuclei of the target, fission of nuclei of target material.

Figure 4 represents results on relative heat deposition (ratio of total rate of heat deposition $Q$ to beam power $N_{beam}$) in different materials (targets of optimal size w.r.t. the yield) at different proton beam energies.

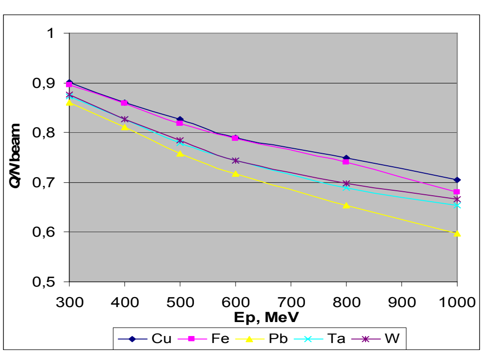

Figure 4: Relative total heat deposition in target.

Specific heat deposition is maximal along the beam injection axis. The maximum values of the specific heat deposition for a narrow beam are presented in Fig. 5.

In Fig. 6 we show calculated values for longitudinal heat deposition in copper target in comparison with experimental data [6]. The figure shows satisfactory correspondence of calculations with experiment.

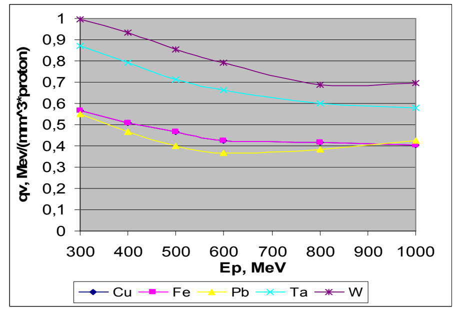

Figure 5: Maximal specific heat deposition for different targets.

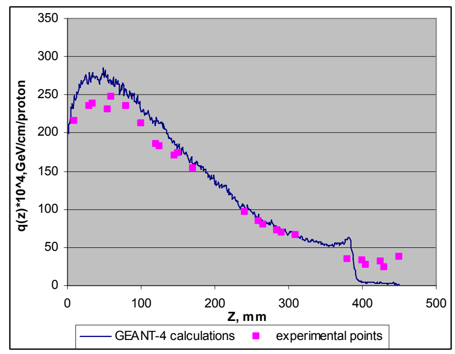

Figure 6: Longitudinal heat deposition in copper target. Proton energy 800 MeV.

## CONCLUSION

1. Comparison of GEANT-4 calculations with experimental data confirms its applicability for ADS target calculation and design.
2. For EA with sub-critical reactor with power output of 200 MW at $k_{eff}$ = 0.98 and 5mA accelerator current neutron yield should be as large as 6.5 neutrons/proton which can be achieved for heavy metal targets and beam energies slightly above 400-450 MeV.
3. For cylindrical targets optimal dimensions with respect to neutron yield are: diameter D=2...3 $\lambda_{in}$ , length $L \approx D$, deepening of beam injection point $z_0 \approx 0.3\lambda_{in}$ .
4. GEANT-4 gives a fair description of heat deposition in metal targets.

# END TO END BEAM DYNAMICS AND RF ERROR STUDIES FOR LINAC4

G. Bellodi, M. Eshraqi, J-B. Lallement, S. Lanzone, A.M. Lombardi, E. Sargsyan, CERN, Geneva, Switzerland
R. Duperrier, D.Uriot, CEA, Gif-sur-Yvette, France

Linac4 is a normal conducting $H^-$ linac to be built at CERN as a new injector to the PS Booster and later on as a front end of a possible MultiMegaWatt Linac Facility. The layout consists of a $H^-$ RF source, a magnetic LEBT, a RFQ (accelerating the beam from 45 keV to 3 MeV), a chopper line, a conventional Drift Tube Linac (from 3 MeV to 50 MeV), a Coupled Cavity Drift Tube Linac (from 50 MeV to 102 MeV) and a π-mode structure (PIMS, from 102 to 160 MeV), all operating at a frequency of 352 MHz. End-to-end beam dynamics simulations have been carried out in parallel with the codes PATH and TRACEWIN to optimise the design and performance of the accelerator and at the same time to guarantee a cross-check of the results found. An extensive statistical campaign of longitudinal error studies (static and dynamic) was then launched for validation of the proposed design and to assess the maximum level of RF jitter/inaccuracies (in both phase and amplitude) the system can tolerate before beam quality at injection in the PS Booster - and later in the Superconducting Proton Linac (SPL)- is compromised.

## LINAC4 LAYOUT

A 2 MHz RF volume source and 1.9m long 2-solenoid LEBT supply the initial $H^-$ beam at 45 keV (a 400 µs long pulse at 2 Hz repetition rate for 80 mA current). This is first accelerated to 3 MeV by a 352 MHz RFQ, before entering a 3.6 m long chopper line consisting of 11 EM quadrupoles, 3 bunchers and 2 deflecting plates. Here micro-bunches are removed from the pulse to achieve a cleaner injection of the Linac4 beam in the PS Booster ring downstream. The beam is then accelerated to 50 MeV by a 352 MHz conventional Drift Tube Linac (DTL), composed of 3 separate tanks each fed by one klystron. There are 111 drift tubes, each equipped with a Permanent Magnet Quadrupole. The DTL is followed by a Cell-Coupled Drift Tube Linac, which takes the beam to 102 MeV through a series of 7 modules (21 tanks coupled by 3's) operating at 352 MHz and powered by individual klystrons. Transverse focusing is provided by 21 electromagnetic quadrupoles placed between tanks. Acceleration to the final energy of 160 MeV is then carried out by 12 Pi-Mode Structure (PIMS) tanks at 352 MHz, each composed of 7 cells, and 12 EM quadrupoles. The first 4 tanks are powered individually, while the last 8 are coupled in pairs onto a same klystron. The last 2 tanks have a lower nominal accelerating field, to allow for the possibility of energy painting at injection in the PSB [1]. The layout here described is the result of several revisions of previous designs [2], the main changes being in the values of the transition energies and in the final choice for one single frequency (352 MHz), to make for a simpler design.

## END-TO-END BEAM DYNAMICS

Each section of Linac4 has been studied and optimized independently before a campaign of end-to-end simulations was launched to identify overall bottlenecks and limitations. The codes PATH[3], TRACEWIN[4], TOUTATIS[5], and PARMTEQ[6] have been used for these studies, providing mutual crosscheck of the results.

The $H^-$ beam pulse current from the source is 80 mA, and the duty cycle is 0.1% in an initial phase when Linac4 is used as injector of the PS Booster ring, and a duty factor of 6% for a later use as front end for the SPL (value used for the safety and loss studies).

Space charge effects dominate at low energy, causing some beam degradation and losses in the RFQ and chopper line. The RFQ can accelerate with <5% losses beams in the 20-100 mA range, with 8% transverse emittance growth for 70 mA current. The chopper line consists of two deflecting plates housed inside quadrupoles and driven at an effective voltage of 500V to remove 133/352 micro-bunches in the pulse, which are kicked onto a conical shaped dump. About 5% of the unchopped beam is lost here, whereas the fraction of chopped beam that is transmitted past the dump into the Linac, and might need to be eliminated at the lowest possible energy is ~0.05%. The beam current available at the end of the chopper line would thus be 65 mA per pulse without chopping, and 40mA with chopping on.

After the dump the beam is matched into the first tank of the DTL, with a FFDD focusing scheme. Most of the transverse emittance growth (almost 20%) occurs at this transition, when after a relatively slow phase advance

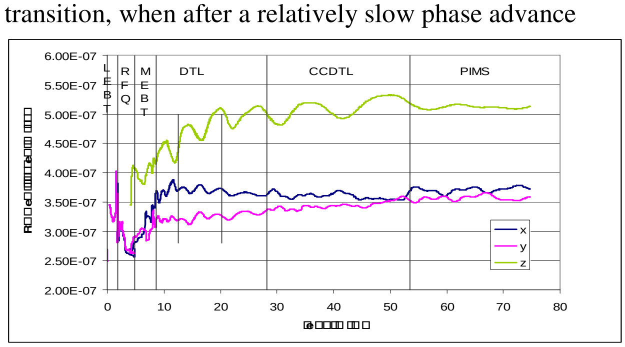

Figure 1: Transverse and longitudinal RMS emittance growth along the chopper line and Linac.

regime in the chopper (1 FODO per 10 βλ), the beam is compressed back in volume to fit a faster phase advance focusing channel (see Fig.1). The synchronous phase is ramped from -30 to -20 deg in Tank1 and then kept constant in the rest of the DTL (where the focusing scheme changes to a FODO type). At 50 MeV the beam is transferred to a CCDTL structure, composed of 3-gap cavities with an average phase of -20 deg, 4 MV/m accelerating field and a focusing period of 7βλ. Finally at 102 MeV a 352 MHz Pi-Mode Structure has been eventually adopted, with -20 deg average synchronous phase and a 9βλ focusing period.

Accurate matching between different types of structures allows for a very smooth variation of phase advances and good control over potential emittance growth. The evolution of the RMS emittances in the 3 planes is shown in Fig.1 for PATH calculations with a 2D space charge model. TRACEWIN results for a 3D model only differ by up to 10%. A measure of the design solidity is given by the aperture over RMS beam size ratio, shown for the transverse and longitudinal planes in Fig.2 and 3. The longitudinal acceptance has been defined in an "equivalent" way to the transverse one, as ratio between the phase and energy width of the linearised bucket, and the RMS beam phase and energy spread.

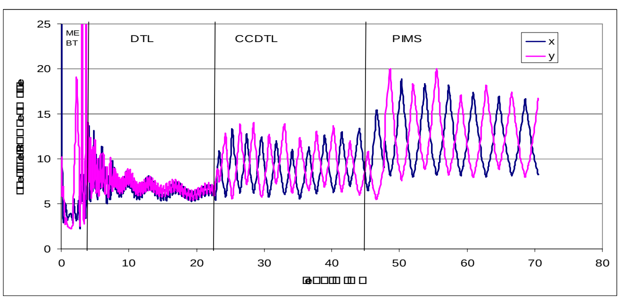

Figure 2: Aperture over RMS beam size ratio for chopper-DTL-CCDTL-PIMS.

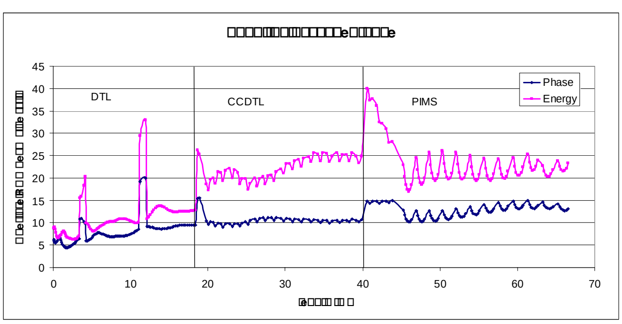

Figure 3: Longitudinal acceptance over RMS beam size ratio for DTL-CCDTL-PIMS. The bucket phase and energy width are taken as: $\Delta\phi=\pm 3/2\phi_s$ and $\Delta W=\pm 2\sqrt{[qmc^3\beta^3\gamma^3 E_0 T(\phi_s\cos\phi_s-\sin\phi_s)]/\omega}$.

The transverse acceptance bottleneck is located in the RFQ and chopper line, whereas for the longitudinal plane both the phase and energy acceptance minima are at the input of the DTL.

## EFFECTS OF RF ERRORS

The beam dynamics results shown so far are for the case of a nominal, perfect machine. Beam degradation induced by machine imperfections has been the subject of a campaign of error studies, aimed at assessing the maximum level of inaccuracies the system can tolerate before beam quality at PS Booster injection is compromised. Several hundred to a few thousand runs were carried out with both PATH and TRACEWIN for a typical 50k particles input beam population for several error scenarios, and results for beam loss, emittance growth, average energy and phase jitter have been statistically analysed. The criteria followed to establish maximum tolerances are:

- maximum average losses (transverse) of 1W/m at 6% duty cycle (shielding requirements)
- maximum longitudinal losses (un-accelerated particles) of 5%
- maximum emittance growth of 15-20% at 2σ level (PSB budget)
- maximum energy jitter at 160MeV (1σ) below ±100keV (transfer line acceptance)

Transverse error studies and steering strategies have been described in detail in [7]. RF errors can be classified as either dynamic or static. To the first category belong klystron phase and energy jitters, varying in time and affecting several gaps at once (all the ones connected onto the same RF supply). In the static category, we have gap amplifier errors mainly due to tuning or machining imperfections. These do not vary in time, they are uncorrelated from gap to gap and can be mitigated by adjusting the RF power around the nominal value.

Table 1: Results of dynamic RF error studies for the DTL (RMS quantities).

| Errors | Phase jitter [deg] | Energy jitter [keV] | 90% emittance [deg MeV] |
|---|---|---|---|
| 0% - 0deg | - | - | 0.734 |
| 0.5%-0.5deg | 0.82 | 13 | 0.745±0.014 |
| 0.5% - 1deg | 0.88 | 18 | 0.751±0.017 |
| 0.5% - 2deg | 1.14 | 31 | 0.774±0.034 |
| 1% - 0.5deg | 1.6 | 23 | 0.757±0.024 |
| 1% - 1deg | 1.6 | 28 | 0.762±0.027 |
| 1% - 2deg | 1.77 | 36 | 0.786±0.047 |
| 2% - 0.5deg | 5.12 | 43 | 0.794±0.07 |
| 2% - 1deg | 5.66 | 46 | 0.799±0.07 |
| 2% - 2deg | 8.55 | 49 | 0.830±0.1 |

Table 1 shows the results of RF klystron error studies for the DTL; the most left-hand column lists all the scenarios examined (amplitude and phase error), with uniformly distributed random errors within the given intervals. The output beam phase jitter is dominated by the klystron field amplitude errors, whereas the output energy deviation is more sensitive to phase errors, though these become negligible when the amplitude jitter is large enough (effects are even more balanced for the longitudinal emittance growth). The 1%-1deg case beam energy error is then propagated as input energy jitter downstream to the following structures (3σ uniformly distributed errors). Tables 2 and 3 list the equivalent results for the CCDTL and PIMS. In the PIMS case the sensitivity to the initial beam jitter is strong only for RF errors smaller than the 1%-1deg level. Above this threshold, klystron errors are the most significant source of deviation from nominal values. For this reason a balance should be kept between the two effects, and similar levels of RF tolerances specified for all types of structures. The criteria to be met at injection in the PSB impose that klystron phases and amplitudes be controlled ideally at the 0.5%-0.5 deg level (but 1%-1deg would still be acceptable).

Table 2: Results of dynamic RF error studies for the CCDTL (RMS quantities).

| Errors | Phase jitter [deg] | Energy jitter [keV] | 90% emittance [deg MeV] |
|---|---|---|---|
| 0. -0.deg | - | - | 0.769 |
| 0.5%0.5deg | 0.5 | 39 | 0.771±0.013 |
| 1% - 1deg | 1 | 63 | 0.773±0.018 |
| 2% - 2deg | 2 | 115 | 0.780±0.030 |
| 5% - 2deg | 4 | 237 | 0.794±0.047 |

Table 3: Results of dynamic error studies for the PIMS (RMS quantities).

| Errors | Phase jitter [deg] | Energy jitter [keV] | 90% emittance [deg MeV] |
|---|---|---|---|
| 0% - 0deg | - | - | 0.740 |
| 0.3%0.3deg | 0.3 | 83 | 0.741±0.001 |
| 0.5%0.5deg | 0.4 | 94.6 | 0.741±0.002 |
| 1% - 1deg | 0.66 | 135 | 0.741±0.003 |
| 2% - 1deg | 0.85 | 225 | 0.742±0.004 |
| 3% - 1deg | 1.1 | 329 | 0.742±0.005 |

RF static error studies have been carried out, assuming either uniformly spread random errors (DTL) or a correlated tilt, i.e. a linear distribution of the errors over all the gaps in one tank, with the central gap at the nominal value (CCDTL) or an elliptical distribution with the nominal value for average (PIMS). The field error amplitude was varied between ±2% and ±10%. Results are summarized in Table 4. Unlike klystrons dynamic errors, that are relevant for causing a beam energy and phase jitter, in the case of gap errors, which are more similar to a systematic imperfection, energy and phase deviations can be adjusted by varying the level of the RF power supplied. What cannot be corrected for is the longitudinal emittance growth, which is therefore the quantity of interest when assessing beam quality degradation. Also, for dynamic errors, it only makes sense to consider RMS effects, whereas the impact of static errors is best evaluated by looking at extreme cases. The results in Table 4 show the different sensitivities of the Linac4 RF structures to gap errors (decreasing with beam energy). A tolerance budget of ±2% field variation for the DTL and CCDTL gaps and ±5% for the PIMS gaps has been assumed as RF specification. No significant beam losses have been observed in any of the error cases examined (both dynamic and static).

Table 4: Gap error studies: average emittance growth with respect to nominal and worst case deviation in no of σ .

## CONCLUSIONS

Nominal beam dynamics for Linac4 has been studied with two different codes, indicating good performance. An extensive statistical campaign of longitudinal error studies has allowed to establish a tolerance budget on RF phase and amplitude errors that should guarantee good beam quality at PS Booster injection.

*Abstract*

The aim of the CLIC Test Facility CTF3, built at CERN by an international collaboration, is to address the main feasibility issues of the CLIC electron-positron linear collider technology by 2010. One key-issue studied in CTF3 is the generation of the very high current drive beam, used in CLIC as the RF power source. It is particularly important to simulate and control the drive beam longitudinal dynamics in the drive beam generation complex, since it directly affects the efficiency and stability of the RF power production process. In this paper we describe the ongoing effort in modelling the longitudinal evolution of the CTF3 drive beam and compare the simulations with experimental results. Our study is based on single bunch simulation.

## INTRODUCTION

The result of PARMELA [1] for the injector (see Fig. 1) was used as the input for PLACET [2] simulation code and for a 1-D analytical model using MathCAD. By these simulation codes, the CL (CTF3 Linac) from girder 3 in the injector (see Fig. 1), CT and CTS lines (See Fig. 1) were simulated. Measurements of the bunch length in CT and CTS lines by using RF deflector of delay loop in the CT line and OTR screen in the CTS line were done and were compared to the result of the simulation.

Table 1: Simulation Codes Comparison

| PARMELA | MathCAD | PLACET |
|---|---|---|
| Injector, Chicane | Girder 3, Chicane, DBA†, CT & CTS lines | DBA, INFN-Frascati chicane |
| Space charge | No space charge | No space charge |
| No wake field | Wake field | Wake field |
| Longitudinal & Transverse | Longitudinal | Longitudinal & Transverse |
| No CSR‡ | No CSR | CSR |

## SIMULATION

*Injector*

In the Injector, the electron beam is produced by a DC electron gun, is bunched at 1.5 or 3 GHz by the bunching system and is accelerated to about 18 MeV.

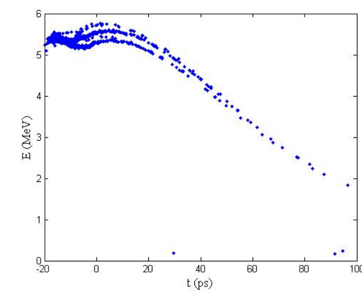

Figure 2: The result from PARMELA after girder 2 and the input for MathCAD.

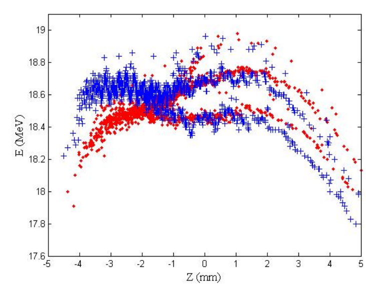

Figure 3: The result from MathCAD (no wake field) and PARMELA (+) after the injector, between z=-5 and z=5 mm. The rest will be cut in the chicane of girder 4.

Fig. 3 shows a good agreement between MathCAD and PARMELA result. In Fig. 13 you will see a little difference in the final bunch length, after the INFN-Frascati chicane.

The main reason for this difference is the space charge effect that is included in PARMELA and it is not included in MathCAD. The space charge effect is even less and hence insignificant in other parts of the machine where the energy is higher.

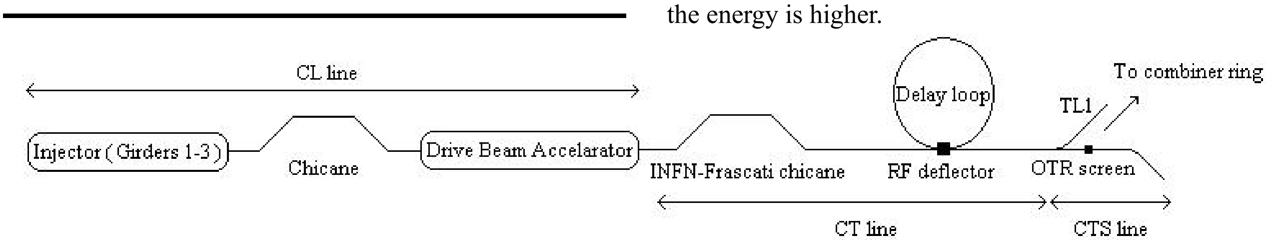

Figure 1: Layout of CTF3 from the injector to the combiner ring.

[*]Presently at Fermilab, [#]Presently at Siemens, †Drive Beam Accelerator, ‡Coherent Synchrotron Radiation.

### *Chicane*

Chicane (in the girder 4) is used for two reasons:

1- To cut the low energy tail of the bunch: Each particle in the bunch travels in a different orbit related to its energy then by using an adjustable slit in chicane it is possible to stop the particles of a chosen energy.

2- To change the bunch length: $R_{56}$=15.2 mm. The simulation shows that the minimum bunch length after the chicane is obtained by the phase of the input RF power source feeding the accelerating structure on girder 3 equal to -3 degree from crest.

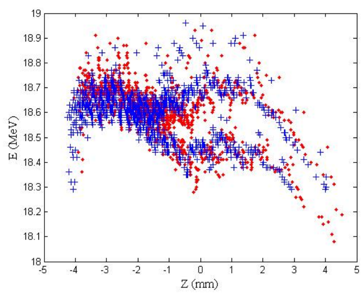

Figure 4: The result from MathCAD (no wake field) and PARMELA (+) after chicane starting from the end of the injector. Input is from PARMELA.

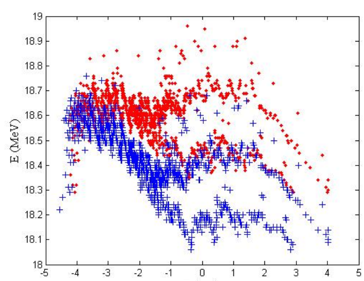

Figure 5: The result from the MathCAD after the chicane with wake field (+) (input for the MathCAD) and without wake field.

### *Drive Beam Accelerator (DBA)*

In the Drive Beam Accelerator (girders 5-15), the electron beam is accelerated to about 120 MeV by structures located in girders 5,6,7,11,12,13,15. Each of these girders has two accelerating cavities and each of these cavities contains 34 cells [3]. (See Fig. 5, 6, 7).

### *INFN-Frascati Chicane*

The INFN-Frascati Chicane is used to change the bunch length ($R_{56}$=0.46 m (calculated by MadX and PLACET), $T_{566}$=-1.14 m (calculated by PLACET)). The optimum bunch length should be around 2 mm r.m.s. that means not too short because of the coherent synchrotron radiation in the delay loop and the combiner ring and not too long because of acceptable injection into the delay loop and the combiner ring. (See Fig. 8, 9).

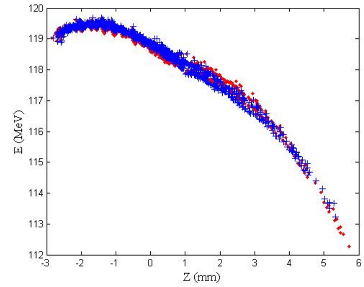

Figure 6: The result from MathCAD and PLACET after the DBA. Input is from PARMELA.

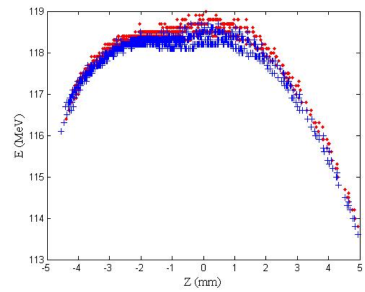

(+)

Figure 7: The result from MathCAD after the DBA with wake field (+) and without wake field. Input is from MathCAD.

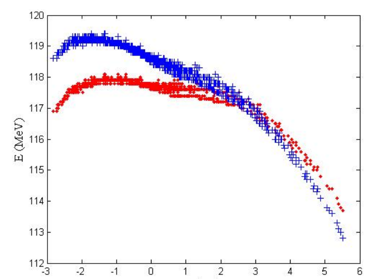

Figure 8: The result from MathCAD before the INFN-Frascati chicane with changing the phase by -20 degree in girder 15 from crest and without changing the phase (+). For both: σ=1.62 mm. Input is from MathCAD.

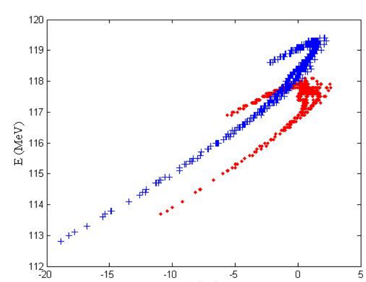

Figure 9: The result from MathCAD after the INFN-Frascati chicane with changing the phase by -20 degree in girder 15 from crest (σ=1.47mm) and without changing the phase (+) (σ=2.43mm). Input is from MathCAD.

## BUNCH LENGTH MEASUREMENT

The RF deflector is a cavity in TE mode that gives a transverse kick to the electron bunch. The RF deflector is used to inject the electron beam into the delay loop but if it is used near zero crossing is useful for the bunch length measurement, making a correlation between transverse and longitudinal positions in the bunch. (See Fig. 10). Therefore the transverse shape on the OTR screen, give the information of longitudinal shape too. [5, 6, 7].

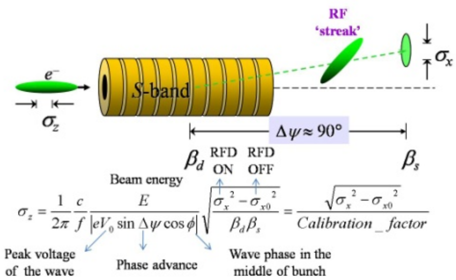

Figure 10: Using RF deflector for bunch length measurement [4]. f=1.5 GHz.

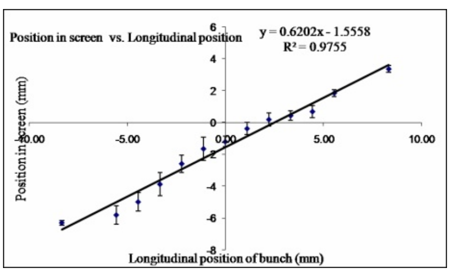

Figure 11: The method for finding the calibration factor that shows the relation between the screen position unit and the longitudinal position unit.

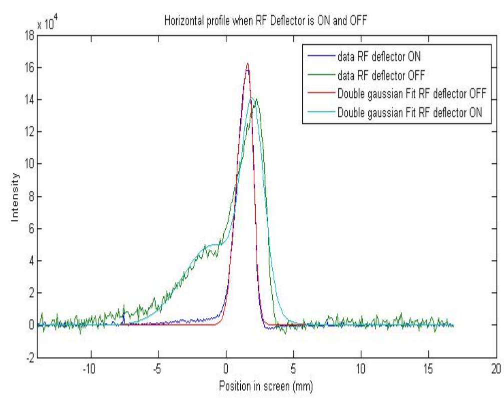

Figure 12: This shows the horizontal profile on screen when the RF deflector is ON and when it is OFF. ($\sigma > \sigma_0$).

In this method the horizontal size of beam on the screen is measured when RF deflector is on ($\sigma$) and off ($\sigma_0$). Instead of finding the magnitude of each parameter in the equation in the Fig. 10, the calibration factor is calculated by a measurement of the beam position on the screen versus RF deflector phase. Fig. 11 shows the result of one measurement. It shows a good linear fit. The slope is the calibration factor. Fig. 13 shows the result of one measurement for different wave phase in the girder 15 (last girder of DBA).

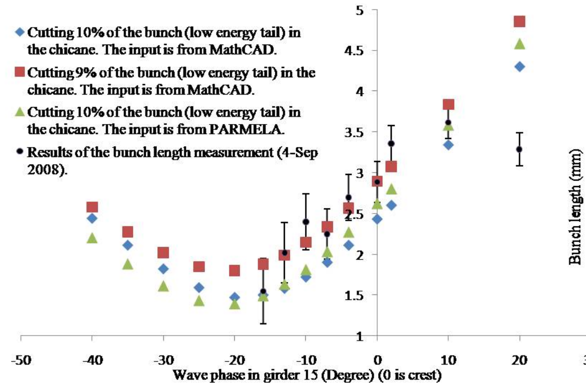

Figure 13: The result of bunch length measurement by RF deflector and the result of different simulations.

## CONCLUSION

Fig. 13 shows a good agreement between simulations by MathCAD and bunch length measurement by RF deflector. The errors in measurement, mainly, are from the jittering of beam on the screen. RF deflector and electron gun are the main source of this jittering. Non-linearity of OTR screen is another reason of errors. The measurement was done by RF pickup too but it didn't show a good agreement but more or less the same shape. The work will continue to find the root of this difference.

## Abstract

In order to contribute to the development of high power proton accelerators in the MW range, to prepare the way for an ISIS upgrade and to contribute to the UK design effort on neutrino factories [1,2], a front end test stand (FETS) is being constructed at the Rutherford Appleton Laboratory (RAL) in the UK [3]. The aim of the FETS is to demonstrate the production of a 60 mA, 2 ms, 50 pps chopped beam at 3 MeV with sufficient beam quality. The results of numerical simulations of the particle dynamics from the charge separation dipole behind the ion source to the end of the MEBT will be presented. Previous measurements showed that the emittance of the beam delivered by the ion source exceeded our expectations by more than a factor of three [4]. Since then various changes in the beam extraction/post accelerator region reduced the beam emittance by nearly a factor of two. Simulations of the particle dynamics in the FETS based on distributions gained from recent measurements of the transversal beam emittance behind the ion source will be presented and the results for different input distributions discussed.

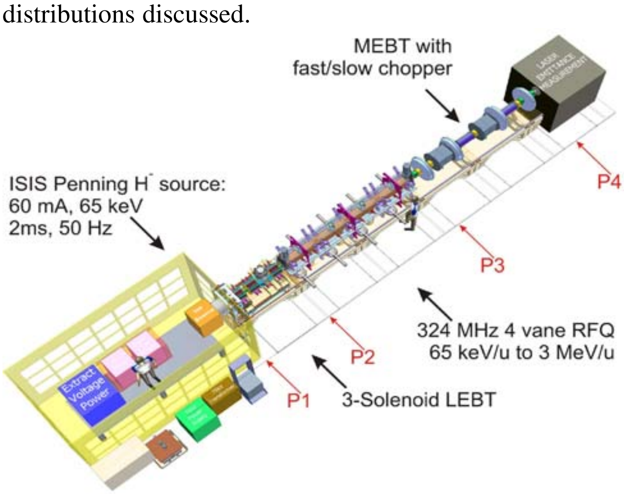

Figure 1: Schematic layout of the FETS set up. For the positions indicated (P1 behind post acceleration at the entrance of the LEBT [z=0mm], P2 at the entrance of the RFQ [z=1770mm], P3 at the RFQ exit [z=5770mm] and P4 at the end of the MEBT [z=10580mm]) the phase space distribution of the beam has been determined with GPT and TRACEWIN.

## INITIAL PARTICLE DISTRIBUTION

The ion source development program, based on the highly successful ISIS $H^-$ ion source at RAL, has already shown encouraging results. The aim is to increase the ion current from 35mA to 70mA, to increase the pulse length from 250μs to 2ms and to improve the beam quality [5]. In order to compare the recent status of the improvement of the ion source emittance and the consequences for the beam transport through the FETS end-to-end simulations have been performed for an idealized (shown in figure 2) and a real measured space phase distribution (shown in figure 3) based on pepper-pot emittance data.

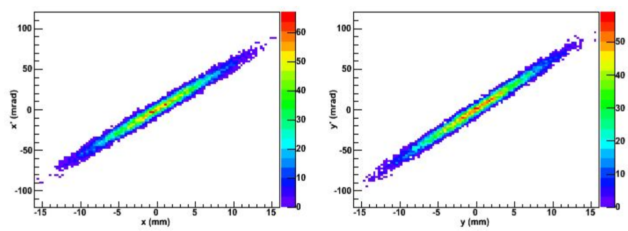

Figure 2: Input particle distribution into the LEBT (P1) for an ideal waterbag beam (input 1) ($\varepsilon_{x,rms}$=0.25 πmmmrad; $\varepsilon_{y,rms}$=0.25 πmmmrad).

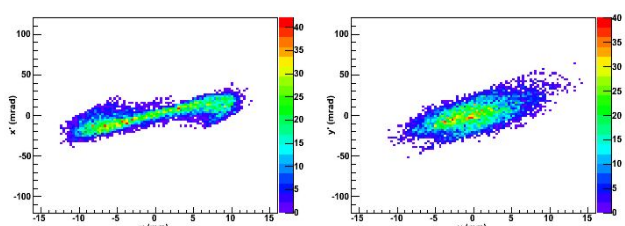

Figure 3: Input particle distribution into the LEBT (P1) for a measured beam distribution (input 2) ($\varepsilon_{x,rms}$=0.58 πmmmrad; $\varepsilon_{y,rms}$=0.52 πmmmrad).

## LEBT SIMULATION AND RESULTS

A 3 solenoid LEBT system similar to the one used at the ISIS injector is under construction and the calculated 3D field distribution of the solenoids (figure 4) is used for particle transport simulation of the LEBT using the GPT code [6, 7].

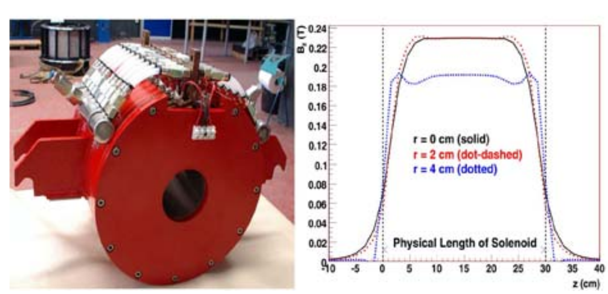

Figure 4: Left: one of three LEBT solenoids for FETS. Right: Magnetic field distribution in the z direction for different radii.

The field strengths of the three solenoids are chosen to optimise beam injection into the RFQ. The result of these optimisations for input distribution 1 is shown in figure 5. The estimated acceptance of the RFQ is drawn as an ellipse in the transversal phase space plots. There is no transversal beam loss in the LEBT and the total transmission (including stripping) into the RFQ acceptance is predicted to be above 90%.

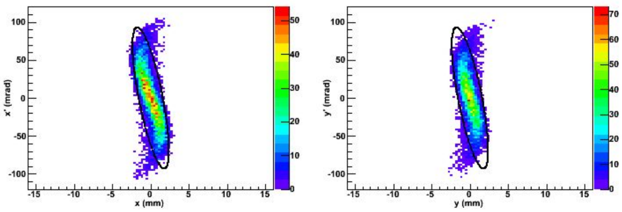

Figure 5: Phase space distributions in the transversal plane at the exit of the LEBT (P2) for input 1 ($\varepsilon_{x,rms}$=0.33 $\pi$mmmrad; $\varepsilon_{y,rms}$=0.33 $\pi$mmmrad).

The beam envelope in both transversal planes in the LEBT using distribution 2 is shown in figure 6 and the phase space distribution is shown in figure 7. Again the acceptance of the RFQ is drawn.

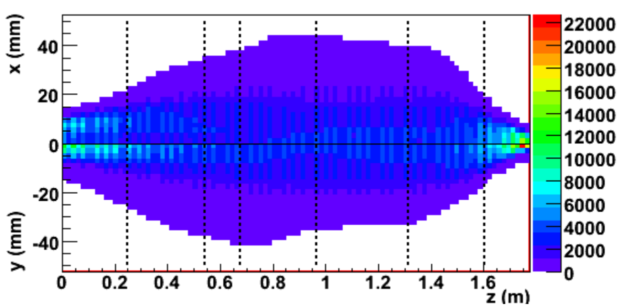

Figure 6:Beam envelope along the length z of the LEBT using the input distribution from the measured beam. Dotted vertical lines show the drift and solenoid sections.

Due to the relatively large size of the beam in the solenoids compared to their aperture (80%) non linear fields cause aberrations (already indicated by the slightly S-shaped phase space distribution in figure 5) and emittance growth. While the absolute increase of the emittance for the waterbag input distribution with $\Delta\varepsilon_{x,y,rms}$=0.08 $\pi$mmmrad is smaller than for the real beam ( $\Delta\varepsilon_{x,rms}$=0.11 and $\Delta\varepsilon_{y,rms}$=0.12 $\pi$mmmrad), the penalty seems to be rather moderate.

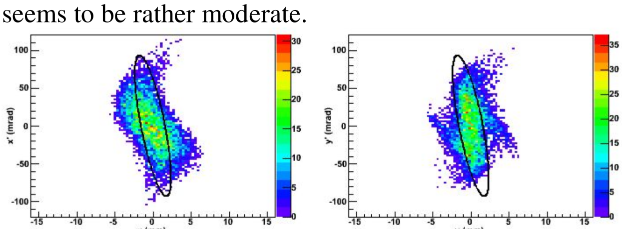

Figure 7: Phase space distributions in the transversal plane at the exit of the LEBT (P2) for input 2 ($\varepsilon_{x,rms}$=0.69 $\pi$mmmrad; $\varepsilon_{y,rms}$=0.64 $\pi$mmmrad).

Even for the presented very preliminary first data the result is surprisingly good and a total transmission into the RFQ acceptance is predicted to be 50%. The simulations performed also show that, independent of the degree of space charge compensation and using the available measured beam emittances, it is always possible to inject the core of the beam into the RFQ by just tuning the solenoid strengths.

## PARTICLE TRANSPORT CALCULATION IN THE RFQ

A preliminary design of the 324 MHz RFQ has been used for particle dynamics simulations. The variation of the RFQ parameters along z is shown in Figure 8. The design was made for an optimized transmission of more than 90% under the estimate of an input beam emittance of 0.25 $\pi$mmmrad. In a first run the particle distribution gained from the GPT simulations of the LEBT with generated data was used for input into the RFQ.

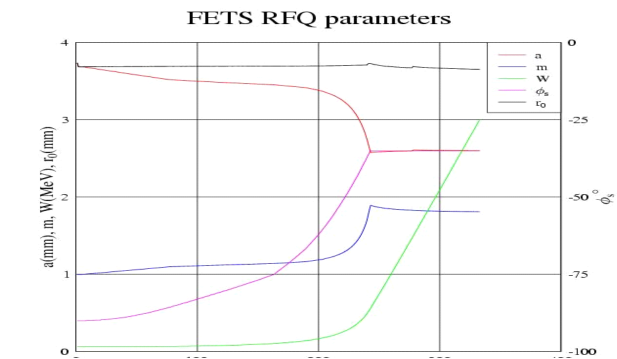

Figure 8: Development of the main RFQ parameters for the FETS along z.

The output distributions of this simulation are shown in figure 9. The transmission through the RFQ was ~96% for all energies and ~91% for an energy of 3MeV. The reduction of the emittance by 15% is caused by the particle losses. Considering this input distribution the design is likely to fulfil the requirements for the FETS.

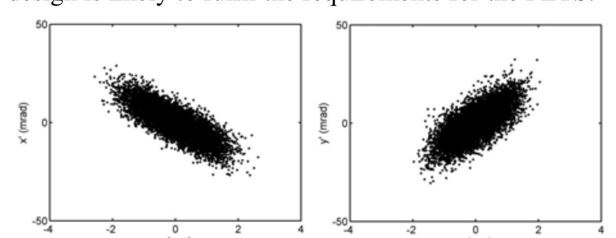

Figure 9: Particle distribution behind the RFQ (P3) for input 1 ($\varepsilon_{x,rms}$=0.28 $\pi$mmmrad; $\varepsilon_{y,rms}$=0.27 $\pi$mmmrad).

Using the second data set and taking into account that, while improved by nearly a factor of two over the last year, the input emittance is still a factor of two larger than the one used for the design, the achievable RFQ transmission of ~52% for all energies (50.5% for 3 MeV) seems to be reasonable but fails to meet the FETS specifications. The transversal output distributions are shown in figure 10. The emittance is reduced by up to 44 % due to the large particle losses but still 30 % larger compared to the results for the waterbag input

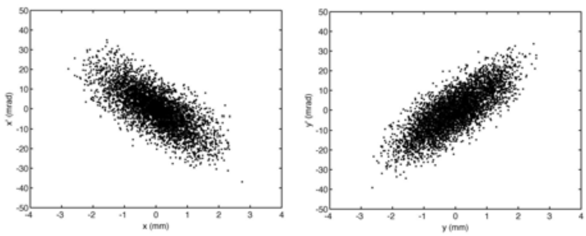

Figure 10: Particle distribution behind the RFQ (P3) for input 2 ($\varepsilon_{x,rms}$=0.46 πmmmrad; $\varepsilon_{y,rms}$=0.47 πmmmrad).

## PARTICLE TRANSPORT CALCULATION IN THE MEBT

A preliminary design of the MEBT consisting of 11 quadrupoles, 4 bunching cavities and a slow and fast chopper with accompanying beam dumps is shown in Figure 11 [8].

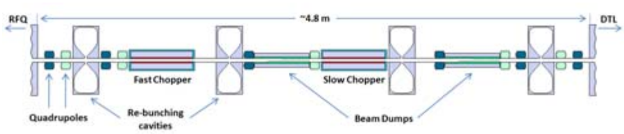

Figure 11: Design of the MEBT.

The output distributions of the simulation are shown in figure 12 and 13. For the ideal case the emittance growth is ~7% in x,x' and ~20% in y,y'. The transmission is ~98%.

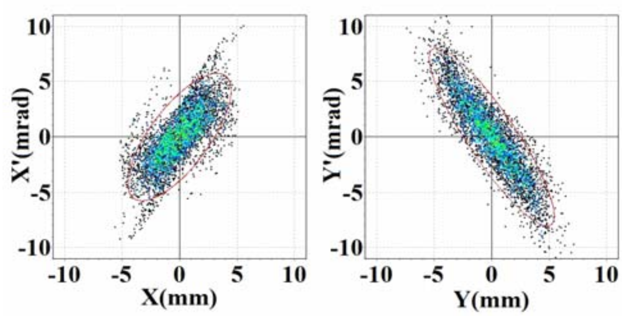

Figure 12: Particle distribution at the end of the MEBT (P4) for input distribution 1 ($\varepsilon_{x,rms}$=0.30 πmmmrad; $\varepsilon_{y,rms}$=0.34 πmmmrad).

For the real beam the emittance growth is -13% in the x,x' space (due to losses) and 4 % in the y,y' space. The transmission is reduced to ~89%.

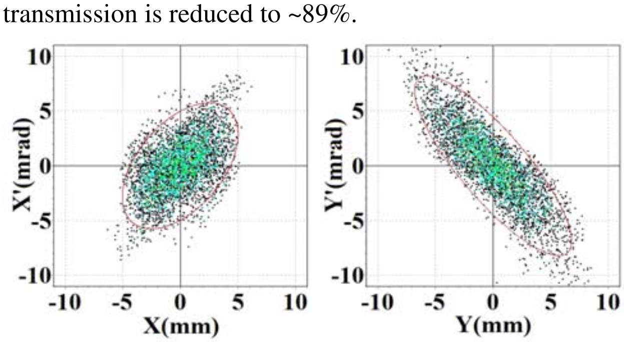

Figure 13: Particle distribution at the end of the MEBT (P4) for input distribution 1 ($\varepsilon_{x,rms}$=0.40 πmmmrad; $\varepsilon_{y,rms}$=0.49 πmmmrad).

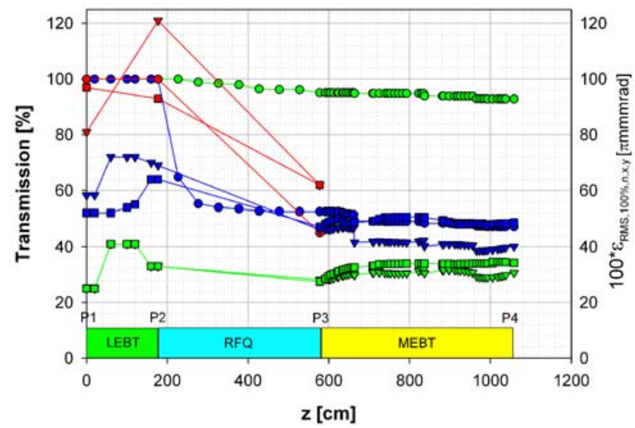

Figure 14: Development of Transmission (solid, circles), and transversal emittances (x is dashed, triangles, y dotted, squares), along beam propagation for ideal (green), initial (red) and new (blue) real input distributions.

## DISCUSSION

The first simulations from the ion source exit to the output of the MEBT show a mixed picture. The presented results based on an artificial input distribution are quite encouraging and with a total transmission from the source to the exit of the MEBT of >90% (100% in the LEBT, 95% in the RFQ and 98% in the MEBT, see figure 14) the goals are nearly reached. This result further proves that the design of the individual sections is sound and the joint performance is satisfactory. On the other hand, the latest results using a measured initial distribution show a dramatic increase of the beam emittance with fatal consequences on beam transmission. For the current status the transmission is expected to be ~46% (100% in the LEBT, 52% in the RFQ and 89% in the MEBT). Due to the large beam losses in the RFQ the total emittance growth is moderate (-10% in x and 23% in y). Serious efforts to reduce the ion source emittance and improve the RFQ acceptance are under way and recent work has already increased the transmission through the RFQ by 10%, but further progress is required.

# BEAM DYNAMICS AND WAKE-FIELD SIMULATIONS FOR HIGH GRADIENT ILC LINACS

C.J. Glasman & R.M. Jones; Cockcroft Institute, Daresbury, WA4 4AD, UK; University of Manchester, Manchester M13 9PL, UK

*Abstract*

Higher order modes (HOMs) are simulated with finite element and finite difference computer codes for the ILC superconducting cavities. In particular, HOMs in KEK's Ichiro type of cavity and Cornell University's Reentrant design are focused on in this work. The aim, at these universities and laboratories, is to achieve an accelerating gradient in excess of 50 MV/m in 9-cell superconducting cavities whilst maintaining a high quality and stable electron beam. At these gradients, electrical breakdown is an important cause for concern and the wakefields excited by the energetic electron beams are also potentially damaging to the beam's emittance. Here we restrict the analysis to performing detailed simulations, on emittance dilution due to beams initially injected with realistic offsets from the electrical centre of the cavities. We take advantage of the latest beam dynamics codes in order to perform these simulations.

## INTRODUCTION

The main superconducting (SC) linacs of the ILC will accelerate electron (positron) beams from energies of 5 (15) GeV to a center of mass energy of 500 GeV at collision. Efficient operation of the machine demands high luminosity collisions which are achieved by accelerating a train of 2625 low emittance bunches particles. This low emittance must of course be preserved in transport through the main linacs and beam delivery system to the interaction point.

Here we consider the main positron linac where the beam quality can be degraded and the emittance can be diluted due to a number of factors including energy spread, phase jitter in cavities, beam position feedback errors, quadrupole magnet misalignments and wakefield effects. We focus on the dilution in the transverse emittance due to long range transverse wakefields. In this case the wakefields are excited by the relativistic particle beam and consist of a series of higher order modes [1]. These wakefields have the potential to not only dilute the emittance, but can also cause a beam beak up instability (BBU) [2].

The ILC will employ superconducting cavities operating at gradients at 31.5 MV/m. It is envisaged that the cavity design will be the TESLA type which has been developed at DESY over a long period [3]. TESLA is a relatively mature design, however there are still significant concerns regarding the limited yield and reproducibility of high gradient cavities.

There is also a concerted international effort focused on increasing the gradient of the SC cavities. Reshaping the cavity has allowed the accelerating gradient to be increased without pushing the magnetic field past the quenching limit (~180 mT) on the walls of the cavity [4]. This has allowed cavity designs which in theory will sustain accelerating gradients in excess of 50 MV/m. There is also a recent design which minimizes both the electric field as well as the magnetic field on the walls of the cavity [5].

In practice only single-cell cavities have reached these gradients, at Cornell University [6] with the Reentrant design and at KEK with the Ichiro design [7]. Complete 9-cell cavities are in the process of being fabricated and tested for both designs with a view to achieving similar gradients. The new high gradient designs operate at the same accelerating frequency as the baseline TESLA design. Furthermore the cavity shapes are similar to that of the TESLA design.

However, the perturbations of the cavity geometry are expected to give rise to a modification of the mode distribution. With this in mind, we carefully investigated the kick factors and mode frequencies in the alternative designs. The transverse long range wakefield experienced by the bunch train is given by:

$$W_T(t) = 2\sum_p K_p \sin(\omega_p t) e^{\frac{-\omega_p t}{2Q_p}}$$

where $\omega_p/2\pi$, $K_p$ and $Q_p$ are the modal frequencies, kick factors [1] and damping Qs respectively for the dipole mode $p$.

These modes have been simulated in detail [8, 9] using parallel finite difference and finite element codes GdfidL [10] and Analyst [11] and this data has been used as input for beam dynamics simulations presented herein, using the codes Lucretia [12] and Placet [13]. The codes track particle bunches through the lattice of the linac in which the energy is increased from 15 GeV to 250 GeV.

The envelope of the transverse long range wakefield is displayed in Fig. 1 with a damping Q imposed on all modes of $10^5$ for the Ichiro cavity. Here it is evident that after 500 bunches (~50 km) the wake has decayed by 6 orders of magnitude. Thus, in all beam dynamics simulations 500 bunches is sufficient to account for the interaction between the wakefield and the multi-bunch train. We report on the results of these simulations in the next section.

## BEAM DYNAMICS SIMULATIONS

In constructing the main linacs of ILC approximately 16,000 cavities will be required. Fabrication of these cavities is expected to introduce random errors in the geometry and thereby alter the modal frequencies and kick factors for each cavity. These errors are in fact necessary in order that the beam receives a random kick from cavity to cavity. A linac made up of identical

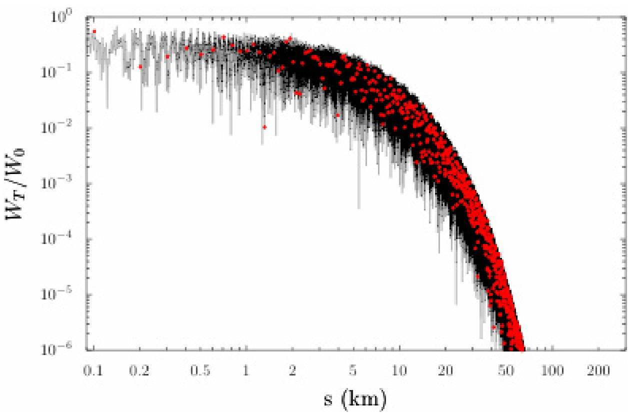

Figure 1: Envelope of long range transverse wakefield for the Ichiro cavity with Q=$10^5$, $W_0$=0.1472 V/pC/mm/m. Points show the location of the bunches.

cavities would impart the same kick coherently on the beam from cavity to cavity. This would resonantly drive beam break up and lead to severe emittance dilution.

The simulations described here are preformed with the Matlab-based code Lucretia. All simulations incorporate manufacturing errors by generating 100 sets of dipole mode frequencies in which each mode has been shifted by a random number generated according to a normal distribution; these define 100 different cavity types. These cavity types are then randomly distributed throughout the linac prior to tracking the beam down the linac. We applied a 1 MHz RMS spread in the dipole mode frequencies and a uniform damping Q of $10^6$. Each bunch was subjected to an injection offset of $\sigma_y$ (~ 6 μm) and trains of 500 bunches were subsequently tracked down the linac at the nominal bunch spacing of 369ns [14]. Placet simulations were also performed, although in this case the cavity mode randomization is achieved in a somewhat different manner; in this case all modes are shifted by the same random factor for each cavity in the linac. Fig.2 illustrates the dilution in the projected emittance for the bunch train at each beam position monitor position in the lattice that results from tracking down 40 machines. Each curve results from a different random seed, and the frequency distributions are distributed randomly over the complete linac. Figs. 3 and 4 present the results for machines consisting of Reentrant and Ichiro cavities, respectively. Fig. 5 displays a comparison of the mean value of the emittance dilution for each cavity type, together with the results of Placet simulations for the Ichiro cavity.

There is a discrepancy between the Lucretia and Placet results for the linac made up of Ichiro cavities. The difference between individual tracking simulations, for Lucretia, illustrated in Fig. 4, was small (~1%) for all cavity types simulated with Placet.

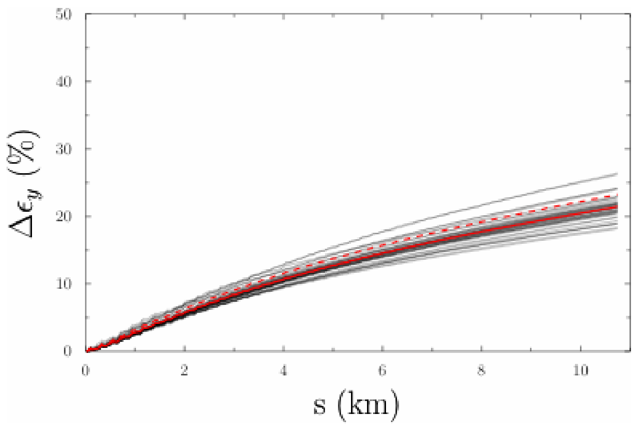

Figure 2: Emittance dilution simulated with Lucretia for 40 machines consisting of TESLA cavities. The mean dilution over all machines is displayed in red, with one standard deviation dashed.

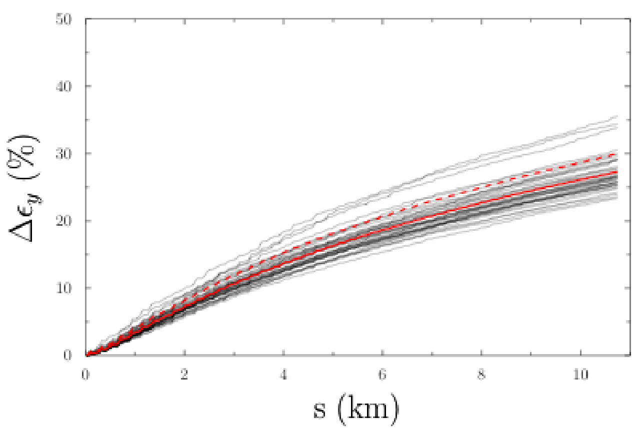

Figure 3: Emittance dilution simulated with Lucretia for 40 machines consisting of Reentrant cavities. The mean curve is displayed in red, with one standard deviation dashed.

The beam dynamics simulations described above incorporated random cavity fabrication errors but did not consider systematic effects.

In practice, superconducting cavities are squeezed to tune and to optimally achieve field flatness in the 1.3 GHz accelerating mode. This process changes the cell geometry and gives rise to a shift in the designed dipole mode frequencies. This tuning effect and those resulting from an amalgam of relaxed tolerances in the manufacturing process can readily make the dipole frequencies significantly detuned. This leads to both systematic and random frequency errors in the dipole modes. The sinusoidal dependence in Eq. 1 indicates that the wakefield time coordinate is determined by the bunch spacing. Consequently shifts in the bunch spacing are to a large extent equivalent to a shift in modal frequencies. Shifting the modal frequencies can push the beam dynamics into a region in which resonant BBU occurs. Clearly these regimes need to be predicted prior to fabrication of the complete linac.

The onset of this instability is predicted by the RMS of the sum wakefield which can be evaluated for small shifts in bunch spacing. Fig. 6 reveals a series of resonances associated with the Ichiro cavity. Applying heavier damping, changing the Qs from $10^6$ to $10^5$, suppresses these resonances significantly.

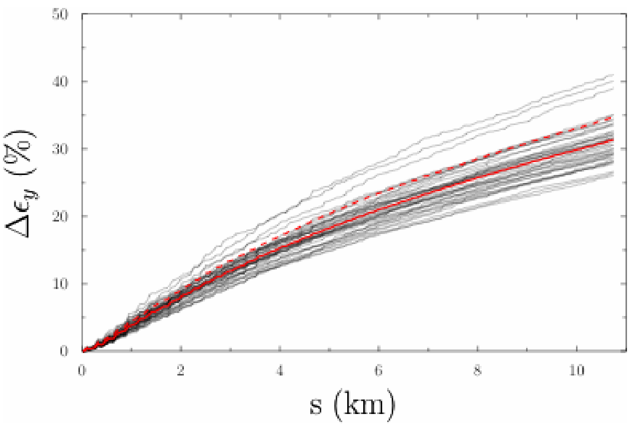

Figure 4: Emittance dilution simulated with Lucretia for 40 machines consisting of Ichiro cavities including the effects of random errors attributed to the manufacturing process. The mean curve is displayed in red, with one standard deviation dashed.

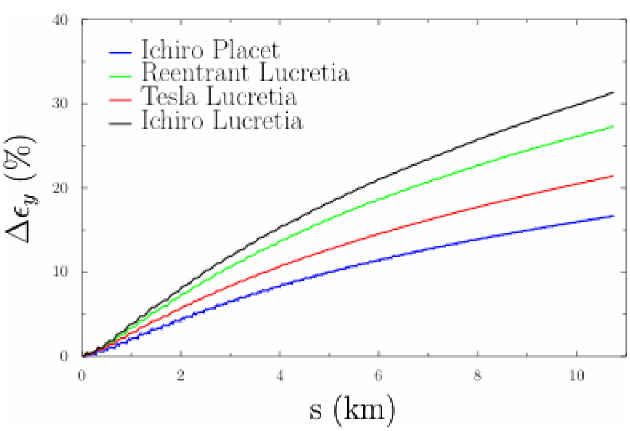

Figure 5: Comparison of the mean emittance dilution for each cavity type simulated with Lucretia. A single simulation undertaken with the code Placet for a linac comprising of Ichiro cavties is displayed in blue.

Earlier work has indicated that severe emittance dilution will occur should the machine be operating close to one of these resonances [15].

## CONCLUSIONS

Beam dynamics simulations have indicated that, with damping with Q~$10^6$, emittance dilution due to long range wakes in the Ichiro and Reentrant cavities is less than 50% at the end of the linac. Increasing This is tolerable performance similar to that of a linac made up of the ILC baseline TESLA cavities.

These simulations assume a bunch spacing of 369ns as detailed in the ILC Reference Design Report however, small deviations in this bunch spacing or equivalent systematic shifts in the HOM frequencies can lead to resonant wakefield effects, as illustrated in Fig. 6.

The damping required to preserve a high quality beam will be investigated with beam dynamics work including different levels of random detuning and systematic shifts to the HOM.

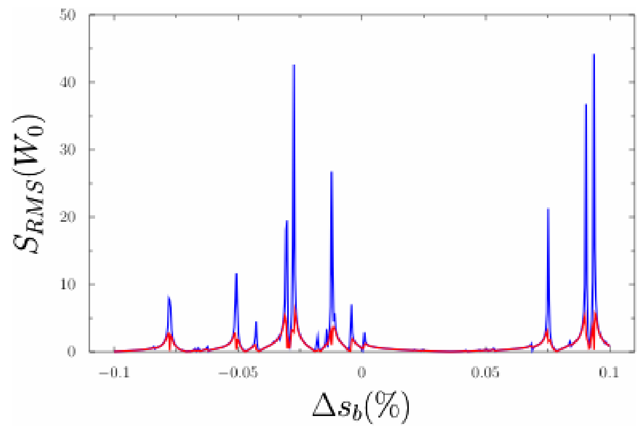

Figure 6: RMS of the sum wakefield as a function of fractional deviations in the bunch spacing. For Q=$10^6$ (blue) and Q=$10^5$ (red).

We note the importance of understanding the inconsistency between the Lucretia and Placet simulations. In order to shed light on the present discrepancy we intend to modify the mode randomization scheme to be consistent between both codes. Additional research is in progress on simulations of emittance dilution issues using Lucretia and including the short range wakefield due to cavity and coupler geometries and realistic component misalignments.

# SCATTERING MATRIX SIMULATIONS OF FIELDS AND DISPERSION RELATIONS IN SUPERCONDUCTING CAVITIES FOR XFEL AND ILC

I. Shinton and R.M. Jones; Cockcroft Institute, Daresbury, WA4 4AD, UK;
University of Manchester, Manchester, M13 9PL, UK

*Abstract*

The globalised cascaded scattering matrix technique is a well proven, practical method that can be used to simulate large accelerating RF structures in which realistic fabrication errors to be incorporated in an efficient manner without the necessity to re-mesh the entire geometry. The globalised scattering matrix (GMS) technique allows one to obtain the scattering matrix for a structure. The method allows rapid e.m. field calculations to be obtained. Results are presented on monopole mode fields and dispersion relations calculated from direct and analytical methods. Analytical approximate results are also presented for the equivalent shunt susceptance of an iris loaded structure.

## INTRODUCTION

In large accelerating structures such as the ILC beam break up and emittance dilution are major design concerns; hence the need to be able to accurately model large fractions of these structures in which effects such as wakefields, trapped modes, coupler kicks have been taken into consideration. GSM has been shown in previous works [1-3] to be capable of being employed to accurately model such large scale structures.

## MODE MATCHING USING GSM

Mode matching is an established technique [4-5] which has been applied to various accelerator problems for sharp transitions consisting of adjoining wide narrow (WN) sections [6-10]. The mode matching technique relies upon splitting the structure into a series of sub-regions (WN or NW regions) in which an analytical solution of Maxwell's equations is given in terms of a series expansion over a set of orthogonal modes. The field solutions are then obtained by matching the field at the interfaces. In principle there are an infinite number of modes excited at a junction. In a practical application of the technique we truncate the series with an appropriate ratio of the modes in the narrow to wide section. Indeed, numerous studies have been preformed on the relative convergence phenomena to determine the optimal ratio of modes [11].

## A MODE MATCHING GSM TECHNIQUE FOR FIELD DETERMINATION

The mode matching procedure presented here differs from previous studies. We will consider the case for a propagating monopole mode launched form one port. We derive an analytical relation for the S matrix for a WN or a NW junction. Let us consider the circular WN junction with n modes in region I (wide) and m modes in region II (narrow) where m<=n. We shall denote "b" as the radius of the wide region and "a" as the radius of the narrow region. Analytical electromagnetic fields $\vec{e}$ in a circular beam waveguide are provided in [12]. The characteristic scalar product is given by $\bar{a}_{nm} = \int_S e_n \cdot \hat{e}_m \partial\Gamma$ (over the aperture S) and this evaluates to:

$$\bar{a}_{nm} = \frac{2a^2 \chi_n J_0(\chi_{0n} a/b)}{b^2 J_1(\chi_{0n})\left((\chi_{0n} a/b)^2 - \chi_m{}^2\right)} \tag{1}$$

where $\chi_{0n}$ is the nth root of $J_0(\chi_{0n})$. For a = b the normalisation in [12] corresponds to $\bar{a}_{nm} = \delta_{nm}$ (where $\delta$ is the Kronecker delta function). The S matrix at the transition is obtained by mode-matching the fields in terms of the modal amplitudes at each transition:

$$S_{21} = 2\left(U + \hat{Z}\bar{a}^t Y \bar{a}\right)^{-1} \hat{Z}\bar{a}^t Y \tag{2}$$

$$S_{11} = \bar{a} S_{21} - U \tag{3}$$

$$S_{22} = 2\left(U + \hat{Z}\bar{a}^t Y \bar{a}\right)^{-1} - U \tag{4}$$

$$S_{12} = \bar{a}\left(U + S_{22}\right) \tag{5}$$

In the above equations U, $Z = Y^{-1}$ is the identity and impedance matrix, respectively. Using Eqs. 1-5 the S matrix of a structure decomposed into WN and NW transitions can be obtained. The e.m field in any structure can be subdivided into one of three different regions, as depicted in Fig. 1. Region 1 lies between z=0 and z=1, here the S matrix consists of the GSM formed z=z1 and z=z3.

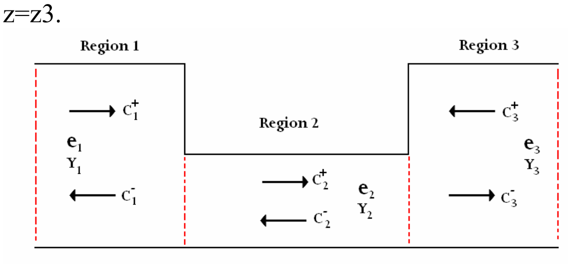

Figure 1: Sketch of WNW transition illustrating incident and reflected modes.

Any subsection of a structure will be classified as a region 2 section, only the first and last sections are classified as region 1 and 3 respectively. The S matrix of any region 2 subsection consists of a propagating matrix representing the infinite propagating wave series $S_{21}^0$ and a reflected matrix $S_{11}^0$ representing the infinite reflected wave series both which are decaying within the subsection [3]. Here the superscripts I and II represent the GSM's left and right of the subsection respectively, $T_z = \delta_{nm} e^{-ik_n z}$ and g is the length of the subsection. Region 3 lies between z=z2 and z=z3, here the S matrix consists of the GSM between z=0 and z=z2. Since the S matrices are directly proportional to the modal amplitudes then after applying the mode matching procedure we obtain the following formulae for the three regions:

Region 1 electric field

$$E_{\parallel} = e_{n1} e^{ik_{n1}(z-z1)} - \sum_{n1=1}^{N} S_{11}(n1,1)\bar{e}_{n1} e^{ik_{n1}(z-z1)} Y_{n1} \quad (6)$$

$$E_{\perp} = e_{n1} e^{ik_{n1}(z-z1)} + \sum_{n1=1}^{N} S_{11}(n1,1)\bar{e}_{n1} e^{ik_{n1}(z-z1)} \quad (7)$$

Region 2 electric field

$$S_{21}^{0} = T_z\left[U - S_{22}^{I} T_g S_{11}^{II} T_g\right]^{-1} S_{21}^{I} \quad (8)$$

$$S_{11}^{0} = T_{-z}\left[U - T_g S_{11}^{II} T_g S_{22}^{I}\right]^{-1} T_g S_{11}^{II} T_g S_{21}^{I}$$

$$S_{11}^{0} = T_{-z}\left[U - T_g S_{11}^{II} T_g S_{22}^{I}\right]^{-1} T_g S_{11}^{II} T_g S_{21}^{I} \quad (9)$$

$$E_{\perp} = \sum_{n_2=1}^{N}\left(T_z S_{21}^{0} + T_{-z} S_{11}^{0}\right)\bar{e}_{n_2} \quad (10)$$

$$E_{\parallel} = \sum_{n_2=1}^{N}\left(T_z S_{21}^{0} - T_{-z} S_{11}^{0}\right)\bar{e}_{n2} Y_{n_2} \quad (11)$$

Region 3 electric field

$$E_{\parallel} = \sum_{n_3=1}^{N} S_{21}(n_3,1) e_{n_3} e^{-ik_{n_3}(z-z2)} Y_{n_3} \quad (12)$$

$$E_{\perp} = \sum_{n_3=1}^{N} S_{21}(n_3,1) e_{n_3} e^{-ik_{n_3}(z-z2)} \quad (13)$$

To verify the essential behaviour of the fields a wide-narrow-wide (WNW) junction is considered. A 2D field plot showing the radial dependence of the field is presented in Fig. 2. This simulation is very efficient as it required no more than a few seconds of CPU time in a PC compared to up to an hour on a comparable PC with a conventional numerical finite element code.

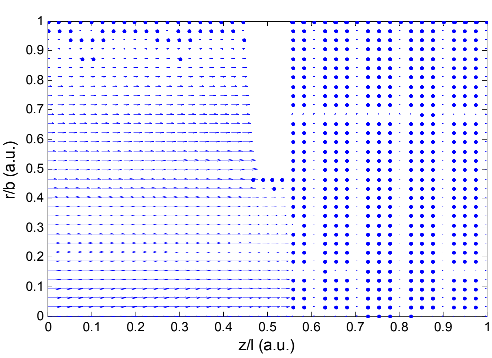

Figure 2: Axial electric $E_z$ for WNW transition as a function of radius and axial position.

## ANALYTICAL FORMULAE FOR DISPERSION CURVES

Combining GSM and mode matching in conjunction with the Bethe hole coupling perturbation theory [5,13] allows exact analytical expressions to be obtained for the normalised susceptance $\overline{B}$ of a structure. We note that $\overline{B}$ is equivalent to the coupling constant κ or fractional bandwidth of the mode. Let us consider the case of a monopole accelerating mode. From circuit theory [14] we can express the relationship between angular frequency ω and phase advance per cell Φ in the thin iris approximation (where κ<<1 ) as:

$$\omega = \omega_{\pi/2}\left(1 - \frac{\kappa}{2}\cos\Phi\right) \quad (14)$$

where $\omega_{\pi/2}/2\pi$ is frequency as a phase advance of π/2. The relationship between phase and susceptance can be derived using either transmission line theory or from considering the ABCD matrix representation [4]:

$$\cos\Phi = \cos(k_z l) - \frac{\overline{B}}{2}\sin(k_z l) \quad (15)$$

In Eq. 15 l is the cavity length and $k_z$ is the propagation constant of the dominant mode: $k_z = \sqrt{(\omega/c)^2 - (\chi_{01}/b)^2}$ (where b is the radius in the cavity region and $\chi_{01}$ is the first root of the Bessel function $J_0$). Provided $k_z l << 1$ then to first order in $k_z l$ Eq. 15 is simplified to:

$$\cos\Phi = 1 - \frac{\overline{B}}{2} k_z l \quad (16)$$

A Bethe hole coupling analysis [5, 13] allows the fractional bandwidth to be obtained as:

$$\kappa = \frac{4a^3}{3\pi l b^2 J_1(\chi_{01})} \quad (17)$$

In Eq. 17 $a$ is the iris radius. Rewriting and comparing Eqns. 15 and 16 in terms of $\cos\Phi$ allows the following equation to be derived in the thin iris approximation:

$$\overline{B} = \frac{3\pi b^4 J_1(\chi_{01})^2 k_z}{2a^3\chi_{01}^2} \quad (18)$$

An exact formulation for the dominant mode can also be obtained by considering a susceptance placed symmetrically and in parallel with a transmission line. The susceptance normalised to the transmission line impedance is then obtained in terms of the reflection coefficient of $S_{11}(1,1)$ the dominant mode: [4]:

$$\overline{B} = \frac{2iS_{11}(1,1)}{S_{11}(1,1)+1} \quad (19)$$

The dispersion curve is obtained from the combination of Eqns. 15 and 18 have a limited domain of applicability due to the thin iris approximation used in obtaining it. An alternative method which circumvents this limitation is to consider the S matrix of a cell in an infinite periodic structure (obtained from GSM):

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \tag{20}$$

In Eq. 20 a represents the incident waves and b the reflected waves on each port, the subscripts refer to the ports. Applying the Floquet condition:

$$b_2 = e^{-i\Phi} a_1 \tag{21}$$

$$b_1 = e^{-i\Phi} a_2 \tag{22}$$

Eqns. 20-22 represent an eigen-mode problem. Provided the field is evaluated sufficiently far away from the junction such that all evanescent modes have decayed to leave only the dominant propagating mode, we can solve for the phase advance. The solution for Φ in terms of the dominant propagating mode scattering matrix parameters is obtained:

$$\cos\Phi = \frac{1 + S_{21}(1,1)^2 - S_{11}(1,1)^2}{2S_{21}(1,1)} \tag{23}$$

The analytical equation for obtaining a dispersion curve using the thin iris approximation (Eqns. 15 and 18), reveals there is little discrepancy between the two methods provided the iris is sufficiently thin (see Fig. 3). However for irises thicker than t=50 μm the Bethe hole coupling formula that the analytical susceptance formula, which Eq. 18 was based on, is no longer valid.

The analytical equation derived by considering the S matrix of a cell in an infinitely periodic structure (Eq. 23) is of course not limited by the thin iris approximation. However, it does require all evanescent modes to be small compared to the dominant mode. A Brillouin diagram is displayed in Fig. 4 from a calculation based on three methods. The transverse mode matching method developed herein is in good agreement with results based on the longitudinal mode matching code KN7C [15,16]. However, there is some discrepancy between HFSS and the other methods. The bandwidth obtained from all three methods is: 1.074%, 1.100% and 1.066% for KN7C, analytical model and HFSS, respectively.

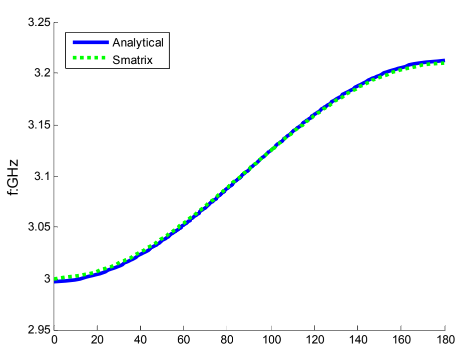

Figure 3: Brillouin diagram calculated using Eq. 15 for a = 7.5 mm, b = 38.23 mm, t = 0.10 mm, l = 6.1 mm. The analytical approximation corresponding to Eq. 18 is given in blue together with the exact model provided by Eq. 19 in green.

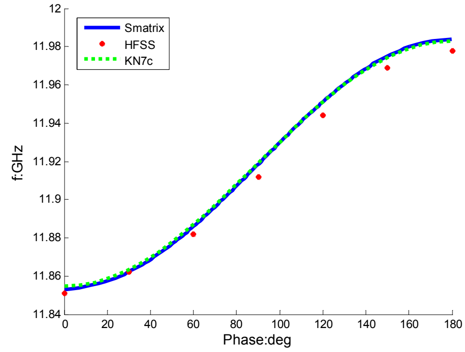

Figure 4: Brillouin diagram calculated using an analytical (Eq. 23 blue) and numerical approaches (HFSS red and KN7c green) for an idealised CLIC_G cell. This structure has been represented as a simplified NWN transition with cell parameters: a = 2.619 mm, b = 9.783 mm, t = 1.202 mm, l = 8.332 mm.

## DISCUSSION

The transverse mode matching method developed herein provides an efficient and accurate means of characterising the fields and dispersion relation of accelerator structures. The analytical dispersion relation and analytic formula for iris suspectance can be applied to specific accelerator cells. However, the geometrical dependence of the analytical formula provides a rapid means of designing accelerator cells with sufficiently thin irises. It is planned to extend the mode matching method to consider aggregate accelerator structures.

*Abstract*

To simulate the SNS linac using the beam dynamics code TRACK and to benchmark the results against the recent commissioning data, we have updated TRACK to support SNS-type elements such as DTL's and CCL's. After successfully implementing and simulating the DTL section of the SNS linac, we have implemented the CCL section and the high energy superconducting (SCL) section up to 1 GeV. Results from end-to-end TRACK simulations of the SNS linac including the RFQ will be presented and discussed.

## INTRODUCTION

In an effort to benchmark the beam dynamics code TRACK [1] againt experimental data from existing linacs, such as the SNS linac, we have updated the code to support new elements such as DTLs and CCLs. We previously reported the results of TRACK simulations for the SNS MEBT and DTL [2]. Recently, we implemented a new subroutine for the simulation of CCL tanks. After building the CCL, SCL and HEBT lattices, we were able to perform end-to-end simulations from the RFQ to the HEBT right before the stripping foil.

After briefly describing the SNS linac lattice, results of the RFQ simulations using TRACK are presented and compared to simulations using the RFQ design code Parmteq [3]. The method of implementing CCL tanks is then presented followed by results of end-to-end simulations of the linac from the MEBT to the HEBT. Possible future developments are discussed at the end.

## THE SNS LINAC

The SNS accelerator facility [4] is designed to provide a 1 GeV, 1.4 MW proton beam to a liquid mercury target for neutron production. The accelerator complex consists of a H− injector capable of producing 38 mA peak current, a 1 GeV linac, an accumulator ring and associated beam transport lines to experimental areas. The linac consists of a 2.5 MeV, 38mA H− front-end injector, a six-tank 402.5 MHz DTL to accelerate the beam to 87 MeV, a four-module 805 MHz Coupled Cavity Linac (CCL) to accelerate the beam to 187 MeV, and a superconducting linac (SCL) to accelerate the beam to 1 GeV. Figure 1 shows a schematic layout of the SNS linac.

# mustapha@phy.anl.gov

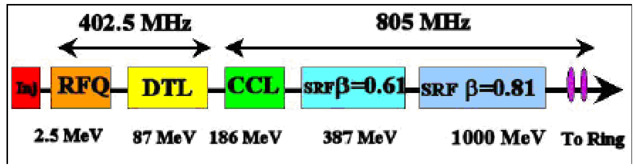

Figure 1: Schematic layout of the SNS linac.

## SIMULATIONS OF THE RFQ

The design parameters of the SNS RFQ [5] are summarized in Table 1. According to these parameters the RFQ lattice was generated using Parmteq from which the TRACK lattice was derived. The simulations were performed using both Parmteq and TRACK. Table 2 compares the calculated transmissions for a 0 mA beam and the actual operating current of 32 mA [6]. We notice differences between TRACK and Parmteq that should be further investigated. However, the two codes agree reasonably well on the output beam parameters. Figure 2 compares the phase space plots at the end of the RFQ and Table 3 compares the values of the normalized rms emittances.

Table 1: Design parameters of the SNS RFQ.

| | |
|---|---|
| **Type** | 4 vane |
| **RF Frequency** | 402.5 MHz |
| **Voltage** | 83 kV |
| **N. Of Cells** | 448 |
| **Length** | 3.723 m |
| **Beam** | H- |
| **Input Energy** | 65 keV |
| **Output Energy** | 2.5 MeV |
| **Peak Output Current** | 52 mA |
| **Long. Emittance** | 103 deg-keV |
| **Trans. Emittance: N-RMS** | 0.21 mm-mrad |
| **Design Transmission** | > 90 % |

Table 2: RFQ transmission for different beam currents calculated using both Parmteq and TRACK.

| Current | Parmteq | TRACK |
|---|---|---|
| 0 mA | 99.4 % | 98.5 % |
| 32 mA | 97.3 % | 91.4 % |

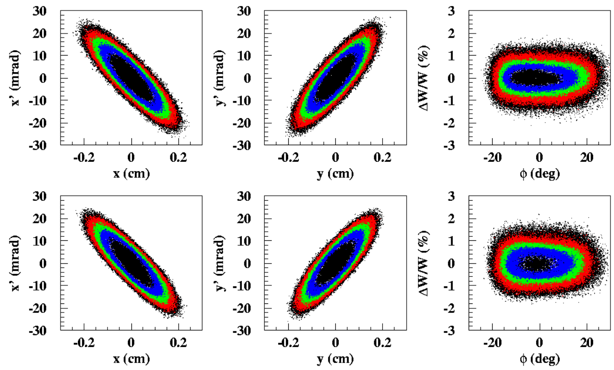

Figure 3: Phase space plots for a 32 mA H- beam at the end of the RFQ. The top three plots are the results of Parmteq and the bottom ones are obtained from TRACK.

Table 3: Normalized RMS beam emittances at the end of the RFQ from both Parmteq and TRACK for 32 mA .

| Emittance: N. RMS | Parmteq | TRACK |
|---|---|---|
| $\varepsilon_x$ (mm-mrad) | 0.213 | 0.204 |
| $\varepsilon_y$ (mm-mrad) | 0.211 | 0.203 |
| $\varepsilon_z$ (deg-keV) | 99.63 | 105.86 |

We have also simulated the RFQ with three different beam currents: 0 mA, 32 mA and 60 mA. The results are shown in Fig. 4. We clearly notice the compression of the longitudinal phase space with increasing beam current. The beam envelopes and emittances along the RFQ are shown in Fig. 5 for a 32 mA H- beam.

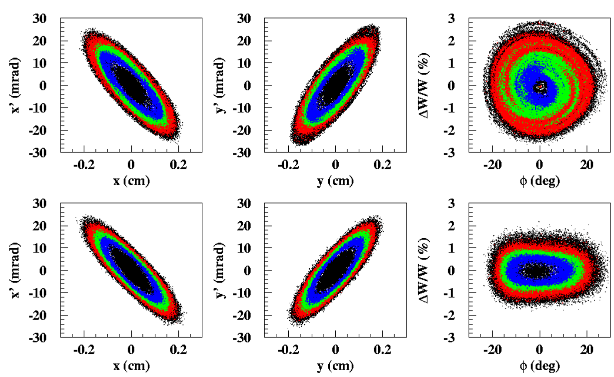

Figure 4: Phase space plots at the end of the RFQ for different beam currents: 0 mA (top) and 32 mA (bottom).

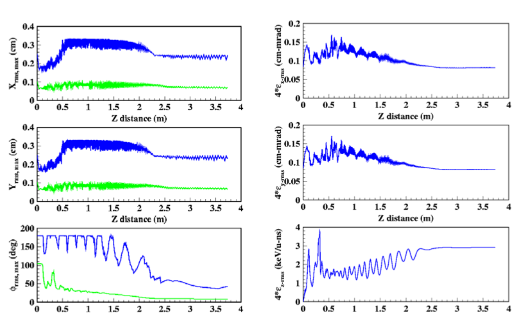

Figure 5: Envelopes and emittances along the SNS RFQ for a 32 mA H- beam.

## IMPLEMENTATION OF THE CCL

As was done for the DTL [2], a new TRACK subroutine was developed for particle tracking in a CCL tank. Unlike a DTL, a CCL has external focusing and several CCL tanks are usually powered by a single Klystron. A special attention should be paid to the phasing of the CCL tanks. Every CCL tank has two input files, one for the cells data and one for the field data. The fields are 2D tables calculated using Superfish [7].

## END-TO-END SIMULATIONS OF THE LINAC

After building the lattices for the CCL, SCL and HEBT we performed end-to-end simulations of the linac from the MEBT to the HEBT right before the stripping foil. Figure 6 shows the envelopes and emittances along the linac for a 32 mA H- beam while Fig. 7 shows the phase space plots at the exit of the linac. We notice how the phase width of the beam expands for injection into the accumulator ring operating at a lower frequency.

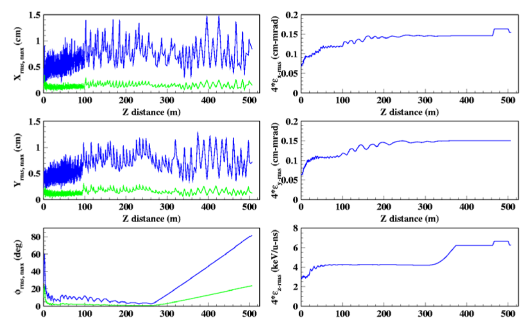

Figure 6: Envelopes and emittances along the SNS linac for a 32 mA H- beam.

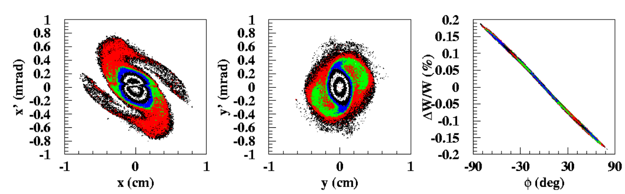

Figure 7: Phase space plots at the exit of the SNS linac; end of HEBT right before the stripping foil. The beam is a 32 mA H- beam.

## SUMMARY AND FUTURE WORK

We have successfully implemented and simulated all the sections of the SNS linac, from the RFQ to the HEBT, using the beam dynamics code TRACK. Future work will focus on end-to-end simulations including machine errors and beam loss analysis in order to compare the results with the experimental data. This is an important step towards the realization of the concept of model driven accelerator.

# MONTE CARLO SIMULATION OF TOUSCHEK EFFECTS IN A LINAC BEAM *

A. Xiao†, M. Borland, ANL, Argonne, IL 60439, USA

## Abstract

We present a Monte Carlo method implemented in the code `elegant` [1] for simulating Touschek scattering effects in a linac beam. The local scattering rate and the distribution of scattered electrons can be obtained from the code. In addition, scattered electrons can be tracked to the end of the beamline and the local beam loss rate and beam halo information recorded. This information can be used for beam collimation system design.

## INTRODUCTION

The Touschek effect is a single Coulomb scattering effect between charged particles in a beam. For a relativistic beam, a small change of transverse momentum results in a much larger change of longitudinal momentum, as the momentum change is increased by the Lorentz factor $\gamma$. When the change exceeds the machine's momentum acceptance, the scattered particle is lost.

The Touschek effect is well understood in storage rings and has been largely ignored for linac beams in the past due to the negligible loss rate. However, this is not the case for an intense electron bunch with ultra-low emittance and very short bunch length that passes through a linac with a very high repetition rate, as occurs in proposed Energy Recovery Linacs (ERLs) [2]. This is a concern for a possible ERL upgrade of the APS, since the radiation shielding of the ring is not designed for high continuous loss rates [3].

Previously, a preliminary theoretical analysis [4] was performed using Piwinski's formula [5]. To better determine the scattered electron distribution and determine precisely the electron loss rate and loss position, we have included a Monte Carlo simulation method in `elegant` for studying the Touschek scattering effect.

In this paper, we review the theory of Touschek scattering, then describe the method used for the Monte Carlo simulation. The scattering rates calculated from the Monte Carlo simulation and Piwinski's formula are compared. The strategy used for calculating beam loss rate and location in `elegant` is then explained. Finally, we give an application example to a proposed APS ERL lattice design.

## THEORY DESCRIPTION

In the center-of-mass (CM) system [1], the probability of one of the two encountered electrons being scattered into a solid angle $d\Omega^*$ is given by the differential Møller cross section [6]

$$\frac{d\sigma^*}{d\Omega^*} = \frac{r_e^2}{4\gamma^{*2}}\left[\left(1+\frac{1}{\beta^{*2}}\right)^2\frac{4-3\sin^2\Theta^*}{\sin^4\Theta^*}+\frac{4}{\sin^2\Theta^*}+1\right], \tag{1}$$

where $r_e$ is the classical electron radius; $\gamma^*$ and $\beta^*$ are the relative energy and velocity of scattered electrons in the CM system, respectively; $\Theta^*$ is the angle between the momenta before and after scattering; and $d\Omega^* = \sin\Theta^* d\Theta^* d\Psi^*$.

The total scattering rate $R$ is given by the integration over all possible scattering angles and over all electrons in the bunch. In the CM system,

$$R^* = 2\int |v^*|\sigma^*\rho(\vec{x}_1^*)^*\rho(\vec{x}_2^*)^* dV^*, \tag{2}$$

where $v^*$ is the scattered electrons' velocity, $\sigma^*$ is the total Møller cross section, $\vec{x}^* = (x^*, y^*, z^*, p_x^*, p_y^*, p_z^*)$, $\rho(x_i^*)^*$ is the electron phase-space density, and $dV = dx^*dy^*dz^*dp_{x1}^*dp_{y1}^*dp_{z1}^*dp_{x2}^*dp_{y2}^*dp_{z2}^*$. $\sigma^*$ is integrated over the solid angle $d\Omega^*$ with $\Theta^* \in (0, \frac{\pi}{2}]$, $\Psi^* \in [0, 2\pi]$:

$$\sigma^* = \int_0^{2\pi}\int_0^{\pi/2}\frac{d\sigma^*}{d\Omega^*}\sin\Theta^* d\Theta^* d\Psi^*. \tag{3}$$

The reason for $\Theta^* \in (0, \frac{\pi}{2}]$ is that, if one electron is scattered into the region $0 < \Theta^* \leq \frac{\pi}{2}$, then the other is scattered into the region $\frac{\pi}{2} \leq \Theta^* < \pi$. The factor "2" in Equation (2) includes both regions.

For the problem we are interested in, we assume that $p_x \ll p_z$ and $p_y \ll p_z$, which means that the Lorentz transformation is mainly taking place along the $z$ direction, and $\sigma^*$ is parallel to the $z^*$-axis. Transforming to the laboratory coordinate system gives

$$|v|\sigma = \frac{|v^*|}{\gamma}\frac{\sigma^*}{\gamma} \tag{4}$$

and

$$R = 2\int |v|\sigma\rho(\vec{x_1})\rho(\vec{x_2})dV, \tag{5}$$

with

$$dV = dx_\beta dy_\beta d\Delta z dx'_{\beta 1}dx'_{\beta 2}dy'_{\beta 1}dy'_{\beta 2}d\Delta p_1 d\Delta p_2. \tag{6}$$

Ignoring coupling, for an electron bunch with Gaussian distribution, the electron's density in phase space $(x_\beta, x'_\beta, y_\beta, y'_\beta, \Delta z, \Delta p/p_0)$ is given by

$$\rho = \frac{N\beta\ \beta}{8\pi^3\sigma\ \sigma\ \sigma^2\ \sigma^2}\exp\left\{-\frac{\Delta z^2}{2\sigma^2}-\frac{1}{2\sigma^2}\frac{\Delta p^2}{p_0^2}\right\}$$
$$\times\exp\left\{-\frac{x^2+(\alpha\ x\ +\beta\ x')^2}{2\sigma^2}-\frac{y^2+(\alpha\ y\ +\beta\ y')^2}{2\sigma^2}\right\}, \tag{7}$$

* Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

† xiaoam@aps.anl.gov

[1] For clarity, we use (*) to denote all quantities in the CM system, as opposed to quantities in the laboratory coordinate system.

where $N$ is the total number of electrons in the bunch; $\beta_{x,y}$ and $\alpha_{x,y}$ are the local optical functions; $\sigma_{x\beta,y\beta}$ are the transverse beam sizes for on-momentum electrons; $\sigma_z$ is the bunch length; and $\sigma_p$ is the energy spread. A scattering event happens when the following conditions are satisfied

$$\begin{aligned} \Delta z_1 &= \Delta z_2, \\ x_{\beta 1} + D_x \frac{\Delta p_1}{p_0} &= x_{\beta 2} + D_x \frac{\Delta p_2}{p_0}, \\ y_{\beta 1} + D_y \frac{\Delta p_1}{p_0} &= y_{\beta 2} + D_y \frac{\Delta p_2}{p_0}, \end{aligned} \tag{8}$$

where $D_{x,y}$ are the dispersion functions.

Equation (5) is a general expression for the Coulomb scattering rate. The Touschek scattering rate (beam loss rate) is $R_T = R(|\Delta p/p_0| > \delta_m)$, where $\delta_m = \Delta p_m/p_0$ is the machine's local momentum aperture, i.e., the momentum aperture relevant to particles scattered at a specific location.

## MONTE CARLO SIMULATION

The method used in `elegant` for simulating electron scattering processes is modified from S. Khan's work for BESSY II [7, 8]. For each simulated scattering event, a total of 11 random numbers are generated and used to determine the position of the scattering event $(x, y, z)$; the momenta of electron 1 $(x'_1, y'_1, \Delta p_1)$; the momenta of electron 2 $(x'_2, y'_2, \Delta p_2)$; and the scattering angles $(\Theta^*, \Psi^*)$. Dispersion corrections are included in the process of assignment. The electron's momenta after scattering are calculated and saved. We compute the integral in Equation (5) using Monte Carlo integration with $N$ uniform distributed samples in the n-dimensional volume $V$, e.g.,

$$\int_V f(\vec{x}) d\vec{x} \approx \frac{V}{N} \sum_{i=1}^{N} f(\vec{x_i}). \tag{9}$$

The average scattering rate is thus given by

$$R_M(|\delta| > \delta_m) = \frac{V}{N} \sum_{k=1}^{M} \left[ \frac{v^*}{\gamma^2} \frac{d\sigma^*}{d\Omega^*} \sin\Theta^* \rho(\vec{x_1}) \rho(\vec{x_2}) \right]_k, \tag{10}$$

where $N$ is the total number of simulated scattering events; M is the total number of scattered electrons with $|\delta| > \delta_m$ (one scattering event may generate one or two electrons with $|\delta| > \delta_m$, and they are counted individually); and $V$ is the total volume in $(x, y, z, x'_1, y'_1, dp_1, x'_2, y'_2, dp_2, \Theta^*, \Psi^*)$ space from which the events are selected. When $M$ is large enough, the simulated scattering rate converges to the analytical scattering rate, see Figure 1. In `elegant`, we use $5 \cdot 10^6$ as the default value of $M$.

Figure 2 shows the excellent agreement in the local scattering rates calculated from Piwinski's formula [5] and our Monte Carlo simulation. The lattice used here is the turn-around arc (TAA) cell of the APS-ERL lattice [9].

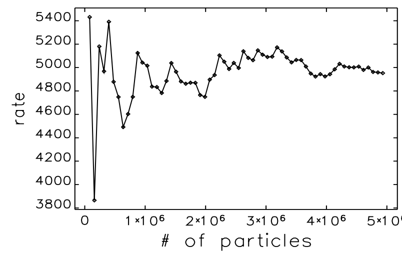

Figure 1: Simulated scattering rate vs. number of simulated scattered electrons.

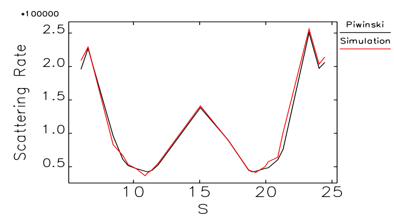

Figure 2: Local Touschek scattering rate: Piwinski formula (black) and Monte Carlo simulation (red).

## BEAM LOSS CALCULATION

To simulate beam loss due to Touschek scattering, we combined Piwinski's formula and the Monte Carlo method in `elegant`. First, the entire beamline is divided into $N_s$ short segments by inserting `TSCATTER` elements as separators. For each segment, we use Piwinski's formula to calculate the total scattering rate (integrated scattering rate $\int R_{Piwinski,i}$) for that segment. The scattered electron distribution at each `TSCATTER` element is generated from the Monte Carlo simulation. Each simulated scattered electron represents many electrons with a local scattering rate $r_i$. Let the total rate each represents for that [illegible] be $R_i$, given by

$$R_i = \frac{r_i}{\sum r_i,} \times \int R_{Piwinski}. \tag{11}$$

The beam loss rate and location can then be calculated through tracking those scattered electrons through the beamline and recording all lost electrons, with $R_i$ providing a weight for each simulated electron's contribution to the total loss rate.

As we pointed out in the previous section, to obtain a reliable scattering rate and a smooth scattered electron distribution, $M$ has to be large enough ($\sim 5 \cdot 10^6$). We also require a large number of segments, $N_s$. That means that we need to track $M \times N_s$ electrons, which requires significant CPU time. This motivated a search for an alternative strategy to reduce the simulation burden. We examined the scattering rate that each simulated electron represents and, not surprisingly, found a large variation. Some simulated electrons represent very likely scattering events, while some represent very low probability events. We sorted all simulated electrons by the associated scattering rate. Figure 3 illustrates the sum of the scattering rate ($\sum r_i$) vs. the number of simulated electrons ($\sum_i$).

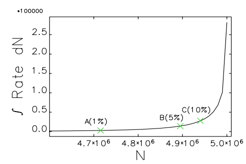

Figure 3: Integrated scattering rate vs. number of simulated electrons. Electrons are sorted with increasing associated scattering rate.

From this plot we can see that about $5\%$ of simulated electrons represent about $99\%$ of the scattering rate, which means that we may track a small portion of simulated electrons and get a fairly good beam loss information. Figure 4 compares the computed loss rate for tracking scattered electrons with $95\%$, $99\%$, and $100\%$ of the total scattering rate, respectively. It's clear that the differences are small and that this strategy can greatly speed up simulation with little sacrifice of accuracy. In `elegant` we use 99% as a default value.

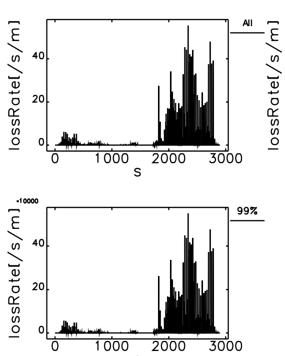

Figure 4: Simulated loss rate vs. position for various values of the scattering rate cut-off.

## APPLICATION TO APS-ERL DESIGN

APS has an eye on a future ERL upgrade, but we are concerned about beam loss issues since the APS tunnel is already built. The allowed beam loss in the APS ring is about 170 pA / 1100 m [10], i.e., 0.15 pA/m. We applied the Monte Carlo simulation to the APS-ERL lattice [9]. We assumed geometric rms emittances of 22 pm, 0.01% rms energy spread, 0.6 mm rms bunch length, 77 pC/bunch, and a 1.3 GHz repetition rate (giving 100 mA average current). Figure 5 shows the beam loss rate from Touschek scattering without sextupole correction in the TAA section. This is well above what is tolerable. A sextupole correction along the TAA section was then added to the lattice by maximizing the minimum value of the local momentum aperture. Figure 5 shows that this significantly reduces the beam loss rate, so that the average loss rate (0.018 pA/m) is well below the desired value.

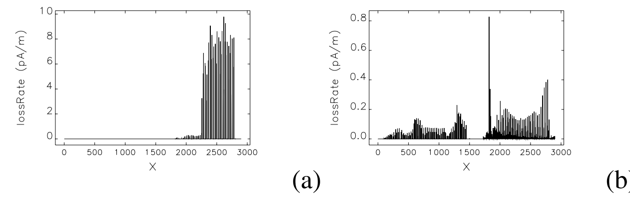

Figure 5: Simulated loss rate vs. position for APS-ERL without sextupole correction in TAA (a) and with optimized sextupole correction (b).

## CONCLUSION

A Monte Carlo simulation of Touschek scattering for a single-pass system (linac or transport line) was implemented in `elegant`. We compared the simulated local scattering rate with the rate from Piwinski's formula and found good agreement that confirms our simulation is correct. We also developed a strategy to speed up the simulation by tracking only those simulated scattered particles that represent the bulk of the scattering events. The application to a proposed APS-ERL lattice shows that the Touschek scattering effect is serious in an intense high-brightness electron beam. An optimized sextupole correction must be employed to lower the beam loss to a safe value. This simulation can also provide information for beam collimator design and verify the collimator system's efficacy.

# STUDY OF IBS EFFECTS FOR HIGH-BRIGHTNESS LINAC BEAMS *

A. Xiao†, ANL, Argonne, IL 60439, USA

## ABSTRACT

Intrabeam scattering (IBS) may become an issue for linac-based fourth-generation light sources such as X-ray free-electron lasers and energy recovery linacs (ERLs), both of which use high-brightness electron beams with extremely small emittance and energy spread. Any degradation of this extremely high beam quality could significantly reduce the machine's performance. We present here a strategy first used in the code `elegant` [1] for simulating IBS effects for high-brightness linac beams. We also present an application to a possible ERL upgrade of the Advanced Photon Source.

## INTRODUCTION

Particles in a beam exchange energy between transverse and longitudinal oscillations due to Coulomb scattering. Depending on the scattering angles, the process leads to a diffusion in beam size (intrabeam scattering or IBS) or beam loss (Touschek effect).

The theory of IBS is discussed in several publications [2, 3]. A number of codes (e.g., ZAP [4], MAD-X [5]) have been developed for calculating the beam size growth rates. In the past, particle densities were not very high, so the growth times were much longer than the time spent traversing a typical linac. Thus, codes were designed for the stored beam case only with a constant beam energy. Linac-based fourth-generation light sources, such as X-ray free-electron lasers and Energy Recovery Linacs (ERLs [6]), require a high-brightness electron beam with extremely small emittance and energy spread. Any degradation of the beam quality could significantly reduce the machine's performance. Since the IBS growth time becomes much shorter for a high-brightness beam, IBS effects may become an issue even for a linac beam.

To investigate this issue, we modified the IBS calculation in `elegant` to include vertical dispersion effects and added the ability to handle acceleration. We applied our code to a proposed APS-ERL [7, 8] upgrade lattice also. Our results show that the IBS effects is moderate with the designed beam parameters.

## CALCULATION OF IBS GROWTH RATES

A detailed formalism for intrabeam scattering, taking into account the variation of lattice functions with azimuth, has been developed by Bjorken and Mtingwa [3]. The expression of emittance growth rate $\tau_d$ in the direction $d$ ($x$, $y$, or $z$) is given by (3.4) in [3] as:

$$\frac{1}{\tau} = \frac{\pi^2 c r_0^2 m^3 N ln\Lambda}{\gamma\Gamma} f,$$

$$f = \left\langle \int_0^\infty \frac{\lambda^{1/2} d\lambda}{\sqrt{|A|}} \left\{ TrL^d Tr[A^{-1}] - 3Tr[L^d (A)^{-1}] \right\} \right\rangle, \tag{1}$$

where $c$ is the speed of light, $r_0$ is the classical particle radius, $m$ is the particle mass, $N$ is the number of particles per bunch (or in the beam for unbunched case), $ln\Lambda$ is a Coulomb logarithm, $\gamma$ is the Lorentz factor, $\Gamma$ is the 6-dimensional invariant phase-space volume of the beam,

$$\Gamma_B = (2\pi)^3 (\beta\gamma)^3 m^3 \varepsilon_x \varepsilon_y \sigma_p \sigma_z \qquad (bunched)$$

$$\Gamma_U = 4\pi^{5/2} (\beta\gamma)^3 m^3 \varepsilon_x \varepsilon_y \sigma_p (2\pi R) \quad (unbunched), \tag{2}$$

and $A = (L + \lambda I)$, with

$$\begin{aligned} L &= L^x + L^y + L^z, \\ L^x &= \frac{\beta}{\varepsilon} \begin{pmatrix} 1 & -\gamma\phi_x & 0 \\ -\gamma\phi_x & \gamma^2(\frac{D^2}{\beta^2} + \phi_x^2) & 0 \\ 0 & 0 & 0 \end{pmatrix}, \\ L^y &= \frac{\beta}{\varepsilon} \begin{pmatrix} 0 & 0 & 0 \\ 0 & \gamma^2(\frac{D^2}{\beta^2} + \phi_y^2) & -\gamma\phi_y \\ 0 & -\gamma\phi_y & 1 \end{pmatrix}, \\ L^z &= \frac{\gamma^2}{\sigma^2} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \end{aligned} \tag{3}$$

Here, $\phi_{x,y} = D'_{x,y} + \frac{\alpha\ ,\ D\ ,}{\beta\ ,}$; $\varepsilon_{x,y}$ and $\sigma_{p,z}$ are beam distribution related quantities; and $\beta_{x,y}, \alpha_{x,y}, D_{x,y}, D'_{x,y}$ are local optical functions.

Equation (3), which includes vertical dispersion effects, is used in `elegant` for calculating the beam size growth rate. We found there are missing terms in MAD-X in the expressions for $a_{x,y}$ and $b_{x,y}$ used in formula (8) in [9], as confirmed by the developer [10]. The following equations show the differences between $a_x$ in `elegant`,

$$\begin{aligned} a_x &= 2\gamma^2 \left( \frac{H}{\varepsilon} + \frac{H}{\varepsilon} + \frac{1}{\sigma^2} \right) - \frac{2\beta}{\varepsilon} - \frac{\beta}{\varepsilon} \\ &\quad - \frac{\beta\ H}{H\ \varepsilon} + \frac{\beta}{H\ \gamma^2} \left( \frac{2\beta}{\varepsilon} - \frac{\beta}{\varepsilon} - \frac{\gamma^2}{\sigma^2} + \frac{6\beta}{\varepsilon} \gamma^2 \phi_x^2 \right) \end{aligned} \tag{4}$$

* Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

† xiaoam@aps.anl.gov

and $a_x$ in MAD-X,

$$
\begin{aligned}
a_x \quad &= 2\gamma^2 \left( \frac{H}{\varepsilon} + \frac{H}{\varepsilon} + \frac{1}{\sigma^2} \right) \\
&- \frac{\beta}{H} \frac{H}{\varepsilon} + \frac{\beta}{H} \frac{}{\gamma^2} \left( \frac{2\beta}{\varepsilon} - \frac{\beta}{\varepsilon} - \frac{\gamma^2}{\sigma^2} \right)
\end{aligned} \tag{5}
$$

with

$$
H_{x,y} = \frac{D_{x,y}^2 + \beta_{x,y}^2 \phi_{x,y}^2}{\beta_{x,y}}.
$$

To further improve accuracy, we also moved the Coulomb logarithm $ln\Lambda$ into the average bracket in Equation (1), since it varies with location also.

To test the code, we simulated the emittance growth rate using the APS1nm [11] lattice and compared our results with ZAP and MAD-X. The beam parameters used in simulation are given in Table 1 (varied parameters are show in a bold face).

Table 1: Parameters used in Code Comparisons

| Index | Energy GeV | $N_b$ $10^{10}$ | coupling | $\sigma_p$ $10^{-3}$ | $\sigma_z$ mm |
|---|---|---|---|---|---|
| 0 | **3.0** | 2.0 | 0.01 | 1.11 | 6 |
| 2 | **5.0** | 2.0 | 0.01 | 1.11 | 6 |
| 4 | **7.0** | 2.0 | 0.01 | 1.11 | 6 |
| 5 | 7.0 | **2.0** | 0.01 | 1.11 | 6 |
| 7 | 7.0 | **6.0** | 0.01 | 1.11 | 6 |
| 9 | 7.0 | **10.0** | 0.01 | 1.11 | 6 |
| 10 | 7.0 | 2.0 | 0.01 | **1.11** | 6 |
| 12 | 7.0 | 2.0 | 0.01 | **3.0** | 6 |
| 14 | 7.0 | 2.0 | 0.01 | **5.0** | 6 |
| 15 | 7.0 | 2.0 | 0.01 | 1.11 | **2** |
| 17 | 7.0 | 2.0 | 0.01 | 1.11 | **6** |
| 19 | 7.0 | 2.0 | 0.01 | 1.11 | **10** |
| 20 | 7.0 | 2.0 | **0.01** | 1.11 | 6 |
| 22 | 7.0 | 2.0 | **0.03** | 1.11 | 6 |
| 24 | 7.0 | 2.0 | **0.05** | 1.11 | 6 |

Figure 1 shows results from `elegant`, ZAP, and MAD-X. It shows that our results agree with the other two codes very well in a large range of parameters. The differences due to the missing terms are minor and negligible in our test run, as are the differences due to variation in $ln\Lambda$.

To verify the calculation with non-zero vertical dispersion, we performed the following test: first we set $\epsilon_x = \epsilon_y = \epsilon_0$ and computed the horizontal growth rate; then we exchanged the horizontal and vertical plane optical functions and computed the vertical growth rate. The resulting vertical growth rate should be the same as the original horizontal growth rate. Figure 2 shows simulation results before and after exchange of the optical functions, demonstrating that our vertical dispersion implementation is correct.

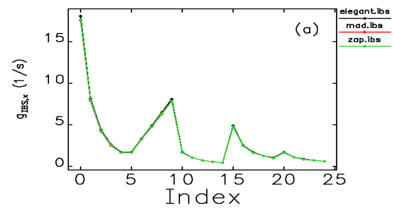

Figure 1: Comparison of calculated IBS growth rate from `elegant`, MAD-X, and ZAP. See Table 1 for the meaning of the Index.

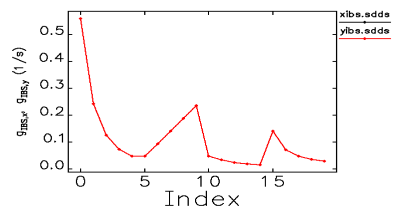

Figure 2: Demonstration that the vertical dispersion calculation is correct (xibs.sdds and yibs.sdds have their horizontal and vertical optical functions exchanged).

## IBS GROWTH RATES FOR ACCELERATING BEAM

To calculate the IBS growth rates for a beam with acceleration is straightforward. First, we calculate the IBS growth rates locally with local beam energy and emittance, then integrate over the beam's path length $s$. Note that, since there are no synchrotron oscillations in a linac, the formula for unbunched beam should be used and results in a factor of 2 increase in the longitudinal growth rate [12]:

$$
\frac{1}{\tau_z}\left[Unbunched\right] = 2\frac{1}{\tau_z}\left[Bunched\right]. \tag{6}
$$

The evolution of beam size is simulated through tracking using a specially designed element, `IBSCATTER`. First the entire beamline is divided into several segments by inserting `IBSCATTER` elements between selected existing elements. The normalized beam emittance is assumed constant within each segment, and the integrated IBS growth rates are calculated using the input beam parameters (for the first `IBSCATTER` element) or the parameters at the exit of the previous `IBSCATTER` element. The scattering action takes place at each `IBSCATTER` and the beam parameters are updated. This is done either by inflating the beam phase-space coordinates by factors that provide the equivalent size changes, or by adding appropriately scaled random values to the simulation particle coordinates. This is continued until the end of the beamline. Since the growth rates depend on beam size, the user needs to perform tests to determine how many `IBSCATTER` elements are needed. For example, in a linac the IBS growth rates are much higher in the low-energy region compared to the high-energy region.

Because the IBS growth rates are energy dependent, special caution is needed for calculations for accelerating beam. At the beginning of acceleration, the beam energy varies significantly. Figure 3 illustrates the energy change along the first sector of an APS-ERL design [7, 8]. We don't have an analytical method to calculate the IBS growth rate in this case. The integration is done using the local IBS rate at each element and the distance between elements. In such a case, the user needs to split their accelerating cavity into several pieces, so that $\gamma$ has no large changes between elements. We split our rf cavities into 100 pieces. It's not necessary to put an `IBSCATTER` element after each element, since the effects of IBS on the beam size will only manifest themselves some distance downstream. The code will take care of beam size change vs. energy in computing the local IBS growth rate.

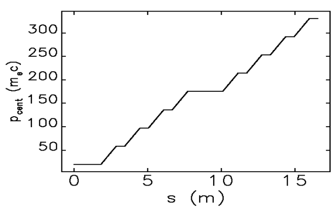

Figure 3: Energy vs. $s$ at the first sector of APS-ERL.

## EXAMPLE

In this section we present an example of an IBS calculation for an APS-ERL design. We assumed that the 10 MeV beam from the pre-injector has normalized emittances of 0.1 $\mu$m, 0.1% rms energy spread, 0.6 mm rms bunch length, and 19 pC/bunch. Figure 4 shows the beam size evolution as the beam passes through the beamline to the exit of the APS. We see a moderate but noticeable bunch lengthening due to IBS effects. But the normalized emittance dilution is minor compared to the emittance dilution from other effects, such as quantum excitation.

## CONCLUSION

A more general IBS growth rate calculation including vertical dispersion effects and beam energy variation was added to `elegant`. The code was benchmarked with ZAP and MAD-X for vertical dispersion equal to zero and against itself by exchanging the horizontal and vertical plane parameters. Insertion of many scattering elements, `IBSCATTER`, allows simulation along a transport line or a linac. An application was made to a possible APS-ERL upgrade. Results show that the IBS effects are moderate with the proposed beam parameters.

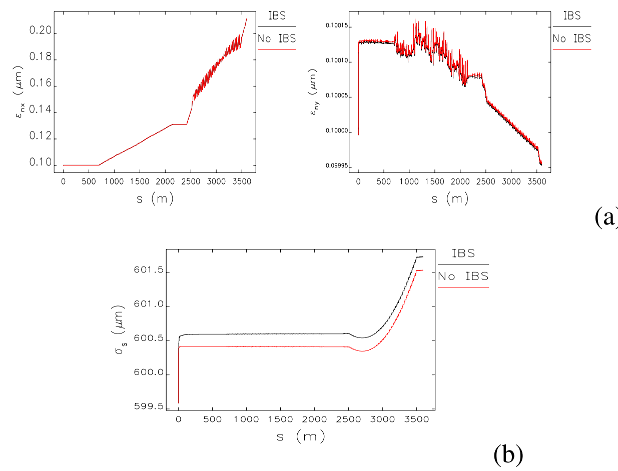

Figure 4: Evolution of beam dimensions for a proposed APS-ERL lattice, with and without IBS. (a) Effective normalized emittance. (b) Bunch length.

# ORTHOGONAL BASIS FUNCTION APPROXIMATION OF PARTICLE DISTRIBUTION IN NUMERICAL SIMULATIONS OF BEAMS *

Balša Terzić†, NICADD, Northern Illinois University, DeKalb, IL 60115, USA

Numerical simulations of charged particle beams require an approximation to the particle distribution being simulated. We present a mathematical formalism for approximating two-dimensional (2D) particle distribution using a basis composed of scaled and translated Gauss-Hermite (STGH) functions. It is computationally efficient, because it only requires the values of the particle distribution at $(N+1)\times(M+1)$ nodes, where $N$ and $M$ are the highest basis function retained in the expansion in each coordinate. After outlining the mathematical formalism for the expansion, we compare it to the cosine expansion which is currently used in a code simulating coherent synchrotron radiation. The advantages of the STGH approximation over the cosine expansion are demonstrated by comparing the computational costs and execution times, as well as manifesting that unphysical fluctuations in the tail of the approximation which plague cosine expansion are not a factor in the new method. All these features make the STGH approximation valuable for $N$-body codes simulating the dynamics of multiparticle systems.

## INTRODUCTION

The normalized Gauss-Hermite functions are given by

$$\psi_n(v) = \frac{1}{\sqrt{2^n n! \sqrt{\pi}}} H_n(v) e^{-v^2}, \qquad (1)$$

where the $H_n(v)$ are the Hermite polynomials. They are orthonormal on $(-\infty, \infty)$ with the weight $w(v) = e^{v^2}$:

$$\int_{-\infty}^{\infty} \psi_n(v)\psi_m(v) e^{v^2} dv = \delta_{nm}, \qquad (2)$$

where $\delta_{nm}$ is a Kronecker delta. The basis composed of Gauss-Hermite functions $\{\psi_n\}_{n=0}^{N}$ are often used in various areas of physics, because of their relationship to normal distribution. The Gauss-Hermite spectral methods, while possessing some useful properties, only yield good approximation when scaled. Scaled Gauss-Hermite functions have been used earlier in the context of beam simulations [1, 2, 3]. While most of our motivation and justification for using scaled Gauss-Hermite function coincides with theirs, the mathematical formalism and computational implementation we present here are different. In the new method: (i) no underlying ellipsoidal distributions are assumed; (ii) the computation of the scaled Gauss-Hermite expansion here is done in a more direct and efficient way; (iii) the Poisson equation and the self-fields are directly obtained, without an expensive multidimensional integration. The results reported in the earlier work – most notably appreciable increase in accuracy and computational efficiency over the existing particle-in-cell (PIC) codes – gives us a reasonable expectation that the approach we present here is indeed superior to the existing gridless approaches. The efforts to integrate this 2D formalism into an existing 2D beam simulation code, as well as extending it to 3D and implementing a full 3D gridless $N$-body code as an alternative to PIC codes, are currently underway [4].

## SCALED AND TRANSLATED GAUSS-HERMITE BASIS

The 2D gaussian-type functions (i.e., functions which decay at infinity at least like $\exp\left(-px^2 - qy^2\right)$, with $p, q$ some positive constants) can be well-approximated by a finite Gauss-Hermite expansion

$$f(x,y) = \sum_{n=0}^{N}\sum_{m=0}^{M} a_{nm}\psi_n(\alpha_1(x-\bar{x}))\psi_m(\alpha_2(y-\bar{y})), \qquad (3)$$

where $\alpha_1, \alpha_2 > 0$ and $\bar{x}$, $\bar{y}$ are constants. In solving differential equations, it is important to be able to express derivatives of the function in the same basis. This is achieved via recurrence relations of Gauss-Hermite polynomials [6]:

$$\begin{aligned} H_{k+1}(z) &= 2zH_k(z) - 2kH_{k-1}(z), \\ H'_k(z) &= 2zH_{k-1}(z). \end{aligned} \qquad (4)$$

This ability to express coefficients of the derivatives of the function in terms of coefficients of the function itself renders solving the Poisson equation in this basis trivial.

In pseudo-spectral methods, such as the collocation method used in [5], the optimal pseudo-spectral points are the roots of the $H_{N+1}(x)$ and $H_{M+1}(y)$, denoted by $\{\gamma_j\}_{j=0}^{N}$ and $\{\beta_k\}_{k=0}^{M}$, respectively. The collocation points are arranged in descending order, i.e., $\gamma_0 > \gamma_1 > ... > \gamma_N$ and $\beta_0 > \beta_1 > ... > \beta_M$. If the eq. (3) is satisfied at the collocation points, then it can be written as

$$f(\tilde{\gamma}_j, \tilde{\beta}_k) = \sum_{n=0}^{N}\sum_{m=0}^{M} a_{nm}\psi_n(\gamma_j)\psi_m(\beta_k), \qquad (5)$$

where $0 \le j \le N$, $0 \le j \le M$, and

$$\tilde{\gamma}_j = \frac{\gamma_j}{\alpha_1} + \bar{x}, \qquad \tilde{\beta}_k = \frac{\beta_k}{\alpha_2} + \bar{y}. \qquad (6)$$

* Work supported by the Department of Defense under contract N00014-06-1-0587 with Northern Illinois University.
† bterzic@nicadd.niu.edu

It is now convenient to take advantage of the following relation for Hermite polynomials [6]:

$$\sum_{k=0}^{n} \frac{H_k(x)H_k(y)}{2^k k!} = \frac{H_{n+1}(x)H_n(y) - H_n(x)H_{n+1}(y)}{2^{n+1}n!(x-y)}, \tag{7}$$

which, for $0 \le i, j \le N$ and $0 \le k, l \le M$, leads to

$$\sum_{n=0}^{N} \psi_n(\gamma_i)\psi_n(\gamma_j) \sum_{m=0}^{M} \psi_m(\beta_k)\psi_m(\beta_l) = C_{ik}\delta_{ij}\delta_{kl}. \tag{8}$$

From eq. (8) it follows for $0 \le i \le N$ and $0 \le k \le M$:

$$C_{ik} = \sum_{n=0}^{N} [\psi_n(\gamma_i)]^2 \sum_{m=0}^{M} [\psi_m(\beta_k)]^2 \tag{9}$$

after which we finally we obtain the expression for coefficients $a_{nm}$, with $0 \le n \le N$ and $0 \le m \le M$:

$$a_{nm} = \sum_{j=0}^{N}\sum_{k=0}^{M} \frac{1}{C_{jk}} f(\tilde{\gamma}_j, \tilde{\beta}_k)\psi_n(\gamma_j)\psi_m(\beta_k). \tag{10}$$

By utilizing the property in eq. (7), evaluation of the expansion coefficients $a_{nm}$ no longer requires integration over the entire distribution function, but only its value at the nodes. Combining eqs. (5) and (10) yields a STGH approximation to function $f$.

The scaling factors $\alpha_1$ and $\alpha_2$ for the normalized distribution function $f$ are computed from the standard deviation in $x$- and $y$-coordinates:

$$\alpha_1 = \frac{1}{\sqrt{2}\sigma_x}, \qquad \alpha_2 = \frac{1}{\sqrt{2}\sigma_y}, \tag{11}$$

while $\bar{x}$ and $\bar{y}$ are simply first moments of the DF in $x$- and $y$-coordinates, respectively.

## APPLICATION TO SIMULATIONS OF MULTIPARTICLE SYSTEMS

The STGH expansion is well-suited in the context where one needs an analytical approximation to the microscopic Klimontovich density distribution:

$$f(x, y) = \frac{1}{N_{\text{part}}} \sum_{i=1}^{N_{\text{part}}} \delta(x - x_i)\delta(y - y_i), \tag{12}$$

where $N_{\text{part}}$ is the number of macroparticles. The STGH expansion can be tailored to the 2D gridless $N$-body simulation of charged-particle beams [7, 8] in which:

1. discretely-sampled macroparticle distribution is analytically approximated by a cosine expansion;
2. the Poisson equation is solved to obtain corresponding potential and forces acting on each macroparticle;
3. each macroparticle is advanced a small time-step $\Delta t$.

The STGH seeks to improve on computationally expensive cosine expansion in Step 1, while providing an efficient way to compute the potential and forces.

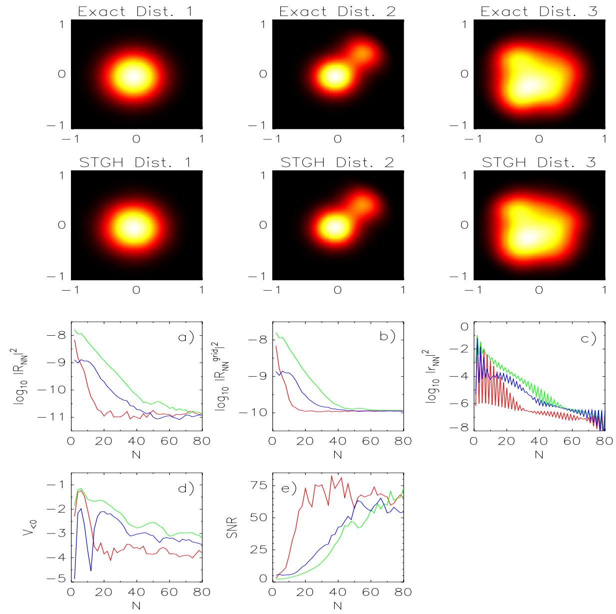

Figure 1: Three "toy" analytical distributions (superpositions of 1, 2 and 50 gaussians): exact (top row); approximated by STGH with $N = M = 80$ (second row); convergence estimators $|R_{NM}|^2$, $\left|R_{NM}^{\text{grid}}\right|^2$, $|r_{NM}|^2$ versus the number of expansion coefficients $N = M$; fraction of negative volume (panel d) and signal-to-noise ratio (panel e).

## [illegible]

The STGH algorithm for computing coefficients $a_{nm}$ can be outlined as follows:

1. tabulate unchanging quantities $\frac{\psi\ (\gamma\ )\psi\ \ (\beta\ )}{C}$;
2. compute scaling and translation factors $\bar{x}$, $\bar{x}$, $\alpha_1$, $\alpha_2$;
3. evaluate $f\left(\tilde{\gamma}_j, \tilde{\beta}_k\right)$;
4. compute coefficients $a_{lm}$ [eq. (10)].

Steps 2-4 are repeated at each time-step of the simulation. Evaluation of $f\left(\tilde{\gamma}_j, \tilde{\beta}_k\right)$ in Step 3 is the key to the STGH approximation. It can be done by counting the number of particles in some small neighborhood of the node ([illegible]), and normalizing it. We also tested alternative adaptive estimators, but the difference was not appreciable enough to warrant substantial increase in computational effort.

## [illegible]

Convergence and accuracy of the STGH can be quantified using several quantities.

### [illegible]

(i) $L_2$-norm of the difference between the exact and approximated distributions:
$R_{NM}(x, y) = f_{NM}^{\text{apx}}(x, y) - f^{\text{ex}}(x, y)$;
(ii) signal-to-noise ratio (SNR):

$$SNR \equiv \left[\sum_{i=1}^{K}\sum_{j=1}^{K}\left(f_{ij}^{\mathrm{apx}}\right)^2\right]^{\frac{1}{2}}\left[\sum_{i=1}^{K}\sum_{j=1}^{K}\left(f_{ij}^{\mathrm{ex}}-f_{ij}^{\mathrm{apx}}\right)^2\right]^{-\frac{1}{2}}.$$

(Figure 1 shows these for three analytical "toy" distributions.)

[illegible] not [illegible]

(i) $L_2$-norm of the difference between the approximated and gridded distributions:
$R_{NM}^{\mathrm{grid}}(x,y) = f_{NM}^{\mathrm{apx}}(x,y) - f^{\mathrm{g}}(x,y)$;
(ii) correction to the expansion from one step to another:
$r_{NM}(x,y) = f_{N-1M-1}^{\mathrm{apx}}(x,y) - f_{NM}^{\mathrm{apx}}$.

## STGH VS. COSINE EXPANSION: ACCURACY AND EFFICIENCY

We compare the cosine and STGH expansion on a set of particle distributions containing $10^6$ macroparticles, generated from realistic simulation [9].

[illegible] As quantified by $|R_{NM}^{g}|^2$, $|r_{NM}|^2$, the STGH is at least as accurate as the cosine expansion (Fig. 2, second and third row).

[illegible] STGH expansion is considerably faster than cosine expansion – by about 5-25 times – because it does not require expensive trigonometric function evaluations, and each coefficient does not require integration (summation) over all particles in the distribution (Fig. 2, fourth row).

[illegible] Fraction of negative particle distribution for STGH expansion is considerably lower – by at least an order of of magnitude (Fig. 2, fifth row; Fig. 3). This is because the cosine basis functions are non-decaying, while the STGH basis functions decay exponentially.

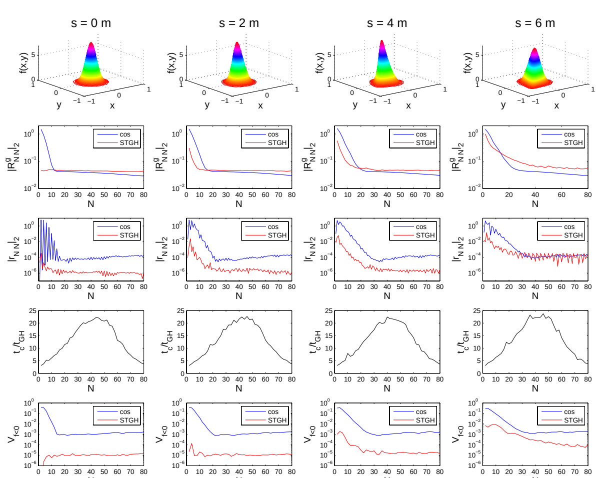

Figure 2: Particle distribution from a beam simulation with $N_{\mathrm{part}} = 10^6$ macroparticles at $s = 0, 2, 4, 6$m, gridded on a $128 \times 128$ grid. For the cosine (blue lines) and the STGH (red) expansion: second and third rows show convergence estimators $\left|R_{NM}^{\mathrm{grid}}\right|^2$, $|r_{NM}|^2$; fourth ratio of execution speeds; and fifth fraction of negative volume.

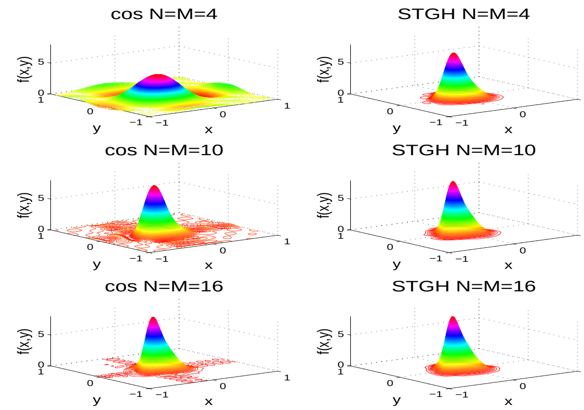

Figure 3: Approximations to the particle distribution from a beam simulation with $N_{\mathrm{part}} = 10^6$ macroparticles at $s =$ 4m with the cosine expansion (left column) and the STGH (right column), with $N = M = 4$ (first row), $N = M = 10$ (second row), $N = M = 16$ (second row).

## CONCLUSION

We presented the STGH expansion which is well-suited when an analytical approximation of the distribution sampled by $N_{\mathrm{part}}$ macroparticles is needed. We have shown that in the context of simulations of charged particle beams, the STGH approximation is more accurate and about an order of magnitude faster than the cosine approximation. It is also immune to a problem of unphysical wiggles in the tails of the distribution, which is intrinsic to cosine expansion. Therefore, the STGH provides a more accurate approximation in the tails of the distribution, which is of pivotal importance to beam halo simulations. Overall, the STGH represents a significant improvement over the existing analytic approximations used in beam simulation codes.

# THE OPEN ARCHITECTURE SOFTWARE INTEGRATION SYSTEM (OASIS) FOR CREATING PBO LAB MODULES

G. H. Gillespie and B. W. Hill
G. H. Gillespie Associates, Inc., P. O. Box 2961, Del Mar, CA 92014, USA

A specialized software package has been developed that enables the rapid implementation of custom beam optics modules that run in the Particle Beam Optics Laboratory (PBO Lab™). PBO Lab is a commercially available software application that supports a suite of accelerator codes for design, operations, and personnel education. The intuitive and easy-to-use graphic user interface (GUI) is largely responsible for the popularity of PBO Lab. The Open Architecture Software Integration System, or OASIS, builds upon the capability of PBO Lab to host a suite of different codes. OASIS provides an innovative framework that allows users to readily create new PBO Lab modules without writing or compiling any source code. OASIS has been used to develop several new modules for PBO Lab. This paper presents a summary of the OASIS framework and describes some of the features used in creating a new PBO Lab module for one example optics code.

## INTRODUCTION

PBO Lab has been used to support beamline design, personnel training, and accelerator operations for over a decade and delivers a suite of Application Modules that implement a variety of trusted optics codes [1]. The PBO Lab GUI provides a common graphic user interface for creating and editing iconic object-based computer models of accelerators and beamlines.

OASIS leverages the mature software framework utilized by PBO Lab [2], and extends its capabilities to provide users with a familiar environment from which to create their own PBO Lab Application Modules [3]. The PBO Lab Beamline Object Model [4] is the underlying persistent representation that allows multiple optics codes with varying input/output requirements to utilize a single beamline model description. Multiple optics codes run side by side in PBO Lab's sophisticated drag-and-drop graphic user interface. PBO Lab generates the native input and processes the native output, for the different optics codes, from a single beamline model.

## THE OASIS FRAMEWORK

The OASIS framework is a collection of abstract and concrete classes, and their interfaces which comprise a generic subsystem used to implement Application Modules in PBO Lab. It provides a reusable, generic OASIS Module, or "OModule," that encapsulates the user interface and data interface functionality required for running in the multi-module PBO Lab environment. Figure 1 illustrates the abstract layer diagram for the PBO Lab/OASIS application framework. User developed Application Modules are implemented dynamically in PBO Lab with this generic reusable Application Module (OModule) design pattern.

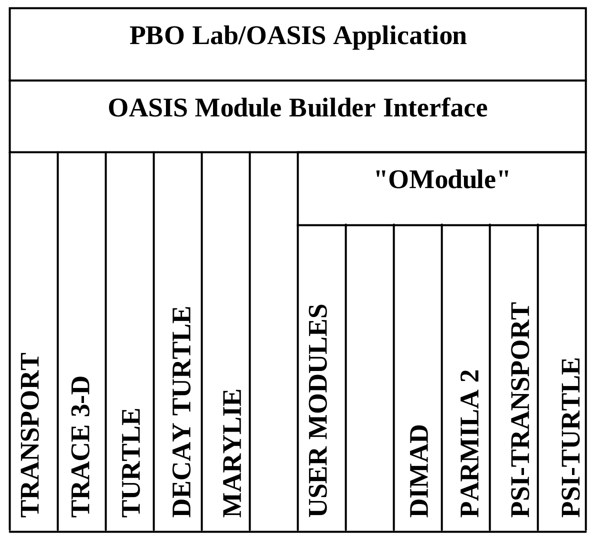

Figure 1: Layer diagram for PBO Lab Framework and Open Architecture Software Integration System.

An OModule has both a user interface component and a computational component. The user interface component is created in the OASIS Module Builder Interface which is an extension to the drag-and-drop PBO Lab GUI. The computational component may be a library (.dll) or executable (.exe) application. No source code needs to be compiled or linked to use the Application Module in PBO Lab.

## OASIS MODULE BUILDER

The OASIS Module Builder Interface, used to create PBO Lab Application Modules, is an intuitive extension of the standard PBO Lab interface, providing users with a familiar environment to create custom Application Modules that run seamlessly in the PBO Lab GUI without writing or compiling any source code. The OASIS Module Builder is itself a very specialized PBO Lab Module: it is a Module for the specification of other Application Modules. The OASIS Module Builder provides an interactive environment to incrementally create and test Application Modules in the PBO Lab GUI. Detailed specifications to fully define the requirements for the generation of a native input file for an optics code are accomplished through the familiar PBO Lab GUI, which has been extended to support the OASIS Module Builder Interface.

Application Modules are exported from the OASIS Module Builder for use in PBO Lab using a PBO Lab module definition (.omod) file. Figure 2 illustrates the process. The module definition file utilizes an enhanced version of the PBO Lab persistent Beamline Object Model representation [4]. The object model has been expanded to include specifications that define the native input/output requirements for a given optics code, and to include a variety of other specifications and constraints that encapsulate the operations and commands of the target optics code.

Iconic representations (Piece Components) of physical beamline elements and non-physical beamline operations, in the Module Builder Interface, are used to access and specify most input requirements for a target optics code.

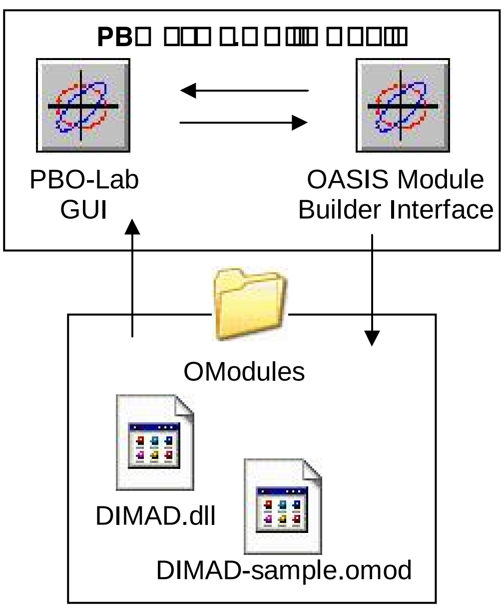

Figure 2: Application Modules can be interactively developed and executed in the Module Builder Interface and exported for use directly in the PBO Lab GUI as (.omod) OModule definition files.

## MODULE BUILDER EXAMPLE

Piece Components are categorized into three types, Optics Pieces, Parameter Pieces and Command Pieces. Optics Pieces are used to represent physical beamline elements and include a variety of standard Pieces available in the PBO Lab Palette Bar [5]. Customizable Optics Pieces can be used to add additional optics elements. The Parameter Piece type provides a customizable generic interface and is typically used to support parameters not associated with any particular physical optics element. Command Pieces are used to implement Application Module commands or operations supported by the target optics code. Command Pieces provide a versatile method of encapsulating the wide variety of commands that can be specified for a given optics code. Command Pieces do not represent physical beamline elements, although they can be located at specific locations in the beamline model, where they are evaluated sequentially to produce the appropriate command instructions in the native input file for the given optics code.

Each optics code has its own unique “commands” or “operators” that encapsulate the computational capability for that code. This code-specific functionality is implemented in an Application Module using a set of Command Pieces. An example of such a Command Piece, created for a DIMAD Application Module, is illustrated here.

The DIMAD program [6] was developed to study particle motion in both beamlines and circular machines. The code uses a matrix formalism through second order. It is perhaps most commonly used at facilities operating electron accelerator systems.

There are several Command Pieces defined for the DIMAD Application Module. For illustrative purposes, the implementation of DIMAD's Least Squares Fit operation will be described here. (The Least Squares Fit operation is described in Section 2.15 of reference [6].)

The DIMAD Application Module “Least Squares Fit…” Command Piece implements a variety of native instructions required to direct the DIMAD computation engine to perform a particular fitting operation [6]. The definition of the “Least Squares Fit…” Command Piece in the OASIS Module Builder Interface involves both the specification of the required input parameters and the syntax used to generate instructions for the DIMAD native input file.

A generic Command Piece serves as a template and is initially created on the Work Space [5] of the Module Builder Doc Window using a menu command that prompts the user to name the new Command Piece. The named piece can then be dragged to the Model Space [5] where double-clicking the piece icon will open its Command Piece Specification Window. From there, additional windows are accessed that provide for the definition of input parameters and the specification of the native syntax required for the command to be processed by the target optics code (i.e. DIMAD). Once the Command Piece is defined, it will be available for use with the DIMAD Application Module in PBO Lab. Figure 3 shows two of the input parameter tab pages defined in this way for the “Least Squares Fit…” Command Piece.

The “Least Squares Fit…” Command Piece is added to a PBO Lab beamline to direct the DIMAD computation engine to perform the prescribed fitting operation. From the DIMAD Command Menu, the “Write and Run DiMadInput” command is used to generate the native DIMAD input, execute the DIMAD computation engine, and open the resulting output file.

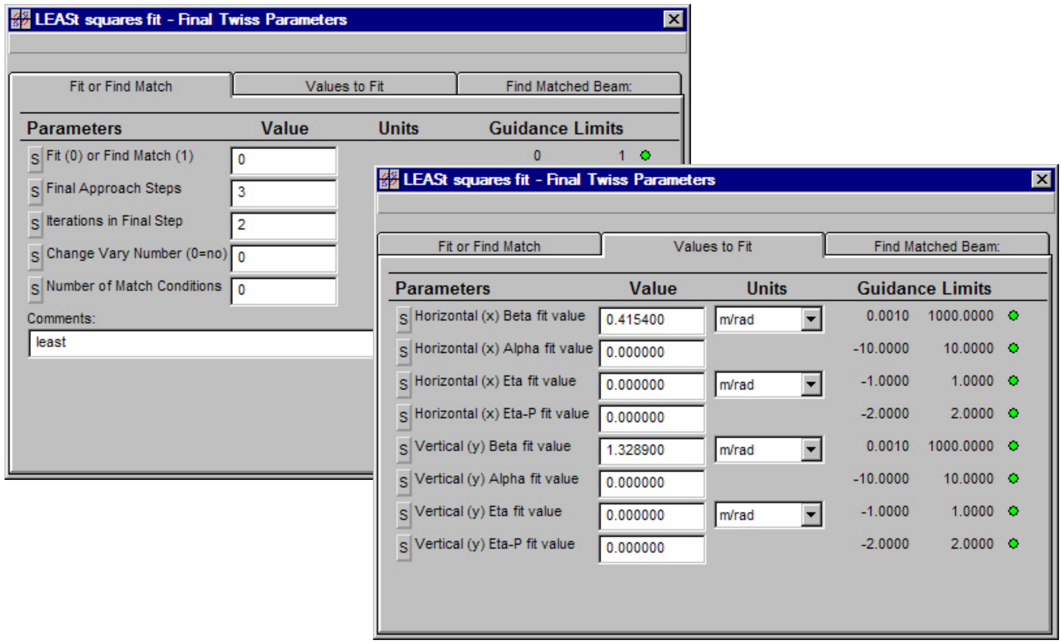

Figure 3: Input parameter tab pages for the “LEASt Squares Fit…” Command Piece window.

The first four letters of the Command Piece name, "LEASt squares fit ..." are intentionally capitalized: those letters represent the DIMAD keyword for this operation. However, users need not know this keyword, nor learn any of the other input file syntax and format for DIMAD's least squares fitting operation. The Command Piece Window (Figure 3) provides text descriptions of all parameters. The OASIS Module Builder syntax specification for this Command Piece provides PBO Lab with the necessary instructions needed to write the parameters in the correct format, and in the correct location, to the DIMAD input file. Users simply set the fitting goals using the parameters of the Command Piece Window illustrated in Figure 3.

The least squares fitting computation is just one example of available operations implemented for the DIMAD Application Module. A variety of other calculations are also implemented using other DIMAD Command Pieces.

## SUMMARY

A specialized software package has been developed called the Open Architecture Software Integration System, or OASIS, that can be used to create custom Modules for the Particle Beam Optics Laboratory (PBO Lab). OASIS builds upon the capability of PBO Lab to host a suite of different codes, and provides an innovative framework that enables users to rapidly implement custom beam optics modules. The custom modules will run in PBO Lab without writing or compiling any source code.

# AN INNOVATIVE GRAPHIC USER INTERFACE FOR PARMILA 2

G. H. Gillespie and B. W. Hill
G. H. Gillespie Associates, Inc., P. O. Box 2961, Del Mar, CA 92014, USA

## [illegible]

A new graphic user interface (GUI) has been created for the PARMILA 2 program. PARMILA 2 is an advanced version of the historical PARMILA program originally developed to design and model drift tube linear (DTL) accelerators. PARMILA 2 expands upon that capability to support the design and simulation of coupled cavity linear (CCL) accelerator structures, coupled-cavity drift tube linac (CC-DTL) structures, superconducting accelerator structures, as well as DTL structures and transport lines that can include magnetic, radiofrequency and electrostatic beam optics elements. A new software package called the Open Architecture Software Integration System, or OASIS™, has been used to develop an innovative graphic interface for the PARMILA 2 program. OASIS provides a framework for developing custom modules for the Particle Beam Optics Laboratory (PBO Lab™) software. The framework can be used to create new PBO Lab modules [illegible] *a* [illegible] Tools in the OASIS software were utilized to define the GUI features of the new PARMILA 2 module. Existing PARMILA 2 executables, including Parmila.exe, Lingraf.exe and readdst.exe, have been linked to GUI commands utilizing other tools within the OASIS framework. This paper presents an overview of the new PARMILA 2 module and illustrates some of the GUI features.

## INTRODUCTION

PARMILA (Phase and Radial Motion in Ion Linear Accelerators) is a well established computer code [1] used for the design and simulation of proton (and heavier particle) linear accelerators. The program has a long history and the version 2 developed at the Los Alamos National Laboratory includes design capabilities for drift tube linacs (DTLs), coupled cavity linacs (CCLs), coupled cavity drift tube linacs (CCDTLs) and several types of superconducting linac structures [2, 3]. One challenge to users of PARMILA has been acquiring a good knowledge of the detailed input file format required by the program. The development of an intuitive, easy-to-use graphic interface for PARMILA 2, as an Application Module of the Particle Beam Optics Laboratory (PBO Lab), directly addresses that challenge.

PBO Lab is a modular suite of commercial software applications which has Application Modules that support a variety of particle beam optics programs and other accelerator-related codes [4]. Each optics program Application Module incorporates a specific particle beam optics modeling or simulation program. Available modules include TRANSPORT [5], TURTLE [6], MARYLIE [7], TRACE 3-D [8] and DECAY-TURTLE [6]. Other modules are also available, including an Optimization Module utilizing the NPSOL [9] and MINOS [10] nonlinear constrained optimization programs, and specialized modules for modeling electrostatic elements [11] and traveling wave accelerator components [12]. PBO Lab provides a common graphic user interface (GUI) for constructing and editing iconic object-based computer models of accelerators and beamlines. The common GUI for optics programs in PBO Lab simplifies the task of carrying out calculations for a given beamline. PBO Lab assures that the input files for every optics program represent the same beamline, and PBO Lab will automatically display graphical results that may otherwise require post-processors. Users do not need to construct input files in the format required by a specific program -- PBO Lab takes care of all the needed bookkeeping, and the object model automatically creates the necessary input files following simple menu commands issued by a user.

## PBO LAB PARMILA-2 MODULE

The requirements to develop a workable GUI for PARMILA were outlined some years ago [13] and a prototype concept was described at the 1994 Linac Conference [14]. For a variety of reasons, further progress was limited until a new approach for creating optics code GUIs for PBO Lab became available. The new approach was provided by the Open Architecture Software Integration System, or OASIS. Developed under the auspices of the U. S. DOE Small Business Innovation Research (SBIR) program, OASIS [15] provides the type of reusable framework required for rapidly creating PBO Lab Application Modules without the need to write any new source code, for either the GUI (PBO Lab) or the associated physics code (e.g. PARMILA). In brief, OASIS is a new PBO Lab Module that is used to create additional PBO Lab Modules, where the GUI and related object model themselves provide the creative framework.

The document (or start up) window for the PARMILA-2 Module is basically the same as that for any other PBO Lab Module. Figure 1 illustrates an example document window which has an iconic description of a drift tube linac (DTL) model displayed. The DTL model was created by using the "drag and drop" construction kit of the PBO Lab software. Several custom features of the PARMILA-2 Module are pointed out in Figure 1.

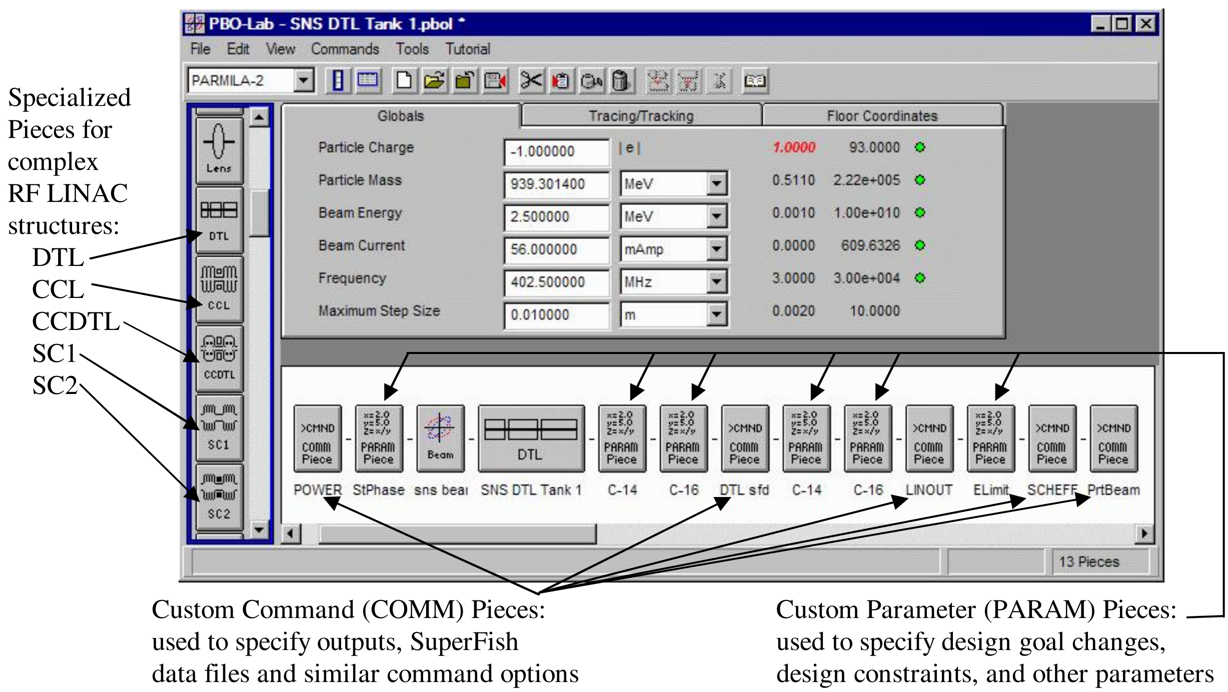

Figure 1: The standard PBO Lab Document Window is used for the PARMILA-2 Module. This example shows a beamline model for a single-tank drift tube linac (DTL) accelerator.

Figure 1 shows a number of icons representing new PBO Lab Pieces created for the PARMILA Module. The new Pieces are of three types: Palette Pieces, Command (COMM) Pieces and Parameter (PARAM) Pieces. Each of the newly created Pieces corresponds to specific lines in a PARMILA 2 input file [3]. Table 1 summarizes most of the new Pieces. The entries listed for the COMM and PARAM Pieces give the corresponding PARMILA keywords implemented for those Piece types.

The PBO Lab data input windows (Piece Windows) provide a complete description of the command or parameter that will be utilized -- not just the keyword. It is beyond the scope of this paper to describe the implementation in detail here, but an example illustrates how this assists users. Figure 1 illustrates the use of several PARMILA "Change" types. These are identified by the Piece comments "C-14" and "C-16" which appear as labels below the corresponding PARAM Pieces.

In constructing a PARMILA-2 beamline, a scrolling list window is used to select Pieces that contain Change types. Figure 2 shows the list window for the PARMILA-2 Parameter Pieces. All PARAM Pieces are given brief word descriptions. Figure 2 illustrates the selection "m. Ramp Quads w Energy" which corresponds to Change type 14, discussed in the PARMILA 2 documentation in subsection "m" of the Change section. Similarly, the item "o. Gradient of First DTL Quad" corresponds to Change type 16. A Change type PARAM Piece, that is selected and created using the "Create Piece" button shown in Figure 2, will have a default label (e.g. "C-12") which identifies the Change type that will appear in the PARMILA 2 input file (e.g. "CHANGE 12"). Users need not look up any Change type code, or the format for a Change type, in order to implement a specific type of Change. Users simply select from the descriptions appearing in the PARMILA-2 Parameter Piece list window (Figure 2).

Table 1: Examples of custom PBO Lab Pieces developed for the PARMILA 2 Module using the OASIS framework. PARMILA 2 keywords implemented through COMM and PARAM Pieces are listed under the respective columns.

| Palette Pieces | Command (COMM) Pieces | Parameter (PARAM) Pieces |
|---|---|---|
| DTL, CCL | SCHEFF, LINOUT, POWER, | Change Types (20+ Pieces) |
| CC-DTL | PrtBeam, SFDATA, TRANSPORT, | ExQ Types (7+ Pieces) |
| SC1, SC2 | Quad OPTIONS, MPOLES, … | Elimit, StartPhase, ErrorSeed, … |

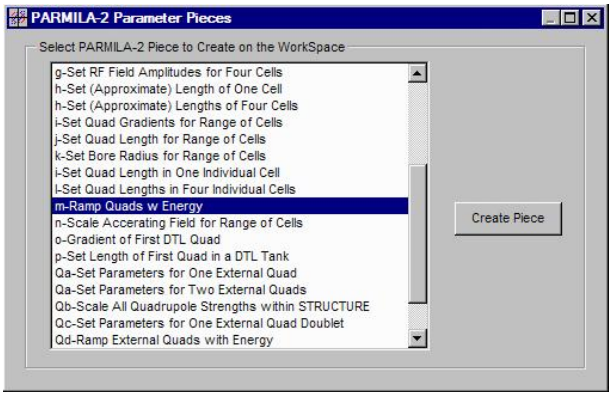

Figure 2. Scrolling list window used for selecting and creating PARMILA-2 Parameter Pieces.

Other custom Command and Parameter Pieces developed for the PARMILA-2 Module provide simple text descriptions of their function. The corresponding Piece Windows likewise provide descriptive information useful for specifying any needed input parameters. The format and syntax for each line in the PARMILA 2 input file is automatically handled by the PARMILA-2 Module.

Standard transport elements supported by PARMILA 2 (i.e. drifts, quadrupoles, bends, etc.) are implemented using the standard PBO Lab Pieces for those elements, requiring no additional objects in the PBO Lab object model. In a few cases, additional parameters have been added to the standard Pieces in order to support specific PARMILA capabilities, such as specifying the number of times space charge forces are computed in a drift element.

The PARMILA program can be used in a design mode or a simulation mode, and the new Module has been developed to support both modes. Location specific commands and parameters are set up using the custom created Command and Parameter Pieces.

## SUMMARY

An innovative GUI has been developed for the PARMILA 2 accelerator design code, implemented as an Application Module for the Particle Beam Optics Laboratory. This new PBO Lab PARMILA-2 Module was created using the Open Architecture Software Integration System.

# SIMULATION OF EMITTANCE GROWTH USING THE UAL STRING SPACE CHARGE MODEL

Richard Talman, Cornell University, Ithaca, NY, USA, Nikolay Malitsky, Brookhaven National Laboratory, Upton, NY,USA, and Frank Stulle, CERN, Geneva, Switzerland

*Abstract*

Evolution of short intense electron bunches passing through bunch-compressing beamlines is simulated using the UAL (Unified Accelerator Libraries) string space charge formulation.[1] Excellent agreement is obtained with results obtained experimentally at CTF-II, the CERN ``Compact Linear Collider" test facility[2]. The 40 MeV energy of these data is low enough for Coulomb and Biot-Savart forces to be important and high enough for coherent synchrotron radiation and centrifugal space charge forces to be important. UAL results are also compared with CSRtrack [3] results for emittance growth in a 50 MeV "standard" chicane. Vertical space charge forces are found to be important in this (low energy) case.

## CALCULATIONAL MODEL

Particles are treated as strings as regards their fields but as points as regards their dynamics. Bunch evolution is treated as standard tracking but with intrabeam scattering. The force on particle A due to the (properly-retarded) field of the string associated with particle B is expressed in terms of (closed-form) elliptic integral functions. In the (rare) case when the bunch straddles a magnet edge all particles are assumed to be on the same side of the edge as A. All results have become essentially independent of the number N of macroparticles for N>400, but N-values as great as 3200 have been used in some cases. Summed over all B, for every particle A there are N impulses, making N-squared calculations per evolution step. Even so, all calculations have been done on a laptop.

CSR (coherent synchrotron radiation) results from self-work of the bunch acting on itself---validity of Newton's third law requires the inclusion of field momentum. All static (electric and magnetic) forces plus all coherent longitudinal (CSR) and transverse CSCF (centrifugal space charge force), as well as radiative effects, are included. Since there is no need for "regularization" to suppress singularity, bends and drifts are treated homogeneously. Extreme relativistic approximations (such as neglect of vertical forces) are avoided.

## SIMULATION OF CTF-II MEASUREMENTS

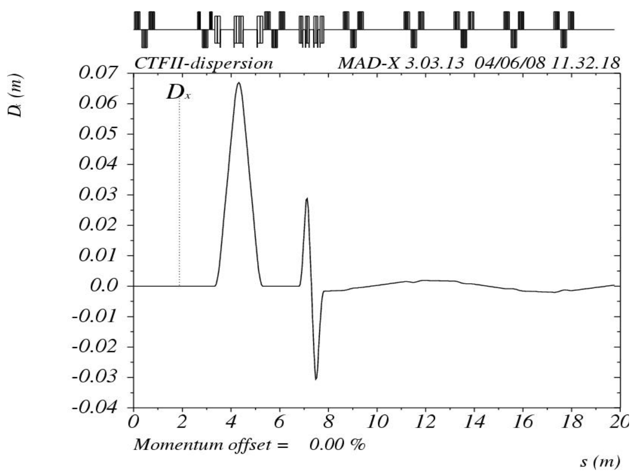

Figure 1: Beamline dispersion, showing "compressor" chicane (C shape) and "shielded" chicane (S shape).

Emittance growth in a bunch compressor has been studied experimentally[2] at the CTF-II (CERN Compact Test Facility), shown in Fig. 1, using electrons of energy 40 MeV. No shielding of CSR by vacuum chamber walls was detected, and the present simulation assumes this to be true. Input and output momentum spectra are shown in Fig. 2. Substantial momentum spreading is visible.

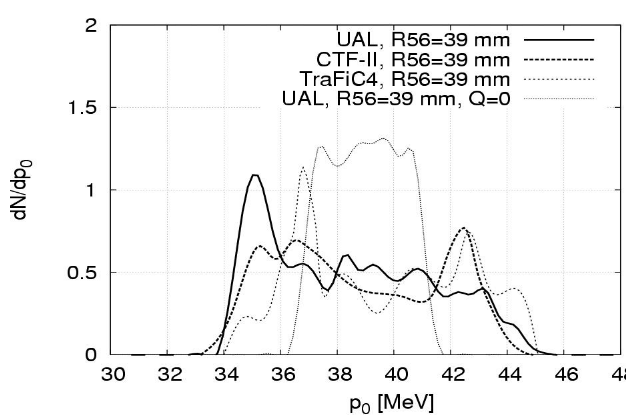

Figure 2: Bunch momentum spread at beamline output with no space charge (narrow square pulse) and with Q=10nC, as measured (label CTF-II) and as simulated by UAL and by (an early version of) TraFiC4.

Dependence of CSR energy loss on bunch length and on R56 value at S-chicane location, was measured for Q=15nC. See Fig. 3. The present simulation, having no empirically adjustable parameters, agrees well within error bars with the measurements. This confirms theoretical expectations concerning CSR.

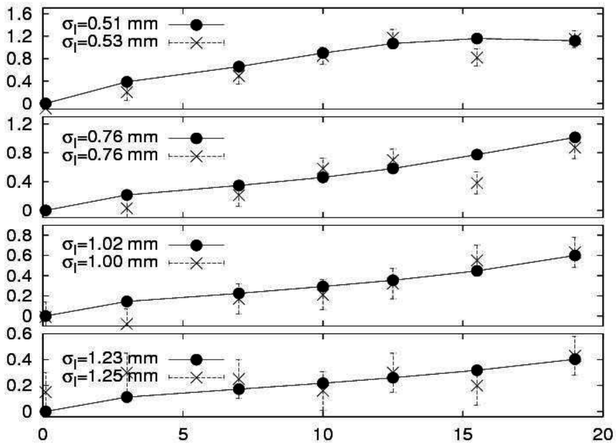

Figure 3: Energy loss in MeV as function of S-chicane R56 value in mm, for the four values of r.m.s. bunch length (adjusted using the C-chicane) labeling the figures. The measured values have error bars.

An unexpected (at the time) result reported was a quite strong increase in horizontal emittance for small beta function values at the C-chicane location (with S-chicane turned off). The data and simulation is shown in Figure 4. The present simulation agrees at least semi-quantitatively with the measurements.

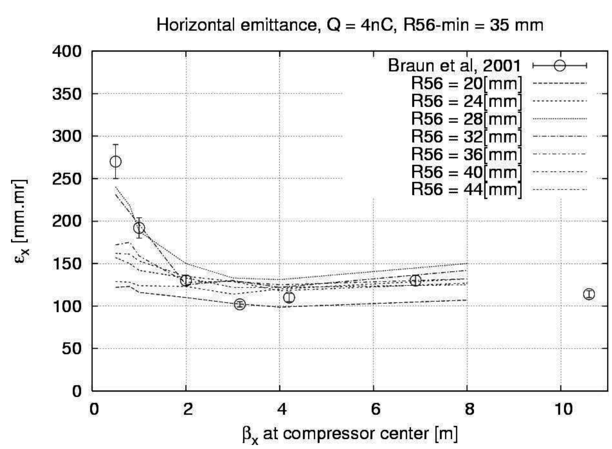

Figure 4: Dependence of output horizontal emittance on horizontal beta function at the C-compressor.

## UAL CSRTRACK COMPARISON

To enable controlled comparison of UAL with the CSR-aware code CSRtrack[3], the 50 MeV benchmark chicane shown in Fig. 5 was designed. Parameters are given in Table 1. All distributions are Gaussian.

Table 1: Chicane and Beam Parameters

| Chicane Parameters | Symbol | Value, Unit |
|---|---|---|
| Dipole length | $L_B$ | 0.50 m |
| Drift length | $L_D$ | 5.00 m |
| Drift length | $L_i$ | 1.00 m |
| Total chicane length | $L_{\text{tot}}$ | 13.00 m |
| Nominal bending angle | $\alpha_0$ | 2.77 deg |
| Nominal momentum compaction | $R_{56}$ | -25.00 mm |

| Electron Beam Parameters | Symbol | Value, Unit |
|---|---|---|
| Electron energy | $E_0$ | 50 MeV |
| Bunch charge | $Q_0$ | 1.0 nC |
| Initial rms bunch length | $\sigma_{s,i}$ | 200 $\mu$m |
| Initial peak current | $I_{p,i}$ | 600 A |
| Initial uncorrelated rms energy spread | $\sigma_{E,rms}/E_0$ | 0.01 % |
| Initial energy-position correlation | $1/E_0\, dE/ds$ | -20.1 m$^{-1}$ |
| Initial normalized emittance | $\epsilon_{n,x}$ | 1.0 mm mrad |
| | $\epsilon_{n,y}$ | 1.0 mm mrad |
| Twiss functions at chicane entrance | $\beta_{x,i}$, $\alpha_{x,i}$ | 80.41 m, 6.254 |
| | $\beta_{y,i}$, $\alpha_{y,i}$ | 22.80 m, 3.110 |

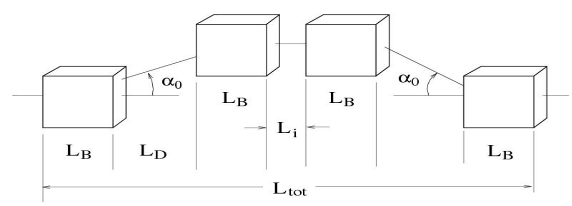

Figure 5: Chicane sketch.

Due to the low energy but high bunch intensity this benchmark case is deliberately made extreme regarding CSR emission and emittance blow-up.

To emulate CSRtrack (which neglects vertical intrabunch forces) the UAL simulation was run with all vertical intrabunch forces suppressed. This simplification is justified at high electrons energies since then the electromagnetic fields are confined to a narrow cone, i.e. vertical and also horizontal field components are small. But it should breakdown at low energies. Table 2 shows excellent agreement of simplified UAL and CSRtrack simulations for the benchmark case; the output vertical emittances 74.1 and 72.6 mm.mrad, differ by 2 percent. Figure 6 shows final horizontal phase space distributions. The most striking difference is the speed advance of UAL over CSRTrack by several orders of magnitude.

Table 2: UAL CSRtrack Comparison

| Quantity | Unit | CSRtrack | UAL-NoVert | UAL-True |
|---|---|---|---|---|
| $\epsilon_{x,n}\|_{in}$ | mm.mrad | 1.005 | 0.982 | 0.982 |
| $\epsilon_{x,n}\|_{out}$ | | 74.10 | 72.6 | 57.2 |
| $\epsilon_{y,n}\|_{in}$ | mm.mrad | 1.0 | 1.04 | 1.04 |
| $\epsilon_{y,n}\|_{out}$ | | 1.0 | 1.04 | 3.50 |
| $\sigma_E\|_{in}$ | % | 0.402 | 0.40 | 0.40 |
| $\sigma_E\|_{out}$ | | 0.532 | 0.56 | 0.48 |
| $\sigma_l\|_{in}$ | $\mu$m | 200.2 | 199 | 199 |
| $\sigma_l\|_{out}$ | | 190.3 | 191 | 184 |

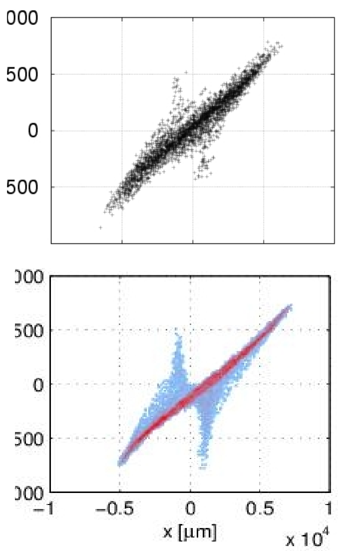

Figure 6: Output phase space distributions, UAL above, CSRtrack below, agree very well (except for a tiny relative horizontal displacement). Residual linear dispersion has been subtracted in these plots.

To investigate the effect of vertical forces, the UAL simulation was also run with all forces, including vertical, retained. According to this simulation the horizontal emittance increase, shown in Table 2, from 57.2 to 72.6 mm.mrad is an artefact of the neglect of vertical forces. Note the substantial increase in vertical emittance, from 1.04 to 3.50 mm.mrad, that accompanies the inclusion of vertical forces.

## ACKNOWLEDGEMENTS

This work is partially supported by the NSF, by the DOE, and by the Commission of the European Communities under the 6th Framework Programme ``Structuring the European Research Area'', contract number RIDS-011899. The Paul Scherrer Institut and the Swiss National Supercomputing Center (CSCS) provided access to a Cray XT3 supercomputing facility.

*Abstract*

The DARHT-II linear induction accelerator (LIA) accelerates a 2-kA electron beam to more than 17 MeV. The beam pulse has a greater than 1.5-microsecond flattop region over which the electron kinetic energy is constant to within 1%. The beam dynamics are diagnosed with 21 beam-position monitors located throughout the injector, accelerator, and after the accelerator exit, where we also have beam imaging diagnostics. We discuss the tuning of the injector and accelerator, and present data for the resulting beam dynamics. We discuss the tuning procedures and other methods used to minimize beam motion, which is undesirable for its application as a bremsstrahlung source for multi-pulse radiography of explosively driven hydrodynamic experiments. We also present beam stability measurements, which we relate to previous stability experiments at lower current and energy.

## INTRODUCTION

The 2-kA, 17-MeV DARHT-II linear induction accelerator (LIA) is unique in that its beam pulse has a long, 1.6-μs flattop during which the kinetic energy varies by less than ±1%. A kicker cleaves four short pulses out of this long pulse, and these are converted to bremsstrahlung for multi-pulse flash radiography of high explosive driven hydrodynamic experiments.

The long-pulse 2-kA beam is produced in a 2.5-MV diode. A diverter switch (crowbar) is incorporated to shorten the 2-μs flat-top pulse to as little as 200 ns flat-top (Fig. 1). After leaving the diode, the beam is accelerated by six induction cells to ~3.5 MeV, and then enters a transport zone designed to scrape off the long rise time, off-energy beam head. As in previous experiments [1,2,3], this beam-head clean-up zone (BCUZ) was configured to pass almost the entire beam head. The main LIA has 68 induction cells that have been upgraded to provide enough potential to accelerate the beam to more than 17 MeV. Each accelerating cell incorporates a solenoid to provide the focusing field for beam transport, as well as dipoles for beam steering.

The solenoids in the injector cells are tuned so that none of the off-energy electrons in the ~500-ns beam head are lost, even in the absence of accelerating fields. The solenoids through the main accelerator were tuned to transport a matched beam through a field increasing to more than 1 kG on axis to suppress beam breakup (BBU).

The tunes for the DARHT-II magnetic transport were designed with two envelope codes, XTR [4] and LAMDA [5]. These solve the beam-envelope differential equations keeping terms that are dropped from the usual paraxial approximation [6]. Initial conditions for XTR and LAMDA were provided by simulations of the space-charge limited diode using the TRAK gun-design code [7] and the LSP particle-in-cell code [8].

Non-invasive DARHT-II beam diagnostics, such as beam position monitors (BPM), are used on every shot [2,3]. Invasive diagnostics, such as a magnetic spectrometer and beam current profile imaging, are only occasionally used [1,2,9].

## RESULTS

There was no loss of beam current through the LIA during the time that the accelerating cells were energized, as shown in Fig. 1, which is an overlay of beam current measurements though the injector and accelerator for a single shot. The ~7-MHz oscillation on the beam head is the result of large capacitances and inductances on the diode structure. The loss of some current in the beam head as it transited the BCUZ is evident. For these data, the current was terminated by the crowbar, which was timed to coincide with the end of the accelerating cell pulse. The red cursors in Fig. 1 delineate the 1.6-μs flattop used for the four radiography pulses. Slight beam loss in the BCUZ during the risetime is evident. Figure 2 shows the electron kinetic energy measured with our magnetic spectrometer. The kinetic energy of the accelerated beam exceeds 17.0 MeV for more than 1.6 μs. For this measurement five of the LIA cells were turned off, which reduced the energy by ~1.3 MeV from that expected with all 74 cells.

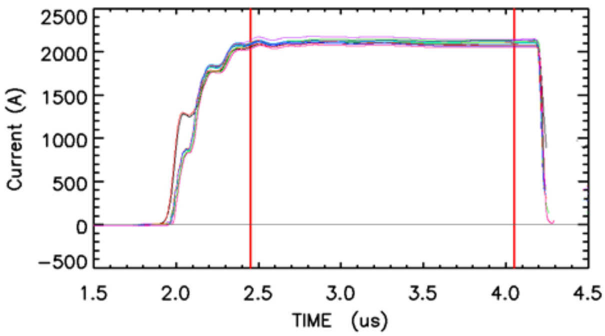

Figure 1: Overlay of beam current measurements in injector and accelerator. Red cursors indicate the 1.6-µs flattop region used for the four radiography pulses.

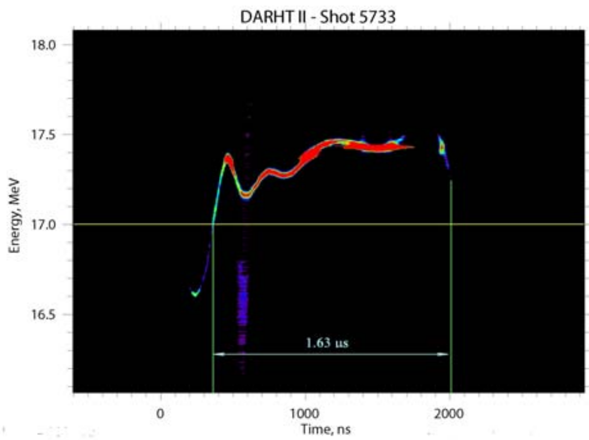

Figure 2: Magnetic spectrometer measurement of electron kinetic energy.

Low frequency beam motion at the exit of the accelerator was dominated by an energy dependent sweep. This sweep is undesirable because it effects the locations of the four radiography pulses, so we must understand it, and reduce its amplitude . While head-to-tail sweep is a characteristic of the resistive wall instability, we believe it unlikely that this instability is responsible for the sweep in DARHT-II. In a uniform strong solenoidal focusing field the distance for an initial perturbation to exponentiate is approximately $L = 3.1Ba^3/I_b/(\tau\rho)^{1/2}$, where $a$ is the pipe radius in cm, $B$ is the field in kG, $I_b$ is the beam current in kA, $\tau$ is the pulse-length in µs, and $\rho$ is the pipe resistivity in µΩ-cm [10]. Based on this theory, we estimate that the growth of an initial perturbation in DARHT-II is less than 60% over the length of the LIA. Moreover, in a strong solenoidal focusing field like DARHT-II the growth is independent of energy, in contradiction to our sweep data, which show a strong correlation with the energy variation illustrated in Fig. 2. The other likely cause of sweep is corkscrew, or the interaction of the energy-varying beam with a few accidental dipoles. Indeed, the observed sweep amplitude can be fit to a model of dipole deflection resulting from the observed energy variation (Fig. 3). Suppression of corkscrew by using steering dipoles has been demonstrated on other LIAs [11]. In an initial attempt to reduce our sweep amplitude, we used only a few of the available steering dipoles. We were able to reduce the sweep to an amplitude acceptable for commissioning the multi-pulse radiography target, and for our first radiographs of an upcoming hydrodynamic test. This initial attempt reduced the sweep amplitude by ~40% over the 1.6-µs flat top (Fig. 4). We anticipate further improvements in the future by using more of our dipoles.

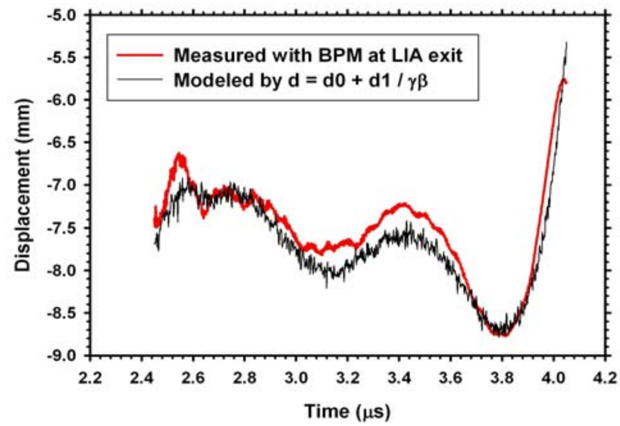

Figure 3: Comparison of measured sweep with model of sweep caused by beam energy variation interacting with a single accidental dipole.

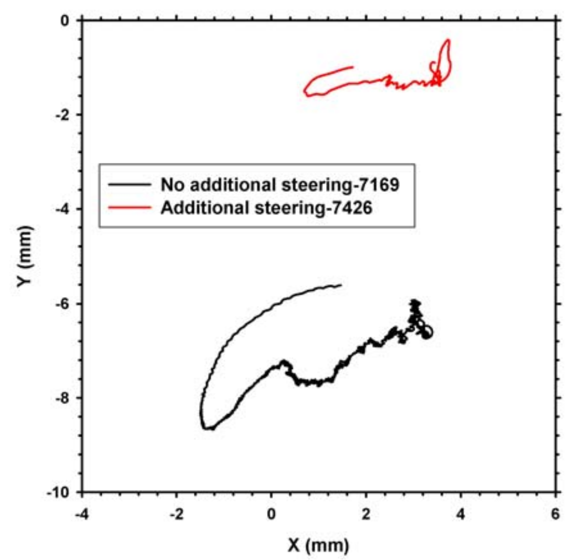

Figure 4: The beam sweep at the accelerator exit was reduced by using additional steering dipoles. Two different shots are shown. Black (lower): nominal steering. Red (upper): additional steering.

High-frequency motion due to low-amplitude BBU was observed at the accelerator exit [12]. For the DARHT-II LIA parameters theory predicts that the BBU amplitude saturates at $\xi(z)=(\gamma_0/\gamma)^{1/2}\xi_0\exp(\Gamma_m)$, where subscript zero denotes initial conditions, and $\gamma$ is the usual relativistic mass factor, and $\Gamma_m = I_b N_g Z_\perp \langle 1/B \rangle / 3\mathrm{x}10^4$ [13]. Here $I_b$ is the beam current in kA, $N_g$ is the number of gaps, the transverse impedance $Z_\perp$ is in $\Omega$/m, and the average focusing force $\langle 1/B \rangle$ is in $\mathrm{kG}^{-1}$. This theoretical prediction was confirmed in earlier experiments with legacy cells [3], and those results were used to design a tune with magnetic field strong enough to suppress the BBU to amplitude small enough that it did not significantly affect the measured radiographic spot size [15]. The observed BBU with this tune agrees with the earlier measurements and with this theory as shown in Fig. 5.

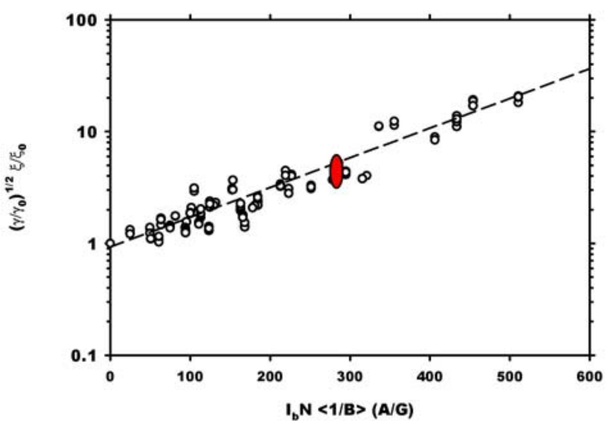

Figure 5: BBU growth in DARHT-II. Open circles: data obtained in low-current, low-energy experiments with legacy cells [3]. Filled oval: range of data obtained during commissioning the 2-kA, 18-MeV accelerator incorporating upgraded cells. The dashed line corresponds to the transverse impedance of the legacy cells.

In conclusion, we have now operated the DARHT-II accelerator at its fully rated current, energy, and pulse width. Even at the full 2-kA current, the solenoidal magnetic field of the tune was strong enough to suppress the BBU to acceptable amplitude. After some additional steering to reduce the sweep, the beam was stable enough for us to proceed with commissioning the multi-pulse kicker and bremsstrahlung converter for radiography.

# ARTIFICIAL INTELLIGENCE RESEARCH IN PARTICLE ACCELERATOR CONTROL SYSTEMS FOR BEAM LINE TUNING*

Martin Pieck†, Los Alamos National Laboratory, NM 87544, USA

*Abstract*

Tuning particle accelerators is time consuming and expensive, with a number of inherently non-linear interactions between system components. Conventional control methods have not been successful in this domain, and the result is constant and expensive monitoring of the systems by human operators. This is particularly true for the start-up and conditioning phase after a maintenance period or an unexpected fault. In turn, this often requires a step by step restart of the accelerator. Surprisingly few attempts have been made to apply intelligent accelerator control techniques to help with beam tuning, fault detection, and fault recovery problems. The reason for that might be that accelerator facilities are rare and difficult to understand systems that require detailed expert knowledge about the underlying physics as well as months if not years of experience to understand the relationship between individual components, particularly if they are geographically disjoint. This paper will give an overview about the research effort in the accelerator community that has been dedicated to the use of artificial intelligence methods for accelerator beam line tuning.

## BEAM LINE TUNING

A typical accelerator beam line includes trim magnets for steering, quadrupole magnets for focusing, Faraday cups and stripline detectors for measuring current, and profile monitors for measuring beam size and position. Beam loss monitors give information about loss of beam through miss-steering. Unfortunately, real systems rarely work as they are designed. Problems arise from imperfect beam production, residual magnetic fields, poorly modeled beam behavior, misplaced or flawed control elements, and changes to the design or use of the facility after it has been built. Beam line designers consider these problems and build diagnostic components into the beam lines. Profile monitors and current detectors are used to measure beam parameters throughout the line to provide information for verifying or correcting beam characteristics. Even so, imperfect detectors, system errors, and noise due to various effect cause beam line control to be difficult at best. Surprisingly, few attempts have been made to apply intelligent accelerator control techniques to help with beam tuning, fault detection, and fault recovery problems.

*This work has benefited from the use of the LANSCE at LANL. This facility is funded by the US DOE and operated by LANS for NSSA under Contract DE-AC52-06NA25396.

## PREVIOUS AI ATTEPMPTS TO ACCELERATOR CONTROL

An early example of AI technology applied to accelerator control can be found in Higo et al. [1]. In this work a rather simple objective of maintaining a given system or operation condition has been discussed. AI is relevant here for dealing with the complex problems of generalized hysteretic and stochastic effects.

Weygand [2] reports on a development for a knowledge-based, domain specific expert system at Brookhaven National Laboratory. The purpose of the expert system is to aid in the control of the Heavy Ion Transfer line (HITL) and in turn to minimize down time after a change in running conditions or the start of a new run. Due to the complexity of the expert system it was divided up into three domains (control, device beam influence, and device cause and effect segment). Separate from that is the goal-solving mechanism of the program. This goal-solving function takes a specified high level goal, and then, by developing a tree of sub-goals, attempts to solve the given goal via a hill-climbing technique. However, the system doesn’t take into account that conditions may change during the execution of the solution.

Other attempts at intelligent control for accelerators include the ISIS tune advisor (Schultz et al. 1990), the LAMPF Beam Loss Expert (Clearwater et al. 1986), and a learning system based on RL4 (Clearwater et al. 1990). The ISIS tune advisor and LAMPF Beam Loss Expert were both expert systems for indirect control which were never implemented as general or real-time control solutions. The learning system used knowledge-based induction for off-line learning of beam position monitor placement, but was not implemented as a general learning algorithm.

Neural networks have been applied to accelerator control for actual manipulation of control parameters as well as for simulation. Howell et al. [3] used neural networks for modeling and control of a negative-ion accelerator source at Los Alamos National Laboratory to predict the beam characteristics of the source for given changes in control settings. However, the success was rather limited.

Brown [4] developed an automated controller based on an artificial neural network and evaluated its applicability in a real-time environment. This capability was developed within the context of a small angle negative ion source on the Discharge Test Stand at Los Alamos National Laboratory. Using no knowledge of operating conditions, the controller begins acquiring rough snapshot of the operational condition. Once the rough approximation of the condition has been determined, the network formulates a model from which it determines the best operating point. The controller takes the ion source to that operating point for a reality check. As real data is fed in, the model of the operating surface is updated until the neural network's model agrees with reality. The controller then uses a gradient ascent method to optimize the operation of the ion source. Mead (1994) presents some successful control examples of the above application.

The SETUP program developed at CERN (Bouche 1995) is representative of efforts to apply AI techniques to small subsystems. SETUP is only used for pre-control equipment setup. The program uses an object-oriented description language for representing control actions. The reasoning system searches the oriented graph defined by an object description to make decisions about equipment setup without human assistance. The program provides a good example of using object models for control decision making. It does not attempt to perform real-time control or use on-line feedback from the system.

Arruat [5] reports on symbolic computing programs that address not only the manipulation of mathematical functions, but also process control. He uses symbolic computing as a tool for developing algorithmic engines that can be fully integrated in the controls environment and facilitates modular design of control systems. He reports that this technique has been applied to a special class of accelerator problems, namely the beam steering in transfer lines and accelerator rings in the CERN PS Complex.

In his Ph.D. dissertation Jennings [6] developed and implemented a new model of multi-agent coordination, called *Joint Responsibility*, based upon the notion of joint intentions. The Responsibility framework was devised specifically for coordinating behavior in complex, unpredictable and dynamic environments such as particle accelerator control. Jennings contribution was that he noticed that in a distributed multi-agent system when anything unexpected happened (i.e. new information invalidated existing goals, synchronization between actions was disrupted or agents had misinterpreted the situation) the multi-agent community would act incoherently. This incoherence occurred because agents did not embody sufficient knowledge about the process of team problem solving. Jennings provided agents with an explicit model of joint problem solving about which they could reason when deciding how to interact with others. This new development found its application in ARCHON.

ARCHON (1993-1996) was Europe's largest ever project in the area of Distributed Artificial Intelligence (DAI) and applied to CERN control systems for controlling and diagnosing faults in one of their particle accelerators (called the Proton Synchrotron (PS)). The Archon-project, which Jennings was in charge of, provided the architecture for integrating multiple pre-existing expert systems to exchange information and, therefore, increase the overall performance.

Another application of AI techniques in operating a larger system is in the field of fault detection and system diagnosis. Leger et al. (1996) points out that in order to operate a successful plant, continues improvement must be made in the areas of safety quality and reliability. Central to this continuous improvement is the early or proactive detection and correct diagnosis of process faults. The paper examines the feasibility of using cumulative summation control charts and artificial neural networks together for fault detection and diagnosis (FDD). The control chart and neural network are linked by using a characteristic fault signature pattern for each fault, which is to be detected and diagnosed.

In one of the first papers from Klein and Luger [2] on beam tuning, a framework of a general purpose intelligent control system for a particle accelerator has been presented. Results of coupling neural network and expert systems technology to solve several standard accelerator tuning problems based on realistic simulations have been discussed. The authors also examine the effectiveness of additional heuristic search techniques such as genetic algorithms. However, the algorithm did not converge towards specific solution methods to create the desired result. To solve the problem, the authors also examined the capabilities of an analytic control algorithm, fuzzy logic (FL) control, and genetic algorithm searches. It was noticed that the accuracy of the FL solution depended greatly on the quality of the knowledge the author placed in the system. The genetic algorithm is an appropriate heuristic for focusing control because it can search large solution spaces in non-linear domains.

In continuation of their earlier work Klein and Luger (Klein et al. 1997(a)) have identified two different sources of control information that must both be incorporated into any successful automated control system. The first source includes analytic domain knowledge necessary for modeling the accelerator and beam line. The second, equally important source is experiential knowledge about the specific facility and group of components being controlled.

Stern (Stern et al. 1997) reports on the continuing work of Klein on coordinating the activity of the control subsystems to adaptively execute sustained sequences of control actions of the type required to tune the whole accelerator in a coordinated fashion. The discussed control system employs a multi-layer organization in which knowledge–based decision making is used to dynamically configure a lower level optimization and control algorithm. An object-oriented physical access layer supported by a distributed control system allows abstraction from the lower level details of hardware manipulation, signal processing, and synchronization.

This hybrid architecture integrates a variety of methodologies, including teleo-reactive trees for dynamic exception handling and re-planning.

In Klein's last paper [7] he discusses the results of their research on the use of Teleo-Reactive programming as a high level control mechanism. According to the authors, control of particle accelerators requires a hybrid architecture which includes methodologies for planning, intelligent search, and pattern recognition. The author's suggestion is that control must be distributed and hierarchical to utilize parallel problem-solving in the face of time-sensitive control requirements and to decompose complex control problems into more manageable subtasks. As a high level control mechanism, the authors used a planning technique known as Teleo-Reactive (TR) programming developed by Nils Nilsson at Stanford. TR programming combines the responsiveness of an analog feedback loop and the goal-oriented behavior of a production system, to allow the control system to govern the execution of its tasks in a dynamic environment. The system has been successfully tested at both the Brookhaven National Laboratory ATF and at the ATLAS facility at Argonne National Laboratory.

Fiesler [8] reports on a suit of tests on predictive algorithms to determine their ability to learn from and find relationships between large numbers of variables. In particular, they used COMFORT, a particle accelerator simulator, to generate large amounts of data. They eventually compared the results among several fundamentally different types of algorithms, including least squares and hybrid neural networks with real data that were obtained from Brookhaven National Laboratory.

## SUMMARY

It seems surprising that virtually all research on AI applied to particle accelerator stopped around the year 2000. This certainly can't be explained with the Y2K problem. Nevertheless, it seems like interest and/or funding must have stopped around that time. The alternative is, of course, that the research in the area wasn't promising or the problem was so complex that researchers did not find the return of investment very appealing to them.

Nevertheless, the author of this paper sees a great chance for AI to make its comeback in accelerator control rooms. The first and foremost reason is that running these machines has become a time and cost critical issue. The older an accelerator gets the more maintenance/upgrade work needs to be invested. This is in turn creates a problem since users/experimenters are paying to do their experiments and extensive maintenance/upgrade work reduces experimental time. With less time for experiments less money comes in for maintenance. However, less maintenance means that the accelerators become more error/fault prone. Therefore, managers have to balance down time vs. beam time and try to minimize conditioning, start-up time and fault recovery time. In addition, managers increase their attention to preventive maintenance (predicting when something might happen and then to something beforehand).

Speeding up beam tuning, advanced fault detection, and preventive maintenance (sometimes referred to as structural health) are areas where AI can and has already made an impact. Specifically applied to accelerator controls, expert beam tuning systems have been around for more than a decade, fault recovery programs got more attention at the end of the century. On the other hand preventive maintenance has never been applied to accelerator facilities. So, there is a chance here to lead the way.

*Abstract*

SLAC's Advanced Computations Department (ACD) has developed the first high-performance parallel Finite Element 3D Particle-In-Cell code, Pic3P, for simulations of RF guns and other space-charge dominated beam-cavity interactions. As opposed to standard beam transport codes, which are based on the electrostatic approximation, Pic3P solves the complete set of Maxwell-Lorentz equations and thus includes space charge, retardation and wakefield effects from first principles. Pic3P uses advanced Finite Element methods with unstructured meshes, higher-order basis functions and quadratic surface approximation. A novel scheme for causal adaptive refinement reduces computational resource requirements by orders of magnitude. Pic3P is optimized for large-scale parallel processing and allows simulations of realistic 3D particle distributions with unprecedented accuracy, aiding the design and operation of the next generation of accelerator facilities. Applications to the Linac Coherent Light Source (LCLS) RF gun are presented.

## INTRODUCTION

The Office of Science in the U. S. DOE is promoting the use of High Performance Computing (HPC) in projects relevant to its mission via the 'Scientific Discovery through Advanced Computing' (SciDAC) program which began in 2001 [1]. Since 1996, SLAC has been developing a parallel accelerator modeling capability, first under the DOE Grand Challenge and now under SciDAC, for use on HPC platforms to enable the large-scale electromagnetic and beam dynamics simulations needed for improving existing facilities and optimizing the design of future machines.

## METHODS

In the following, a brief introduction to the employed methods for solving the full set of Maxwell's equations in time domain in the presence of charged particles is given.

### *Maxwell Finite Element Time-Domain*

In our approach, Ampère's and Faraday's laws are combined and integrated over time to yield the inhomogeneous vector wave equation for the time integral of the electric field:

$$\varepsilon \frac{\partial^2}{\partial t^2} \int_{-\infty}^{\mathbf{t}} \mathbf{E}\, \mathrm{d}\tau + \nabla \times \mu^{-1} \nabla \times \int_{-\infty}^{\mathbf{t}} \mathbf{E}\, \mathrm{d}\tau = -\mathbf{J}, \quad (1)$$

where $\mathbf{E}$ is the electric field intensity, $\mathbf{J}$ is the electric current source density, and $\varepsilon$ and $\mu$ are the electric permittivity and magnetic permeability.

The computational domain is discretized into curved tetrahedral elements and $\int_{-\infty}^{t} \mathbf{E}\, \mathrm{d}\tau$ in Eq. (1) is expanded into a set of hierarchical Whitney vector basis functions $\mathbf{N_i}(\mathbf{x})$ up to order $p$ within each element:

$$\int_{-\infty}^{t} \mathbf{E}(\mathbf{x}, \tau)\, \mathrm{d}\tau = \sum_{i=1}^{N} e_i(t) \cdot \mathbf{N_i}(\mathbf{x}). \quad (2)$$

For illustration, $N_2 = 20$ and $N_6 = 216$. After accounting for boundary conditions at domain boundaries and between neighboring elements, a global number of expansion coefficients is obtained, representing the field degrees of freedom (DOFs) of the system.

Substituting Eq. (2) into Eq. (1), multiplying by a test function and integrating over the computational domain $\Omega$ results in a matrix equation, second-order in time. The unconditionally stable implicit Newmark-Beta scheme [2] is employed for numerical time integration. The resulting sparse positive definite system matrix is distributed over the compute nodes and is either factorized with a direct solver for smaller problems, or the linear system is solved iteratively at each time step with a conjugate gradient method with suitable preconditioners.

At a given moment in time, the electric field $\mathbf{E}$ and the magnetic flux density $\mathbf{B}$ are then easily obtained from the solution vector $\mathbf{e}$:

$$\mathbf{E}(\mathbf{x}) = \sum_{\mathbf{i}} (\partial_{\mathbf{t}} \mathbf{e})_{\mathbf{i}} \cdot \mathbf{N_i}(\mathbf{x}) \quad (3)$$

and

$$\mathbf{B}(\mathbf{x}) = -\sum_{\mathbf{i}} (\mathbf{e})_{\mathbf{i}} \cdot \nabla \times \mathbf{N_i}(\mathbf{x}). \quad (4)$$

### *Particle-In-Cell (PIC)*

Numerical charge conservation is critical during the self-consistent simulation of charged particles and electromagnetic fields. If the discrete analogs of the two Maxwell divergence equations $\nabla \cdot \mathbf{B} = \mathbf{0}$ and $\nabla \cdot \mathbf{E} = \rho$ are satisfied at $t = 0$, then it is sufficient to fulfill the discrete versions of wave Eq. (1) and the continuity equation

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} = \mathbf{0}$$

in order to maintain charge conservation at all times. In our approach, these conditions are satisfied by using Whitney basis functions and starting with a charge-free simulation domain.

Freely moving charges are modeled by a number of macro particles specified by position $\mathbf{x}$, momentum $\mathbf{p}$, rest mass $m$ and charge $q$ attributes. The total current density is then approximated as

$$\mathbf{J}(\mathbf{x}, t) = \sum_i \rho(\mathbf{x} - \mathbf{x_i}, t) \cdot \mathbf{v_i}(t),$$

with $\mathbf{v} = \frac{\mathbf{p}}{\gamma m}$, $\gamma^2 = 1 + |\frac{\mathbf{p}}{mc}|^2$ and $\rho$ the macro particle charge density, currently implemented for point charges and Gaussian line currents (which act as smoothing filter). The macro particles obey the classical relativistic collisionless (Newton-Lorentz) equations of motion,

$$\begin{aligned} \frac{d\mathbf{r}}{dt} &= \mathbf{v}, \\ \frac{d\mathbf{p}}{dt} &= q(\mathbf{E} + \mathbf{v} \times \mathbf{B}), \end{aligned}$$

which are integrated using the standard 'Boris' pusher, an explicit method splitting the momentum update into two accelerations and one rotation [3].

### *Causal Moving Window*

FE methods are most efficient when using (adaptive) $hpq$-refinement, where $h$ stands for the mesh resolution, $p$ for the polynomial order of the basis functions and $q$ for the degree of mesh curvature. Our current implementation supports static $h$- and $q$-refinement ($q$=1,2) as well as adaptive $p$-refinement ($p$=0...6), where each element is assigned an independent value of $p$ and its basis functions that are shared with neighboring elements are restricted to the highest common order. This requires a consistent set of hierarchical FE basis functions.

Higher-order elements not only significantly improve field accuracy and dispersive properties [4], but they also generically lead to higher-order accurate particle-field coupling equivalent to, but much less laborious than, complicated higher-order interpolation schemes commonly found in finite-difference methods.

Orders of magnitude in computational resources can be saved, while preserving full simulation accuracy, by restricting higher-order $p$-refinement to regions that are inside the causal range of the particle bunch. Since a change of the selected basis functions requires reassembly of the system matrix, adaptive $p$-refinement is usually only done from time to time, in accordance with the particle dynamics. Fig. 1 shows a Minkowski spacetime diagram indicating the causal domain for a bunch transiting through a compact structure. The causal domain can be determined from the bunch emission and exit spacetime positions, and non-causal fields are neglected by not including their elements in the computation. A resulting parallel partitioning after dynamic load balancing is shown in Fig. 2.

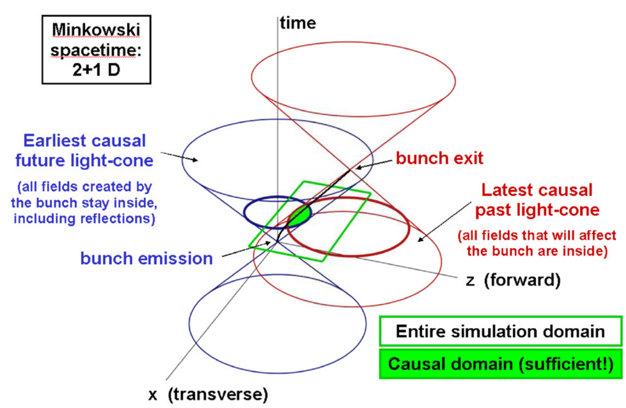

Figure 1: 2+1D spacetime diagram indicating the causal field domain for an accelerated particle bunch inside the gun at a snapshot in time.

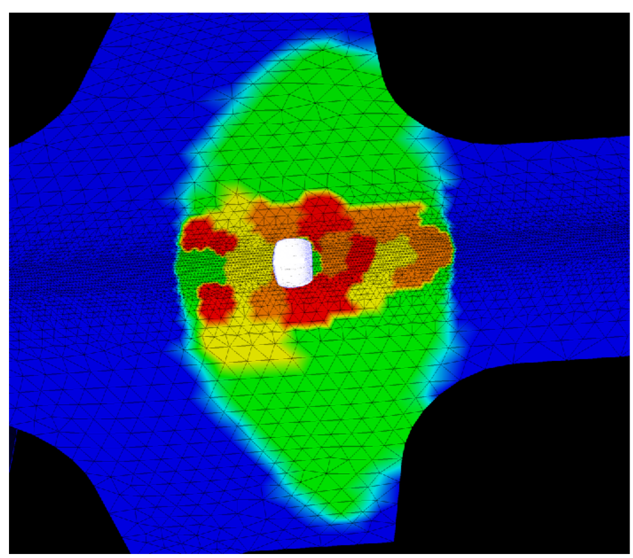

Figure 2: Example of a Pic3P simulation employing the causal moving window technique. Elements outside the causal domain are neglected in the field computations and are indicated by the blue color. Elements and fields in the causal domain are partitioned onto all CPUs with dynamic load balancing and are indicated by different colors. Macro particles are distributed among all CPUs and are shown in white.

## RESULTS

PIC simulations of the 1.6 cell S-band LCLS RF gun are presented [5]. In the simulations, the gun is driven by the $\pi$-mode with a peak accelerating field gradient of 120 MV/m at the cathode (the cavity wall). A cold, uniform, 10 ps long (flat-top), cylindrically symmetric electron bunch of 1 mm radius is emitted, centered around a phase of -58° with respect to the crest. Solenoidal focusing fields are neglected for simplicity. These parameters allow comparisons between the 3D codes Pic3P and PARMELA and the 2D codes Pic2P and MAFIA.

For Pic3P simulations, a conformal, unstructured 3D (1/4) mesh model with 305k tetrahedral elements is used, with $h$-refinement along the beam trajectory. High fidelity cavity modes are obtained with ACD's parallel FE frequency domain code Omega3P and directly loaded into Pic3P. Fig. 3 shows the evolution of the normalized transverse RMS emittance during transit through the gun for different bunch charges. There is excellent agreement between Pic3P and the 2D results from Pic2P and MAFIA, as expected from the high cylindrical symmetry in the fields and the convergence behavior of the codes. PARMELA results differ as space charge effects are significant, presumably because it ignores wakefield and retardation effects, as detailed in a previous study[6]. By using the causal window technique in Pic3P (cf. Fig. 1 and 2), the problem size was reduced by one order of magnitude without a loss of simulation accuracy. Note that Pic3P is able to solve problems that are several hundred times larger than what is needed here in order to reach convergence in the bunch emittance. Parallel dynamic load balancing and excellent scalability to thousands of CPUs result in fast turn-around times. Results on large-scale, realistic 3D simulations have been presented in the past [7].

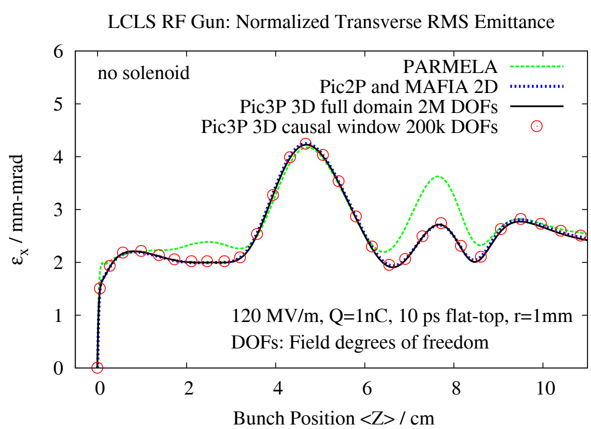

Figure 3: Comparison of normalized transverse RMS emittance as a function of beam position in the LCLS RF gun as calculated by PARMELA, Pic2P and MAFIA 2D (both agree), and Pic3P, where the causal window technique reduces the problem size by one order of magnitude.

## CONCLUSIONS

The parallel Finite Element 3D electromagnetic PIC code Pic3P, the first such successful implementation, was used to model space charge effects in the LCLS RF gun from 1$^{st}$ principles, including space charge, wakefield and retardation effects. On a cylindrically symmetric benchmark case, Pic3P shows excellent agreement with 2D codes such as MAFIA and Pic2P. Results from the electrostatic code PARMELA differ as wakefield and retardation effects are neglected.

Pic3P employs state-of-the-art parallel Finite Element methods on conformal, unstructured meshes with unconditionally stable time integration and self-consistent higher-order particle-field coupling. In combination with novel causal moving window techniques and dynamic load balancing, Pic3P allows parallel 3D PIC simulations of high-brightness, low-emittance electron injectors with unprecedented accuracy, aiding the design and operation of the next generation of accelerator facilities.

# BEAM DYNAMICS AND WAKE-FIELD SIMULATIONS FOR THE CLIC MAIN LINACS

V. F. Khan, R.M. Jones, Cockcroft Institute, Daresbury, WA4 4AD, UK
and University of Manchester, Manchester, M13 9PL, UK

*Abstract*

The CLIC linear collider aims at accelerating multiple bunches of electrons and positrons and colliding them at a centre of mass energy of 3 TeV. These bunches will be accelerated through X-band linacs, operating at an accelerating frequency of 12 GHz. Each beam readily excites wake-fields within the accelerating cavities of each linac. The transverse components of the wake-fields, if left unchecked, can dilute the beam emittance. The present CLIC design relies on heavy damping of these wake-fields in order to ameliorate the effects of the wake-fields on the beam emittance. Here we present initial results on simulations of the long-range wake-fields in these structures and on beam dynamics simulations. In particular, detailed simulations are performed, on emittance dilution due to beams initially injected with realistic offsets from the electrical centre of the cavities.

## INTRODUCTION

The CLIC scheme aims at colliding electrons and positrons at a centre of mass energy of 3 TeV. The main accelerating cavities of CLIC are normal conducting copper structures, designed to operate at 12 GHz. As the beam transits these accelerating cavities it receives a tranverse momentum kick which has the potential to result in serious beam disruption. This kick is proportional to the $a^3$, where "a" is the iris dimension. It is interesting to note that for the CLIC scenario the average iris is ~3.0 mm compared to 35 mm for the ILC superconducting cavities (which operate at an L-band frequency of 1.3 GHz). Thus, the kick imparted to the beam in the CLIC design is a factor of 1600 greater than that of the ILC cavities. Clearly, the wake-field will require careful suppression and the impact on emittance dilution will necessitate a beam dynamics study including realistic fabrication tolerances.

The present baseline design for CLIC relies on heavy damping (with Qs as low as 10) in order to suppress these wake-fields. The wake-field suppression in this case entails locating the damping materials in relatively close proximity to the location of the accelerated beam. Here a strategy originally employed for the NLC [1] in which moderate damping is imposed (Q~500) together with detuning of the characteristic modes of the structure is used. The potential advantage of this alternative method lies in the ability to locate the damping materials outside the immediate vicinity of the beam and to provide a means of diagnosing the location of the beam and cell misalignments from the radiation at the damping ports [2].

We have already considered a design in which we prescribed a Gaussian dipole mode distribution with an optimised bandwidth of 3.3 GHz for the first band together with interleaving of successive structures [3]. The detuning resulted in a wake-field which was suppressed by almost two order of magnitude at the first trailing bunch in the CLIC train of 312 bunches. In this work we focus on the parameters of the present baseline design known as CLIC_G which consists of 24 cells. We retain the dimensions of the end cells and the intermediate cells are modified with a view to enforcing a Gaussian distribution in the kick factor weighted distribution [1]. Enforcing a fixed geometry to the end cells results in a reduced dipole mode bandwidth. As a consequence of this fixed dipole bandwidth the wake-field at the first few trailing bunches is insufficiently damped. Interleaving successive structures results in an improved overall suppression in the wake-field. Nonetheless, even with 8-fold interleaving of structures the envelope of the wake-field is still unsatisfactory. To ameliorate the effect of this wake-field on emittance dilution we have modified the structure geometry with a view to locating the first few trailing bunches at the zero crossing point in the wake-field. To assess the practicality of this method we have undertaken a series of beam dynamics simulations entailing tracking the beam through the complete CLIC main linac. We present initial results on this study herein. The RMS of the sum wake-field also provides evidence as to whether beam break up (BBU) is occurring and we study this parameter also.

## BASELINE CLIC STRUCTURE

The fundamental parameters of the present baseline structure known as CLIC_G are delineated in Table 1. From an analysis of electrical breakdown the group velocity of the fundamental mode should be kept as small as is commensurate with a practical filling time. With this in mind, the geometry of the end cells is invariant to within a factor of ~10%. Intermediate cells are varied in

Table 1: Parameters of updated CLIC baseline structure CLIC_G [4].

| Structure | CLIC_G |
|---|---|
| Frequency (GHz) | 12 |
| Average iris radius/wavelength $\langle a\rangle/\lambda$ | 0.11 |
| Input /Output iris radii (mm) | 3.15, 2.35 |
| Input /Output iris thickness (mm) | 1.67, 1.0 |
| Group velocity (% c) | 1.66, 0.83 |
| Number of cells per cavity | 24 |
| Bunch separation (rf cycles) | 6 |
| Number of bunches in a train | 312 |

order to enforce a Gaussian distribution of the kick factor weighted distribution. The resulting wake-field for a structure of N cells is calculated from the modal summation:

$$W(t) = 2\,\mathrm{Im}\left\{\sum_{p=1}^{N} K_p \exp\left[i\omega_p t\left(1+\frac{i}{2Q_p}\right)\right]\right\} \quad (1)$$

where for the p[th] mode $\omega_p/2\pi$, $K_p$ is the coupled mode frequency and kick factor, respectively. A damping factor $Q_p$ has also been incorporated. Furthermore, it is convenient to display the maximum excursion in the wake-field and this is obtained by replacing the Im factor in Eq. (1) with the absolute value.

Our design focussed on a 24 cell structure and 8-fold interleaving of the structure (making the structure effectively 192 cells). We investigated a Gaussian kick factor weighted distribution with a standard deviation $\sigma$ from the central value $\omega_c/2\pi$. The optimised design features a bandwidth of $\Delta\omega/2\pi = 3\sigma = 5.8\%\ \omega_c = 1$ GHz. The envelope of the wake-field for a single, non-

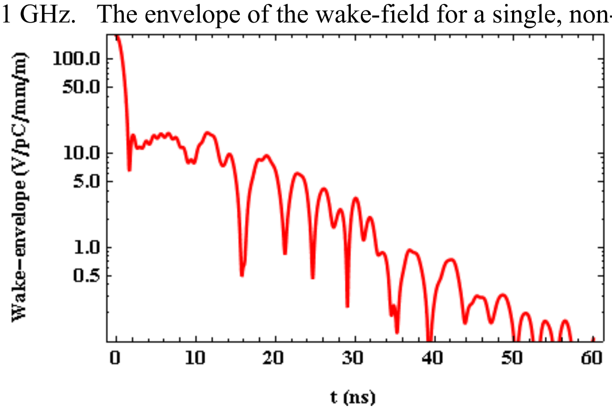

Figure 1: Envelope of the wakefield of 24 cell structure, CLIC_ZC with Q ~500.

interleaved structure is illustrated in Fig. 1. For this bandwidth, the wake-field is insufficiently damped as at the first trailing bunch it is 74% of the peak value (~177 V/pC/mm/m). Interleaving structures reduces the amplitude of the wake-field experienced by the first trailing bunch is reduced to ~ 26% of the peak value. The amplitude of the wake-field for the first 4 trailing bunches is displayed in Fig 2.

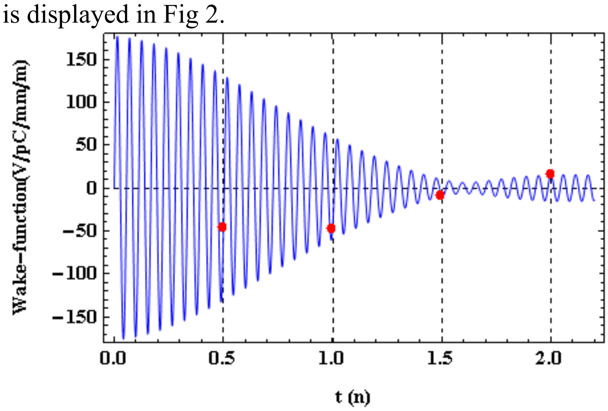

Figure 2: Wake-function of a modified CLIC_G structure, representing the wake at first four trailing bunches.

## PERTURBED BASELINE STRUCTURE

The wake felt by the bunch is obtained with Eq. 1. The oscillations in the wake-field amplitude are due to the corresponding sinusoidal term. We adjust the mode frequencies to force the bunches to be located at the zero crossing in the wake-field. This can be achieved in a straightforward manner for the first few trailing bunches by shifting the mode frequencies of all cells. In practise this is achieved by systematically shifting all cell dimensions (aperture and cavity radius). The parameters of 7 fiducial cells of a 24 cell structure, which we refer to as CLIC_ZC, are presented in Table 2. Here a is the iris radius, b is the cavity radius, t is the iris thickness, $v_g/c$ is the group velocity of the fundamental mode and $\omega_1/2\pi$ is the first band dipole frequency. The ratio of average iris radius to wavelength ($\langle a\rangle/\lambda$) is 0.103. In order to maintain the group velocity of CLIC_G it was necessary to change the first cell iris radius by 160µm and the last cell iris radius by 220µm.

The group velocities of the fundamental mode are retained within the tolerable limits of 10% [5] by modifying the iris thickness of the cells accordingly. The wake-envelope of the detuned CLIC_ZC structure is relatively invariant with respect to the shifted perturbation in cell parameters.

Table 2. Parameters of the detuned CLIC_ZC structure.

| Cell. | a (mm) | B (mm) | t (mm) | Vg/c (%) | $\omega_1/2\pi$ (GHz) |
|---|---|---|---|---|---|
| 1 | 2.99 | 9.88 | 1.6 | 1.49 | 17.57 |
| 4 | 2.84 | 9.83 | 1.4 | 1.38 | 17.72 |
| 8 | 2.72 | 9.80 | 1.3 | 1.29 | 17.85 |
| 12 | 2.61 | 9.78 | 1.2 | 1.18 | 17.96 |
| 16 | 2.51 | 9.75 | 1.1 | 1.06 | 18.07 |
| 20 | 2.37 | 9.73 | 0.96 | 0.98 | 18.2 |
| 24 | 2.13 | 9.68 | 0.7 | 0.83 | 18.40 |

However, there is a considerable difference in the wake-field experienced by the first trailing bunch, which is 1.7 % of peak value in this case. The corresponding wake-field is illustrated in the Fig. 3 for the first 4 trailing bunches.

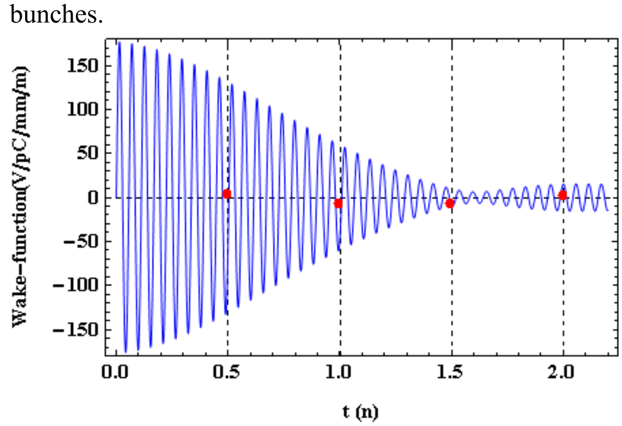

Figure 3: Wake-field of the CLIC_ZC structure. The wake-field at the location of the bunch is indicated by the dots.

In order to further improve wake-field suppression we incorporated 8-fold interleaving of the mode frequencies of successive structures and this is illustrated in Fig. 4. for a Q of 500, it is notable that the wake-field is below unity after approximately 15 ns, i.e. 30 trailing bunches.

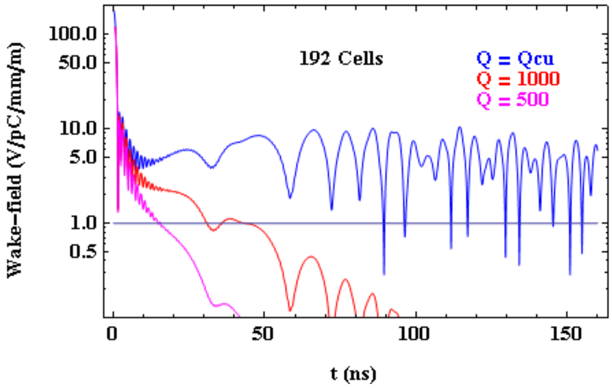

Figure 4: Envelope of wake-field for an 8-fold interleaving of dipole mode frequencies in the CLIC_ZC structure.

## BEAM DYNAMICS SIMULATIONS

The emittance dilution due to these long-range wake-fields is evaluated by tracking the progress of the beam throughout the complete linac. For this purpose we utilised the code PLACET [6]. However, an indication as to whether BBU occurs is also provided by the RMS of the sum wake-field, $S_{RMS}$ [7]. This is a direct and straightforward calculation. As a prelude to full beam dynamics tracking simulations we investigated the sensitivity of $S_{RMS}$ to small fractional errors in the bunch spacing. This is illustrated in Fig. 5 for both a single structure and an interleaved structure. At the nominal bunch spacing $S_{RMS}$ is ~33 V/pC/mm/m for a single structure and it is reduced to ~7 V/pC/mm/m for an 8-fold interleaved structure.

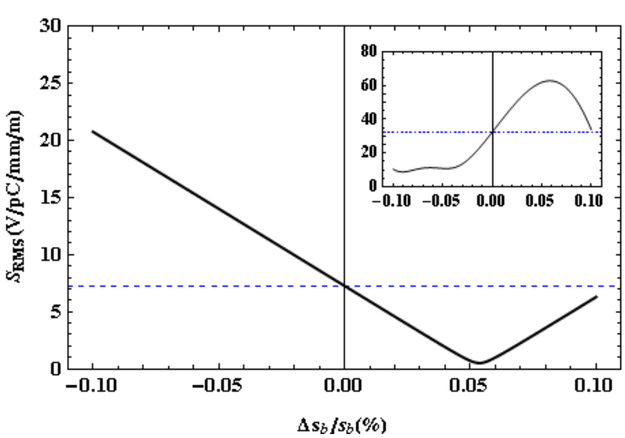

Figure 5: $S_{RMS}$ of a 24 cell structure interleaved 8-fold with a damping Q of 500. The 24 cell non-interleaved structure result is shown inset.

We also tracked the beam through the complete linac and computed the projected emittance of the beam. The results of this initial study indicate that a single, non-interleaved structure gives rise to a huge emittance growth, as expected. However, for an 8-fold interleaved structure the emittance dilution is reduced to ~ 70% at the nominal bunch spacing. This is still not acceptable

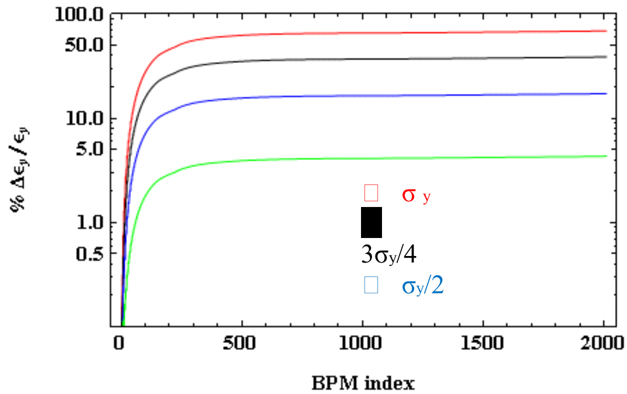

Figure 6: Emittance dilution in an 8-fold interleaved CLIC_ZC structure for various beam offsets.

from the perspective of the impact on beam luminosity. However, further optimisation may lead to a further reduction in the beam emittance. Detailed results on this study are displayed in Fig. 6. in which the emittance dilution down the linac is evaluated for several injection offsets in the beam from the centre of the linac.

## DISCUSSION

Interleaving the dipole frequencies of successive structures reduces the overall emittance dilution significantly. A beam subjected to a $\sigma_y$ injection offset results in an emittance dilution of ~70% at the nominal bunch spacing. Additional simulations conducted on the sensitivity of the emittance dilution to systematic fabrication errors indicate a strong sensitivity. However, a more careful randomisation of the zero crossing point in groups of structures has the potential to reduce the emittance dilution.

## ACKNOWLEDGMENTS

We have benefited from valuable discussions with W. Wuensch and A. Grudiev regarding the recent structures and with D. Schulte, B. Dalena and A. Latina on the beam dynamics code PLACET.

# PREDICTION OF 4ν=1 RESONANCE OF A HIGH INTENSITY LINAC*

D. Jeon#, SNS, ORNL, Oak Ridge, TN 37831, U.S.A.
I. Hofmann, L. Groening, G. Franchetti, GSI, Darmstadt, Germany

*Abstract*

The 4ν=1 resonance of a linac is demonstrated when the depressed tune is around 90°. It is observed that this fourth order resonance is dominating over the better known envelope instability and practically replacing it. Simulation study shows a clear emittance growth by this resonance and its stopband. Experimental measurement of the stopband of this resonance is proposed and conducted in 2008 using the UNILAC at GSI. This study will serve as a benchmarking and guidance for the experiment.

## INTRODUCTION

Recently many high intensity linacs have been designed or constructed like the SNS (USA) [1], J-PARC (Japan) [2], or people are trying to increase the intensity of existing linacs such as the UNILAC of GSI (Germany) [3]. For the high intensity linacs, it is the utmost goal to minimize the beam loss of halo particles by avoiding or minimizing contributions of various halo formation mechanisms. One such mechanism is the envelope instability [4]. So far the high intensity linac design such as the SNS linac has avoided the $\sigma_{ot}$ = 90° phase advance because of the envelope instability [1].

Until 1998, mismatch was the primarily studied mechanism of halo formation. Late 1998, Jeon found a case of halo formation induced by the $2\nu_x$-$2\nu_y$=0 resonance from the space charge potential in the ring [5]. Further studies of halo formation and/or emittance growth by space charge and resonances are reported in [6] and by space charge coupling resonance studies of linac such as [7]. Besides these, halo formation by non-round beam was reported [8] and halo formation by rf cavity [9].

In this paper, we will report about a collaborative effort between FAIR-GSI and SNS concerning the 4ν=1 resonance of a high intensity linac. We are preparing for an experiment to measure the stop-band of this resonance using the UNILAC at GSI. Numerical simulation is performed with 50 000 to 100 000 macroparticles with the PARMILA code [10]. Space charge tune shift is about -20°.

## THE LINAC FOURTH ORDER RESONANCE

The study shows that the 4ν=1 resonance occurs when the phase advance with space charge σ is slightly lower than 90° for a linac just like a ring through the space charge octupole potential for a variety of beams including Gaussian, waterbag, etc.. For the phase advance with space charge σ > 90°, no resonance effect is observed, as shown in Fig. 6.

### *Crossing the Resonance from Below 90 °*

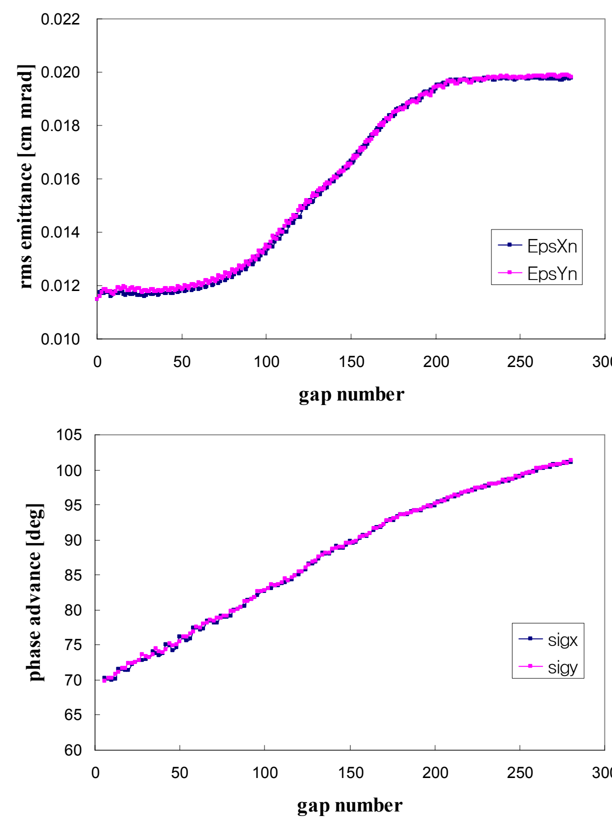

Figure 1: Top plots display rms emittance vs gap number and bottom plots the phase advance with space charge when the beam crosses the resonance from below.

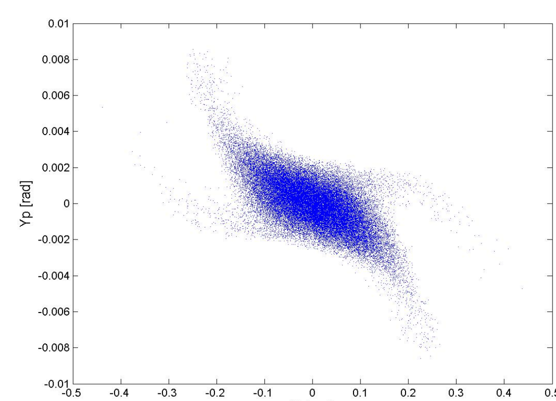

Figure 2: Plot of the beam distribution in Y phase space at the 96th gap. Transport of beam particles along the separatrices is observed.

* See acknowledgement
#jeond@ornl.gov

We performed a simulation of beam crossing the resonance from below 90°. Fig. 1 shows the normalized rms emittance growth as the beam crosses the 4ν=1 resonance together with the variation of the depressed phase advance σ. When the depressed phase advance with space charge σ reaches about 75°, emittance starts to grow. The initial beam is a well matched Gaussian beam to the linac and the emittance growth is solely due to the resonance crossing. The same phenomenon is observed with waterbag beam.

When the beam crosses the resonance from below 90°, the stable fixed points move from afar to the origin and beam particles are transported along the separatrices, not captured by the stable islands. This is well illustrated in Fig. 2.

### *Crossing the Resonance from Above 90 °*

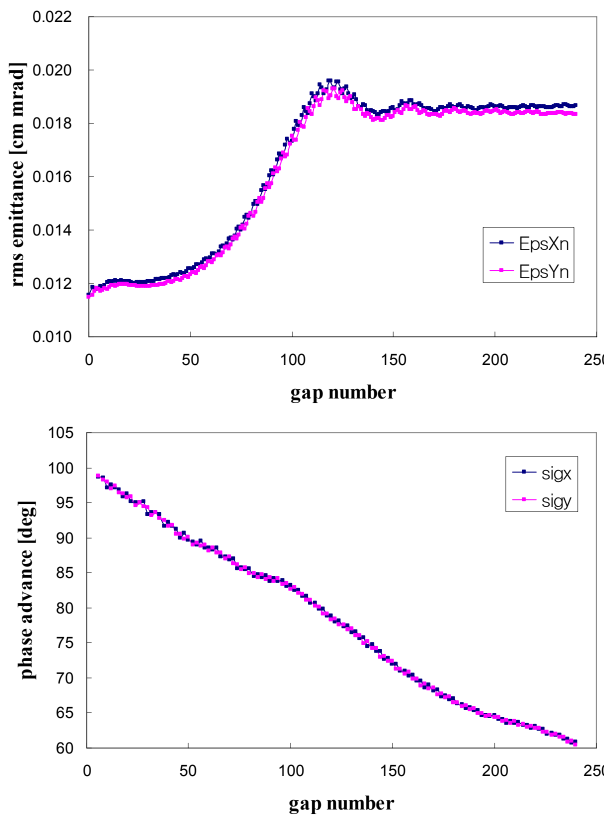

Figure 3: Top plots display rms emittance vs gap number and bottom plots the phase advance with space charge, when the beam crosses the resonance from above.

We performed a simulation of beam crossing the resonance from above 90°. Fig. 3 shows the normalized rms emittance growth as the beam crosses the 4ν=1 resonance along with the variation of the depressed phase advance σ. As the depressed phase advance σ crosses 90°, emittance starts to grow. The initial beam is a well matched Gaussian beam to the linac. For σ > 90°, there is no resonance effect.

When the beam crosses the resonance from above 90°, stable fixed points move away from the origin to afar. Unlike rings, tune change rate is not slow enough for adiabatic capture of beam particles by the stable islands. So beam particles are not entirely captured as illustrated in Fig. 4.

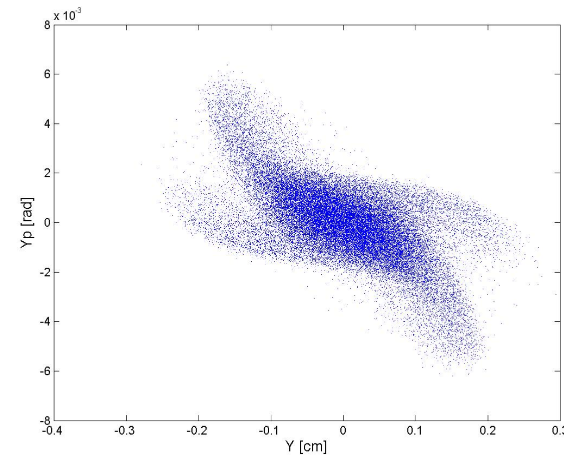

Figure 4: Plot of the beam distribution in Y phase space at the 88$^{th}$ gap.

### *Measurement of the Stopband*

We are preparing for an experiment to measure the stop-band of the 4ν=1 resonance with an emittance scanner installed right after the first DTL tank A1 of the UNILAC. Figure 5 displays the simulation of the sum of transverse rms emittances vs. zero current phase advance. About 45% of rms emittance increase is anticipated due to the resonance.

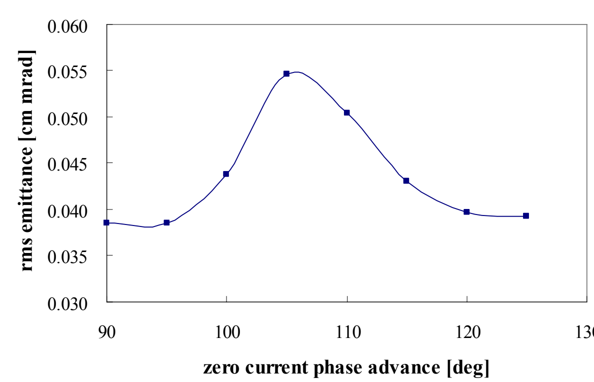

Figure 5: Plot of the sum of the normalized rms emittance $\varepsilon_x + \varepsilon_y$ vs. zero current phase advance.

### *Envelope Instability??*

High intensity linac design has avoided the 90° phase advance because of the well known envelope instability. Our study indicates that the 4ν=1 resonance is dominating over the envelope instability and practically replacing it. We did not observe the envelope instability during the simulation for the phase advance around 90° as shown in Fig. 5. For $90° \leq \sigma_o \leq 95°$, no appreciable emittance growth is observed. It should be noted that the initial beam is well matched to the linac.

Considering this, it should be stated that the high intensity linac design should avoid 90° phase advance because of the 4ν=1 resonance rather than the better known envelope instability. The effect of the envelope instability can actually be minimized – in theory - by nearly perfect envelope matching, whereas the 4ν=1 resonance is independent of the rms matching.

### *Rms Emittance vs. Phase Advance*

Simulation is done to study the equilibrium rms emittance as a function of the depressed phase advance σ. For this simulation, σ is kept constant throughout the linac. Figure 6 shows plots of the ratio of the final transverse emittance over the initial emittance as a function of the depressed phase advance σ. Rms emittance grows as a power of 3.5 up to 90° and there is no emittance growth beyond 90°. Two cases are simulated and plotted; one is with a tune depression of -23° and the other -20°.

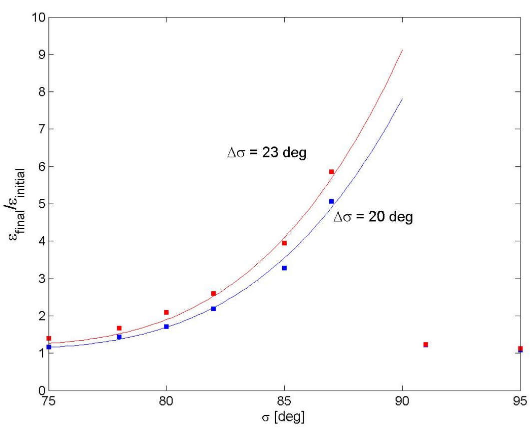

Figure 6: Plots of the rms emittance vs. the depressed phase advance σ. No emittance growth occurs for σ > 90°.

### *Effect of Mismatch*

When strong mismatch is applied to the initial beam distribution, the effect of mismatch is manifested on top of the 4ν=1 resonance, as shown in Fig. 7. Obviously the fourth order resonance remains dominant, and there is not enough time for the envelope instability to take over. In both planes, initial $\beta_x$ and $\beta_y$ are increased by 40%.

## CONCLUSION

The 4ν=1 resonance of a linac is demonstrated through space charge potential when the depressed tune is around 90°. It is observed that this fourth order resonance is dominating over the better known envelope instability and practically replacing it. It needs to be rephrased that the high intensity linac design should avoid 90° phase advance because of the 4ν=1 resonance rather than the better known envelope instability.

## ACKNOWLEDGEMENT

This work is a result of the collaboration between GSI-FAIR and SNS. # TRANSVERSE MATCHING OF THE SNS LINAC BASED ON PROFILE MEASUREMENTS *

Dong-o Jeon#, Oak Ridge National Laboratory, Oak Ridge, TN37831, U.S.A.

*Abstract*

For a high intensity linac such as the SNS linac, it matters to match transversely adequately to minimize the beam mismatch and potential beam loss. The technique of doing the matching using the wire-scanners in series was employed [1]. It was verified that matching was improved through the matching technique based on the beam profile measurements from wire-scanners in series.

## INTRODUCTION

The Spallation Neutron Source (SNS) linac accelerates intense $H^-$ beams to energy of 1-GeV, delivering more than 1.4 MW of beam power to the neutron production target [2]. Being a high intensity linac, a primary concern is the uncontrolled beam loss and radio activation of accelerator components. Mismatch generating beam halo, it is important to accomplish adequate level of transverse matching between sections of linac.

When emittance measurement device is available, minimization of rms emittance proves to be effective in doing the matching as for the SNS DTL (Drift Tube Linac) tank 1 commissioning [3].

Alternatively wire-scanners installed in series can be used to transversely matching between two different structures of the SNS linac [4,1]. During the beam operation runs, the matching technique based on beam profile measurements was tested and the results are presented here. The previous work [5] was for a relatively low beam current around 15 mA. This study is focused on the performance for high current (~ 32 mA) and for an incoming beam with a large envelope oscillation.

## MATCHING DTL TO CCL

We applied the technique based on profile measurements to matching the Drift Tube Linac (DTL) to the Coupled Cavity Linac (CCL). The beam energy is 86.6 MeV coming out of DTL. The peak beam current used for the measurement was 34 mA. We performed a Gaussian fit to the measured beam profile and obtained its beam size $\sigma$. By fitting the beam envelope from the Trace3D code to the wire-scanner profile data, we obtained the input beam Courant-Snyder parameters $\beta$ and $\alpha$, and the beam emittance $\varepsilon$, as shown in Fig. 1. With the beam parameters of the incoming beam determined, the matching quadrupoles are optimized using the Trace3D code to do the matching.

The first four wire-scanners were used by the matching program to predict a better matching. This matching technique is robust for quite high peak current beam. Figure 1 shows the data before the matching exercise and Fig. 2 the data after the matching. The solid circles in Figs. 1 and 2 represent profile measurements from wire-scanners in CCL module 1 and 2. The blue color represents the x beam size and the red the y beam size. It is clear that the matching in x plane is improved significantly and that a slight improvement is observed in y plane (y plane was already close to well matched condition). We observe an overall improvement in matching. The measured normalized rms emittances are $\varepsilon_x$=0.283 and $\varepsilon_y$=0.320 [mm mrad] of the equivalent uniform beam distribution having the same rms beam size as the beam profile.

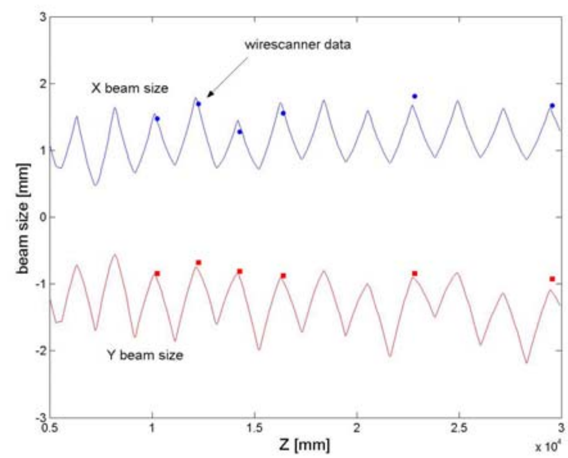

Figure 1: Plots of beam profiles before matching DTL to CCL. Solid lines are plots of beam size $\sigma$ [mm] from the Trace3D program and solid circles are wire-scanner profile data. The peak beam current is 40 mA.

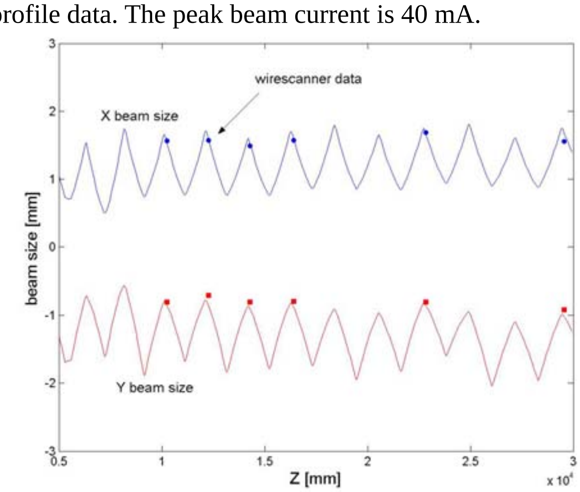

Figure 2: Plots of beam profiles after matching DTL to CCL. Solid lines are plots of beam size $\sigma$ [mm] from the Trace3D program and solid circles are wire-scanner profile data.

* SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy.
#jeond@ornl.gov

In the previous work [5], when matching in one plane is improved significantly, matching of the other plane degraded slightly. We improved fitting routine with a modified figure of merits. This routine seems to be robust to a high current beam or to a beam with a significant envelope oscillation as shown in the following section.

## MATCHING SCL TO HEBT

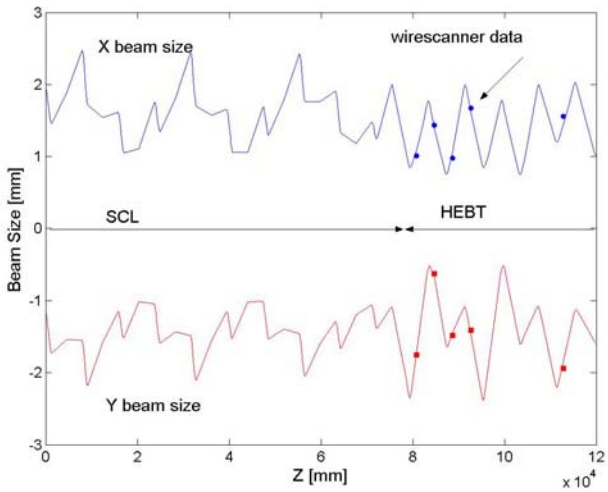

Figure 3: Plots of beam profiles before matching SCL to HEBT. Solid lines are plots of beam size σ [mm] from the Trace3D program and solid circles are wire-scanner measurement data.

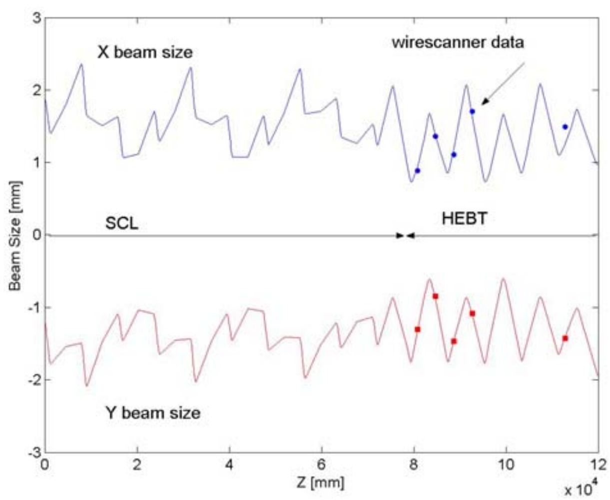

Figure 4: Plots of beam profiles after matching SCL to HEBT. Solid lines are plots of beam size σ [mm] from the Trace3D program and solid circles are wire-scanner measurement data.

We applied the same technique to matching the Superconducting Linac (SCL) to the High Energy Beam Transport (HEBT). The focusing of SCL is provided by doublets and HEBT by FODO. The solid circles in Figs. 3 and 4 represent the beam profile data from the wire-scanners in the HEBT and the solid lines represent simulated beam profile obtained from the Trace3D code. The blue color represents the x beam size and the red the y beam size. It should be noted that there is a mild beam envelope oscillation at the SCL.

By fitting the beam envelope from the Trace3D code to the wire-scanner profile data, we obtained the input beam Courant-Snyder parameters β and α, and the beam emittance ε, as shown in Fig. 3. Table 1 lists the input beam parameters at Z=0 in Fig. 3. $\varepsilon_x$=0.420 and $\varepsilon_y$=0.358 are the normalized rms emittance [mm mrad] of the equivalent uniform beam distribution having the same rms beam size as the beam profile. Figure 3 shows the data before the matching exercise and Fig. 4 the data after the matching. The envelope oscillation in the SCL is pretty severe, resulting in relatively high rms emittance values.

The matching exercise primarily improves the matching in the plane where the mismatch is pronounced. This routine proves to be quite robust even when there is a significant mismatch/envelope oscillation to the incoming beam, as demonstrated in this case.

Table 1: Input Beam Parameters

| | **X plane** | **Y plane** |
|---|---|---|
| ε [mm-mrad] | 0.420 | 0.358 |
| β [m] | 15.107 | 6.556 |
| α | -1.938 | -0.544 |

## CONCLUSION

A study of transverse matching of the SNS linac is performed. Positive results are obtained showing that the matching is improved for high current and significant mismatch. Further matching study will be conducted for other sections of the SNS linac.

# PHASE LAW OF A HIGH INTENSITY SUPERCONDUCTING LINAC*

D. Jeon# and J. Galambos, SNS, ORNL, Oak Ridge, TN 37831, U.S.A.

*Abstract*

The importance of a proper phase law is recognized to tune the synchronous phase of each superconducting cavities of a high intensity proton superconducting linac such as the SNS linac. The factors to be optimized are 1) maximizing the longitudinal acceptance 2) better matching throughout the linac and 3) achieving maximum beam energy. The driving force behind this study is how to effectively control the large voltage fluctuation from cavity to cavity, achieving low beam loss and high beam quality.

## INTRODUCTION

Recently many high intensity linacs have been designed or constructed like the SNS (Spallation Neutron Source) [1], and J-PARC (Japan) [2]. Part of the SNS linac is a pulsed superconducting linac (SCL) accelerating from 186 MeV to 1 GeV. There is a significant spread of the cavity field from cavity to cavity as shown in Fig. 1. Besides, there are cavities turned off for various reasons. If the synchronous phase is set to design values which assumes uniform cavity voltage, cavity field variation and off cavities lead to significant perturbation to the beam, potentially leading to beam loss. So the goal is how to 1) preserve beam quality, 2) minimize beam loss and 3) get as high beam energy as possible. In this paper, we report the important factors to be considered in achieving the three goals.

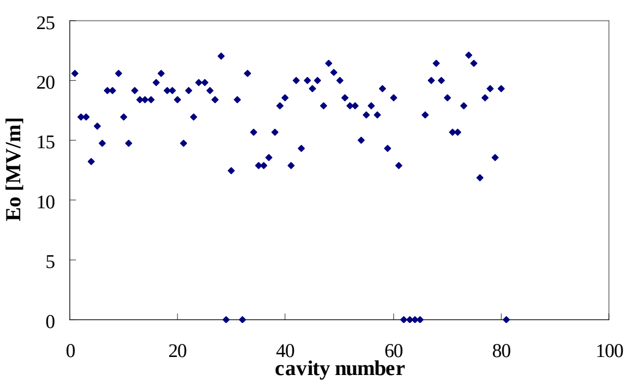

Figure 1: Plot of cavity field Eo vs. cavity number. Quite significant variation is observed besides that six cavities are off.

## IT MATTERS HOW TO SET THE PHASE

Each superconducting cavity of the SNS linac is fed by individual klystron, leaving us a lot of freedom how to set the phase of each cavity. One approach is to vary the synchronous phase $\phi_s$ of each cavity to compensate the variation of Eo from cavity to cavity, hoping to provide smooth focusing across the superconducting linac. We call this method "Smooth Focusing Optics (SFO)" for the sake of convenience. The other approach is to fix the synchronous phase of most of the cavities to design values and vary the phase of a handful of carefully chosen cavities only. We call this method "Constant Phase Optics (CPO)". Figure 2 shows how the synchronous phase of each cavity is set for the two optics.

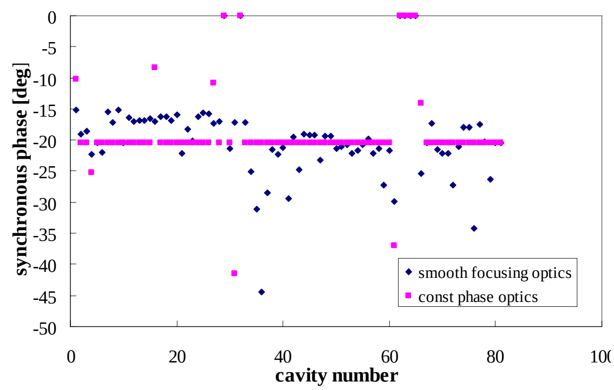

Figure 2: Plot of synchronous phase of the smooth focusing optics in blue and that of the constant phase optics in magenta. Phase of cavities that are off is set to zero in the plot.

### *Longitudinal Acceptance Matters*

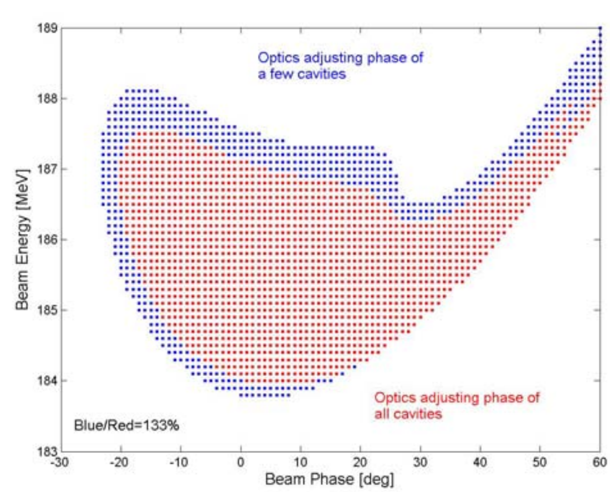

Figure 3: Longitudinal acceptance of the two optics. The constant phase optics in blue produces 33 % bigger acceptance than the smooth focusing optics in red.

* SNS is managed by UT-Battelle, LLC, under contract DE-AC05-00OR22725 for the U.S. Department of Energy.
#jeond@ornl.gov

One of the primary advantages of setting the phase of each superconducting cavities according to the constant phase optics is that we can get bigger longitudinal acceptance, even though the output beam energy is the same (less than 0.5 MeV different). As shown in Fig. 3, the acceptance of the constant phase optics produces about 33 % bigger acceptance than the smooth focusing optics. The blue solid squares represent the acceptance of the constant phase optics and the red squares the smooth focusing optics.

At the end of each beam operations, survey of residual activation throughout the entire accelerator is routinely performed. Figure 4 shows the residual activation of the superconducting linac measured at 30 away. The 11/26/2007 120 kW run was performed with the “Constant Phase Optics (CPO)”, while the 08/13/2007 run and 08/27/2007 run with 150 kW and 160 kW of beam power with the “Smooth Focusing Optics (SFO)”. Radiation survey indicates that the residual activation of 340 kW run is comparable to that of 160 kW run.

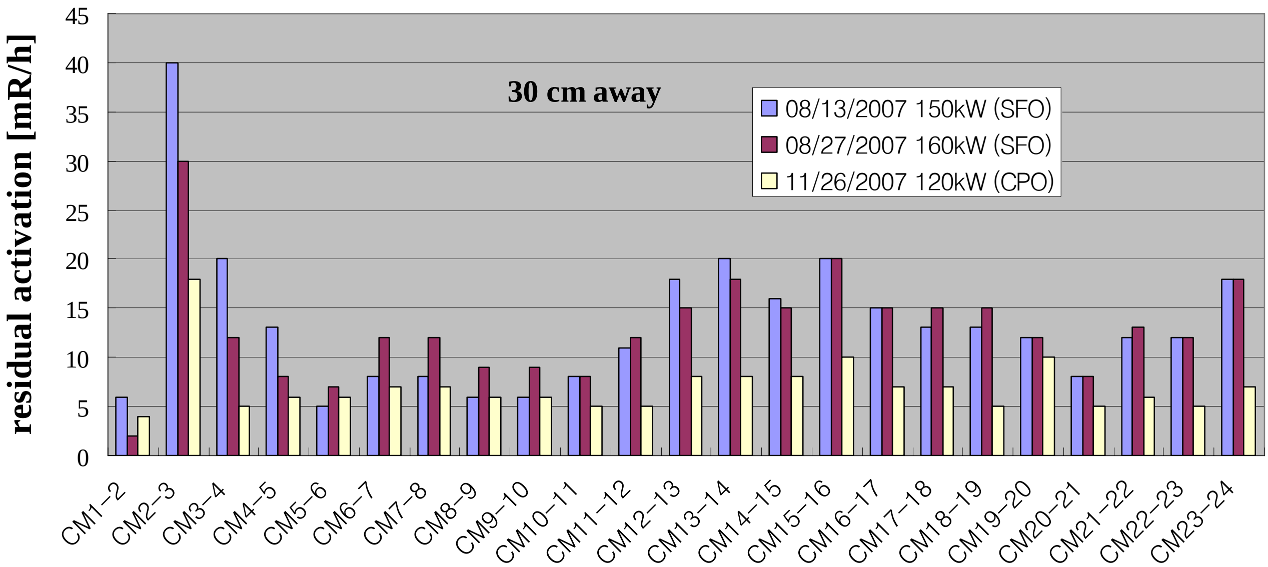

Figure 4: Plots of the residual machine activation 30 away after the beam operation for three different run periods. The 150 kW (08/13/2007) run and the 160 kW (08/27/2007) run used the “Smooth Focusing Optics (SFO)”, while 120 kW (11/26/2007) run the “Constant Phase Optics (CPO)”. CM1-2 means that between the cryo-module 1 and 2.

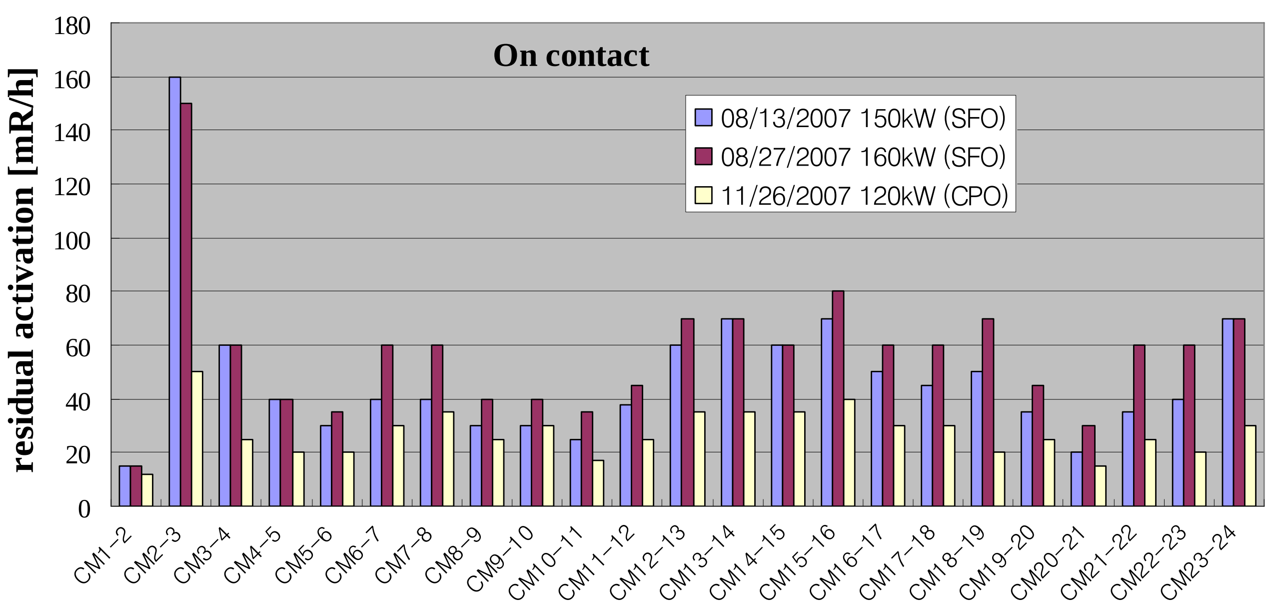

Figure 5: Plots of the residual machine activation on contact after the beam operation for four different run periods. The 150 kW (08/13/2007) run and the 160 kW (08/27/2007) run used the “Smooth Focusing Optics (SFO)”, while 120 kW (11/26/2007) run the “Constant Phase Optics (CPO)”.

Table 1: Cumulative Beam Power

| | **Cumulative beam power** | **Time lapsed for survey** |
|---|---|---|
| 08/13/2007 | 27970 kWh | 40 hours |
| 08/27/2007 | 25350 kWh | 63 hours |
| 11/26/2007 | 22450 kWh | 49 hours |

Table 1 lists the cumulative beam power delivered to the target in [kWh] and the time between the radiation survey and the production run for each period listed on the left.

### *Matching Matters*

Matching is also an important factor as shown in Fig. 6. Without proper matching, the orientation of the acceptance may not line up with the beam distribution, more prone to spilling beam particles outside the rf bucket, even though the overall area of the acceptance may remain the same. The acceptance in Fig. 3 is for well matched case. It should be noted that the difference primarily in orientation and also in shape.

Figure 7 shows the Trace3D envelope profiles for the constant phase optics used in the November, 2007 run and for the smooth focusing optics used in the August, 2007 run. The cavity field and phase are shown in Figs 1 and 2. For these runs, six superconducting cavities were off. Judging from the longitudinal beam envelope, the longitudinal matching from the medium beta section to the high beta section is marginal for the smooth focusing optics used then.

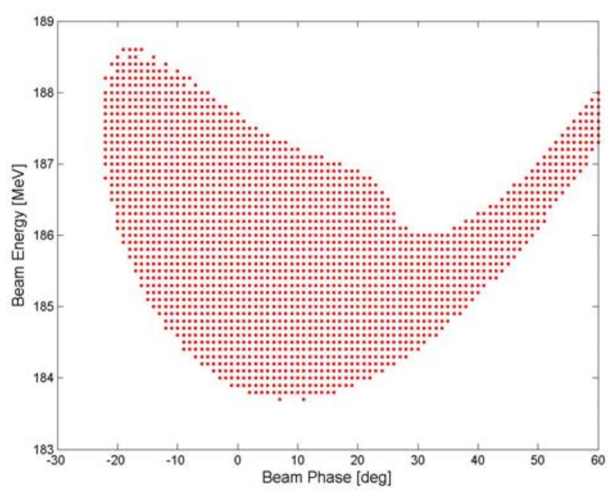

Figure 6: Plot of the longitudinal acceptance when the phase of all cavities are set to the design values without any matching.

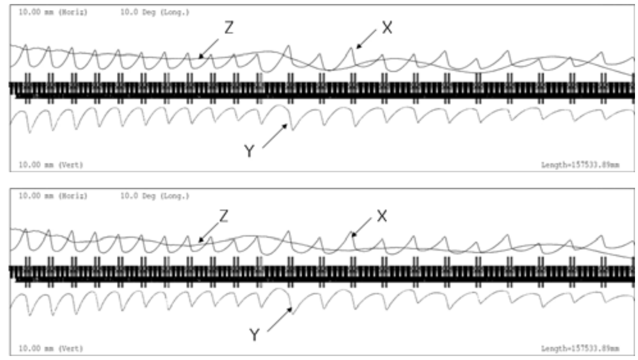

Figure 7: Trace3D envelope profiles for the smooth focusing optics (upper plot) and those for the constant phase optics (lower plot).

## CONCLUSIONS

Study shows that it is important to get as big a longitudinal acceptance as possible while maintaining reasonable matching throughout the superconducting linac in order to minimize beam loss for the SNS superconducting linac.

# PRECISE CONTROL OF COOLING WATER SYSTEM FOR STABILIZATION OF 125 MEV LINAC AT LEBRA*

T.Sakai#, T.Kuwada, M.Inagaki, I.Sato, ARISH, Nihon University, Tokyo, 102-8251, Japan
T.Tanaka, K.Hayakawa, Y.Hayakawa, Y.Takahashi, K.Nakao, K.Nogami, LEBRA, Nihon University, Funabashi, 274-8501, Japan

## Abstract

The 125-MeV linac at the Laboratory for Electron Beam Research and Application (LEBRA) in Nihon University has been used for the generation of the near-infrared FEL and the Parametric X-ray Radiation (PXR). Currently the FELs from 0.855 to 6μm and the PXR X-rays from 5 to 20keV are available at LEBRA.

Precise experiments using the light sources require a high stability in both the wavelength and the intensity of the lights. Though the linac was operated with the cooling water stabilized at 30±0.2°C, periodical fluctuation of the electron beam energy and the beam orbit suggested that the stability of the cooling water temperature was not sufficient. With this condition a large fluctuation (±15%) was observed for the PXR intensity.

After the improvement of the fine cooling water system and the water flow path, fluctuation of the cooling water temperature at the supply head of the accelerating tubes and the electromagnets was suppressed to within ±0.01°C. As a result of the improvement the PXR intensity fluctuation at the X-ray output port has been suppressed to within ±2% for the operation over several hours.

## INTRODUCTION

Research of a high performance electron linac for the generation of Free Electron Laser (FEL) and Parametric X-ray Radiation (PXR) has been continued at the Laboratory for Electron Beam Research and Application (LEBRA) of Nihon University as a joint research with the High Energy Accelerator Research Organization (KEK) [1],[2]. The experiments using coherent X-rays or FELs generally require a high stability electron beam in order to keep high spatial definition and stability of wavelength and intensity.

The electron beam from the linac at LEBRA was stabilized with the klystron RF phase feedback and the beam energy feedback systems [3]. Then the work on the beam stabilization has been devoted to the improvement of the linac cooling water system, because it was found that the effect of the temperature change in the linac cooling water was not sufficiently suppressed by the feedback systems. This paper reports on the achievement of the precise stabilization for the accelerator cooling water temperature and the resultant effect on the stability of the light sources.

## LEBRA 125MEV ELECTRON LINAC

The linac consists mainly of the 100kV DC electron gun, the pre-buncher, the buncher and the three 4m long regular accelerating structures. The accelerating RF has been powered by two S-band klystrons (the peak output power of 20MW has been achieved at the repetition rate of 12.5Hz and the pulse duration of 20μs) [4]. After the improvement of the linac cooling system the accelerating structures, the bending magnet coils and the PXR Si target crystal have been cooled with the water precisely controlled by a single fine cooling unit. On the other hand, the klystrons, the klystron focus coils and the RF dummy loads have been cooled with the coarse cooling water. The layout of the LEBRA electron linac is shown in figure 1, and the specifications of the linac are listed in table 1.

The saturated FEL lasing has been obtained in the wavelength region of 0.855-6μm, with the maximum macropulse output energy of approximately 60mJ/pulse at a wavelength of 1725nm [1]. The PXR generator covers the X-ray energies from 5 to 20 keV by using Si(111) planes as the target and the second crystals[2]. These light sources have been used for the variety of user's experiments [2],[5].

Table 1: Specifications of the LEBRA Electron Linac

| | | |
|---|---|---|
| Maximum Energy | 125 | MeV |
| DC gun voltage | -100 | kV |
| Accelerating RF frequency | 2856 | MHz |
| Klystron peak RF power | 30 | MW |
| Number of klystrons | 2 | |
| Macropulse duration | 5~20 | μs |
| Repetition rate | 2~12.5 | Hz |
| Macropulse beam current | 200 | mA |
| Energy spread(FWHM) | 0.5~1 | % |

## PROBLEMS IN THE COOLING WATER SYSTEM

The diagram of the original water flow path in the cooling system for the LEBRA linac is shown in figure 2. The water temperature in the fine cooling system was 30 ±0.2°C at the normal operation. The fluctuation of the PXR intensity measured using an ion chamber was approximately ±15% of the average value, strongly depending on the change in the cooling water temperature. By adjusting the control parameters of the fine cooling

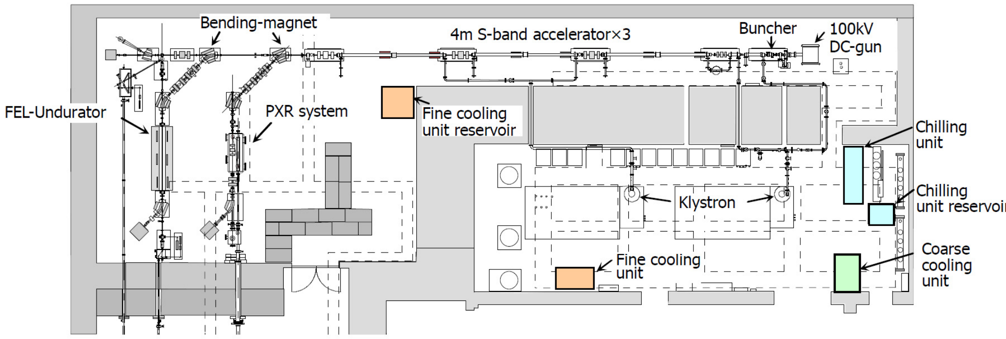

Figure 1: Layout of the 125MeV electron linac at LEBRA.

system the fluctuation of water temperature was suppressed to within ±0.1°C and the dependence of the X-ray intensity became insignificant. Then, however, the main source of the intensity fluctuation still as large as ±10% was found to be the vibration of the Si target caused by the high pressure flow of the cooling water.

The investigation of the water flow path revealed another problem of the fine cooling system. The fast change in the temperature of the chilled water caused by on/off of the compressor was found to be transmitted instantly from the chilling unit to the accelerating tubes and the bending magnets, which resulted in the fluctuation of the energy and the position of the electron beam. This implied that the action of the three-way valve was not sufficiently fast to compensate the rapid change of the chilled water temperature.

The stability of the coarse cooling water temperature was sufficiently good for a coarse cooling system. However, the klystron output RF phase was obviously

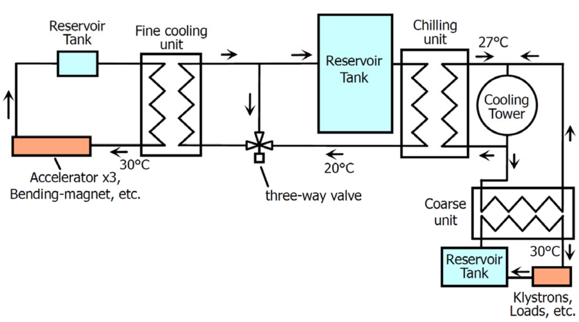

Figure 2: The diagram of the original water flow path in the cooling system for the LEBRA linac.

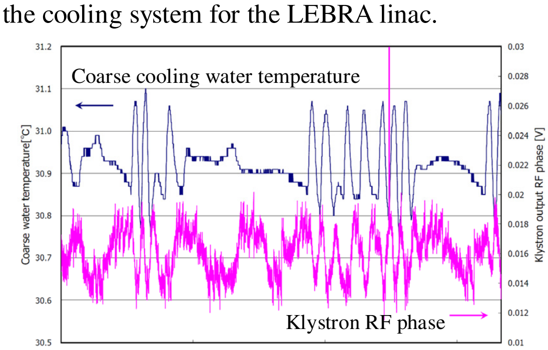

Figure 3: The behaviours of the coarse water temperature and the klystron output RF phase.

depending on the coarse cooling water temperature as shown in figure 3. The temperature of the coarse cooling water at the normal operation was controlled by the action of the three-way valve following to the changes in the temperature of the coarse cooling water itself and the water recirculated through the cooling tower. A rapid change in the temperature of the water from the cooling tower was caused by on/off of the compressor in the chilling unit as well as the cooling fan in the cooling tower. Therefore, the action of the chilling unit had a strong effect on the fluctuation of the output RF phase of the klystron.

## IMPROVEMENT OF COOLING WATER TEMPERATURE STABILITY

### [illegible] C[illegible] Wa[illegible] S[illegible]

Improvement of the cooling water system was undertaken in two steps. In the first step, the setup of the fine cooling system was changed as follows. An additional three-way valve was placed in order to regulate the temperature of the chilled water recirculating through the fine cooling unit. The direction of the fine cooling water flow was reversed so that the rapid change of the water temperature induced in the heat exchanger was reduced in the reservoir tank before flowing through the accelerating tubes and so on, which worked quite effectively in combination with the increase of the reservoir tank volume from 120L to 800L. Then, the cooling water for the PXR Si target was separated from the main path, directly returned to the reservoir tank in order to bypass the high pressure water pump and avoid

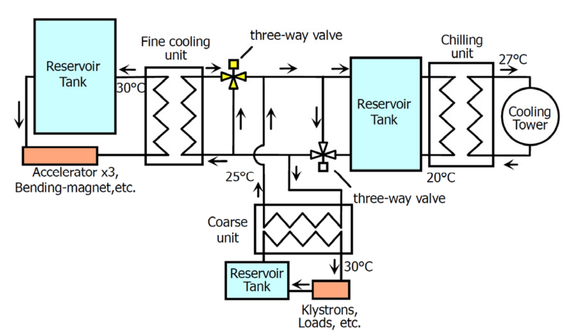

Figure 4: The diagram of the improved cooling water system.

the vibration of the target.

In the second step, the setup of the coarse cooling system was changed. The cooling water from the cooling tower was replaced by the chilled water, because the fluctuation of the regulated chilled water temperature was less than ±0.1°C which was far more preferable than the former for the precise control of the coarse cooling water temperature. The diagram of the cooling water system after the improvement is shown in figure 4.

## [illegible]/[illegible]

After the improvement of the fine cooling water system and the water flow path, the fluctuation of the cooling water temperature at the supply head of the accelerating tubes and the electromagnets was stabilized to 30±0.01°C. On the other hand, the coarse cooling water temperature was stabilized to 30±0.05°C. The behaviours of the cooling water temperatures over a few hours in the original and the improved setups for the fine and the coarse cooling water systems, respectively, are compared in figure 5. The water temperature was measured using an Extremely-Thin-Platinum-Resistance-Thermometer (ETPRT, 0.2 mmt). As shown in figure 6, the X-ray intensity fluctuation measured at the X-ray output port has been reduced from ±10% to ±2% by the improvement of the fine cooling water system. Due to a high stability of the electron beam and the X-ray intensity, the X-ray image by the diffraction enhanced imaging (DEI) method has been obtained clearly. The DEI image of a tetra fish is shown in figure 7.

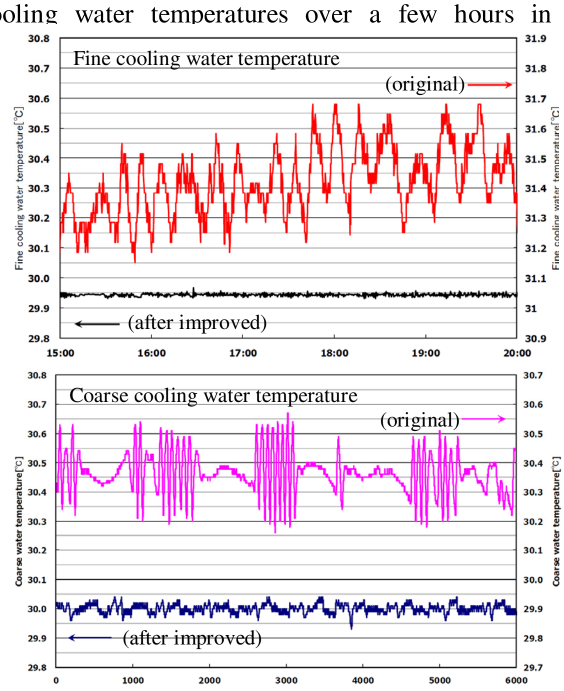

Figure 5: The comparison of the water temperature between the original and the improved setups for the fine and the coarse cooling system, respectively.

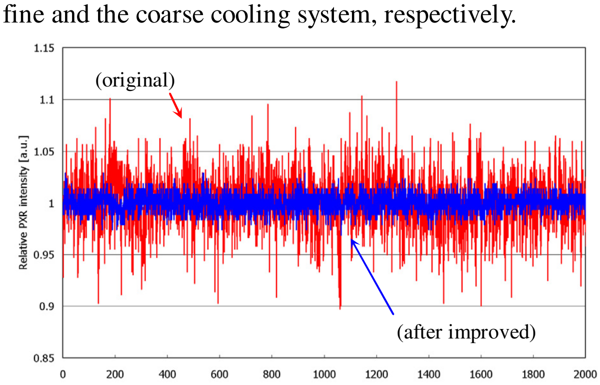

Figure 6: The comparison of the X-ray intensity fluctuation between the original and the improved fine cooling system.

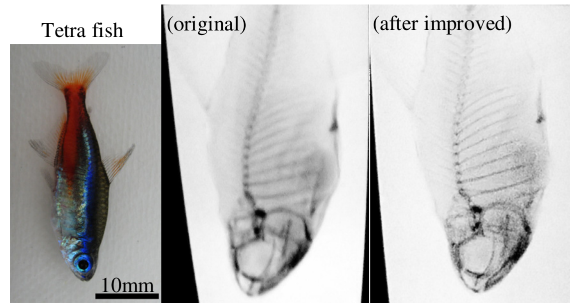

Figure 7: DEI images of a tetra fish taken with the original and the improved cooling water system, respectively (16keV, exposure time 15min (net 21ms) using the IP.).

## CONCLUSION

Precise experiments using the FEL or the PXR beam require a very high stability in both the wavelength and the intensity of the light sources. After the improvement of the cooling water system, the temperatures of the fine and the coarse cooling water systems were stabilized to 30±0.01°C and 30±0.05°C, respectively. Combined with the improvement of the water flow path, the PXR intensity fluctuation at the X-ray output port has been suppressed to within ±2%, resulting in appreciable effect in the DEI experiment using PXR.

# CONTROL SYSTEMS FOR LINAC TEST FACILITIES AT FERMILAB*

J. Patrick and S. Lackey, Fermilab, Batavia, IL, U.S.A.

*Abstract*

Fermilab is constructing superconducting RF test facilities for development of technologies to be used in future linear accelerator projects. Two of these facilities, the High Intensity Neutrino Source, (HINS) and the New Muon Laboratory, (NML) are proto-type linacs which will run with beam. Originally the NML facility was primarily an R&D facility for the proposed International Linear Collider. Now both HINS and NML are focused on R&D for the Project X [2] high intensity proton linac proposed for Fermilab. The requirements for these facilities vary but all involve collaboration and flexibility for integrating various new instruments. Tight timing requirements and automation are also required. Some facilities require integration into the existing Fermilab controls system. The controls also must be robust so as not to interfere with the main purpose of the facilities. We will outline the plan for accomplishing this task as well as the current status.

## STATUS AND REQUIREMENTS

### *HINS*

HINS (High Intensity Neutrino Facility) [2] is a 60 MeV proton or H- accelerator being built in the Meson Detector Building at Fermilab. It consists of an ion source, RFQ, room temperature and superconducting RF cavities, focusing solenoids, and diagnostic instrumentation. It is initially using an instance of the SNS low level RF system [3] to control the klystron. This =and a desire to create graphical user interfaces easily without programming resulted in the decision to use EPICS for the HINS control system. The SNS LLRF system will be replaced with a new design within a year to accommodate longer pulse lengths and control multiple cavities per klystron using vector modulators.

As in any pulsed machine, it is important to be able to correlate data from the various front ends and instruments. Special time stamping which includes either pulse identification and/or synchronization across computers will be required.

### *NML*

The NML facility is intended to test cryomodules developed for the ILC or the proposed Project X linac. Initially RF testing on a single cryomodule will be performed with no beam. Eventually the facility will support electron beam operation through 3 cryomodules at energies up to 750 MeV. The NML facility is a stand alone system which will not have to interoperate with the rest of the Fermilab complex. The low level RF system presently in use is from DESY and was developed in the DOOCs control system. There may be equipment which other laboratories may bring for testing purposes but the main objective of this facility will be the testing of the cryomodules themselves. The correlation of data by RF pulse is a requirement for NML as well.

The aggressive schedule demands that especially the cryogenic system and RF system be controllable this fall. Depending on the funding profile, beam will come somewhat later. For this reason, the Fermilab Control System will be used at NML.

There is an NML control room with operator consoles but it will most likely not be manned 24 hours per day so some oversight at least during off hours will be required.

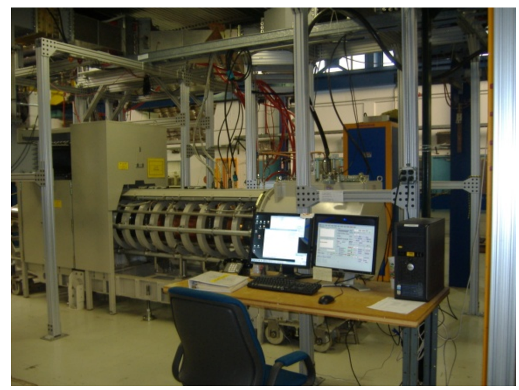

Figure 1: HINS Console and Klystron.

### *HTS*

The Horizontal Test Stand is also in the Meson Detector Building and has been operating for the past year. The purpose of this facility is to test dressed cavities at full RF power before they are installed in cryomodules. It makes use of the DOOCs based low level RF system as well as EPICs input/output controllers for processing loops and interfacing to systems such as vacuum and high level RF interlocks and control.

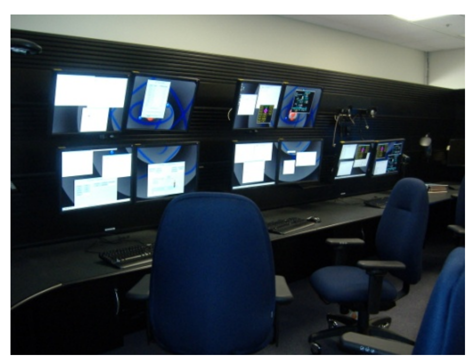

Figure 2: NML Control Room.

* Operated by Fermi Research Alliance, LLC under Contract No. DE-AC02-07CH11359 with the United States Department of Energy

### *Operational Considerations*

From the view point of the Operations Department as well as the Controls Department, it is much preferred that one control system be used to control all of these areas rather than multiple, parallel control systems; one alarm handler, one method of data logging, one database, one graphical user interface, etc. The operations staff will be located in one location, the Accelerator Division Main Control Room.

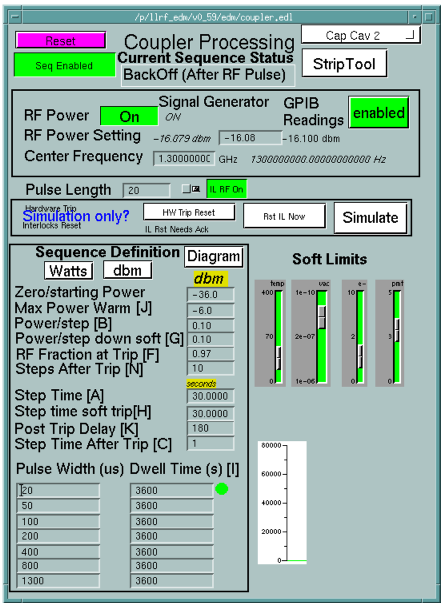

Figure 3: HTS Coupler Processing GUI

## PHILOSOPHY AND GOALS

Accelerator control systems are often required to integrate disparate systems such as LabView or SCADA systems into one global, cohesive control system.

It is our preference to maintain one standard protocol within the system rather than incorporate a variety of protocols. This implies that the integration be accomplished at the lowest level possible.

The Fermilab Control System offers some facilities that are lacking in some other systems which we find extremely useful. These include most importantly, the logging of settings, the parameter page, fast time plots and snapshots, and a central device database.

There are however some aspects of other control systems which would be very useful to add to our system such as a modern graphical display builder, built in mechanisms for simple automation or PID loops, and easy to use front end builders. Extending our controls protocol to enable data correlation is also a goal.

These test areas can be the opportunity to incorporate new functionality into our system while the complex is operating without adversely affecting operation of the collider and neutrino programs.

If successful, the HINS linac may become the front end of the Project X linac. In which case, the HINS control system would need to interface with the rest of the Fermilab controls system.

Project X also is a collaborative effort which means instruments and equipment will be developed at other institutions to be integrated into the system at Fermilab. Many of these institutes already use and understand EPICS and would be more comfortable supplying EPICS drivers for their equipment. All of this implies integration of EPICS into the Fermilab control system in some fashion.

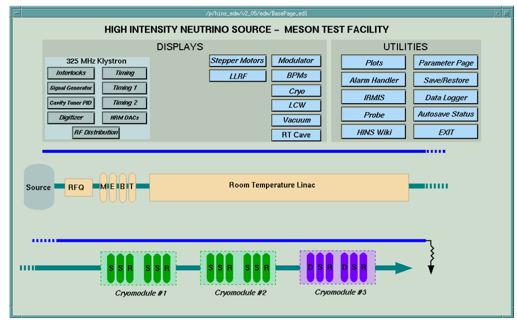

Figure 4: HINS Controls Base Page.

## POSSIBLE SOLUTIONS

The TINE control system in use at DESY has solved a similar problem by incorporating a TINE task in the EPICs IOCs and DOOCs front ends [4]. We are investigating how to implement a similar approach in our system.

We have a graphical user interface builder which has been in use for some time but has functional limitations. We are increasing the functionality of our GUI builder. Also an extension for the EPICs GUI builder, edm, has been created to interface directly with the Fermilab control system protocol.

## SUMMARY

Superconducting RF Test facilities at Fermilab have been run using a mix of control systems, including EPICS and DOOCS, independent of the main accelerator complex. As these efforts have become focused on R&D for the future Project X linac at Fermilab, it has become a goal to provide more commonality and interoperability between these facilities and the main Fermilab control system. It is planned to support EPICS IOCs and selected tools in the main system for cases where that may be the appropriate choice for some subsystem. These facilities will provide a test bed for the future Project X linac control system.

## ACKNOWLEDGEMENTS

This work is the result of the efforts of people from the Accelerator, Computing and Particle Physics Divisions at Fermilab. The authors would like to also thank those from Argonne, DESY and the Spallation Neutron Source who have answered many EPICS, DOOCs and TINE questions.

# THE DARHT DATA ACQUISITION, ARCHIVAL, ANALYSIS, AND INSTRUMENT CONTROL SYSTEM (DAAAC), AND NETWORK INFRASTRUCTURE.*

R. Archuleta, L. Sanchez, LANL, Los Alamos, NM 87545, USA

*Abstract*

The Dual Axis Radiographic Hydrodynamic Test Facility (DARHT) at Los Alamos National Laboratory is the world's most advanced weapons test facility. DARHT contains two linear accelerators for producing flash radiographs of hydrodynamic experiments. High-speed electronics and optical instrumentation are used for triggering the accelerators and collecting accelerator data. Efficient and effective diagnostics provide basic information needed to routinely tune the accelerators for peak radiographic performance, and to successfully monitor the accelerators performance. DARHT's server and network infrastructure is a key element in providing shot related data storage and retrieval for successfully executing radiographic experiments. This paper will outline the elaborate Data Acquisition, Archival, Analysis, and Instrument Control System (DAAAC), as well as the server and network infrastructure for both accelerators.

## INTRODUCTION

The DARHT facility consists of two accelerators, DARHT-I and DARHT-II. The data acquisition systems are elaborate and heavily instrumented with beam and pulse power diagnostics. Since accelerator data storage and retrieval is crucial in monitoring and executing radiographic experiments, the server and network infrastructure must be isolated and reliable.

## DATA ACQUISITION SOFTWARE

DARHT-I and DARHT-II use the Data Acquisition, Archival, Analysis, and Instrument Control System (DAAAC, V4.0) software package from Voss Scientific [1]. This software is used for automating remote instrumentation setup and control, documentation, data archival, and data analysis. The DAAAC software runs on computers running the Windows XP operating system.

The user interface consists of five modules; Archive, Acquire, Analyze, CalMan, and NetCom which operate as one system (see Figure 1).

* This work supported by the US National Nuclear Security Agency and the US Department of Energy under contract DE-AC52-06NA25396

LA-UR-08-06026

The Archive module is the database management tool which allows users to select databases, import or export data, and organize and transfer data. This module manages the various databases that have been created under DAAAC. It provides access to waveforms, images, single point data, informational notes, and accelerator diagnostic data logs that have been stored into a particular database. The Analyze module is the data analysis display tool which is used for examining and processing waveforms, single point data, images, informational notes, and accelerator diagnostic data logs.

Raw and processed data is shown by this module after the data is captured by the Acquire module and processed by the CalMan module. Once the data is displayed by this module it can be examined using tools that apply directly to the data presentation. These tools include such mechanisms as cursors, combining data into single plots, sub-sampling data or computing Figures of Merit (FOMs). In addition to FOMs, there are other tools for performing various mathematical functions. The Acquire module manages instrumentation communication, and controls acquisition sequence and automatic data processing. The CalMan module is used for documenting every channel's signal path, providing a graphical display of the test setup, and organizing the signal line components. The NetCom module is the mechanism that coordinates actions between the other DAAAC modules and the Microsoft Structured Query Language (SQL) Database. The DAAAC architecture uses inter-process communication (IPC) to exchange information between the five modules to operate as a single integrated system [1].

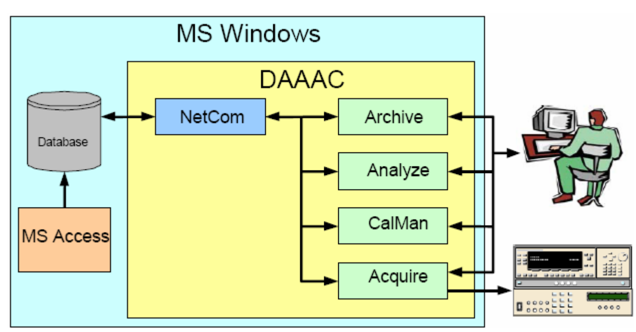

Figure 1: The DAAAC modules.

An additional DAAAC embedded piece of software is the Data Migration tool which migrates data from each accelerator SQL database into Microsoft Access database files. This migration allows for remote users to access the data without having SQL software to poll data from the SQL database elevating the risk of data loss and corruption of the database. The migrated Access databases are also used as a backup to the SQL database. If the accelerator's SQL database data becomes corrupt or lost it can be fully restored using the Access databases causing minimal accelerator down time. DARHT-I and DARHT-II DAAAC software produces binary data files (FlatFiles) on a per shot basis for further analysis using software created with IDL, a data visualization and analysis software development tool. These FlatFiles are available on a website for user specific access which allows internal and external laboratory collaborators to access accelerator data.

Both DARHT-I and DARHT-II run DAAAC in "Networked" mode which supports several data acquisition stations, each running its own copy of DAAAC (see Figure 2). Each data acquisition station controls and acquires data from its own set of connected instruments. DARHT-I has seven dedicated data acquisition stations and DARHT-II has nineteen dedicated data acquisition stations. Each accelerator has a test director which is the primary DAAAC station that instructs the other stations to perform an acquisition and to transmit data. All data is acquired by data acquisition stations and stored in a database. DAAAC stations running the Analyze module retrieve data from the database for analysis and display. Running DARHT-I and DARHT-II in networked mode allows the test director to perform ganged calibrations on the remote dedicated data acquisition stations. The capabilities of running in a network mode with a test director allows for modifications to the accelerators timing sequence through the test director to the associated data acquisition equipment.

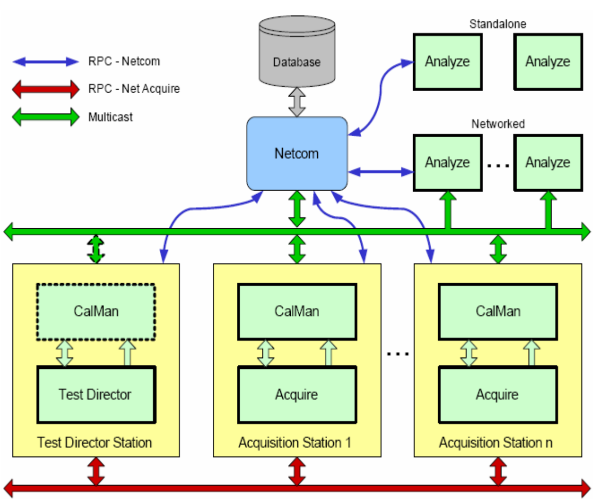

Figure 2: Networked dataflow and communication protocols.

Communication protocols used by Netcom and NetAquire is inter-process communication (RPC) technology that allows a computer program to cause a subroutine or procedure to execute in another address space (commonly on another computer on a shared network) without the programmer explicitly coding the details for this remote interaction. Multicast is the delivery of information to a group of destinations simultaneously using the most efficient strategy to deliver the messages over each link of the network only once, creating copies only when the links to the multiple destinations split. Internet Protocol (IP) Multicast is a technique for a one to many communication over an IP infrastructure, which the implementation occurs on the IP routing level.

## DATA ACQUISITION HARDWARE

The Data Acquisition system for the DARHT accelerators is elaborate and heavily instrumented. Table 1 and Table 2 illustrate the amount of instruments we are using for recording data from and controlling instruments on both DARHT-I and DARHT-II accelerators.

Table 1: DARHT-I Data Acquisition Hardware

| | |
|---|---|
| Server | 1 |
| DAAAC Acquire Stations | 7 |
| DAAAC Analysis Stations | 5 |
| Recording Instruments (45 DC271 Digitizers, and 11 TDS684 Digital scopes) | 56 |
| Digital Delay Generators | 29 |

Table 2: DARHT-II Data Acquisition Hardware

| | |
|---|---|
| Server | 1 |
| DAAAC Acquire Stations | 19 |
| DAAAC Analysis Stations | 9 |
| Recording Instruments (70 DC440, 32 DC282, and 140 DC271 Digitizers) | 242 |
| Digital Delay Generators | 28 |

The type of equipment used for the accelerators are the Compact PCI 21 and 8 slot Acqiris crates from Agilent Technologies which are populated with DC271, DC440, DC282, and DC271V digitizer modules. These crates communicate to our DAAAC Acquire stations using high speed MXI-3 interfaces. The DC271 is a 4 channel, 1 GHz bandwidth and 1-4 Giga Sample per second (GS/s) sampling rate Acqiris digitizer with oscilloscope characteristics. The DC440 is a high-resolution, high-speed dual-channel digitizer for frequency domain applications (2-channel, 100MHz, 400 MS/s and 4 Mpoint acquisition memory). The DC282 is a 4 channel, 2-8 GS/s high-speed digitizer. We also use Stanford Research Systems (SRS) Digital Delay Generators (DG535) for accelerator triggering and timing. These DG535s use the general purpose interface bus (GPIB) communication protocol for interfacing to the DAAAC stations. In addition to the DG535s we use Tektronix TDS 684 oscilloscopes on DARHT-I which also use the GPIB communication protocol.

DARHT diagnostics provide basic information needed to routinely tune the accelerators for peak radiographic performance. Beam position monitors (BPMs) are used to measure beam current and position for both accelerators. DARHT-I has a total of 26 BPMs, and DARHT-II has a total of 31 BPMs which are used on every beam shot. In addition to the BPMs both accelerators use cell voltage monitors (CVM) which are used to measure induction cell accelerating potential. DARHT-I has a total of 64 CVMs, and DARHT-II has a total of 74 CVMs which are also used on every beam shot.

Information needed to monitor the accelerators performance is provided by our diagnostics. DARHT I and DARHT II both have 20 Injector diagnostic parameters including voltages and currents which are used on a per shot basis.

## DARHT SERVER/NETWORK INFRASTRUCTURE

Storage and retrieval of DARHT accelerator data is crucial in monitoring and executing radiographic experiments. The server and network infrastructure must be isolated and reliable.

DARHT-I relies on a data storage server running the NetCom module which is the interface between DAAAC and the Structured Query Language (SQL) Database. This server is running a Microsoft SQL 2005 database which is the repository for DARHT-I diagnostic data and station configurations. DARHT-I and DARHT-II severs are Microsoft Windows 2003 servers which are configured with 1 terabyte of data storage, 4 gigabytes of memory and has a 3.7 gigahertz dual core processor.

DARHT-II also relies on a data storage server running the NetCom module. This server is running a Microsoft SQL 2005 database which is the repository for DARHT-II diagnostic data and station configurations.

DARHT-I and DARHT-II also have a server running a Microsoft SQL 2005 database for storing and retrieving accelerator controls data. These accelerator control parameters such as; pulse power, magnet, and vacuum controls data for both accelerators for monitoring performance.

There are over 90 controls and data acquisition stations throughout the facility. The servers and stations are on a local are network (LAN) (see Figure 3). They are isolated from the outside network. The DARHT accelerators have two domain controllers which are running the Microsoft Windows 2003 Server operating system with Active Directory service installed. Active Directory enables centralized, secure management of the DARHT facility local area network. This network was established to enhance and secure crucial accelerator data and to avoid other network traffic. All diagnostic and control systems within the DARHT facility local area network are on a 1 gigabit per second fiber network which allows for speedy storage and retrieval of accelerator data.

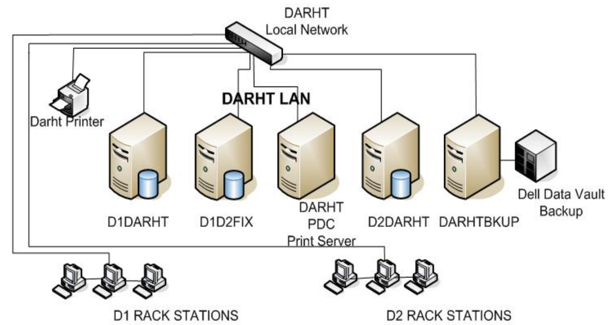

Figure 3: DARHT accelerators local area domain.

A bridge server (see Figure 4) was added as part of the DARHT facility local area network to allow specific users on the Los Alamos National Laboratory open network and the Windows Active Directory (WIN) Domain to access a copy of the accelerator's diagnostic and controls data. This data on the bridge server is synchronized with the data on the data acquisition servers using PeerSync commercial software. To accomplish data storage and retrieval across the DARHT facility local area network and the Laboratory open network the bridge server is configured to operate with dual 1 gigabit per second fiber network interfaces. This bridge server is a Microsoft Windows 2003 file server which is configured with 6 terabytes of data storage, 4 gigabytes of memory and 2.3 gigahertz quad core processor. To insure proper data storage we maintain our own backup system via a tape library storage unit which uses 800 gigabyte (compressed) tapes.

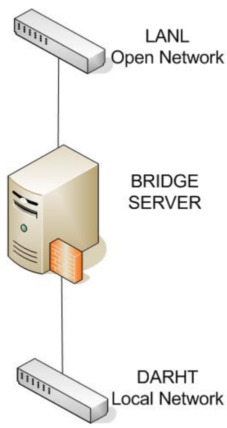

Figure 4: DARHT accelerators bridge and file server.

## SUMMARY

The DARHT accelerator's triggering and data collection is elaborate and heavily instrumented with state-of-the-art diagnostics, server, and network equipment. Efficient and effective diagnostics, server, and network infrastructure is crucial for successfully executing radiographic experiments at DARHT.

# THE DUAL AXIS RADIOGRAPHIC HYDRODYNAMIC TEST (DARHT) FACILITY PERSONNEL SAFETY SYSTEM (PSS) CONTROL SYSTEM*

E. Jacquez, LANL, Los Alamos, NM 87545, U.S.A.

*Abstract*

The mission of the Dual Axis Radiograph Hydrodynamic Test (DARHT) Facility is to conduct experiments on dynamic events of extremely dense materials.

The PSS control system is designed specifically to prevent personnel from becoming exposed to radiation and explosive hazards during machine operations and/or the firing site operation. This paper will outline the Radiation Safety System (RSS) and the High Explosive Safety System (HESS) which are computer-controlled sets of positive interlocks, warning devices, and other exclusion mechanisms that together form the PSS.

## BASIC OPERATIONAL OVERVIEW

Physical barriers and alarms are interlocked to the PSS. Door interlocks are located throughout the building. Other physical barriers include the Firing Point boundary fence, interlocked firing point gates, and perimeter warning lights and sirens.

The PSS logic is shown in Figure 1. The PSS is passive in that no external arming, conditioning, or operator intervention is required other than selecting the operational mode and executing the sweep.

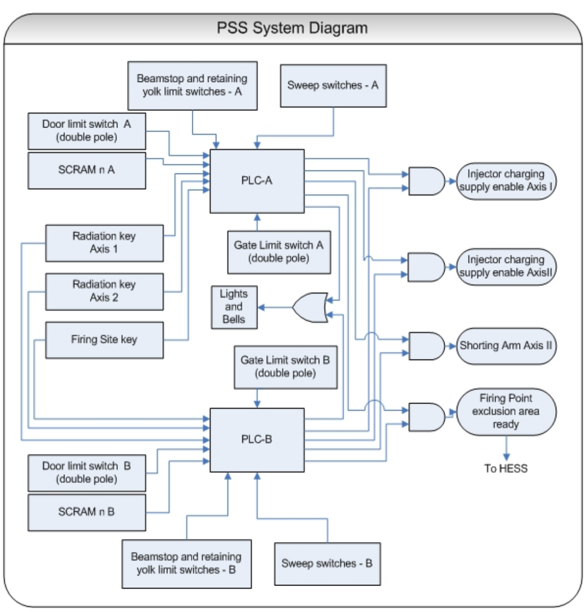

Figure 1: System diagram of PSS.

*This work supported by the US National Nuclear Security Agency and the US Department of Energy under contract DE-AC52-06NA25396
LA-UR-08-06022

A physical inspection, or sweep, of all exclusion areas ensures that affected hazardous areas are clear of personnel before any hazardous operation begins.

SCRAM actuators that inhibit radiation production are located throughout all potential radiation areas.

Located before the beam exit of each accelerator hall, the beamstop is designed to block the beam from reaching beyond the thick-walled accelerator halls. The beamstops allow beam production internal to the accelerator halls and inhibit radiation from reaching the firing point.

The PSS inhibits radiation production and explosive permissions depending on the modes of operation selected. The modes of operation for each axis are described below in Table 1.

Table 1: Operations Modes

| Mode | Activities |
|---|---|
| 0 | beam off |
| 1 | beam in the accelerator hall |
| 2 | beam in the hall and on the firing point |
| 3 | beam in the hall on the firing point in combination with explosives operations on the firing point |

The entire facility operation must be defined by the mode for each axis i.e., Mode 1, 1 (Axis I Mode 1, Axis II Mode 1; Mode 1, 3 (Axis I Mode 1, Axis II Mode 3); etc). The mode of operation defines the requirements for personnel exclusion in an area and therefore procedural sweep patterns. The PSS software controls are programmed to allow certain modes for each axis depending on the mode of the other axis. The modes of operation are shown below in Figure 2.. Up to two modes may be selected simultaneously, depending on the modes selected in Table 1 of this document.

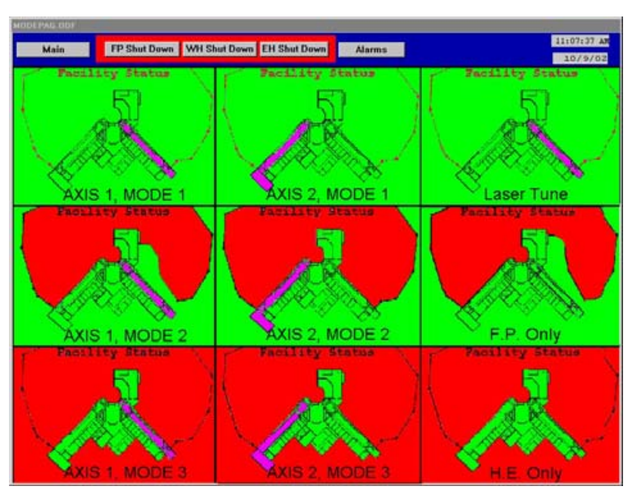

Figure 2: Mode select page.

# PSS CONTROL FUNCTION OVERVIEW

The two safety systems (RSS / HESS) that make up the PSS share hardware, software, and have similar sweep protocols. Input hardware mechanically fails in the safe position or condition. The PSS has three subcomponents: 1) the computer systems; 2) the field device hardware, including the interlocks and wiring for buttons and switches; and 3) redundant Programmable Logic Controllers (PLC's). (Operator PCs interface with PLCs.)

The PSS ensures that proper exclusion areas are secured and boundaries are maintained, depending on the mode of operation. The RSS maintains the exclusion areas around the accelerator where radiation production is the hazard. The HESS limits the manner in which the DARHT Detection Chamber (DDC) executes arming and detonation hardware for explosive tests.

The system provides a signal to inhibit beam production if access control to exclusion areas is lost. Requirements associated with these functions are determined by modes of operations in Table 1 of this document.

## *Radiation Safety System*

The RSS is integral to both axes of DARHT. When combined with administrative controls, the RSS eliminates the potential of personnel accessing areas in which they may receive exposure during beam production.

The RSS consists of those elements of the PSS that limit access to areas around the accelerator. Included in the RSS are: administrative controls, Standard Operating Procedures, Hazard Control Plans (HCPs), and a passive computer-based series of hardwired interlock devices.

The system monitors the physical barriers that prevent personnel from entering a radiation area while the injector is capable of producing radiation as illustrated in Figure 3. The RSS provides an interface between the operators and the machine environment to ensure that the hazard area is clear of personnel when a radiation hazard is present and monitors and detects access after a sweep and search process. The safety relays that permit the charging of each injector is controlled by redundant PLC units. These units must agree before the relay permits charging of the injector.

## *High Explosive Safety System*

When combined with administrative controls, the HESS limits the potential of injury to personnel from high explosives by monitoring interlocks.

The high explosive firing system uses a conventional modular capacitive discharge unit (CDU) system. The modular CDU system contains up to 12 CDUs, or 24 CDUs when two units are used together. The system fires only when commanded and with no time delay to meet the usual demands on a CDU system. The safety features prohibit charging of the capacitor until safety interlocks are complete. If an interlock is breached or control of the exclusion area is lost, the safety features discharge the capacitor, and the detonator will not fire. The CDU control system stops on any error and must return to the start of the control sequence.

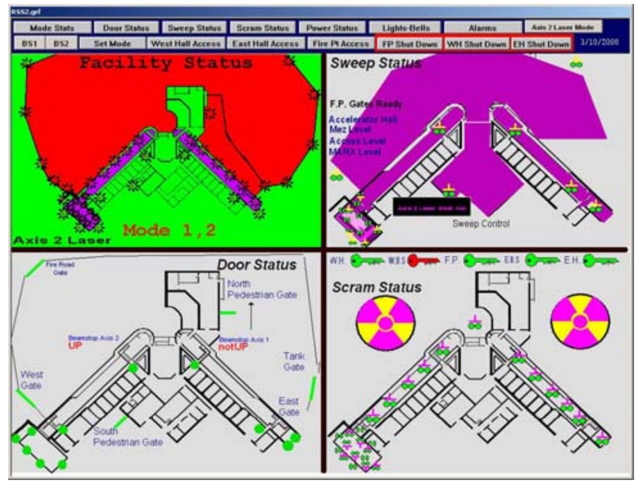

Figure 3: Facility status page.

# PSS SYSTEMS, SUBSYSTEMS, AND MAJOR COMPONENTS

Several of the PSS major subsystems and components are described in the following subsections.

## *PLC Hardware*

The dual PLC hardware system consists of two identical Modicon PLCs and I/O field interface hardware that provide redundant inhibit paths. The PLCs provide protection for both axes in an integrated fashion, depending on the mode selected. Each PLC executes identical programmed logic which manages the interlock hardware.

The computerized PSS control hardware is based on Modicon "Quantum" PLC's and remote "Quantum" I/O hardware from Schneider Electric. The PLC executes safety-system logic independently of the DARHT PSS display screen (HMI).

## *Software*

The software consists of Concept by Schneider Electric for the PLCs, GE Fanuc® iFIX™ automation software for the Human-Machine Interface (HMI), Windows®XP, and I/O driver software. Application specific software is developed in-house. The modular programming software, Concept, provides the platform for application specific software. The HMI software, iFIX™, provides operator visibility. Together, the PLC and HMI software monitor such activities as doors opening and engagement and disengagement of other interlocks and switches. HMI software allows process visibility to the operators. The HMI graphically presents the condition of the interlocks, progress of the sweep, SCRAM button status, beamstop position, and other elements of the safety system in the control room.

The HMI applications software has been successfully used at the integrated test stand during development and on Axis I and Axis II of the DARHT Facility. The HMI software offers third-party integration compatibility for even greater application potential such as VP-Link, simulator software used to test modifications offline and to qualify the PSS software on the integrated test stand. It is flexible and reliable configurable for I/O management and visibility.

The software was developed using DOE Order 1330.1D as a guideline. Documentation includes a software Development Plan, HMI/PLC Test Procedure, and a Software Backup Plan. A Functional Verification Checklist is used to ensure that the system functions as intended.

### *Hardware*

PSS Hardware and ANSI colored signs mark entrances to hazard areas. Hardware is verified during semiannual testing of the PSS. Lights and bells overlap in their visible and audible coverage and are evaluated for operation during each sweep in addition to the semiannual verification.

The PSS uses a dual set of I/O communication lines and applies error checking to ensure the integrity of communication to the I/O as seen in Figure 3. Two separate and independent configurations of the interlock hardware are installed to provide redundant inhibit paths. A power loss will result in a PSS fail-safe position that inhibits the high explosive and accelerator interlocks.

### *Keys*

There are individual keys for each axis and a separate key for the firing point that in conjunction with the PSS provide protection for authorized entries into exclusion areas, inadvertent production of radiation, and or high explosive events. The beamstop locks are a separate core.

Each accelerator axis has a Radiation Key that must be properly positioned before charging of the respective injector can take place. The Axis I or Axis II Radiation Keys lock/unlock the doors to the Axis I or Axis II accelerator halls. For radiation production, the Axis I or Axis II key must be inserted in a PSS cored switch located in the accelerator control room at the main console. The Axis I and Axis II keys have unique lock cores.

A Firing Point Key is used to control access to the mode 2 exclusion area. This key locks/unlocks the pedestrian/vehicle gates around the outside perimeter. The core is unique from the Axis I and Axis II Radiation Keys. The key must be inserted in a PSS cored switch located in the accelerator control room at the main console before charging of the injectors can take place in modes 2 or mode 3 for either axis. This key is not used if both accelerator axes are in Mode 0 or 1.

The beamstop keys are used at the location of the Axis I and Axis II beamstops to allow the raising of the respective beamstop. Its core is also unique from that of the other three keys. When the beamstop is lowered into the path of the electron beam for Mode 1 operation, the key is removed from the beamstop core and will remain inserted into the beamstop DARHT operations key control console. For Mode 0, the keys remain in the controlled key lockbox located in the accelerator control room. For mode 2 and mode 3, the respected beamstop key remains in the beamstop lock located on the side of the beamstop.

## SUMMARY

The PSS is designed specifically to include a combination of engineering and administrative controls. The hardware is designed in a redundant fail-safe manner that ensures optimal safety of DARHT personnel. The system is verified on a semiannual basis or whenever a modification is made. The multiple modes of operation allow for each axis to run independently or in combined modes of operation which benefits the diverse experiments which occur at the DARHT facility.

# UNIQUE FEATURES OF THE J-PARC LINAC AND ITS PERFORMANCE - LESSONS LEARNT

A. Ueno#, J-PARC, JAEA, Tokai, Naka, Ibaraki, 319-1195, Japan

*Abstract*

The J-PARC (Japan Proton Accelerator Research Complex) linac has been successfully commissioned up to its design energy of 181MeV and almost the first stage design peak intensity of 30mA. The following unique methods and hardware features adopted in the J-PARC linac are explained and those results are presented in this paper. The surface production dominating Cs-free $H^-$ IS (Ion Source) with magnetic focus LEBT (low energy beam transport), macro-beam-pulse shaping method related with the J-PARC 30mA-RFQ (Radio Frequency Quadrupole linac) design, a stable one-shot operation method, beam suspending method for machine protection, RF-chopper system related with the operation parameter of the RFQ, one-turn injection into the following J-PARC RCS (Rapid Cycling Synchrotron), transverse matching using TRACE3D PMQ (Permanent Magnet Quadrupole) elements approximating the fringe field effects of the electro-quadrupole magnets, PR (Periodic Reverse) electroforming for high-duty compact DTQ (Drift Tube Quadrupole) coil and thick pure plating of DTL (Drift Tube Linac) and SDTL (Separated-type DTL) and 2 cavity behaviour of SDTL fed with one Klystron.

## OVERVIEW OF J-PARC LINAC

As shown in Fig. 1, the J-PARC linac consists of 34 accelerating cavities (RFQ, DTL1~3, SDTL1A~15B), IS, LEBT, MEBT1 (Medium Energy Beam Transport 1) and beam transport to RCS [1]. Since the uncoupled SDTLnA and B (n=1~15) are fed RF-power by one klystron, 19 klystrons are used for acceleration. At the J-PARC first stage, the J-PARC linac accelerates an $H^-$ beam with a peak intensity of 30mA up to the energy of 181MeV with a pulse width of 500μs and a repetition rate of 25Hz.

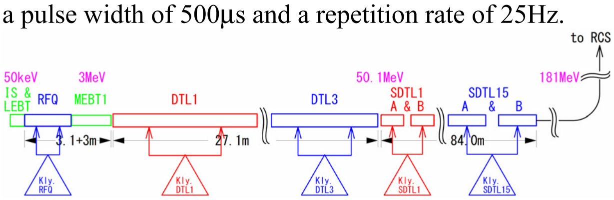

Figure 1: Scheme of J-PARC linac.

## SURFACE PRODUCTION DOMINATING CS-FREE IS & MAGNETIC FOCUS LEBT

In almost all of IS's for high intensity $H^-$ accelerators, Cs is seeded on PE (Plasma Electrode) in order to increase $H^-$ production efficiency. Since the thickness of the Cs layer affects to the efficiency greatly, it is not so easy to keep $H^-$ intensity constant with the Cs seeded $H^-$ IS. Also the frequency of sparking in high-voltage gaps of IS or RFQ is increased by the Cs. For stable operation, Cs-free IS is adopted for J-PARC. In order to minimize emittance growth by using SCN (Space-Charge Neutralization) measured as more than 90% [2], the magnetic focus LEBT composed of two solenoid and one ejection angle correction magnets is adopted. A schematic drawing of the IS and LEBT is shown in Fig. 2.

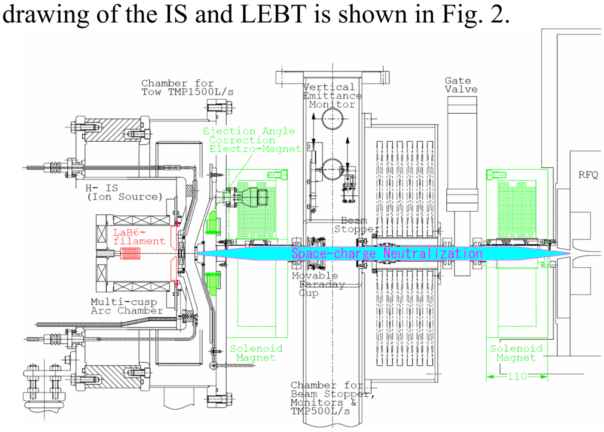

Figure 2: Schematic drawing of IS and LEBT.

On 1995, in a Cs-free IS, a 16mA $H^-$ beam was produced by using a cylindrical arc-chomber (D150mm, L150mm), a $LaB_6$-filament, a PE shown as Fig.3(a) and an arc-current of 220A [3]. Although the plasma density was increased by using a smaller arc-chamber (D100mm, L125mm) and a higher arc-current of 290A, the intensity had been limited to 16mA by using the PE shown as Fig. 3(b), for two years. After the success of 4mA intensity increase by only increasing the temperature of PE with a thermal insulator ceramics flange shown as Fig. 3(c), various shapes of PE's shown in Fig. 3 were examined by the assumption of that surface $H^-$ production was dominating. Finally, a 38mA $H^-$ beam was produced by using PE shown as Fig.3(h) [4]. The $H^-$ production efficiency seems to be increased mainly by the deoxidization of PE surface made of Mo with the high temperature measured as about 500°C in $H_2$ gas.

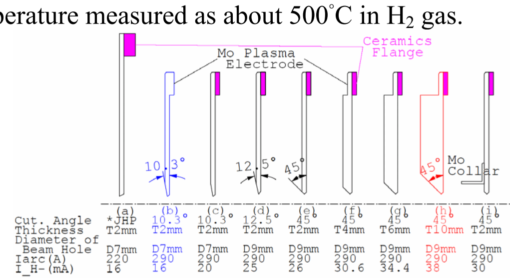

Figure 3: Various shapes of PE's examined.

## MACRO-BEAM-PULSE SHAPING & BEAM SUSPENDING METHODS

In order to avoid emittance rotation problem during the rise-time of SCN, macro-beam-pulse shaping by kicking the beam transversely is not available in magnetic focus

#akira.ueno@j-parc.jp

LEBT. Therefore, macro-beam-pulse is shaped by using RFQ longitudinal acceptance with modulating the injection energy in J-PARC. As shown in Fig. 4, RFQ acceleration starts after more than 100μs from IS arc pulse start and SCN established by low-energy unaccelerated beam transported through the LEBT. The end of macro-beam-pulse is determined by the end of RFQ-RF pulse since its fall-time is fastest. The macro-beam-pulse also ends by ending the RFQ-RF responding to MPS (Machine Protection System) fast interlock [5], for example DTL sparking and so on. In order to suspend beam acceleration for MPS reset time or one-shot operation, only IS arc pulse timing is delayed 0.2 ms after RFQ-RF pulse end where IS extraction voltage is switched off. As shown in Fig.5, no acceleration was observed for the beam with 10keV lower energy than the design energy of 50keV. IS signals {potential, arc voltage, arc current, $H^-$ beam measured by FC(Faraday Cup)} and RFQ RF-field are shown in Fig. 6.

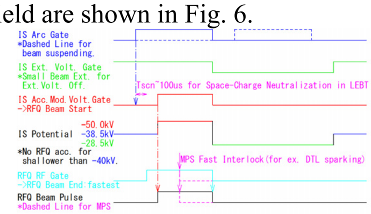

Figure 4: Timing-Chart of J-PARC IS & RFQ.

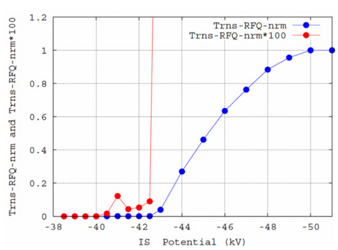

Figure 5: Measured Relationship between IS Potential and RFQ Transmission.

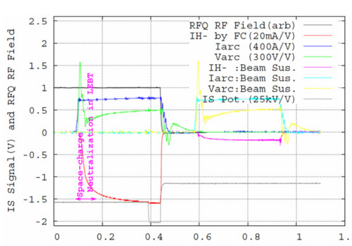

Figure 6: IS Signals and RFQ RF Field.

## *J-PARC 30mA-RFQ Design and Manufacturing*

In order to make the above macro-beam-pulse shaping available and the RFQ as emittance filter in both longitudinal and transverse motions, the RFQ is designed by using codes KEKRFQ [6] and PARMTEQm [7]. By using KEKRFQ, longitudinal and transverse acceptances including space-charge effect are kept constant in GB (Gentle Buncher) section (synchronous phase $\phi_s$= –88°→–30°) and accelerator section ($\phi_s$= –30°), respectively. The designed cell parameters of energy, modulation factor 'm', minimum bore radius 'a' and $\phi_s$ are shown as the functions of longitudinal position in Fig. 7(a). Since 'm' and 'a' change rather rapidly in GB, the accelerating field should be as accurate as possible. The approximated accelerating field used in PARMTEQm is shown as Eq. (1) whose parameters are explained in Fig. 7(b). In the equation, incorrect cell length Lc(i+1) is used to calculate A(i+1). The accelerating field is more accurately approximated by using Eq. (2). In order to stabilize the accelerating quadrupole field of the RFQ against the dipole-mode mixing, PILS's (π-mode Stabilizing Loops) are installed in the RFQ as shown in Fig. 8(a) [8, 9]. The electric field near beam axis is modified as shown in Fig. 8(b), in which the field distribution of one PISL cell length between pares of vertical and horizontal PISL rods calculated by MAFIA [10] are shown.

Figure 8: Inside View of RFQ and Field Distribution near Beam Axis in One PISL Cell Calculated by MAFIA.

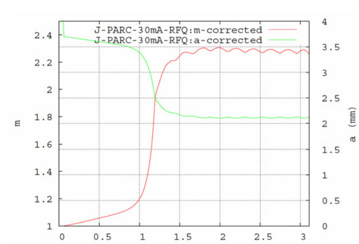

Figure 9: 'm' and 'a' for Design Accelerating Field.

The RFQ was manufactured with corrected 'm' and 'a' shown in Fig. 9.

## RF-CHOPPER & RFQ OPERATION PARAMETER SUITABLE FOR IT

In Figs. 10 and 11, the schematic drawing of MEBT1 and the inside-view of 2 coupled RF-chopper cavities are shown. Beam is deflected and dumped on a movable scraper made of graphite by the RF-field in RF-chopper. By switching RF-power to the RF-chopper, it is possible to produce arbitrary width and number of intermediate-beam-pulses [11, 12, 13]. Although the range of 3MeV-H$^-$ beam is very short (a few μm) and therefore energy density depositing on it is very high, it is confirmed experimentally that graphite stands for design beam duty (30mA*270μs*25Hz) of the J-PARC first stage.

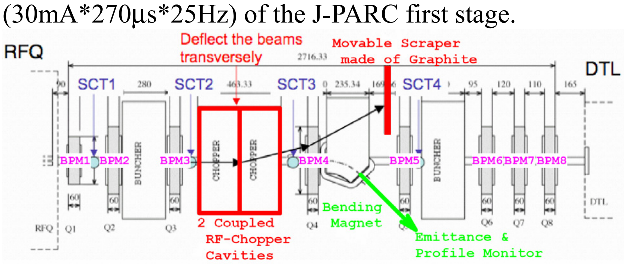

Figure 10: Schematic Drawing of MEBT1.

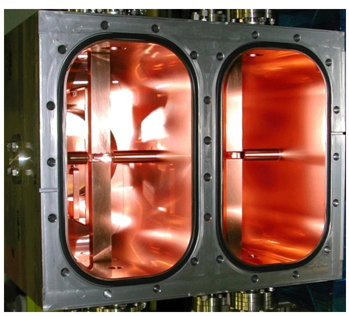

Figure 11: Inside View of RF-Chopper Cavities.

The 'remaining beam' which is deflected by the RF-chopper but undumped and accelerated by the following accelerators should be reduced as small as possible, in order to reduce residual radiation in the RCS. Early in the J-PARC linac commissioning, it was difficult to reduce the 'remaining beam' lower than measurement accuracy especially for high peak intensity beam about 30mA. In order to minimize the longitudinal halo of the beam accelerated with the RFQ, RFQ RF-field and IS potential are searched to minimize the horizontal beam size at the position with dispersion downstream of the bending magnet in MEBT1. The result is shown in Fig. 12.

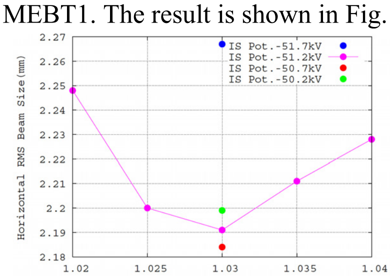

Figure 12: Relationship between RFQ RF-Field & IS Potential and Horizontal RMS Beam Size at Position with Dispersion.

By setting the RFQ RF-field at 3% higher than the design value and the IS potential at –50.7kV, the 'remaining beam' can be reduced lower than the measurement accuracy of linac monitor. By using RCS BLM (Beam Loss Monitor) [14] at the position with dispersion, the 'remaining beam' can be measured most accurately as shown in Fig. 13 in which very slight beam is measured (red line), although all of the beam is deflected by the RF-chopper. The 'remaining beam' due to longitudinal halo will hopefully be eliminated by RF-chopper with half resonant frequency of 162MHz.

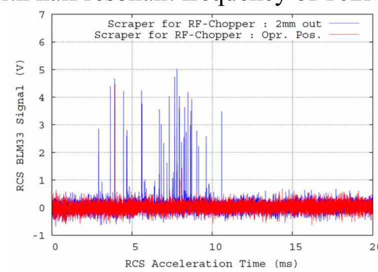

Figure 13: BML Signal during RCS Acceleration Time at Position with Dispersion.

The measured LEBT and MEBT1 SCT signals and RFQ RF-field are shown in Fig. 14. The rise-time of the macro-beam-pulse (blue line) measured by MEBT1-SCT3 (upstream of RF-chopper) is rather short (about 3μs) which is the proof of SCN establishment in the LEBT. The fall-time is much faster than it (about 1μs) since it is determined by 80% of the RFQ RF-field (black line). Two type of chopped beam measured by MEBT1-SCT5 (downstream of RF-chopper) are shown with green (112ns, 22turn) and red (560ns, 1turn) lines artificially.

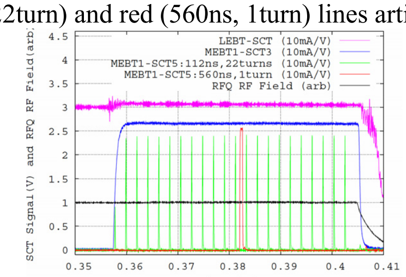

Figure 14: LEBT and MEBT1 SCT Signals and RFQ RF-Field.

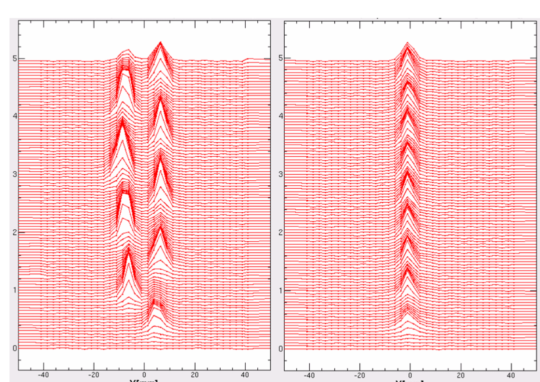

(a) (b)

Figure 15: Mountain Plots of RCS Vertical IPM Signals before (a) and after (b) Injection Error Correction.

One turn injection into the RCS makes injection error correction possible. The beam position and profile measured by an RCS IPM (residual gas Ionization Profile Monitor) as mountain plots during the first 9turns are shown in Fig. 15(a)(before correction) and (b)(after correction).

The RF-field in the RF-chopper, MEBT1-BPM right and left signals are shown as red, blue and green lines, respectively in Fig. 16. The ringing of RF-field at RF on/off transient-time due to RF-power flow between the 2 coupled cavities is observed. The shit of beam position due to the ringing is also observed for about 50ns after beam rise-time. If the affect of the ringing is significant, it can be eliminated by driving each RF-chopper cavity independently with two RF-sources.

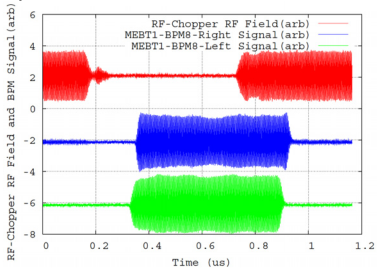

Figure 16: RF-Chopper RF-Field and Right- and LEFT-BPM Signals of MEBT1.

## TRANSVERSE MATCHING WITH TRACE3D PMQ APPLOXIMATION

As reported in the paper of LINAC2002 [17], the fringe field of Q(quadrupole)-magnets should be taken into account. By using 20-pieces of hard-edge magnets (red line of Fig. 17) for each Q-magnet, the ellipses measured in the MEBT1 test setup are reproduced.

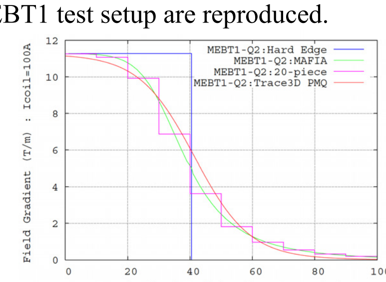

Figure 17: Various Field Distributions of MEBT1-Q2 Used for TRACE3D Calculations.

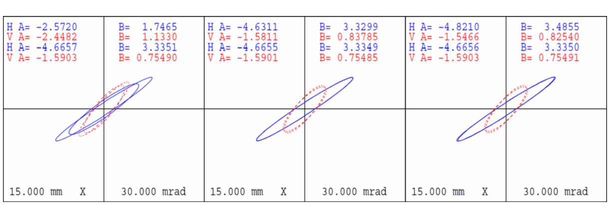


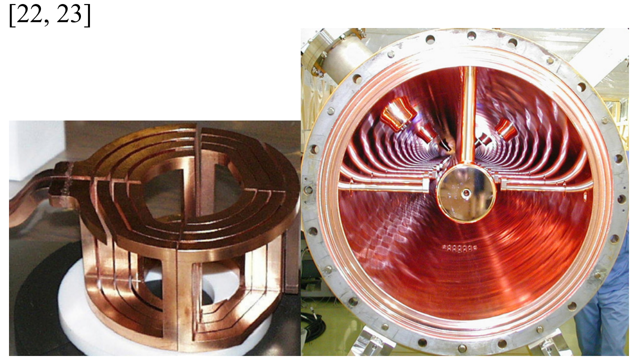
(a) (b) (c)

Figure 18: Measured and Calculated Ellipses in MEBT1 Test by Using Hard Edge Field (a), 20-Pieces Field (b) and TRAC3D PMQ Field (c).

Instead of 20-pieces of hard-edge magnets, PMQ element (magenta line of Fig. 17) of TRACE3D [18] can also reproduce the experimental result as shown in Fig. 18(c). In Fig. 18(a), (b) and (c), measured and calculated ellipses are shown for hard-edge field, 20-pieces field and PMQ field, respectively. Since online control of the J-PARC linac is done by using XAL [19], the PMQ element has been transplanted into XAL [20]. All of Q-magnets in J-PARC linac are treated as PMQ elements.

## DTQ-COIL & CAVITY-PLATING USING PR-ELECTROFORMING

PR(Periodic Reverse)-electroforming, in which electroforming and short electro-polishing is reiterated without any brightening agent, is able to produce thick and pure plating comparable with OFC (Oxygen Free Copper). Compact DTQ-coil shown in Fig. 19(a) was produced with it and is able to be operated with high magneto-motive-force and high-duty (3.5turn, 600A, DC) [21]. As shown in Fig. 19(b), each inside of DTL or SDTL cavity was plated with PR-electroforming. All of DTL and SDTL cavities were successfully high-power RF-conditioned up to 20% higher powers of the design values. [22, 23]



(a) (b)

Figure 19: Photos of DTQ-Coil (a) and Inside View of DTL1 (b).

## 2 CAVITY BEHAVIOR OF SDTL

Each pair of SDTLnA and B (n=1~15) is driven by one klystron. The vector-sum of the two RF-fields is feedback-controlled [24]. However, unexpectedly high RF-field unbalances caused by beam loading are observed in several of the pairs. In Fig. 20, the measured maximum (SDTL03) and minimum (SDTL12) unbalances are shown when a 28mA-beam with 100ms pulse width is accelerated.

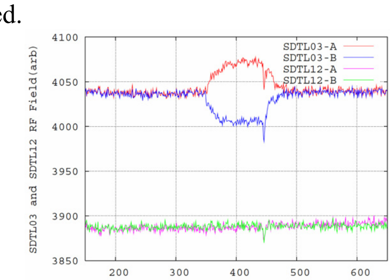


Figure 20: RF-Fields in SDTL03A&B and 12A&B while Accelerating 28mA- and 100µs-Beam.

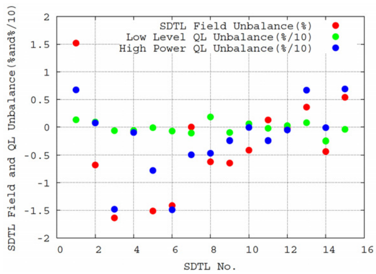

Figure 21:SDTL QL Unbalance (Preliminary) & RF-Field Unbalance while Accelerating 28mA- and 100µs-Beam.

In Fig. 21, the RF-field unbalance UBRF due to beam-loading and the QL (Loaded Q-value) unbalance UBQL calculated with following equations are shown.

UBRFn=(RFnA-RFnB)*2/(RFnA+RFnB)
UBQLn=(QLnA-QLnB)*2/(QLnA+QLnB)

In the latest beam acceleration, preliminarily, each QLnA and QLnB was measured by measuring RF decay-time during high-power operation as shown with blue circles in Fig. 21. The RF-field unbalance due to beam-loading seems to have some relationship with the unbalance of the high-power loaded Q-value, although more accurate measurements are necessary. If the change of the loaded Q-value is correct, multipacting is one candidate of the causes.

## SUMMARY

The following unique methods and hardware features adopted in the J-PARC linac are explained and the performances and problems of them are presented.

- Surface production dominating Cs-free $H^-$ IS
- succeeded in produce more than 30mA stably.
- Macro-beam-pulse shaping by using RFQ longitudinal acceptance with magnetic focus LEBT
- succeeded in producing the pulse with rather high rise- and fall-time. It also makes possible stable one shot operation, fast beam suspending for MPS and so on.
- RF-chopper
- succeeded in reducing the ‘remaining beam’ lower than the measurement accuracy of linac monitor by searching the RFQ operation parameter. One turn injection with it into the following RCS is essential for injection error correction. Two RF-sources are necessary to eliminate the measured RF-ringing. The RF-chopper with half resonant frequency of 162MHz will eliminate the ‘remaining beam’ and makes possible beam intensity double by inevitably used two scrapers.
- Transverse matching with TRACE3D PMQ
- succeeded in representing the fringe field effects. All of Q-magnets in the J-PARC linac are treated as PMQ in XAL and TRACE3D.
- PR (Periodic Reverse) electroforming.
- succeeded in producing high-duty compact DTQ-coil and thick pure plating of DTL and SDTL.
- 2 cavity behaviour of SDTL fed with one Klystron.
- unexpectedly high RF-field unbalance between the 2 cavities are observed. The RF-field unbalance due to beam-loading seems to have some relationship with the unbalance of the high-power loaded Q-value (preliminarily measured).

# STATUS OF THE CONSTRUCTION OF THE SPIRAL2 ACCELERATOR AT GANIL

Tomas Junquera # on behalf of the Spiral 2 project team, IPN (CNRS/IN2P3, Univ. Paris Sud)
91400 Orsay, France

*Abstract*

The Driver Accelerator for the SPIRAL2 Radioactive Ion Beam facility at GANIL (Caen, France) is in the construction phase. Following the initial phase of prototyping development, the series production of major components was recently launched. Important decisions have also been recently taken concerning buildings, RIB operational aspects and related safety requirements.

## INTRODUCTION

The GANIL laboratory (CNRS-CEA) in Caen (France) is one of the major radioactive and stable-ion facilities for nuclear physics, astrophysics and interdisciplinary research in the world. Since the first beams delivered in 1983 the performances of the GANIL accelerator complex, was constantly improved with respect to the beam intensity, energy and available detection systems. A major improvement was the construction of a new Cyclotron dedicated to the production and acceleration of Radioactive Ion Beams (RIB), the Spiral 1 project, which entered into operation in 2002.

Following the recommendations of international committees, the French Minister of Research took the decision in May 2005 to construct a new facility (Spiral 2) in order to enlarge the range of accelerated ions by production of high intensity RIB. On the 1st of July 2005, the construction phase of SPIRAL2 was launched within a consortium formed by CNRS, CEA and the region of Basse-Normandie in collaboration with French, European and international institutions.

The importance of the availability of Radioactive Ion Beams (RIB) has been often underlined in the last years. NuPECC (Nuclear Physics European Collaboration Committee) and ESFRI (European Strategy Forum on Research Infrastructures) established roadmaps and recommendations for the next generation of facilities in Europe. FAIR in GSI laboratory in Darmstadt (Germany) and Spiral 2 in GANIL laboratory are among the selected projects. Both projects are complementary and are based on two different RIB production methods: FAIR is based on In-Flight Fragmentation techniques, while Spiral 2 uses the Isotope Separation on Line (ISOL) techniques.

## THE SPIRAL 2 PROJECT

The radioactive neutron rich beams will be mainly produced via the fission process induced by fast neutrons in a depleted Uranium Carbide (UCx) target (11g/cm3 density), with the aim of $5.10^{13}$-$10^{14}$ fissions/s [1]. For this purpose a high intensity CW driver accelerator will deliver 40 MeV (5 mA) to a thick Carbon target (Converter), and produce a very high neutron flux on the UCx target. The fission process will release radioactive atoms which are ionized and extracted from a target/ion-source system. The produced RIB are finally sent to either a low energy experimental hall, or driven towards a charge breeder and post-accelerated by the existing CIME cyclotron (Spiral 1).

The possibilities offered by the driver accelerator, with its capability to accelerate a large range of high intensity CW ion beams (Table 1 and 2), have opened new complementary opportunities to the Spiral 2 project:

- High intensity stable beams, i.e. Ar, Kr, etc
- Neutron experiments, i.e. time of flight
- Interdisciplinary researchs, i.e. solid state, biology, etc

Table 1: Driver Accelerator Beams

| beam | p+ | D+ | ions | ions |
|---|---|---|---|---|
| Q/A | 1 | 1/2 | 1/3 | 1/6 |
| I (mA) max. | 5 | 5 | 1 | 1 |
| Womin(Mev/A) | 2 | 2 | 2 | 2 |
| Womax(Mev/A) | 33 | 20 | 14.5 | 8.5 |
| CW max beam power (KW) | 165 | 200 | 44 | 48 |

Table 2: Driver Accelerator Characteristics

| |

| **Room Temperature Q-poles** |
| **30 Solid State RF amplifiers (10 & 20 KW)** |

## PROGRESS IN THE CONSTRUCTION OF THE SPIRAL 2 FACILITY

During the last two years (oct. 2006-sept 2008) the activities have evolved in two main directions:

1. Preparation and adoption of decisions around the project phases, considering the different beam users and the main project goals, the consequences on buildings and the safety aspects.

2. Construction and tests of main components of the driver accelerator, essentially the Injector and the SC Linac

# junquera@ipno.in2p3.fr

The new buildings: Driver Accelerator, RIB Production, and two new Experimental Halls, are illustrated in Fig. 1, close to the present buildings (in blue). New experimental halls will be dedicated to high intensity stable beams, neutron experiments, interdisciplinary physics, and low energy RIB experiments.

The production building, which will host the RIB production caves and the RIB transport lines, will be a nuclear class building. The safety requirements imply a double confinement in the whole building that will host the UCx production cave as well as the transport lines for the radioactive beams composed of fission products. The whole vacuum system will be connected to the gas storage system, and a public enquiry will be launched to get the authorization to release gas from the storage facility, after a suitable period of radioactivity decrease.

For the construction of these buildings, and strongly related to the safety authorisation procedures, two phases have been proposed:

1. Driver Accelerator and first experimental areas
2. RIB Production building and associated experimental areas

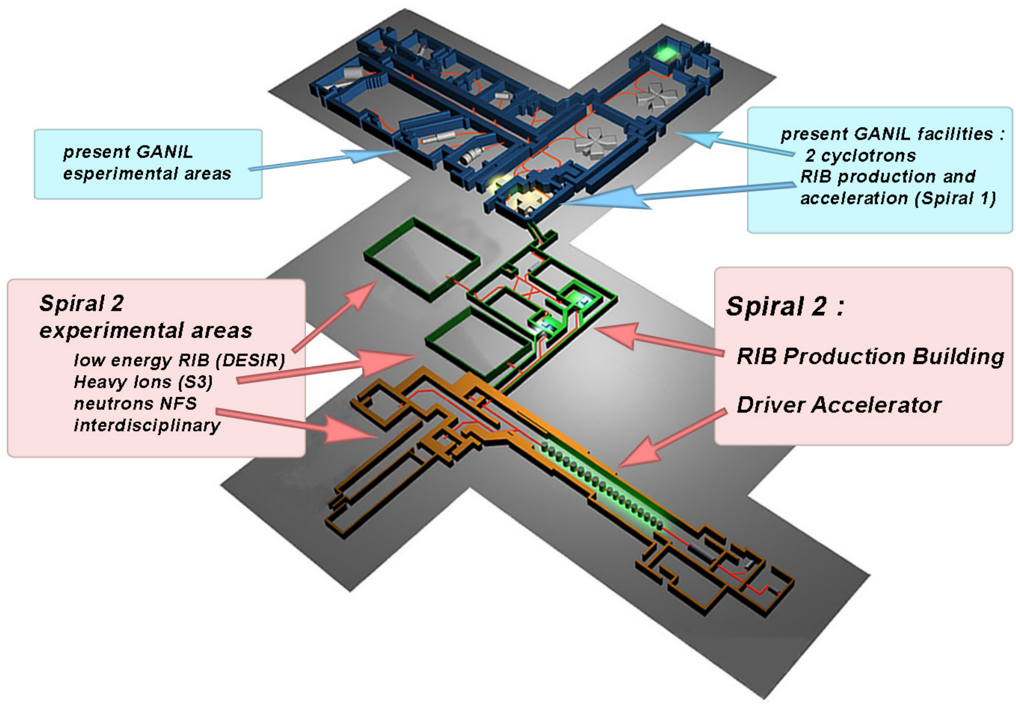

Figure 1: Present facilities at GANIL laboratory and new buildings for SPIRAL 2 Driver Accelerator and associated Experimental Areas.

GANIL is a nuclear facility and, for Spiral 2 authorizations, it is considered as an extension of the existing facility. During the last two years, together with preliminary safety studies, initial talks with the National Nuclear Safety Agency have resulted in a final agreement for the licensing procedure: A global safety report (DAM report) leading to a single Ministry Authorisation Decree with several steps.

This report must include:

- Preliminary Safety report of the two phases
- Operating ranges of the whole facility
- Study of the impact on the environment

The reports to be delivered were defined by a very recent new regulation law (2007) and Spiral 2 is the first major facility for nuclear research to be concerned by these new regulations.

## *Spiral 2 Schedule*

The general schedule of the project is presented in Fig 2, showing the major milestones:

- October 2008: Phase 1 buildings contracts.
- Beginning of 2011 accelerator building available
- Beginning of 2012 for the first beams in the stable ion experimental hall and the neutron time of flight hall
- Mid 2013 for the first RIB and the low energy experimental hall.

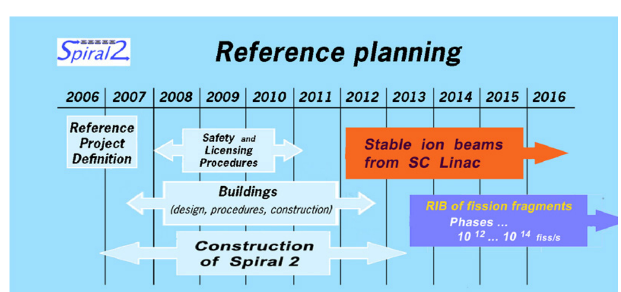

Figure 2 : Spiral 2 schedule.

## BEAM LOSSES AND SAFETY ASPECTS

A complete beam dynamics study of the Linac Driver Accelerator has been completed. It includes the two injectors, the SC Linac and a preliminary version of the High Energy Beam Lines ( Fig 3).

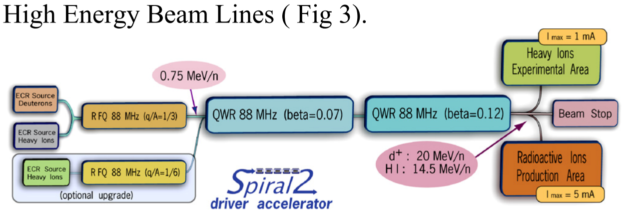

Figure 3: Driver accelerator layout.

Very extensive calculations of mutiple-ion-type beam transport using 3D maps have been performed with various conditions of space charge, and various hypothesis of space charge compensation (including solenoids 3D map) [2]. A dedicated poster covering all the beam dynamic studies is presented in this conference [3].

Two codes were used for this computing: Toutatis for the RFQ and TraceWin/Partran for the Linac . Distributed computing was performed using 40 PC in a client/server network. Errors were introduced in a statistical way for 1400 different Linac configurations and 1 million macro-particles trajectories were analyzed for each configuration. The matching and correction schemes were applied for each Linac.

The main goal of these calculations was to limit the beam losses for safety and machine protection. One important result was to define the precise position of slits in the low energy sections (Fig. 4)

- 3 slit systems to control input emittance in the RFQ and remove beam halo coming from LEBT line.About 40 W beam losses on slits (for 5 mA deuteron beam)
- 6 slit systems to remove beam halo coming from the RFQ before the entrance of the SC linac. About 6x125 W beam losses on slits (for 5 mA deuteron beam).

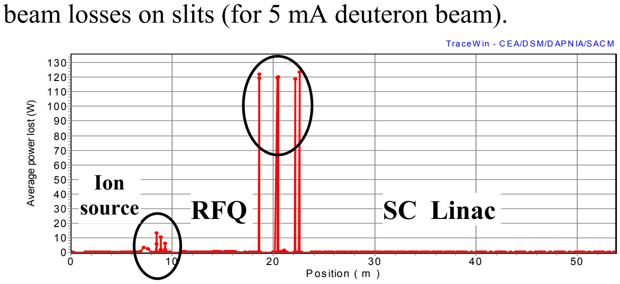

Figure 4: Beam losses on the slits.

The errors introduced in these calculations are of two types:

- Corrected (alignment, QWR steering effects, etc)
- Uncorrected (vibrations, stability of magnet currents, RF voltage, phase, etc)

The uncorrected errors are responsible for a very low level of losses: 0.20 W for the SC linac (average value of 1400 computed linacs), this corresponds to 0.2W for a length of 30m, ~6 mW/m.

Most of these losses are located in the firsts QWR of both low and high energy sections (Fig. 5)

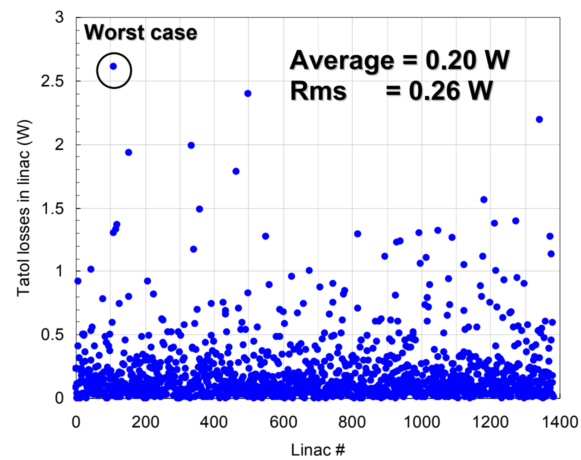

Figure 5: Statistical study of Linac losses.

Based on preliminary experience in other high intensity accelerator projects and performed calculations, a reasonable level of losses goal of ~1 W/m could be adopted. In order to stay well inside this level of losses in the Spiral 2 project, the decision was taken to install a big number of beam diagnostic systems, special mechanical adjustments systems for all the components and magnetic correcting devices all along the Linac.

The safety goals, in terms of dose rates for the Spiral 2 project are shown in the following table:

Table 3: Safety Goals in Terms of Dose Rates

| | Technical Staff | People/Environment |
|---|---|---|
| Normal operation | < 2 mSv/year | < 10 µSv/year |
| Incidental situation | < 10 mSv/year | < 10 µSv/incident |
| Major incident | < 20 mSv/incident | < 100 µSv/incident |
| Major accident | Variable according to situation and potential impact | < 1 mSv/accident |

The limit dose for offices, labs and workshops where permanent activity is foreseen, is 7.5 µSv/h, the limit for a zone where maintenance operations are possible is 100 µSv/h and zones where dose rates are greater than 10 mSv/h are not accessible.

Activation and dose rates calculation are based on two codes: MCNPX 2.5 for deuteron and neutron transport and Fispack 2007 for activation inventory. All the Linac components were modelled with high degree of geometric detail and material composition.

Two major contributions were studied for the more critical beam: 5 mA deuteron beam at 40 MeV:

1) interaction between deuterons and materials
2) interaction between the generated neutron yield and materials.

Both mechanisms originate high material activation, and the main contributing isotopes were identified: Co56, Fe55, Co57, Mn54, CO58 and Cr51 (for stainless steel material). Hands on maintenance operation conditions are presently under study, taking into account different levels of beam losses along the Linac and considering reasonable decay times after beam shutdown.

## BUILDINGS STUDIES AND CONSTRUCTION

During the last year an intensive work has been developed for the definition of the buildings technical specifications, followed by a call for tenders and the analysis of proposals. At the present time we are very close to final contract agreement for the phase 1 (driver accelerator and stable ions experimental areas). The major decision was to install all these facilities underground. The level of Linac tunnel floor will be -9 m with a beam line at -7.5 m and an available tunnel height of 6 m. A technical tunnel running parallel to the Linac tunnel will allow installing cables, water cooling and some RF and electronics components that must be located in the linac proximity.

All the technical activities (labs and workshops, including the SC cavities preparation area, clean room and cryogenics tests) will be installed at the ground level. The RF amplifiers and the Helium liquefier will be also installed on top of the Linac minimising the distances to the cryostats and RF couplers. Total surfaces of the two levels, including the wall thickness are 8300 m2. Figure 6 shows a preliminary sketch of the underground tunnel. The height of the tunnel is 6 m and the width is 4.5 m, a crane covers all the tunnel length for manipulation of heavy components like cryomodules and Q-poles. The access to the Linac tunnel for components installation is made through special pits and elevators.

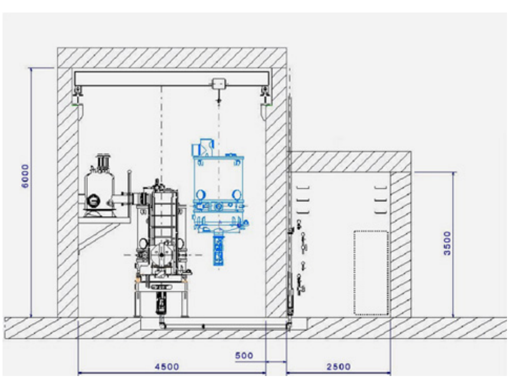

Figure 6: Underground Linac tunnel sketch.

## PROGRESS IN THE CONSTRUCTION OF ACCELERATOR COMPONENTS

### *Injector*

Complete tests of the two ion sources and the RFQ cavity are planned before the buildings completion and final installation of the components in the Linac tunnel. The Heavy Ions source with its mass analyzer and beam diagnostics will be tested in the CNRS/LPSC laboratory in Grenoble. The assembly has presently started and the first Ion Source measurements will start in January 2009.

The light ion source (proton and deuteron) with its beam transfer line and diagnostics will be tested in the CEA/Saclay laboratory, starting in mid-2009.

The construction of the RFQ cavity has started this year and after a final assembly and preliminary RF tests at the end of 2010, the cavity will be installed on the low energy deuteron line for beam tests in 2011.

### *SC Linac*

All (12+14) SC QWR contracts are presently placed in two different companies. The first series QWR for the high energy sections (β=0.12) have been delivered. The performances reached for the first cavity in a recent test in July 2008 are shown in Fig. 7. After some conditioning needed to overcome multipacting barriers, a very high gradient was reached (9 MV/m, for a max. nominal operating gradient in the accelerator of 6.5 MV/m) and the losses at 4 K were well inside the expected range. The low energy (β=0.07) QWR prototypes exhibit also very good performances, gradients higher than 10 MV/m. The contract for the manufacturing of the series QWR is already agreed and the first cavities will be delivered starting in March 2009.

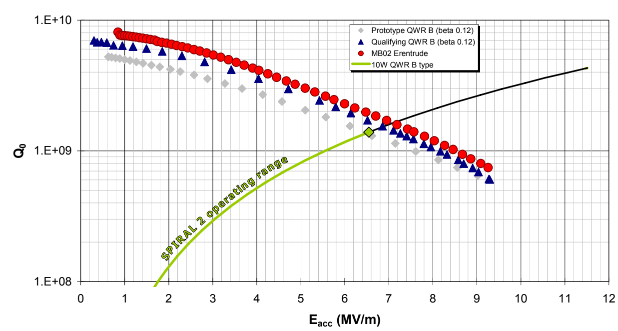

Figure 7: Accelerating gradient performances of β=0.12 QWR ( 2 prototypes and first of serial production).

Concerning the RF power couplers, the CNRS/LPSC laboratory in Grenoble developed a two years long prototyping program. Several prototypes models were tested at high power (40 KW) and a careful study of the multipacting and conditioning aspects was completed. These couplers have a fixed coupling position on the cavities, so the Qext adjustment must be done for the maximum current to be accelerated (5mA). The nominal CW RF operating power ranges between 5 KW and 15 KW.

### *First Cryomodules Tests in Orsay and Saclay Laboratories*

The two first crymodules, low and high energy, have been assembled and tested at 4 K integrating all RF (power couplers, amplifiers, tuners) and cryogenic interfaces (valve boxes and He transfer lines). The results obtained (CNRS/IPN Orsay laboratory, Fig. 8) with the high energy cryomodule (including two β=0.12 cavities) are completely satisfactory, a gradient of 8 MV/m was obtained with the power coupler, all the cryogenic measurements have confirmed a low level of static losses (13 W at 4 K), a new tuner system using a movable piston was also successfully operated. All the cryogenic interfaces operates very satisfactorily allowing the launch of all the series components contracts.

The low energy cryomodule, which integrates only one cavity is presently in the final test period at the CEA/Saclay laboratory Fig. 9. The initial cryogenic tests have confirmed a good performance for the static cryogenic losses, 7 W at 4K, and a very satisfactorily operation of all cryogenic interfaces. The complete test with power coupler, amplifier and tuning system will be performed next month.

A poster covering all the technical aspects and tests performed is presented in this conference [4].

Figure 8: High Energy cryomodule tested at CNRS/IPN Orsay laboratory.

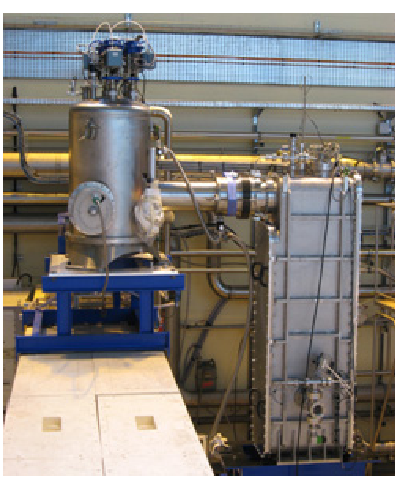

Figure 9: Low Energy cryomodule tested at CEA/Saclay laboratory.

### *RF Systems*

Two types of RF amplifiers have been studied :

- RFQ amplifiers: 4 x 60 KW tube amplifiers
- QWR amplifiers : 12 x 10 KW and 14 x 20 KW solid state amplifiers.

One model of each amplifier type was constructed for prototyping purpose. All the prototypes were successfully tested, reaching the nominal power and exhibiting stable operation behaviour during long term tests. A dedicated poster is presented in this conference [5] giving all the results of tests and technical specifications

Between the RFQ and the first QWR of the superconducting Linac, a long Medium Energy Beam Transfer line imposes the installation of 3 re-bunchers to to optimize the beam longitudinal phase length.

An original 3-gap cavity has been designed with very large beam holes (diameter 60mm) providing up to 120 kV of effective voltage. A poster describing this design is presented in this conference [6].

The control of all RF cavities of the Driver Accelerator will be performed by a new Digital Low Level RF system which is presently under development and will cover all the particular needs in terms of independent amplitude and phase of each cavity, as well as the accurate control of its associated tuning system.

## ACKNOWLEDGEMENTS

This work is the result of a large Project Team composed of people from GANIL and associated CEA and CNRS laboratories. It is also the result of an exceptional international collaborative effort of many accelerator experts in the world. Peer reviews, technical meetings, workshops, etc. have largely contributed to assess and establish the grounds for the design and construction of this new facility.

*Abstract*

In its June 2007 session the CERN Council has approved the White Paper, which includes construction of a 160 MeV $H^-$ linear accelerator called Linac4, and the study of a 4 GeV Superconducting Proton Linac (SPL). Linac4 will initially replace Linac2 as the injector to the PS Booster, improving its performance up to the levels required for producing the ultimate LHC luminosity. In a later stage, Linac4 is intended to become the front-end of SPL in a renewed injection chain for the LHC, which could be progressively constructed over the next decade. After briefly introducing the motivations and layout of the new injector chain, the talk will present the characteristics of the new linacs and give an overview of their main technical features and the R&D activities pursued within the HIPPI Joint Research Activity.

## INTRODUCTION

In its June 2007 session the CERN Council has approved the White Paper "Scientific Activities and Budget Estimates for 2007 and Provisional Projections for the Years 2008-2010 and Perspectives for Long-Term", which includes construction of a 160 MeV $H^-$ linear accelerator called Linac4, and the study of a 5GeV, high beam power, superconducting proton Linac (SPL).

Both those activities aim at rejuvenating the present proton injectors which –although well-performing for the time being - date from the 60-70s and are working, since some years, well beyond their design intensity and very close to their technical limits.

## PRESENT LHC INJECTORS

All the protons at CERN are produced by a duoplasmatron ion source giving in excess of 300 mA of beam current, composed by about 2/3 of protons [1]. The source provides a 100-150 µs beam with a repetition rate of 1.1 Hz. The beam, extracted at 90 keV, is further accelerated by a Linac (Linac2) up to 50 MeV and then injected in the 4 rings of a 25 m radius synchrotron, called the CERN PS Booster (PSB). The PSB, commissioned in 1972, brings the beam energy to 1.4 GeV and injects in another synchrotron, 100 m in radius, called the Proton Synchrotron (PS). CERN PS was commissioned in 1959 and accelerates the beam up to 26 GeV. All the above accelerators are located on the original CERN Meyrin site and serve several experimental facilities like ISOLDE, the antiprotons facility (AD), nTOF and the experiments in the East Area [2].

A fraction of the proton pulses from the PS is sent to the Super Proton Synchrotron (SPS), 1000 m in radius, to be accelerated to 450 GeV and then, amongst other, be injected in the Large Hadron Collider (LHC). The SPS was commissioned in 1976. A sketch of the present CERN accelerator is shown in Fig 1.

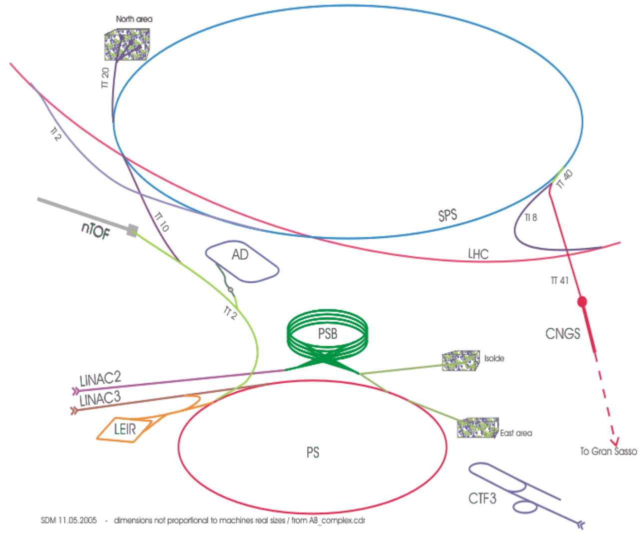

Figure 1: Layout of the present LHC proton injectors.

### *Linac2 and the Reasons for Its Upgrade*

Linac2 [3] was commissioned in 1978 and it consists of a three Alvarez-type Drift Tube Linac (DTL) tanks, operating at the frequency of 202.56 MHz. Electromagnetic quadrupoles are housed inside the 128 drift tubes necessary to bring the beam energy from 0.75 to 50 MeV. Until 1993 the pre-injector was a 750 kV Cockcroft-Walton, which was then replaced by a 4-vane Radio Frequency Quadrupole (RFQ2) [4], capable of delivering almost 200 mA of protons to the DTL. Linac2 is working at a current well beyond its design limit (150 mA) and the RF hardware is working at its technical limit. Besides, the output energy of 50 MeV is too low for any further current increase in the PSB, limited by space charge detuning at injection.

All the above reasons motivate the construction of Linac4 [5], accelerating $H^-$ to an energy of 160 MeV, which halves the space charge detuning at PSB injection and allows charge exchange injection.

### *Upgrade of the Injectors*

Linac4, which is approved to provide $H^-$ for the PSB operation in 2013, can be the first stage of a more global injector upgrade, which includes a Superconducting Proton Linac (SPL) [6] delivering a 4 GeV beam to a new synchrotron (PS2). PS2 could inject in the SPS at 50 GeV opening the potential for a higher proton beam flux from the SPS [7]. A technical design study on SPL and PS2 are due to be completed by 2011 when a decision on further upgrades could be taken. The layout on the Meyrin site [8] is shown on Fig.3. In the next two sections the ongoing activities for Linac upgrades will be described.

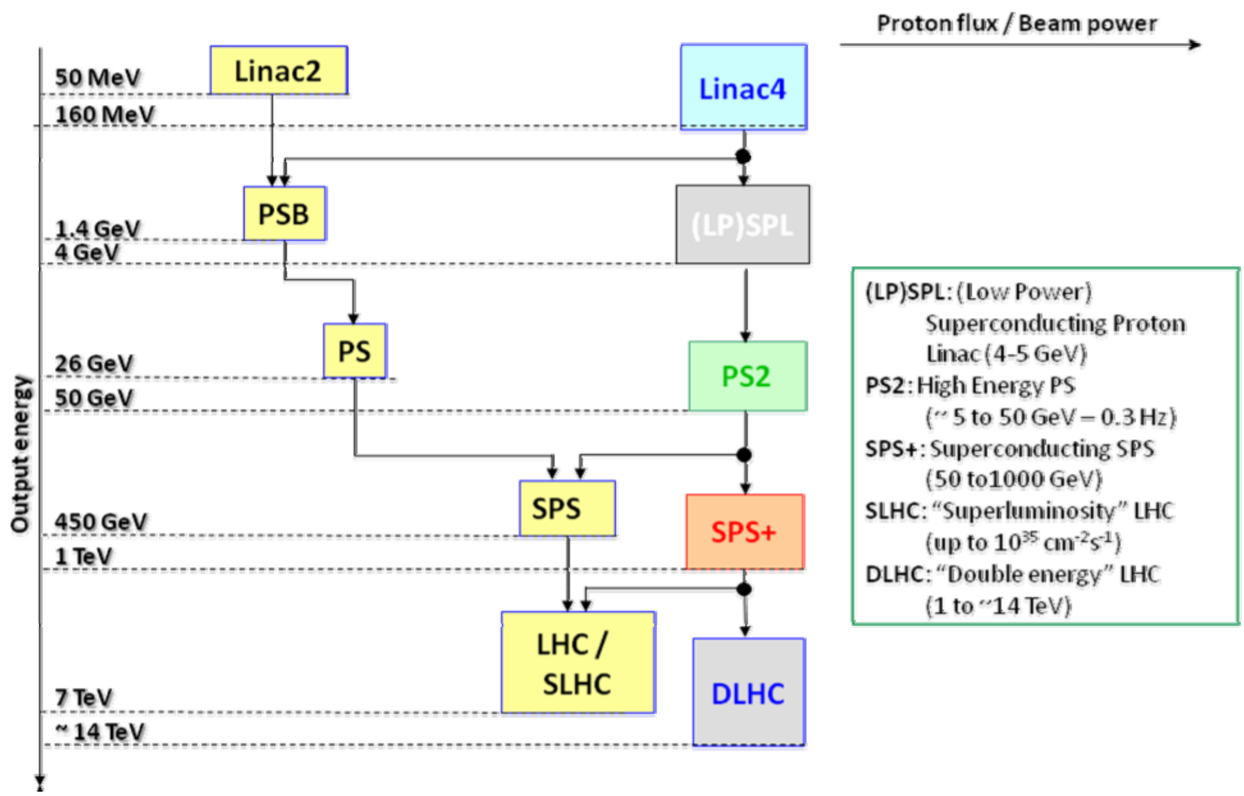

Figure 2: Block diagram of the present CERN proton injectors (left) and the possible staged upgrade (right).

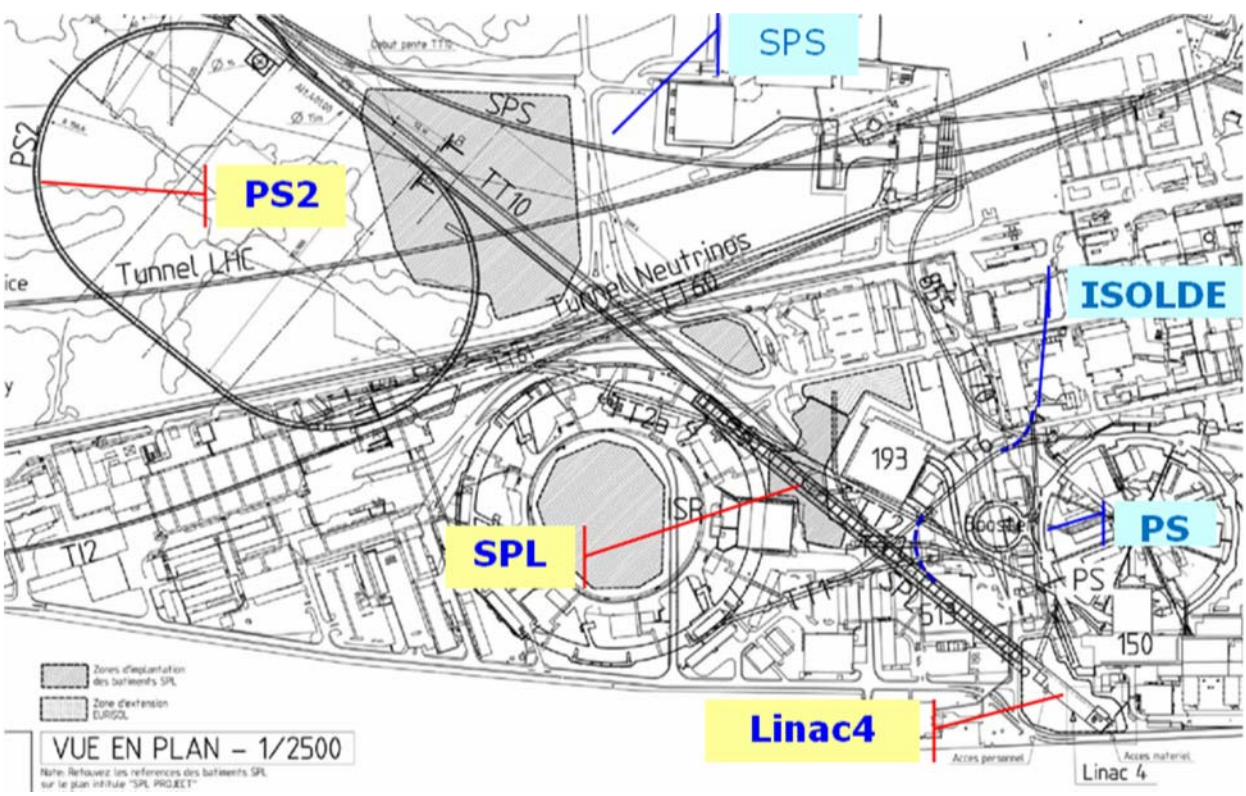

Figure 3: Layout of the new injector on the CERN Meyrin site.

.

## LINAC4

The Linac4 project started officially in January 2008 with the goal of having a Linac injecting 160 MeV $H^-$ beam in the PSB by 2013. The main characteristics of the beam from Linac4 are summarised in Table 1. In brackets the values to be achieved for future (Low Power-)SPL operation.

Table 1: Linac4 Beam Characteristics

| Ion species | $H^-$ |
|---|---|
| Output kinetic energy | 160 MeV |
| Bunch frequency | 352.2 MHz |
| Max. repetition rate | 1.1 (2) Hz |
| Beam pulse duration | 0.4 (1.2) ms |
| Chopping factor (beam on) | 65% |
| Source current | 80 mA |
| Linac current | 64 mA |
| Average current during beam pulse | 40 mA |
| Average beam power | 2.8 kW |
| Particles / pulse | $1.0\ 10^{14}$ |
| Transverse emittance in -rms | 0.25 mm mrad |
| Transverse emittance out - rms | 0.4 mm mrad |

### *Linac4 Layout*

Linac4 is a normal conducting linear accelerator operating at the frequency of 352MHz. The first element of Linac4 is a 2MHz RF volume source [9] which provides a 400 µs 80 mA $H^-$ beam at 45 keV with a repetition rate of 2 Hz. The first RF acceleration (from 45 keV to 3 MeV) is done by a 3 m long Radio Frequency Quadrupole [10]. At 3 MeV the beam enters a 3.6 meter long chopper line, consisting of 11 quadrupoles, 3 bunchers and two sets of deflecting plates. The beam is then further accelerated to 50 MeV in a conventional Drift Tube Linac (DTL). The DTL, subdivided in 3 tanks, is 19 meters long. Each of the 111 drift tubes is equipped with a Permanet Magnet Quadrupole (PMQ). The acceleration from 50 to 100 MeV is provided by a Cell-Coupled Drift Tube Linac (CCDTL). The CCDTL is made of 21 tanks of 3 cells each for a total length of 25 meters. Three tanks are powered by the same klystron, and constitute a module. The focusing is provided by electromagnetic quadrupoles placed outside each tank, with the option of using Permanet Magnet Quadrupoles between coupled tanks. The acceleration from 100 to 160 MeV is done in a π-Mode structure. The PIMS is made of 12 tanks of 7 cells each for a total of 22 m. Focusing is provided by 12 Electromagnetic Quadrupoles (EMQ). A 60 m long transfer line, composed of 2 horizontal and 2 vertical bendings, 15 quadrupoles and a debuncher cavity connects the Linac4 tunnel to the present Linac2 to PSB transfer line.

### *Prototyping Activities*

Prototyping activities have been going on since 2004, in order to prepare the Linac4 technical design report and to help choosing the most reliable technology and the best engineering solution for the components of Linac4. Prototyping activities include the realisation of a chopper device complete with its driver; two prototypes for the DTL; three prototypes of PMQ for the DTL; two prototypes for the CCDTL and a cold model of the PIMS structures. A list of the issues addressed and the achievements of the past and ongoing prototyping activities is given in the following:

- Chopper structure: a meander type structure printed on alumina substrate has been realised in collaboration with industry. Electrical and vacuum tests have confirmed the final choice of material and geometry. Assembly in a quadrupole has been demonstrated. [11]
- A driver for the chopper plates has been realised in house and a commercial amplifier has been bought and tested. Both solutions present advantages and disadvantages. The required voltage and repletion rate for LP-SPL operation has been achieved. The ultimate repetition rate operation (40 MHz) is still to be fully demonstrated. [12]
- A cold model of the DTL has been realised to test the tuning capability [13]
- A mechanical model of the DTL has been realised to test the mechanical tolerances achievable with the chosen assembly procedure [13]
- Two models (1 and half cell) of CCDTL have been tested at high power [14]
- A cold model for the PIMS is undergoing RF measurements[15]
- A klystron test stand has been set-up to demonstrate the operation of decommissioned LEP klystron in pulsed mode.

### *The 3 MeV Test Stand*

Experience with other Linacs and dedicated beam dynamics studies [16] show that the most difficult part to master in a high intensity Linac is the low energy part, where the beam is slow and under the influence of strong space charge. Besides, issues like neutralisation at the lowest energy and non-standard beam distribution can result in beam parameters that severely differ from computational prediction. In order to have enough time to study and master the low energy beam a test stand including the source, the Radio Frequency Quadrupole and the chopper line is being put in place in the PS south hall, with the aim of being operational by 2010, before the final Linac4 building will be available. The 3 MeV test-stand will be equipped with a dedicated diagnostics line and a state-of-the-art device capable of detecting the population of adjacent microbunches (spaced by 2.8 ns) with a dynamic range of $10^6$[23]. The goal of the 3 MeV test stand is to demonstrate the capability of delivering a 70 mA , 400 µs long, beam at 3 MeV of energy, matched to the DTL and adapted to the 1 MHz PSB bucket, i.e. with 123 over 352 pulses removed and intercepted by the in-line beam dump [17].

# SUPERCONDUCTING PROTON LINAC

The location [8] of Linac4 has been chosen to allow using Linac4 as the front end of a Superconducting Proton Linac delivering a 4-5 GeV beam. The SPL could initially be configured for "low power" and serve as injector for a new 50 GeV Synchrotron (PS2) and later be configured for high power and serve as a multi-megawatt proton facility for future physics needs, e.g. a neutrino factory. The LP-SPL (and PS2) would complete the re-juvenation of the CERN LHC injectors while leaving 50% of the pulses available for nuclear physics experiments, e.g. an upgraded ISOLDE. Linac4 can work as front end for the LP-SPL without major modification, whereas for the SPL a new source and new electronics and power supplies should be procured. The shielding, the alignment and the correction system of Linac4 is designed to work at the highest possible beam duty cycle, 6%.

The goal of the SPL activities is to complete a Technical Design Report by the year 2011 when a decision on the construction of the SPL and PS2 could be taken. Should this decision be positive a LP-SPL could be available in 2017.

The main parameters of LP-SPL and SPL are listed in Table 2.

Table 2: SPL Parameters

| | **LP-SPL** | **SPL** |
|---|---|---|
| Energy [GeV] | 4 | 5 |
| Beam power [MW] | 0.192 | >4.0 |
| Repetition rate [Hz] | 2 | 50 |
| Average pulse current [mA] | 20 | 40 |
| Source current [mA] | 40 | 80 |
| Chopping ratio [%] | 62 | 62 |
| Beam pulse length [ms] | 1.2 | 0.4-1.2 |
| Beam duty cycle [%] | 0.24 | 2.0- 6.0 |
| Number of klystrons (704 MHz, 5 MW) | 24 | 53 |
| Geometric cavity beta | 0.65/1.0 | 0.65/1.0 |
| Number of cavities | 42/160 | 42/200 |
| Cavities/klystron | 8 - 16 | 4-8 |
| Cavities/cryostat | 6/8 | 6/8 |
| Length including Linac4 [m] | 459 | 534 |

## *Nominal Layout*

The layout of the SPL is based on 704 MHz 5-cell elliptical cavities. Two building blocks are used in the layout: a low-beta module (beta=0.65, Eacc=19MV/m) and a high-beta module (beta=0.92, Eacc=25 MV/m), see Fig. 4 and 5. A low beta module contains 6 cavities and two quadrupole doublets (2 periods), a high beta module contains 8 cavities and one doublet. Seven low beta modules are used to bring the energy from 160 MeV to 589 MeV and 20/25 high beta modules bring the energy to 4/5 GeV. Special attention has been paid in the beam dynamics design to achieve a proper matching between the two sections.

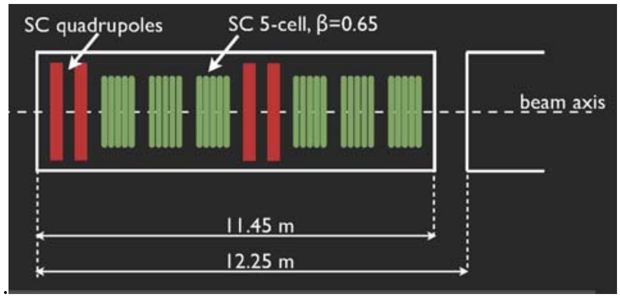

Figure 4: Low beta module.

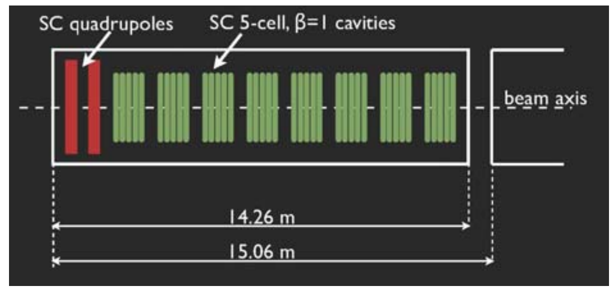

Figure 5: High beta module.

## *Research Activities*

Several themes have been identified for the R&D necessary to complete a Technical Design Report for the SPL. The main activities are listed in the following:

- Tests of surface treatment techniques on a 704 MHz, low beta single cell cavity from CEA are expected for 2009. The goal of this test is to verify the efficiency of electro-polishing low beta cavities.
- Prototypes of β=0.65 and β=0.92 5-cell cavities are to be developed with the aim to demonstrate the gradients of 19 MV/m and 25 MV/m, which have so far been assumed in the beam dynamics design.
- The design of a cryostat adapted to house 704 MHz cavities.
- Ideally, equip a cryostat with 8 cavities 5-cell Beta=0.92 and perform for high power RF tests.
- Development of a plasma generator for the 2 MHz RF source as a part of the European FP7 activities.
- Development of a low level RF system.

# ACTIVITIES WITHIN HIPPI

HIPPI (High Intensity Pulsed Proton Injector) is a Joint Research Activity in the framework of CARE [18] (Coordinated Accelerator Research in Europe), within the 6$^{th}$ European Framework Program (2004-2008). Ten European laboratories participate in HIPPI and the projects supported within HIPPI are Linac4, FAIR and the ISIS upgrade.

The scientific work in HIPPI is organized in 4 work packages addressing the issues of normal conducting structure (WP2), superconducting structures (WP3), chopping (WP4) and beam dynamics (WP5).

A lot of the prototyping work for Linac4 was fostered by HIPPI. In particular in the work package normal conducting structure activities on CCDTL prototyping were very instrumental to the choice of an optimised design for the structure [19].

The original design of Linac4 considered a 704 MHz Side Coupled Linac Structure for the energy 90-160 MeV. Prototyping work and studies were carried out on this structure which wasn't eventually retained [20].

Part of the work in WP3, the study of superconducting spoke cavities [21], was the basis for the study of an alternative Superconducting layout for the high energy part of Linac4. This solution was also discarded with the reason that a short superconducting section added unnecessary complexity for Linac4 itself, but it allowed to explore all possibilities.

For the chopper prototyping, the work within HIPPI was fundamental for the developing of a meander structure adapted to 3 MeV and its integration in the 3 MeV beam line. The prototyping activity was fully covered by HIPPI [22]. The system is ready to be tested at the 3 MeV test-stand.

The work within WP5 included beam dynamics and instrumentation. The development of a time resolved device [23] able to access the efficiency of the chopper is instrumental to the measurement program of the 3 MeV test stand.

## ACKNOWLEDGEMENTS

We acknowledge the support of the European Community-Research Infrastructure Activity under the FP6 "Structuring the European Research Area" programme (CARE, contract number RII3-CT-2003-506395).

We acknowledge the support of ISTC projects 2888 and 2875 for DTL and CCDTL prototyping activities.

We acknowledge the support of the IPHI projects in the mechanical, RF and beam dynamics design of the RFQ and for the diagnostic line of the 3MeV test-stand.

# LASER ACCELERATION OF QUASI-MONOENERGETIC MeV-GeV ION BEAMS

J.C. Fernandez, LANL, Los Alamos, New Mexico

*Abstract*

Laser interactions with thin solid targets can produce sheath fields of tens of TV/m, which have been used to accelerate ions to several MeV with ps pulse lengths, high currents, and low transverse emittance. While previous results have had 100% energy spread, recent experiments using foils coated with a few monolayers have produced quasi-monoenergetic beams with 17% energy spread near 3 MeV. Such beams may be of interest as injectors or sources. Simulations show the potential for acceleration to hundreds of MeV or GeV energies using very thin foils.

# LINAC R&D FOR THE ILC TECHNICAL DESIGN REPORT

M. C. Ross, Fermilab, Batavia

## Abstract

The International Linear Collider (ILC) Technical Design Report (TDR) is scheduled for publication in 2012. The TDR will include an updated ILC baseline technical design description, results from critical R&D programs in support of key parameter choices, and one or more models for a Project Implementation Plan with an associated value estimate. The focus of linac R&D is to: 1) achieve the specified superconducting rf cavity accelerating gradient of 35 MV/m with a corresponding production yield, 2) design and test cryomodule assemblies that include "plug-compatible" sub-components with specified interfaces, and 3) demonstrate system performance with nominal ILC high intensity beams. In keeping with the international nature of the project, R&D is underway at ILC partner institutions with results and infrastructure that are shared throughout the project effort. This paper describes the technical challenges to be addressed and summarizes ongoing activities and plans.

# ILC SITING IN MOSCOW REGION NEAR DUBNA AND ILC RELATED ACTIVITY AT JINR

Yu. Budagov, Yu. Denisov, I. Meshkov, G. Shirkov, A. Sissakian, G. Trubnikov, JINR, Dubna, 141980, Russia

*Abstract*

The investigations on ILC siting in the Dubna region and ILC technical activity at JINR are presented. International intergovernmental status of JINR, stable geological and plain relief conditions, comfortable location and well developed infrastructure create a set of advantages of the JINR site in the neighborhood of Dubna. The shallow layout of accelerator tunnel makes it possible to use a communication gallery at the surface instead of second one. This is an effective way of significant cost reduction of all conventional facilities and explicit labor of the project.

Besides JINR physicists take part in several fields of activity in ILC: works on photo injector prototype, participation in design and construction of cryomodules, laser metrology, etc. [1].

## INTRODUCTION

The last Global Design Effort (GDE) and ILC Steering Committee (SC) meetings took place at JINR, in Dubna on June 3-7, 2008. These meetings were dedicated to ILC convention facilities and siting and were focused at proposals of JINR [2]. The meetings finished with helicopter flight for leaders of ILC SC and GDE along the ILC possible layout (Fig. 1).

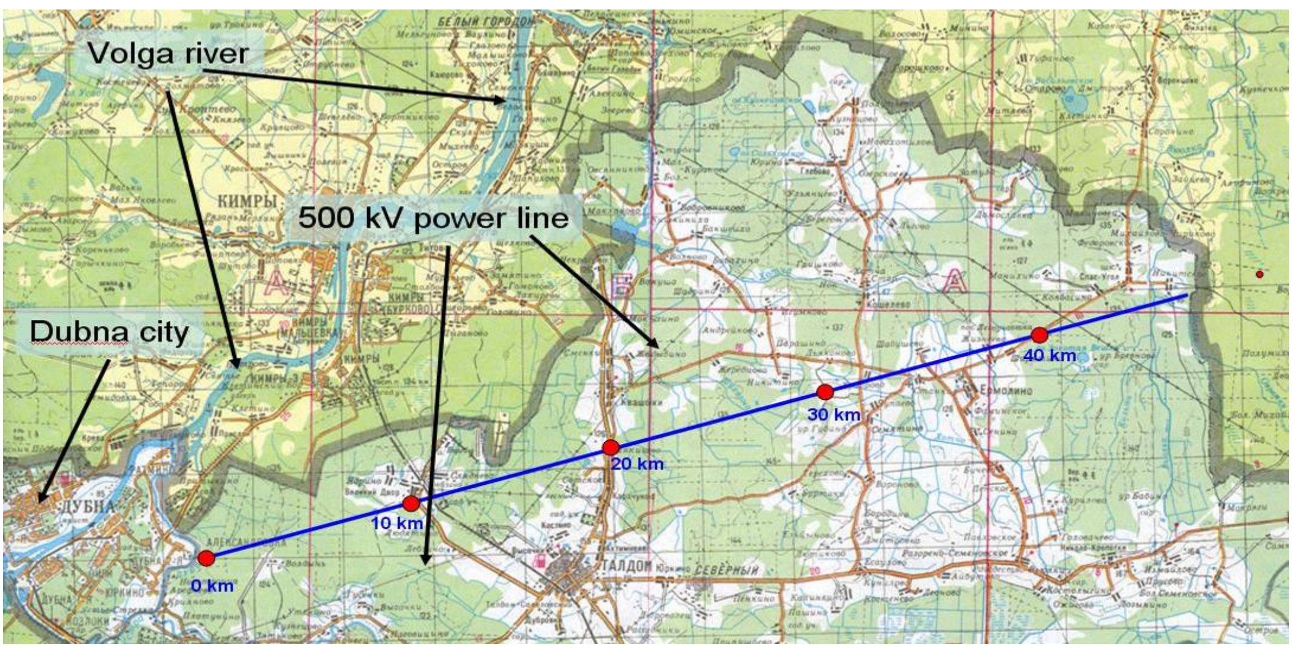

Figure 1: Planned location for ILC near Dubna, Moscow region.

The international scientific community has demonstrated a considerable interest to the proposal of ILC construction in Russia, in Dubna region, where JINR has essential benefits and privileges as an International Intergovernmental Organization and has a unique experience of organization and successful realization of large-scale research projects based on wide cooperation of scientific centers and industrial enterprises of many countries.

Taking into account that the ILC project is considered by the international scientific community as a strategic priority in the field of high energy physics after the LHC era, the International Scientific Council of the JINR has supported the idea of ILC siting in the Dubna region and has recommended to take part in preparation of the collider project. These recommendations had been approved by the Committee of Plenipotentiaries of the JINR Member States. The ILC project and it's siting in the Dubna region have been discussed and supported at different meetings of the Russian Academy of Sciences (RAS).

The initiative to host the ILC in the Dubna site has been strongly supported by the Moscow region governor B. Gromov.

## DUBNA SITE DESCRIPTION

The ILC linear accelerator is proposed to be placed in the northern part of Moscow region to the north-east from the existing scientific center JINR in the town Dubna (Fig. 1). This area is thinly populated, the path of the accelerator traverses only two small settlements and a railway with light traffic between the towns Taldom and

Kimry at the distance up to 50 km from Dubna. The region is mainly covered with forest with small inclusions of agricultural lands (see Fig. 2) and it is uniform along the line of 150-200 km in this direction.

Figure 2: The typical view of ILC proposed area from helicopter.

This area is situated within the Russian plate, a part of the Eastern European ancient platform, is a stable, steady structural element of the earth's crust. The characteristic feature of this territory is the uniformity, monolithic character of the surface. The existing rises of the relief in the form of single hills and ridges have smoothed shapes, soft outlines and small excesses. The territory of the area is waterlogged. The absolute marks of the surface range from 125 to 135 m with regard to the Baltic Sea level (see Fig. 3).

The ILC area is located in the southern part of a very gently sloping saucer-shaped structure – the Moscovian syneclise. Alluvial deposits are bedded above, i.e. fine water-saturated sands, 1-5 m of thickness. Below one can find semisolid drift clay of the Moscovian glaciations with inclusions of detritus and igneous rocks. The thickness of moraine deposits is 30-40 m. Under the moraine of the Moscovian glaciations fluvioglacial water-saturated sands and loams of the Dnieper glaciations are bedded. Jurassic clays and carboniferous limestone of the platform mantle are spread under the overburdens at the depth of 50-60 m. This has been confirmed by the geological survey carried out during the selection of site for construction of the U-70 accelerator.

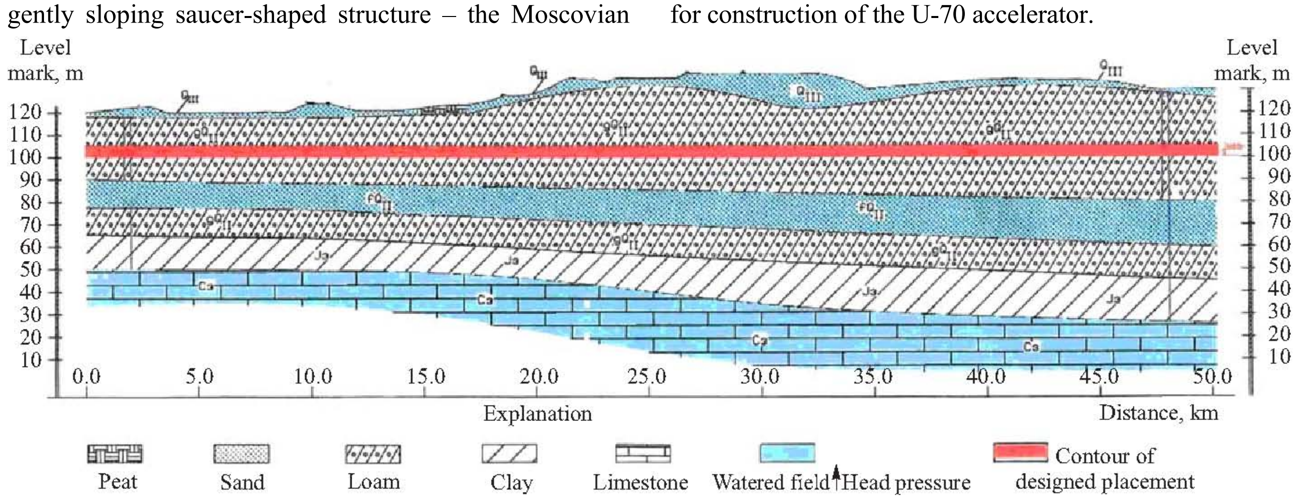

Figure 3: Engineering-geological sectional view along the ILC path axis.

The ILC linear accelerator is proposed to be placed in the drift clay at the depth of 15÷25 m so that below the tunnel there should be watertight soil preventing from the underlying groundwater inrush. This will make it possible to construct tunnels of the accelerating complex using tunnel shields with a simultaneous wall timbering by tubing or falsework concreting. Vertical shafts, experimental and service halls, and some other underground service volumes could be constructed in the cut and cover way and this should sufficiently reduce the price of civil engineering construction.

JINR and Dubna have at their disposal all the necessary infrastructure to accommodate specialists for the period of the accelerator construction, to accumulate the equipment, to provide for the project-production support during manufacturing of the special-purpose equipment at the enterprises located in Dubna and the region. The town Dubna possesses all the necessary means of transport to deliver all kinds of the equipment of the accelerator itself and its technological systems: highways, railways, waterways (the Volga River and Moscow channel). The international airport "Sheremetyevo" is situated at the distance of 80 kilometers from Dubna.

The northern part of Moscow region and the neighboring regions have enough of objects of generation, transmission and distribution of electrical energy. There are first-rate generating stations: the Konakovo electric power station and the Udomlia atomic power plant. Two trunk transmission lines with the voltage 220 and 500 kV pass through the territory of Dubna and along to the possible ILC line. The preliminary study of the existing possibilities of the power supply for the accelerator and its infrastructure with the total power up to 300 MW resulted in the convenient variant: construction of the 220 kV power line, 35-40 km long, directly from the center of generation – the Konakovo power station to the central experimental zone of the accelerator.

## ONE TUNNEL SOLUTION

A possible one-tunnel solution for the accelerator structure and convention facilities for Dubna site is presented in Fig. 4. The scheme is as follows:

- the main technological tunnel with accelerating structures, magnetic elements for beam focusing and diagnostics means will be put on depth of ~ 20м so that from below and above the tunnel there will be an impermeable stratum preventing break of underground waters;
- communication tunnel (collector) will be placed directly above the technological one near the ground surface at the depth of 3-4 m practically following its form. This tunnel is necessary for power supplies, RF power sources, data storage devices, electronic and control systems, etc.;
- technological connection between the accelerator tunnel and collector will be provided by vertical shafts of various diameters made by drilling;
- connection of ground and underground structures will be provided by vertical and horizontal shafts (stairs, elevators, etc).

The one-tunnel design is economically and technically preferable for a number of reasons:

- communication tunnel practically can be of any size to discharge the basic tunnel. Moreover it can be made by open way that is rather inexpensive;
- vertical communication service lines (service ducts) can be made by means of drilling that is rather cheaper then underground horizontal lines; their number and sizes can be optimized, and waterproofing will not be required as well;
- export of ground waters will be performed directly on the surface without pumping facilities;
- operation of communication tunnels will be substantial simplified;
- technological and cable communications between the communication tunnel and ground buildings and constructions will be considerably reduced.

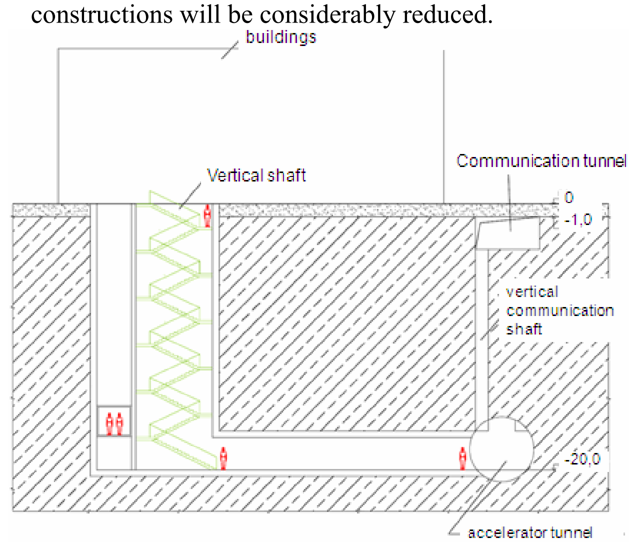

Figure 4: One tunnel solution.

## ILC ACTIVITY AT JINR

The JINR is carrying out active work to develop international cooperation in the ILC project and in the related projects, in the XFEL and CLIC projects in particular. The scientists from JINR participate in all international forums and committees on the ILC. JINR has successfully organized wide cooperation in Russia in order to perform experimental and theoretical investigations on the project with Russian research centers: BINP of Siberian Brunch of RAS, Institute for Applied Physics (IAP) of RAS (Nizhniy Novgorod), GSPI, Physical Institute of RAS etc.

JINR in collaboration with KEK (Japan), DESY (Germany) and IAP of RAS is carrying out research and design works for creation of the injector, an electron source on the base of a photoemissive gun. Creation of the test bench to study properties of photocathodes, new materials and also creation of new unique laser system are planned (Fig. 5). The test bench on the base of the linear accelerator of electrons LINAC-800 for adjustment of beam diagnostics tools will be made in JINR. The injector will be a part of the bench.

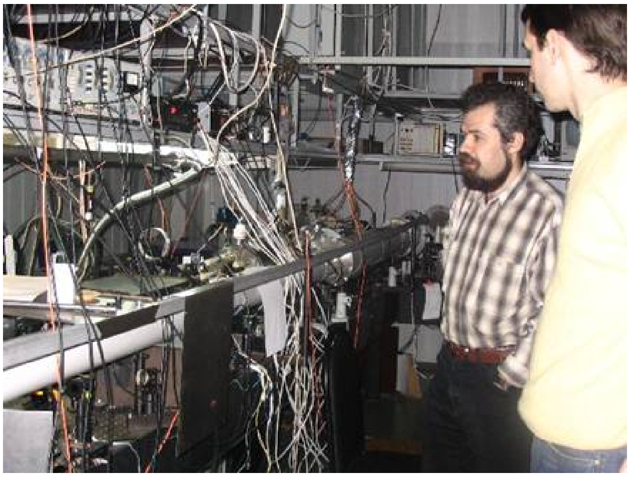

Figure 5: JINR and IAP experts at the superpower laser system at IAP of RAS in Nizhniy Novgorod.

Specialists from JINR and VNIIEF (Sarov) have studied the production of bimetal tubes (stainless steel and titanium) by explosion welding (Fig. 6). The tube is used as a transitional load-bearing element in the 4th generation cryomodule construction for the ILC.

Figure 6: Explosion welding of bimetal tubes.

The R&D works have result in developing the pilot technical process for production of bimetal billet of the tube by explosion welding and researching a micro-structure of the weld joint.

JINR develops a test bench at CERN for the precise laser metrology. The precision of 1.0 micron of laser beam position is achieved on the base of 100 m. At JINR it is planned to set this system at the LINAC-800 accelerator complex on the base of 2 x 250 m.

DR magnetic system simulations and magnet prototype construction in collaboration with SLAC are in progress. The aim is to design and possibility to construct and to test at JINR a series of magnetic system elements (dipole magnets) of ILS damping ring.

A series of activities in the field cryogenic engineering and diagnostics has been started and well developed at JINR.

## CONCLUSION

The main advantages of the ILC construction in Dubna are as follows:

- JINR as a basic international intergovernmental organization.
- Prevalent legal practice makes it possible to get the land of the ILC location to permanent free use just as it has been done for JINR, according to the agreement between JINR and the RF government.
- The proposed territory is extremely thinly populated and practically free of industrial structures, rivers and roads.
- The area is absolutely steady seismically and has stable geological characteristics.
- A flat relief and geological conditions allow to place ILC on a small depth in the dry drift clay and to perform construction of tunnels, experimental halls and other underground objects with the least expenses, including cut-and-cover.
- The only one shallow tunnel with accelerator structures and communication gallery on the surface
- Sources of the electric power of sufficient capacity.
- The developed system of transport and communication services.
- Presence of a modern network and information infrastructure, including one of the largest Satellite Communication Center.
- The special economic zone of Dubna with preferential terms for high technology technical production.
- A powerful scientific and technical potential of Dubna town.

Realization of such a wide scale project namely in Dubna will let Russia to become in a perspective future by a leader and center of attraction for scientists from Russia and neighbor countries. Another obvious factor is an attraction of significant investments and financial resources at all stages of the project including further exploitation of the new accelerator center during long years. Creation of ILC accelerator complex as international collaboration will raise prestige of the fundamental science in a total and the role of Russia as one of the world leader.

# STATUS AND FUTURE PROSPECTS OF CLIC

S. Döbert, for the CLIC/CTF3 collaboration, CERN, Geneva, Switzerland

*Abstract*

The Compact Linear Collider (CLIC) is studied by a growing international collaboration. Main feasibility issues should be demonstrated by 2010 with the CLIC Test Facility (CTF3) constructed at CERN. The CLIC design parameters have recently been changed significantly. The rf frequency has been reduced from 30 GHz to 12 GHz and the loaded accelerating gradient from 150 MV/m to 100 MV/m. A new coherent parameter set for a 3 TeV machine will be presented.

The status and perspectives of the CLIC feasibility study will be presented with a special emphasis on experimental results obtained with CTF3 towards drive beam generation as well as progress on the high gradient accelerating structure development.

The frequency change allows using high power x-band test facilities at SLAC and KEK for accelerating structure testing at 11.4 GHz. The design gradient of 100 MV/m has been achieved in a recent test at SLAC with a very low breakdown-rate.

## INTRODUCTION

There is a consensus in the community of high energy particle physicists that LHC physics results need to be complemented in the future by experiments done with a high-energy lepton collider in the TeV centre-of-mass energy range [1]. A promising candidate for such a facility is CLIC, a linear collider aiming at a centre-of-mass energy of 3 TeV and a luminosity in the range of $10^{34}$ $cm^{-2}$ $s^{-1}$ presently studied by a large international collaboration [2, 3].

In a linear collider the particles have to be accelerated in a single pass to the final energy, 80% of the facility length is used for acceleration. Naturally the emphasis for the R&D on CLIC is on the rf system which has to reach a maximum accelerating gradient and efficiency to keep the length and cost limited. The CLIC scheme uses high-frequency normal conducting accelerating structures and a two beam scheme to cope with these challenges. In 2007 the rf frequency has been reduced from 30 GHz to 12 GHz and the accelerating gradient from 150 MV/m to 100 MV/m for CLIC. This change was motivated by high gradient constraints found experimentally which made the ambitious goal of 150 MV/m unrealistic. A general optimization study taking into account these rf constraints showed that the new parameters represent an optimum with respect to luminosity and cost [3].

The CLIC Test Facility CTF3 [4] is being built at CERN by the CTF3 collaboration to investigate and demonstrate the key technical issues of the CLIC scheme. This feasibility study should conclude in 2010 with a Conceptual Design Report for CLIC.

## COMPACT LINAER COLLIDER CLIC

The compact linear collider CLIC uses high-frequency high-gradient normal conducting rf accelerating structures to accelerate the electrons. An accelerating gradient of 100 MV/m at 12 GHz allows to keep such a facility bellow a length of 50 km. The 12 GHz rf power needed to energize the accelerating structures is extracted from a drive beam running parallel to the main beam. This two beam scheme is an efficient and less costly way to provide the rf power needed for acceleration as compared to the use of 12 GHz klystrons. In order to achieve the luminosity needed for the experiments the electrons and positron beams need to be produced with extremely small emittances, accelerated and transported without significant degradation and finally focused to spot sizes in the nm range. The main parameters of CLIC can be found in table 1.

Table 1: CLIC Main Parameters

| | | |
|---|---|---|
| Centre of mass energy | 3 | TeV |
| Luminosity (in 1% energy) | $2*10^{34}$ | $cm^{-2}$ $s^{-1}$ |
| Number of particles per bunch | $3.72*10^{9}$ | |
| Bunch separation | 0.5 | ns |
| Number of bunches per train | 312 | |
| Proposed site length | 48.4 | km |
| AC to beam power efficiency | 7.2 | % |

### *The Facility Layout*

A schematic layout of CLIC is shown in figure 1. A central injector complex prepares the ultra low emittance beams needed for high luminosity collisions. The complex contains the positron and polarized electron sources, pre-damping and damping rings, bunch

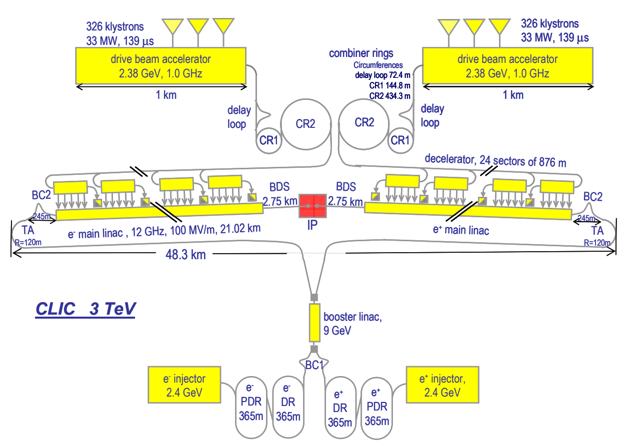

Figure 1: Schematic CLLC layout (not to scale).

compressors and a 9 GeV booster linac. These beams are then transported by a long transfer line to both ends of the linear collider. The corresponding drive beams providing the rf power for acceleration are also generated in a central location. The high-current low-energy drive beams are than decelerated along the main linacs transferring the power to the main beam which is accelerated in parallel.

### Drive Beam Generation

A unique feature of the CLIC scheme is the rf power source using a high current drive beam. A long 139 µs long pulse train with 4.2 A average current and a 500 MHz bunch spacing is accelerated efficiently to 2.38 GeV using 1GHz klystrons and fully loaded accelerating structures. This bunch train is then combined into 24 beam pulses with a pulse length of 240 ns with 100 A average current and 12 GHz bunch spacing in a sequence of delay loop and combiner rings. The details of the beam combination are explained in the test facility section below. The generated drive beam pulses are then sent along the linac towards the extremities and then with precision timing injected into the corresponding decelerator section (see layout). The drive beam can be seen as a very efficient rf pulse compression system which allows to transform the rf power generated efficiently with low peak power and long pulse length into short pulses with high peak power needed for acceleration. The drive beam parameters are listed in table 2.

Table 2**:** Drive Beam Parameters

| | | |
|---|---|---|
| Drive Beam Linac | | |
| Linac RF frequency | 999.5 | MHz |
| Beam energy | 2.38 | GeV |
| Klystron peak power | 33 | MW |
| Number of klystrons | 326*2 | |
| Pulse length (bunch train) | 139 | µs |
| Beam current | 4.2 | A |
| RF-to-beam efficiency | 93 | % |
| Compressed beam | | |
| total compression factor | 24 | |
| Pulse length | 240 | ns |
| Beam current | 100 | A |
| Beam energy after deceleration | 240 | MeV |
| Number of pulses per cycle | 24 | |

### Decelerator

Each decelerator sector is designed to extract 90% of the drive beam energy. During this process the size and the energy spread of the beam increases significantly.

The key equipment of the decelerator sector is the Power Extraction and Transfer Structure (PETS) [5]. These structures are large-aperture travelling wave structures resonant at 12 GHz with an active length of 21 cm. They have a high group velocity ($v_g/c$ =48%) and are equipped with damping slots all along the structure loaded with rf damping material. Each PETS extracts 136 MW of 12 GHz rf power to feed a pair of accelerating structures. A total of 36000 of these structures are needed for CLIC. Prototypes of these unconventional structures fabricated in octants have been built and will be high power tested this fall both with klystrons at 11.4 GHz and with beam in CTF3 at 12 GHz. The CTF3 program includes a test beam line to study and bench mark the challenging beam dynamics of the CLIC decelerator.

### Accelerating Structure

A sophisticated optimization procedure taking into account constraints from beam dynamics, cost and high gradient constraints resulted in a new accelerating structure for CLIC [3]. An optimum was obtained at 12 GHz with a loaded gradient of 100 MV/m. The structure has a constant gradient design with a rather small aperture and a group velocity of only 1.7 % at the entrance of the structure. The rf pulse length needed to accelerate the 312 bunches is 240 ns including the filling time. This requires strong higher order mode damping provided by four waveguides in each cell. The low power consumption and the short bunch spacing made possible by the HOM damping results in a high rf-to-beam power efficiency of 27.7% for this structure. A total of 30 km active acceleration will be needed for both linacs which imposes a trip rate better than 3 $10^{-7}$ per meter. The main parameters of the CLIC accelerating structure are listed in table 3.

Table 3: Accelerating Structure Parameters

| | | |
|---|---|---|
| RF frequency | 11.994 | GHz |
| Loaded acceleration gradient | 100 | MV/m |
| Input Power for 100 MV/m | 64 | MW |
| Maximum surface field | 245 | MV/m |
| Active structure length | 0.23 | m |
| $\langle a/\lambda \rangle$ | 0.11 | |
| RF to beam efficiency | 27.7 | % |

A recent high power test of a low group velocity prototype at 11.4 GHz reached 100 MV/m unloaded gradient with a pulse length of 230 ns and a trip rate below $10^{-7}$/m [7]. The structure tested had a constant loaded gradient design with a strong tapering of the aperture towards the end. The electrical surface field reached therefore more than 300 MV/m.

### Beam Quality Issues

One of the biggest challenges for the CLIC scheme is to generate the ultra low emittance beams required to achieve the high luminosity. The normalized emittance needed at the IP is 660 nm in horizontal and 20 nm in the vertical plane. The beam has to be focused down to a spot size of 40 nm in horizontal and 1 nm in vertical. The damping ring is designed to reach emittances of 381 nm in the horizontal plane and 4.1 nm in the vertical plane using high field wigglers [8]. Therefore the beam transport and acceleration allow only very small emittance growth. This imposes very strict alignment and jitter tolerances. CLIC will have to rely extensively on beam based alignment procedures and active vibration stabilisation of focusing elements. The most severe constraints are on the final focus quadrupoles which have to be stabilized in the sub-nm range for frequencies above 4 Hz. Some R&D has been done already showing a proof of principle stabilization of a quadrupole to the level of 0.5 nm [9].

## THE CLIC TEST FACILTY CTF3

The CLIC scheme comprises a number of novel concepts and challenging parameters which have to be validated experimentally. Therefore the CLIC Test Facility was designed to demonstrate the feasibility of the following key issues until 2010.

- The feasibility of the CLIC rf power source: Generating a drive beam using bunch combination with rf deflectors with high efficiency.
- Demonstrating the main linac rf structures by operating a two-beam acceleration sub-unit at nominal rf parameters.
- Validating the CLIC decelerator concept by operating several deceleration modules in series and extracting 12 GHz power.

The test facility was constructed in stages starting in 2001 re-using equipment and infrastructure from the former LEP pre-injector. The layout of the facility is shown in figure 2. A thermionic electron gun provides a beam current of nominal 3.5 A. The beam is subsequently bunched by a 1.5 GHz subharmonic system and by a 3 GHz travelling wave buncher. The high-bandwidth 1.5 GHz buncher cavities allow the phase coding of the beam by switching the phase of their TWT-drivers by 180 deg. This results in a 1.2 μs long bunch train which consists of eight 140 ns long sub-trains captured alternately in odd or even buckets of the following 3 GHz rf acceleration system. A total of 16 accelerating structures are used to accelerate this beam up to 150 MeV at the end of the linac. The one meter long acceleration sections have been optimized for full beam loading at nominal current and are equipped with strong higher order mode damping in each cell [10] to avoid beam break up in the linac. At the end of the linac a magnetic chicane allows for bunch compression or stretching. The nominal operation mode foresees bunch stretching to avoid coherent synchrotron radiation effects in the rings. After the rings the bunches are compressed again in the second transfer line (TL2 [11]) for efficient rf power production. The phase coded 140 ns long sub-trains are alternately injected into the delay loop with 1.5 GHz deflectors. After one turn the bunches of the delayed trains are interleaved in between the bunches of the following sub-train. After the delay loop the beam consists of four 140 ns long sub-trains with an average current of 7 A and 3 GHz bunch spacing and a 140 ns gap between them. A second stage of bunch combination and frequency multiplication is done in the combiner ring. Here 3 GHz rf deflectors are used to create a time-dependent closed orbit bump, which allows to interleave the bunches of four subsequent sub-trains into one. Finally the fully generated drive beam has a pulse length of 140 ns with an average current of 28 A and 12 GHz bunch spacing. This beam is then sent to the CLIC Experimental hall (CLEX), where 12 GHz rf power is extracted by power extraction structures (PETS). The CLEX area comprises an independent 200 MeV probe beam (Califes [12]) which will be used for the two beam acceleration demonstration experiments in the two beam test stand (TBTS [13]). One PETS will be powering up to two accelerating structures. In addition a test beam line (TBL) [14] will be installed consisting out of 16 deceleration modules which will produce a total of 2.4 GW of 12 GHz rf power by extracting roughly 50 % of the drive beam energy. This experiment will be used to validate the CLIC decelerator concepts. CTF3 cannot achieve CLIC parameters in all aspects due to the financial constraints of this R&D effort but is believed to demonstrate the key technical issues and provide relevant bench marks for scaling to the nominal CLIC parameters. Table 4 shows the main differences between CTF3 and CLIC parameters.

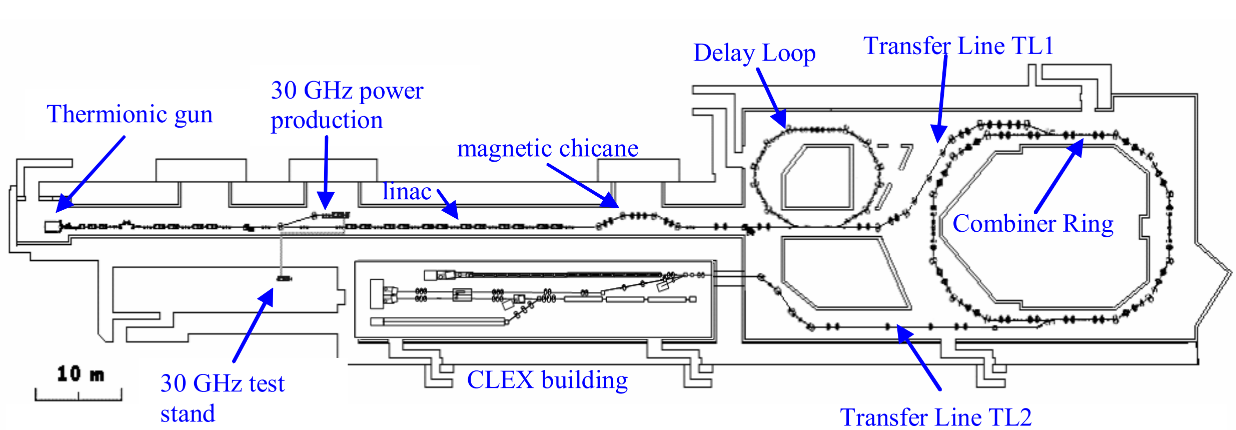

Figure 2: Layout of CTF3.

Table 4: Comparison CLIC-CTF3

| | CLIC | CTF3 |
|---|---|---|
| Drive Beam energy | 2.4 GeV | 150 MeV |
| Drive Beam current | 100 A | 28 A |
| Drive Beam RF Frequency | 999.5 MHz | 3 GHz |
| Train length in linac | 139 μs | 1.5 μs |

## STATUS AND FIRST RESULTS

The construction of CTF3 is advancing according to schedule. This installation of TL2, the two beam test stand and the probe beam have been completed and commissioning with beam started in CLEX this summer. The first PETS in the two beam test stand and the prototype module in TBL are scheduled to be tested this fall. The remaining 15 modules of TBL will be installed in stages during 2009 and 2010. This will complete the installation of the CTF3 base line program. The facility is operated routinely for about 7 months a year. A number of milestones towards a feasibility demonstration of the CLIC scheme have been already achieved.

### *Full Beam Loading Operation*

It is essential for the CLIC scheme that the rf power source reaches a high efficiency. Therefore the drive beam accelerator is operated with full beam loading. An efficiency of power transfer to the beam of 95.3% has been measured [15]. Figure 3 shows the measured rf power signals with full beam loading. Each structure provides 6.5 MV/m of acceleration for 30 MW input power. The shape of the rf signals before the beam are caused by an rf pulse compression system, which will, however, not be used in CLIC. The CTF3 linac is routinely operated with full beam loading for several years and no signs of beam break up have been found thanks to the strong high order mode damping in each cell of the drive beam accelerator structures.

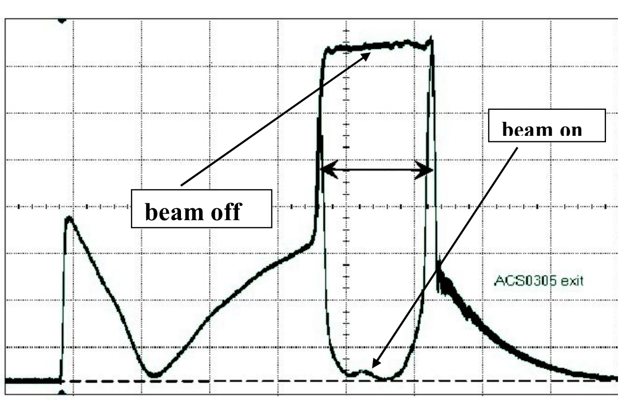

Figure 3: Demonstration of full beam loading.

### *Bunch Phase Coding*

The phase coding of bunches within sub-trains with a sub-harmonic bunching system was commissioned in 2005 [16]. The rf phase of these bunches can be switched by 180 deg in about 4 ns. The bunching process is not perfect yet and produces satellites in the wrong 3 GHz bucket with about 8% intensity of the main bunch. These satellites are lost during recombination in the delay loop. This inefficiency can be avoided in CLIC if a photo-injector is used and the phase coding can be done by the laser.

### *Delay Loop Operation*

Every other phase coded sub-train can now be delayed and combined with the following one as shown in figure 5. A 1.5 μs long bunch train consisting out of ten 140 ns long sub-trains was combined by separating the odd trains with the 1.5 GHz rf deflector and interleaving them with the even sub-trains, again with the rf deflector after one turn in the delay loop. In this example the combination was done for 5 sub-trains. The missing intensity in the delay loop is the 8% satellites from the bunching process which are lost later on.
The delay loop has an isochronous lattice to avoid bunch lengthening and uses a wiggler magnet to fine tune the path length of the beam to be an integer of the rf wavelength.

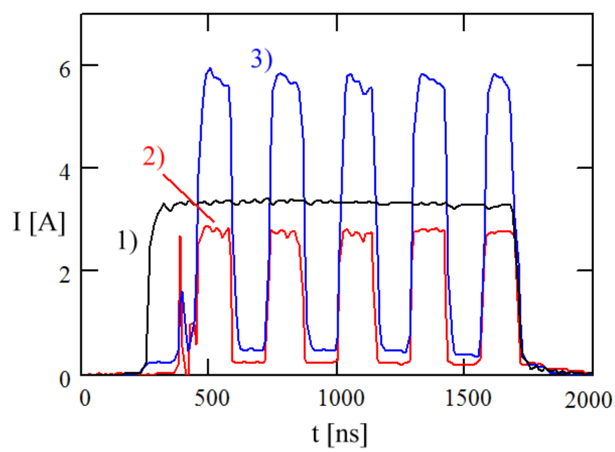

Figure 4: Beam current as function of time, measured: 1) before, 2) in, 3) after the delay loop. The sub-trains combined are 140 ns long.

### *Combiner Ring Commissioning*

The last step of the drive beam generation in CTF3 is done by the combiner ring. Four 140 ns long sub-trains with 3 GHz bunch spacing are combined to a current of 28 A. Two 3 GHz rf deflectors are used in the ring to inject the bunch trains and to keep them on a closed orbit while circulating in the ring. A wiggler magnet is used to adjust the path-length of the ring to insure the correct phasing in the rf deflectors.

For initial commissioning a 1.2 μs long 3 GHz bunch train was used straight from the linac without going through the delay loop, it has therefore no gaps between the sub-trains. A combination of such a beam is shown in figure 6, where 2.6 A beams from the linac were interleaved to reach 8.5 A. The combination suffered from a vertical instability discovered during commissioning. The instability is caused by the vertical deflecting mode of the rf deflectors. This mode had been shifted by polarising rods but not actively damped. HOM-damping has to be incorporated in a new set of deflectors required to demonstrate combination at full current. More details on the combiner ring commissioning can be found in [17].

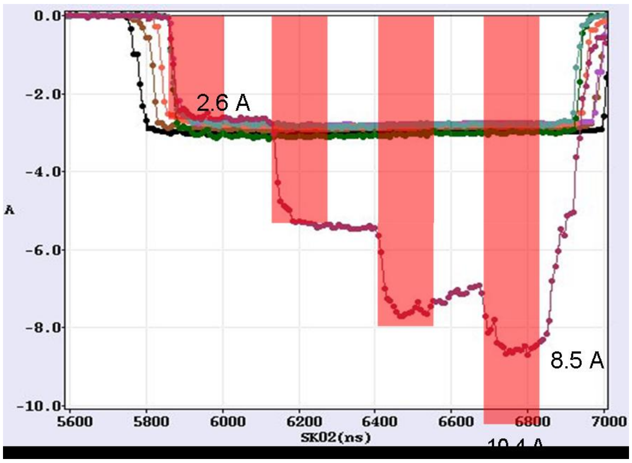

Figure 5: Interleaving of 4 bunch trains.

## CONCLUSIONS AND OUTLOOK

The CLIC collaboration has worked out a new consistent parameter set for CLIC with a luminosity in the range of $2*10^{34}$ $cm^{-2}$ $s^{-1}$ at 3 TeV, using 12 GHz rf and 100 MV/m accelerating gradient. First very promising results from a prototype test of a CLIC type accelerating structure at 11.4 GHz have been already obtained. Currently a conservative parameter set for a 500 GeV machine together with an upgrade scenario to 3 TeV is under development [2].

The CTF3 project is on schedule to fulfil its objective to demonstrate the feasibility of the main issues for CLIC by 2010. A number of questions have already been answered, such as full beam loading operation of the Drive Beam linac, and the bunch interleaving scheme.

A CLIC conceptual design report is scheduled to be finished by end 2010. The detailed technical design is expected to take another five years after this.

## ACKNOWLEDGEMENT

This work is done by the CTF3 collaboration currently consisting of the following institutes: Ankara University Group (Ankara and Gazi), Budker Institute of Nuclear Physics (BINP), CEA (IRFU Saclay), CERN, CNRS IN3P3 (LAL, LAPP, LURE ), DAE India (RRCAT) DOE USA (Northwestern Univ. Illinois, SLAC, JLAB), Helsinki Institute of Physics (HIP), IAP Nizhny Novgorod, INFN Frascati, JINR Dubna, MEC Spain (CIEMAT Madrid, IFIC Valencia, UPC Barcelona) NCP Pakistan, Norwegian Research Council (University of Oslo), PSI Switzerland, STFC UK (J.Adams Inst., Royal Holloway London), Ukraine Nat. Acad. Sci (IAP NASU), Uppsala University.

# DESIGN AND PERFORMANCE OF L-BAND AND S-BAND MULTI BEAM KLYSTRONS

Y. H. Chin, KEK, Tsukuba, Japan.

*Abstract*

Recently, there has been a rising international interest in multi-beam klystrons (MBK) in the L-band and S-band, with active development taking place. These MBKs are developed by industries such as Toshiba, Thales and CPI for the European X-FEL project or at the Naval Research Laboratory for high-power, low-voltage, broadband radar/radio communication systems. Some of them are already in operation at full specification and are commercially available. MBKs have distinctive advantages to conventional single-beam klystrons in their ability to produce high power with high efficiency and large bandwidth at lower voltage in compact body. This paper reviews the design and performance of these multi-beam klystrons, and describes future development plans.

## INTRODUCTION

Klystrons have been always the major sources of high power RF in particle accelerators. The development of new types of klystrons has made large and important contributions in achieving significant advances in energy outreach of linear accelerators. The historical growth in klystron power in the past 60 years since WWII shows that the output power increases 10-fold every 14 years. Recent projects and proposals of high-energy super-conducting linacs demand high power klystrons with high efficiency (60-70%) and long pulse duration (an order of 1ms). The peak power delivered by a long pulse Single-Beam Klystron (SBK) is limited by the high voltage that its gun can withstand. A lower cathode voltage (more exactly speaking, the maximum surface electric field in the gun region) is desirable to ensure reliable operation without gun arching or voltage breakdown. However, in a single-beam klystron, the simultaneous optimization of output power, voltage and efficiency is nearly impossible, since the pervenace determines the relationship of all other operating parameters and even an achievable maximum efficiency of the tube.

When one designs a single-beam klystron for a given output power $P_{out}$, he first has to choose the pervenace, p, given by $p=I/V^{3/2}$, where I is the beam current from a cathode and V is the cathode voltage. The pervance indicates how much beam current comes out of the cathode when the voltage V is applied between the cathode and the anode. There is the empirical relation between the perveance and the achievable highest efficiency, $\eta_{max}$, given by [1]

$$\eta_{\max}(\%) = 78 - 16 \times p\,(\mu\text{-perveance}). \quad (1)$$

Figure 1 illustrates this relationship. This figure indicates that a lower perveance beam with weaker space-charge forces enables stronger bunching and thus consequently higher efficiency.

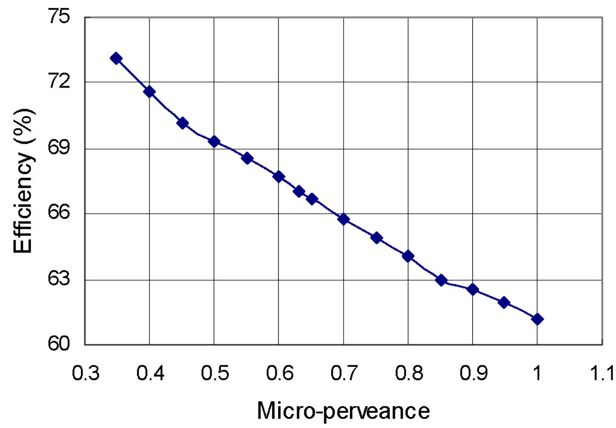

Figure 1: The empirical relation between the perveance and the achievable highest efficiency, $\eta_{max}$.

Once the efficiency ($\eta \le \eta_{\max}$) of the tube is assumed, the cathode voltage is determined from the relation

$$P_{out} = \eta IV = \eta p V^{5/2}. \quad (2)$$

In this circumstance, only way to increase the output power without increasing the voltage, or reduce the voltage without reducing the output power, is to increase the perveance, i.e., the beam current. However, a high perveance is strongly undesirable since (1) it provides a lower efficiency (2) it requires a larger cathode current loading resulting in a shorter cathode lifetime (see Fig.2) (3) it requires stronger magnetic fields for beam focusing which can lead higher system volume and weight (4) it has a higher risk of gun oscillation and gun arching. In conclusion, the choice of perveance in a single-beam klystron is always a compromise between high power and efficiency and tube reliability.

A breakthrough solution to this gridlock is to use multiple low perveance beamlets in parallel in the same vacuum envelop. The number of beamlets introduces a new degree of freedom in parameter space. In a Multi-Beam Klystron (MBK), a high current electron beam is separated into multiple parallel beamlets,

- each with a sufficiently low current density (perveance) to ensure efficient electron bunching and a high efficiency,
- while the high total perveance of beam current provides the required high output power.

The co-existence of these two different perveances in the same device is the great advantage of MBK to SBK, which allows simultaneous optimization of efficiency and output power. Each beamlet propagates in individual drift tube, paralleled to, but isolated from each other and are allowed to interact only in common RF cavities. Schematic presentation of MBKs is shown in Fig.3

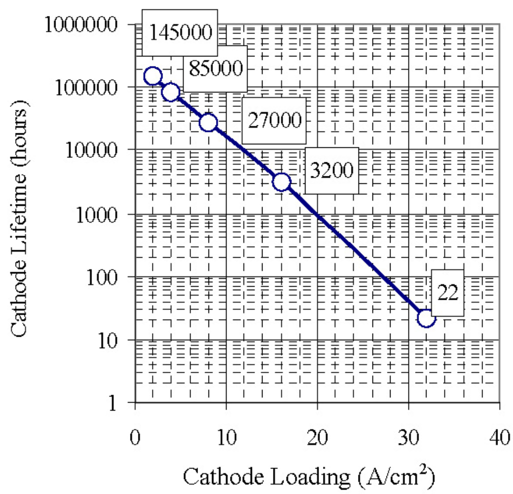

Figure 2: Empirical relation between the cathode loading and expected lifetime of the cathode.

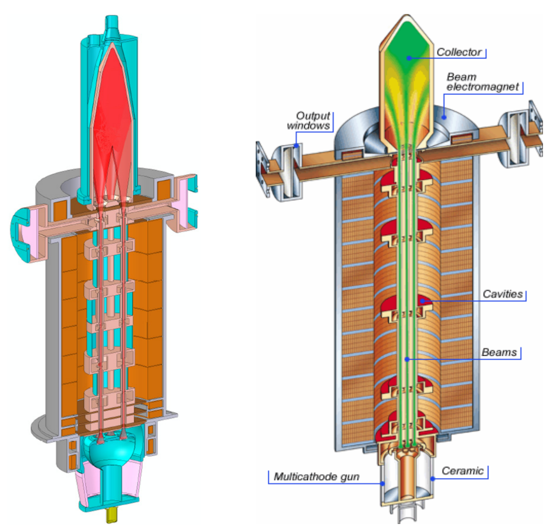

Figure 3: Schematic presentation of MBKs (Toshiba E3736: left and Thales TH1801: right).

For a given output power, a lower cathode voltage is required in a MBK compared to a SBK. The combination of high total beam current and lower beam-induced voltage in a common output cavity makes it possible for a lower external Q-factor, facilitating higher bandwidth operation.

## HISTORICAL BACKGROUND

The concept of multi-beam klystron is not new. It was proposed as early as the middle of the 20th century in both the Former Soviet Union and France. MBK development in the US all but ceased after the early 1960s, since it was thought that potential benefits of MBK technology did not overweight the added device complexity and associated cost [2]. In the last three decades, MBK development has occurred primarily in the Former Soviet Union for mobile ground-based, airborne and space-based radar and radio-communication systems because of its advantages in high power, efficient, broadband operation capability at lower voltage in compact and lightweight body. Few details were published to outside world before the end of Cold War, as they were developed primarily for military applications. Recently, other countries have revived their activities in MBK for similar applications.

Under the renewed interest in US, Naval Research Lab recently built a broadband (6%), S-band, 600kW, 8-beam MBK for shipboard radar/communication systems [2]. Table 1 summarizes its parameters and measurement results. They employ the typical design of MBK for a large instantaneous bandwidth, with eight clustered beamlets around the geometric axis, interacting with four common $TM_{010}$ cylindrical cavities (see Fig. 4).

Table 1: Parameters and Measurement Results of Naval Research Lab's S-band, 600kW, 8-beam MBK

| **Parameter** | **Measured** | **Unit** |
|---|---|---|
| Central Frequency | 3.2 | GHz |
| Peak Output Power | 600 | kW |
| Beam Voltage | 45 | kV |
| Beam Current | 32 | A |
| RF Pulse Duration | 5 | µs |
| Efficiency | 39 | % |
| Bandwidth | 6 | % |
| Gain | 30 | dB |

## L-BAND 10MW MBK FOR TESLA

Recently, there has been a rising international interest in MBK for applications in particle accelerators, with active development taking place, in France, US, and Japan. That began about 10 years ago, when DESY started its efforts to develop an L-band 10MW MBK with Thales (France) for the TESLA [3] (now XFEL [4] and ILC) project. Thales started the design work in late 1990, and the full power test of the first MBK was done successfully at DESY in May 2000 [1]. CPI joined this effort with its own design in 2001 [5] and the test of the first CPI MBK was done at DESY in September 2005. At last but not least, Toshiba joined the worldwide effort of MBK development with its own design in 2002. Although it was late start, they built and successfully tested the vertical MBK at DESY in June 2006 [6]. They then built the first horizontal MBK for XFEL and the full power test was done successful at DESY in February 2008 [7].

The major challenges to design and operation of L-band (1.3GHz) MBK for TESLA are (1) “super-high” peak (10MW) and average (150kW) power requirements (2) a high efficiency (≥65%) required at this power level (3) multiple and uniform beam cathodes that stably sustain long beam pulse operation (1.7ms at 115kV at 10Hz repetition rate) with long tube lifetime (>60,000hrs). However, the required instantaneous -1dB bandwidth is only 3MHz unlike a broadband MBK for radars. At acceptance test at DESY, a tube has to satisfy all requirements for operation parameters. Transfer curves (RF output power vs. RF drive power) need to be smooth without any discontinuity, meaning no sign of multi-pactoring or parasitic oscillation. 24 hours continuous operation without fault by gun or window arching is also required at the end of test.

## DESIGN AND PERFORMANCE

Development of “super-high” power MBKs is relatively new area, and there is no standard design model yet. In fact, the all three MBKs (Thales, CPI and Toshiba) have different designs with their own pros and cons. Success of any MBK among them will greatly help to establish a design model for future MBKs in a centimetre-wavelength band. The following assessments are based on the author’s analysis of pros and cons of different design approaches when he made the basic design of the Toshiba MBK in 2002, which later became Toshiba E3736.

### *Thales MBK TH1801*

Thales design is the conventional “clustered-beam approach” for a radar requiring a large instantaneous bandwidth. This design uses 7 beamlets (6 on a circle and 1 at the center), each with 0.5 μ-perveance [1]. They enter the center of cylindrical common cavities operating in the fundamental ($TM_{010}$) mode through individual drift tubes. Figure 5 shows the photograph of the multi cathode gun (left) and the cross sectional view of $TM_{010}$ cylindrical cavity. This design provides the most compact and lightweight MBK. The primary drawback to this design is that clustered beamlets are closely packed near the center of the tube. The consequent small cathodes and poor beam area compression (9:1) lead to high cathode loading (5.5A/cm$^2$), which in turn results in the relatively short cathode lifetime (36,000hrs). Use of recent long-life, high emission current density cathodes may ease this concern.

In reality, the lifetime of a tube is likely to be determined by, not the cathode loading itself, but deposition of Barium, evaporated from cathodes, on focus electrode or anode. For this reason, lower operating temperature of cathodes (lower cathode loading), and larger deposition area of Barium (larger focus electrode and larger anode) help to significantly extend the arc-free lifetime of a tube. In this sense, the Thales design may inherit the typical problem of relatively short lifetime of MBK for radar/radio-communication systems.

Another characteristic of Thales design is the conflicting role of the center beamlet. If only off-axis beamlets are used, the pervenace of each beamlet will be 0.58μ-perveance, and the achievable highest efficiency is 68.7%, according to the relationship (1). Addition of the center beamlet helps to reduce the single beam pervenace to 0.5μ-perveance, and increase the achievable highest efficiency to 70%. The current loading of each cathode is also reduced, benefitting longer cathode lifetime. On the other hand, the center beamlet experiences a larger voltage across the gap of a cavity than the off-axis beamlets due to the field shape, and the R/Q of the center gap is 40% higher than those of the off-axis gaps. Therefore, the center beamlet will develop different bunching from other beamlets, which will perturb coherent excitation of $TM_{010}$ modes at the cavities, in particular at the output cavity. As will be seen soon, the measured efficiency of Thales TH1801 is 65%, 5% lower than the achievable highest efficiency of 70%. A challenge of this design is to find methodology for improvement of efficiency and peak power.

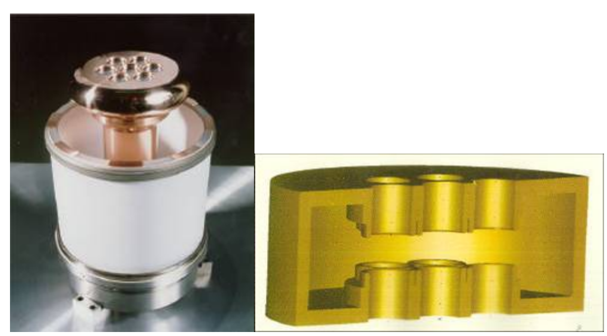

Figure 5: The multi cathode gun (left) and the cross section of $TM_{010}$ cavity (right) of Thales TH1801.

Eight Thales TH1801 tubes have been built and successfully tested (except #2) at DESY. Figure 6 shows its photograph. The typical test results are summarized in Table 2. The early two TH1801 tubes showed gun arching problems. The small cathodes and the large cathode loading were suspected as the causes. However, thoroughly investigation at Thales revealed that the cause was a gun oscillation and the problem was fixed. Since then, no sign of degradation has been observed. The horizontal version, which fits in the accelerator tunnel, is almost ready to be delivered for testing at DESY in fall 2008.

Figure 6: Thales TH1801.

Table 2: Typical test results of Thales TH1801 at DESY.

| Parameter | Measured | Unit |
|---|---|---|
| Peak Output Power | 10.2 | MW |
| Beam Voltage | 117 | kV |
| Beam Current | 131 | A |
| RF Pulse Duration | 1.5 | ms |
| Repetition Rate | 10 | Hz |
| Efficiency | 65 | % |
| Bandwidth | >10 | MHz |
| Gain | 48.2 | dB |

## *CPI MBK VLK-8301*

CPI takes a unique approach [5]: Their MBK has six weakly-coupled single-beam klystrons in parallel, sharing the same modulator, but with its own cathode, collector and individual cylindrical $TM_{010}$ cavities except for input and output cavities. They are coupled by large common input and output cavities operating in the higher-order ($TM_{020}$) mode. The beamlets are set on a large bolt circular diameter (26.7cm) and interact with the second radial peak of the axial electric field in the $TM_{020}$ cavities.

The advantage of this design is the ability to use large cathodes with small cathode current loading (2.2A/cm$^2$) and resulting long cathode lifetime (>100,000hrs).

The disadvantage is an increase of the complexity of the tube, in particular, in design of proper focusing system to provide minimum radial fields for 13.4cm off-axis beamlets. The tube has high volume (a major diameter of 53cm) and is heavyweight: the tube weights 900kg, three times heavier than Thales TH1801 (300kg). Use of large $TM_{020}$ cavities also increases a number of parasitic modes and a risk of their undesirable oscillation.

Use of intermediate individual cavities raises concern on efficiency degradation. In a klystron, the beam-induced voltages in cavities amplify the bunching in beams. The induced voltage is a function of the cavity characteristics (R/Q, resonant frequency, etc.) and the beam characteristics (beam current, size, etc.). In a MBK, the currents and sizes of individual beamlets will not in general be exactly balanced. Therefore, even if all the cavities are exactly same, the beam-induced voltages at each individual $TM_{010}$ cavity will differ, depending on the characteristics of each beamlet. As a result, each beamlet will develop slightly different bunching, and this difference will be amplified as they interact with successive intermediate individual cavities. If the cavities are not balanced either, say, due to deformation during bake-out or heating during operation, the synergy effects of unbalanced beamlets and unbalanced individual cavities will further deviate the synchronous bunching of beamlets. When all beamlets meet at the common output cavity, a loss in synchronization of bunching in amplitude and phase will degrade the efficiency. In Thales and Toshiba designs, they use only common cavities where all beamlets excite the same $TM_{010}$ modes together and receive the same voltages together. Therefore, they are less susceptible to unbalance in beamlets and cavities.

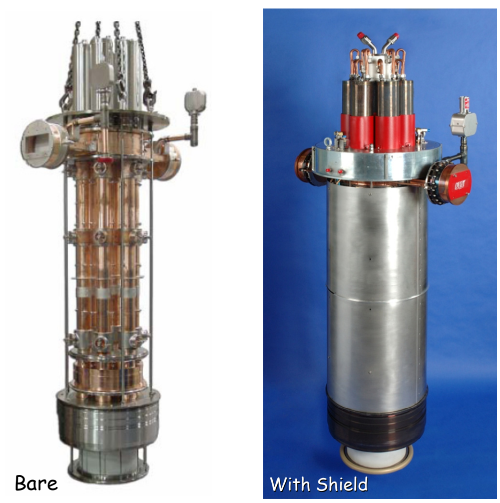

Figure 7: CPI VLK-8301. Bare (left), shielded (right).

VLK-8301 was tested at DESY in September 2005. It did not make full 10MW peak power at full pulse length. The best result was 8.1MW peak power at 1.3ms pulse length at 10Hz repetition rate with efficiency of 53.5%. It attained 9MW peak power at a short pulse length of 0.3ms. The test results are summarized in Table 3. The tube is now in use at DESY for the cryomodule test stand.

Table 3: Test Results of CPI VLK-8301 at DESY in 2005.

| Parameter | Measured | Unit |
|---|---|---|
| Peak Output Power | 8.1 | MW |
| Beam Voltage | 115 | kV |
| Beam Current | 131 | A |
| RF Pulse Duration | 1.3 | ms |
| Repetition Rate | 10 | Hz |
| Efficiency | 53.5 | % |
| Bandwidth | >5 | MHz |
| Gain | 48 | dB |

CPI is currently developing a second-generation, horizontal version of MBK, VKL-8301B. In this new design, they utilize 7 ring-shaped cavities operating in the fundamental $TM_{010}$ mode, just like the Toshiba design, instead of $TM_{020}$ cylindrical cavities used in the first generation. The horizontal VKL-8301B is expected to be delivered to DESY in fall 2008.

### *Toshiba MBK E3736 and E3736H*

Toshiba approach is a “simple and symmetric” design [6]. They use common ring-shaped cavities for all cavities, operating in the fundamental $TM_{010}$ mode, to ensure sufficient beam separation (spaced on a diameter of 12cm, not 26.7cm like CPI), while still keeping the overall size small to reduce cost and complexity. The 6cm separation of beamlets allows to use large cathodes (a diameter of 38mm), and the cathode current loading is 2.1A/cm$^2$, as small as CPI VLK-8301 for long lifetime (>100,000hrs).

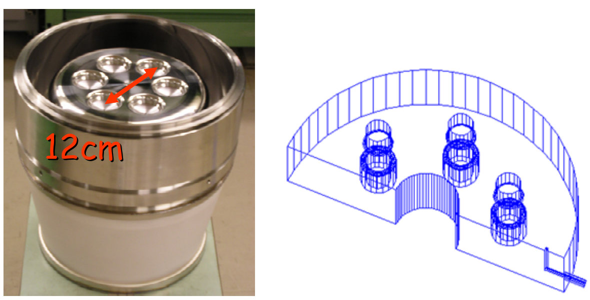

Figure 8: The multi cathode gun (left) and the ring-shaped $TM_{010}$ cavity (right) of Toshiba E3736 and E3736H.

The distinctive advantage of this design is the ability to optimize the cavity structure, the beam separation, the cathode diameter and the number of beamlets for optimum operational performance of the tube, by adjusting the overall sizes of ring-shaped cavities: the diameter of ring is a relatively free parameter, while the width of ring is constrained by the operation frequency of 1.3GHz. Despite of great benefits of the sufficient beam separation and the large cathode size, the tube weights only 340kg, 13% heavier than Thales Th1801. An added advantage of the fundamental mode operation is to make the tube more tolerant to manufacturing errors and cavity deformation due to bake-out or heat deposition.

The first tube, the vertical E3736 (Fig. 9 left), was successfully tested at DESY in June 2006 to full peak and full average RF power at full pulse length [6]. The second tube, the horizontal version, named E3736H (Fig. 9 right), was also tested successfully at DESY in February 2008[7]. Their test results are summarized in Table 4.

Toshiba E3736H was the first horizontal MBK for the XFEL project, delivered, successfully tested and accepted by DESY. The vertical version has been operated for more than 750 hours at the full power in about 80% of time. The horizontal version has been operated for more than 850 hours, in use for investigation of RF behaviour such as temperature stability, harmonic level, and phase stability, etc., which will be of great help for XFEL operation.

Figure 9: Toshiba vertical E3736 (left) and horizontal E3736H (right).

Table 4: Test Results of Toshiba E3736 and E3736H Measured at DESY in 2006 and 2008, Respectively

| Parameter | E3736 | E3736H | Unit |
|---|---|---|---|
| Peak Output Power | 10.2 | 10.1 | MW |
| Beam Voltage | 115 | 118 | kV |
| Beam Current | 134 | 130 | A |
| RF Pulse Duration | 1.5 | 1.5 | ms |
| Repetition Rate | 10 | 10 | Hz |
| Efficiency | 66 | 65.4 | % |
| Bandwidth | 3.5 | 3.5 | MHz |
| Gain | 49 | 48 | dB |

## CONCLUSIONS

The good performance of the Thales and Toshiba L-band MBKs operating in the fundamental modes of cylindrical cavities (Thales) or ring-shaped cavities (Toshiba) demonstrates that their design approaches are sound and valid in this wave-length band. The Toshiba design is more advantageous in a shorter wave-length, because of greater flexibility in design of the gun region. In a longer wave-length, Thales design is an attractive choice, since it provides a compact and low-cost tube. The MBK technology and its distinctive advantages over SBK will greatly benefit and advance linear accelerators.

# POSITRON BEAMS PROPAGATION IN PLASMA WAKEFIELD ACCELERATORS

Patric Muggli
University of Southern California, Los Angeles, CA 90089, USA

*Abstract*

Preservation of beam emittance is a concern in all accelerators. The formation of a beam charge halo in a plasma wakefield accelerator (PWFA) driven by a single positron bunch is observed. This phenomenon is also observed in numerical simulations. These simulations indicate that it results in significant emittance growth of the positron bunch. We discuss theses results as well as possible means to preserve the positron emittance.

## INTRODUCTION

In conventional accelerators using magnetic optics and rf waves in resonant cavities to focus and accelerate particles, positive and negative charge particles can be accommodated by merely a change of current sign in the magnets and phase in the rf.

In plasma-based accelerators (PBAs) the plasma itself sustains the focusing and the accelerating fields. Plasmas are composed of particles of opposite charge, electrons and protons or ions, but of very different mass. Therefore, the light electrons are the mobile species, while the heavier ions are usually considered as immobile on the time scale of an electron plasma period. In the linear theory of PBAs where the relative plasma density perturbations $\delta n/n_e$ ($n_e$ the background plasma density) and wakefield amplitudes are small, the plasma wave is also symmetric for opposite sign charges, providing a simple 90° phase shift of the wave or wake.

However, the nonlinear or blowout regime of PBAs [1] offers some striking advantages over the linear regime for accelerating electrons. In this regime all the plasma electrons are blown out of a volume encompassing the drive and the witness beam. This regime is reached when the drive particle bunch density $n_b$ is much larger than the plasma density: $n_b >> n_e$, or when the drive laser intensity exceeds a threshold value. In this regime the accelerated beam propagates in a pure ion column that acts as a long focusing element free of geometric aberrations. Also, the accelerating field ($\approx\delta n/n_e$) is larger than in the linear regime. In fact, all current PBA experiments operate in this regime. These experiments have shown emittance preservation of the incoming beam [2,3], matching of the beam to the plasma focusing [3], and energy doubling of 42 GeV incoming electrons in only 85 cm of plasma [4], all the above in beam driven PBAs or plasma wakefield accelerators (PWFAs). Acceleration of electron bunches to hundreds of MeVs with narrow energy spread was also demonstrated in this regime in PBAs driven by intense laser pulses or laser wakefield accelerators (LWFAs) [5,6,7]. In this case, access to the nonlinear regime is necessary since the source for the accelerated beam is the trapping of the plasma electron triggered by the breaking of the plasma wave. In recent all these experiments the accelerating gradient exceeded 50 GV/m.

## POSITRON BEAMS IN PLASMAS

The situation is very different for the acceleration of positron beams in plasmas. No blowout regime exists because the mobile plasma species is still the electrons, and to focus the positron beam by partial charge neutralization the plasma electrons have to flow through the positron bunch. As a result, in uniform plasmas the electrons do not form a large region (of the order of the plasma wavelength cubed as in the case of an electron bunch) where the wakefield can be uniform enough to accelerate the positron bunch with low energy spread and to focus it while preserving its low incoming emittance. This is true whether the drive beam is a laser pulse or a particle bunch. For instance, simulations indicate that the accelerating field driven by single bunch positron beams is smaller [8] than that driven by an electron bunch with similar parameters. Also, emittance growth of the incoming bunch along the plasma is expected as a consequence of the non-linear focusing force exerted by the plasma onto the bunch. Acceleration and propagation of positron beams in plasmas have not been studied as extensively as they have been with electrons. This is of course due primarily to the fact that short, high current positron bunches are not readily available, except at the Stanford Linear Accelerator Center (SLAC).

The acceleration of positrons in the wakefield driven by a single positron bunch has been demonstrated [9]. The focusing of a positron beam by a short, high-density gas jet plasma was also demonstrated [10]. The effect of the propagation of the same positron beam along a $L_p$=1.4 m, low density ($<10^{12}$ cm$^{-3}$) plasma column was studied in detail with picosecond time resolution along the ≈10 ps long bunch [11]. However, in these experiments the product of plasma density and plasma length ($n_eL_p<3\text{x}10^{12}$ m$^{-2}$) was too small for the beam to significantly evolve in its transverse dimensions along the plasma.

In order to gain large amounts of energy (>10 GeV) the positron beam will have to propagate through a long ($L_p$>2 m), dense ($n_e>10^{16}$ cm$^{-3}$) plasma, since accelerating gradients of 5 to 10 GV/m are desirable. The effect of the non-ideal wakefield will therefore accumulate and emittance preservation is an open question.

We present here some experimental and simulation results demonstrating the formation of a beam halo around a single positron bunch propagating through a 1.4-

m-long plasma, as well as the corresponding emittance growth [12].

## EXPERIMENTAL SETUP

Figure 1 shows a schematic of the experimental set up. The ultra-relativistic ($E_0$=28.5 GeV, $\gamma$≈56,000) beam available at the SLAC Final Focus Test Beam [13] facility with ≈1.8x$10^{10}$ positrons is focused near the entrance of the plasma. The typical transverse beam size at the waist is $\sigma_{r0}$≈25 $\mu$m (round beam). The bunch length is $\sigma_z$≈700 $\mu$m (or 2.3 ps). Because of scattering in the entrance beryllium window, the upstream optical transition radiation (OTR) foil and the thin pellicle mirror that makes the ionizing laser pulse collinear with the positron beam, the normalized emittances at the plasma entrance are $\varepsilon_{Nx}$≈380 and $\varepsilon_{Ny}$≈80 mm-mrad. Here the $x$ direction is in the horizontal plane, and $y$ in the vertical plane. The beam propagates along $z$. The beam transverse size and shape are monitored ≈1 m upstream and downstream of the plasma using OTR. The visible OTR light is imaged onto CCD cameras to record images for each bunch.

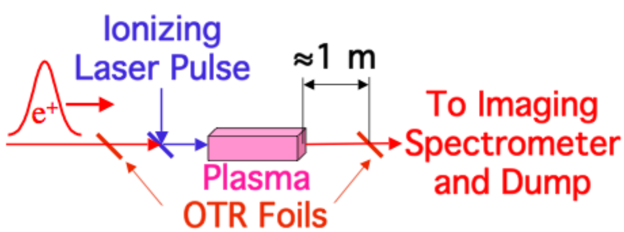

Figure 1: Schematic of the experimental setup. The beam transverse size and shape are monitored ≈1 m upstream and downstream of the plasma using optical transition radiation (OTR).

The plasma source consists of a hot lithium (Li) vapor contained in a heat-pipe oven [14,15]. A 20 ns uv laser pulse with a wavelength of 193 nm (6.4 eV/photon) ionizes the low ionization potential (5.4 eV) Li. The laser beam, and therefore the plasma, is made collinear with the positron beam by reflection off a 45°, 150 $\mu$m-thick glass pellicle coated for high reflectivity at 193 nm. The laser beam is also focused along the lithium vapor column to compensate for the uv photons absorption and thereby maintain a constant (±5%) plasma density over the column length. The plasma density is obtained from the measurements of the lithium neutral density and absorbed uv energy. The measurements of the positron characteristics with plasma ($n_e$>0) are acquired with the positron bunch traveling along the plasma 200 ns after the laser pulse. Every fourth event is recorded with the laser firing after the positron bunch ($n_e$=0) in order to continuously monitor the incoming beam characteristics. The plasma length is $L_p$=1.4 m, and $n_e$ is varied between ≈$10^{13}$ cm$^{-3}$ and ≈5x$10^{14}$ cm$^{-3}$ by adjusting the laser pulse energy. The maximum ionization fraction is ≈13%.

## HALO FORMATION, EXPERIMENT

Figure 2 show two images of the beam recorded at the downstream OTR foil location. With $n_e$=0 (Fig. (a)) the beam transverse shape is elliptical because of the round transverse size at the beam waist and the unequal emittances. The projections of the beam along the $x$ and y directions are Gaussian to a good approximation. The corresponding transverse sizes are $\sigma_x$≈1430 $\mu$m (large) and $\sigma_y$≈310 $\mu$m (low emittance plane).

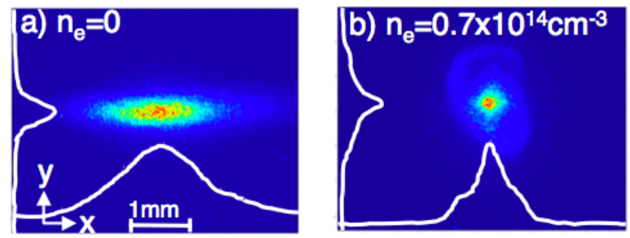

Figure 2: Experimental images of the beam recorded at the downstream OTR foil location. The white lines show the transverse beam profiles obtained by summing the images along the perpendicular direction. (a) With $n_e$=0, the beam profiles are Gaussian to a good approximation. The different $x$ and $y$ sizes are the result of the different emittances. (b) With $n_e$=0.7x$10^{14}$ cm$^{-3}$, the image and the profiles exhibit a dense core surrounded by a charge halo (from [12]).

Figure 2 (b) shows an image of the beam after traveling through the $n_e$=0.7x$10^{14}$ cm$^{-3}$ plasma. This image shows that the beam has a tightly focused core, with a strong reduction of the beam transverse size in the $x$, large emittance plane. A halo of charge also appeared in the two planes, but is most noticeable in the $y$, low emittance plane. The transverse profiles are not Gaussian anymore, but instead reflect the core and halo structure. In order to describe these non-Gaussian profiles, a two-triangle fit [16]] is used to quantify the bunch core size as well as the relative amount of charge in the core and halo.

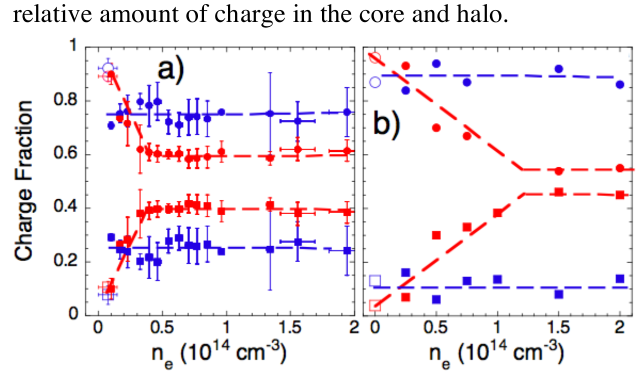

Figure 3: Charge fraction in the beam core (circles) and halo (squares) in the $x$ (blue symbols) and y plane (red symbols) as a function of $n_e$ obtained (a) from experimental OTR images (see Fig. 2) and (b) from simulations generated images. The beam parameters are those of the experiment. The lines are added to suggest trends.

Figure 3(a) shows the relative amount of charge in the focused core and in the halo as a function of $n_e$ for densities up to $2x10^{14}$ cm$^{-3}$. These measurements are obtained from OTR images such as those on Fig. 2. In the $y$ plane charge transfers from the core to the halo from $n_e$=0 to ≈$0.3x10^{14}$ cm$^{-3}$. Then the charge fractions remain approximately constant at 60% and 40% in the core and halo, respectively. In the $x$ plane the charge fractions remain at 75% and 25% for all $0<n_e<2x10^{14}$ cm$^{-3}$.

## HALO FORMATION, SIMULATION

The numerical code QuickPIC [17] is used to simulate the propagation of the positron bunch along the plasma. The positrons are then ballistically propagated a distance of one meter to generate images to be compared with those measured in the experiment at the location of the downstream OTR foil. Figure 4 show the evolution of the beam transverse size along the plasma obtained from one of these simulations. The beam parameters are those of the experiment, and the plasma density is $n_e=10^{14}$ cm$^{-3}$. Over the first 10 cm the plasma focuses the beam. This effect is similar to the size reduction measured downstream from the plasma in ref. 11. The $n_eL_p$ product is small, $10^{13}$ cm$^{-2}$ in this case, and the plasma focusing force nonlinearities have not yet strongly spoiled the beam transverse phase space. The beam size is therefore reduced. Note that this focus occurs at a distance into the plasma that is shorter than the distance an electron beam with identical parameters would focus at. The betatron wavelength for electrons in a pure ion column with an ion density equal to $n_e$ is $\lambda_\beta=2\pi(2\gamma)^{1/2}c/\omega_{pe}$, where $\omega_{pe}=(n_e e^2/\varepsilon_0 m)^{1/2}$ is the electron plasma angular frequency. The focus would appear at $\lambda_\beta/4$≈28 cm. This shorter focusing length reflects the fact that the plasma electron charge density can exceed the background density $n_e$ and therefore the focusing force exceed that experienced by an electron beam in the same situation.

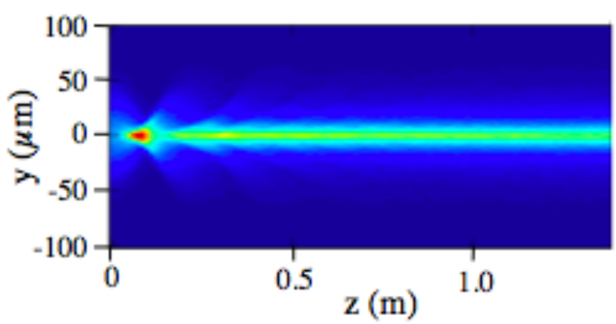

Figure 4: Beam transverse distribution ($y$, low emittance plane) along the $L_p$=140 cm, $n_e=10^{14}$ cm$^{-3}$ plasma obtained from numerical simulations. The beam parameters are those of the experiment.

After the first pinch the beam expands again, but does not come to a clear second pinch. Instead, the beam profile has a focused core on axis surrounded by charge in a beam halo, as seen on Fig. 2, and as seen on simulated images [12]. The beam profile then remains essentially constant over the length of the plasma from $L$=0.5 m to $L_p$=1.4 m, and $n_eL_p=1.4x10^{14}$ cm$^{-2}$.

Figure 3 (b) shows the charge fraction in the beam core and halo at the downstream OTR location as a function of $n_e$ and can be compared to the experimental result of Fig. (a). Similarly to Fig. (a), Fig. (b) also shows a continuous transfer of charge from the core to the halo. However, this transfer process extends over a higher density range than observed in the experiment, up to ≈$1.2x10^{14}$ cm$^{-3}$. At higher $n_e$ the fractions remain at 55% and 45% in the core and halo, respectively, values similar to those measured in the experiment. Beam transverse size measurements show excellent agreement with the sizes calculated from simulations images [12]. They also indicate that the beam exits the plasma with approximately equal transverse sizes.

The formation of the halo is the result of the nonlinear focusing force from the non uniform neutralization of the positron space charge by the plasma electrons rushing through it. The halo formation is therefore expected to lead to emittance growth. The bunch emittance is obtained from simulation results.

## EMITTANCE GROWTH, SIMULATION

The normalized rms emittance of the beam in the $x$ plane is calculated from the particles position $x$ and momentum $p_x$ as:

$$\varepsilon_{Nx} = \gamma\left(\left\langle x^2\right\rangle\left\langle x'^2\right\rangle - \left\langle xx'\right\rangle^2\right)^{1/2}$$

where $x'=p_x/<p_z>$, <.> stands for the quantity average, and $<p_z>$ is the beam average longitudinal momentum. A similar expression is used for the $y$ plane normalized emittance.

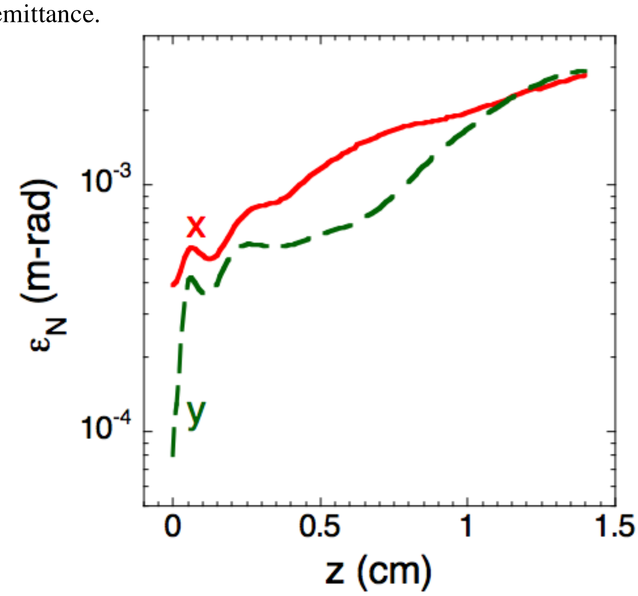

Figure 5: Evolution of the beam emittances ($x$ plane, red continuous line, $y$ plane green dashed line) along the plasma with $n_e=2x10^{14}$ cm$^{-3}$ obtained from numerical simulations. Both final emittances are ≈$3x10^{-3}$ m-rad, corresponding to an emittance growth by a factor of ≈8 in the $x$-plane and 38 in the $y$-plane. The beam parameters are those of the experiment.

Figure 5 shows the evolution of the positron bunch normalized emittance in both transverse planes along the plasma. In the low emittance $y$ plane the emittance quickly grows from the incoming 80 mm-mrad over the first few centimeter of plasma, to become approximately equal to the $x$ emittance. After that the two emittances grow together and remain approximately equal. Both final emittances are $\approx 3\text{x}10^{-3}$ m-rad, corresponding to an emittance growth by a factor of ≈8 in the $x$ plane and 38 in the $y$ plane. As noted before, the beam transverses sizes are also about equal (as for example on Fig. 2 (b)).

## EMITTANCE PRESERVATION

The results presented here above show charge halo formation and emittance growth when a single positron propagates in a uniform plasma suitable for acceleration of trailing particles [9]. However, future plasma-based linear collider will use a drive/witness bunch scheme. In that scheme, a first bunch (electron or positron) drives the wake and loses energy, while a witness bunch, following about a plasma wavelength behind the drive bunch, only gains energy. A similar scheme will be used in a laser-driven PBA, with the drive bunch replaces by a laser pulse. The emittance preservation of a positron witness bunch has not been studied in a two-bunch scheme and will be the subject of future simulation work. However, the use of a plasma with an on-axis hollow channel has been proposed to increase the accelerating gradient in the single positron bunch case [18]. Hollow plasma channels may also have an effect on the emittance of the bunch. Hollow plasma channels also have advantageous effects for laser-driven PBAs [19]. Preliminary results seem to indicate that a plasma hollow channel guides the positron beam and minimizes the beam distortion [20]. The challenge is to find a configuration that generates a region of the wake large enough to encompass a high charge positron bunch, a region in which the accelerating gradient is large and uniform, and the focusing force linearly increasing with radius. An alternative approach is to shape the witness bunch in its transverse and longitudinal dimensions in order to compensate for the non uniformities of the wake fields.

## POSITRONS ON ELECTRON WAKE

Short, high-charge positron bunches are difficult to produce. It may therefore be advantageous to accelerate the positron witness bunch in the wake driven by an electron bunch [21,22]. This scheme would increase the efficiency of a future PBA $e^-/e^+$ collider by avoiding the generation of a positron drive bunch. It is also similar to that of a positron bunch in the wake driven by a laser pulse. The scheme is shown on Fig. 6. The positron bunch is placed right after the density spike created by the expelled plasma electrons returning on axis, the region where the wakefield is both accelerating and focusing for positrons. This region becomes narrower as the wake is made more nonlinear. A scheme was recently proposed [22] to create the positron beam inside the plasma, thereby avoiding all the issues associated with the generation, transport and timing of a positron bunch ≈100 $\mu$m behind an electron bunch. The positron bunch is generated by $e^-/e^+$ pair creation in a high-Z foil embedded into the plasma, The incoming electron beam is split in a drive/witness bunch train using for example a mask technique [23]. After the foils, two positron bunches overlap in space and time with the two incoming electron bunches. The plasma wakefields act to select and preserve only the drive electron bunch and the positron witness bunch or positron beam load. The positron beam load size must be adjusted to fit inside the favorable wake volume. Simulations show that $\approx 10^8$ positrons with energies >5 MeV can be injected into, and trapped by the plasma wake. They can be accelerated to ≈5 GeV in one meter with a relative energy spread of ≈8%. The positron beam load normalized emittances are 20 and 25 mm-mrad in the $x$ and $y$ plane, respectively.

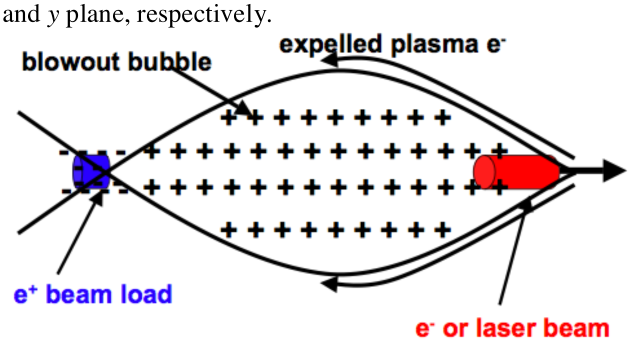

Figure 6: Schematic of the acceleration of a positron bunch ($e^+$ beam load) on the wake driven by an electron bunch or a laser pulse, from ref. 22.

## SUMMARY

The acceleration of positron bunches in high-gradient PBAs while preserving the quality of the incoming bunch is key for a future plasma-based $e^-/e^+$ high-energy collider, whether driven by a laser pulse or a particle bunch. Experimental results obtained with a single positron PWFA show the appearance of a beam charge halo after the propagation through a 1.4 m-long plasma with a density in the 0.5-5x$10^{14}$ cm$^{-3}$ range. Simulations show that this halo formation is the indicator of emittance growth along the plasma. Halo formation and emittance growth are the result of the nonlinear force exerted by the plasmas onto the positron bunch. Unlike in the case of an electron bunch whose emittance can be preserved in the nonlinear blowout regime, the preservation of the emittance of a positron beam in a plasma is more challenging. This issue must be studied using full-scale numerical simulations and confirmed by experiments. Possible solutions include the use of a hollow plasma channel and the careful placing of the positron bunch in a lower plasma density, more linear-like wake.

# CONTROL, STABILITY AND STAGING IN LASER WAKEFIELD ACCELERATORS

D. Panasenko, LBNL, Berkeley, California

## Abstract

Laser driven plasma wakefields have recently accelerated electron beams with quasi-monoenergetic energy distributions and with gradients of ~100 GV/m. Stabilization and optimization of beam quality are now essential. Recent LBNL experiments have demonstrated control of self trapping, resulting in reproducible bunches at 0.5 GeV. Further optimization has been demonstrated using plasma density gradients to control trapping, producing beams with very low absolute momentum spread at low energies. Simulations indicate that use of these beams as an injector greatly improves accelerator performance and experiments are now underway to demonstrate such staging, which will be a crucial technology for laser driven linacs. This talk will cover recent progress in LWFAs to obtain more reproducible, higher quality beams and also cover staging prospects for high energy laser linacs.

# STATUS AND UPGRADE PLAN OF 250 MeV LINAC AT CLS

X.F. Shen, M.S. de Jong, L.O. Dallin, R.M. Silzer and T. Summers

CLS Inc., University of Saskatchewan, Saskatoon, SK S7N 0X4, Canada

### [illegible]

The Canadian Light Source (CLS) 250 MeV linac, originally constructed in the 1960's, serves as the injector for the 2.9 GeV synchrotron radiation facility [1] located on the University of Saskatchewan campus. The linac has operated reasonably well for routine operation of the light source. However, the long-term goal of operating the CLS storage ring in top-up mode will place increased demands on the linac for stability and availability that cannot be met with the existing system.

Consequently, an upgrade is planned over the next two years to get higher beam stability, reliability and reproducibility. In this paper, the existing linac system will be described and the planned upgrade will be reported.

## INTRODUCTION

The 150 MeV linac, with three Varian accelerating sections, was originally constructed in the mid-1960's for nuclear physics research in the Saskatchewan Accelerator Laboratory. In the 1980's, the linac was upgraded to 300 MeV with the addition of three SLAC-type accelerating sections.

In 1999, the nuclear physics research program was shut down, and the linac was incorporated into the injection chain for the 2.9 GeV synchrotron storage ring of Canadian Light Source. In this upgrade the control system was partially modified to use the EPICS system with the exception of the electron gun and modulator high voltage control. The timing, trigger system and instrumentation were also upgraded. Linac operation for the injector only requires short bunch trains (less than 200 ns) with repetitions rates less than 2 Hz. Extensive changes to the modulators were made including the pulse-forming-networks (PFNs) the high voltage power supplies and thyratrons. Some ion pumps and CCGs were upgraded in the vacuum system. About 15% of the magnet power supplies were changed to fit new requirements. The video deflector was modified to produce bunch train lengths of up to 136 ns, corresponding to 68 bunches at 500 MHz. Figure 1 shows the 250 MeV linac tunnel with the 220 kV electron gun.

## LINAC STATUS

### [illegible]

The linac consists of a high-current gun with a buncher section (manufactured by Haimson) and six 2856 MHz rf sections, and is operated at 250 MeV. After the linac, there is an Energy Compression System (ECS), which reduces the 1% energy spread from the linac by a factor of 10, followed by a transport line to the 2.9 GeV booster synchrotron for the main storage ring.

The electron gun can provide up to 1A beam current at 220 keV. In normal operation, the gun emits 125 mA peak beam current. The buncher section compresses the bunch phase to about 12º and increases beam energy to 13 MeV [2]. Beam current at this point is about 70 mA. There are three Varian style acceleration sections that can provide approximately 50 MeV and three SLAC style sections which provide 40 MeV per section. Each section is supplied RF power by an ITT 8568 klystron.

The linac main parameters are listed in Table 1. The linac is shown in Fig. 1. The linac control schematic is shown in Fig. 4.

Table 1: General parameters of the CLS injector linac.

| | |
|---|---|
| Type of structure | TW disc-load WG |
| Frequency | 2856 MHz |
| Length of section | 3 m and 5 m |
| Total number of section | 3(3m) & 3 (5m) |
| ***RF source*** | |
| Peak power of klystron | 20 MW |
| Number of klystrons | 6 |
| RF pulse length | 2.5 μs |
| ***Main Linac Beam*** | |
| Energy | 250 MeV |
| Beam Current | 60 mA |
| Beam Pulse Length | 2 ns ~136 ns |
| Repetition Rate | 1 Hz |
| Energy spread (without ECS) | <1.0% |
| Energy spread (with ECS) | 0.1% |

Figure 1: CLS 250 MeV linac.

## [illegible]

After four years of operations following commissioning of the storage ring, routine injections use a 250 MeV, 60 mA beam, and 2 ns to 136 ns variable bunch train length. The bunch length is selected by a video deflector, corresponding to the requirements of the storage ring injection or the light source users. Figure 2 shows the beam currents from the linac. The red (top) trace is the signal picked up from a toroid, located just after the end of the linac, which has some distortions at the rising and falling edges caused by the toroid slow time response. The blue (bottom) trace shows the signal from a FCT installed after the small rf section used for the Energy Compression System (ECS). The current uniformity along the bunch train is quite good, with typically less than 10% variation.

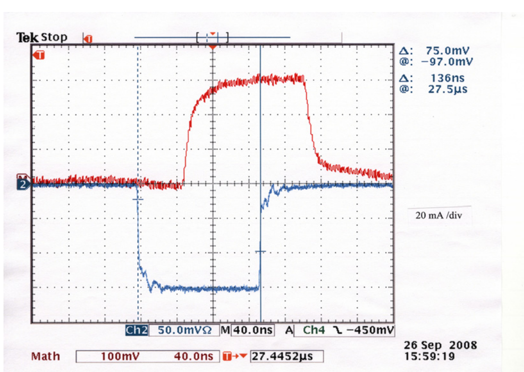

Figure 2: Linac beam current.

During normal storage ring operations, the linac is used only for about 15 minutes every 12 hours. Figure 3 shows the typical daily performance of CLS storage ring. In addition, an in-line beam stop can be placed in the linac-to-booster transport line to allow independent linac operation between storage ring injections. When operated in this mode, the linac operation has been quite reliable with less than 10% of storage ring down-time attributable to the linac.

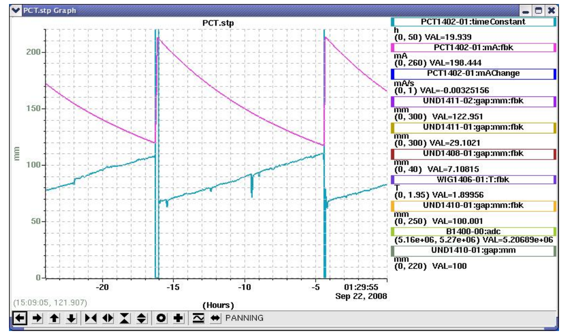

Figure 3: CLS storage ring daily performance. Current is routinely filled to 250 mA every 12 hours. The top trace shows the current decay between refills. The bottom trace shows the beam lifetime.

However, after a period of a few weeks, the operating point for the linac tends to drift, resulting in reduced injection efficiency into the storage ring and requiring some time to re-optimize the linac operation. As well, some linac and rf system components are over 40 years old and are nearing or at the end of their useful operating lifetime. CLS is now considering top-up operation of the storage ring, which requires continuous operation of the linac at a very low repetition rate (~ 0.01 Hz). This places much greater demands on the stability and reliability of the linac.

Thus, most of the following issues need to be addressed for good long-term operation in top-up mode:

- Linac average output energy changes slightly over time.
- The beam energy spread grows over time reducing injection efficiency.
- Beam energy changes from shot to shot, resulting in large variations in current injected into the storage ring.
- Some acceleration sections are quite old and were operated with bad vacuum conditions for many years,.
- Several rf power source parts have no available replacements.
- The Varian section’s expected lifetime was about 20 years, but now they have already worked for over 40 years.
- Unfortunately, because of space limitations in the 1980’s upgrade, the six modulators were installed into the original three modulator cabinets, which has caused serious cross-talk between modulator pairs.
- Electron beam diagnostics are inadequate for automatic control and effective optimization.

## UPGRADE PLAN

A linac upgrade plan has been developed to address these problems for future operation, and will be implemented over the next two years.

### [illegible]

- Four new acceleration sections will replace the existing three Varian sections and a vacuum-contaminated SLAC section. This will both reduce the VSWR trips and solve bad vacuum condition problem.
- A new solid-state RF drive amplifier will replace the existing klystron amplifier.
- All high-voltage modulators will be replaced to stabilize the beam energy jitter which is caused by cross-talk in the modulator triggering circuits.
- Phase detectors and a feedback system will be incorporated to stabilize the beam energy.

### [illegible]

- All controls will be upgraded to the EPICS system.

### [illegible]

- All toroids used to measure the beam currents will be replaced by either fast toroids or fast current transformers.
- All beam profile monitors will be replaced.
- An Emittance measurement device will be considered.

### [illegible]

- Replacement of all old ion pumps and ion pump controllers.
- Installation of more CCGs and TCGs to monitor pressure in all sections,
- Replacement of all vacuum valves.

### [illegible]

- All old DC magnet power supplies will be replaced to stabilize the beam parameters and increase the operation reliability.

# ARIEL AND THE TRIUMF E-LINAC INITIATIVE, A ½-MW ELECTRON LINAC FOR RARE ISOTOPE BEAM PRODUCTION

S. Koscielniak, F. Ames, R. Baartman, R. Dawson, J. Drozdoff, Y. Bylinsky, K. Fong, A. Hurst, D. Karlen, R. Keitel, R. Laxdal, F. Mammarella, M. Marchetto, L. Merminga, A.K. Mitra, K. Reiniger, T. Ries, R. Ruegg, I. Sekachev, G. Stinson, V. Verzilov
TRIUMF*, 4004 Wesbrook Mall, Vancouver, BC V6T 2A3, Canada

*Abstract*

TRIUMF, in collaboration with university partners, proposes to construct a megawatt-class electron linear accelerator (e-linac) as a driver for U(γ,f) of actinide targets for nuclear astrophysics studies, and $^{9}Be(\gamma,p)^{8}Li$ for beta-NMR materials science. The e-linac is part of a broader proposal for an expansion of the TRIUMF rare isotope beams capability through a new facility to be named ARIEL. The e-linac design and prospects for funding are elaborated.

## INTRODUCTION

TRIUMF, in its Five Year Plan 2010-2015 proposes to build the Advanced Rare IsotopE Laboratory (ARIEL) to augment the Rare Isotope Beam (RIB) science program at the ISAC facility. ARIEL, Figure 1, will have four major components: (i) an electron linac photo-fission driver, (ii) a new target hall to be located in a western extension of the existing ISAC building, (iii) a new proton beam line from the H- cyclotron, and (iv) a new RIB "front end". The accelerators and target station(s) will be connected by new 60 metre long beam lines in a common tunnel. The project will be staged. In the first stage, a 100 kW capable linac, a single target station, the e and p beam lines, ion sources and mass analyzers and RIB transport lines to the existing ISAC RFQ and linacs will be constructed. The second stage occurs in the 2015-2020 Plan: the electron linac and target station are upgraded to the full 1/2 –MW capability, an additional target station is added, and the "front end" is completed by the addition of new RIB accelerators, thus facilitating up to three simultaneous RIB, two of which may be accelerated beams. The science program is sketched in Ref.[1] and concepts for the e-linac design and RIB front end are presented in Refs.[2,3].

**Ariel** is a fictional sprite who appears in Shakespeare's play *The Tempest*. The counterpart of Ariel's master *Prospero* is the ISAC science program with its suite of world-class experimental apparatus eager to command the production of more beams and new beams. Adding the electron linac will double the RIBs, and adding the new proton beam line and second target station will triple the RIB production and science output. The '-el' ending of Ariel translates in Hebrew as 'God,' placing Ariel inline with benevolent spirits; and indeed the new accelerator will bring many benefits to TRIUMF.

*TRIUMF receives federal funding via a contribution agreement through the National Research Council of Canada.

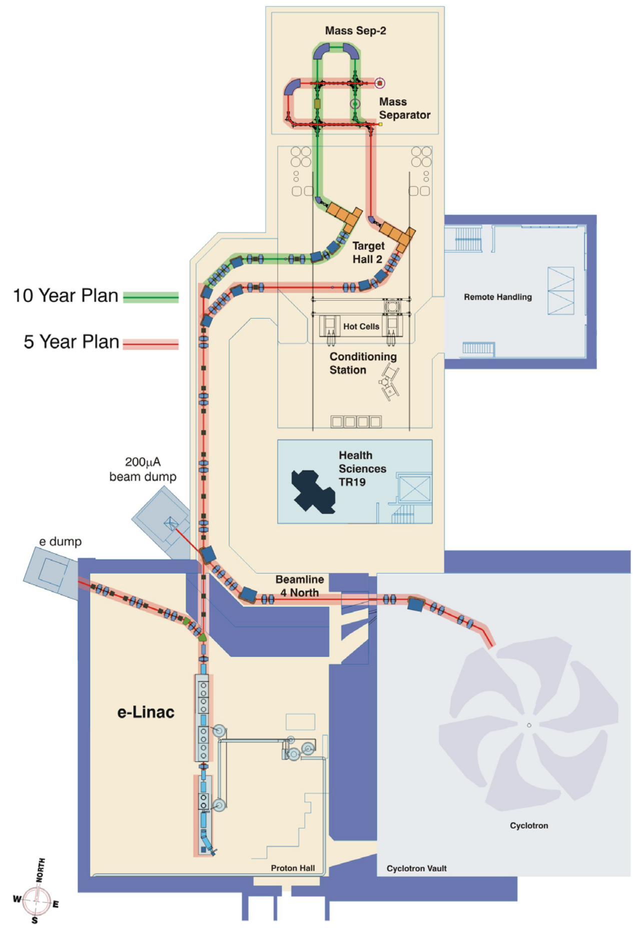

Figure 1: ARIEL infrastructure and layout.

- New Science: nuclear physics with neutron-rich RIBs, and $^{9}Be(\gamma,p)^{8}Li$ production for β-NMR studies in Materials and Molecular Sciences.
- An independent driver for RIB production that complements the cyclotron proton driver.
  - Implements strategy of multiple beams (e, p) to multiple users to accelerate science output.
  - E-linac will operate through annual cyclotron shutdowns providing a strong year-round RIB experimental program.
- Leverages valuable existing infrastructure:
  - Proton Hall, shielded vault with services
  - World-class experimental apparatus (detectors)
  - Builds further SCRF expertise base from β«1, 100 MHz, 4K quarter-wave structures to β=1, 1 GHz, 2K elliptical structures.

- Prepares Canada for SCRF projects world-wide (e.g. CERN-Superconducting Proton Linac, ILC).
- Qualifies a Canadian commercial partner (PAVAC) to build SCRF elliptical cavities.
- Test bed for 4th generation light source technologies.

The centre piece of this program is the high average current continuous-wave electron linear accelerator (e-linac) founded on superconducting RF technology.

## E-LINAC DESIGN OVERVIEW

Three goals have shaped the conceptual design of the e-linac: (1) the utilization of existing technology wherever possible; (2) c.w. operation at high average power; and (3) flexibility toward operation and re-configuration.

From the outset we have opted to base the e-linac design around Tesla Test Facility (TTF) technology developed for TESLA, XFEL [5] and ILC[6]. This is for two reasons: to benefit from the extensive SRF development for these accelerators, and to prepare Canada for participation in high-energy physics projects such as CERN-SPL and the International Linear Collider. However, if given free rein we would have come to similar conclusions.

The TESLA/ILC cavity unit has become a building block for SRF linac design. Though it is the starting point for the e-linac design, commonality with the ILC stops at the cavity level and does not extend to cryovessel or RF power sources. The ILC is a low duty factor machine whose design is limited by the achievable gradient. The e-linac design is driven by the challenges of continuous operation at high average current. Particular challenges are the input coupler design and the 2 Kelvin heat loads. For example, the average power sustained by an ILC input coupler is ≤ 16 kW. In the fission-driver linac, 500 kW of CW RF power has to propagate through the input couplers and cavities into the electron beam. CW operation poses some challenges compared with XFEL or ILC designs, but these challenges are starting to be met in light source designs[4].

Basing the design on existing technology, the e-linac adopts a High-Level RF (HLRF) building block of one 130 kW klystron, two 60 kW couplers and one 9-cell cavity. Five such units operated at 10 MV/m coupled with 10 mA beam current consume 100 kW/cavity and result in a beam energy of 50 MeV. Though the gradient planned for e-linac is a modest 10 MV/m, we intend to leave an upgrade path to an Energy Recovery Linac (ERL) or Recirculating Linear Accelerator (RLA) operated at 20 MV/m; and the cavity fabrication and niobium surface preparation will be consistent with that goal.

The baseline configuration splits the entire e-linac into a low energy injector and the main linac; driven by one and four HLRF blocks, respectively. This choice would allow the linacs to be re-configured at some later date, by the insertion of return arcs, as a test bed for ERL (20 mA, 80 MeV) or RLA (2 mA, 160 MeV) technology. With marginal incremental investments, e-linac could serve as a test-bed for a Compton Scatter Source of hard x-rays or a staging post to an IR or THz FEL or Coherent Synchroton Radiation source. The return arcs are not costed in this proposal, nor a photo-cathode gun; but HOM absorbers, variable coupling ratio and piezo tuners form part of the baseline design.

## E-LINAC TECHNICAL DESIGN

The 50 MeV, 10 mA, capable CW linac is based on TTF super-conducting radio-frequency (SRF) technology at 1.3 GHz and 2K; and consists of an electron gun, buncher, injector cryomodule, and two main-linac cryomodules. Figure 2 shows the e-linac baseline layout as it will appear in 2017. The injector module contains a capture section, followed by acceleration in a 9-cell cavity to a few MeV. Each of the main linac cryomodules, accelerating by 20 MeV, contains two 9-cell cavities.

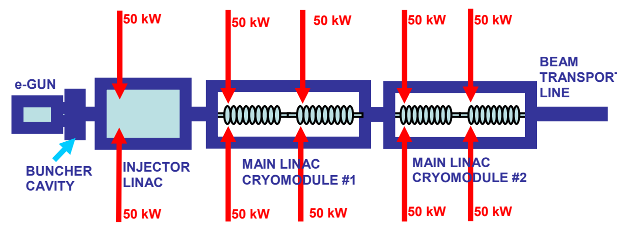

Figure 2: E-linac layout and power distribution.

In the first stage, to be completed mid-2013, the injector the first of the main linac modules, and single IOT and klystron drivers are installed providing 25 MeV, 4 mA. In the second stage, to be implemented 2017, the second of the main linac modules is added along with additional high-power RF sources to achieve the final ½-MW goal. The decision to divide the main linac into two modules stems mainly from the anticipated funding envelope.

We now focus on some technical details of the e-linac. Multiple stages of bunching are required to prepare the beam for on-crest acceleration in the main linac. There is progressive bunching at the source, buncher cavity and capture section at entrance of the injector linac.

### *Electron Source*

The fission-driver specification is more relaxed than a comparable ERL injector to a Free Electron Laser. Light sources need 6D high-brilliance beams. By contrast, the fission driver eliminates its beam on target and so a 100 kV thermionic gun (30 µm normalized) is employed. A diode type gun has been received from TJNAF and will be converted to triode operation; modulating the grid causes the gun to be conducting for ≤ 45° of the RF cycle allowing the beam to emerge pre-bunched at the anode.

Figure 3 shows the gun test bed at TRIUMF; vacuum components and HV power supplies are on order. The final source will output 170 ps FW bunches each of 16 pC with a bunch repetition rate of 650 MHz.

### *Buncher Cavity*

The buncher cavity is used to prepare the beam for the injector linac. The buncher is a normal conducting RF cavity excited at 650 MHz with an amplitude of 15 kV and phased at 90° with respect to the beam. The power requirements are modest and are met with a commercial solid-state amplifier.

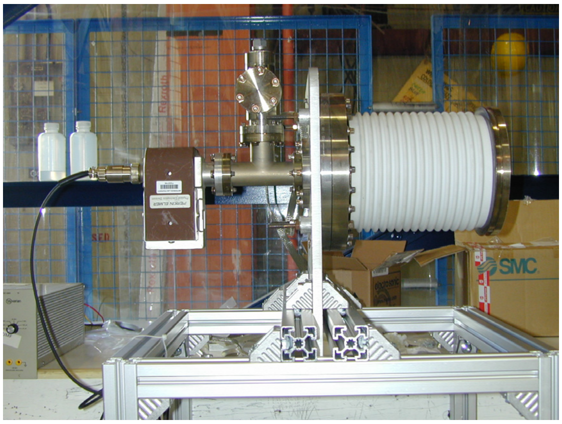

Figure 3: Ex-TJNAF thermionic gun at TRIUMF.

## *Injector Linac*

The injector linac is composed of a capture section, followed a 9-cell SRF cavity. The injector terminates in an electron beam analysis section. A short, 2-magnet dog-leg is envisioned immediately downstream of the injector linac for compatibility with later ERL or RLA options.

Injecting a 100 keV beam ($\beta$=0.55) directly into a $\beta$=1 RF structure results in inefficient acceleration because of the mis-match in transit time. There are also possible deleterious transverse effects associated with such low energy injection into a high-gradient SRF structure. So the capture section performs two functions: additional bunching and modest acceleration. The capture section could be implemented as either a graded-beta structure; or independently phased cells. Both NC and SC structures are possible; cost favours the latter. A detailed analysis will be performed leading to a final choice between these options. The capture section is driven by Inductive Output Tubes (IOTs).

## *Main Linac*

The main linac consists of four 9-cell TTF-style SRF cavities housed in two cryomodules. The cavities operate at 10 MV/m, and each has an active length of 1 m.

We confine the gradient options to ≤ 20 MV/m because this is the limit achievable with buffer chemical polishing (BCP) alone of the niobium surfaces. BCP is readily available at TRIUMF, whereas electro-polishing is not. The e-linac cavities will be constructed in collaboration with a BC-based engineering company, PAVAC, with the intention of introducing to Canada the capability to fabricate and process elliptical Nb cavities. The company presently makes bulk-niobium quarter-wave cavities [7] for the ISAC-II project.

## *RF Power Source*

A variety of manufacturers offer pulsed klystrons rated at up to 5 MW peak and 100–250 kW average power, but the reduced duty factor means they are not applicable to the fission driver. Several manufacturers at present have the capability to build a 120 kW CW klystron, but only *e2V* has recently delivered such a product – six units for the Cornell ERL injector[4]. The *e2V* K3415LS klystrons match the e-linac baseline specification. However, *e2V* has recently redirected its business strategy and ceased production of these klystrons. For the e-linac RF source we rely on the offer from *CPI Microwave Power Products*. Their device will be based on the 1.5 GHz, 110 kW klystron developed for the FEL injector at TJNAF. With minor modification, this will be capable to deliver up to 150 kW of RF power at 1.3 GHz in CW operation.

At present, the highest power-rated commercially available CW input coupler at 1.3 GHz is the 60 kW Cornell-designed coaxial coupler available from *CPI-Eimac*; and this is chosen for the baseline.

## *Funding Prospects*

The ARIEL facility is a major component of the 2010-2015 TRIUMF Five Year Plan (5YP), and its funding will be pursued in that context with the National Research Council Canada. There exists also another funding route for e-linac: the Canada Foundation for Innovation (CFI) which proceeds by bi-annual competitions. The University of Victoria, TRIUMF and other Canadian universities actively propose to obtain CFI funding to leverage the 5YP and submitted the Letter of Intent January 15th 2008.

On June 23rd, CFI designated the e-linac proposal as a National Project Application, not subject to institutional caps. On June 30th, a collaboration of 14 universities submitted the official Notification of Intent, and CFI responded by inviting the submission of the Full Proposal by October 3rd 2008, the final day of this conference. The CFI competition results are to be made public in June 2009, and an announcement of the TRIUMF five year funding is expected in February 2010.

## *Conclusion*

E-linac will be an exemplar CW high-power, high-current linac. Due to the intrinsic power efficiency of SRF technology and the compactness and high accelerating gradient of L-band structures, their adoption provides a cost effective approach to a MW-class fission driver. Many of the major sub-system components have been identified. There are cell, cavity, input coupler, klystron, mechanical tuner, HOM damper and cryostat designs either pre-existing or close to the e-linac requirements; and their adoption will speed project completion and reduce R&D costs.

# PROPOSAL FOR A 15 MeV SUPERCONDUCTING ELECTRON LINAC FOR THE DEINOS PROJECT

J-L. Lemaire, P. Balleyguier, D. Guilhem, J-L Flament, V. Le Flanchec, M.Millerioux, S. Pichon
CEA, DAM, DIF, Bruyères le Châtel, 91297 Arpajon, Cedex, France

The design of a 15 MeV, 2 kA peak current, electron accelerator for the DEINOS project is presented. It is dedicated to a new radiographic facility. The accelerator is based on a DC photo-injector and a RF superconducting linac. Up to twenty electron micro-pulses, 100 ps time duration and 200 nC bunch charge are emitted at 352 MHz repetition rate from a $Cs_2Te$ photocathode and accelerated to 2.5 MeV in the DC diode before injection into a superconducting linac.

A general description of the main accelerator components and the beam dynamics simulations are presented.

## INTRODUCTION

The former DEINOS project which name stands for "**DE**monstrateur d'**IN**jecteur **O**ptimisé pour un accélérateur **S**upraconducteur**"** was consisting of a DC photo-injector coupled to a RF superconducting accelerator (Fig. 1). It is a new versatile scheme based on rather well tested technologies. It has been proposed to produce flash X-ray pulses from very intense electron beams impinging on a high Z material target. A final beam transport allows tight beam focusing on the conversion target [1].

In order to meet the specifications of the radiographic need, 2 µC- 51 MeV- 60 ns, compactness and low cost, the machine could be made of the assembly of a 352 MHz RF linear accelerator and a photo-injector, provided the photo-injector delivers the proper bunches.

Electrons bunches are emitted from a $Cs_2Te$ photocathode driven by a 266 nm wavelength laser and extracted in a DC gun. A pulsed power supply made of a prime power, a Blumlein and coaxial transmission lines drives the diode accelerating voltage.

The voltage applied to the accelerating gap of the diode can reach a value up to 2.5 MV. Time duration of the voltage plateau is set by the Blumlein to be 60 ns.

A short drift section between the photo-injector and the linac allows room for the injection of the photocathode laser beam, a vacuum valve and beam diagnostics.

Optimizations of the photo-injector, the RF accelerator and radiographic parameters led to a design for which the accelerator machine could deliver 20 bunches at 352 MHz. Each bunch of 100 ps time duration would carry 100 nC. This can be done with a UV laser illuminating the photocathode in synchronism with the linac RF in order to recapture the bunches in the RF cavities without any losses.

All the main technical issues that were identified to building the photo-injector (large size diameter and high quantum efficiency $Cs_2Te$ photocathodes, UH Vacuum level - $10^{-10}$ mbar, high voltage insulator barrier, electron gun and diode geometry, stability of the high voltage driver and stability of the laser) could be worked out with this new demonstrator, at lower budgetary cost. A new orientation has been decided for the project in order to build a reduced scale model.

Then a 15 MeV accelerator scheme based on the early architecture consisting of a DC photo-injector and a superconducting RF linac made of only one cavity, has been proposed as a new facility for radiography applications.

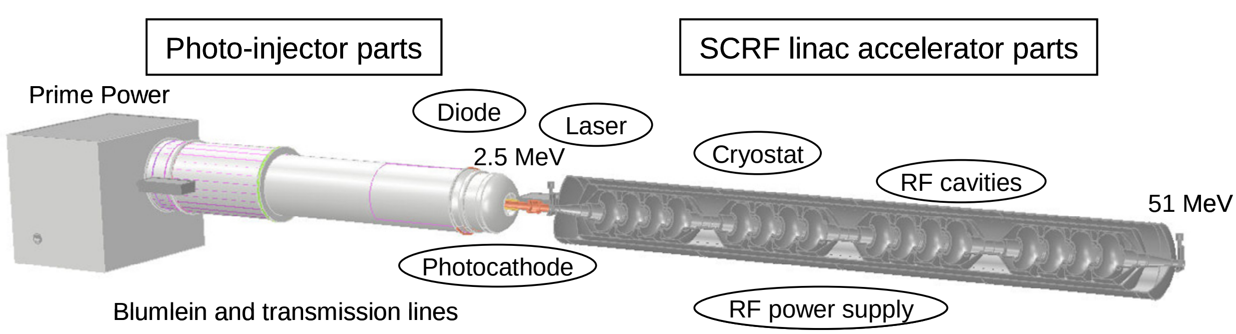

Figure 1: Artist's view of the DEINOS project.

## PHOTO-INJECTOR

The photo-injector consists of a pulsed DC high voltage gun diode under UH Vacuum. High voltage can be tuned from 1.5 to 2.5MV.

The diode is followed by a solenoid lens either to propagate the beam through a short beamline along which various beam diagnostics are installed (emittancemeter, Faraday cup, pulsed current transformer, Cerenkov screen, streak camera), or to focus the beam at a waist before entering the next SCRF accelerator module, a 266 nm laser illuminating a removable $Cs_2Te$ 40 mm diameter emissive size photocathode which is inserted under vacuum through remote handling and a high voltage pulse power generator [2].

### [illegible]

Most of the subsystems needed for the high voltage generator are spare pieces from the PIVAIR prototype injector of AIRIX induction radiographic machine. Some have been rebuilt, some have been modified or replaced to deal with the present need. The prime power consists of a 1 µF capacitor bank, which is switched through the primary of an iron-core high voltage pulse transformer (Stangenese manufacturing).

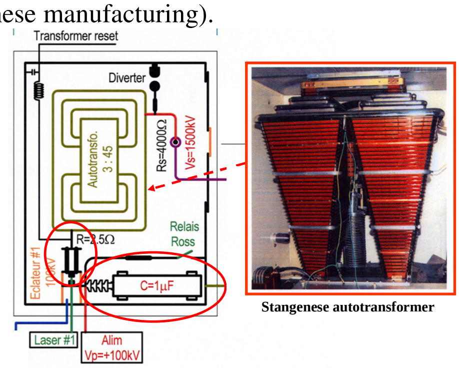

Figure 2: Prime power.

The secondary of the transformer is electrically tied to the Blumlein which is charged to a maximum voltage of 1.5 MV. The outer leg of the Blumlein is switched out with a laser triggered SF6 gas switch. Coaxial transmission lines also called output lines finally transform the output voltage to the required maximum 2.5 MV voltage on diode and parallel resistor load. Figure 2 shows parts of the prime power refurbishing, which is now completed.

### [illegible]

The interface separating the oil medium insulator inside the coaxial transmission line from the vacuum of the diode part is a major component of the photo-injector. The insulator design is a challenge as far as fabrication is concerned. Compatibility between the high voltage hold off, the mechanical size and stresses and the attainable vacuum as low as $10^{-10}$ mbar during static operation (beam off) requires specific materials. Optimized geometries and shapes must be manufacturable from candidate like ceramic or borosilicate materials. Feasibility comparisons have been carried out. We ended up to a vacuum insulator stack made of alumina rings and intermediate metallic washers as shown in Fig. 3.

Electrode geometries have been optimized to achieve lowest and constant E peak field values on surface of electrodes. Voltage hold off must be safe up to the maximum accelerating voltage of 2.5 MV applied for a time duration of 100 ns.

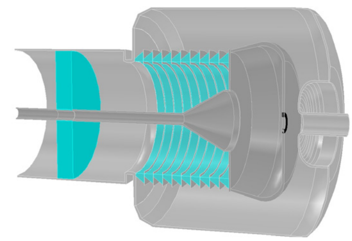

Figure 3: Reversed axial ceramic stack HV insulator.

### [illegible]

The driving laser must provide a maximum of bursts of 20 topped hat pulses of 100 ps FWHM separated by 2.84 ns. The laser system is shown in Fig. 4. It consists of a 500 mW, 1064 nm wavelength Nd:$YVO_4$ SESAM oscillator.

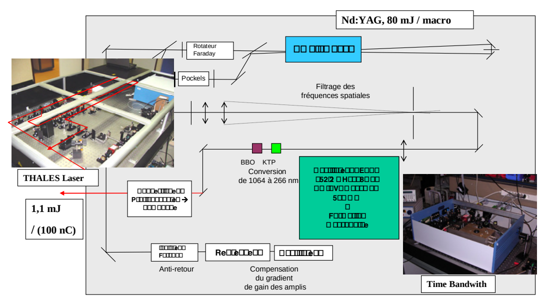

Figure 4: Laser chain.

It is actually able to deliver 2 separated in time trains. Each train of 60 ns time duration carries 20 bursts. After pulsed shaping, amplification and frequency quadrupling, the energy to be delivered to the photocathode is 25 µJ per burst at 266 nm. Rms jitter value is 2 ps and achieved value of beam homogeneity is 4% rms.

### [illegible]

Robust photoelectric cathodes are being investigated and fabricated in a separated photocathode bench. Transfer from this preparation chamber and the photo-injector is done thanks to a transportation system that moves cathodes one by one in a unit chamber tight to the diode vessel. A set of 3 cathodes is stored. The cathodes are kept under UHV wait then to be loaded in the DC gun using the remote handling device. Photocathode fabrication has started with 30 mm diameter molybdenum cathode. Tellure is first evaporated for 8 nm thickness followed by cesium deposition. Deposition is stopped when the measured photocurrent reaches a maximum and stays constant (Cs thickness is then about 50 nm). So far Q.E is not yet reproducible enough for our application mainly due to CO pollution. It varies from 1 % to 16 %

(Fig. 5). A parametric study is been carried on over several parameters such as cathode temperature value during deposition process, speed of evaporation, thickness of cesium deposit on tellure, surface emission homogeneity. Robustness of $Cs_2Te$ photocathodes against specific gas pollution will be tested next before going to nominal larger size diameter cathodes.

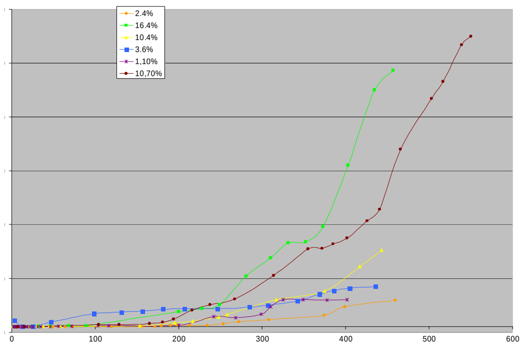

Figure 5: Q.E. vs Cs thickness deposit (x100A°).

## SC-LINEAR ACCELERATOR

Superconducting accelerator structures give more compact machine for equivalent energy stored in the cavity than room temperature ones. To compensate for the loading in order to accelerate properly the high charged bunches, the linear accelerator has to be superconducting. Therefore mean beam energy from bunch to bunch decreases. Beam dynamics must deal with the resulting energy spread of the beam to be delivered on target.

### [illegible]

The SC-Linac is a close replica of a 4 cells superconducting LEP2 module. We have presently chosen the niobium deposit on to copper manufacturing. The accelerating field of 7.5 MV/m fits the design. $Q_0$: 3.2 $10^9$. Total stored energy: 160 J and beam loading requirement is 1.2 J/ bunch@100 nC. Effort is being done to low down the static cryogenic losses.

### [illegible]

Solid-state RF power supply can be used and requires 20 kW of RF power. A prototype unit of 2.5 kW was constructed successfully.

### [illegible]

Beam dynamics of the whole accelerator machine has been carried out thanks to the simulation chain described in [3]. The linac RF cavity phase is tuned to end up with the lowest rms beam energy spread. Two different machine configurations have been studied: 10 bursts of 100nC/bunch and 5 bursts of 200nC/bunch which accelerated beam simulation is shown in Fig. 6.

The two configurations give very close results (difference of only 5% in the spot size value). The 5 bursts train configuration @200nC per bunch allows a short radiographic imaging (13 ns) at same spot size for a 2 kA, 15 MeV beam delivering an integrated X-ray dose of 1.7 Rad. The radiographic facility is very compact.

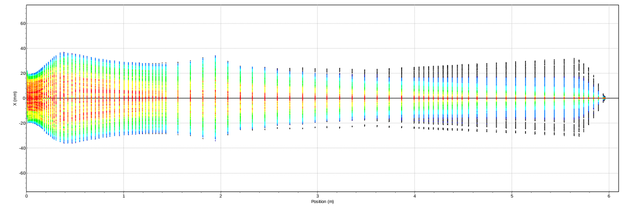

Figure 6: Beam envelope 5 bunches @200 nC per bunch.

## FINAL FOCUSING

One drawback with the large energy spread of the accelerated beam comes from the spot size enlargement due to the chromaticity of the final focusing lens. Three parameters drive this effect:

- space charge of the high charge in every bunch,
- beam loading in the RF-cavity reducing continuously the net accelerating field,
- large longitudinal beam extension over the RF phase, generating RF energy spread.

In order to limit these effects, we have studied a conical solenoid geometry (figure 7).

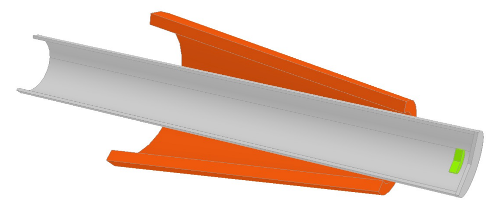

Figure 7: Conical solenoid geometry.

Beam dynamics simulations have showed that the beam spot size on the target can be decreased by about 15 to 20% for large energy spread.

## CONCLUSION

We focused on the description of the accelerator components, achieved, under construction or to be fabricated in order to be used in view of a reduce scale demonstrator for a radiography applications. This new machine is made of a photo-injector, a superconducting RF accelerator and a final focusing. The whole machine simulations have been carried out for a 1µC total charge beam. Two beam configurations were considered: small spot sizes, short time exposure imaging as low as 13 ns can be obtained with electron bunches carrying 200 nC of charge.

*Abstract*

The CLIC project based on the innovative Two Beams Acceleration concept is currently under study at CTF3 where the acceleration of a probe beam will be demonstrated. This paper will describe in details the status of the probe beam linac called CALIFES. This linac (170 MeV, 0.9 A) is developed by CEA Saclay, LAL Orsay and CERN. It has been installed in the new experimental area of CTF3 to deliver short bunches (1.8 ps) with a charge of 0.6 nC to the CLIC 12 GHz accelerating structures. We report new results of beam dynamic and RF simulations considering the new CLIC parameters. The construction of CALIFES in the CLEX building is presented. Recent measurements from the laser system are discussed. Details about the HV modulator tests and the power phase shifter fabrication will be described and the start of commissioning will be also reported.

## INTRODUCTION

The electron linac CALIFES [1] (Figure 1) will produce both single bunch and bunch train spaced by 0.66 ns to X-band structures in order to perform various tests such as beam kick due to RF breakdown or dipole mode excitation, in addition with the Two Beam Acceleration demonstration. The main linac parameters have been updated and are shown in Table 1.

Table 1: CALIFES main parameters.

| Parameters | Value |
|---|---|
| Final linac $e^-$ energy | 170 MeV |
| Emittance rms | < 20 $\pi$ mm.mrad |
| Energy spread (single bunch) | < ± 2% |
| Energy / Phase deviation (multi-bunch) | < ± 1% / < 10 ° at 12 GHz |
| Number of bunches Nb | 1 – 32 - 226 |
| Bunch charge (single/ multi bunch) | 0.6 nC / 6 nC/Nb |
| Initial/final bunch length | 5.3 / 1.8 ps, 1.6 / 0.5 mm |
| Transverse beam size | 0.6 mm x 0.6 mm |
| Bunch spacing | 0.66 ns / 1.5 GHz |
| Train length | 21 – 150 ns |
| Train spacing (rep. rate) | 5 Hz |

## BEAM DYNAMIC AND TRANSIENT RF SIMULATIONS

Due to fact that the flat top duration of the compressed RF pulse (1.3 µs) is close to the structure filling time (1.23 µs), the accelerating field profile must be precisely computed (Figure 2). With a drive frequency slightly above the centre frequency (+ 150 MHz), the filling of the structure is nearly complete after a pulse propagation of 5.5 µs. A quasi steady state is reached and no major changes of the beam quality are expected.

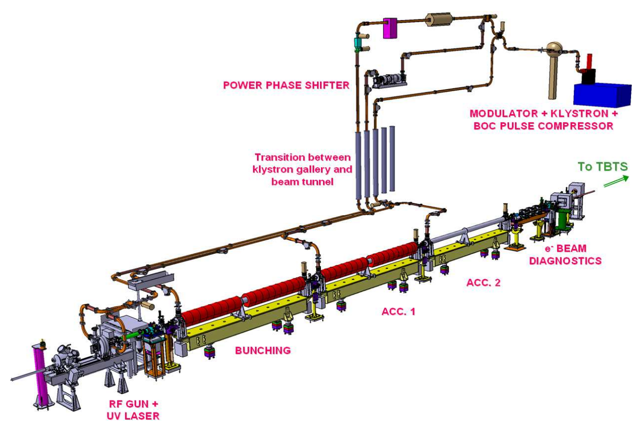

Figure 1: 3D layout of CALIFES.

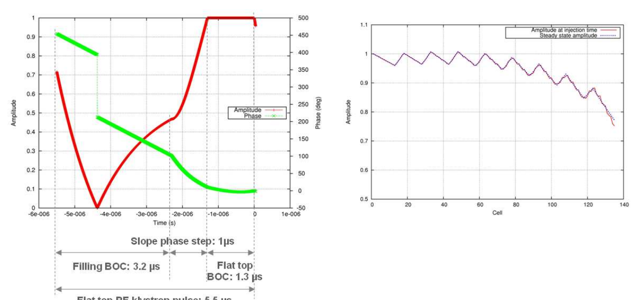

Figure 2: RF pulse shape after compression (left) and amplitude field profile after 5.5 µs (right).

In single bunch operation, simulations showed that the transverse profile at the end of the linac are $x_{rms} \sim y_{rms} \sim 0.6$ mm. The bunch length at the end of the linac is $z_{rms} = 0.176$ mm and the emittance is 13.04 mm.mrad. The final linac energy is 169.6 MeV/c with an energy spread of $\Delta P/P =$ 1.006 %.

In multi bunch operation, we calculated a total energy deviation between the first and last bunch of 5.4 % at 170 MeV and a phase deviation of 15.5° at 12 GHz. The bunch charge will be reduced with the number Nb of bunches, Qb < 6 nC / Nb, such a way that both energy and phase deviations are smaller than respectively 1% and 10° at 12 GHz.

## INSTALLATION IN THE CLEX BUILDING

While the CLEX building was still under construction, a pre-installation of the linac began in Nov. 2006 in building 182 at CERN for two S-band structures re-used from the former LEP injector linac. These elements were transferred in CLEX in June 2007 and the beam stopper, the spectrometer dipole magnet and some supports were quickly installed. All the elements were pre-aligned in less than 1 mm. The BPMs and the dipole steerers are supported by a common girder and alignment support. There were connected to the accelerating sections in Oct. 2007 to allow first alignment procedure and vacuum tests (Figure 3).

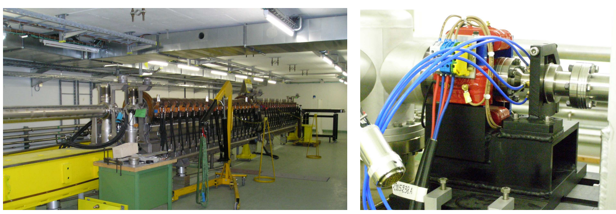

Figure 3: Accelerator sections (left), dipole steerer and BPM (right) installed in November 2007.

After being fine tuned in laboratory, the Video Profile Monitors (VPM) and laser beam line components were progressively installed between Dec. 2007 and May 2008. The high voltage modulator including the oil tank, the PFN rack and the auxiliary power supplies were installed in Dec. 2007 and tested with its dedicated klystron in April 2008. The RF gun was delivered in May 2008 from LAL and a final frequency tuning was completed directly on the linac in June 2008 (Figure 4).

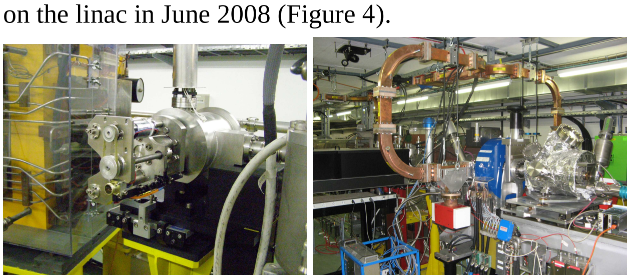

Figure 4: VPM n°2 and RF Gun installed between Dec. 2007 and June 2008.

Some alignment problems for the structures and the beam diagnostic elements were identified, mainly through visual inspection and metrological measurements. The misalignment issues were caused by errors in alignment input data and accidental manipulation of the elements. The final alignment (~ 0.1 mm) has been completed in May 2008.

Finally, the RF network including splitters, windows, couplers and loads were progressively installed during summer 2008 (Figure 5).

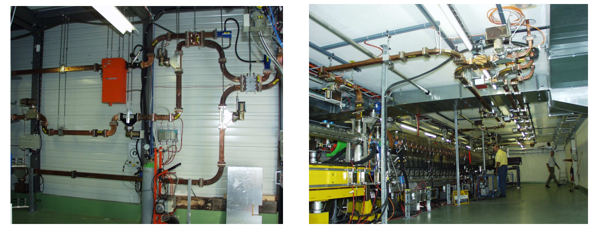

Figure 5: RF network in the klystron gallery (left) and the beam tunnel (right) installed during summer 2008.

## LASER SYSTEM

Since both drive and probe beams must be synchronous, the 10 ps width pulses created in IR at 1.5 GHz for the drive beam are derived after a double amplification. The diode pumped Nd:YLF based amplifiers enhance the laser energy up to 10 µJ per pulses before being gated to create from 0.4 to 150 ns pulse train (pulse pickers). The laser beam is then converted from IR to green by a KTP crystal (10 mm) and from green to UV (261 nm) by a BBO crystal (12 mm) with a specified conversion efficiency of around 35% each.

A transport path of 80 m long under vacuum has been built to deliver the UV pulses to the photocathode. 25% losses are expected in the pulse picker and transport line each. A final UV nominal energy of 370 nJ would give a bunch charge of 0.6 nC considering a quantum efficiency of 1%.

Experiments done in March 2008 showed that the amplified IR pulses energy was limited to 4.3µJ, and that the crystal efficiencies were respectively 13% and 4.3%. This leads to a UV pulse energy of 15 nJ on the photocathode, giving 0.03 nC and 45 mA instead of 900 mA.

The main hypothesis to explain the low conversion efficiency is a presence of a significant DC component around the 10 ps pulses. Remarkably improvements have been achieved very recently, in Sept. 2008 by the CERN team. The UV energy per pulse reached 133 nJ, giving 0.26 nC and 390 mA.

The UV beam transport down to the photocathode has been demonstrated (Figure 6). The oval profile of the beam is mainly due to the high walk-off (85 mrad) combined with the low diameter (130 µm) of the green beam focused on the BBO.

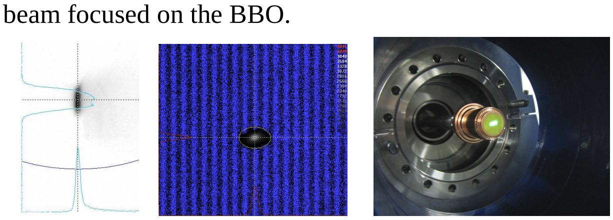

Figure 6: UV beam after the second crystal (left), on the virtual photocathode (middle) and on the photocathode itself (right).

The Pulse Picker has been installed and tested in July 2008. Rise and fall times are fast enough to select the desired number of bunches (Figure 7). The transmission is

81% and no discontinuity has been observed during the flat top.

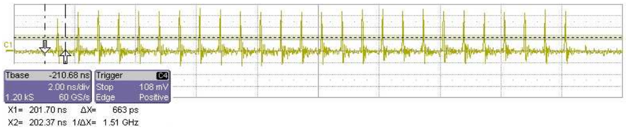

Figure 7: Train of 26 pulses spaced by 0.66 ns gated by the Pulse Picker system.

## BEAM DIAGNOSTICS

The video profile monitors and the five BPM are widely described in [2] and [3]. They have been calibrated and installed in the linac.

For these two diagnostic systems, the control command interface is in progress in order to be able to check the beam profile as well as its position in the control room.

## RF SYSTEM

### *Modulator*

The modulator has been fabricated by PPT (Germany). It delivers quasi-rectangular pulses of 300 kV - 300 A - 7.6 µs at 5Hz to a 45 MW S-band klystron. It has been commissioned first at factory on a dry load at low repetition rate and tested at nominal values on two different klystrons at CERN. A pulse quality problem was discovered during the first high power tests. A ripple of ±4% was measured on the cathode voltage flat top. The problem was identified to be a superposition of a long wave on the flat top and a high frequency noise at the beginning of the voltage pulse. The long wave oscillation has been efficiently removed by a fine tuning of the PFN. The HF noise is believed to be due to fast oscillations in the voltage divider used to measure the pulse in the oil tank. This hypothesis has been confirmed by pulse quality measurements with the RF pulse. The klystron has been driven at saturation up to 42 MW and a remarkably good voltage ripple of ±0.3 % has been deduced from the RF pulse ripple measurement. No signs of HV breakdown were observed.

### *Power Phase Shifter*

The power phase shifter aims at tuning the off crest RF phase of the first section for velocity bunching. This new component is made of three sliding circular waveguides working on the $TE_{01}$ mode. The mode conversion is done by two “wrap around” mode launchers. During its fabrication, the first brazing operation of the two main parts failed. A leakage has been detected and some drips of the brazing alloy appeared. Experiments on samples at different temperatures showed that the chosen alloy was very sensitive to temperature variation during brazing melting period. The converter has been re-used to a scale one prototype to validate a new brazing alloy and check the thermal behaviour of the assembly during the temperature ramping. In particular, the temperature probes inserted in two of the four posts (74 mm height) confirmed that a strong temperature gradient occurs in this region. The cleaning procedure and alignment mechanism have also been improved. The prototype shown in Figure 8 has been successfully brazed in March 2008. The assembly is tight and the join did not produce any drips neither lacks. Two new converters are now under construction and will be available for high power test in March 2009.

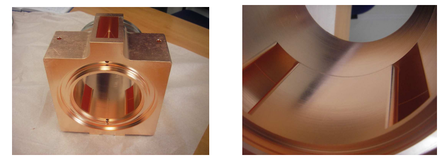

Figure 8: Mode converter prototype for a qualification test of the brazing process.

### *RF Conditioning*

The RF conditioning has started in Sept. 2008. An RF pulsed power of 43 MW – 1µs – 5 Hz has been reached in less than 2 hours. The waveguide pressure stayed below $0.5.10^{-8}$ mbar and only few RF breakdowns were observed on the scope, identified by a fast increase of the reflected power. The filling time of the structures was measured by the time delay between the input and the output incident RF pulse (Figure 9). It is 1.2 µs and in a good agreement with our predictions.

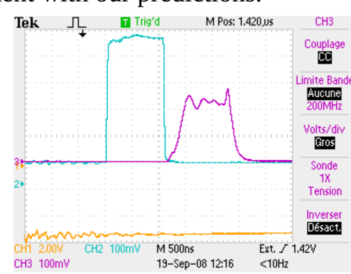

Figure 9: Incident RF pulse at the input (blue) and output (pink) of the 1st travelling wave accelerating structure.

## CONCLUSION

The electron beam line, the laser transport line and most of the RF network are now under vacuum. The RF conditioning will continue during October and the start of operation with beam is planned in Nov. 2008.

## ACKNOWLEGMENTS

We would like to thank our colleagues from CERN for their large contribution on the CALIFES project.

# THE NEW SINGLE BUNCH INJECTOR FOR ELSA

F. Klarner, S. Aderhold, O. Boldt, W. Hillert,
Electron Stretcher Accelerator, Physikal. Institut, Nussallee 12, 53115 Bonn

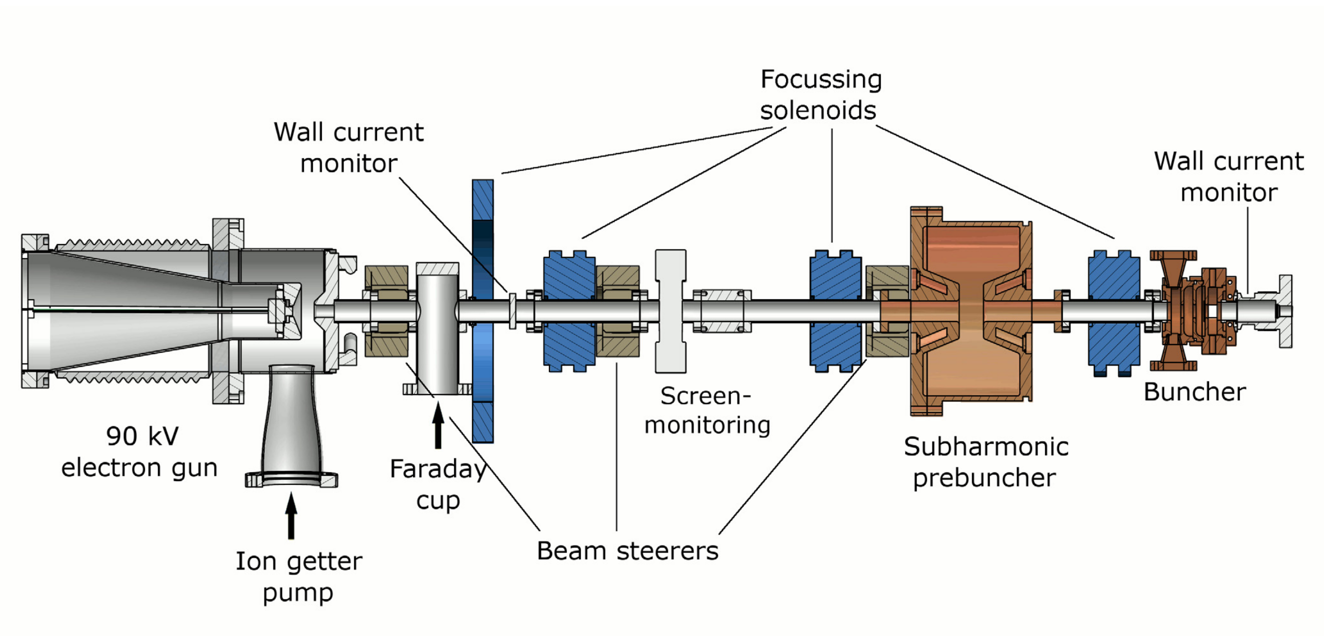

Figure 1: Overview of the new injection system which will be installed at the linear accelerator LINAC I at ELSA.

*Abstract*

Since 1966 a Varian manufactured injector is in use at the ELSA accelerator facility of the University of Bonn for several experiments investigating the subnuclear structure of matter.

The new injector for Linac 1 currently under construction at ELSA is expected to operate in a single bunch mode of 2 A beam current. This mode gives the possibility of deeper background studies in the experimental setup of the CB experiment sponsored by the "Deutsche Forschungsgesellschaft" and to investigate single bunch instabilities within the Helmholtz alliance "Physics at the Terascale". Also, a 2 μs long pulse mode of 500 mA beam current will be available for normal thermionic electron service. The injector delivering a single bunch was designed and optimised with EGUN and numerical simulations based on the paraxial equations. The compression of the pulses created by a pulsed thermionic 90 kV gun is achieved by a 500 MHz prebuncher as well as a β-matching travelling wave buncher running at the linac frequency.

## 90 KV ELECTRON GUN

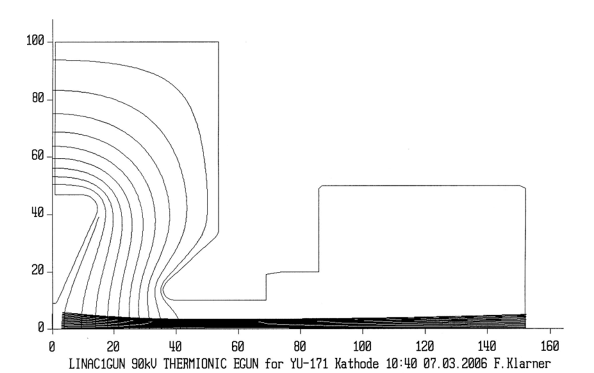

Figure 2: Gun geometry $r$ vs. $z$ in mm with equipotential lines and space charge limited electron rays calculated with EGUN for an anode voltage of 90 kV.

The 90 kV gun is based on a design used in the SBTF test facility at DESY. The design of the cathode conus was adjusted with the computer code EGUN to fulfill the requirements of 2 A single pulse and 500 mA long pulse operation. With a 34 mm wide anode cathode gap this gun has a perveance of 0.16 $\mu A/V^{3/2}$ and delivers a 4.3 A space charge limited current at 90 kV. The EGUN calculated beam propagation is shown in figure 2. The cathode is carried by a conical metallic tube that runs through the 250 mm long ceramic and is flanged at the high voltage end of the isolator. The gun needs a grid electrode near the cathode in order to be pulsed. The EMAC Y-171 cathode-grid assembly, which emits from a circular area of 1 cm² equivalent to 5.64 mm in radius, is used here. The normalized emittance for a 2 A pulse at the gun exit is $\varepsilon = 22.8\ \pi$ mm mrad. Pulsing the cathode will be done by a fast gun pulser housed inside the conical tube right behind the cathode. In single pulse mode the gun, together with this pulser, is expected to deliver FWHM ≤ 2 ns pulses with a peak current of 2 A.

## PREBUNCHING

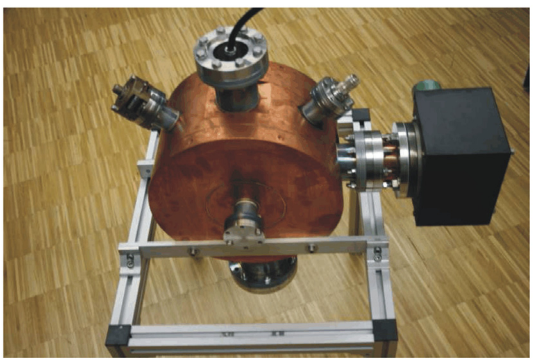

Figure 3: 500 MHz prebuncher.

The 40 mm wide gap of the 500 MHz nosecone prebuncher is centred at $z$ = 112 cm. In order to weaken the requirements for the gun this frequency has to be as low as possible, but nevertheless has to match with the time structure of the bunch train in the stretcher ring ELSA. Therefore in our case the prebuncher has to work at 500 MHz, which implies that the gun pulse for the single bunch has a length in the order of 2 ns. The chosen prebuncher has an untuned resonance frequency of $\nu_0$ = (499.819 ± 0.001) MHz, an unloaded quality factor of $Q_0$ = 15220 ± 196 and a shunt impedance of

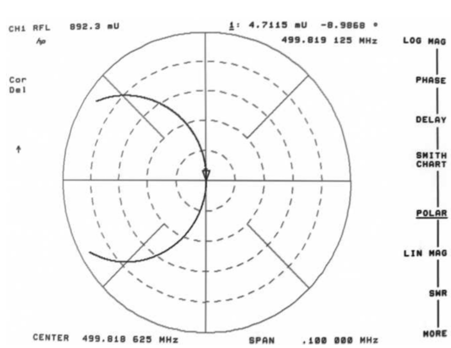

Figure 4: Polar plot of the complex reflection factor close to the first resonace of the prebuncher.

$R_s$ = (1.63 ± 0.05) MΩ. With an injected RF power of 400 W a gap voltage of 36 kV is excited. For a critical RF coupling a new coupling loop has been designed. In figure 4 the measurement of the new coupling loop into the cavity at the first resonance is shown [1].

## TRAVELLING WAVE BUNCHER

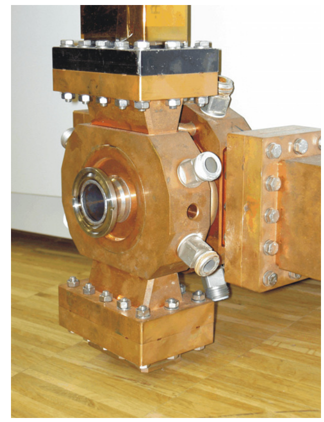

Figure 5: The travelling wave buncher with a view of the exit of the structure. On top a waterload is flanged. On the right hand side is the input of the accelerating RF.

The first cell of the travelling wave buncher is centred 34 cm behind the center of the prebuncher. The 4 cell, 6.7 MV/m structure further compresses the bunches and matches the beta to $\beta = 0.891$ at the exit of the structure. The design of the buncher implements a phase velocity of $v_p$ = 0.0575 c and a group velocity of $v_g$ = 0.010 c. The structure is driven by 2 MW RF power coupled from the linac RF. The passband of the structure is shown in figure 6. After a drift space of 8 cm beyond the buncher the beam is injected into the linac section.

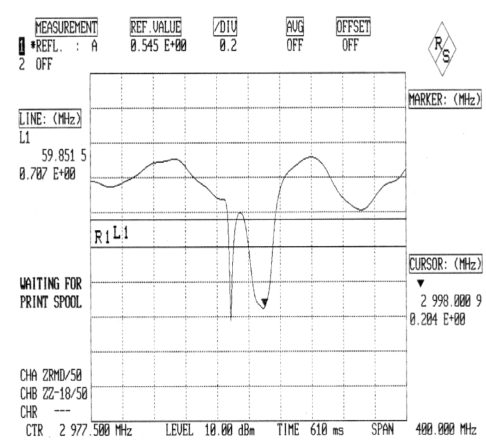

Figure 6: Plot of the reflected power against the RF frequency. The plot shows the passband of the structure.

## TRANSVERSE BEAM DYNAMICS

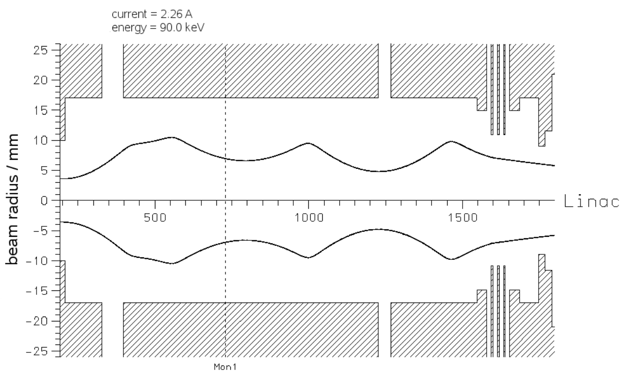

Figure 7: Simulation of a 2 A beam propagating through the beam guiding elements based on the paraxial equations.

The beam pipe has an inner diameter of 34 mm along the injector. Just in front of the entrance of the linear accelerator the aperture is reduced to 21 mm in order to minimize RF leakage out of the linac. Transverse focussing of the beam is achieved by four solenoids. The position and the strength of the solenoids were determined by numerical calculations based on the paraxial equations. The resulting beam propagation is shown in figure 7. Three solenoids with a diameter of 37 mm and a length of 75 mm produce a longitudinal field of 110 Gauss/A.
Due to spacing problems the first solenoid has a diameter of 150 mm. This causes a produced field of 1.1 Gauss/A. Additionally the field is set to zero at the gun cathode by means of a bucking coil.

## MONITORING

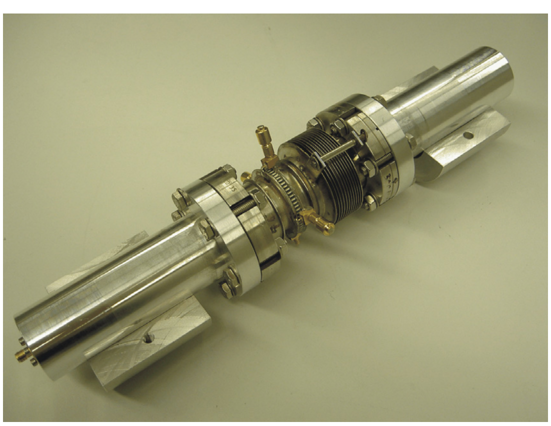

Figure 8: Wall current monitor with a bandwidth of 3 GHz, mounted on a special measurement setup to determine the bandwidth.

The driftspace in front of the prebuncher is used for beam instrumentation to measure the position, the current and the emittance as well as the beam profile. A wall current monitor with higher bandwidth up to 3 GHz is used in order to measure the charge distribution of a single bunch [2]. In figure 8 the wall current monitor is shown on a special measurement setup to determine the bandwidth of the monitor. The measurement has shown that the monitor is useable for signals up to 3 GHz.

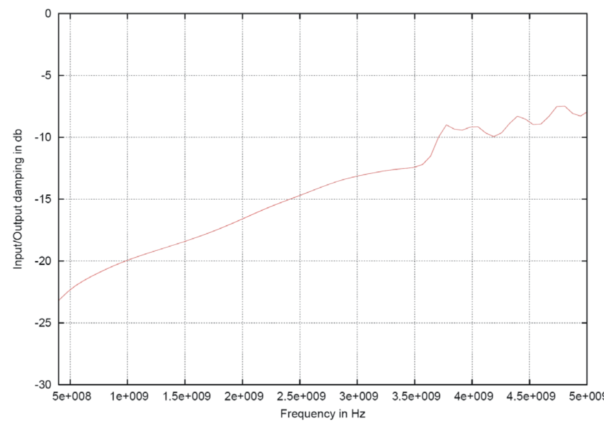

Figure 9: Measurements of the bandwidth of the wall current monitor. The results give an estimate of the bandwidth of the monitor. It appears, that the monitor will be useable for a range up to 3 – 3.5 GHz.

## CONCLUSION

In order to achieve the possibility of operating ELSA in a single bunch mode a new injector is designed and still under construction. The design of the injector for Linac 1 at ELSA is based on a conservative scheme using a thermionic high intensity pulsed gun, one subharmonic bunchercavity and a travelling wave buncher. The bunching is expected to compress the bunches to less than 0.1 ns before entering the linear accelerator. To specify the real bunch length deeper studies with a computer code like PARMELA are necessary. Unwanted transverse dynamics are compensated by solenoid fields and correctors. The bunch leaves the injector with an energy of about 615 keV.

# IMPROVING THE SUPERCONDUCTING CAVITIES AND OPERATIONAL FINDINGS AT THE S-DALINAC*

R. Eichhorn#, A. Araz, M. Brunken, J. Conrad, H.D. Graef, M. Hertling, F. Hug, C. Klose, C. Liebig, M. Konrad, T. Kuerzeder, M. Platz, A. Richter, S. Sievers and T. Weilbach
S-DALINAC, Institut fuer Kernphysik, TU-Darmstadt, D-64293 Darmstadt, Germany

*Abstract*

After 15 years operating the S-DALINAC the design quality factor for the superconducting cavities has still not been reached. Currently, the cavities are heat treated at 850 C in an UHV furnace installed in Darmstadt three years ago. We will report about the furnace, the heat treatment procedure and the results of subsequent surface resistance measurements.

Prior to the heat treatment the field flatness of some of the 20 cell elliptical cavities has been measured, leading to unexpected operational findings to be reported: operating and frequency-tuning the cavity for several years led to heavy distortions of the field flatness. This might be an indication that the frequency tuning of the cavity done by compressing the cavity longitudinally, does not act uniformly on each cell even though the cavity is only supported at the end cells. The paper will close with a status report on machine operation and modifications undertaken during the last two years.

## INTRODUCTION

The superconducting Darmstadt electron linear accelerator S–DALINAC was put into operation in 1987. It consists of ten superconducting 20 cell niobium cavities, operated at 2 K at a frequency of 2.9975 GHz. With a design accelerating gradient of 5 MV/m and a design quality factor of $3 \cdot 10^9$ in cw operation, the final energy of the machine is 130 MeV which is reached when the beam is recirculated twice [1]. The layout of the S–DALINAC is shown in Fig. 1.

The first set of cavities was built in the 80's at Interatom using low RRR material, so the observed performance regarding the gradient and the quality factor was rather poor [2]. Accordingly, a second set of cavities was ordered in the 90's made from RRR 300 material.

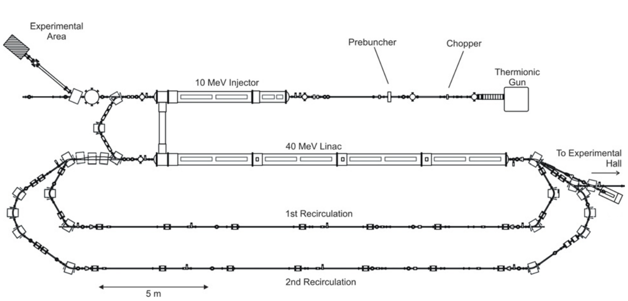

Figure 1: Floor plan of the S-DALINAC.

These cavities, welded at Dornier, are used since then. All of them reach the design gradient, some exceeding it by more than 50% [3]. The accelerator performance however did not benefit from this improvement: Due to the limited refrigerator power of some 100 Watt and the rather low Q of the cavities (typically below $1 \cdot 10^9$) the cavities have to be operated below their maximum gradients. Many measures have been taken in the past [4], all of them helped improving the Q but none was able to solve the problem completely.

## CAVITY FIRING

The high temperature vacuum firing has proven to be an inherent part of the surface preparation of superconducting cavities. This procedure is applied to stress anneal the niobium and to remove hydrogen from the material inoculating cavities against the "Q disease" during their operation. The S-DALINAC niobium cavities were heat treated at 750 C after their commissioning as well. However recent studies have shown that the niobium is still contaminated by hydrogen which can be explained by doubting the temperature measurement during the first firing.

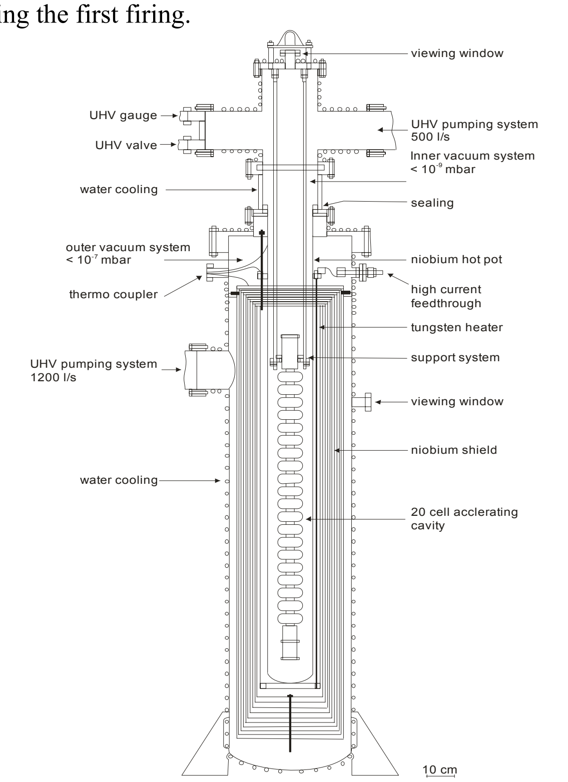

Figure 2: Side view of the UHV furnace in Darmstadt.

*Work supported by the DFG through SFB 634
#eichhorn@ikp.tu-darmstadt.de

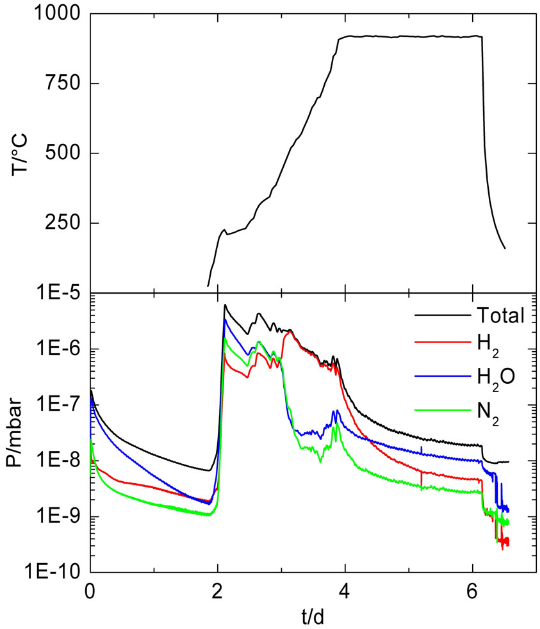

Figure 3: Temperature and partial pressure of the residual gas inside the furnace during the firing procedure. At 300 C hydrogen becomes dominant indicating a huge reservoir.

The high temperature vacuum furnace shown in Fig. 2 allows temperatures of up to 1800 C. It was put into operation at Darmstadt in 2005 after relocation from Wuppertal. Its construction and basic parameters are described in [5]. Up to now a total of 7 cavities were heat treated.

Once the cavity was mounted inside the furnace, the temperature was increased steadily up to 800 C, keeping the vacuum pressure below $1{\cdot}10^{-5}$ mbar. The residual gas in the furnace was analyzed using a mass spectrometer; the temperature was measured with a pyrometer. The heat treatment procedure lasted typically 8 to 10 days. A typical temperature and gas profile is shown in Fig. 3.

By taking the throughput of the ion getter pump, the integrated partial pressure and the amount of niobium, a hydrogen contamination of the cavity of some 30 ppm could be estimated - values above 2 ppm are thought to cause Q-disease [6]. After the heat treatment, the cavities were taken out of the furnace and mounted directly inside the accelerator cryostat without any intermediate preparation step. After cooling down to 2 K, the quality factor improved from $7{\cdot}10^8$ to $1.5{\cdot}10^9$ by this treatment being still below design. Unfolding the contributions to the quality factor leads to a residual resistance of 60 nΩ.

For cavities contaminated with hydrogen a high residual resistance would be expected, but for cavities fired at 800 C lower values are anticipated.

Out of the data two objectives can be deduced: First, the contribution coming from the frozen magnetic flux is in the order of the BCS value. This has to be improved by adding additional shielding against the earth magnetic field. Second, the residual resistance is even higher and exceeds values achieved elsewhere by far. This indicates that the process of preparing and/or mounting of the cavities still need to be improved, for example by applying a hydrofluoric acid polishing after the heat treatment. Both will be addressed in the future.

## FIELD FLATNESS CHANGES

When the cavities had been installed more than 10 years ago, all cavities were tuned to a flat field profile to ensure optimum performance. During operation, continual measurements of the pass-band frequencies indicated a change in field profile which only could be quantified by dismounting the cavities. So before the cavities were heat treated as described above, a field profile was measured with a bead-pull measurement set- up. The field distribution of six cavities measured so far is shown in Fig. 4.

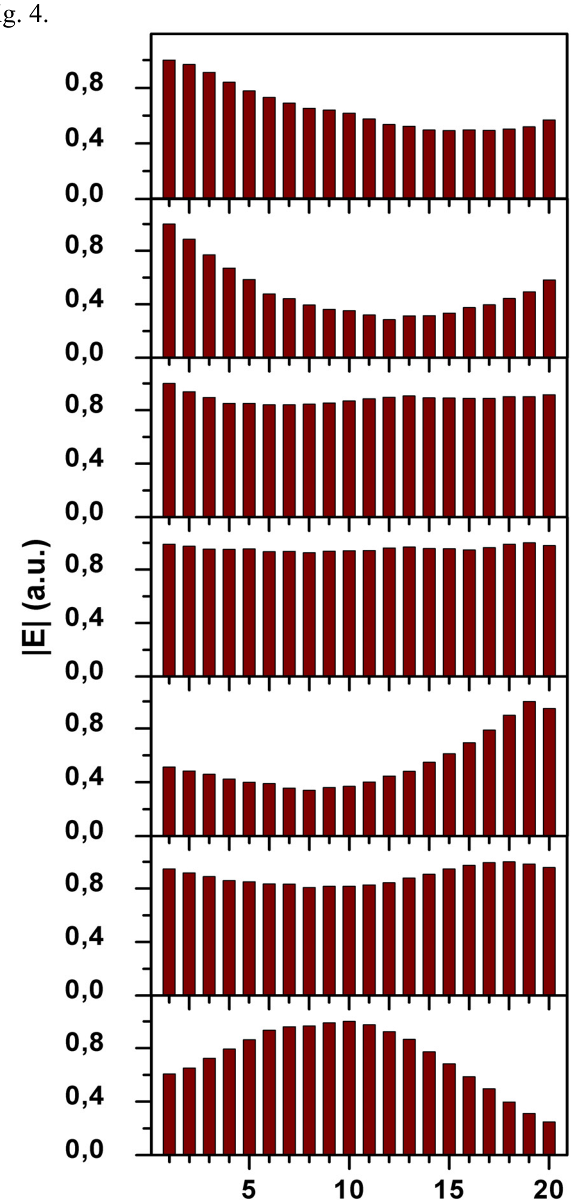

Figure 4: Measured field flatness of six cavities being in operation for some 10 years. Some cavities display a heavily distorted field profile that could be restored during the tuning procedure.

Obviously, the field flatness of some cavities is heavily distorted after several years of operation, while other cavities are still more or less field flat.

During operation the cavity frequency is adjusted by a tuner changing the overall length of the cavity. The tuner acts on the cut-off tubes of the cavity only, while the elliptical cells hang freely in between. This should lead to a uniform distribution of the forces along the cavity and thus to an undisturbed field profile, which seems to be true for some cavities but wrong for the others (with distorted field profile). The measurement shown in Fig. 4 suggests that the tuning force does not act uniformly over the cavity length for all cavities, which might be caused by two reasons: Some friction between the cavity support frame and the cavity reducing the forces from cell to cell might be one explanation. The other, which seems to be more attractive, is that the elliptical cells have different mechanical spring constants making the cavity itself mechanically inhomogeneous.

Investigations on this findings will go on, however it could be stated that tuning the cavity by changing the total length – commonly used in other places too – in our case leads to unwanted distortions in the field profile differing from cavity to cavity.

However, all cavities could be retuned to a flat field profile by squeezing the individual elliptical cells.

## COLD LEAK PROBLEMS

During last year's operation, several cold leaks developed, degrading the cavity performance and disrupting the accelerator operation. After several time consuming investigations the reason for these cold leaks could be determined: The HELICOFLEX® gasket used to seal the cavity flange against the coupler (see Fig. 5) became untight, especially after an insitu-baking procedure followed by an immediate cool-down to 2 K. After checking all parameters to lie within specifications the reason for this was localized: the HELICOFLEX® gasket made out of aluminum was hard enough to cave the flat cavity flange (made out of RRR30 Niobium) after many years of operation, some 50 thermal cycles and approximately 10 replacements of the gaskets. As the tightness of this gasket is ensured by pressing it to a nominal thickness which is ensured by a nose-piece in the coupler flange, the score mark in the cavity flange reduces the compression of the gasket and thus explains the failure in tight sealing.

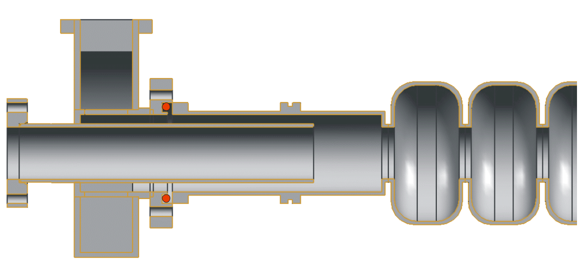

Figure 5: Cross section of the coupler to cavity transition. The HELICOFLEX® gasket used is marked red.

Currently, all HELICOFLEX® gaskets are replaced by gaskets with overmeasure (by adding the depths of the score to the gasket thickness), not solving the principle problem but ensuring tightness without machining the ultraclean surface of the cavity or the coupler.

Figure 6: Picture of the cavity flange displaying an obvious score mark.

*Abstract*

The current upgrade for the injector mainly involves the superconducting rf part. In order to increase the maximum current from 60 µA to 150 or 250 µA the power coupler design had to be modified, resulting in major changes in the whole cryo-module.

Second, an additional polarized electron source (SPIN) has been set-up at an offline test area. There, the polarized electrons are produced by photoemission at a strained GaAs cathode on a 100 kV platform. The test beamline includes a Wien filter for spin manipulation, a Mott polarimeter for polarization measurement and additional diagnostic elements. We will give an overview to the project, report on the status and present first measurement results including the proof of polarisation.

## INTRODUCTION

The superconducting Darmstadt electron linear accelerator S-DALINAC [1] is a recirculating linac, using ten superconducting niobium cavities at a frequency of 2.9975 GHz. It was first put into operation in 1987. Running at a temperature of 2 K the main acceleration is done by ten 20 cell elliptical cavities with a design accelerating gradient of 5 MV/m. The first pair of those cavities is used in the injector section of the machine. Behind this section it is possible to use the beam for nuclear physics experiments with a maximum energy of 10 MeV or the beam can be bent into the main linac. With its two recirculations and an energy gain of 40 MeV per pass the maximum design energy of the S-DALINAC is 130 MeV which can be used for several experiments in the adjacent experimental hall. The layout of the machine is shown in Fig. 1.

#eichhorn@ikp.tu-darmstadt.de

## POWER UPGRADE

The S-DALINAC uses cryostat-modules with two cavities per module. Each cavity has an rf input coupler, which is capable of a maximum power of 500 W. Assuming a 5 MV/m gradient the beam current is limited to 60 µA for the injector and 20 µA for the main linac, which might be higher for lower beam energies.

For future astrophysical experiments behind the injector, beam currents of 150 µA and above as well as energies of up to 14 MeV are demanded. Therefore, modifications in the injector linac had to be made.

### *New Power Couplers*

The first step was to design and build new power couplers providing the necessary rf power of up to 2 kW to the cavities. While the existing couplers are coax-to-coax couplers [2] and limited to 500 W, the newly designed couplers are of waveguide-to-coax type [3]. One essential design feature of the old coupler was kept, namely the minimized transversal fields being a major concern in the low energy part of the accelerator. This was accomplished by using two diaphragms, reducing the excitations of the transverse electromagnetic fields in the beam pipe below -40 dB.

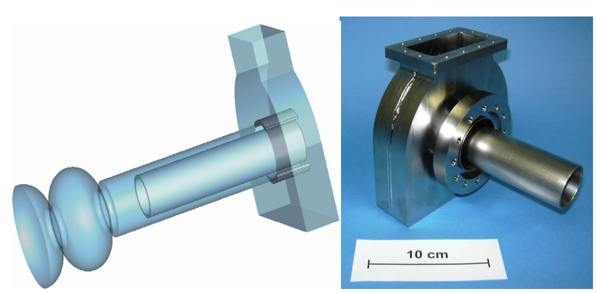

Figure 2: The design and the finally fabricated waveguide-to-coax coupler for the injector upgrade.

Figure 2 gives on the left side an impression, how the coupling from waveguide to coax and to the cavity along its cut-off tube is realized. The external quality factor of $5{\cdot}10^6$ ensures acceleration of beam currents ranging from 150 to 250 µA.

The coupler was made out of bulk niobium. The fabrication including the EB-welding was done by the FZ Juelich. Currently, the chemical cleaning of the couplers is underway.

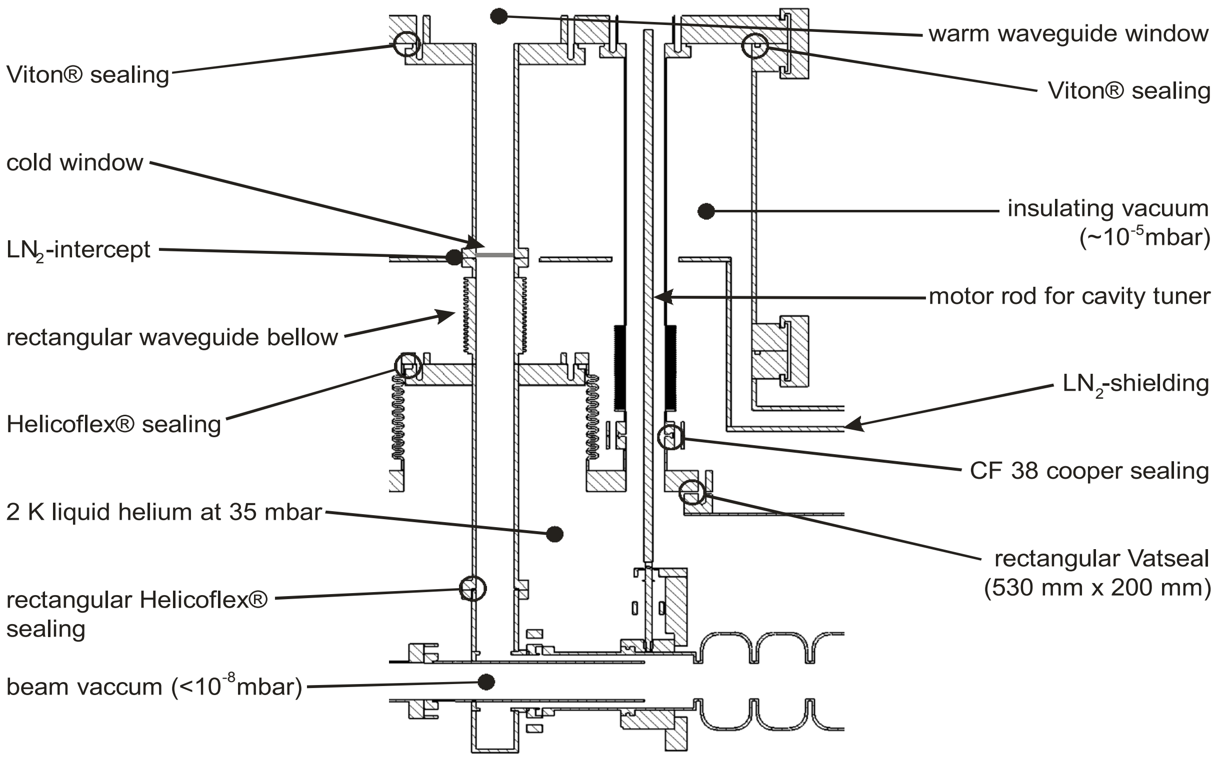

Figure 3: 2-D cut of the cross-section of the waveguide transition line surrounding from the helium vessel through the whole module. The different pressure stages and the position of sealings and other elements are shown.

## *Design of the New Cryostat*

In the current design, the rf transmission line to the power couplers has a diameter of only 21 mm. For the new couplers, a WR-284 waveguide (cross area 72×34 mm$^2$) has been chosen. Accordingly the existing cryostat-module had to be modified:

The cavities together with their tuners and the couplers are located inside the helium vessel. The vacuum inside the beam-pipe is below $10^{-8}$ mbar, while the pressure in the liquid helium is at 35 mbar (2 K operation). The thermal shield between the helium vessel and the outer vessel is cooled by liquid nitrogen. Together with the insulation vacuum of $10^{-5}$ mbar and some 20 layers of super-insulation a minimum heat transfer is ensured (being 4 W per cryo-module currently).

The actual design consists of a complex waveguide which will be flanged to the coupler. Welded to this waveguide is a circular flange sealing the helium vessel. The counter-flange provides a bellow to compensate small vertical and angular displacements while oversized holes are planned to have additional freedom in the horizontal direction. To avoid vacuum forces on the coupler this bellow can be fixed by threaded rods.

To seal between insulating vacuum and atmospheric pressure Viton® gaskets are intended. To keep the static heat losses per transition line below 0.4 W it has a thermal intercept to the nitrogen-shield behind the waveguide bellow. Furthermore, a cold waveguide window could be installed at this position to reduce the heat radiation from the ambient window to be installed outside the cryo-module.

Figure 3 shows the cross-section of the module allowing an insight to the positions of the gaskets, bellows and the different pressure vessels. The big apperture of the helium vessel has to be sealed by a customized VATSEAL® gasket. An additional tube holds a rod for coarse tuning of the cavity. Its motor is placed outside the module at ambient. In addition, the cabling of the magneto-restrictive (fine-) tuner and other electrics like temperature sensors or heaters are located inside that tube.

# POLARIZED ELECTRON SOURCE

To complement the present experimental program with polarized electron and photon scattering experiments a new source for polarized electrons, the S–DALINAC Polarized INjector SPIN, is developed [5]. Therewith, experiments are planned studying parity violation in nuclei or measuring the fifth structure function in electron scattering. With these experiments results obtained at other accelerator laboratories can be extended to lower momentum transfer values.

## *Test-Stand Set-up*

The new source consists of a cathode on a HV platform, a chopper and prebuncher system, a Wien filter and a Mott polarimeter for spin manipulation and polarization measurement. To set-up and test the electron source independent from the accelerator operation of the

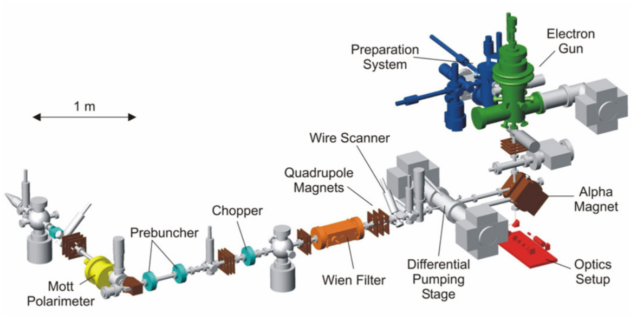

Figure 4: Schematic drawing of the SPIN test-stand. A laser beam focused onto the cathode produces a polarized electron beam by photoemission. After pre-acceleration to 100 keV it is injected into the horizontal beam-line where its properties can be studied. The chopper and prebuncher system is currently installed.

source independent from the accelerator operation of the S–DALINAC, an offline-test-stand has been built.

Figure 4 gives an overview about SPIN. The electrons are produced inside an ultra-high vacuum chamber at a GaAs cathode. For the first tests, bulk GaAs cathodes were used, whereas strained-superlattice cathodes will be used for regular operation. A laser beam is focused from an optics setup below the electron source onto the photocathode and produces the electrons by photoemission. These electrons are accelerated by the platform voltage to 100 keV and bent by an alpha magnet into the horizontal beam-line, where the beam properties can be measured. The whole design is based on the MAMI polarized source [6], but is compared to it more compact due to the limited space in the accelerator hall.

### *Recent Results*

After extracting the first beam, the transverse properties were measured using a wire scanner. The beam profile was determined to have approximately a gaussian shape with an x/y beam radius of .44/.41 mm, respectively. The normalized transversal emittance has been determined to $\varepsilon_{n,x} = (0.146 \pm 0.037)$ mm mrad and $\varepsilon_{n,y} = (0.197 \pm 0.089)$ mm mrad respectively being comparable with the MAMI source. The beam current reached so far was 3 μA.

The polarization of the electron beam was measured by Mott scattering where one uses the effect that the Coulomb potential has a term which is proportional to the scalar product of the angular momentum and the spin of the incident electron (spin-orbit interaction). This results in a right-left asymmetry of the angular distribution of the scattered electrons which is proportional to the polarization P of the electron beam. The Mott polarimeter used houses four silicon surface barrier detectors which are oriented in two perpendicular scattering planes to measure both transverse polarization components simultaneously.

As targets, self-supporting gold foils of the thickness in the range from 42.5 nm to 500 nm are used. From the left/right asymmetry measured, the degree of polarization was determined to be (33.4±1.6)% which agrees very well with common values for bulk GaAs cathodes. For the superlattice photocathode to be used during accelerator operation, the polarization was determined to be (72.1 ± 2.1)%.

## SUMMARY AND OUTLOOK

Currently, the design of the cryo-module for the power upgrade is finalized. The chemical treatments for the waveguide couplers are underway and three new cavities have been ordered to complete the module (one cavity spare). Including tests of all components and completion of construction, the timetable aims for a first test in spring 2009.

At that time, the installation of the polarized electron source and its subsystems at the S–DALINAC accelerator vault is planned. Currently, the test stand is completed by adding the chopper and prebuncher system and improvements on the laser system to increase the beam current are pursued.

First results of both upgrade projects, the polarized source and the power upgrade of the injector are expected in late summer 2009.

# RECENT CHANGES TO THE $e^+/e^-$ INJECTOR (LINAC II) AT DESY

M. Hüning#, M. Schmitz, DESY, Hamburg, Germany

*Abstract*

The Linac II at DESY consists of a 6A/150kV DC electron gun, a 400 MeV primary electron linac, an 800 MW positron converter, and a 450 MeV secondary electron/positron linac.

The Positron Intensity Accumulator (PIA) is also considered part of the injector complex accumulating and damping the 50 Hz beam pulses from the linac and transferring them with a rate of 6.25 Hz or 3.125 Hz into the Synchrotron DESY II. The typical positrons rates are $6{\cdot}10^{10}$/s.

DESY II and Linac II will serve as injectors for the two synchrotron light facilities PETRA III and DORIS. Since PETRA III will operate in top-up mode, Linac availability of 98-99% is required. DORIS requires positrons for operation. Therefore during top-up mode positrons are required for both rings. In order to maintain its reliability over the operation time of the new facility PETRA III, the major components of the linac were renovated. Some components were redesigned taking into account experience from 30 years of operation.

## INTRODUCTION

The Linac II was built in the late 1960s to provide electrons and positrons for the Deutsches Elektronen Synchrotron (DESY) at higher energies (200 MeV) than the at that time existing linac (50 MeV) [1]. It consisted of 14 S-band travelling wave structures operating at 2.998 GHz and 20 MW input power and 4 µs pulse duration. The setup was modified since by introducing SLED (SLAC energy doubler) cavities for pulse compression and injecting into the Particle Intensity Accumulator (PIA). PIA was built to achieve short damping times for the positrons to be injected into the electron/positron storage ring collider PETRA. The pulse compression scheme enabled an energy increase to 450 MeV and allowed reduction of RF stations to 12, but required together with the high revolution frequency of PIA a reduction of beam pulse duration.

Today DESY II with its injector Linac II provides electrons and positrons for the synchrotron radiation facility DORIS, the synchrotron radiation facility under construction PETRA III, and for test beam targets inside DESY II. The injection into HERA via PETRA II is shut off, but there is an option to inject directly into HERA if there is the requirement by future projects.

## LINAC OVERVIEW

### *Injection System*

The primary electron beam is produced by a 120 kV pulsed DC diode gun. Beam pulses of up to 6 A and 4 µs duration are produced. The cathode is made by a thoriated tungsten plug, heated by a 3 kV, 1.2 kW bombarder. For best performance the cathode plug has to be carborized.

An electrostatic chopper forms beam pulses of 2 ns to 30 ns duration, depending on the operation conditions. In electron mode the primary beam is used directly, which reduces the required average beam current. A 2.998 GHz prebuncher cavity is fed by a portion of the first structure's forward RF power drawn from a directional coupler. The beam then enters the first accelerator section, which is not tapered.

### *Accelerator Sections*

The linac sections are 5.2 m long travelling wave S-band structures, operating at 2.998 GHz. They are constant gradient structures with an on-axis load. Therefore the last six of their 154 cells are coated with an absorbing material and add little to the total accelerating voltage. The fill-time of the structures is 740 ns. The original structures were replaced by a design made for the S-Band Linear Collider Test Facility [2].

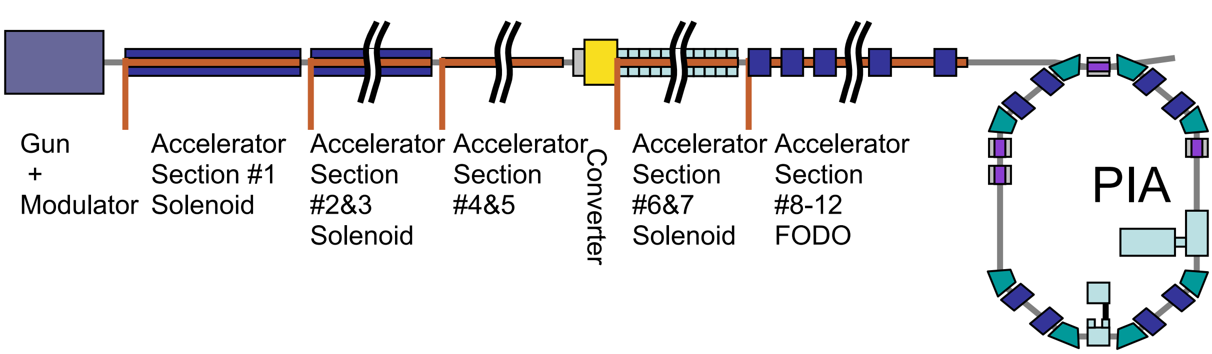

Figure 1: Schematic layout of the Linac II at DESY. The 6 A primary beam is produced in a 120 kV pulsed DC gun and directed onto a converter target at approximately 400 MeV. The secondary beam is accelerated to 450 MeV and injected into the Positron Intensity Accumulator (PIA).

# corresponding author: markus.huening@desy.de

All but one RF stations are equipped with SLED cavities for pulse compression, increasing the peak power from 20 MW to 90 MW. With this the structures achieve an average gradient of 18 MV/m or 90 MV/structure. The klystron drive is provided by the RF station number 9, which therefore cannot use the SLED scheme. Phase and amplitude are adjusted via high power phase shifters and adjustable attenuators. The phase jump for the SLED is produced individually by PIN-diodes in the drive of each klystron.

### Converter

At approximately 400 MeV there is the converter target. The beam current at this point usually is 2 A. The target consists of a tungsten plate with a thickness of 7 mm. An 1.8 T pulsed solenoid coil serves for focusing the secondary beam into the following acceleration sections, which in turn are surrounded completely by 0.4 T solenoid magnets. An off-axis hole in the target allows the primary beam to be steered through the target to be used directly in electron mode.

Six linac sections are available to bring the secondary beam energy to 450 MeV. Out of these six one usually is in stand-by mode and two are used off-crest with variable opposite phases to allow for adjustment of the final energy.

### PIA

The electrons or positrons at 450 MeV are injected into the PIA ring. The revolution frequency in PIA is 10.4 MHz and so is the frequency of its RF system [3]. The beam is damped longitudinally with only the 10.4 MHz RF system to 1.2 ns (RMS) [4]. A second RF system at the $12^{th}$ harmonic produces a bunch length of 380 ps (RMS). The damping time of the synchrotron oscillation is 12.9 ms, the damping time of the betatron oscillation is 23.6 ms. The theoretical horizontal emittance is 300 nm, the vertical emittance is 15 nm.

One full accumulation lasts 160 ms or 320 ms, depending on the mode of operation. This corresponds to 8 or 16 pulses of the linac. Only 4 respectively 12 shots are injected, the other 20 ms cycles are: 1 empty, 1 additional damping with only 10.4 MHz RF, 2 damping with 10.4 MHz and 125 MHz RF.

In the 3.125 Hz mode of operation $2{\cdot}10^{10}$ positrons can be accumulated routinely. This corresponds to an efficiency of 4‰ from beam on target to accumulated particles.

## MAJOR CHANGES

### RF System

The klystrons are powered by line-type modulators which are switched with a thyratron. The thyratrons were successively changed from CX1168 to CX1836A, which can handle higher voltages. Although the switching voltage (up to 38 kV) is within the specifications of the old thyratron, a better lifetime and reliability is expected with the new one. Experience over 270000 hours of operation confirms this.

### Converter

The target and its surroundings were rebuilt completely to remove technical risks and to allow better handling of the radioactive target after use. Firstly, all movable parts were eliminated because the high radiation levels around the target quickly destroy all motors and end-switches. Even the mechanical parts of the movers tend to suffer from corrosion. Secondly all braze joints of water filled parts were avoided or designed outside the vacuum. This applies especially to the vacuum feedthroughs of the solenoid coil and the water cooling of the target itself. Here the design benefits from the reduction of movable parts.

The output port was connected with a clamp-flange to minimize the time needed for dismounting the activated target. This turned out to be problematic for tightening the vacuum system. So in the new design a standard CF type flange is used. The copper seal at the same time serves as a collimator.

Handling the activated target after a few years of operation used to be a problem. Therefore the new target is equipped with a permanent shielding. A first layer of 20 cm Aluminium serves to reduce activation in the proximity of the converter while being little activated itself. A second layer of 5 cm lead protects persons working near the target.

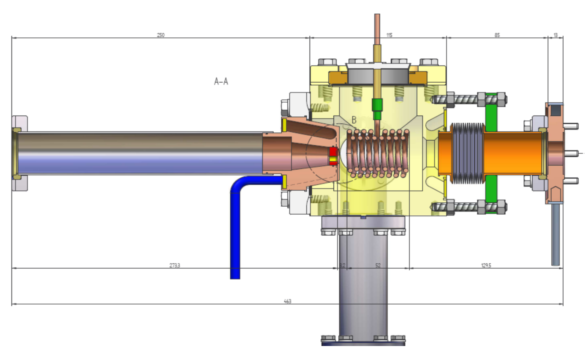

Figure 2: CAD model of the modified positron converter. In comparison to the old design all movable parts were eliminated and there are no more braze joints of water filled parts in vacuum.

A removable rail system eases the handling of the whole unit. Fixed end-points serve as references for the installation of prealigned converter targets.

### Vacuum System

In places where it had not been done already, the vacuum chambers of aluminium and with DIN-type flanges were replaced by stainless steel with CF-flanges. In the wake of these works BPMs were introduced.

### *Beam Position Monitors*

While PIA was equipped with BPMs from the beginning, the linac and the adjacent transport lines were not. In the recent shutdown Button-BPMs [5] were added to the transport line between linac and PIA (LP-Weg) and the transport line between PIA and DESY II (L-Weg). The BPM in the second straight – at 7 meters from the septum – was replaced by a new type of higher bandwidth.

Because of sensitivity and noise restrictions in the readout electronics, only damped bunches with high peak current can be resolved. For the BPMs before PIA and for the first turn in PIA readout electronics based on filtering the 3 GHz component of the button signal is being developed. For the first turn in PIA this adds the benefit of being able to distinguish the injected beam bunched at 3 GHz from the 10.4 MHz bunches already circulating in the ring.

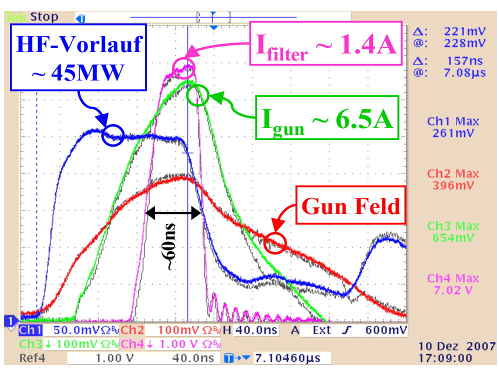

Figure 3: Scope traces of RF-gun pulses. At very high forward power of 45 MW over 160 ns filtered beam currents of 1.4 A are achieved

### *Gun*

One problem connected with the current gun is the ceramic high voltage isolator at the same time sealing the vacuum against the oil of the modulator. Should this ceramic break, it would cause irreparable damage to probably the whole linac. Second, it is becoming increasingly harder to find suppliers for the carborized cathode plugs. Third, due to the bunching scheme a substantial portion of the primary beam is lost at high energies along the linac.

To remedy these problems a replacement of the gun is being considered. In the moment a design by MAX-Lab [6] is being evaluated. This is an RF-gun with thermionic cathode. To avoid beam losses along the linac, an energy filter is used to cut away low energy electrons. The required beam pulses are much shorter than the time constant of the gun cavity. Therefore very high forward power is used to power the gun.

At 20 MW forward power stable beam current of 900 mA has been achieved over 1 month of continuous operation. Since this current was measured behind the energy filter, it is assumed that it would reach the converter target. At higher forward power self-enhancement by back bombardment occurs. Higher beam currents are achieved at the cost of unstable operation.

With slightly reduced performance 900 mA are acceptable for the Linac II, nevertheless tests with laser enhancement are planned.

## CONCLUSION

The Linac II provides electrons and positrons for the synchrotron and the storage rings at DESY. It has been renovated and upgraded to sustain its stable and reliable operation. The converter was completely redesigned, a new gun is still being evaluated.

## ACKNOWLEDGEMENTS

Work described in this paper was funded through the PETRA III project. The authors would like to thank MAX-Lab for providing an RF-gun and energy filter for testing.

# DEVELOPMENT OF TIMING AND CONTROL SYSTEMS FOR FAST BEAM SWITCH AT KEK 8 GeV LINAC

K. Furukawa*, M. Satoh, T. Suwada, KEK, Tsukuba, 305-0801, Japan
T. Kudou, S. Kusano, MELCO SC, Tsukuba, 305-0045, Japan
A. Kazakov, GUAS/SOKENDAI, Tsukuba, 305-0801, Japan
G. Lei, G. Xu, IHEP, Beijing, 100049, China

*Abstract*

The 8 GeV Linac at KEK provides electrons and positrons to Photon Factory (PF) and B-Factory (KEKB). Simultaneous top-up injections have been considered for both PF and KEKB rings in order to improve the injection efficiency and the experimental stability. Therefore, fast beam-switching mechanisms are being implemented, upgrading the timing and control systems. While the old timing system provides precise timing signals for 150 devices, many of the signals are now dynamically switched using an event system. A new scheme has been developed and tested to enable double-fold synchronization between rf signals. Fast controls of low-level rf, beam instrumentation, kickers, a gun, and beam operation parameters are also upgraded for fast and precise tuning of those parameters. The system has been developed since 2006, and is being deployed under the beam operation in 2008.

## INTRODUCTION

The KEK Linac injects electron and positron beams with different characteristics into four storage rings, KEKB-HER, KEKB-LER, PF and PF-AR. It takes 30 seconds to 2 minutes in order to switch the beam modes, depending on the magnet standardization [1]. When the beam development study is performed at PF ring for example, the experiment at KEKB is disturbed. Especially with the crab cavities installed at KEKB, the luminosity tuning is sensitive to the constant beam conditions at the both HER and LER rings and simultaneous injection to those rings is preferable. At the same time, the top-up injection is increasingly demanded at the PF ring in order to achieve higher-quality experimental data.

Thus, the fast beam-mode switching system has been designed and implemented [2]. In the system many hardware pieces of equipment are installed including pulsed magnets, fast rf system, and so on. Beam optics development is also performed in parallel to support the wide dynamic range of beam energy and charge, namely 3-times different energy and 100-times different charge.

Control and timing systems is upgraded as well to meet the requirement of the beam-mode switch in 50Hz (20ms). In order to notify the switching event globally along the 600-m Linac, an event system has been introduced [3]. It has been tested since 2006 and installed for the operation in autumn 2008. The system enables fast switching of many parameters of timing-signals, magnets, microwave systems, and beam instrumentations.

## FAST BEAM-MODE SWITCHING

There are a few beam modes defined at the Linac. It took more than 30 seconds for more than 20 items to switch. And it is considered important to switch at least following beam modes.

- KEKB HER : 8 GeV electron, 1.2-nC, 2 bunches.
- KEKB LER : 3.5 GeV positron, 1.2 nC, 2 bunches (10-nC primary electron).
- PF ring : 2.5 GeV electron, 0.1 nC, 1 bunch.

Here, 2 bunches in a pulse are separated by 96 ns. A fast switch of those beam modes is challenging because the dynamic range of the beam characteristics is very large. An adaptive beam optics scheme is being developed. In order to enable this scheme several hardware components had to be improved. And following parameters are changed within 20ms.

- Magnet: a pulsed bending magnet, several pulsed steering magnets, and a pulsed positron capture coil.
- Microwave: phase and timing of low-level rf, timing of high-power rf.
- Gun: grid-pulser selection, bias voltage, pico-second timing.
- Beam instrumentation: synchronized and fast beam-position-monitor read-out, pulse selection for wire-scanners and streak-cameras.
- Injection: selection of septa and kickers, interface to bucket selection systems.
- Operation: beam stabilization feedback, beam mode sequence pattern generation, mode-dependent parameter manipulation and archiving.

In order to achieve synchronized controls over Linac and beam transport lines for KEKB and PF, a global event notification system has been installed. Errors are not allowed because of safety reasons as the beam power varies 10 to 100 times [4]. The parameters for each mode have to be manipulated easily to optimize the beam tuning and the physics experiment conditions. It almost corresponds to building of three virtual accelerators.

* <kazuro.furukawa@kek.jp>

## EVENT DISTRIBUTION SYSTEM

In the old system beam-modes were notified through two mechanisms. Four separate cables were connected to important control stations in order to indicate four independent pulse characteristics, such as the beam existence and the synchronized beam measurement. More detailed information was transferred via normal control features through control networks. Timing signals were transferred to 15 timing stations through a coaxial cable, which provides a 50 Hz pulse and a 571 MHz clock [5].

When the beam mode was changed, more than 500 parameters were changed. It took more than 30 seconds mainly because many magnets had to be standardized.

In the new system, it was decided to introduce the series-230 event system that was developed for Diamond light source [6]. With an event generator (EVG230) installed at the central station, event receivers (EVR200/EVR230RF) can receive information through an optical fiber connection. EVRs can provide,

- Sequence of programmed events in a pulse,
- Regenerated clock signal (114.24 MHz in our case),
- Up to 14 delayed timing signals (with precision less than 10 ps),
- Shared data buffer up to 2 k bytes.

Because they are transferred through a single fiber connection, the maintenance is expected to be straightforward.

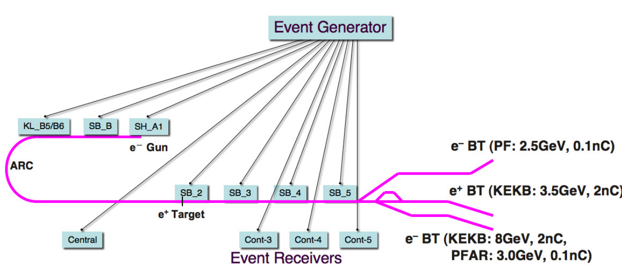

Figure 1: Layout of new event system.

Figure 1 shows 11 EVRs installed along the Linac. They are believed to be enough to control three beam-modes. Seven of those EVRs reside close to the existent timing stations, whose functionalities are being moved to EVRs. The number of components is reduced as an EVR can generate 14 precise delayed timing signals. Thus, most of the remaining old timing stations will be replaced by EVRs near future. Some devices, such as streak cameras, require better timing precision, so that a precise re-synchronization module is being developed.

The event rate is chosen to be 114.24 MHz, which is same frequency as the first sub-harmonic buncher and 1/25 of the main Linac frequency. The rf signal of 114.24 MHz is fed into EVG and used to transfer events and other data to EVRs in a star-like topology. Most of the EVR stations are connected through fan-out modules with multi-mode optical fibers, which were laid more than 10 years ago. Some of further stations are connected with single-mode optical fibers, replacing small-form-factor pluggable (SFP) modules at the fan-out module and EVRs.

The EPICS driver software is employed, and is extended to support new features of the series-230 system. The CPUs and the operating system of the VME computers are MVME5500 and VxWorks-5.5.1, respectively. The combination was chosen to satisfy the realtime performance requirements to the system and to enable the maximum coherence of the resources in KEK and EPICS community [7].

## BEAM MODE PATTERN GENERATION

Approximately 50 event codes are defined so far. Some of them are directly related to one of the beam modes, and some others are related to one of the accelerator equipment. Each beam pulse, every 20 ms, is accompanied with a sequence of several event codes, which contains at least an event related to the beam mode of the present pulse and that of the next pulse. Some event codes received at an EVR system trigger EPICS software to control equipment connected.

Some of the equipment can respond to 50 Hz controls, however, others impose restriction rules in choosing pulses. The beam repetition request from each ring may vary depending on the beam and experimental conditions in the ring. Thus, it is complicated to arbitrate and design the pattern of the beam-mode pulse train. At the same time, however, it should be flexible.

As the modification of the software on the EVG system may interrupt the beam operation, it was decided to generate the pattern in a separate program. The present pattern generation scheme is developed in a scripting language for rapid prototyping.

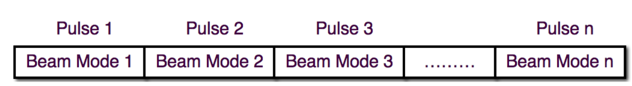

Figure 2: Beam-mode pulse pattern. A certain beam mode is assigned to each beam pulse, and several event codes accompany each beam mode.

The pattern such as Fig. 2 is designed in the program. The length of the pattern can be any number less than 500 (10 seconds), and it can be downloaded any time into the EVG system. Once it is loaded, it repeats forever until the next one is loaded, then the previous one is replaced at the end of the pattern. The EVG system generates a related event code sequence automatically following the pattern.

## EQUIPMENT CONTROLS

EVR modules directly drive timing signals, responding to event codes. The pulse widths are normally fixed, however, the timing delays are modified dependent on the event codes that correspond to one of the beam modes. Those timing signals are connected to devices such as pulsed magnets, low-level rf, high-power sources, beam instrumentation, and injection systems in order to switch the beam and to adjust the beam characteristics.

The phase values in the low-level rf systems (LLRF) are essential in order to define the profile, absolute value and spread of the beam energy. At the end of each pulse LLRF parameters are changed to prepare the next LLRF pulse as in Fig. 3.

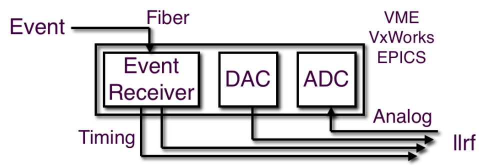

Figure 3: Six LLRF stations are controlled by EVR systems.

Currently, six pulsed magnets are installed in Linac, a bending magnet to feed the beam to the transport lines, a pulsed coil to efficiently capture the positron, and pulsed steering magnets to create a beam orbit bump to guide a beam around the positron target. They are separately triggered by timing signals from nearby EVR systems depending on the beam modes.

Beam instrumentations are also important to ensure the beam properties. Approximately 100 beam-position monitors (BPM) are utilized to monitor, stabilize and analyze the beam [8]. The old system reads the information only once a second. However, it is required to read every pulse if we switch the beam.

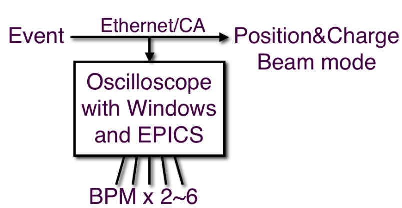

Figure 4: 24 oscilloscopes are installed to read 100 BPMs in 50 Hz distinguishing the beam modes.

The new system employs 24 oscilloscopes (Tektronix DPO7104) [9]. EPICS software is embedded on to those oscilloscopes with Windows. They can acquire the BPM signals in 10 Gsample/s and analyze the beam properties applying more than 20 coefficients per BPM. They can process the signals every pulse recognizing the beam modes and distinguishing two bunches 96 ns apart. Because the event system cannot be embedded on oscilloscope, events are delivered through the normal control network.

For some of the beam instrumentations such as streak cameras that do not recognize 50 Hz switched signals, a timing signal for only a selected beam mode is delivered.

## RF SYNCHRONIZATION

Both of the ring rf frequencies are independently and continuously adjusted in order to compensate the ring circumference variations. KEKB and Linac frequencies have a common source because the tolerance of the injection timing jitter is less than 30 ps. For PF ring, double-fold synchronization module was developed to choose a timing that synchronizes within a certain jitter between PF revolution frequency and Linac frequency. Currently, the jitter is set to 300 ps.

## CONCLUSION

The features of this new event-based control system is being validated under the beam operation. It is proved to satisfy the fast switch requirements. The system is expected to realize a sensitive and stable tuning of KEKB with crab cavities for a higher luminosity and a top-up injection at PF ring, simultaneously. More software development may be needed to support the beam operation with those three virtual accelerators enabled by the event system. An integrity monitor of the system is being developed as well to ensure the correct operation.

## ACKNOWLEDGMENTS

The authors would like to thank Dr. E. Björklund at LANL, Dr. T. Korhonen at PSI, and Mr. J. Pietarinen at MRF for their providing us EPICS event software and for valuable discussions.

## [illegible]

Electron and positron injections from the KEKB injector linac to storage rings have been switched in a typical cycle of five minutes. The switching involves a mechanical movement of a positron production target from and to a beam line. It prevents from faster switching, like pulse-to-pulse switching. A target assembly with a small hole beside a target material and four pulse steering magnets are installed. For positron injection pulses, the pulse steering magnets are off and electron beams irradiate the target to produce positrons. While, for electron injection pulses, the pulse steering magnets are excited to create a orbit bump in order for the electron beams to go through the hole and bypass the target. This paper describes details of a system for the pulse orbit bump and results from recent beam studies.

## INTRODUCTION

The KEKB injector linac supplies electron and positron beams to the KEKB storage rings HER (8.0 GeV e-), LER (3.5 GeV e+) and to the two synchrotron radiation facility rings PF (2.5 GeV e-) and AR (3.1 GeV e-) as well. Each ring requires different beam properties; a time-structure, a particle charge, an energy and an intensity. Parameter setting of the linac, called as "injection mode", is switched for an appropriate beam to be generated, accelerated and sent into a selected ring. In this mode switching, parameters like a choice of the pre-injector, electron gun settings, magnet currents, acceleration phases, rf pulse timings and so forth are changed. Mode switching between the electron and the positron injection for HER and LER rings is frequent in typically 5 minutes cycle. Each switching takes 30 seconds in completing to change parameters. Most of the linac operation time is occupied for KEKB continuous injection. It is interrupted by injections to PF (once a day) and to AR (twice a day), each takes 15 minutes to fill up the storage ring. Switchings from KEKB to PF or AR and its reverse have taken a few minutes until recently, since it needed to change a current slowly for a large bending magnet to keep its hysteresis cycle. However, recently, a demand of continuous PF injection was brought up for keeping its storage current constant. It is beneficial for some synchrotron radiation users, but it was not compatible with the KEKB continuous injection. To solve this issue, much efforts have been made to realize quasi-simultaneous electron injection to KEKB HER and to PF [1]. It can be achieved by injecting both beams from the same pre-injector, installing a pulse bending magnet and a new beam transfer line for PF, pulse-to-pulse switching of acceleration rf phases for 8.0 GeV and 2.5 GeV beam energies, setting up focusing and steering magnets compatible for these different beam energies [2]. This unification of these two injection modes has almost been completed and it will be used for an autumn run this year (2008).

Next step of the unification is that of the KEKB electron and positron injections. Positrons are produced by irradiating a metal target with electron beams. A target is placed on a beam line halfway across the KEKB linac. The target is retracted from the beam line during an electron injection and inserted during a positron injection. Mechanical movement of the target takes a few seconds. It is desirable keep constant storage currents in both of electron ring and positron ring for a beam collision tuning to achieve superior luminosity. To realize pulse-to-pulse switching of the electron and positron injection modes, it was proposed to use a target assembly with a small hole beside a target material in order to fix it on a beam line and to let electron beams bypass through the hole with pulse steering magnets only for electron injection pulses.

In the following chapters, details of the target assembly, the pulse steering magnets and recent results of beam studies are given.

## TARGET BYPASS ORBIT FOR PULSE-TO-PULSE MODE SWITCHING

### [illegible]

In designing a bypass orbit to avoid the target retraction, first considered has been a large orbit bump to bypass not only the target but positron focusing solenoids and a capture system. It needed an independent bypass beam line apart more than 300 mm from the original beam line and also huge pulse magnets to bend 4-GeV electron beams in large angle. Thus, it was too costly. More practical and economical solution was to make a small hole in a target assembly beside the target material and to make a bump orbit of only some millimeters height. This small orbit bump can be contained in a present beam ducts and in apertures of accelerating structures. Fig. 1 shows a bypass orbit bump and a beam line layout around the positron production target. A component denoted as PT21T in the figure is a positron production target and the thick green lines show an aperture of the target hole. Center of the hole is 5.2 mm aside horizontally from a beam line center. Focusing quadrupoles setting is based on a candidate beam optical calculation which is compatible for HER and PF injections. A purple line shows a bump orbit and red

* takuya.kamitani@kek.jp

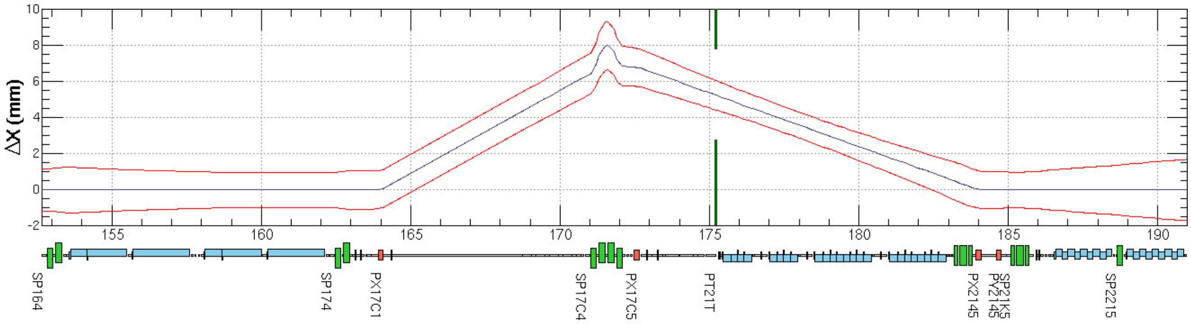

Figure 1: Target bypass orbit and beam-line component layout around the positron production target.

lines show a beam envelope in 3-sigma extent assuming a design emittance of electron beam for HER injection: $\gamma\epsilon = 1.0 \times 10^{-4} m$. A envelope of PF injection beams is not described here since its size is typically much less than that of HER beam. About 3 meters upstream of the target, there is a quadrupole quartet (illustrated in green rectangles) to focus electron beam onto the target. At just downstream of the target, there is a positron-focusing solenoid region in 8 meters long and capture accelerating structures (blue rectangles) in it. Three horizontal pulse steering magnets (PX17C, PX17C5, PX2145) and a vertical steering (PY2145) are installed (orange rectangles). Horizontal steering magnets make a closed orbit bump to let electron beams go through the hole. Since the focusing quadrupole quartet is inside the bump, it contributes to kick the beam toward the beam line center and help the second steering magnet. The vertical steering magnet is used to compensate a vertical kick from edges of the solenoidal field.

## [illegible]

For positron production, 4.0-GeV electron beam (beam intensity 10 nC/bunch, 1 or 2 bunches/pulse, maximum pulse repetition 50 Hz) irradiates a tungsten target. A 14-mm thick amorphous tungsten had been used as a target material. Recently, a 10-mm thick crystal tungsten has been developed for practical use, which resulted in 25% increase of the positron intensity [3]. Transverse cross section of the crystal tungsten is a square in shape, 4.5 mm on a side. The target is combined in a copper support by the hot isostatic pressing method. Cooling water pipe is wound around the support and connected by brazing. In a present injection mode switching, the target assembly is mechanically moved. The target is retracted from a beam line for electron beams to pass through during electron injections, and it is inserted in the beam line for positron production during positron injections. The target is driven by a pressurized air and it takes a few seconds to complete the movement. A cycle period of the retraction and the insertion is limited to be longer than 5 minutes for avoiding a breakage of a vacuum bellows in a long-term operation. To realize a beam mode switching without moving the target, a hole 5.0 mm in diameter is penetrated beside the target as shown in Fig. 2.

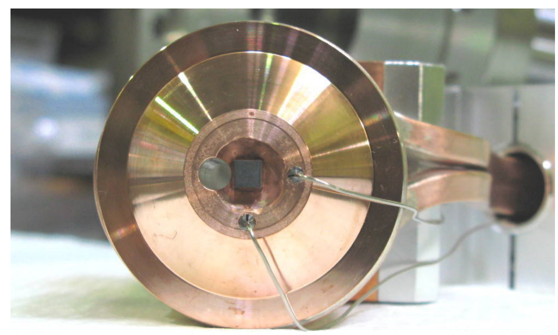

Figure 2: Positron production target assembly with a hole.

## [illegible]

To make a bump height of the target bypass orbit sufficient for the target hole, pulse steering magnets should generate 1.0-mrad transverse kick angle for the 4-GeV electron beam. To achieve this specification, modification of used magnets in the TRISTAN accelerator was considered. The candidate magnet has dimensions of 330 mm in yoke width, 280 mm in yoke height and 170 mm in pole length. This size is suitable for installing into available spaces in the linac beam line. It could generate 0.0593 Tesla dipole field with a maximum DC current of 10 A, which corresponds to 0.56-mrad kick angle for 4.0 GeV beam. To meet the specification requirement on the field strength, a pole gap of the magnet was modified from 70 mm to 35 mm, by fabricating additional pole head and welding to an existing pole. It doubled the field strength at the same current to meet the specification. This modification resulted in significant increase of a coil inductance from 32 mH to 57 mH. In this situation, the maximum current which can be supplied to the magnet is limited by a induction voltage a power supply can manage. We use a sine-like pulse shape with a offset to make an initial and a final time derivates of the supplied current to be zero, because an edged shape of the pulse current give larger induction voltage. Bipolar pulse power supplies, BP4610 and BP4620 of the NF corporation are used as amplifiers of input pulses from function generators. The power supplies can tolerate an induction voltage by a pulse longer than 40-ms cycle. Thus, it can excite a bump orbit at maximum repetition of 25 Hz. In a case of 50 Hz injection, we will switch the power supplies to a DC mode. A timing of the orbit bump excitation with respect to beam arrival has 0.5 ms jitter from a constraint in bucket selection.

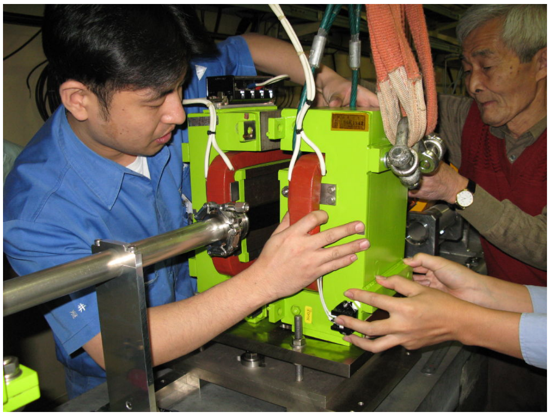

Figure 3: Pulse steering magnet for target bypass orbit

## [illegible]

Preliminary beam studies have clarified some issues on this scheme of mode switching using a bump orbit through the target hole:

- When the bump height is large, certain beam loss occurs because some fraction of electrons hit vacuum ducts around the region of the quadrupole quartet. Vacuum ducts whose inner shape was a circle of 10.0 mm in radius was replaced by that of elliptical shape whose major axis is 14.5 mm.
- Preliminary target hole diameter 3.0 mm was not sufficiently tolerant for beam transmission. It was enlarged to 5.0 mm in the most recent target.
- Setting of the pulse steering magnets for the bump orbit and beam transmission performance are dependent upon a focusing strength of the quadrupole quartet. In the most promising optical setting in views of beam transmission and matching to a downstream optics, the quadrupole strength was set to a medium value between that for an previous HER injection optics and that for optimum focusing onto the target [2].

Beam studies are performed quite recently to measure a beam transmission performance after these improvements. Fig. 4 shows beam transmission ratios for 1st and 2nd bunches of the HER injection beam and for the PF beam. We define a standard charge by a beam charge measured at a downstream of the bump orbit when bump height is zero and the target extracted. The transmission ratio in vertical axis of the figure is calculated as a measured beam charge divided by the standard charge. The bump height in horizontal axis is defined as a difference of an orbit position at the target from that when pulse steering magnets are off. It should be noticed that these values are not absolute orbit position. Dashed the blue and aqua lines show measured beam transmission ratio of two bunches of a HER beam with the target extracted. Degradation in a right-hand shoulder is caused by beam loss at vacuum ducts. While, the solid lines in same colors are those for the case the target is inserted. At each bump height of the maximum transmission for the first and second bunches, differences of the values for the cases with and without the target is less than 5%. Thus, it shows that 95% of the beams can be pass through even with an aperture limited by the hole. Optimum bump heights for the first and second bunches of the HER coincides in a range of 0.1 mm. It shows that the orbits for them are very close in 0.1 mm and a common bump height can achieve a transmission close to the optimum. Dashed and solid red lines show the transmission for PF beams. The optimum transmission for PF beam is better than 95%, but the optimum bump height differs about 0.6 mm from those of HER beams. This significant orbit difference forces a compromised bump height in order to make it common for the HER and PF beams. It results in slightly degraded transmission. It need more careful tuning to make these orbit to be closer for better tranmission. If the tuning cannot improve the situation, pulse-to-pulse variation of the bump height will be necessary and requires some upgrades in the pulse power supply control system. After all, even in a compromised bump height, 90% transmission is achieved both for HER beams and for PF beam.

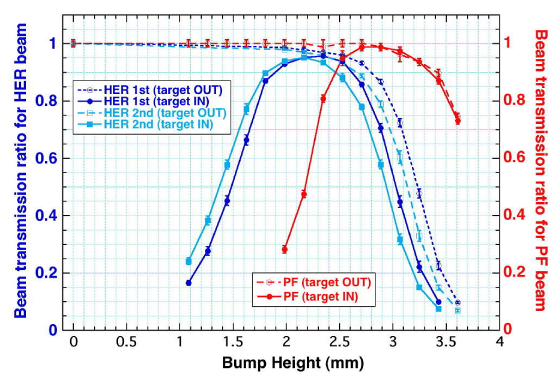

Figure 4: Measured beam transmission performances.

# OBSERVATIONS OF TWO MICROBUNCHES AFTER A 180-DEGREE ARC SECTION AT THE KEKB LINAC

Y. Ogawa#, M. Yoshida, KEK, Tsukuba, Japan

*Abstract*

The KEKB linac [1] continuously injects 8-GeV electron and 3.5-GeV positron beams into the KEKB rings: HER (high energy ring) and LER (low energy ring). The energy spread of the 8-GeV electron beam, which is accelerated to an energy of 1.7-GeV at a 180-degree arc section and reaccelerated after this arc to a final energy of 8 GeV, is optimized by adjusting rf acceleration phases so as to assure efficient injections. When rf phases after the arc are slightly changed or drifted for some reasons, the beam not only shows larger energy spreads but also indicates two clusters on a beam profile monitor located at large energy dispersions. In this connection, a longitudinal beam profile was measured before and after the arc section with streak-camera systems utilizing OTR (Optical Transition Radiation). The observed bunch shape clearly shows a two-microbunch structure, suggesting that it could be generated in the arc section. Various experimental data as well as some CSR-related speculations are presented.

## INTRODUCTION

In high-luminosity machines like the KEKB factory, stable beam injections are absolutely essential to retaining the optimum luminosity. The injection efficiency is quite dependent upon the quality of injected beams, especially upon the energy spread. Thus the energy spread of the electron beam for the KEKB has been always kept at a minimum enough for stable injection by adjusting rf acceleration phases.

The KEKB electron beam is accelerated to an energy of 1.7-GeV at a 180-degree arc section and reaccelerated after the arc to a final energy of 8 GeV (Fig. 1). During tuning processes of the energy spread, we have found that the energy profile at the end of the linac shows peculiar behaviour, splitting into two clusters if the rf phases after the arc are not optimized, while we have not observed the same phenomenon before the arc section. Although the phenomenon itself is quite stable and reproducible, we examined as a first step the rf system looking for some unstable components, but did not find any causes attributed to the rf system. Meanwhile we have taken various observation data concerning this phenomenon, which are reported in this paper together with some CSR-related speculations.

## EXPERIMENTAL CONFIGURATION

A schematic view of the experimental setup is shown in Fig. 2. The parameters relevant to the 8-GeV single-bunched electron beam are summarized in Table 1. The energy profile of the beam is observed by a screen monitor using an alumina fluorescent plate (AF995R, Desmarquest Co.) located at the 8-GeV energy-analyzer line; the energy separation of the two clusters is measured by changing rf phases of appropriate accelerator sections corresponding to an energy range of about 5 GeV. The time structure of the bunch is investigated with streak-camera systems (Hamamatsu Photonics K. K.) utilizing OTR located before and after the arc, which have a time resolution of two or three picoseconds.

Table 1: Beam Parameters

| | |
|---|---|
| Energy | 8 GeV |
| Acceleration Frequency | 2856 MHz |
| Charge | 1 nC (single bunch) |
| Bunch Length (σ) | 4.7 ps (single bunch) |
| Energy Spread (σ) | 0.05 % |
| Emittance $\gamma\beta\varepsilon$ (σ) | 0.31 mm |
| Maximum Repetition | 50 pps |
| Energy at the Arc Section | 1.7 GeV |

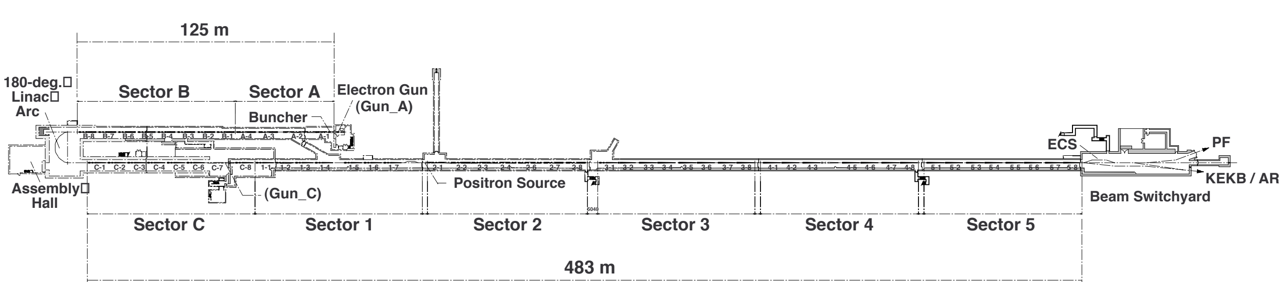

Figure 1: Layout of the KEKB linac. The KEKB electron beam is accelerated to an energy of 1.7-GeV at a 180-degree arc section and reaccelerated after the arc to a final energy of 8 GeV.

#yujiro.ogawa@kek.jp

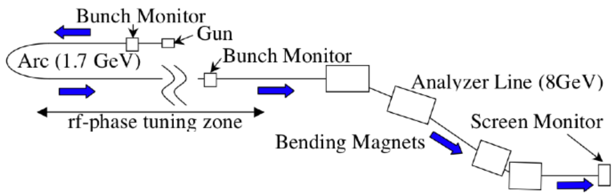

Figure 2: Schematic view of the experimental setup. The longitudinal phase space of the single-bunched electron beam is diagnosed by two methods: one with the bunch monitors before and after the arc, the other utilizing the 8-GeV energy analyzer line located at the end of the linac.

## EXPERIMENTAL RESULTS

### *Observation on the Screen at Large Dispersions*

Fig. 3 shows the photographs of energy profiles observed on the screen monitor located at the energy-analyzer line in two cases: Fig. 3a for the single bunch in optimum rf acceleration phases and Fig. 3b for those split into two clusters in non-optimum rf phases. Since the alumina fluorescent plate has a long image lag when irradiated by charged beams, the beam repetition was decreased to 0.5 Hz so as to check if two clusters shine at the same time. This has verified that the observed phenomena are not caused by some energy-jitter effects but due to the real two independent clusters with different energies.

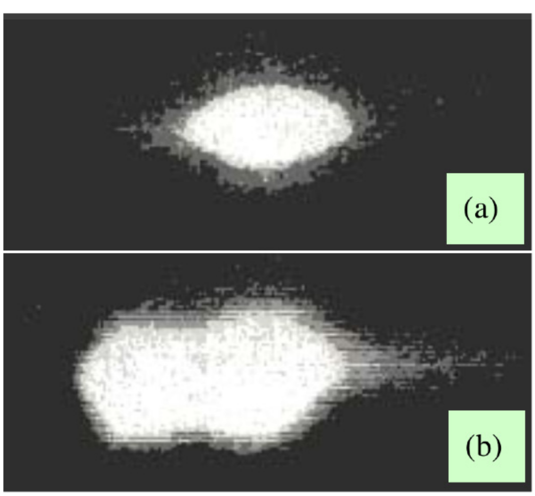

Figure 3: Energy profiles observed on the screen monitor at large dispersions: (a) for the single bunch in optimum rf acceleration phases and (b) for those split into two clusters in non-optimum rf phases.

### *Measurements of the Bunch Structure*

This fact has pushed us to figure out time structures of the bunch with streak-camera systems utilizing OTR located before and after the 180-degree arc section. The results are shown in Fig. 4; one observed before the arc (a), the others after it (b, c). Fig. 4b and 4c clearly indicate a two-microbunch structure with a time interval of about 20 ps irrespective of rf phases, while the bunch shape before the arc (Fig. 4a) has just a single peak. Since the measurements were carried out in integration modes of the streak camera systems to improve S/N ratios for a small charge of 1 nC or 2 nC, it remains unclear whether the results could conclude the actual existence of two microbunches after the arc, which might hint that the phenomena should take place during passage through the arc.

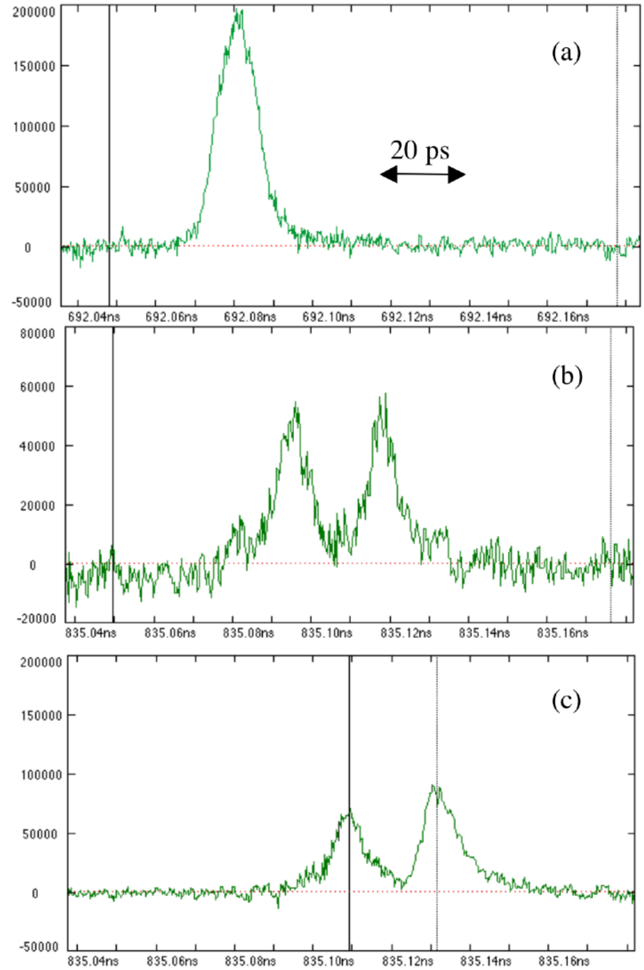

Figure 4: Bunch structure measured with streak-camera systems utilizing OTR located before and after the 180-degree arc section: (a) observed before the arc, (b) and (c) after the arc. (a) and (b) are the cases for a charge of 1 nC, while (c) is for 2 nC.

We also checked the charge dependence of the phenomena anticipating the wake-field issue, but the time interval of the two microbunches shows weak or no dependence on the charge (Fig. 4c).

### *Energy Separation as a Function of rf Phases*

In order to clarify the two-microbunch structure, we have examined whether the energy separation of the two clusters seen by the screen monitor at large dispersions really varies with rf phases. Fig. 5 shows unequivocal dependences of the energy separation of the two clusters on the rf acceleration phases confirming the existence of two microbunches.

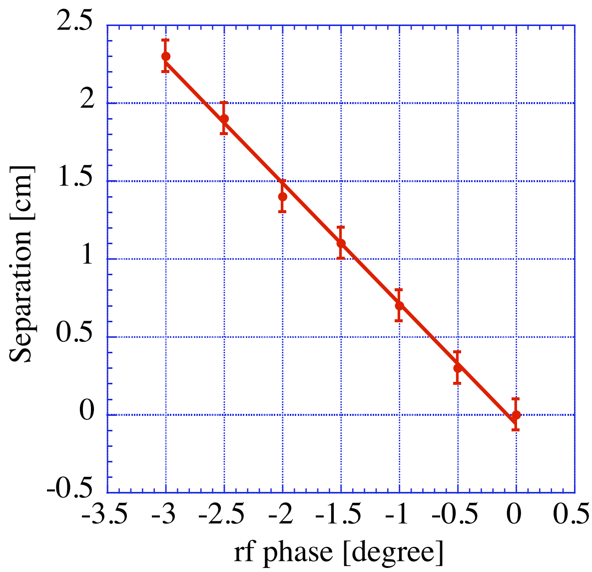

Figure 5: Energy separation of the two microbunches as a function of the rf phases. The data points are fitted with the function $x$ given in the text.

## DISCUSSIONS

### *Cross-Check of the Measurements*

The measurements by the bunch monitor after the arc (Fig. 4b) shows that the time interval of the two microbunches is about 20 ps, which should be compared with the value obtained from the rf-phase dependence of the energy separation of the two clusters (Fig. 5). If the two microbnches really exist, their energy separation $\delta E$ is written as,

$$\frac{\delta E}{E} = \frac{E_{rf}}{E_0}(\cos\phi_2 - \cos\phi_1),$$

where $E_{rf}$ is the corresponding energy of the sections for rf phase tuning, $E_0$ the total energy (8 GeV), $\phi_1$ the rf phase of the first microbunch, $\phi_2$ that of the second microbunch. The observed separation on the screen ($x$) is proportional to $\delta E$,

$$x = A\eta_x \frac{\delta E}{E},$$

where $\eta_x$ is the dispersion function at the measurement point, $A$ the calibration factor. Defining the following quantities,

$$\phi_{rf} = \frac{\phi_1 + \phi_2}{2},\ \ \delta\phi = \phi_2 - \phi_1,$$

$x$ is represented by

$$x(\phi_{rf}) = -2A\eta_x \frac{E_{rf}}{E_0} \sin\frac{\delta\phi}{2} \sin\phi_{rf}.$$

The data points in Fig. 5 are fitted with this function on the assumption that

$$A = 0.8,\ \ \eta_x = 400\ cm,\ \ E_{rf} = 5.25\ GeV,$$

from which we obtain $\delta\phi$ :

$$\delta\phi = 12 \pm 1\ [\text{degree}],$$

corresponding to the time interval $\delta t$ :

$$\delta t = 12 \pm 1\ [\text{ps}].$$

This is to be compared with the value (20 ps) obtained by the bunch monitor, showing a certain amount of difference, which should be attributed to the uncertainties concerning the calibrations of the streak camera systems and the factor $A$.

### *Some Speculations on CSR Effects at the Arc*

The experimental results suggest that the observed phenomena might originate at the arc section, which is designed to be achromatic and isochronous. The CSR effects could be primarily not the issue because the bunch length is not so small and not even compressed in the arc. During passage of the arc, however, it might happen that an initial density fluctuation with a characteristic length much shorter than the bunch length could radiate coherently, leading to microbunching phenomena observed in our linac if the CSR effects are enhanced in the arc [2]. The simulations based on the CSR effects are in preparation and will be reported elsewhere.

## CONCLUSIONS

We have observed peculiar phenomena in the energy profile of the KEKB 8-GeV electron beam during rf phase tuning, splitting into two clusters like microbunches. In order to check the existence of microbunches, we performed a series of experiments. The results surely indicate that microbunching happens at the 180-degree arc section when the rf acceleration phases are not optimized for an energy spread. Further experiments as well as some simulations related to CSR effects are to be carried out in the near future.

*Abstract*

KEK injector linac provides an injection beam for four storage rings, KEKB high energy electron ring(HER), low energy positron ring(LER), PF-AR electron ring, and PF electron ring. The injection beams for these rings have different energies and intensities. Recently, a requirement of simultaneous injection among these rings arises to make a top-up injection possible. Magnetic field of the DC magnets to confine the beam to the accelerating structures can not be changed during a pulse-to-pulse, although the beam energy can be controlled by fast rf phase shifters of the klystrons. This implies that a common magnetic field of the bending magnets and the quadrupole magnets should be utilized to deliver beams having different characteristics. Therefore, we have designed a multi-energy optics for the KEKB-HER electron ring(8 GeV, 1 nC/pulse), the PF electron ring(2.5 GeV, 0.1 nC/pulse), and the KEKB-LER positron ring(3.5 GeV, 0.4 nC/pulse). We present a performance of the multi-energy injector linac for the PF ring and the KEKB-HER.

## INTRODUCTION

A new injection scheme has been developed, which is so called a pulse-to-pulse injection with multi-energy linac for the KEKB-HER, the KEKB-LER, the PF ring. The pulse-to-pulse injection means that the beam can be switched and injected to the desired rings within 20 msec at a minimum duration. However, the beam energy is different among these rings. Difficulties arise from that most of magnets can not change the magnetic field by a pulse-to-pulse duration. Therefore, we have developed a new optics to use a common magnetic field for the different beam energies, such as 2.5 GeV for the PF and 8 GeV for the KEKB-HER. The KEKB-LER injection has been still tested and under development in this scheme, however, the strategy is a similar way of the PF and the KEKB-HER.

The injector linac has 7 sectors, A-sector and B-sector before 180° arc(J-arc) and 1-sector to 5-sector after the J-arc. The energy of the J-arc is 1.7 GeV and the multi-energy scheme focuses on the region from the C-sector to the 5-sector. A pulse bend is placed in the 5-sector and the 2.5 GeV beam is kicked out to the transport line of the PF ring, while the 8 GeV beam passes through the ECS(the energy compression system) to the KEKB-HER transport line.

## OPTICS

A fundamental block of the linac is an acceleration unit that consists of an S-band klystron and four 2 m-long accelerating structures. The klystron drives these accelerating structures which have a common phase of the microwaves. The accelerating structures in the acceleration unit have the same field gradient in principle. Eight acceleration units make a sector, typically. A sub-booster supplies microwaves to each klystron in the sector and adjusts the phase for a beam passage.

A doublet or a triplet of quadrupole magnets is placed in every one or two acceleration unit and makes a cell of a periodic lattice. In the case of an electron injection, an electron beam is accelerated from 1.7 GeV up to 4.8 GeV between the C-sector and the 3-sector. A positron target to make a positron beam is placed in the 2-sector. In the case of a positron injection, a primary electron beam hits the positron target and positrons are generated by means of electro-magnetic showers. On the other hand, a small hall($\phi$=3 mm) is placed in the vicinity of the target so that an electron beam can pass through the positron target for the electron injection. In order to make this possible, it is necessary to squeeze the beta function at the hall as small as possible and to make a local bump orbit by using pulse steerings in the horizontal plane.

The electron beam injected to the PF ring is decelerated down from 4.8 GeV to 2.5 GeV between the 3-sector and the 5-sector, while the electron beam is accelerated up to 8 GeV for the KEKB-HER. In the multi-energy region, the phases of the sub-boosters are shifted by 180° approximately between the acceleration and the deceleration. In practice, an off-crest phase typically shifted by 6° from the crest phase is used to compensate the energy difference between the head and the tail of a bunch due to the wake field. The deceleration phase is

$$\phi_{dec} = \phi_{acc} + 180^\circ - 2\Delta\phi, \quad (1)$$

where $\Delta\phi$ is the phase shift from the crest phase. Further more, a few klystrons in the 3-sector would be a stand-by mode to adjust the beam energy so as to be 2.5 GeV. The stand-by mode implies an off-timing trigger for the beam passage. Both the 2.5 GeV and 8 GeV beam would be adjusted by the energy-feedback system[1] precisely. The energy feedback system consists of a set of two klystrons and adjust the phase. The off-crest phases are used in the opposite side of the crest for each klystron to compensate the energy spread. Those sub-boosters and the energy feedback system utilize a phase shifter with a solid-sate device and can change the phase by a pulse-to-pulse duration.

The DC magnets are used in the lattice for the quadrupole and steering magnets. Therefore, the beams which have a different energy must be transported with a common magnetic field from the 3-sector to the 5-sector(multi-energy region). The optics is designed for the 2.5 GeV beam as a base line since there is a matching section in the transport line for the KEKB ring and not for the PF ring. The beta functions and beam energies for the 2.5 and the 8 GeV beams are shown in Fig. 1. The betatron phase advance of the cell is 90° typically in most sectors. However, the phase advance in the multi-energy region should be optimized so as to make the beta function enough small for the the different beam energy. In the 2.5 GeV optics, the phase advance for each cell is designed to be 108° approximately in the 4-sector and the 5-sector. While, the phase advance of the cell would become 40°∼50° for the 8 GeV optics. The optics design would suppress a large beam size in the multi-energy region for the both 2.5 and 8 GeV beam.

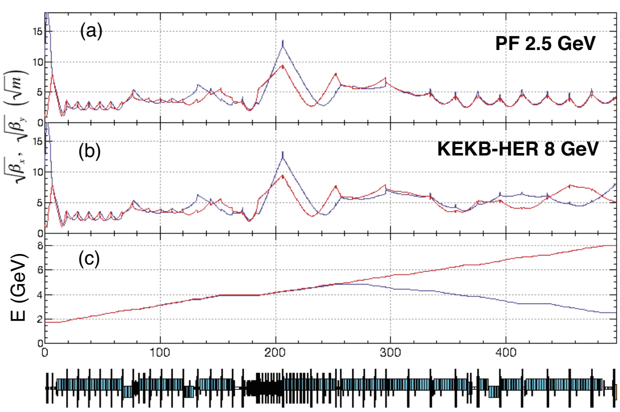

Figure 1: Optical parameters for (a) 2.5 GeV PF, (b) 8.0 GeV KEKB-HER, and (c) beam energy.

In the optics calculation, the SAD code[2] is utilized. We assumed that the beam energy at the exit of the buncher section in the A-sector would be 20 MeV which is measured by a energy analyzer cosists of a well calibrated bending magnet and a beam screen monitor. The beam energy is calculated by using a peak acceleration field of an accelerating structure, a phase, a klystron status[3]. The calculated energy would have errors due to a characteristic of the accelerating structure and the beam loading. Therefore, the absolute value of the beam energy should be adjusted to be the desired energy at the end of linac for each injection. A normalization factor is used to scale the beam energy to 1.7 GeV at the J-arc, 2.5 GeV for the PF ring, and 8 GeV for the KEKB-HER. The relative energy among the accelerating structures should be kept since the relartive error of the energy gain from the accelerating strucure would be small. Although the normalization factor is an overall factor, the normalization factor of 8 GeV is used for the 2.5 GeV beam in the common energy region which is between the J-arc and the entrance of the multi-energy region.

Twiss parameters at the entrance of the C-sector are matched so as to be the design values using the matching section in the J-arc. The matching procedure is based on emittance measurements with wire scanners[4]. From the C-sector to the 5-sector, k values correspond to the magnetic field of the quadrupoles are determined so that the beta functions become the design values by means of a fitting procedure with the SAD code.

## CORRECTION OF OPTICS

The optics is corrected by a single-kick method. A single-kick orbit induced by a steering is measured by beam position monitors(BPM) which are placed next to each quadrupole magnet. Since the single-kick orbit is a relative orbit displacement by a single steering, we do not have to consider an absolute beam position.

The measured orbits are compared with the design orbits calculated by optical parameters based on the k value of the quadrupoles and the calculated beam ebergy described in the previous section. A fudge factor is introduced to correct the k value so that the measured orbits agree with the design orbits. The definition of the fudge factor, $a_f$, applied to the k value is written by

$$K_{ps} = a_f \cdot K_d, \tag{2}$$

where $K_{ps}$ is a k value set to the real magnet and $K_d$ is a k value of the design value. The deviation from the design of the k value of the $m$-th quadrupole can be estimated by solving following equations:

$$\Delta x_i^{(j)} = \sum_{m=1}^{M} R_{y,im}^{(j)} \Delta K_m \tag{3}$$

$$\Delta y_i^{(j)} = \sum_{m=1}^{M} R_{x,im}^{(j)} \Delta K_m \tag{4}$$

where $\Delta x_i^{(j)} = x_{m,i}^{(j)} - x_{d,i}^{(j)}$, $x_{m,i}^{(j)}$ and $x_{d,i}^{(j)}$ are the measured and the design orbit at the $i$-th BPM induced by the $j$-th steering in the horizontal plane, and $y$ is the same as $x$. The response matrix, $R_{x,y}$ is calculated by the SAD code. The fudge factor is $a_{f,m}^{-1} = 1 + \Delta K_m / K_{d,m}$ and includes not only a field gradient error but also an energy error. Here, $xy$ couplings are ignored because it is a higher order effect and it should be small.

In the optics correction, we use 22 kinds of single-kick orbits typically to obtain fudge factors of the quadrupole magnets and the fudge factors are determined at the 2.5 GeV lattice. During the optics correction, we found a miss connection of power supplies to quadrupole magnets. In this case, both a large fudge factor and a large field gradient error are appeared at a specified quadrupole magnet(QD484, QF484). In this manner, the single-kick method is also effective to find a machine error. The fudge factor after fixing the connection problem is shown in Fig. 2(c). The fudge factors are within 3%. Figure 2 shows a comparison of the measured and the design single-kick orbit for the 2.5 GeV beam before and after the optics correction. Introducing the fudge factors, the measured single-kick orbit is consistent with the design orbit. All other single-kick orbits are similar to Fig. 2 and consistent with each design orbit.

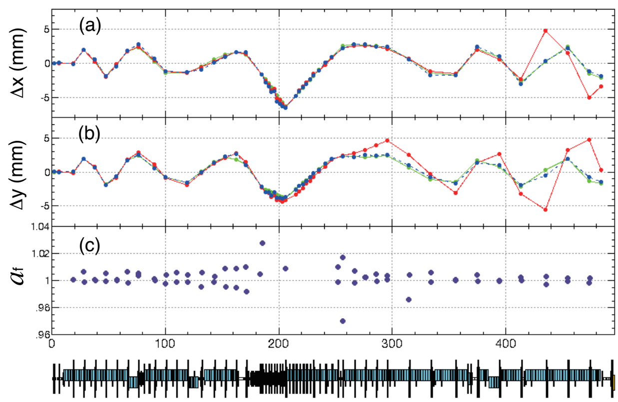

Figure 2: (a): Horizontal orbits for design(green), measured before correction(red), and measured after correction(blue). (b): The vertical orbits are the same as the horizontal. (c): Fudge factors for quadrupoles.

The optics is evaluated by the wire scanner in the 5-sector. The measured optical parameters for 2.5 GeV in front of the pulse bend are listed in Table 1. The optical parameters are well matched to the design values since the B$_{mag}$ parameters are very close to 1.

Table 1: Optical parameters for 2.5 GeV measured by the wire scanner in the 5-sector.

| | **horizontal** | **vertical** | unit |
|---|---|---|---|
| Beta function | 10.36 | 13.08 | m |
| Normalized emittance | 288 | 161 | nm |
| B$_{mag}$ | 1.01 | 1.05 | |

## ORBIT CORRECTION AND FEEDBACK

Beam orbits are required to be fixed and stable at the end of linac. A position and an angle of the 2.5 GeV beam should be zero at the pulse bend. At the same time, a position and an angle of the 8 GeV beam should also be zero at the ECS. We have developed a tuning technique to adjust both orbits for 2.5 GeV and 8 GeV simultaneously by using a common magnetic field of DC steerings. In order to adjust the orbit for 8 GeV, a local bump method is utilized. While the local bump is closed at 2.5 GeV, the local bump is not closed at 8 GeV in general. Therefore, the orbit for 8 GeV can be adjusted independent on the 2.5 GeV orbit. On the other hand, the beam orbit for 2.5 GeV is controlled by two steerings. However, these two steerings would affect the orbit for 8 GeV. In spite of this, the orbit response of two steerings can be canceled by adjusting the local bump height. The orbits for 2.5 GeV and 8 GeV can be adjusted by solving a following equation:

$$\begin{pmatrix} \Delta x_1 \\ \Delta x_2 \\ \Delta X_1 \\ \Delta X_2 \end{pmatrix} = \begin{pmatrix} m_{11} & m_{12} & 0 & 0 \\ m_{21} & m_{22} & 0 & 0 \\ n_{31} & n_{32} & n_{33} & n_{34} \\ n_{41} & n_{42} & n_{43} & n_{44} \end{pmatrix} \begin{pmatrix} \theta_1 \\ \theta_2 \\ h_1 \\ h_2 \end{pmatrix}, \quad (5)$$

where $x$ and $X$ are a beam position for 2.5 GeV and 8 GeV, respectively, $\theta$ is a kick angle of a steering, and $h$ is a local bump height. The orbit response matrix, $m_{ij}$ and $n_{ij}$, is calculated by the SAD code. Vertical positions, $y$ and $Y$, are adjusted by the similar way of the horizontal positions. In this procedure, the positions at two BPMs is necessary at least to adjust the position and the angle. We use two local bumps and two steerings to control the orbits. The phase advance between two local bumps is about 90° which corresponds to two cells of the lattice in the case of 8 GeV.

We consider the orbit feedback system by using this technique. This is a slow orbit feedback since the steerings are DC magnets and beam positions measure by BPMs for 2 sec intervals so far. The slow orbit feedback for the multi-energy beam can suppress an orbit drift for a long term .

## CONCLUSION

We have present the optics designed for the multi-energy injector linac. The beams which have the different energies, such as 2.5 GeV and 8 GeV, can be successfully transported to the end of linac with a common magnetic field of the quadrupoles and steerings. As the next step, the multi-energy injector linac together with the positron injection to the KEKB-LER, the beam energy of 3.5 GeV, is under development.

## ACKNOWLEDGMENT

We would like to thank K. Oide and A. Enomoto who have supported the program for the pulse-to-pulse injection to the PF and the KEKB rings.

# PRESENT STATUS OF THE KEK INJECTOR UPGRADE FOR THE FAST BEAM-MODE SWITCH

M. Satoh# for the IUC* Accelerator Laboratory, High Energy Accelerator Research Organization (KEK), 1-1 Oho, Tsukuba, Ibaraki, 305-0801

*Abstract*

The KEK Linac provides the four different quality beams for the four independent rings. The KEK Linac upgrade aiming a fast beam-mode switch operation is now in progress so that the KEKB continuous injection and PF top-up injection can be carried out at the same time. In this paper, we will report the present status of the KEK Linac upgrade in detail.

## INTRODUCTION

The KEK Linac provides the beams of the different modes sequentially with four storage rings (KEKB 3.5 GeV positron/ 8 GeV electron, Photon Factory (PF) 2.5 GeV electron and Advanced Ring for pulse X-rays (PF-AR) 3 GeV electron).

For a typical operation, the PF and PF-AR need the beam injection twice a day on scheduled time. On the other hand, the KEKB rings are operated by the continuous injection mode (CIM) for keeping the stored current almost constant. In the CIM operation, the switch time between the electron and positron modes takes about a half minute so that all settings of magnet power supplies, RF phases and timings should be changed according to the electron and positron beam properties. In the near future, the PF top-up operation will be started to enhance the integrated photon flux. For these reasons, the linac upgrade is strongly required for a fast beam-mode switch [1, 2, 3 and 4].

Figure 1 shows the schematic drawing of ultimate fast beam-mode switch operation. In this operation scheme, we will change only the minimum parameters of the timing signals and Low-Level RF (LLRF) phases, and all the rest of parameters like DC magnet settings are never changed even for the different beam-mode. In the final stage of the linac upgrade, the beam mode can be changed in every 50 Hz of an arbitrary beam-mode pattern.

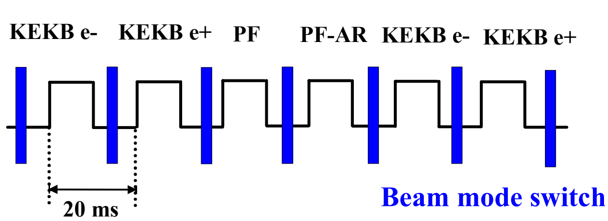

Figure 1: Schematic drawing of fast beam mode.

## UPGRADE PLAN

### *Outline*

This project is a phased upgrade, and the phase-I has been already completed in the summer of FY2005. The detailed upgrade phases are shown in following sub-sections.

### *Phase-I*

In the phase-I, the new PF-BT line has been constructed for shortening the beam-mode switch time between the KEKB and PF modes. Here, the initialization procedures of the energy compensation system (ECS) bends are required since the original DC switch bend was placed downstream of the ECS bends. In order to bypass the ECS, a new DC switch bend has been installed by removing four accelerating structures, and a new PF-BT line of 60-m-long has been constructed [5].

After the phase-I, the beam-mode switch between the KEKB and PF modes does not need to change the ECS parameters. The round trip mode switch time including PF injection was reduced by half from 5.5 min. to 2.5 min. In addition, the beam injection efficiency has been increased.

### *Phase-II*

The phase-II aims to perform the fast beam-mode switch between the KEKB electron and PF modes up to 50 Hz. For the phase-II and later, we will use the new operation scheme called “Multi-Energy Linac” [6 and 7]. In this scheme, the common magnet settings are used for the different beam modes. The adjustment of the beam energy is performed by a fast control of LLRF phase. Though PF ring injection requires the 2.5 GeV electron, the beam is accelerated up to about 5 GeV in the multi-energy scheme. After then, the beam energy is adjusted to 2.5 GeV by using the deceleration RF phases. This method is effective for enlarging the common optics region. The result of a preliminary machine study shows that this scheme is feasible for a realistic beam operation. In this autumn, the more detailed machine study will be carried out to develop the daily operation parameters.

### *Phase-III*

In the phase-III, the fast beam-mode switch will include the KEKB positron mode. In the current operation, the positron production target is controlled by a mechanical movement. For the fast beam-mode switch between the electron and positron modes, the positron target with a hole will be used. In this scheme, the fast beam-mode switch will be performed by a fast control of the electron beam orbit at upstream of the positron target.

The tungsten crystalline target with a hole has been installed as shown in Fig. 2. A centre of a hole is placed 4.5 mm apart from that of a crystalline tungsten target. The diameter of a hole is about 5 mm. The electron beam goes through the inside of a hole for the electron mode, whereas the electron beam hits the centre of target for the positron mode.

In the machine study, it was measured that almost 100% of the electron beam can traverse the inside a target hole in comparison with a normal operation (target removed). We convinced that this scheme is applicable to the practical beam operation. For a fast control of the beam orbit upstream target, the pulsed steering magnets have been installed in the winter of FY2007.

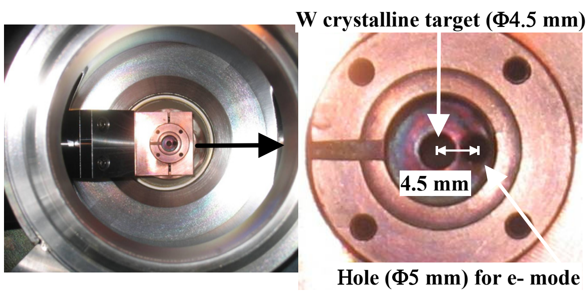

Figure 2: Photograph of tungsten crystalline positron production target with a hole.

### *PF-AR Injection*

The full energy injection of PF-AR is very difficult since the current beam energy at AR-BT is limited up to 3.1 GeV. One solution is to use the 3.5 GeV positron beam of KEKB positron mode for the PF-AR injection, though this scheme involves the installation of a pulsed bend and the improvement of two power supplies at the AR-BT line. In addition, all quadrupole magnets and vacuum chambers should be remodelled for increasing magnetic field. The detailed design study is now in progress, and its result will be reported elsewhere.

## PULSED BEND SYSTEM

For the fast beam-mode switch, the PF beam should be selectively kicked out toward the PF-BT by using the pulsed bend. The DC switch bend installed in the phase-I was replaced by the new pulsed bend system in the last winter maintenance. Table 1 shows the main parameters of the pulsed bend system. The photograph of pulsed bend is shown in Fig. 3.

Though the 2.5 GeV electron are used for the PF injection, the pulsed bend was designed for the beam operation up to 3 GeV. The maximum beam repetition is 25 Hz, and its output current has the half-sinusoidal shape of 200 μs. The both at long and short term stability of power supply output current was satisfied less than 0.1%.

The 1200-mm-long ceramic chamber has been also installed, and its cross-section is a race track-shaped. To avoid the heating, the inner wall of ceramic chamber was coated with 1-μm-thick Ti.

In the first week of February 2007, the PF top-up test operation has been successfully performed during single-bunch user operation. Figurer 4 shows the stored current stability of the PF ring. In this machine study, we can achieve the stability of $10^{-3}$ by using a newly installed slit at the PF-BT. The pulsed bend has worked well during the one week continuous operation without any problem.

Table 1: Main Parameters of Pulsed Bend System

| | | |
|---|---|---|
| Pulsed bend: | | |
| | Beam bending angle: | 7 deg. (up to 3 GeV) |
| | Max. magnetic field: | 1.36 T |
| | Gap: | 157 x 30 mm (W x H) |
| | Coil: | 1 tuen |
| Power supply: | | |
| | Max. current: | 32 kA (12.5 Hz) |
| | | 27 kA (25 Hz) |
| | Pulse width: | 200 μs (half-sinusoidal) |
| | Stability: | 0.1% |
| Ceramic chamber: | | |
| | Length: | 1200 mm |
| | Coating: | Ti (1 μm) |

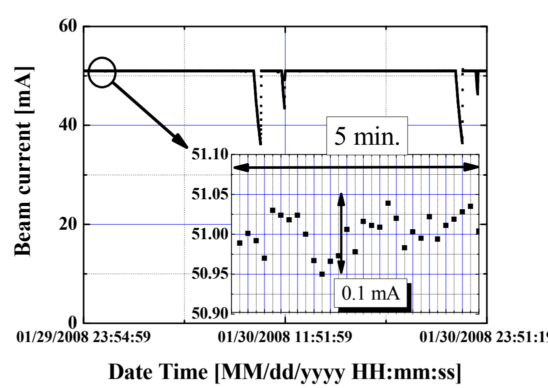

Figure 4: Stability of stored beam current at PF ring for single-bunch Top-up injection study.

## OTHER NEW SUBSYSTEMS

### *Beam-Charge Interlock System*

Toward the fast beam-mode switch operation, a new PLC-based beam-charge interlock system was developed for radiation safety [8]. This system restricts a regulated amount of integrated beam charges traversing through at several locations for machine protection, and it also monitors the amount of integrated beam charges delivered to the four different storage rings at the linac beam switchyard.

The beam charges delivered from an electron gun are measured with the beam-charge interlock system. This system consists of the wall-current monitors, beam-charge integration circuits, and a PLC-based control system. This system sends the beam abort signals directly to another radiation safety system with hard-wire cables when the amount of the integrated beam charges is beyond the prescribed threshold level. This system has been already used for a daily operation.

### *Timing System*

In the present timing system, about 150 timing delay modules based on VME-bus and CAMAC (TD4V/ TD4) are used for controlling the timing signals distributed to the many different types of local controllers. The timing system upgrade is indispensable since it is very difficult for the current system to realize a fast timing control.

The event generator and receiver (EVG/EVR) system based on VME64x-bus was adopted as a new timing system [9, 10, 11 and 12]. In the new system, one EVG and eleven EVRs are connected via optical fibre. The event information (beam-mode), RF clock (114 MHz), timestamp and data buffer can be quickly transferred from EVG to EVR. In addition, the number of used module for the timing system can be drastically reduced by using the EVG/EVR system. This can gratefully increase the reliability of timing system and beam operation. The operation software based on EPICS system has been already developed. One EVR and nine EVRs are already utilized for the beam operation. In the near future, the overall system test will be carried out for the practical operation after the two rest EVRs will be installed.

## SUMMARY AND FUTURE PLAN

The KEK injector upgrade aiming the fast beam-mode switch is in progress so that the KEKB CIM and PF top-up injection can be simultaneously performed. For this upgrade, the pulsed steering and bend system have been already installed. The almost part of new timing system works for a beam commissioning. In addition, many software development and update are going on. This upgrade will be very effective to increase the beam operation efficiency of KEK Linac. Eventually, the operational availability of each ring will be also greatly enhanced.

# PRESENT STATUS OF THE BEPCII LINAC

Pei Guoxi* for BEPCII-Linac Group
Institute of High Energy Physics, IHEP, Beijing, P. O. Box 918, 100049, China

*Abstract*

After the major upgrades in 2005, the BEPCII injector linac has been commissioning and working smoothly for more than two years. A 1.89GeV, 61.5mA positron beam at the linac end has been obtained, and the highest injection rate into the ring of 80mA/min. at 50pps is reached, much higher than the design goal of 50mA/min. The machine is working stably, and the mal function was only about 2% in the past two years, including the system test and the commissioning.

## INTRODUCTION

The BEPCII [1] is a factory type $e^-e^+$ collider with a luminosity of $1\times10^{33}\,cm^{-2}s^{-1}$ in the Tau-Charm energy region (2-5 GeV). On-energy injection scheme with an injection rate of > 50mA/min (almost twenty times of BEPC number) for $e^+$ beam requires the existing BEPC injector linac be upgraded with higher performance [2]. The BEPCII linac major upgrades were completed in 2005, and we got the first positron beam of ~50mA on March 19th. On December 23rd, 2007, an acceptance test group organized by the Chinese Academy of Sciences has fully checked the linac beam performance. The measured beam energy, current, emittance, energy spread, orbit and energy stabilities were well reached their design goals, as shown in Table 1.

Table 1: The Design and Reached Beam Performance

| | | Design | Reached |
|---|---|---|---|
| Beam Energy（GeV） | | 1.89 | 1.89 |
| Beam Current（mA） | $e^+$ | 37 | 66 |
| | $e^-$ | 500 | 550 |
| Emittance（1σ,μm) | $e^+$ | 0.40 | 0.35 (x) 0.27(y) |
| | $e^-$ | 0.10 | 0.097 (x) 0.079 (y) |
| Energy spread（1σ,%） | $e^+$ | 0.50 | 0.37 |
| | $e^-$ | 0.50 | 0.30 |
| Repetition rate (Hz) | | 50 | 50 |
| Beam orbit stability(mm) | | 0.30 | ≤0.15 |
| Beam energy stability (%) | | 0.15 | ≤0.05 |
| $e^+$ injection rate(mA/min.) | | 50 | 61.5 |

## OPERATIONAL STATUS

From October, 2006, up to now, the BEPCII only had two shut down time [3, 4, 5]. One was from early August to early October, 2007, which was for the BEPCII interaction region installation. We also took this chance to replace 5# RF unit's waveguide, which was badly damaged and confined the high power transmission. The other one was from March to May, 2008, for the BESIII installation. General speaking, in almost 20 months, the linac performance was excellent. The mal function including those happened at system test and commissioning time was only about 2%. The positron beam current at the linac end exceeded 60mA, which is good for a much higher injection rate. The injection rate of 61.5mA/min. listed in Table 1 was an average number. Actually, the peak value often reached 80mA/min. at 50pps as mentioned in the abstract, which indicates the injector linac's capability. The switch time for electron and positron modes change was less than 10 seconds. And the highest electron energy has reached 2.7GeV, so in the operation for the BERF early this year the top off injection at 2.5GeV with one RF unit stand-by has been adopted as shown in Fig. 1.

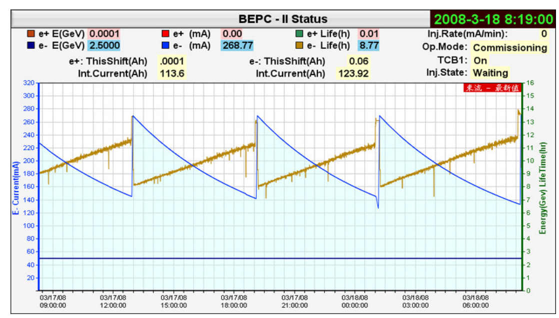

Figure1: The plot for top off injection.

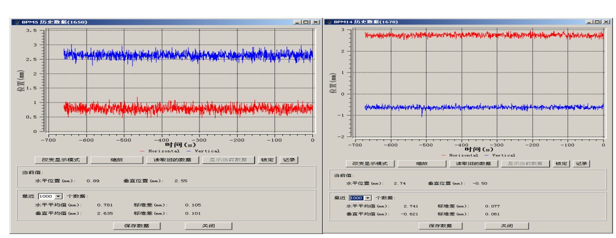
In what follows we will present some details concerning the beam as well as machine stability issues.

### *Beam Orbit Stability*

There are 19 BPMs along the linac. With these BPMs we can easily observe the beam position and the orbit stability. Figure 2 shows a good electron orbit at BPM5 and BPM14, the jitter is less than 0.1mm (1σ).



BPM5 BPM14

Figure 2: Beam position stability at BPMs 5 and 14.

### *Beam Energy Stability*

The beam energy stability can be measured by the BPMs located at a large dispersion region in the beam transfer line. Figure 3 shows the plot of beam position varied within ±1.0mm, seen by a BPM in the e- beam transport line, where the dispersion function is 2.0m. It indicated that the beam energy jitter was about ±0.05%, much smaller than the beam energy spread (±0.5%).

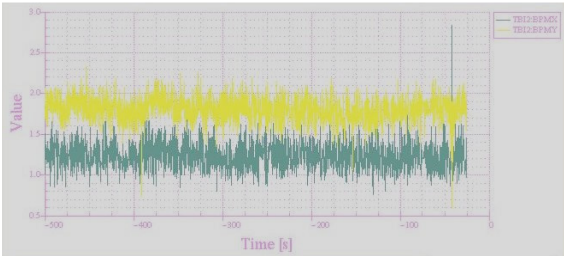


Figure 3: Beam energy stability.

Usually, the energy jitter comes from modulator's beam voltage pulse to pulse jitter, and the voltage stability within ±0.15% is essential. To reach the goal, a lot of measures have been used, including using a De-Qing circuit to stabilize the charging voltage, using a Thyristor voltage regulator with feedback control to stabilize the modulator DC voltage, and using a high precision stabilizer for the klystron filament.

### *The Problems Encountered*

1) The unit 5# RF system arcing was a BEPC times' problem, and because of the tight budget we didn't replace them during the BEPCII linac major upgrades while hoped the problem could be solved through high power processing. After several times processing both in 2006 and 2007, the problem was still there. In July 5~6, 2007 we made an experiment again to identify the arcing place, and found it was at a branch waveguide right downstream the 3dB high power splitter, not in the RF structures as guessed before by analyzing the RF waveforms at different places as shown in Fig. 4.

Figure 4: The schematic of unit $5^{\#}$ RF system.

2) In middle of December, 2006, a big beam orbit oscillation (8~10mm) was observed at TEBPM1, a BPM located at the dispersion region (2m) of the electron transfer line. Because no correlated orbit oscillation was found at other linac BPMs, so we identified it was an energy jitter. After many correlation experiments we found that the arcing of a directional coupler load at the RF drive line caused 6º phase jitter of the 6# and down stream RF units, which agreed well with the observed orbit oscillation at TEBPM1. Figure 5 is the correlation plot between the phase of the 6# RF unit and orbit oscillation at TEBPM1.

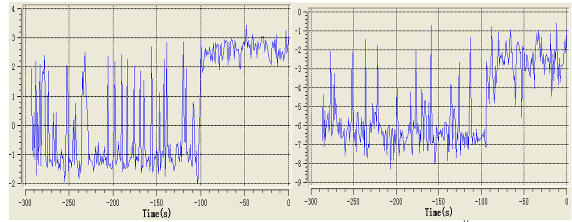

Figure 5: Correlation experiment plots of $6^{\#}$ phase jitter (left) and orbit oscillation at TEBPM1 (right).

3) In February, 2008, the machine worked at 5pps for the BSRF operation, and we found an energy jitter of 0.3~0.5% which came from linac, and electron energy was also lower than before. The phases and amplitudes of all the RF power sources, the timing system as well were checked with no problems. But when investigating beam voltage jitter at the first RF power source we found the RF pulse width was shorten because the modulator high voltage pulse was delayed by 0.7μs. The source was power line loose connection for the thyratron. After fixed the problem, the energy jitter disappeared.

4) Over Current Protection (OCP) sometimes occurred at the BEPCII modulators, which is a common problem for the conventional (resonant charging type) modulator, caused by continues conduction of the thyratron and will shut off main breaker of the modulator. The main causation of continues conduction is that it's difficult for a conventional modulator circuit to ensure enough recovery time for the thyrstron. For reducing thyratron continues conduction, normally we tune the reservoir voltage and operate it at lower gas pressure.

## FUTURE PLAN

The existing BEPCII bunching system consists of an S-band pre-buncher and a buncher, and beam pulse width from the gun is about 1.6ns (bottom width). So the linac is not single bunch operation, while with one main bunch and some satellite bunches. The satellite bunches are troublesome and make operation not clean, and cause the beam instability. The sub-harmonic bunching system can solve all these problems with higher transmission efficiency. Figure 6 shows the compassion between the present bunching system and the system with two SHBs. Except the solid state RF amplifiers are under test, almost all the system constructions are completed, and waiting for installation. Figure 7 shows the SHB cavity tuning at the laboratory, pre-installation and alignment. Figure 8 is the pictures of SHB RF amplifier under test.

Once the SHB system completed, we can hope to adopt the two bunch acceleration mode so as to double the injection rate into the ring. The pulse generator and timing system are ready.

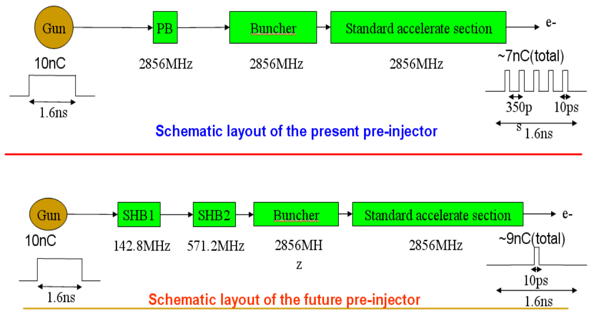

Figure 6: Bunching system compassion.

Figure 7: SHB cavity tuning (left) and system pre-installation (right).

Figure 8: Pictures of RF amplifier under test.

Recently, high energy physicists have interests in the energy region of 2.1~2.3GeV, and strongly request the BEPCII injector linac energy be upgraded to 2.3GeV. The design positron energy for the present linac is 1.89GeV, but can be increased up to 2.1GeV because of design margin. In order to realize 2.3GeV top off injection for positron beam, we need further upgrade the machine, and the simplest way is replacing four 50MW RF power sources with 80MW ones. The linac energy upgrade proposal has been submitted to Chinese Academy of Sciences, and waiting for approval.

## SUMMARY

In last two runs, the BEPCII injector linac worked excellently for both the BSRF operation and the ring commissioning. All the design goals have been reached and passed the acceptance test organized by the Chinese Academy of Sciences. The highest injection rate into the ring even reached 80mA/min. at 50pps, much higher than the design goal of 50mA/min.

The SHB system as one of the second phase upgrades is in progress, but a little bit delayed and missed the chance to be installed during last machine shut-down. Now the system is almost ready, and waiting for next chance installation, hopefully in 2009 summer shut-down.

## ACKNOWLEGEMENT

The work is supported by the BEPCII project headquarters. Thanks to all members of the BEPCII linac group for their great contributions to the successful linac upgrades and operations. Thanks also go to S.Ohsawa, K. Furukawa and T. Suwada of KEK for their helpful discussions on the beam instability issues.

# STATUS OF AN AUTOMATIC BEAM STEERING FOR THE CLIC TEST FACILITY 3*

E. Adli†, R. Corsini, A. Dabrowski, D. Schulte, S.H. Shaker,
P. Skowronski, F. Tecker, R. Tomas, CERN, Geneva, Switzerland

*Abstract*

An automatic beam steering application for CTF 3 is being designed in order to automatize operation of the machine, as well as providing a test-bed for advanced steering algorithms for CLIC. Beam-based correction including dispersion free steering have been investigated. An approach based on a PLACET on-line model has been tested. This paper gives an overview of the current status and the achieved results of the CTF3 automatic steering.

## INTRODUCTION

The Compact LInear Collider (CLIC) study has shown that advanced beam-based correction will be needed to reach nominal performance of several parts of the collider [1], [2]. The CLIC Test Facility 3 (CTF3) has been constructed at CERN in order to demonstrate feasibility of several key concepts of CLIC [3]. New areas are added to CTF3 for each new phase, making operation more complicated, and it is therefore of significant interest to ease the operation of this machine. The purpose of the work described here is thus two-fold:

- test of correction algorithms devised for CLIC on a real machine
- aid operation of CTF3 by automating beam steering (currently performed by hand)

## CORRECTION APPROACHES

The correction algorithms investigated here are "all-to-all" (A2A) and dispersion-free steering (DFS) [4]. In this paper we use "correction" and "steering" interchangeably. Both algorithms can be implemented using response matrices. Their effect when applied to a defined lattice segment is ideally:

- A2A: steers the beam to get BPM zero-readings, by simply inverting the response matrix of the nominal machine optics
- DFS: minimizes the difference of dispersive trajectories, using responses corresponding to optics with different $\Delta p/p$; weighted against A2A

Matrix inversion for both candidates is performed in the Least-Squares sense, using SVD. Smoothing can be introduced by taking out corrector modes corresponding to small singular values, effectively smoothing out noise effects. Furthermore, defect BPMs and/or correctors can be taken easily into account by zeroing rows and/or columns of the response matrix. A2A and DFS then find the global solution within the defined lattice segment (this is why we say "all-to-all" rather than "1-to-1").

For quick and effective correction computer model generated responses are needed. With model-based steering, one can perform all-to-all steering for a lattice segment in few tens of seconds. In comparison, to obtain machine responses in CTF3 takes from 1/4 h to 1/2 h per optics, per plane, totaling to hours if one wants to do dispersion-free steering. On the other hand, model-based steering require a good correspondence model/machine, and obtaining the needed model accuracy might be challenging.

## TEST-CASE: THE CTF3 LINAC

The CTF3 linac, characterized by operation with full beam-loading [5], was chosen as "test-lattice", because of higher applicability wrt. [1], [2]. We apply correction on a straight part of the linac, with regular lattice structure consisting of 11 girders ("nr. 5" to "nr. 15"), where each girder supports a quadrupole triplet, one corrector coil, and one BPM, as shown in Figure 1. For girders 5,6,7,11,12,13 and 15 there are in addition two accelerating structures, fed by one klystron, located between the corrector and the BPM.

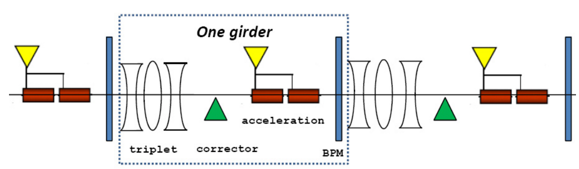

Figure 1: Structure of the CTF3 linac (not to scale).

### *Dispersion and Emittance Growth*

Dispersion measurement and DFS were in this work performed by scaling magnet currents. We therefore consider only dispersion building up from the start of the test-lattice (we do not consider, and cannot mitigate, upstream dispersion). There are no powered dipoles in the test-lattice, so the dispersion comes mainly from parasitic dispersion due to quadrupole offsets (we also get a small contribution from the correctors, dispersion due to incoming beam offset/angle and due to transverse wakes). We note that our 11 cell lattice accomodates little more than a single betatron-oscillation, and we therefore expect dispersion to be small, even for the uncorrected case (no resonant build-up possible). The CTF3 component alignment tolerance is 100 $\mu$m

† Erik.Adli@cern.ch, University of Oslo and CERN

rms. PLACET simulations estimate the resulting dispersion growth to 5 mm (rms of 100 seeds). By simulation we estimate emittance growth without correction, assuming a bunch-length of 1.6 mm and an initial normalized emittance of 100 $\mu$m, to be in the order of percent, and an ultimate test of DFS would be to compare emittance growth before and after correction.

## MODEL IDENTIFICATION

A linac model implemented in PLACET was to be used for the model-based correction. It was decided to verify and eventually improve the model before using it for steering. An attempt to use "LOCO-type" global identification [6] was initiated (not applied to the linac before), and a new identification code was written in Octave for this purpose. Improvement of the model with this method turned out to be difficult because of the triplet cells (see below) combined with imprecise response measurement (the same response point was found to vary up to 10% rms, due to beam jitter, different working points, hysteresis etc).

### *Triplet Cells*

The linac focusing is done with quadrupoles in triplets, powered 2+1 or 1+1+1, with a single BPM and corrector per triplet cell (see Figure 1). The similarity of difference orbit when changing either of the outer quadrupoles, as well as almost opposite orbit of the middle quad, leads to near degeneracies which becomes difficult to resolve with imprecise data. Quantitatively we see this by error propagation through the covariance matrix $(\frac{\partial E}{\partial K}^T \frac{\partial E}{\partial K})^{-1}$ [7]; inputting the imprecision of the response points, the standard uncertainty of the parameter estimates is for many of the quadrupoles of the same order as the parameter itself, even when disregarding the first few triplet cells (the least constrained ones). As comparison, with quadrupole currents frozen, the uncertainty of the corrector gains is $\sim 1\%$. The phase-difference between model and machine was shown to be reasonable small by direct SVD analysis, and it was therefore decided to go on with quadrupole parameters frozen. The trustworthiness of individual corrector gain identification with quadrupoles frozen is not clear, and therefore the only parameters fitted before correction was global scaling + the ratio of the calibration factor of the two different corrector types in the test-lattice.

### *Requirement for Model-machine Correspondence*

After identification we still have a certain mismatch between model and machine. We want to estimate, by simulation, the error accepted on the model parameters while still achieving adequate correction. To study this, A2A was applied to a perturbed model using ideal model responses. Each quadrupole strength was randomly scaled by an rms value of $\sigma_{\Delta k}$ %. The maximum resulting BPM readings after 5 iterations of A2A, averaged over 100 machines, are shown in Table 1. For strength rms error of up to 12%, A2A still converges to BPM readings $< 100\mu$m (Perfect BPMs were assumed for these simulations).

Table 1: Correction Convergence with Model Discrepancy

| $\sigma_{\mathbf{\Delta k}}[\%]$ | 4 | 6 | 8 | 10 | 12 | 14 | 16 | 20 |
|---|---|---|---|---|---|---|---|---|
| **y [mm]** | 0 | 0 | 0.02 | 0.04 | 0.1 | 0.3 | 0.7 | 3.6 |

## CORRECTION RESULTS

### *All-to-all*

Using machine responses both planes were corrected to within 0.15 mm rms in two iterations (this illustrates some imprecision in the machine responses and/or machine jitter). Then, correction was performed using responses calculated from the PLACET model. The calculation of the responses takes less than 5 seconds. Both planes did converge, but needed up to to four iterations before reaching the convergence criterion, showing that the model of the linac is not perfect but good enough for steering. Each iteration takes from 10 to 20 seconds, depending on whether a corrector has to switch polarity or not.

Non-functioning correctors or BPMs can be taken into account by first identifying them (e.g manually or from machine responses). A device is disregarded by the algorithm by simply setting the corresponding row or column to zero. One corrector was very unreliable during this work (DVD1420), and was turned off and the corresponding column set to 0. The resulting system is under-actuated (10 correctors and 11 BPMs), and instead of trying to achieve zero BPM readings A2A finds the least-square solution. The result after model-based A2A correction, with one defect corrector in the vertical, is show in Figure 2. The oscillatory pattern in the vertical corresponds to the uncorrectable BPM mode, belonging to the zero singular value which is due to the defect corrector. Dispersion after A2A steering was measured to less than 5 mm (error margin of about 0.5 mm). This is comparable to dispersion measured after manual correction of the machine. We conclude that model-based all-to-all correction seems to work well, is reasonably fast, and robust wrt. corrector or BPM defects.

### *Dispersion Free Steering*

Since A2A correction gives a very small residual dispersion (showing reasonably small misalignments), we do not expect to improve this result, given the beam jitter and limited BPM resolution of 10 $\mu$m. As test-case we instead *simulate* misalignment of 3-6 mm for a few BPMs. A2A will now steer the beam into the simulated centre, creating a position bump in the real trajectory. The red line of Figure 3 shows the position bump (the plot shows *real* BPM readings, as opposed to the readings with *simulated* misalignments that the correction algorithm sees). This bump increases the local dispersion by a factor 3, up to 15 mm, as shown in red in Figure 4.

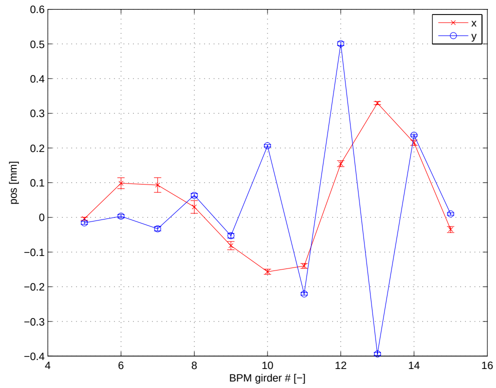

Figure 2: Model-based A2A (BPM readings for both planes).

One of the salient features of dispersion-free steering is that absolute BPM position readings are mostly disregarded, and instead difference readings are used to minimize the difference of dispersive trajectories. We therefore expect a successful DFS to find an orbit with smaller dispersion than A2A, while being mostly oblivious to the simulated BPM misalignment. However, the performance of the DFS depends on the precision with which the difference orbit can be obtained. We had dispersion of $\sim 10$ mm and a dispersion measurement precision of $\sim 0.5$ mm for $\Delta p/p = 10\%$, with present machine conditions. It was therefore not straightforward to find a good solution for DFS, but after substantial trials with different weighting wrt. the zero-reading ($w_1/w_0$=10 used), different SVD-cuts (70% used) and different $\Delta p/p$ (0.2 used), solutions were found that clearly indicates how the dispersion and position bump is reduced, shown in blue in Figure 3 and 4. The BPM readings including the simulated misalignments (seen by our correction algorithms) would show a large bump after the DFS, giving operators indications of large BPM misalignment. Finally, we note that applying DFS without simulated BPM misalignment gave similar performance as with these misalignments.

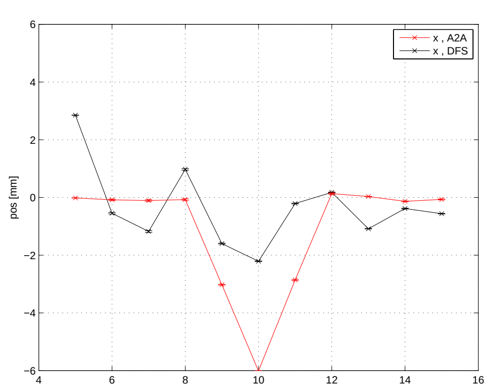

Figure 3: DFS versus A2A (*real* BPM readings after correction).

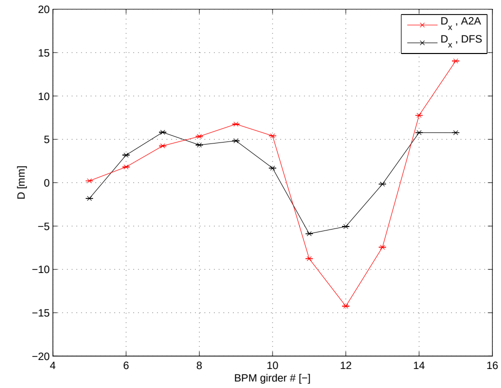

Figure 4: DFS versus A2A (dispersion after correction).

The initial large offset after DFS is due to incoming beam offset/angle (reproduceable in simulations). Machine-based responses were used for the dispersion-free steering. The results show that when dispersion is significant after A2A correction, for instance due to large BPM misalignment, DFS can provide a solution with lower dispersion and at the same time indicating the source of the problem. However, as correction algorithm for CTF3, DFS does not give a clear advantage over A2A.

## CONCLUSIONS

The triplet structure impeded further model improvement. Model-based A2A has been applied successfully in a robust way to the CTF3 linac. DFS performance was superior to A2A in a test-case with artificially large BPM misalignment. However, for nominal linac operation we recommend A2A because of its faster execution.

## ACKNOWLEDGEMENTS

# DESIGN OF THE TAIL CLIPPER COLLIMATOR FOR CTF3

R. Chamizo, H. H. Braun, N. Chritin, D. Grenier, J. Hansen, Y. Kadi, L. Massidda, Th. Otto, R. Rocca, R. Zennaro, CERN, Geneva, Switzerland.

*Abstract*

The CERN CLIC Test Facility (CTF3) aims at assessing the feasibility of the future multi-TeV Compact Linear Collider (CLIC). The CTF3 Tail Clipper Collimator (TCC) will serve to adjust the bunch train length of the beam extracted from the combiner ring, in combination with a fast kicker magnet. In addition, the TCC will operate, when required, as an internal beam dump. The challenge of the TCC design is to meet the requirements of both collimation and dump operational modes for a low energy $e^-$ beam (100-300MeV) of 35A peak intensity. The TCC collimator will be installed in January 2009 in the TL2 transfer line of CTF3. This paper describes the final design of the TCC and the main issues related to its integration in the line.

## INTRODUCTION

The CTF3 facility [1] is a demonstrator of the technical feasibility of the key concepts of the novel CLIC RF power source, e.g., generation of high-charge, high-frequency electron bunch trains by beam combination and operation with a fully-loaded drive-beam accelerator. The CTF3 facility includes a 70 m long linac followed by a 42 m delay loop, an 84 m combiner ring (CR) and a CLic EXperimental area (CLEX). The TCC is a combined collimator/dump and will be installed in the transfer line from the CR to the CLEX. It will serve to shorten the pulse length of the accelerated beam for 12 GHz RF generation in the CLEX (collimation mode). A fast kicker magnet [2] will deflect vertically an adjustable fraction of the pulse length. The TCC will absorb the deflected pulse while the rest will be transferred to the CLEX. The TCC will also serve to intercept the full beam (dump mode) for safe installation work in the CLEX. The main beam parameters considered for the design of the TCC are summarized in Table 1.

Table 1: CTF3 Beam Parameters Relevant for the TCC Design

| | | |
|---|---|---|
| Particles | $e^-$ | |
| Beam energy @ TCC | 150 | MeV |
| Repetition rate | 0.8 – 5.0 | Hz |
| Incoming pulse duration | 140 | ns |
| Peak beam pulse current | 35 | A |
| Beam size range (rms, 1σ) | σh=2-5; σv=1 | mm |
| Beam deflection @ TCC | >6 | mm |
| Average beam power | 3.7 | kW |

## THE TCC DESIGN

### *Thermo-Mechanical Considerations*

The dump mode of the TCC represents the most demanding case of operation from the thermo mechanical point of view and it has been considered as the determining condition for the design. The TCC will intercept a 150MeV $e^-$ beam of average power equal to 3.7kW. In the collimation mode, the absorbed power will be less than this.

In order to determine the most appropriate material for the TCC jaw, detailed studies with the Monte-Carlo code FLUKA were performed for assessing the amount of energy deposited on the TCC. Fig. 1 shows the temperature profile (instantaneous) in the jaw after one pulse impact (beam: 150MeV, 5 pulses/s, 3.7kW) for Aluminium, Graphite and Glidcop® jaws.

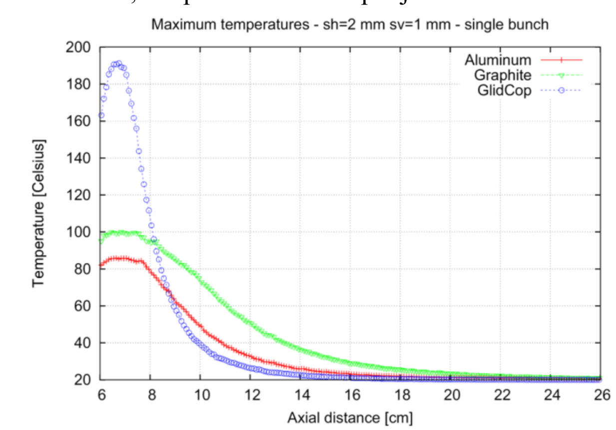

Figure 1: Temperature profile in the TCC jaw after one pulse impact for the studied materials.

Previous thermo-mechanical studies [3] have concluded that, structurally, the most critical case of impact occurs during an impact placed below 1.3mm from the jaw surface. The thermal loads calculated with FLUKA were given as input to an ANSYS® FE model of the TCC jaw, reproducing this particular case. The results obtained are summarized in Table 2.

Table 2: Temperature and Internal Stresses Obtained by ANSYS Simulation for the Studied Materials

| $e^-$ beam (σh=2 - σv=1, mm), 150Mev, 3.7kW, 5 pulses/s | Al | Glidcop | Graphite |
|---|---|---|---|
| Yield Strength (MPa) | 55 | 255 | 30 |
| ΔT (140ns) (ºC) | 58 | 166 | 78 |
| Maximum stress (140ns) (MPa) | 79 | 265 | 2 |

The instantaneous increase of temperature (ΔT) due to the pulse impact originates high internal stresses in the jaw. Graphite was considered as the most convenient material for the jaw since the maximum stress is well below the yield strength value.

### The Active Part - Jaw

The active part of the TCC will be made of a high-density graphite jaw held inside a water-cooled copper vacuum chamber. The high outgassing rate of graphite makes it critical to limit its increase of temperature in order to respect the vacuum requirements of the line ($10^{-8}$ mbar).

A first solution with the graphite block shrink-fitted inside the copper was considered too risky. In fact, in order to limit the temperature increase and avoid dangerous internal stresses in the graphite, the tolerance of the shrink fitting obtained by a coupled thermo-structural simulation in ANSYS was in the range of 10-20μm. A hypothetical sudden thermal contact between graphite and copper could compromise the integrity of the graphite due to the high internal stresses generated by the thermal gradient. An alternative solution was selected, forcing a gap between the graphite and copper and creating a continuous thermal contact by means of a copper foil acting as a spring. Fig. 2 shows the design of the active part of the TCC.

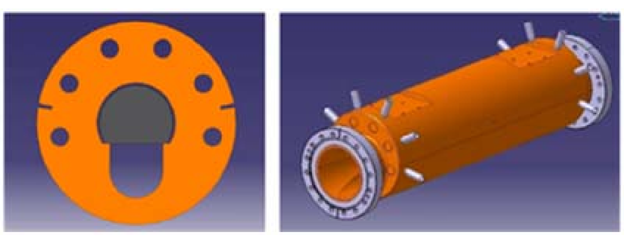

Figure 2: Front view (left) and isometric view (right) of the active part of the TCC.

Even though the thermal contact is not as efficient as a direct contact, the temperature of the graphite will be well under control. The maximum temperature in the graphite is 112°C (in steady state) as shown in Fig. 3.

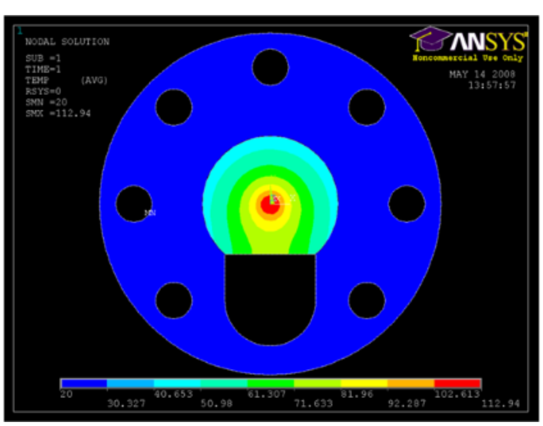

Figure 3: Temperature distribution in TCC active part during dump operation.

### Wakefield Calculation

The possible presence of wake fields induced by the beam passing through the TCC has been computed with GDFIDL [4], which provides the time domain computation of a wake generated by a single bunch. By combining the results with the appropriate delay it is possible to see if a multi-bunch beam could generate a build-up of the wake; see Fig. 4.

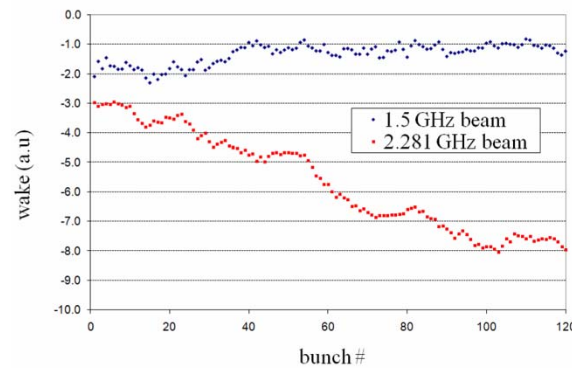

Figure 4: The wake seen by different bunches. The value for bunches with a spacing of 1.5 GHz (real operation) is constant. An artificial bunch frequency of 2.281 GHz served to validate the method; in this case the build-up is evident.

For a frequency of 1.5 GHz or multiples the wake does not build up. A successive FFT of the wake has provided the impedance of the device, and no indication of a resonance at a multiple of 1.5 GHz has been found. Anyhow the presence of a dipole mode at 2993 MHz required a careful study. The impedance of the mode (R=300 Ohm) was computed with HFSS [5]. For a 3 GHz beam of 100 MeV and a current of 35/4 A the normalized transverse kick induced by this mode is only 0.06 mrad.

### Actuator System

In the collimation mode, the jaw must be movable, in the vertical plane (plane of deflection of the beam), between +20 and -10 mm, with respect to the reference beam trajectory. In the dump mode, the jaw must completely block the beam aperture. In addition, the TCC is a fail-safe mechanism and the dump position can be reached by cutting the electrical current.

The TCC is supported by two movable tables that provide the movement range needed for the collimation and dump modes. The upper table enables the movement for the operation in the collimation mode. The movement is provided by a stepper motor connected to three screw jacks. The motor system gives a positioning accuracy and resolution well within the TCC specification (0.3 and 0.1 mm respectively). The displacement is also monitored by one potentiometer that will serve to detect any motor failure. A pneumatic cylinder attached to the lower table lifts the ensemble to the collimation mode position (up). For dump operation, the compressed air inside the cylinder is released and the TCC reaches the dump position (down) by its own weight.

End switches and mechanical stops limit the maximum and minimum ranges of movements for both collimation and dump operation.

## INTEGRATION ISSUES

A detailed FLUKA simulation of the operation in dump mode (150MeV e- beam, 3.7kW, 5 pulses/s) was performed in order to study the effect of the radiation on other components of the beam line.

The TCC will be installed 50cm upstream of a set of quadrupole magnets. Experimental results [6] show an important degradation of the mechanical properties of the insulating resin (Araldite) used in the manufacturing of the quadrupole coils when irradiated above 3MGy. The FLUKA analysis concluded that the absorbed dose in the quadrupole was mainly due to photons. Although the average energy of photons and neutrons are of the same order (9.7MeV for photons and 1.8MeV for neutrons), the fluence of photons at 5Hz is four orders of magnitude higher than that of neutrons ($10^{15}$ $cm^{-2}s^{-1}$ for photons, while for neutrons is $10^{11}$ $cm^{-2}s^{-1}$). The predicted absorbed dose in the quadrupole magnet was equal to 27MGy after one-year operation (1000 hours at 5 Hz), much higher than the absolute limit of 3MGy.

In order to preserve the integrity of the quadrupole, a combined internal-external shielding of the TCC was foreseen. Inside the TCC assembly, a copper block, as shown in Fig. 5, will shield the graphite jaw.

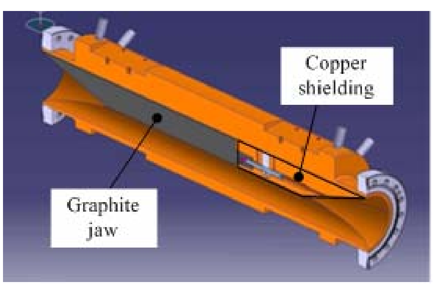

Figure 5: Final bi-material jaw of the TCC.

Fig. 6 shows the final layout of the TCC in the TL2 line of the CTF3 facility.

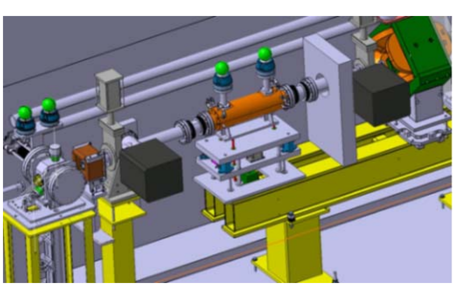

Figure 6: Layout of the TCC in the CTF3 facility.

The external shielding will consist of a 10cm lead plate placed between the TCC and the quadrupole magnet. The predicted absorbed dose in the quadupole in this configuration is equal to 0.1MGy, much lower than the mentioned threshold (Fig. 7).

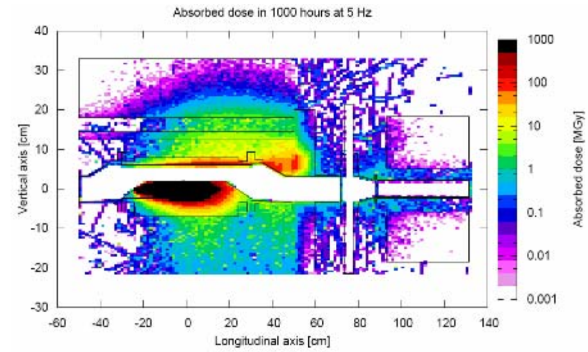

Figure 7: Absorbed dose in the TCC and downstream quadrupole after internal and external shielding.

In addition, the analysis of the ambient dose equivalent rates [7] in the accessible areas surrounding the facility led to the design of an iron local shielding that will fully enclose the TCC in order to respect the radiation protection regulations.

## CONCLUSIONS

The TCC will be installed in the CTF3 facility by January 2009 and it will operate in both collimation and dump modes with a 150MeV e- beam of 35A peak intensity. The design of the active part responds to the thermo-structural constraints for both operation modes. The design intends to minimize any degradation of the vacuum quality in the line due to the outgassing of the graphite during the beam impacts. Additional aspects concerning the integration of the TCC in the facility and the impact on the surrounding equipments during its operation have been treated. The adopted multi-shielding solution guarantees the integrity of the equipments and respects the radiation protection regulations in the adjacent accessible areas.

## ACKNOWLEDGEMENT

The authors would like to thank L. Bruno, A. Ferrari, C. Kharoua and K. Samec for their helpful discussions.

# THE 150 MeV PULSE ELECTRON LINAC WITH 1 mA AVERAGE CURRENT*

M.I. Ayzatsky, A.N. Dovbnya, V.N. Boriskin, I.V. Khodak, S.G. Kononenko, V.A. Kushnir, V.V. Mytrochenko, S.A. Perezhogin, Yu.D. Tur. Kharkov, NSC/KIPT, Kharkov, 61108, Ukraine

*Abstract*

The project of the accelerator driven subcritical assembly facility is under development in the National Science Center "Kharkov Institute of Physics and Technology". The important component of the facility is an electron linac with the particles energy of 100…200 MeV and average beam current of 1 mA. In this paper we focus on the S-band electron linac design. The accelerator scheme includes the injector based on evanescence waves, RF chopper, five accelerating structures and energy compression system. The calculation results of accelerating structure performances and linac systems are considered in the paper.

## INTRODUCTION

The developing facility consists of the linac, the system of the beam transport to the target complex, the neutron-producing target and the subcritical assembly of the fuel elements.

Using of the linac as the subcritical assembly driver makes a number of demands. The electron energy at the linac exit must be 100-200 MeV. On the one hand, it provides rather high yield of the neutrons, and on the other hand - the volume of the neutron target will be large enough for the energy density decrease and the target cooling conditions improve. The existing high-frequency linac power supplies and the injector systems allow obtaining the average current at such linac exit in the necessary electron energy range near 1 mA. Considerable average beam power (about 100 kW) obviously demands minimizing the high-energy particles loss during their acceleration and transport.

## THE FACILITY POSITION AND STRUCTURE

The linac will be placed in the building of the linac LU-2000 in NSC KIPT. Such placing of the complex doesn't need the new fundamental construction, allows using the existing engineer infrastructure after its major reconstruction. The existing power system allows power supplying of all systems of the linac. New equipment placing is possible after the demounting of the existing equipment. The accelerating sections of the developing linac will be placed after the 36$^{th}$ section of the linac LU-2000. The layout of the linac main parts is presented in Fig. 1.

The accelerator itself consists of the electron source, injector (I), five S-band accelerating sections (1s-5s) and the system of energy compression (SEC). The system of energy compression includes the debuncher (D) and the compensation accelerating section (CS). At the accelerator exit there are placed the magnetic electron energy analyzer (M1) and the dipole magnet (M2), providing the electron beam injection into the transport system to the target complex. The main elements for the beam focusing are the short solenoid on the first section (S) and the doublets of the quadruple lenses, placed on each section. The beam current transformers and the beam position monitors will be placed after the injector and each section exit.

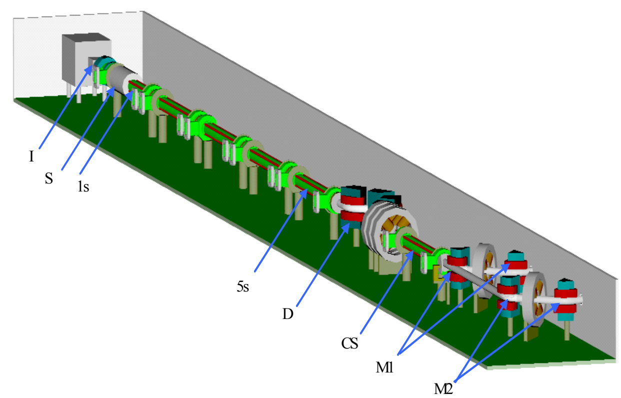

Figure 1: Placing of the accelerator main elements.

The accelerator RF power supply system is planned to be created at the base of six klystrons SLAC 5045 (produced by SLAC, USA). Proceeding from the average beam power 100 kW, the current pulse repetition rate and the pulse duration are chosen 300 pps and 3.0 µs respectively. In this context the standard mode of the klystron SLAC 5045 will have to be changed (see Table 1).

Table 1: Klystron parameters

| Parameter | Standard mode | Required mode |
|---|---|---|
| RF frequency, MHz | 2856 | 2856 |
| Pulse repetition rate, pps | ≤ 180 | 300 |
| Max. pulse RF power, MW | 67 | 29.9 |
| RF pulse duration, µs | 3.5 | 3.2 |
| Average RF power, kW | 37 | 31.2 |

* Work supported by STCU project P233

## INJECTOR

One of the main conditions of obtaining the minimal energy electron spread at the accelerator exit is the demand of the length and form of the electron bunch, formed in the initial part of the facility – in the injector. We suppose to use the bunching system on the evanescent oscillations [1]. The prototype injector for the developing linac is the accelerator electron injector for the storage ring H-100M [2]. According to the calculations and the preliminary testing of the injector prototype such system allows to form effectively the electron bunches at the pulse current up to 1.5 A and at energy of particles of about 1 MeV.

The code POISSON/SUPERFISH [3] has been applied for the calculations of the injector resonance and magnet system characteristics. The particle dynamics in the bunching system has been simulated using PARMELA code [4]. The electron injector (see Fig.2) with operating frequency 2856 MHz provides the minimal bunch phase size at the minimal energy spread and the electron current up to 1.5 A at the injector exit.

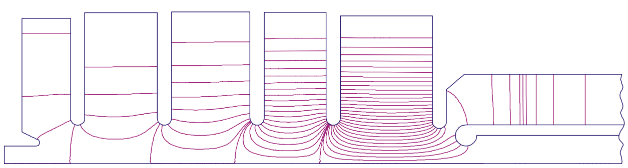

Figure 2: The injector resonance system geometry and the longitudinal RF electric field distribution.

The simulation has been held taking into account space charge forces for the electron beam with the initial energy 25 keV and the current 1.2 A. To decrease the radial beam size the injector is equipped with a solenoid. At the pulse current 1.07 A at the bunching system exit the beam has the following parameters: normalized emittance ($1\sigma$), $\varepsilon_{rms\ x,y}$=21 mm·mrad; phase spectrum width $\Delta\varphi$=9.8° (for 70% of the particles); energy spread $\Delta W/W$=6.3%, (for 70% of the particles); energy at the spectrum maximum W=1.2 MeV; beam size d=1.55 mm. The phase-energy electron beam distribution at the injector exit is shown in Fig. 3.

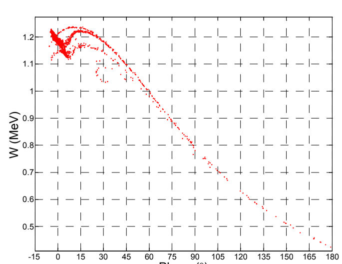

Figure 3: The phase-energy particle distribution at the injector exit.

However, in the interval between the bunching system and the accelerating section the bunch phase duration is increased. At that the phase distribution of the particles has the extended "tail". As the numerical simulation has shown, those periphery particles form the energy halo. That's why it is important in this case to apply the additional methods for the phase compression or phase selection. After the analysis we have considered the possibility to use the chopper system [5, 6]. This system is composed of a RF cavity, a drift tube and a collimator. The most simple is to use the cylindrical cavity with the $TM_{110}$ mode. We have carried out the numerical simulation of the particle motion in the injector system with such chopper. It is shown (see Fig. 4) that using of that device allows to decrease substantially extension of the "tail".

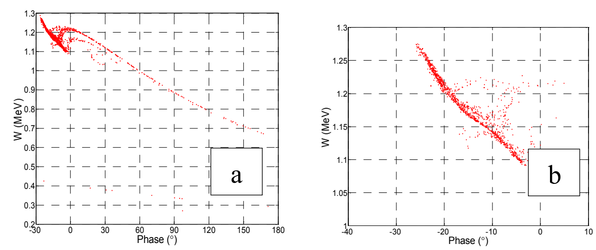

Figure 4: The phase-energy particles spread at the input of the first accelerating section without chopper (a) and with chopper (b).

In general, the main disadvantage of this method is the increase of the transverse beam emittance. However, if during the bunch forming the particles motion in different phase planes is connected, the inverse picture can be observed – in the chopper the particles with bad radial characteristics are also chopped off. Thus, in our case, the particle losses are 29.4% of the particles at the injector exit and the decrease of rms emittance of the chopped beam in a beam scanning plane up to 12 mm·mrad is observed.

## ACCELERATING SECTIONS

The accelerating system of the accelerator includes five accelerating sections, where the electron beam with the pulse current up to 1 A, pulse duration 3 µs and the repetition rate 300 pps should gain energy about 150 MeV. When choosing the section parameters the simulation of the particle dynamics in the injector and the sections in the steady state mode has been carried out with the PARMELA program. On the base of simulation the homogenous travelling wave accelerating structure with the $\pi/2$ phase advance per cell has been chosen. The length of each of five accelerating sections and the filling time are 4.15 m and 0.368 µs respectively, shunt impedance is 52.8 MOhm/m, attenuation is 0.088 1/m, Q-factor is 11200. For suppression of BBU the radial slots in the accelerating wave-guide irises will be used. The length of the slots and their orientation will vary along the accelerating section. At the supplying RF power for each section of 28.8 MW the electrons energy at the fifth section exit is 154 MeV at the pulse current 0.75 A. The other parameters are shown in Table 2.

To decrease the energy spread there has been settled the system of energy compression at the fifth section exit. It consists of the «magnetic chicane» type debuncher and the additional accelerating section. For the correct operating of such device at the accelerator exit

Table 2: Beam parameters at the fifth section exit

| | d, mm | $\varepsilon_n$ mm·mrad | $\Delta\varphi$° | $\Delta W/W$ % |
|---|---|---|---|---|
| 70% of particles | 1.4 | 15 | 14 | 4,9 |
| 99% of particles | 3.3 | 170 | 24 | 8 |

there has been formed a special phase-energy electron distribution. The preliminary calculation of the system of energy compression (SEC) has been carried out with the MADX program [7]. The final calculation of SEC and the accelerator as a whole has been carried out with the PARMELA program. The simulation results are presented in Fig. 5.

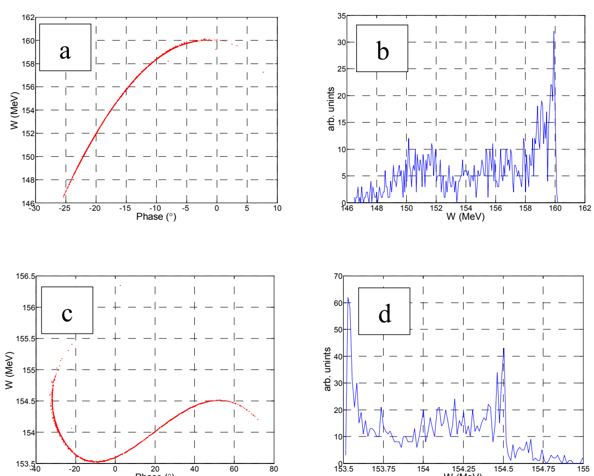

Figure 5: Phase-energy distribution and the energy spectrum at the fifth section exit (a, b) and the SEC exit (c, d).

It is seen, that SEC allows to decrease the energy spread of 99% of the particles from 8 % to 0,7% . At that the normalized emittance of the beam doesn't exceed 180 mm·mrad, and the beam loss are absent in that system. At the same time it should be noted that the work of that system taking into account the beam loading of the compensating accelerating section needs further study.

## BEAM MONOCHROMATIZATION IN THE TRANSIENT MODE

The beam energy spread as a whole is determined by both the acceleration steady state mode (considered above) and the beam loading effect. Decrease of influence of transient has been achieved by the selection of the optimal current pulse delay relative to RF pulse. As the results of the calculations we have obtained the optimal values of the pulse delay time for each of five sections: 0.399 µs, 0.323 µs, 0.23 µs, 0.139 µs, 0.045 µs. From the calculation results (see Fig.6) it follows that the particles accelerated during the transient (about 15% of all particles) have the energy spread at the linac exit less than 1%.

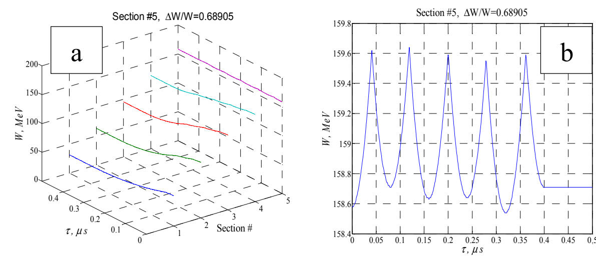

Figure 6: Electron energy during the transient at each section's exit (a) and at the accelerator exit (b).

## SUMMARY

Researches on design of the high power pulse linac for the neutron source on the base of a subcritical assembly is under way in NSC KIPT. The simulation results show that the chosen accelerator scheme allows obtaining the beam with the required for the facility work parameters: W=154 MeV, $\Delta W/W<1\%$, $P_{cp}$ =104 kW.

# INJECTOR OF INTENSE ELECTRON BEAM

M. Ayzatskiy, V. Mytrochenko NSC/KIPT, Kharkov, 61108, Ukraine

## ABSTRACT

The results of beam dynamic simulation in a S-band injector that can be used for creation of the powerful electron linac are presented in the report. The injector consists of a diode electron gun with beam current of up to 2 A at energy of electrons of 25 keV, the klystron type prebuncher and the three cavity buncher. In the buncher, due to the special choice of eigen frequencies of resonators, maximal amplitude of the field on the axis of resonators exponentially increases from the first (downstream of the beam) resonator to the last resonator. It allows to realize an effective bunching the intensive electron beam and accelerating it to relativistic velocities. For achievement a low transversal beam emittance the injector is placed into the external magnetic field. The injector provides more than 1 A of beam current with particle energies of about 1 MeV. Attention is paid to research of transients and stability of injector work.

## INTRODUCTION

Often it is necessary to provide ampere range beam at an exit of the pulsed electron S-band linacs with high beam power because a duty factor of pulsed klystron amplifiers is about 0.1%. Use of relatively low voltage electron guns (several tens of kilovolts) in a linac injector facilitates obtaining high reliability of the linac at compact linac dimensions. Bunching system based on evanescent waves (see for example [1]) is very suitable to generate electron bunches from continuous beam emitted from a cathode of such low voltage gun as well as to accelerate particles to relativistic velocities. The above mentioned bunching system comprised of five cells has exponential rise of on-axis field from the entrance of the electron beam into the buncher to the it exit. This rise is provided by correspondent choice of cell dimensions. To provide flexibility of the system at bunching and accelerating of the ampere range electron beam it was decided to change the first two cells of the buncher with a klystron type prebuncher and drift space. To prevent degradation of transversal beam emittance the prebuncher and buncher are placed into solenoidal magnetic field. This paper is devoted to brief description of simulation algorithms of beam dynamics in a system comprised of the prebuncher and the three cell buncher as well as to review of simulation results.

## SIMULATION ALGORITHMS

The POISSON/SUPERFISH [2] group of codes was used to calculate characteristics of resonance and magnetic systems of the injector. Simulation of electron motion in the injector was performed using the PARMELA [3] code. Beam parameters of the ampere range diode gun [4] was calculated with EGUN [4] code. Study of unsteady self consistent beam dynamics in the injector were performed both with technique [6] and with developed by us program COUPLRES. Technique [6] solves self-consistent equations of field excitation in axially symmetrical cavities both by an electron beam and by an external RF generator. The PARMELA code is used in this technique to simulate particle motion in evaluated field to get needed data at each temporal step of the equation solution. This technique takes into account only one mode of a cavity field.

COUPLRES (COUPLing RESonators) allows to describe unsteady processes arising at interaction of electron beam with electromagnetic systems that can be represented as a chain of coupled cavities. This code is elaborated on a base of mathematical model that is development of the coupled cavity model by correct taking into account self-consistent beam dynamics in fields excited both by external sources and by particles itself. At the moment the model takes into account only fields that are symmetrical relatively the main direction of beam propagation. The base of the model is decomposition of a considered electromagnetic system into closed volumes and representation of fields inside of the volumes as an expansion into a series of eigen functions (solenoidal and potential) of closed cavities. Particles are injected into a simulated system at certain moments of time. A set of equations to be analyzed consists of particle motion equations and equations for expansion amplitudes (differential equations for basic oscillations and algebraic ones for non-resonant modes).

A developed variant of the code is applicable to describe systems that can be decomposed into cylindrical volumes. In this case there are analytical expressions for the eigen functions. The Runge-Kutta method is used to solve both equations of motion and equations for amplitudes of basic oscillations. At solution of the last equations values of current and charge integrals are kept constant over RF period of the fundamental frequency. Quasi-coulomb fields are represented as expansion into series of solenoidal and potential functions and are evaluated at frequencies $\omega \approx 0$ and $\omega \approx \omega_0$, where $\omega_0$ is frequency of a RF source.

The merit of the code is a possibility to take into account influence of all eigen modes at simulation of time beam dynamics. This feature allows to make an analysis of injector operation stability at bunching and accelerating of intense electron beams.

## SIMULATION RESULTS

Simulations were carried out to attain two aims. On the one hand in was necessary to find configurations both the resonance and magnetic system of the injector that provide effective bunching of the ampere range electron beam at minimal degradation of the transversal emittance. On the other hand stability of the each considered configurations against excitation of parasitic oscillation in the buncher was checked. As a result of preliminary researches we chose injector structure that provides on-axis field distributions shoved in Fig. 1 and Fig. 2.

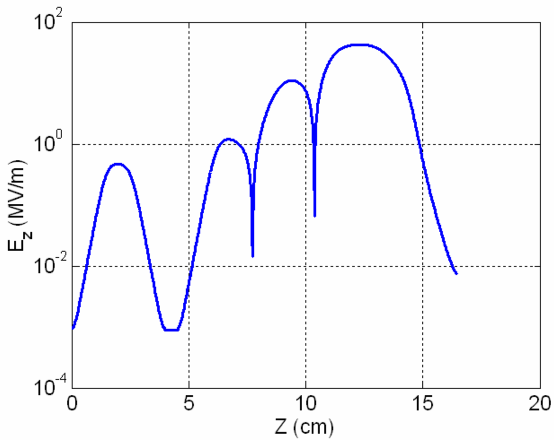

Figure 1: On-axis distribution of the electromagnetic field.

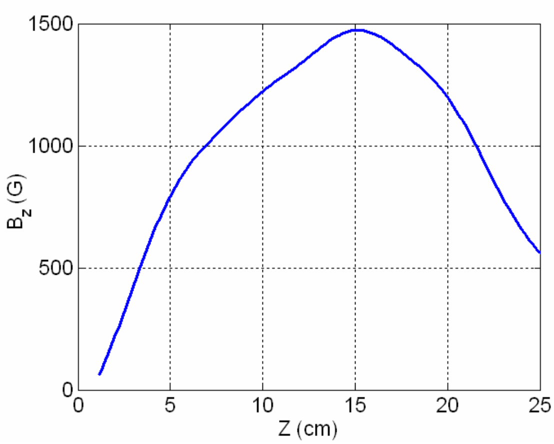

Figure 2: On-axis distribution of the static magnetic field.

Injector parameters and data obtained in self-consistent beam dynamic simulation with technique [6] are listed in Table 1. Beam parameters are given taking into account transients. The COUPLEREZ code gives similar results. It can be seen from Table 1 that the injector provides enough short bunch length at formation of an ampere range beam. High energy of particles allows injection directly into acceleration section with phase velocity that is equal to velocity of the light. We are going to optimize field distribution in the buncher with technique [7] to get shorter bunch in near future.

Some simulated signal waveforms that characterize injector operation are shown in Fig. 3 through Fig. 5.

Analysis of simulation results has shown that some part of electrons uncaptured into process of acceleration in the buncher goes backward through the prebuncher cavity. Current of such electrons can reach 0.15 A at average energy of 0.1 MeV. Interaction of these electrons with prebuncher field sets a feedback loop by beam. For the described injector configuration the feedback does not notably change beam parameters at the exit of the injector, but transient times in cavities are high compare with the case when we do not take back motion into account.

Table 1: Injector Specification

| | |
|---|---|
| Gun current, A | 1.5 |
| Output beam current, A | 1.34 |
| Bunch repetition rate, MHz | 2797.15 |
| RF power supply of prebuncher, W | 570 |
| RF power supply of the buncher, MW | 1.8 |
| RF pulse length, μs | 2.9 |
| Current pulse length, μs | 2.4 |
| Normalized root mean square (RMS) emittance $\varepsilon_{rms\ x,y}$, π·mm·mrad, (1 σ) | 12 |
| RMS beam size ($4\sigma_{x,y}$), mm | 2.8 |
| Bunch phase length (for 70% of particles), ° | 18 |
| Energy spread width (for 70% particles), % | 5.4 |
| Energy of particles, keV | 948 |

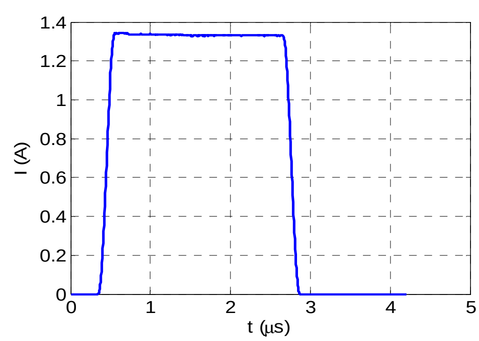

Figure 3: Output current pulse.

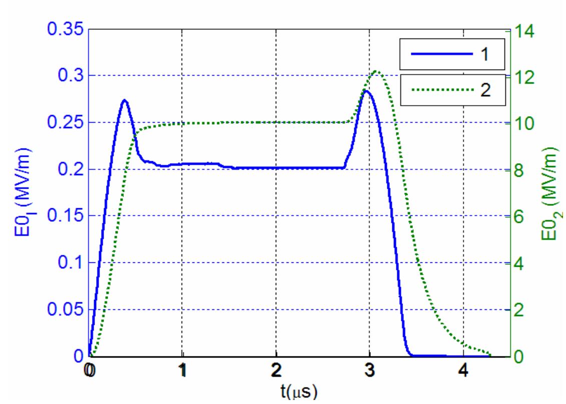

Figure 4: Waveforms of average on-axis field in the prebuncher (1) and in the buncher (2).

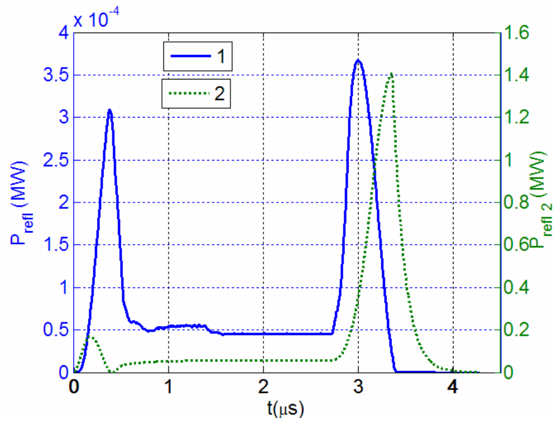

Figure 5: Waveforms of reflected waves from the prebuncher (1) and the buncher (2).

Increase of transient time due to the beam induced feedback can be seen in Fig. 4 and Fig. 5 at temporal interval from 0.5 to 1.5 μs. If we do not include backward propagated electron into consideration, above mentioned features will disappear.

At interaction of intense electron beam with multicavity system there is possibility of field excitation on adjacent modes that can cause unstable operation of the injector. The COUPLRES code was used to analyze stability of considered injector operation at bunching and accelerating electron beam with current up to 2.5 A. It is necessary to note that on-axis field distribution for nearest adjacent modes in the buncher has inverse dependence compare with shown in Fig. 1. That is field amplitude in the first cell has about the maximal level while that in the last cell has very small level. Therefore excitation of the adjacent modes will influence mostly field amplitude in the first cell of the buncher. Fig. 6 shows time dependence of a value that is proportional to field amplitude of $\square_{010}$ oscillation in the first cell of the buncher at no beam load and at acceleration of 1.5 A beam (current pulse length was 4.5 μs in this case). It can be seen decreasing field amplitude at beam injection but after transient is over the steady state regime is established. Therefore a process of bunching and acceleration is stable at such beam current.

## SUMMARY

As a result of carried out simulation we determined configurations of both the resonance and magnetic system of the injector that provide effective bunching of the ampere range electron beam at minimal degradation of the transversal emittance. The injector with the chosen configuration is stable against excitation of parasitic oscillation in the buncher at input currents up to 1.5 A. It was shown that backward propagated electrons interact with the prebuncher and increase transient time.

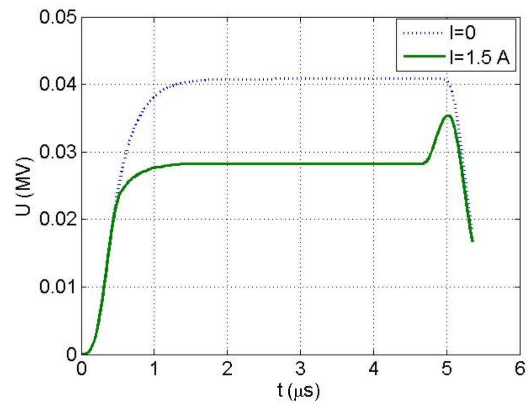

Figure 6: Voltage over the gap of the first buncher cell.

The injector can provide more than 1 A of output current at particle energies about 1 MeV and normalized RMS (1 σ) transverse emittance of 12 π·mm·mrad.

*Abstract*

The DARHT-II accelerator [1] produces a 2-kA, 17-MeV beam in a 1600-ns pulse. After exiting the accelerator, the pulse is sliced into four short pulses by a kicker and quadrupole septum and then transported for several meters to a tantalum target for conversion to x-rays for radiography. We describe the commissioning of the kicker, septum, transport, and multi-pulse converter target. The results of beam measurements made during the commissioning of the downstream transport are described.

## INTRODUCTION

The DARHT–II accelerator beam parameters are 17-MeV and 2.0 kA with a flattop of 1.6 microseconds. The DARHT–II downstream transport was commissioned at reduced energy and current in early 2007 [2]. The beam parameters were 8-MeV and 1.1 kA with a flattop of 1.6 microseconds.

The downstream transport system for the DARHT-II accelerator is designed to extract four short pulses (20-100 nsec) from the 1.6 microsecond beam and deliver these pulses to an x-ray production target for radiography. Figure 1 provides a schematic illustration of the downstream transport beamline.

The high level requirements imposed on the downstream transport are outlined below:

- Deliver four pulses over 1.5-1.6 μsec
- Spot sizes less than 2.3 mm 50% MTF
- Dose format exceeding 100 R, 100 R 100 R and 300 R in each successive pulse

Each of these requirements were met and reproduced over multiple shots. These results will be described. High quality radiographic images with the DARHT-II accelerator impose additional requirements on the beam quality, in particular, the beam motion over flattop. This issue and the methods used to minimize the that have been used to address them are discussed.

*Work supported by USDOE under contract DE-AC52-06NA25396

## LAYOUT AND OPTICS

The beam from the accelerator is focused using the first and third solenoids to produce a small waist at the entrance to the quad septum. This effectively decouples the accelerator from the remainder of the downstream transport. The beam enters the kicker and is either directed downward to the beam dump with a DC bias dipole magnet or the fast kicker is energized to direct the beam straight ahead. The bias dipole deflects the beam by 1-1.5 degrees. This deflection is magnified with a large aperture septum quadrupole tuned to defocus the beam in the vertical plane resulting in a net deflection of about 15 degrees. This also results in a large beam size on the dump which reduces the power density to acceptable levels. A dipole magnet further deflects the beam into the dump. The kicked beam enters the septum quadrupole on axis and the nominally round beam profile becomes elliptical. The function of the small Collins quadrupoles following the septum quadrupole is to transform this elliptical beam back to a round profile. The purpose of the remaining solenoid is to transport the beam to the final focus solenoid which delivers a tightly focused beam to the target.

There are four semi-independent regions in the downstream transport. The first region is from the accelerator to the septum quadrupole and the settings of the first and third solenoids. The second region is the transport to the septum dump. This defines the required settings of the bias dipole, septum quad and the septum dipole. The third region includes the four Collins quadrupoles that are used to return the beam back to round. The forth region consists of a transport solenoid and a final focus solenoid to produce a small beam size on target. The last transport solenoid was not used.

Beam position and current measuring diagnostics are located throughout the downstream transport. Beam profile imaging stations were located at the accelerator exit, between the 1$^{st}$ and 2$^{nd}$ Collins quadrupole magnets, and after the 4$^{th}$ solenoid.

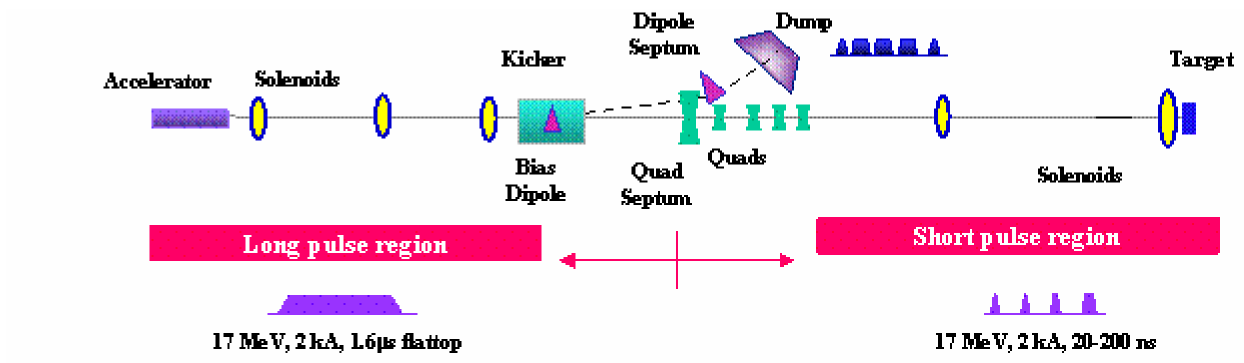

Figure 1: Schematic layout of DARHT 2nd Axis downstream transport.

## COMMISSIONING

The beam profile of the beam exiting the accelerator could not be measured due to the high power density of the beam. As a result, it was necessary to tune S1 and S3 based on beam profile measurements at the imaging station between the 1st and 2nd Collins quadrupole magnets. The desired beam profile was an upright ellipse with a vertical to horizontal aspect ratio of about 2:1. This was achieved as shown in the left image in Figure 2. The right image in Figure 2 shows the transverse beam distribution after S4.

The beam envelope and entrance conditions in the downstream were inferred from the magnet settings and images. Figure 3 shows the resulting beam envelope.

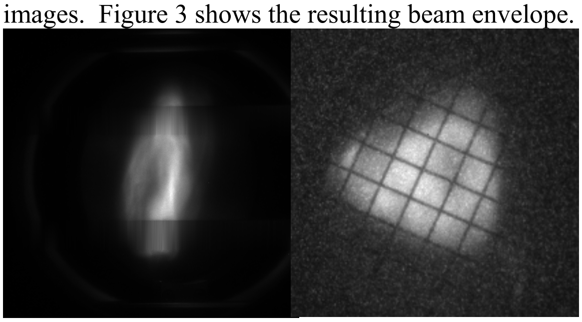

Figure 2: Beam images between the 1st and 2nd Collins quadrupoles (left), and after the 4th solenoid (right).

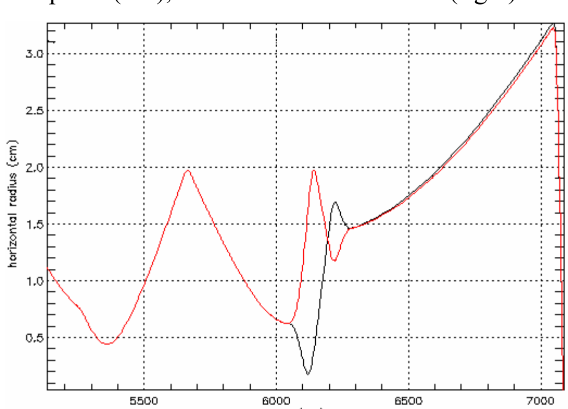

Figure 3: Beam envelope in the downstream transport based on initial conditions inferred from magnet settings and beam profile measurements.

## RESULTS

We will report results on the beam transport of four pulses to the target, and spot size and dose measurements of these pulses. through the kicker and quadrupole region, kicker performance, estimates of the emittance growth through the kicker and quadrupole region, stability of the kicked beam parameters at the beginning and end of flattop, studies of beam induced gas desorption at the septum edge, and spot size measurements of the four beam pulses on target.

### *Kicker Performance*

The kicker is nominally programmed to kick up to four pulses spaced over the flattop. The pulse lengths can be adjusted from 20 to 250 nsec. Figure 4 shows a typical beam current profile at the injector (black), accelerator exit (blue) and target (red). The four kicked pulses have lengths of 35, 40, 40, and 100 nsec respectively. The beam current is about 2 kA. The spacing from the beginning of P1 to the end of P4 is 1.5 usec demonstrating the first high level requirement.

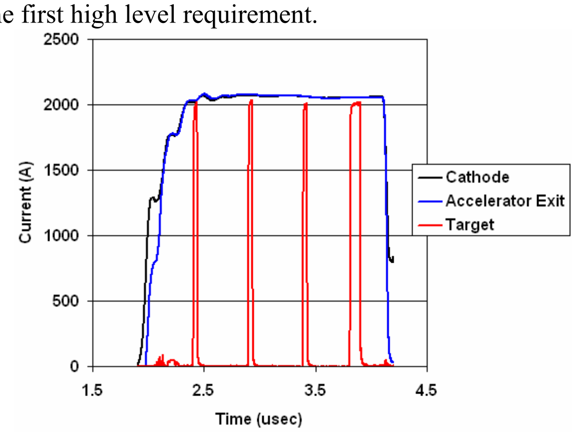

Figure 4: Beam current profile at injector, accelerator exit and target showing four kicked pulses.

### *Beam Size on Target*

The size of the x-ray spot on the target was measured using the Time-Resolved-Spot-Size camera as described by McCuistian et al. [3]. A series of measurements were made using the pulse format shown in Figure 4. The x-ray images and the calculated 50% MTF (Modulation-Transfer-Function) are presented in Figure 5. The values for the 50% MTF of the four pulses are all significantly smaller than the second high level requirement of 2.3 mm and are comparable to or less than the measured beam size for the DARHT 1st axis. The plots on the right side of the images compare the MTF of the single pulse from the first axis (grey) with that calculated for the corresponding second axis pulse (black). The larger high frequency or wave-number structure in the 2nd axis x-ray images translates directly into higher quality radiographic images.

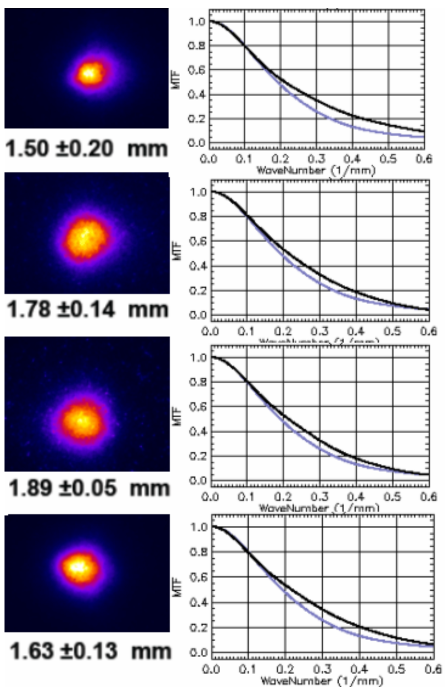

Figure 5: X-ray images of a four pulse target shot with measured 50% MTF and calculated MTF.

### *Dose Measurement*

The dose was measured with a diamond radiation detector (DRD) located approximately 30 cm downstream from the x-ray target. Measurements were made on the DARHT 1st and 2nd axes and the DRD is described by Bender [4]. The dose on the 1st axis was also measured using a calibrated dose calorimeter [5]. This provides a calibration for the DRD measurements. Table 1 presents the pulse length, dose and dose rate for the pulse format presented in Figure 4. The measurements correspond to five beam shots taken under identical conditions. The standard deviation in the dose and dose rate was less than 1%. This result exceeds the third high level requirement.

Table 1: Pulse Format and Dose

| Pulse | Pulse length (ns) | Dose at 1 m (R) | Dose Rate (R/ns) |
|---|---|---|---|
| P1 | 34.4 | 169 | 4.92 |
| P2 | 37.1 | 186 | 5.00 |
| P3 | 36.1 | 170 | 4.71 |
| P4 | 93.9 | 444 | 4.73 |

### *Beam Motion Over Four Pulses*

The beam motion of the four pulses at the x-ray production target must be kept to a very small fraction of the x-ray spot size. Studies of the beam transport from the accelerator exit to the target were performed and resulted in beam motion requirements of less than 2 mm and 2 mrad in both transverse planes at the accelerator exit. This was achieved in accelerator commissioning as described by Ekdahl et al.[6]. The measured beam motion between P1 and P4 was about 0.3 mm in both transverse planes. Subsequent studies have shown that the beam trajectory through the kicker can significantly alter the beam motion over flattop due to the action of image currents and charges on the kicker electrodes. Beam induced kicker steering is described by Caporaso et al [7]. Beam motion in the vertical plane can be minimized by independent controls on the kicker voltage for the four pulses. The horizontal beam motion on the target will be defined by the initial beam motion at the accelerator exit and the beam trajectory through the kicker. Beam studies have demonstrated that the trajectory through the kicker can be adjusted to reduce the horizontal beam motion in target. Further studies are required determine the minimal beam motion on target.

## CONCLUSIONS

The DARHT-II scaled accelerator downstream transport and target systems were successfully commissioned. The high level requirements for pulse length, spot size and dose were successfully demonstrated.

# DIGITALLY CONTROLLED HIGH AVAILABILITY POWER SUPPLY

David MacNair, Stanford Linear Accelerator Center, Menlo Park, CA

## *Abstract*

This paper reports the design and test results on novel topology, high-efficiency, and low operating temperature, 1,320-watt power modules for high availability power supplies. The modules permit parallel operation for N+1 redundancy with hot swap capability. An embedded DSP provides intelligent start-up and shutdown, output regulation, general control and fault detection. PWM modules in the DSP drive the FET switches at 20 to 100 kHz. The DSP also ensures current sharing between modules, synchronized switching, and soft start up for hot swapping. The module voltage and current have dedicated ADCs (>200 kS/sec) to provide pulse-by-pulse output control. A Dual CAN bus interface provides for low cost redundant control paths. Over-rated module components provide high reliability and high efficiency at full load. Low on-resistance FETs replace conventional diodes in the buck regulator. Saturable inductors limit the FET reverse diode current during switching. The modules operate in a two-quadrant mode, allowing bipolar output from complimentary module groups. Controllable, low resistance FETs at the input and output provide fault isolation and allow module hot swapping.

## OVERVIEW

The next linear collider will require several thousand magnet power supplies. This is a far greater number then any linear accelerator has used to date. To achieve equivalent or better availability of the beam will require improved availability of all systems. Significant increases in availability can come from improved reliability of modules, but an order of magnitude improvement can only come from redundant modules.

Power supplies will consist of parallel power modules in a N+1 redundant arrangement. Individual modules can fail without causing the power supply to lose regulation of the magnet current. Individual modules must provide for fault isolation to allow the power supply to operate with a failed module. The isolation will also allow for hot swapping of modules.

The individual modules will be autonomous so that there is no single point of failure. A digital controller will provide module control and fault detection. The controller provides a dual CAN bus interface for redundant power supply control.

## POWER MODULE

The power supply architecture is based on shared central bulk AC-DC power supplies with redundant buck regulators for each load. The power supplies are assumed to be in the 5 to 50 kW range consisting of redundant 1 to 10 kW modules. The modules will provide a voltage regulated output set by CAN bus broadcast messages from redundant magnet current regulators. The modules will use buck regulators with FETs in place of free wheeling diodes. This provides lower conduction losses and eliminates the non-linear discontinuous conduction region at low current. The two quadrant operation allows two power supplies operating with complimentary outputs to drive bipolar loads.

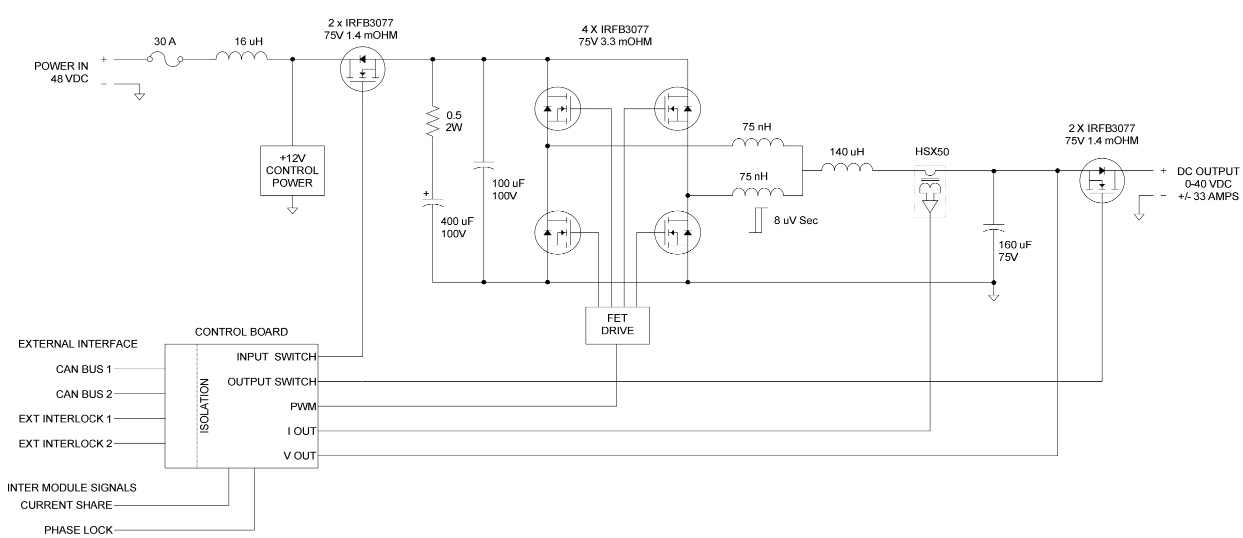

Figure 1: Two quadrant DC-DC converter with input and output FET switches.

*Work supported by the U.S. Department of Energy under contract number DE-AC02-76SF00515. SLAC-PUB-13415

Each module has FETs on the input and output. These allow failed modules to be isolated from the power source and load, and also allow modules to be replaced (hot swap) while the power supply is operating. Since the FETs ON resistance has a positive temperature coefficient, they can be easily paralleled to lower the conduction losses.

Ideally the upper and lower switching FETS would be driven synchronously, one turning on exactly as the other is turning off. This technology exists for low power (<100 watts) devices, but not for the high power devices. If the FETs are switched at the same time, there is a period where both are conducting (shoot through). This current is wasted as heat in the FETs. The existing FET drivers do not control the propagation delays and rise times to the extent needed for synchronous switching.

Adding a delay between turn ON and turn OFF eliminates shoot through losses, but adds losses from the FET body diode. When a FET with reverse current flowing is turned off, the current is shunted to the FET body diode. The diode has a large reverse recovery charge that increases with current and temperature.

## *Four FET Buck Regulator*

The buck regulator topology chosen uses 4 FETs instead of the usual 2. This allows for two small saturable ferrite chokes to be included. These provide a 100 nanosecond delay to allow the FET diodes conducting reverse current to recover before seeing the full bulk voltage. This greatly reduces the reverse current and switching losses in the FETs, and reduces the snubber circuit requirements.

The power supply controller sets the FET turn on sequence according to the polarity of the output current. For positive output current, the bottom two FETs will be carrying current in the reverse direction. When a bottom FET turns off, the opposite side upper FET turns on. When a top FET turns off, the bottom FET on the same side turns on. For negative output current, the top two FETs will be carrying current in the reverse direction. When a top FET turns off, the opposite side bottom FET turns on. When a bottom FET turns off, the top FET on the same side turns on. The module controller senses the polarity of the output current with a hall effect current sensor in series with the output inductor.

## *Digital Module Controller*

A major goal of this project is to design a power module control board that can be used with a power supplies with a large range different outputs. This will provide a common interface for most of the power supplies needed for the NLC.

The power module controller for redundant modules has to address the following requirements;

- Stability: Operate in a stable manner in parallel with other modules under all possible load conditions.
- Load Sharing: The output current of each module should be within 10% of other modules.
- Failure Detection: The controller needs to be able to sense and report a module that is not operating properly.
- Soft Start: The controller needs to be able to smoothly turn on and off a single module in a power supply without disturbing the power supply output.
- Autonomous Operation: The controller needs to be independent of all other module controllers to eliminate any single point failures.
- Redundant Communications: The controller will support dual CAN bus interfaces for redundant control.
- Module Synchronization: Each controller will provide a delay lock loop to lock the switching frequency and phase to the other modules.

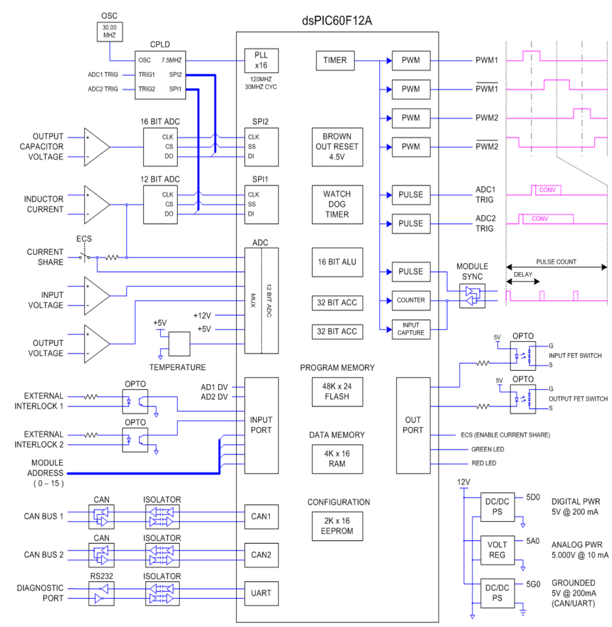

Figure 2: Power module controller block diagram.

## *Module Controller*

The processor used for the project is a Microchip dsPIC60F12A. It offers a high performance processor with a large array of external interfaces in a small inexpensive package. The processor executes 30 MIPs, or 300 instructions per cycle for a 100 kHz switching rate. It has a Harvard architecture with a 24 bit instruction path, and 16 bit data paths. It has two 40 bit accumulators with automatic limiting (saturation) of results. This eliminates range checking of results in the PID algorithms. The external interfaces include a dual CAN bus, UART, 8 PWM outputs, 2 SPI interfaces, and a 12 bit ADC with 16 input channels.

The maximum switching frequency for the design is 100 kHz (10 μs period), but may be programmed to be as low as 20 kHz. Two external serial ADCs are used to allowing reading the output voltage and output current on each cycle. A 16 bit ADC is used for the output voltage, and a 12 bit ADC for the output current. The noise from the hall effect current transducer limits the current resolution to less about 10 bits. The analog input to the ADCs is allows for under and over range conditions. All zero's or one's from an ADC is considered as a hardware fault.

The controller is referenced to the negative output of the power module. The CAN bus interfaces and diagnostic UART use digital isolators to provide a ground referenced control interface.

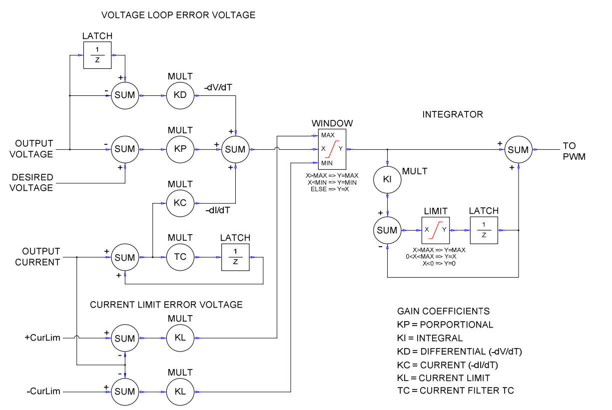

Figure 3: Control algorithm.

## *Controller Algorithm*

The controller uses a modified PID algorithm. The Proportional and Derivative terms are combined to form an error signal. The error signal is integrated to generate the Integral term. The error signal and integral are summed to generate the PWM on time.

The current limit operates as a window function for the error signal. The controller determines the minimum and maximum error signals that will keep the output current in range. The voltage and current loops share the same integral term to allow glitchless switching between voltage control and current limit.

The controller uses two derivative terms; dV/dT and dI/dT. The main function of the derivative term is to damp the response of the output LC filter. Using two derivatives allows better response for all possible load conditions.

The PWM outputs of the dsPIC processor have a 33 ns resolution. The input to the PWM algorithm is a 12 bit integer. The actual resolution of the PWM ranges from 8 to 10 bits, depending on the frequency. The input signal is truncated before being applied to the PWM, with the remainder from the truncation being applied to future cycles. This extends the resolution of the ADC, but adds some small lower frequency harmonics to the output.

The PWM algorithm allows setting minimum and maximum duty cycles. When a value less then the minimum is requested, the PWM maintains the minimum pulse width, but skips cycles to maintain the average value equal to the requested value. The on time remains constant, but the frequency changes to provide the correct average value.

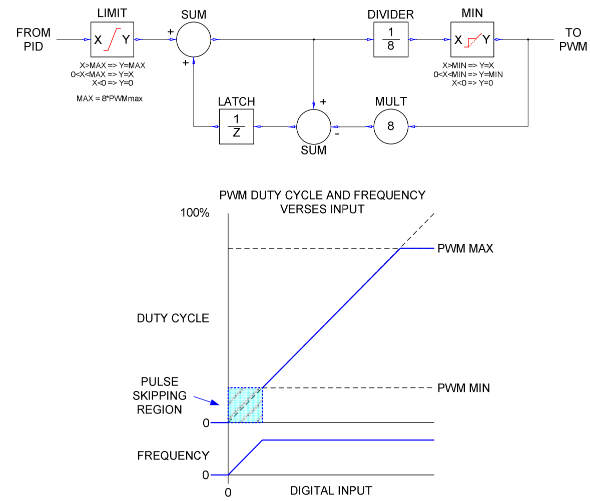

Figure 4: PWM algorithm.

## TEST RESULTS

To date, 5 test power modules have been built. They have been tested with using Microchip development boards that use the internal 12 bit ADC. The losses in the module were less then 22 watts for a 33 amp output. This puts the full load efficiency of the power section at better then 98%. The unit requires 3 watts of control power, and another 3 watts for the input and output FET switches. The complete module full load efficiency should be better then 97%. More then half of the losses are due to the resistance of the inductors, PCB traces, and FETs. The FET switching losses are a minor contribution.

The circuit design and PCB layout of the controller has been completed. When the controllers are built, they will allow testing of the parallel and redundant operation of the power modules.

## CONCLUSION

Power supplies with high efficiency and reliability that support redundant operation are technically strait forward. There are additional costs involved with additional hardware for redundant operation, and over sizing of components to improve efficiency and reliability.

Redundant power supplies are becoming available for high availability computer systems, but these fixed output voltage and low power make them inappropriate for powering magnets. There is currently not adequate demand for redundant 1 to 100 kW power supplies to have commercial sources available.

This project will continue to develop the power supply controller to demonstrate a power supply made from redundant modules. This will provide a better understanding of the issues involved in providing ultra reliable power supplies for the next linear collider.

# RF CONTROL AND LONGITUDINAL BEAM STABILITY IN ENERGY RECOVERY LINACS

A. Neumann, M. Abo-Bakr, J. Knobloch, BESSY GmbH, Berlin

## Abstract

Most concepts for next generation light sources base on linear accelerators (linac) due to their excellent beam properties. In case of high electron energies and extreme average currents Energy Recovery Linacs (ERL) are mandatory. In this paper we investigate the rf field stability in a generic superconducting, cw operated ERL. By using rf control cavity simulations and longitudinal beam dynamics the influence of rf field stability on the energy recovery process is analyzed. Since the ERL aims for a small net beam loading cavities are operated at a high loaded quality factor. Therefore they are operated at a low bandwidth and are very susceptible to microphonics detuning. We considered the field stability under the influence of limited rf power, mechanical cavity detuning, varying beamloading, synchronization deviations and varying bunch parameters at injection into the linac. The resulting temporal and energy jitter at the linac end will be transformed in the return arc and leads to rf phase deviations on the return path. Implications of varying beam loading on the ERL performance are examined.

# OPTIMIZATION OF LATTICE FOR AN ERL UPGRADE TO THE ADVANCED PHOTON SOURCE*

M. Borland†, V. Sajaev, ANL, Argonne, IL 60439, USA

*Abstract*

An Energy Recovery Linac (ERL) is one possibility for an upgrade to the Advanced Photon Source (APS). In addition to the linac itself, our concept involves a large turn-around arc (TAA) at 7 GeV that would eventually accommodate many new beamlines. Previously, we based the TAA design on isochronous triple-bend achromat (TBA) cells, since these are expected to provide some immunity to the effects of coherent synchrotron radiation. In the present work, we compare the previous TBA-based design to a new design based on double-bend achromat (DBA) cells, in terms of emittance growth, energy spread growth, and energy recovery. We also explore the trade-off between optimization of the beta functions in the straight sections and minimization of emittance growth.

## INTRODUCTION

An ERL [1] upgrade to the APS promises a revolutionary improvement in x-ray properties. In previous work [2] we made use of a TBA-based cell design for the TAA for the ERL upgrade. This choice was inspired by the desire to make an isochronous system with cancellation of coherent synchrotron radiation (CSR) effects [3, 4]. However, we found that CSR effects were very small, even as we increased the charge in the beam. Hence, we hypothesized that perhaps a simpler cell design might be acceptable. In this paper, we show results for a DBA-based design and compare these to the previous TBA-based design. (The APS ring portion of the ERL is necessarily DBA, since we don't propose to replace the APS ring. However, for simplicity we'll refer to "TBA" or "DBA" designs based on the optics design used for the non-APS portions.)

We also noted previously that with smaller beta functions at the insertion devices, x-ray brightness might be increased beyond what was predicted in [2]. In the second part of this paper, we explore the potential benefit and issues related to smaller beta functions.

## NEW ARC DESIGN

To develop the new arc design, we started with the APS cell including the Decker distortion[5], since this cell design is close to what we want. We then used `elegant` [6] to evolve this cell as follows: (1) Bending angle per cell of $\pi/24$ (48 cell turn around), just as for the TBA design. (2) $\eta_x = \eta'_x = 0$ in straights. (3) Increase space for insertion devices (IDs) from 4.8 m to 8 m. (4) $\beta_x \approx \beta_y \leq 5\text{m}$ at center of ID straights. (5) Mean arc radius of 230 m, just as for the TBA design. (6) Minimize the $I_2$, $I_3$ and $I_5$ radiation integrals. (7) Similar maximum lattice beta functions as the TBA design, e.g., $\sim 25\text{m}$. As Figure 1 shows, it was possible to make $\beta_x \approx \beta_y \approx 3\text{m}$, which has advantages for brightness compared to the $\beta_x = 12\text{m}$ and $\beta_y = 4.7\text{m}$ values for the TBA. It is likely this could be achieved in the TBA only by moving away from the CSR canceling tunes and perhaps giving up isochronicity.

We attempted to simplify the DBA cell by having doublets on each side of the ID instead of triplets. We did not find a solution that had satisfactory emittance growth and beta functions. Hence, the promise of the DBA to simplify the cell structure didn't bear fruit. We eliminate one dipole magnet, but the dipoles are longer.

We also performed a DBA-based design of the arcs ("transport arcs") that bring the beam into and out of the APS ring. The constraints are very similar to those just listed, except there is no need for long straight sections. The mean radius was 75 m with a total bending angle of 72 degrees in 8 cells, as in the TBA design.

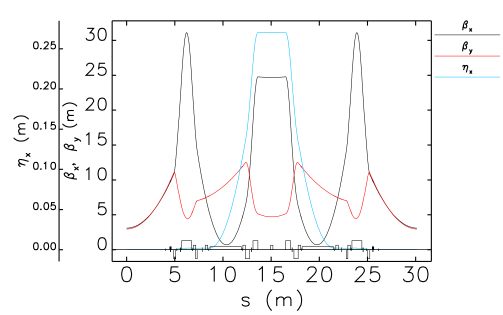

Figure 1: Optics for turn-around arc DBA cell.

## TRACKING COMPARISON

The next step is to compare tracking results for the DBA and TBA designs. We are interested in absolute energy loss, energy droop (deviation from reference), energy spread increase, and emittance increase. Mechanisms involved are classical, incoherent, and coherent synchrotron radiation. All the tracking studies used `Pelegant` [7] and the high-coherence-mode beam parameters [8], i.e., 0.1 $\mu$m initial normalized emittance with a 2-ps rms bunch length. For consistency with previous work, we assumed an initial

* Work supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.
† borland@aps.anl.gov

energy spread of 0.1% rms, which is very likely too large but which doesn't impact our results.

We found that neither design has a worrisome energy droop. As Figure 2 shows, the DBA design is superior overall in terms of energy spread growth. This is in spite of larger growth in the TAA and results from very low growth in the transport arcs. Clearly, we might combine the TBA-based TAA with our DBA-based transport arcs if we wished. The emittance grows more rapidly in the DBA version of the TAA, then at about the same rate in the transport arcs and the APS itself. These differences are negligible.

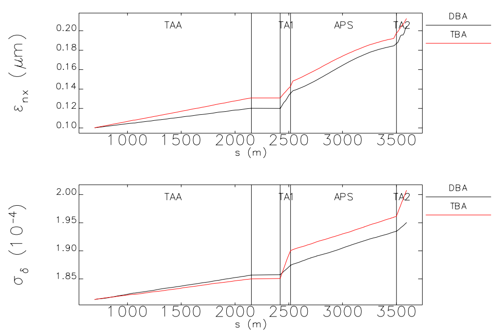

Figure 2: Evolution of normalized rms horizontal emittance and rms fractional momentum spread in 7-GeV portion for the two designs.

For the deceleration phase, increasing fractional energy spread and beam size may lead to beam loss. The final longitudinal distribution, shown in Figure 3, exhibits low- and high-energy tails, resulting from non-isochronous transport. The effects are worse in the all-DBA design, but still present in our "TBA" design because the APS portion is still DBA. This can be mitigated by moving the rf phase in the deceleration stage, at the cost of less efficient energy recovery. This is shown in Figure 3 for a deceleration phase that is 0.5 degree off trough. The average final momentum increases by only 1.5%.

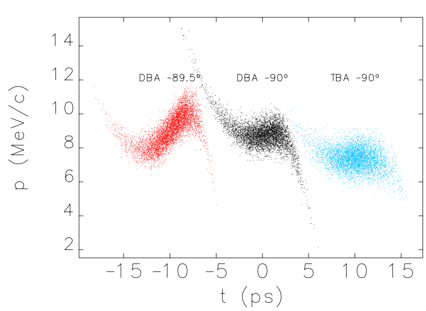

Figure 3: Comparison of final longitudinal phase space for three cases. Data are offset horizontally for clarity.

In passing, we note that one advantage of the TBA design is that the $R_{56}$ is adjustable. Hence, we could perhaps adjust the total $R_{56}$ of the 7-GeV transport lines to be zero, something we can't do with an all-DBA system. This would result in lower post-deceleration energy spread.

Next, we performed tracking with CSR to compare the DBA and TBA lattices. We are most interested in the 25 mA high-coherence mode [8], which has 19 pC per bunch. We also looked at the high-flux mode, which has 77 pC per bunch, leaving the emittance fixed for simplicity in comparisons (in reality the emittance is expected to increase four-fold). As seen from Figure 4, the effects of CSR are quite modest. This is the same result as we saw for the TBA-based design. Of course, these studies are for a very smooth initial distribution. Since the all-DBA lattice has considerable path-length dispersion, we must look carefully at possible microbunching instabilities [9]. This is the subject of another paper in these proceedings.

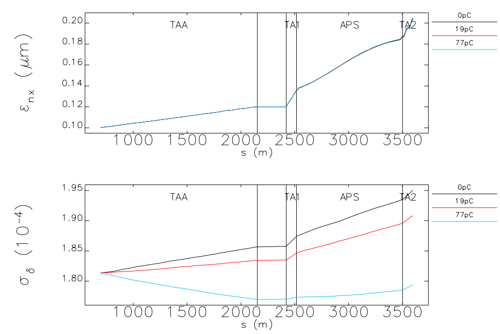

Figure 4: Evolution of normalized rms horizontal emittance (top) and rms fractional momentum spread (bottom) in 7-GeV portion of DBA design for three charge levels.

We next used `sddsanalyzebeam` and `sddsbrightness` [10] to compute the x-ray brightness for U33 undulators of various lengths at various locations, including emittance and energy spread growth. We found that the DBA-based design is about 70% brighter than the TBA-based design in the TAA, and basically indistinguishable in the APS itself. The improvement in the TAA results from the smaller beta functions in the straight sections.

## BRIGHTNESS OPTIMIZATION

The brightness improvement from the DBA cell design is, of course, not inherent in the DBA but results simply from the improved beta functions. Ideally, the beta function of the electron beam would be the same as the beta function of the single-electron undulator radiation. The latter is $\beta_r = \epsilon_r/\sigma_{r'}^2$, where $\epsilon_r = \lambda/(4\pi)$ is the intrinsic radiation emittance, $\sigma_{r'} = \sqrt{\lambda/(2L)}$ is the intrinsic radiation divergence, $\lambda$ is the radiation wavelength, and $L$ is the undulator length [11]. The result, $\beta_r = L/(2\pi)$, is quite small and not easily obtained in a storage ring. With the greater optical freedom of a single-pass system, it might be feasible.

Toward this end, we used `elegant` to rematch the APS DBA cell for a grid of target $\beta_x$ and $\beta_y$ values at the ID. We included the following constraints: (1) $\eta_x = \eta'_x = 0$ at

ID. (2) Maximum beta functions under 70 m in both planes, in order to reduce beam motion, halo generation, and optics sensitivity to the orbit. That 70m is necessary and sufficient is an educated guess at this point. (3) Acceptable emittance growth, implemented by constraining the cell's equilibrium emittance $\epsilon_0$ to less than 10 nm. Although the equilibrium emittance is not of course directly relevant, it provides an intuitive way to constrain $I_5$.

The maximum beta function constraint proved difficult. By introducing small gradients in the dipoles, we reduced this problem and got significantly smaller beta functions in the straight sections. We limited ourselves to $|K_1| \leq 0.05\mathrm{m}^{-2}$, which might require only pole-face windings.

In an attempt to ensure that chromatic effects are manageable, we eliminated all solutions for which our present maximum sextupole strength of $K_2 = 31.5\mathrm{m}^{-3}$ was insufficient to correct the chromaticity to zero. We also removed all solutions for which $\max(\beta_{\{x,y\}} \geq 75$ m and $\epsilon_0 \geq 11$ nm. This eliminated about 17% of the solutions.

Following matching, we chose to compute the x-ray brightness at Sector 35 (the end of the APS portion of the ERL), since it is the most sensitive to emittance increase. To save computation, instead of tracking we estimated the emittance using [12]

$$\Delta\epsilon_x = \frac{55 r_e \hbar}{48\sqrt{3} m_e c}\gamma^5 I_5, \quad (1)$$

where $I_5$ is the radiation integral for 35 sectors. Similarly, the fractional energy spread growth is [13]

$$\Delta\sigma_\delta^2 = \frac{55 r_e \hbar}{24\sqrt{3} m_e c}\gamma^5 I_3. \quad (2)$$

We checked these equations against tracking with `elegant` for the nominal design and got good agreement.

The beam parameters at the entrance of the APS portion are $\epsilon_x = 10.9$ pm, $\epsilon_y = 7.1$ pm, and $\sigma_\delta = 0.0186\%$. After computing the beam properties at Sector 35, we used `sddsbrightness` to determine the brightness for the first three harmonics assuming at 4.8-m undulator and 25 mA average beam current. We found the largest improvement in brightness for $\beta_x = 1.0\mathrm{m}$ and $\beta_y = 1.1\mathrm{m}$, the smallest we could get in both planes (see Figure 5). This solution is close to the limits for maximum beta functions, emittance increase, and sextupole strength. As Figure 6 shows, the improvement in brightness relative to the reference case is a factor of 2.5.

## CONCLUSION

Based on an analysis of emittance growth including coherent synchrotron radiation, we found no advantage to a TBA-based design for the turn-around arc and transport arcs in an APS ERL upgrade. Even for 77 pC/bunch, the use of CSR-canceling optics appears to be unnecessary, which relaxes several constraints on the lattice. This would allow, for example, optimization of the beta functions at the insertion devices, giving significantly improved brightness.

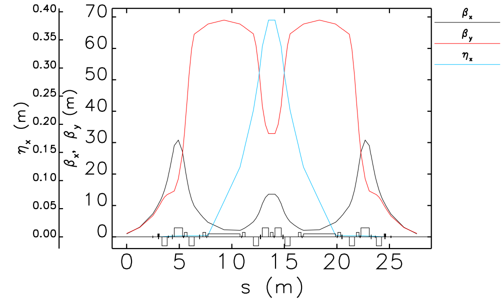

Figure 5: Optics for optimized APS DBA cell.

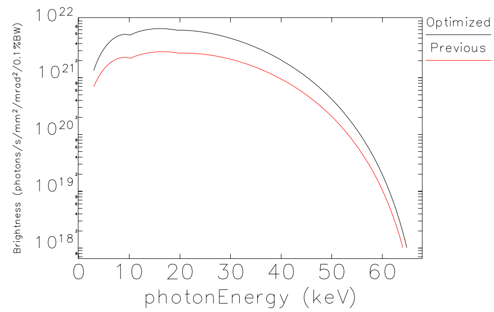

Figure 6: Comparison of brightness for the optimized APS DBA cell and the previous solution.

We showed an example of applying this, albeit to the APS DBA cell only, gaining a factor of 2.5 in the brightness. Strong path-length dispersion in the all-DBA design may increase the growth of microbunching in the beam, which is the subject of another paper in these proceedings.

# GROWTH OF DENSITY MODULATIONS IN AN ENERGY RECOVERY LINAC LIGHT SOURCE DUE TO COHERENT SYNCHROTRON RADIATION AND LONGITUDINAL SPACE CHARGE*

M. Borland †, ANL, Argonne, IL 60439, USA

*Abstract*

An Energy Recovery Linac (ERL) is one possibility for an upgrade to the Advanced Photon Source (APS). Such a system involves not only a long linac, but also long transport lines with many dipole magnets. Since the bunches are short, we may expect that coherent synchrotron radiation (CSR) and longitudial space charge (LSC) will have an effect on the beam dynamics. Although previous studies have shown minimal effects for an initially quiet beam distribution, the possibility of a microbunching instability seeded by initial density modulation must be evaluated. We present and discuss simulation results showing the growth of density modulations in two possible lattices for an ERL upgrade of the APS.

## INTRODUCTION

The first hint that CSR could amplify initial density modulations in a beam in a single-pass system came from modeling [1] of the Linac Coherent Light Source (LCLS) with `elegant` [2]. Subsequently, theoretical analysis [3] for the TESLA Test Facility predicted an even more severe problem when LSC was included. This was subsequently confirmed by modeling with `elegant` for the LCLS [4]. What is critical in the LCLS and other similar systems is the alternation between long linear accelerators in which LSC effects accumulate and one or more bunch compression systems in which CSR effects act.

An ERL [5] upgrade to the APS promises a revolutionary improvement in x-ray properties. We have developed a concept for an "ultimate" ERL upgrade to the APS [6] that involves a long, single-pass 7-GeV linac and a large 7-GeV turn-around arc. The potential for build-up of CSR and LSC effects in such a system seems clear, due to the length of the linac and transport line, as well as the large number of dipole magnets. In addition, the bunch duration is relatively short ($\sim$2 ps rms) and the normalized emittance is very small ($\sim 0.1\ \mu$m), as is the rms fractional momentum spread ($\sim 0.02\%$). Like the LCLS and other high-performance injectors, the ERL injector is likely to be driven by a shaped laser pulse [7], which opens up the possibility that significant density ripples will be imparted to the beam at the cathode. Hence, in spite of the low charge (under 100 pC), there is reason to be concerned about potential microbunching growth.

We've investigated this for two possible optical configurations of the ERL: (1) The original "TBA" configuration [6, 8], with triple-bend-achromat (TBA) cells outside the APS and double-bend-achromat (DBA) cells inside the APS. (2) A new DBA configuration, with DBA cells throughout. A comparison of these configurations is offered elsewhere in these proceedings.

In the present work, we begin our simulations at the 10-MeV point. Full simulations starting at the cathode are obviously desirable, but beyond our scope at this time.

## SIMULATION METHODS

The approach we have taken is very similar to what was done for LCLS and FERMI [9, 4, 10], where we obtained a growth curve for density modulations. We performed a series of simulations for various bunch charge, modulation wavelength, and modulation depth with CSR, LSC, and linac longitudinal wakefields. CSR was included using `elegant`'s line-charge model [11, 12], including CSR in drift spaces. This model includes the transient build-up of CSR in each dipole, but does not include shielding. Shielding will in fact have some effect on the "bulk CSR," i.e., CSR at the wavelengths related to the overall bunch length [13]. However, it will have a significantly diminished effect at the shorter wavelengths corresponding to density modulations.

LSC was included using an impedance-based method [4]. An LSC kick was added after each linac structure as well as at the center of each ID straight section. This made use of a newly-added feature in `elegant`, namely, the ability to insert an LSC kick that integrates the effect of an LSC applied over a user-specified length of the beamline. This approach is valid as long as the relative longitudinal motion of particles is not too great, which is the case when we place kicks at each ID straight section.

Control of noise is essential to getting reliable results. We followed the algorithm in [4, 10] fairly closely: 1. Choose a density modulation wavelength and depth. We used depth values between 0 and 10%, inclusive. The 0% runs are helpful in baselining the effects of noise. 2. Choose the bin size to be 1/24$^{\rm th}$ of the wavelength. This means the Nyquist frequency is 12 times the wavelength. 3. Set the low-pass noise filter cutoff to 1.5 times the modulation frequency. Combined with item 2, we smooth and interpolate features at the modulation frequency on the

† borland@aps.anl.gov

scale of the bin size. 4. Choose the number of particles such that there are at least 1000 particles per bin in the center of the distribution. This provides additional control of binning noise. 5. Generate a distribution with the desired modulation and the required number of particles. The distribution is Gaussian in the longitudinal coordinate $z$, with the modulation imposed by multiplying the Gaussian distribution function by $1 + d \cos 2\pi\lambda z$, where $\lambda$ is the modulation wavelength and $d$ is the modulation depth. 6. Perform tracking, recording time histograms along the system. Unlike the LCLS case, we are in principle interested in the modulation at each straight section. We recorded histograms after each set of linac structures (typically eight cavities) after each achromat in the turn-around arc (TAA), input transport line, APS, and output transport line.

The initial beam parameters were 19 pC/bunch, 0.01% rms energy spread at 10 MeV with a normalized emittance of 0.1 $\mu$m [7, 14, 15]. Gaussian distributions were used in all six phase space coordinates. For tracking, we used `Pelegant` [16], the parallel version of `elegant`. Typically 42 processors were used with up to 7.2 million simulation particles, requiring up to 24 hours for a single run. We also performed tracking with 77 pC/bunch and the same initial beam parameters, although in reality the emittance and initial energy spread would be higher.

Analysis of the simulation data used power spectral densities (PSDs) of the longitudinal histograms along the accelerator. For each location $s$, modulation depth $d$, wavelength $\lambda$, and charge $q$, we integrated the PSD between $0.9f_0$ and $1.1f_0$ to get a value $E(s, d, \lambda, q)$, where $f_0$ is the frequency corresponding to $\lambda$. The quantity $E'(s, d, \lambda, q) = E(s, d, \lambda, q) - E(s, 0, \lambda, q)$ is the adjusted value, with any contribution from noise removed. The quantity $G = \sqrt{E'(s, d, \lambda, q)/E'(0, d, \lambda, q)}$ is the gain relative to the initial modulation strength.

## RESULTS AND DISCUSSION

Figures 1 and 2 show the results for the all-DBA lattice, while Figures **??** and **??** show the results for the TBA lattice. What's plotted is the maximum gain seen at any location as a function of the initial modulation wavelength, for several values of the initial modulation depth. Varying the modulation depth helps ensure that results have converged and that we are in the linear regime.

The results of our analysis show the same general features as those for FEL driver linacs: low gain for long wavelengths and increasing gain for shorter wavelengths, but with a cutoff at very short wavelengths. For most cases, we don't see any significant difference as the initial modulation depth is varied. This is typical when the gain is small. However, for the all-DBA lattice with 77 pC/bunch, the gain is somewhat high and it doesn't appear that the results have fully converged. Apparently the maximum gain is $\sim$ 5, so for 1% initial modulation, the depth is only $\pm 5\%$. More work is needed to determine why this hasn't converged, since it should be in the linear regime.

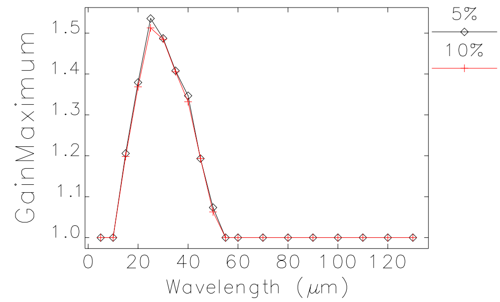

Figure 1: Maximum microbunching gain for 19 pC/bunch in the DBA lattice.

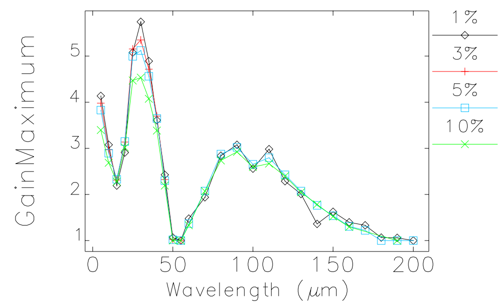

Figure 2: Maximum microbunching gain for 77 pC/bunch in the DBA lattice.

Comparing the results for 19 pC/bunch, the DBA lattice shows about 15% higher maximum gain than the TBA lattice. This is perhaps not unexpected given the larger $R_{56}$ of the all-DBA lattice (0.57m compared to 0.24m).

For 77 pC/bunch, the results are not too different for wavelengths above 50 $\mu$m, with the DBA lattice showing about 25% higher maximum gain. However, for short wavelengths the DBA lattice is significantly worse, with maximum gain of $\sim$ 5 compared to $\sim$ 2. Note that the short-wavelength gain for 77 pC/bunch is overstated because we used unrealistically small emittance and energy spread. Exploration of this effect is in progress.

Although the maximum gain is not small, it should not degrade performance for users. For example, Figure 5 com-

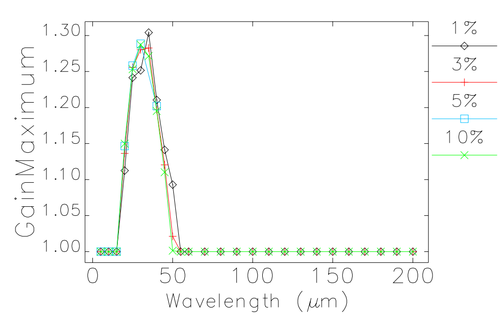

Figure 3: Maximum microbunching gain for 19 pC/bunch in the TBA lattice.

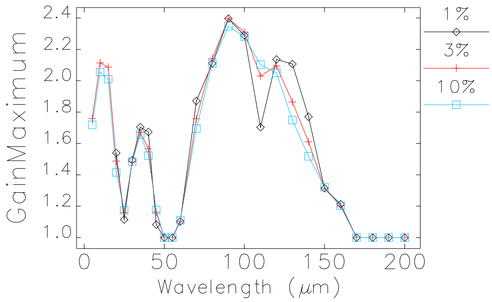

Figure 4: Maximum microbunching gain for 77 pC/bunch in the TBA lattice.

pares the normalized horizontal emittance at the ID straight sections for the DBA lattice with 77 pC/bunch for three cases: 5% and 10% initial modulation depth at 30 $\mu$m, and no initial modulation. We see that the effect is negligible.

More interesting, although still negligible, is the effect on the energy spread, shown in Figure 6. We see that the bulk CSR effect (0% modulation) results in a decrease in the energy spread in the turn around arc (TAA), followed by an increase in subsequent sections. That some decrease may occur is plausible given that the initial energy spread of the beam is dominated by rf curvature effects. Bulk CSR tends to flatten the sinusoidal distribution in time-momentum space, resulting in lower energy spread. This can't happen indefinitely and the energy spread begins to increase when the beam transits the stronger dipoles in the Transport Arc into the APS. That this effect would be stronger when a short-wavelength density modulation is present was not expected and is still surprising

Inspection of the longitudinal distribution after deceleration shows no significant effect of the initial modulation. Hence, we have no added concerns about transporting the decelerated beam efficiently.

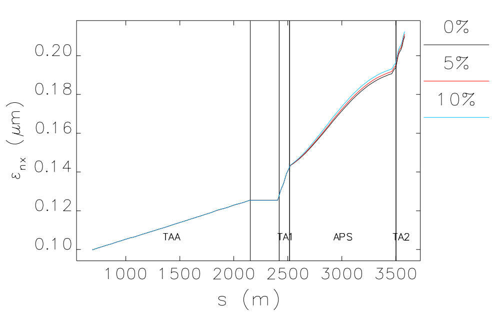

Figure 5: Effect of an initial 30-$\mu$m density modulation on the normalized rms horizontal emittance seen at the ID straight sections, for 77 pC/bunch. The line for 5% initial modulation is only slightly above that for 0% modulation. The labels refer to the TAA, input and output transport arcs (TA1 and TA2), and the APS ring.

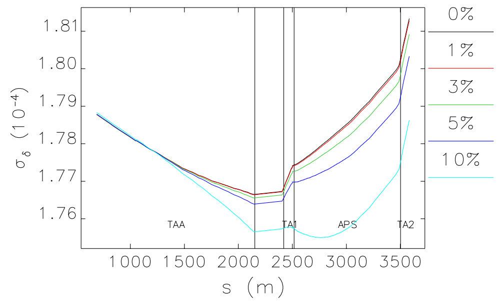

Figure 6: Effect of an initial 30-$\mu$m density modulation on the rms fractional energy spread seen at the ID straight sections, for 77 pC/bunch, for various initial modulation depths. See Figure 5 for an explanation of the labels.

## CONCLUSION

We have used `Pelegant` to model the propagation of initial density modulations from the 10-MeV point in an APS ERL upgrade. Although significant gain, up to 30-fold, was found for 77 pC/bunch in the all-DBA lattice, it appears this will have little or no impact on the beam quality seen by users. Density modulation growth does not appear to be a strong reason to favor the TBA-based design over the all-DBA design. Additional modeling is needed to extend the simulations to the cathode.

## ACKNOWLEDGEMENT

The author wishes to thank Yusong Wang for his efforts in parallelizing `elegant`, which made this work possible.

# EXPLORING BENEFITS OF USING RF DEFLECTION FOR SHORT X-RAY PULSE GENERATION FOR AN ENERGY-RECOVERY LINAC UPGRADE TO THE ADVANCED PHOTON SOURCE*

V. Sajaev#, M. Borland, ANL, Argonne, IL 60439, U.S.A.

*Abstract*

One option for the Advanced Photon Source (APS) upgrade is an energy-recovery linac (ERL). In its main operating mode, the ERL rms bunch length would be two picoseconds. Even though this bunch length is already a factor of 20 shorter than the present APS bunch length, some experiments might benefit from even shorter x-ray pulses. For the APS storage ring, we plan to use an rf deflection technique [1] to generate one-picosecond-long x-ray pulses. In this approach, an rf cavity is used to deliver a longitudinally dependent vertical kick to the electron beam and then a pair of slits is used to slice the vertically streaked x-ray beam (see Figure 1). Here, we investigate the possibility and benefits of utilizing this technique to generate shorter x-ray pulses in an ERL.

## ANALYSIS

Let's consider the beam motion after the first cavity, which provides time dependent vertical kick:

$$y_0'(t) = \frac{V}{E}\sin(\omega t) \approx \frac{V}{E}\omega t \, ,$$

where $V$ is the deflecting cavity voltage, $\omega$ is the deflecting cavity frequency, $E$ is the beam energy, and we have assumed that the beam is short enough to stay within the linear part of the rf waveform. At the location of the undulator, the beam will have the following coordinates [2]:

$$y_{ID}(t) = \frac{V\omega t}{E}\sqrt{\beta_{RF}\beta_{ID}}\sin(\psi) \, ,$$

$$y_{ID}'(t) = \frac{V\omega t}{E}\sqrt{\frac{\beta_{RF}}{\beta_{ID}}}\left(\cos(\psi) - \alpha_{ID}\sin(\psi)\right) ,$$

where $\beta$ and $\alpha$ are Twiss functions, and $\psi$ is the betatron phase advance. These equations describe the vertical position and angle of the beam slice located at longitudinal position $t$. Each beam slice has beam size $\sigma_y$ and divergence $\sigma_{y'}$. Considering the undulator radiation divergence $\sigma_\theta$, the photon beam position and its vertical size a distance $L$ down the beamline are

$$y_L(t) = y_{ID}(t) + y_{ID}'(t)\cdot L =$$

$$= \frac{V\omega t}{E}\left(\sqrt{\beta_{RF}\beta_{ID}}\sin(\psi) + L\cdot\sqrt{\frac{\beta_{RF}}{\beta_{ID}}}\left(\cos(\psi) - \alpha_{ID}\sin(\psi)\right)\right),$$

$$\sigma_L^{\,2} = \sigma_y^{\,2} + L^2\left(\sigma_{y'}^{\,2} + \sigma_\theta^{\,2}\right).$$

At this point, an asymmetrically cut crystal can be used to compress the photon pulse as shown in Figure 2. Such a crystal performs horizontal sheering as shown by the red arrows, and the resulting minimum pulse length after the crystal is $\sigma_s = \sigma_y / \tan(\vartheta)$. The same length can be achieved by using slits instead of the crystal to slice the beam along the horizontal axis. The minimum achievable pulse length is

$$\sigma_t = \frac{\sigma_L}{dy_L(t)/dt} =$$

$$= \frac{\frac{E}{V\omega}\sqrt{\sigma_y^{\,2} + L^2\left(\sigma_{y'}^{\,2} + \sigma_\theta^{\,2}\right)}}{\left(\sqrt{\beta_{RF}\beta_{ID}}\sin(\psi) + L\cdot\sqrt{\frac{\beta_{RF}}{\beta_{ID}}}\left(\cos(\psi) - \alpha_{ID}\sin(\psi)\right)\right)} .$$

There are two phase-advance values between the cavity and the undulator that simplify the expression above by zeroing the sine or cosine term. One can see that having *sin(ψ)* equal zero rather than *cos(ψ)* allows for achieving shorter pulses assuming reasonable values for beta functions and distance to the beamline optics. The expression can be simplified for this case as follows:

$$\Delta t = \frac{E}{V\omega}\sqrt{\frac{\beta_{ID}}{\beta_{RF}}}\sqrt{\sigma_{y'}^{\,2} + \sigma_\theta^{\,2}} \, . \qquad (1)$$

This expression is the same as obtained in Ref. [3] with the addition of a beta function ratio. Looking at this equation, one can see what steps are necessary to achieve as short a pulse as possible: higher rf voltage and frequency, smaller ratio of beta functions, and smaller electron beam size divergence and undulator radiation divergence.

#sajaev@aps.anl.gov

Extensive optimization of all parameters for achieving short pulses was performed for the APS storage ring [4]. Simulations rather than analysis of Eq. (1) were used for a number of reasons: the bunch length of the APS (70 ps rms) was comparable to the rf wavelength, making the rf kick strength nonlinear with the particle position in the bunch; vertical beam emittance was dependent on the deflecting rf voltage due to nonlinear coupling in the sextupoles; and second harmonic radiation in undulator affected the achievable pulse length.

For the ERL beam, the electron bunch duration (2 ps rms) is much shorter than the rf period, which keeps the entire beam in the linear region of the rf waveform. Sextupoles can be safely removed from the lattice between the cavities, thus removing beam emittance dependence on the rf voltage. For a longer undulator, the effect of the second-harmonic radiation also becomes less important. For the APS ring, having initial large vertical beam size presents difficulties for pulse compression using asymmetrically cut crystals [5], which is much less of an issue for the ERL since the beam size and divergence at the crystal will be smaller. Therefore, we will first analyze Eq. (1) and then perform simulations for cases of interest.

First, we will write Eq. (1) using expressions for the electron beam divergence and photon beam divergence:

$$\Delta t = \frac{E}{V\omega}\sqrt{\frac{\beta_{ID}}{\beta_{RF}}}\sqrt{\frac{\varepsilon_y}{\beta_{ID}} + \frac{\lambda}{2L_U}}\ ,$$

where $\lambda$ and $L_U$ are radiation wavelength and undulator length respectively, and we assumed that the beta function slope is zero in the middle of the undulator. According to this equation, the minimum pulse length depends on seven different parameters (we don't consider beam energy $E$ as a parameter – it is always 7 GeV).

For our analysis here we assume the following fixed parameters: $\beta_{ID}$=2 m, $\beta_{RF}$=20 m, $\varepsilon_y$=10 pm. The beta function choice is somewhat arbitrary (but reasonable). The emittance value was given by ERL gun simulations [6]. To analyze the effect of the undulator length on the achievable pulse duration, we further assume the following values for rf and radiation wavelength: V=6 MV, $\omega=2\pi\cdot 2.8$ GHz, and $\lambda$ =1.2 Å (photon energy 10 keV). Figure 3 shows the dependence of the pulse length on the undulator length. One can see that there is definitely a benefit in increasing undulator length from 2.4 m (standard APS undulator length) to at least 5 m. Considering also that longer undulators provide more photons, for our further analysis we chose an undulator length of 10 m. Figure 4 shows the dependence of the pulse length on the photon energy for three different rf settings: 4 MV and 1.4 GHz, 6 MV and 2.4 GHz, and 8 MV and 5.6 GHz. One can see that pulse length shows little change after about 10 keV, but different rf settings (different curves on the plot) affect pulse length significantly. For the most extreme rf values of 8 MV and 5.6 GHz, an rms pulse duration of about 25 fs could be achieved. Figure 5 shows pulse length as a function of rf voltage and frequency for 10-keV photon energy to demonstrate possible trade-offs between rf voltage and frequency.

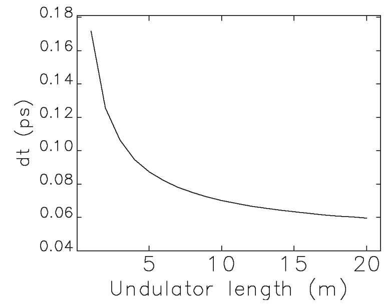

Figure 3: Minimum pulse length dependence on the undulator length for V=6 MV, $\omega=2\pi\cdot 2.8$ GHz, and $\lambda$ =1.2 Å.

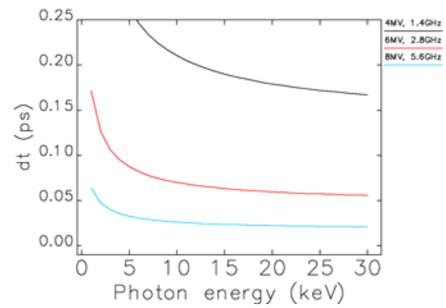

Figure 4: Minimum pulse length dependence on the photon energy for different rf voltages and frequencies.

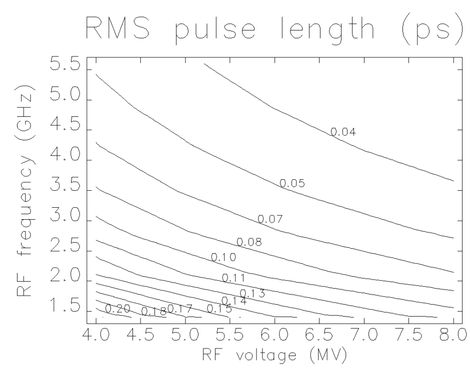

Figure 5: Minimum pulse length as a function of rf frequency and voltage.

## SIMULATIONS

We performed detailed simulations for the particular set of parameters shown in Table 1.

Table 1: Parameters Used in Simulations

| | |
|---|---|
| Beam energy | 7 GeV |
| RF voltage | 6 MV |
| RF frequency | 2.8 GHz |
| ID beta function | 2 m |
| RF beta function | 20 m |
| Vertical emittance | 10 pm |
| Undulator length | 10 m |
| Photon energy | 10 keV |

A description of the ERL lattice can be found in [7]. The insertion with deflecting cavities was placed at the end of the turn-around arc (TAA). For simplicity, we used TAA sectors for insertion but removed the dipoles and sextupoles. Deflecting cavities and the undulator were located in successive ID straight sections. The full insertion consists of four sectors with the symmetry point in the middle. The first sector brings the vertical beta function to 20 m at the first deflecting cavity, a second sector brings the beta functions to 2 m at the undulator, and the rest is reflectively symmetric. The vertical phase advance of each sector was tuned to 0.5 and the natural chromaticity was also minimized. The accelerator code `elegant` [8] was used for lattice matching and particle tracking.

For the initial particle distribution we used the results of a gun simulation with 0.1-micron normalized emittance [6]. The bunch was then tracked through the entire linac and TAA. At the insertion entrance, the vertical beam emittance was close to 11 pm·rad. At the undulator location, the photon distribution was generated by combining the electron distribution and the single-electron radiation pattern. The photon distribution was then propagated 30 m to a point where either an asymmetrically cut crystal can be used to compress the pulse or a slit can be used to slice it. Figure 6 shows the pulse shape before and after compression. The resulting rms pulse duration after compression was 62 fs. If calculated using Eq. (1), the pulse duration would be 70 fs.

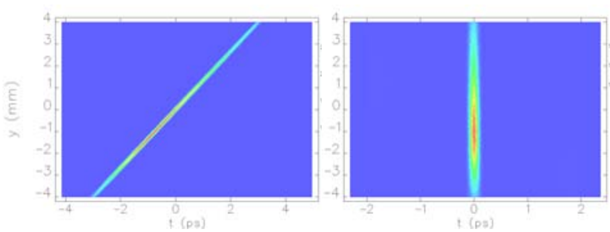

Figure 6: Photon pulse shapes before (left) and after (right) compression.

Figure 7 shows the pulse profile. One can see small peaks at around ±2 ps. These are produced by the second-harmonic undulator radiation. The intensity of the peaks is about 0.3% of the main peak intensity.

From our previous analysis of the rf deflection for the APS storage ring [3], we know that the vertical kick can increase the vertical beam emittance due to magnet nonlinearities and chromaticity between the cavities. Figure 8 shows the emittance at the exit of the insertion after the second cavity, as a function of rf frequency for two different rf voltages. A diamond symbol represents the point corresponding to the parameters in Table 1. The increase in this case is 6%, which can be tolerated. However, if one considers increasing the voltage and frequency, then the emittance increase might present a challenge and might require special study to mitigate the problem.

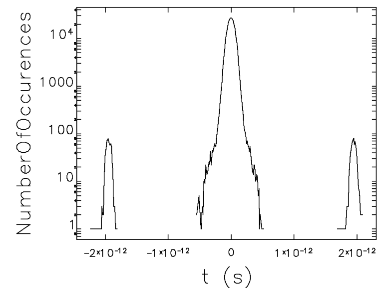

Figure 7: Photon pulse profile. The rms pulse length is 62 fs. Small peaks at around ±2 ps are produced by the second-harmonic radiation.

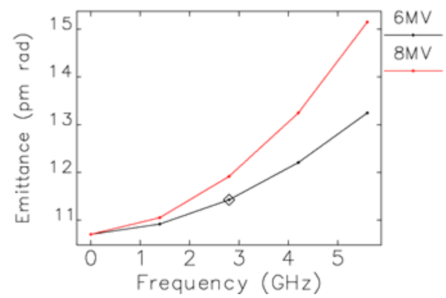

Figure 8: Vertical beam emittance after the second deflecting cavity for different rf frequencies and voltages. A diamond symbol shows the point corresponding to the parameters in Table 1.

## CONCLUSION

We have studied the application of an rf deflection scheme for achieving short pulses at an APS ERL. We have found that an rms pulse duration of 62 fs can be achieved with the beam and rf parameters shown in Table 1, which are very similar to those considered for the APS storage ring. We confirmed through tracking that vertical emittance of the beam does not increase significantly after the second cavity. We also have found that for some extreme rf parameters (8 MV and 5.6 GHz), the rms pulse length can be decreased to 25 fs.

# SIMULATION OF LINEAR LATTICE CORRECTION OF AN ENERGY-RECOVERY LINAC DESIGNED FOR AN APS UPGRADE*

V. Sajaev#, ANL, Argonne, IL 60439, U.S.A.

*Abstract*

An energy recovery linac (ERL) is a possible candidate for an upgrade of the Advanced Photon Source (APS). Our ERL design includes full-energy linac, large turn-around arc that could accommodate new x-ray beamlines, and APS itself. In total, the beam trajectory length would be close to 3 km. The ERL lattice has a strong focusing to limit emittance growth, and it includes strong sextupoles to keep beam energy spread under control and minimize beam losses. As in storage rings, trajectory errors in sextupoles will result in lattice perturbations that would affect delivered x-ray beam properties. In storage rings, the response matrix fit method is widely used to measure and correct linear lattice errors. Here, we explore the application of the method to the linear lattice correction of ERL.

## INTRODUCTION

Linear optics measurement and correction using response matrix fit is well known and widely used on modern circular machines. The purpose of this work is to simulate the application of the same method to a non-closed beamline.

Theoretically, there is no big difference between response matrix measurement for closed and non-closed beamlines. The orbit equations are well-known and look similar (top equation is for non-closed trajectory and bottom is for closed trajectory, $\theta$ – is the kick strength):

$$x(s) = \theta\sqrt{\beta_s\,\beta_\theta}\,\sin(\psi_s - \psi_\theta),$$

$$x(s) = \frac{\theta}{2\sin(\pi\nu)}\sqrt{\beta_s\,\beta_\theta}\,\cos(\psi_s - \psi_\theta - \pi\nu)\,.$$

The measured trajectories in both cases depend on beta functions and phase advances and therefore could be used to derive linear optics. The main practical difference is that in the case of non-closed beamline, the response matrix is triangular with zeros in the top right triangle.

## SIMULATION DETAILS

At APS, we have been using response matrix fit method for many years [1]. We added an option of working with non-closed trajectories to our existing program. From our experience, we know that at APS the main source of focusing errors are non-zero orbits in sextupoles and we also know that the focusing errors from sextupoles cannot be precisely represented by nearest quadrupoles [2]. Therefore we decided to include sextupole displacements in error simulation. The following set of errors was used for simulations:

* Work supported by the U.S. Department of Energy, Office of Science, office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

#sajaev@aps.anl.gov

Table 1: Errors used in Calculations

| | |
|---|---|
| Quadrupole gradient error | 0.1 % |
| Quadrupole tilt | 0.001 rad |
| Sextupole X and Y displacement | 1 mm |
| Corrector calibration error | 5 % |
| Corrector tilt | 0.001 rad |
| BPM calibration error | 2 % |
| BPM tilt | 0.001 rad |
| BPM measurement noise | 1 μm |

Sextupole displacements were chosen rather large because trajectory errors in sextupoles are defined not by the accuracy of sextupole alignment but by the accuracy of nearest BPM offset which could be large. The errors were generated using Gaussian distribution with 2 sigma limit.

For optics correction simulation we used only APS portion of the ERL because the Turn-Around Arc design has not been finalized to a level of BPM and corrector locations. The lattice of the APS portion is described in [3], the lattice functions of one APS sector are presented in Figure 1. The main difference from the present APS storage ring lattice is zero dispersion in ID straight sections to decrease electron beam size dependence on energy spread. The APS consists of 40 nearly identical sectors.

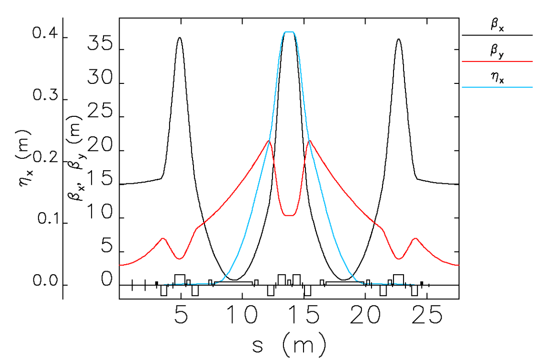

Figure 1: Lattice functions of one sector of the APS portion of the ERL.

Special attention was paid to the choice of correctors used for response matrix measurement in our simulations. APS storage ring has 8 correctors and 11 BPMs per sectors (in most sectors). Presently, for real measurements we use only 27 correctors in each plane (out of 320) evenly distributed along the ring and all BPMs. We limit the number of correctors in order to save measurement time and also to limit the size of the fitting problem. If all the correctors were used, the size of the response matrix derivative would be 15 Gb, which would be too big. Our experience shows that with 27 correctors we still have enough data for an accurate fit. In case of a circular machine, the location of correctors used for the response matrix measurement is not important as long as they are separated by some phase advance. However, the situation is different for a non-closed beamline where measured trajectory is affected only by elements that are located after the steering magnet. Therefore, for a non-closed beamline, different steering magnets provide different amount of useful information. Obviously, one would want to use as many steering magnets in the beginning of the beamline as possible while keeping them at some phase space distance. For our simulations, we used 27 correctors in each plane spread over first six sectors (out of forty) and none after that.

The following procedure was used to simulate the entire process of measurement and optics correction (`elegant` [4] was used for all beta function and trajectory calculations):

- `elegant` parameter file is generated with element errors;
- trajectory is corrected (because the sextupole displacements could lead to large trajectory errors) using 2 correctors per sector;
- "measured" response matrix and dispersion are calculated on the corrected orbit, response matrix is generated from two trajectories for each corrector using the same plus-minus delta approach that we use in real measurements;
- response matrix fit is calculated (dispersion included);
- quadrupole gradient errors opposite to those found in the response matrix fit are applied to correct the optics, and the resulting beta functions are compared with the ideal beta functions

The entire process was run 100 times with different error seeds. Figure 2 shows typical beta functions before beta function correction. For each case, we have calculated relative beta function difference between actual and ideal beta functions and its rms value (the rms value is calculated using all beta function points along the beamline). Figure 3 shows histogram of rms of relative beta function errors before correction. Average rms of the relative beta function difference over all cases is 0.71 for horizontal and 0.47 for vertical plane.

## CORRECTION RESULTS

All APS quadrupole magnets have separate power supply. Therefore, the straightforward way to correct the optics is to apply opposite quadrupole gradients. However, this method has some drawbacks that prevent us from using it in real life. To achieve the best possible response matrix fit, we use as many singular values in matrix inversion as possible. This might lead to appearance of large quadrupole errors in the solution. After we calculated beta functions using quadrupole errors from the response matrix fit, we use inverse beta function response matrix to correct the difference between measured and ideal beta functions. We also adjust the number of singular values in this inversion until we get satisfactory correction accuracy while still keeping quadrupole changes small. This allows us to minimize real quadrupole changes during optics correction at APS storage ring.

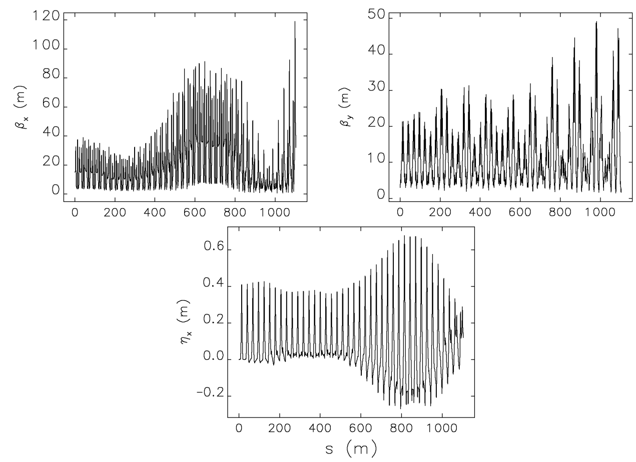

Figure 2: Typical beta functions before beta function correction. Top left – horizontal, top right – vertical, and bottom is dispersion.

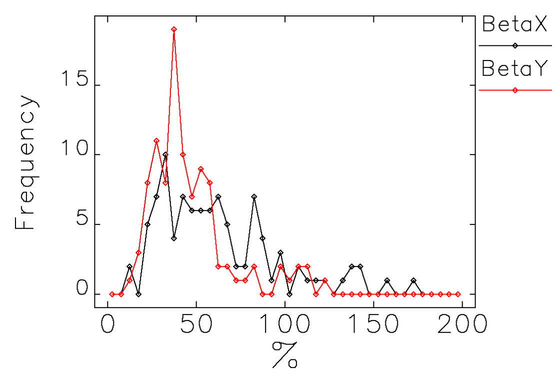

Figure 3: Histogram of the relative beta function error rms before beta function correction. Histogram is calculated over the set of 100 different error seeds. For every seed, the relative beta function error was calculated, and then rms was calculated using all beta function points along the beamline.

However, these arguments are not important for the optics correction simulation here, so we used the straightforward approach to keep our simulations simple. Figure 4 shows histogram of rms of relative beta function errors after correction. Average rms of the relative beta function difference over all cases is 0.03 for horizontal and 0.02 for vertical plane. Figure 5 shows typical lattice functions after correction.

We can estimate the effect of residual dispersion perturbation on the beam size using typical ERL parameters: $\varepsilon$=10pm and $\sigma_E$=0.02%. Maximum beam size increase at ID location due to energy spread contribution using dispersion on Figure 5 (bottom plot) is about 15%. If such accuracy of dispersion correction turns out to be not satisfactory, it can be corrected separately afterwards since the dispersion (unlike beta functions) can be directly measured by scanning beam energy.

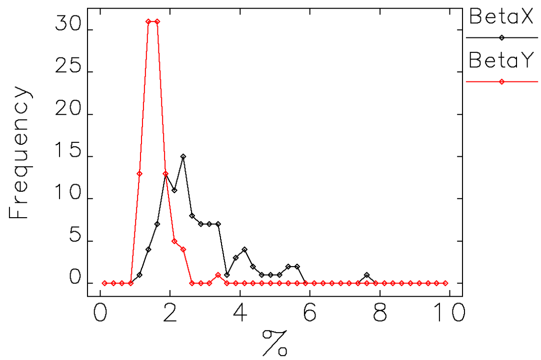

Figure 4: Histogram of the relative beta function error rms after beta function correction. See Figure 3 for comment on plot units.

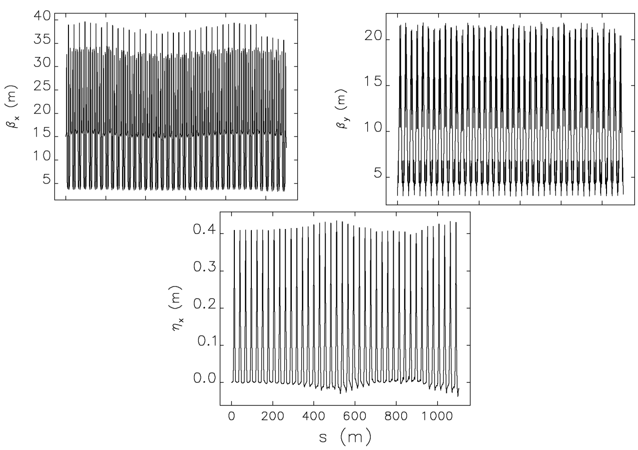

Figure 5: Typical beta functions after beta function correction.

One can ask why the correction is not perfect. Two reasons are obvious – due to BPM noise the response matrix measurement is not accurate and due to the fact that the focusing errors come from sextupoles but are corrected using quadrupoles in different locations. These reasons are likely to explain short-scale perturbations in beta functions. But we can also see a long-scale smooth variation in the horizontal beta function on Figure 5. The reason for that is inaccurate determination of focusing errors in the very beginning of the lattice because the first quadrupoles and sextupoles have only few trajectories going through them. If this argument is true, then the beta function variation can be corrected by adjusting initial beta functions at the entrance of the lattice. Figure 6 shows horizontal beta functions that were obtained by varying incoming beta function and its slope. A small change in initial beta function conditions allows correcting the long smooth variation seen on top left plot of Figure 5 thus confirming that quadrupole errors in the beginning of the beamline were not determined correctly. To improve accuracy for first elements of the measured beamline, one might use several correctors upstream of measured portion of the beamline.

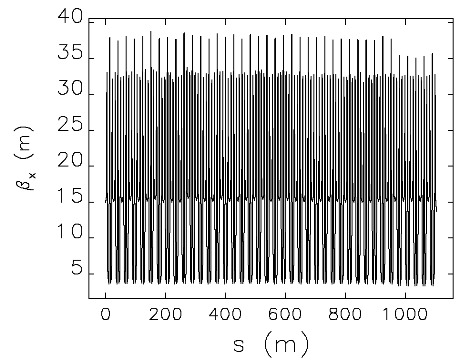

Figure 6: Horizontal beta function with adjusted initial conditions (to be compared with the top plot of Figure 5). A step change at the last 5 sectors is due to sector design difference.

During our simulations, we have also found that if the focusing errors of the lattice are large enough, sometimes the response matrix fit does not converge because the initial approximation (ideal lattice) is too far from the lattice with errors. We have tested the following procedure that helps in case of convergence problem: split lattice in pieces and perform response matrix fit piece by piece (not necessarily to be done to a very accurate level) and apply corrections from piece by piece solutions. After this step, the new lattice with errors is closer to the initial lattice and therefore can be solved without problems. This piece by piece approach will probably have to be used anyway when correcting optics of the entire ERL just to avoid long measurements and huge matrices. We have tested and confirmed that one can measure and correct only a part of the non-closed beamline.

## CONCLUSION

We have simulated optics correction for non-closed beamline using response matrix fit. As example we used suggested APS lattice in ERL mode. We have found that response matrix fit can be used to measure and correct linear lattice successfully. We have confirmed that one can measure and correct only a part of non-closed beamline which will be useful for large ERLs.

Author would like to thank M. Borland for useful discussions.

## Abstract

An ampere class 20 MeV superconducting Energy Recovery Linac (ERL) is under construction at Brookhaven National Laboratory (BNL) [1] for testing concepts for high-energy electron cooling and electron-ion colliders. One of the goals is to demonstrate an electron beam with high charge per bunch (~ 5 nC) and extremely low normalized emittance (~ 5 mm-mrad) at an energy of 20 MeV. Flexible lattice of ERL loop provides a test-bed for testing issues of transverse and longitudinal instabilities and diagnostics of intense CW e-beam. The superconducting 703 MHz RF photoinjector is considered as an electron source for such a facility. At first we develop the straight pass (gun -- 5 cell cavity -- beam stop) test for the SRF Gun performance studies. Then the novel injection line concept of emittance preservation at the lower energy will be tested at this ERL. In this paper we present the status and our plans for construction and commissioning of this facility.

## INTRODUCTION

The R&D ERL facility at BNL aims to demonstrate CW operation of ERL with average beam current in the range of 0.1-1 ampere, combined with very high efficiency of energy recovery. The ERL is being installed in one of the spacious bays in Bldg. 912 of the RHIC/AGS complex.

The ERL R&D program is started by the Collider Accelerator Department (C-AD) at BNL as an important stepping-stone for 10-fold increase of the luminosity of the Relativistic Heavy Ion Collider (RHIC). Furthermore, the ERL R&D program extends toward a possibility of using 10-20 GeV ERL for future electron-hadron/heavy ion collider, eRHIC [2].

Future RHIC upgrades define the goals for the R&D ERL development to test: 1) Test the key components of the High Current ERL based solely on SRF technology; 2) 703.75 MHz **SRF gun** test with 500 mA current; 3) 5-cell **SRF linac** test with HOM absorbers; 4) Single turn - 500 mA test the beam current stability criteria for CW operation; 5) Test the attainable ranges of electron beam parameters in SRF ERL; 6) Demonstrate beam quality close to that required for RHIC electron cooling and scalability to eRHIC.

## GENERAL LAYOUT OF R&D ERL

The R&D ERL design (shown in Fig. 1) has one turn: electrons are generated in the superconducting half-cell gun and injected into the main superconductive linac. Linac accelerates electrons up to 15-20 MeV, when electron bunch pass through a one turn re-circulating loop with achromatic flexible optics [3].

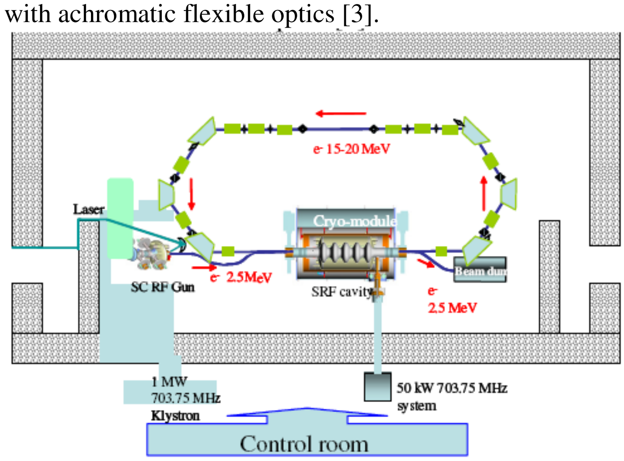

Figure1: Layout of the R&D energy recovery linac in the shielded vault.

The photocathode is located in a high electric field for immediate acceleration of the electrons to as high energy as possible, reducing emittance degradation due to strong space charge force. Furthermore, liner part of space charge effects is compensated by applying a suitable external solenoid magnetic field.

In nominal recovery operation regime the path-length of the loop provides for 180 degrees change of the RF phase, causing electron deceleration (hence energy recovery) down to injection energy. The decelerated beam separates from the higher energy beam and goes to the beam-dump.

## ERL INJECTOR

The electron injector is a central part of any ERL that

* Work performed under the auspices of the US Department of Energy
# dkayran@bnl.gov

has to deliver high brightness electron beam. The BNL R&D ERL injector (see Fig. 2) consist of ½ cell superconducting RF gun with photocathode inside [4], solenoid, four dipoles and two solenoids turned on in opposite direction. The 4th dipole mergers the high and low energy beams. One of the novel systems we plan to use for the R&D ERL is a merging system providing achromatic condition for space charge dominated beam and compatible with the emittance compensation scheme. Focusing of the bending magnets in the merging section has significant effect on the low energy electrons. Different focusing in vertical and horizontal planes (astigmatism) makes impossible simultaneous emittance compensation. Hence, the use of combined function magnets with equal focusing strength in x- and y-direction is necessary.

Table 1: Electron Beam Parameters of the R&D ERL

| **Mode** | **High current** | **High charge** |
|---|---|---|
| Charge per bunch, nC | 1.4 | 5 |
| Injection energy, MeV | 2.5 | 3 |
| Maximum beam energy, MeV | 20 | 20 |
| Average e-beam current, mA | 500 | 50 |
| Bunch rep. rate, MHz | 350 | 9.38 |
| Normilized emittance, mm*mrad | 2.3/2.3 | 4.8/5.3 |
| Rms energy spread, % | 0.5 | 1 |
| Rms bunch length, ps | 20 | 30 |

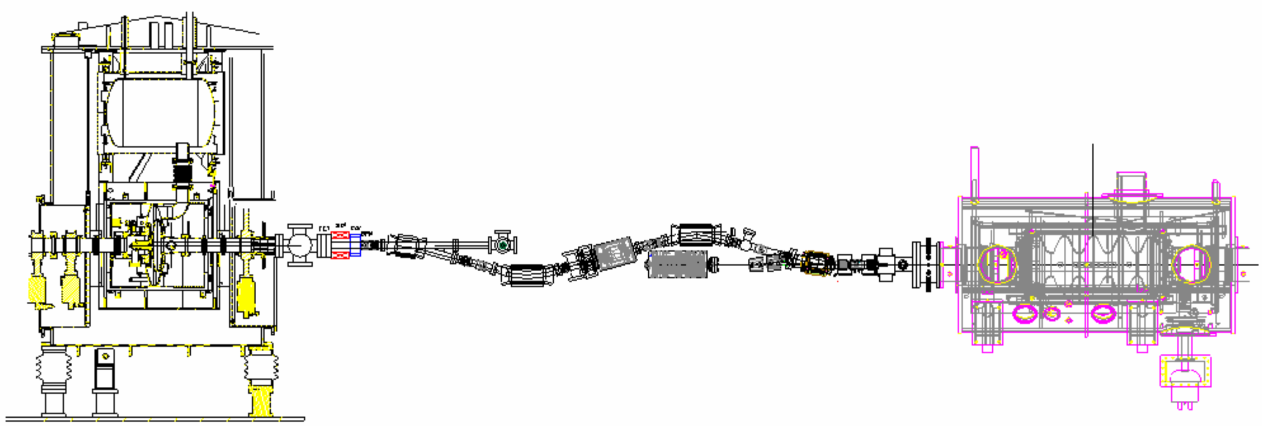

Figure 2: Detailed drawing of SRF Injector for the BNL R&D ERL.

Beam dynamics simulation shows that for Z-merger both vertical and horizontal emittances at the end of the linac can be the same [5].

The main expected electron beam parameters for the BNL R&D ERL obtained by PARMELA [6] simulations are listed in Table 1.

Due to the bends in vertical direction the effect of vertical emittance growth is clear. But at the exit of Z-merger both: vertical and horizontal emittances become almost equal. In case of 5 nC per bunch this equality is broken, the next order nonlinearity start playing a role.

## 5 CELL SRF LINAC

The heart of the ERL facility is 5-cell SRF linac, which is designed for operating with ampere-class CW beam current [7]. The cavity was designed as a “single-mode” cavity, in which all Higher Order Modes (HOMs) propagate to HOM ferrite absorbers through the large beam pipe. Measurements of the damped Q and R/Q of the HOMs and simulations show that in nominal operation regime the cavity is stable to over 20 amperes in a one pass ERL and over 2 amperes for two passes ERL.

The 5-cell SRF linac successfully went through vertical test at Jlab and the 20 MeV/m accelerating voltage was demonstrated [8]. We are finishing of the cryostat assembly (see Fig .3) and the cavity will go through a horizontal (a normal mode of an operation) cold-emission test (CET) in the ERL cave in November 2008.

Figure 3: 5-cell cavity in the cryomodule.

## GUN 5-CELL CAVITY TEST

We will start ERL commissioning from gun through 5-cell cavity (G5) beam test in 2009. The layout of G5 test is shown in Fig. 4.

During the G5 test we will have two modes of measurements:

1) in straight ahead mode: the quadrupole scan and flag will be used to measure projected emittances transverse halo and;
2) turning on bending magnet mode gives the nice opportunity to measure longitudinal parameters of

the electron bunch:: bunch length, longitudinal tails. Slice emittance will be measured using off crest RF operation and slits.

All flags will be driven by multi-position pneumatic actuators, and will have both YAG and OTR capability at each location. Images will be viewed off the ERL plane via mirrors.

The expected parameters for G5 test are summarized in Table 2.

Table 2. Main Parameters of Electron Beam for G5 Test

| | |
|---|---|
| Charge per Bunch: | 0.05-5 nC |
| Gun Energy: | 2.5 -3 MeV |
| Maximum Energy: | 20 MeV |
| Energy spread on crest | 3% ,off crest 15% |
| Max. Average current: | 500 nA |
| Max. Rep Rate: | 100 Hz |
| Average Power: | < 10 W |

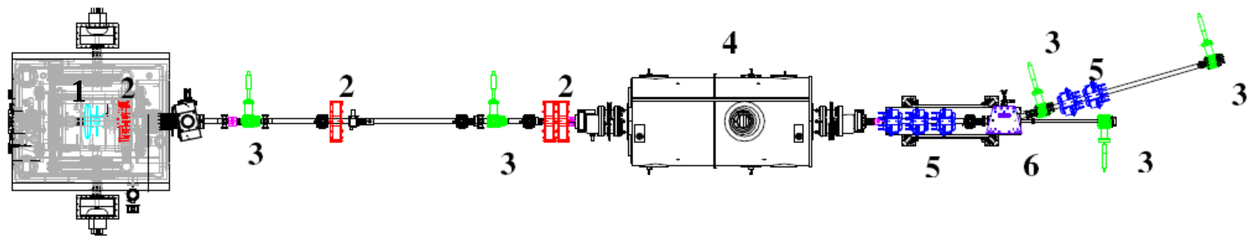

Figure 4: Detailed drawing of G5-test: 1 - 703MHz SRF gun; 2 – solenoids; 3 - beam profile monitors; 4- 5cell SRF cavity; 5-quadrupoles; 6-dipole magnet. 2.5 MeV electron beam from SRF gun propagates through a straight section with beam diagnostics: BPMs, pepper-pot, YaG/OTR screens. Then beam is accelerated in 5-cell cavity to 20 MeV.

## STATUS AND PLANS

Many of the ERL subsystem and most of its infrastructure had been installed in the Bldg. 912 of the CAD complex:

- 5-cell Cavity is being processed and tested at JLAB, cold emission test 5-cell cavity in cryostat at BNL in November 2008
- 1 MW Gun klystron and 50 kW 5-cell cavity transmitter are installed, tested with dummy load at 0.6 MW level
- Recirculation loop magnets and vacuum system components are ready for installation
- Gun drive laser is been procured, will arrive in October 2008
- RF control will be based on the new digital RHIC LLRF. The LLRF system is currently under development.
- Machine protection system is being designed (BLMs, DCCTs)
- Gun is under construction at AES

BNL starts commissioning of the R&D ERL in 2009:

1) the straight pass (G5 test) or the beam quality studies.
2) test concept of emittance preservation in a beam merger in the same configuration as above
3) complete recirculation loop, demonstrate energy recovery with high charge per bunch and high beam current
4) study beam and stability issues relevant for high current ERLs

The availability of high current electron beam with low emittance (see Table 1) opens new perspective of using BNL R&D ERL as an electron beam provider for free electron laser [9]

After the testing main components of ERL in building 912 we are planning to use 20 MeV BNL R&D ERL to do a CeC proof-of-principle experiment to cool Au ions in RHIC at ~ 40 GeV/n [10]. As an example, the layout of CeC proof-of-principle test installed at RHIC IR2 is shown in Fig. 5 PoP CeC experiment using this ERL at RHIC could be possible in 2012

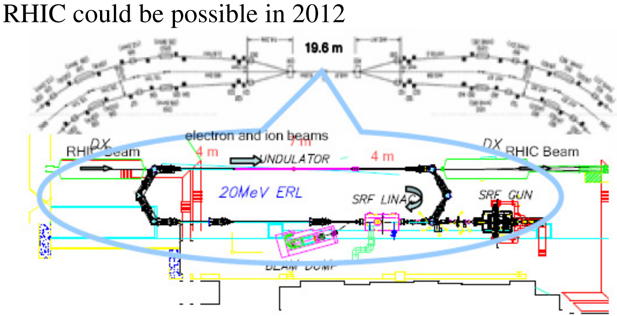

Figure 5: Coherent electron cooling proof-of-principle layout at RHIC IR2.

# ELECTRON LINAC BASED COHERENT RADIATION LIGHT SOURCE PROJECT AT OPU*

S. Okuda#, Y. Sakamoto, R. Taniguchi, T. Kojima, Radiation Research Center, Osaka Prefecture Univ., Sakai, Osaka 599-8570, Japan

*Abstract*

The coherent radiation from an electron bunch of a linear accelerator (linac) has continuous spectrum in a submillimeter to millimeter wavelength range and has an intense pulsed electric field. The purpose of the present work is to establish a new light source of the coherent synchrotron and transition radiation from the electron beams of a 18 MeV S-band linac at Osaka Prefecture University (OPU). The pulse shape of the radiation has been evaluated from the electron bunch shape. The system of the light source has been optimized. The light source will be applied to the excitation of various kinds of matters and to the pump-probe experiments using the electron beam and the coherent radiation.

## INTRODUCTION

The coherent radiation from a short electron bunch of a linac has continuous spectrum in a submillimeter to millimeter wavelength range at a relatively high peak-intensity. After the first observation of the coherence effect in synchrotron radiation the radiation processes have been investigated.

The peak intensity of the coherent radiation is extremely high compared with those of the other light sources. The coherent synchrotron and transition radiation light sources have been applied to absorption spectroscopy for various kinds of matters [1-4], especially for matters with relatively strong light absorbance. Recently, the absorption spectroscopy system using the coherent transition radiation from the electron beams of the L-band electron linac under relatively simple configurations has been established at Kyoto University Research Reactor Institute [5], and has been generally used for experiments.

As well as the applications as probes the high peak intensity and the short pulse shape of the radiation are expected to be used for excitation of matters and time-resolved experiments. Such applications are not performed so far.

The present work has been performed to establish the new coherent radiation light source applied to the excitation of matters and the pump-probe experiments.

## COHERENT RADIATION LIGHT SOURCE

Synchrotron and transition radiation from short electron bunches of a linac becomes coherent and highly intense at wavelengths longer than the bunch length. It has a continuous spectrum in a submillimeter to millimeter wavelength range. The wavelength range of the radiation is determined by the length and the shape of the electron bunch. In general cases the wavelengths correspond to the terahertz and the lower frequencies of light. The peak intensity of the coherent radiation is extremely high compared with those of the other terahertz light sources.

The coherent synchrotron radiation is emitted as a linearly polarized, unipolar and pulsed electric field. The pulse shape of the electric filed is determined by the electron bunch shape. In our previous work investigating the electron bunch form factors from the coherent radiation spectra the bunch shape of an linac beam has been found to be approximated as triangular [6]. The light pulse has a short length corresponding to the bunch length, typically within a few picosecond in the case of the electron bunch of an S-band linac. It might be possible to use the coherent transition radiation for obtaining the similar pulsed light as well as the coherent synchrotron radiation.

The coherent radiation induces intense pulsed electric field in a matter and results in the excitation of it. In the case of the coherent radiation the electric field induced in a matter is expected to be more than 10 MV/cm.

## LIGHT SOURCE SYSTEM

The new light source for the excitation of matters and the pump-probe experiments by using a 18 MeV S-band electron linac at OPU has been investigated.

### *OPU Electron Linac*

The accelerator system of the OPU S-band linac is schematically shown in Fig. 1. Pulsed electron beams are injected from a thermionic triode gun with a cathode-grid assembly. The maximum energy, pulse lengths, the maximum pulse repetition rate of the beam are 18 MeV, 5 ns-5 μs and 500 pulses/s, respectively. The accelerated beam is bent to an underground irradiation room, where the energy spectrum of the beam is measured. In this

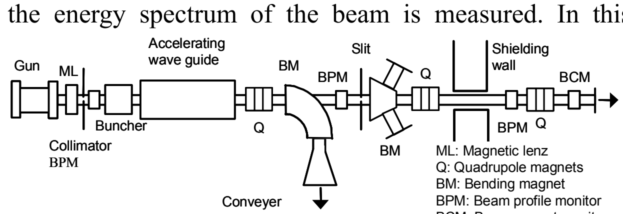

Figure 1: Schematic diagram of the OPU electron linac system.

*Work supported in part by the program of KEK for supporting accelerator research activities in universities, and KAKENHI (20360421).
#okuda@riast.osakafu-u.ac.jp

room a beam scanner for the irradiation over a relatively large area of samples is installed.

The beams transported to the straight direction through a hole in a concrete shielding wall are used in the other irradiation room for various experiments such as irradiation experiments with narrow beams and pulse radiolysis experiments. The present system for the new light source is located in the end of the straight beam line.

The operational conditions of the linac components such as waveguides and the beam steering magnets are optimized to obtain the highest intensity of radiation at the light detector. In this process relatively strong bunch compression in accelerator waveguides results in the increase of the radiation intensity by two or three orders of magnitude. Such conditions have been previously investigated [7]. While the energy spectrum of the electron beam slightly spreads in the operational conditions, this does not affect the straight beam transportation to the light source as shown in Fig. 1.

In order to perform the time-resolved experiments the grid pulser of the electron gun of the linac has been improved for generating short pulse electron beams at a length of 5 ns. It will be improved to be shorter to obtain a single-bunch beam. The trigger system for the pump-probe experiments has already been established for the pulse radiolysis experiments.

### *Evaluation of the Coherent Radiation*

In the usual cases the radiation is suppressed in the relatively long wavelength range because of the limited space of the vacuum chamber made of conductor [8]. The absorption of the light in the path of transportation possibly causes the deformation of the pulse shape. In order to establish a new light source the characteristics of the radiation has been evaluated. The pulse shape of the

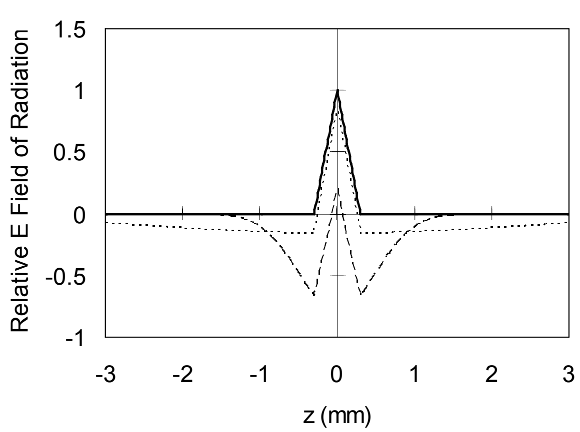

Figure 2: Pulse shape of the electric filed of the coherent synchrotron radiation obtained by calculation for the isosceles triangular electron bunch at a FWHM length of 1 ps. No suppression (solid line) and suppression of radiation at wavelengths longer than a cutoff wavelength of 1 (dashed line) and 5 (dotted line) mm have been assumed.

electric filed of the coherent radiation obtained by calculation for the triangular electron bunch at a FWHM length of 1 ps is shown in Fig. 2. The complete suppression of radiation at wavelengths longer than a cutoff wavelength has been assumed in the calculation. As shown in this figure the peak electric field decreases with the cutoff wavelength. From these results it has been found that the cutoff of radiation at wavelengths shorter than 5 mm should be avoided in order to obtain sufficient peak field intensities of radiation.

The electric field induced in matters by the coherent radiation has been estimated to be higher than 1 MV/cm.

### *Setup for Pump-Probe Experiments*

The important applications of the coherent radiation light source are pump-probe experiments, where matters are excited with the electron beams or the pulsed coherent radiation in a short period which corresponds to the bunch length and is typically within a few picosecond in the case of S-band linac. In the light source project at OPU the system schematically shown in Fig. 3 is established. In this system the coherent synchrotron and transition radiation is used as light sources. The sample is excited by pulsed electrons used for the source of light or by the pulsed radiation. A part of the radiation synchronized with the pumping beam is used as a probe to perform the time-resolved absorption spectroscopy after the excitation. On the path of light a delay line is installed.

The grid pulser of the electron gun of the linac will be improved for generating single-bunch electron beams in the near future.

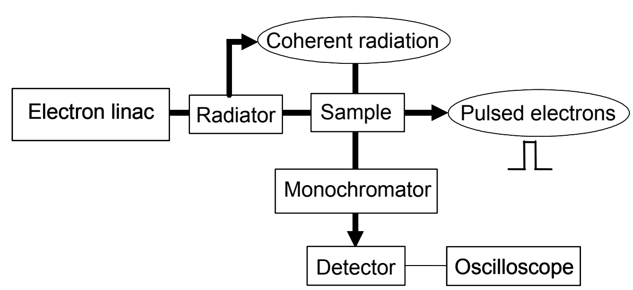

Figure 3: Schematic diagram of the pump-probe experimental setup.

## CONCLUSIONS

Study has been made to establish a new light source of the coherent synchrotron and transition radiation from the electron beams of a 18 MeV S-band linac at OPU. The pulse shape of the radiation has been evaluated from the electron bunch shape. The system of the light source has been optimized. The light source will be applied to the excitation of various kinds of matters and to the pump-probe experiments using the electron beam and the pulsed coherent radiation.

# ENHANCEMENTS TO THE DIAMOND LIGHT SOURCE PRE-INJECTOR LINAC

C. Christou, S. J. Singleton and V. C. Kempson, Diamond Light Source, Oxfordshire, UK

*Abstract*

Modifications have been made to the Diamond pre-injector linac to improve beam stability and to increase the scope of operation of the system. New modes of operation are described and RF stability studies are presented. Operational experience is summarised, and options for future development are considered.

## MODES OF OPERATION

The DLS pre-injector is a 3 GHz, 100 MeV linac delivering up to 3 nC in a bunch train of up to 1000 ns, or a single bunch of up to 1 nC. It has a bunching section and two identical accelerating structures driven by two Thales TH2100 klystrons, and a thermionic DC gun [1].

Beam from the linac is delivered through a full-energy booster to the 3 GeV storage ring. For user operation, beam is injected as required, usually topping up twice a day to the present operating level of 225 mA. During fills the linac and booster are cycled together at 5 Hz

Linac single-bunch operation has recently been incorporated into the Diamond top-up application [2] and into an automated single bunch filling routine for the storage ring, both implemented in Python. For both applications, the linac gun and booster extraction timing is set each shot so that the bunch is injected into the bucket with lowest charge relative to a programmed fill pattern. Linac bunch charge is kept constant for top-up, but is programmed during the single bunch fill to generate a smooth fill in the minimum time: high-charge bunches are first injected into empty buckets, and charge is reduced as the bucket approaches its target. Bunch charge is controlled by setting the bias on the triode gun, as illustrated in Figure 1. Top-up uses low bunch charge, whereas single bunch fill covers the entire range. Single bunch injection efficiency into the booster is 80% at low bunch charge falling to below 50% at high bunch charge. Injection efficiency studies are continuing, with attention being paid to booster chromaticity on injection [3].

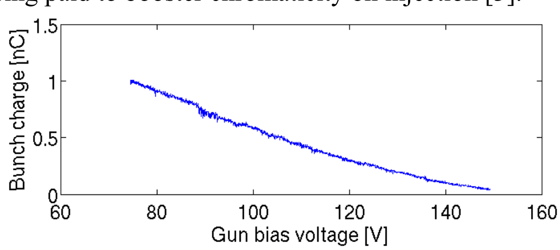

Figure 1: Single bunch charge as a function of gun bias.

Since the beginning of user operations in January 2007 most storage ring fills for user operation have used the multibunch mode of the linac, with trains of 144 buckets injected every 120 buckets over two-thirds of the ring. The 24 bucket overlap overcompensates for the 30 ns rise-time of the linac long-pulse envelope, and generates small peaks in the storage ring fill pattern [4]. The single bunch fill generates a very smooth fill, as shown in Figure 2. The smooth fill from buckets 100 to 600 is much better than that could be achieved by multibunch injection. This figure also illustrates the hybrid fill, which can be routinely generated for users on request. Hybrid fill may be generated by a multibunch two-thirds fill followed by single bunch injection, or by using the single bunch fill for the entire fill. Switching fill modes is quicker, because of the higher charge available in multibunch mode, but the automatic single bunch fill is simpler to carry out.

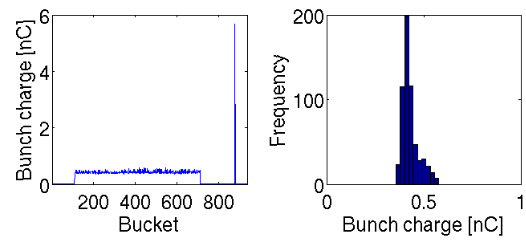

Figure 2: Hybrid fill generated using single bunch fill and histogram of bunch charge over two-thirds fill.

Long-duration tests of linac and booster reliability have been carried out in preparation for routinely offering top-up to users. Figure 3 summarises a continuous linac and booster run (with three short breaks for storage ring fills), showing a very reliable bunch charge delivered to the booster with a mean and standard deviation of 0.125 nC and 0.014 nC respectively over 24 hours.

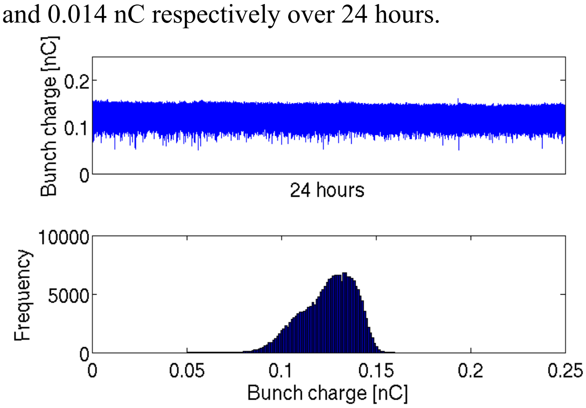

Figure 3: 24 hour run of linac and booster showing the beam delivered to the booster (top) and histogram of bunch charge (bottom).

A recent test of the complete top-up application is summarised in Table 1. At the start of top-up the gun bias was set so that the number of shots per top-up cycle was around 10 to reduce the variation in charge along the bunch train to 10% or less while minimising the disturbance of the stored beam. The number of shots to be fired in each cycle is calculated by the top-up software from the loss of current during the previous cycle, using the average charge injected per shot over the last 10 cycles. Linac bunch charge was consistent over the test, and resulted in a stable, reproducible top-up cycle.

Table 1: Summary of Top-Up Operation Test

| | |
|---|---|
| Duration of test | 7 hours |
| Fill pattern | Two-thirds fill |
| Mean storage ring current | 199.875 mA |
| Storage ring current range | 199.652 mA - 199.875 mA |
| Period between top-ups | 2 minutes |
| Average shots per top-up | 9.22 |
| Current stability | 0.043% |
| Mean charge in BTS | 0.068 nC |
| Mean BTS to SR efficiency | 73.05% |

## STABILITY AND RELIABILITY

A stable linac beam is essential for reliable operation of Diamond with minimum beam losses at booster injection. Continuous application of a constant phase, constant power RF signal to the prebuncher cavity has cured multipacting there, and locking the gun heater power supply and booster dipole to a common 50 Hz oscillator derived from the timing system rather than the mains supply removed the largest variation in booster injection efficiency[4]. A slow variation of booster current still remained after these improvements, with the standard deviation of a moving sample of booster current increasing when the mains frequency drifted from 50 Hz. This was a linac energy effect and is shown in Figure 4.

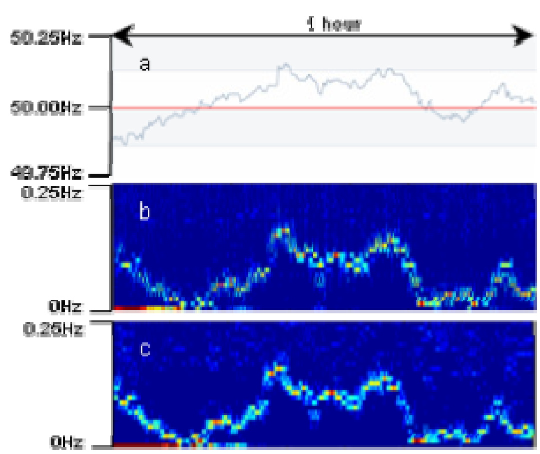

Figure 4: (a) Mains frequency, (b) frequency spectrum of booster current and (c) frequency spectrum of linac beam energy recorded over one hour.

The frequency spectrum of the booster current and the linac energy measured at a BPM in a dispersive part of the LTB correlate strongly with the deviation of the mains frequency from 50 Hz. No such oscillations were seen in the klystron preamplifier, and so it was clear that the oscillation was generated in the klystrons.

Locking the mains-driven klystron filament heaters to the same 50 Hz signal as the gun and the booster dipole removed this effect, as can be seen from Figure 5 in which one klystron filament heater is driven from the mains, and one is driven from the 50 Hz oscillator; the spectral content of the klystron locked to the 50 Hz signal has been removed.

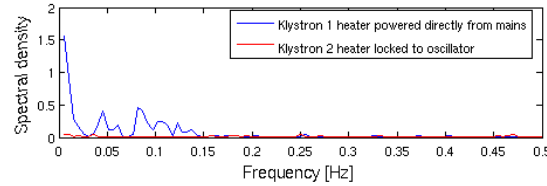

Figure 5: Comparison of klystrons with heater powered by mains (blue) and locked to the timing oscillator (red).

Sensitivity of the linac LLRF to the operating temperature in the controls rack has been noted and is controlled by enhanced cooling of this rack [4]. Further analysis of klystron operation in Figure 6 shows that klystron amplification is roughly linear over the range used in normal operation, usually > 30 W. If the preamplifier output is increased then the klystrons can be moved towards saturation and so the effect of the preamplifier thermal droop will be reduced. Preamplifer output is currently limited by cable losses at 3 GHz. Reconfiguration of the LLRF to reduce losses will also have the benefit of reducing the operating voltage of the klystrons and therefore reduce klystron arcing further.

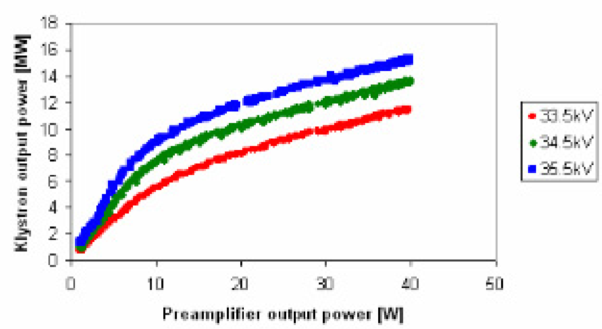

Figure 6: Klystron operation at different values of modulator PFN charging voltage.

Minimisation of klystron arcing is essential for reliable operation of top-up. At the moment klystron arcing is only a problem during klystron start-up following a machine shut-down, when the voltage must be brought up in a slow controlled manner to recondition the gun. A Matlab script has been developed for this. Klystron reconditioning takes roughly ten minutes, after which the arc rate is low, for example there were no arcs in either klystron in either the 24 hour injector test or seven hour top-up tests above. The operating point of the klystron filament is also reviewed annually to minimise arcing, and the filament voltage has been dropped twice in 2 V increments since initial commissioning of the klystrons.

Lifetime is monitored by calculation of klystron perveance during operation. The perveance record of one of the two klystrons since beginning of user operations is shown in Figure 7, showing no significant drop in perveance over this period. The spikes on the plot are artefacts recorded during klystron turn-on and turn-off. The performance of the second klystron is similar.

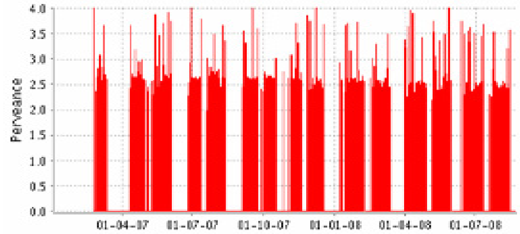

Figure 7: Klystron perveance record.

## SINGLE KLYSTRON OPERATION

Perveance monitoring can be used to give early warning of klystron cathode failure, allowing replacement in a shutdown as far as possible, but unexpected klystron failure may still occur during user operation. One spare klystron is held on site, but standard operation is impossible for the duration of the klystron change and recommissioning. Operation of the injection system with one klystron has therefore been investigated, and injection of beam into the storage ring has been achieved with low-energy single klystron linac operation. Table 2 is a comparison of linac beams generated by one and two klystrons. Some increase of beam energy is possible by running the single klystron at a higher power.

Table 2: Single and Double Klystron Operation

| | One klystron | | Two klystrons | |
|---|---|---|---|---|
| Energy | 44.9 MeV | | 99.9 MeV | |
| Energy spread | 0.3 % | | 0.3 % | |
| | x | y | x | y |
| $\varepsilon_N$ [mm.mrad] | 32.7 | 42.6 | 39.6 | 39.2 |

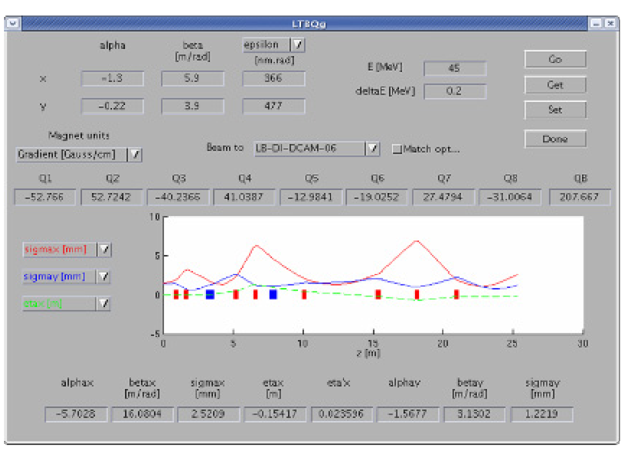

Figure 8: LTB quadrupole current tool.

Operation of the linac with one klystron requires changes to LTB and booster. Quadrupole settings for the LTB at reduced energy were calculated with the LTBQg tool, which performs a least-squares minimisation of the beam size along the transfer line whilst constraining the Twiss parameters at the LTB entrance and exit [5]. Figure 8 shows LTB parameters calculated using this tool.

Injection into the booster was achieved by scaling all magnets at injection according to the reduced beam energy and then empirically optimising the values, this involved modifying the quadrupole power supplies to operate at a lower start value for the ramp. Injection efficiency into booster and storage ring is currently much lower for single klystron operation, but it is expected that this can be improved by further optimisation of operating parameters. Again, booster chromaticity on injection is being studied.

Single klystron operation is only possible by powering the first accelerating structure and drifting through the second structure, and so studies are underway to introduce a switching mechanism in the WR284 waveguide network at the output of the klystrons as shown in Figure 9. This would allow accelerating structure 1 to be powered from klystron 2. Such a switching network is installed in other pre-injector linacs [6, 7].

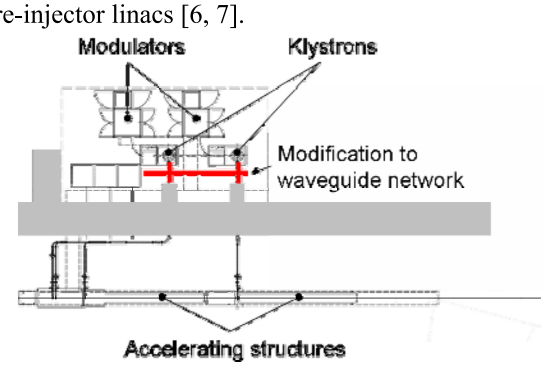

Figure 9: Waveguide modification for klystron switching.

## SUMMARY

Two new modes of operation have been developed in the second year of operation of Diamond: firstly, the Diamond pre-injector linac has been fully incorporated into top-up operation, and secondly high-uniformity storage ring fill has been delivered to users by operating the linac in a programmed single bunch mode. A new fault-mode of operation using one of the two linac klystrons is also under development. Linac stability has been improved by modification of the klystron filament power circuit, and options for further stability and reliability enhancements have been identified in both low-level RF and high-power RF distribution.

# NORMAL CONDUCTING OPTIONS FOR THE UK'S NEW LIGHT SOURCE PROJECT

C. Christou, R. Bartolini, J.-H. Han, H. Huang and J. Kay
Diamond Light Source, Oxfordshire, UK

*Abstract*

This paper considers the design of a normal-conducting linac FEL in the context of the UK's New Light Source project. Capabilities and limitations of this approach are illustrated by reference to a 3 GeV S-band linac design. The effects of high repetition rate operation and RF jitter are considered.

## THE NEW LIGHT SOURCE PROJECT

The UK's New Light Source (NLS) project [1] was launched in April 2008 to consider the scientific case and develop a conceptual design for a possible next generation light source. The outline facility design will be agreed by January 2009 following consultation with the user community throughout 2008 after which a design report and proposal for funding will be prepared for submission in October 2009.

A high (> 400 Hz) repetition rate of single pulses demands superconducting linac technology operating in continuous-wave. Normal conducting linac technology is however significantly cheaper, allowing a higher energy to be reached for a given cost. Design studies are ongoing for both normal conducting and superconducting linacs. This paper reviews the options for a normal conducting NLS design; a companion paper reviews the superconducting approach [2].

## LINAC LIGHT SOURCE PROJECTS

There has been much recent interest in the use of normal conducting technology for linac FELs. Most projects in construction or development use the well-proven S-band technology used at SLAC for several decades whereas SCSS exploits C-band technology developed in the JLC(C) programme. LCLS and SCSS are scheduled for completion in 2009 [3] and 2011 [4] respectively. The study presented here considers an S-band linac for NLS, although X-band technology has not been ruled out, particularly considering possible technology developments following the decision to change the CLIC design frequency to 12 GHz [5].

## NORMAL CONDUCTING TECHNOLOGY

Virtually all high-power klystrons operating today are driven by line-type modulators using a reactive pulse forming network (PFN) and a thyratron switch. The line-type modulator can be the dominant cost driver in a linac [6]. The self-terminating nature of the line-type discharge limits the modulator operation: the pulse length can only be changed by switching the connections to multiple PFNs, and the trailing edge of the pulse is usually not sharp since it depends on the discharge of multiple reactive elements. The modulator cannot drive loads of different impedances, and the thyratron has a limited operational lifetime. The overall efficiency of a line-type modulator is as low as 50% to 60% and the thyratron is a single-point of failure of the modulator.

An approach that would mitigate many of these problems in NLS is the use of an Insulated Gate Bipolar Transistor (IGBT) switch together with a solid state induction modulator: this is a stack of small pulse transformers in which the primaries of the cores are driven in parallel by separate sets of IGBT switches and capacitors operated at relatively low voltage (2-4kV). The high voltage is developed at the secondary in series [7].

Repetition rate of a line type modulator and klystron is limited by modulator charging rate or thyratron recovery time. Incorporation of an IGBT switch increases the available repetition rate from the modulator and power dissipation in the klystron is then the limiting factor.

Table 1: High Power Klystrons of Interest to NLS

| Manufacturer | Thales | Toshiba | SLAC |
|---|---|---|---|
| Model | TH2155 | E3730A | XL4 |
| Waveband | S-band | S-band | X-band |
| Frequency | 2998 MHz | 2856 MHz | 11.42 GHz |
| Peak power | 45 MW | 50 MW | 50 MW |
| Efficiency | 44% | 45% | 40% |
| Gain | 54 dB | 51 dB | 50 dB |
| Pulse length | 3.5 μs | 4 μs | 1.5 μs |

Table 1 shows high power klystrons available in S-band and X-band. S-band klystrons already exist that separately satisfy high average and high peak power demands. The enhanced collector cooling that is provided in the former needs to be combined with a high peak power klystron, and manufacturers have indicated their readiness to supply this; repetition rates of up to 400 Hz are envisaged. A redesign of the klystron gun to reduce the arcing rate is also being discussed.

Table 2: Comparison of the DESY Type II Linac and SLAC 3 m Accelerating Structures available at 2998 MHz

| Property | DESY structure | SLAC structure |
|---|---|---|
| Length | 5.2 m | 3.0 m |
| Shunt impedance | 51.5 MΩ/m | 52 MΩ/m |
| Attenuation | 0.5 Neper | 0.49 Neper |
| Mode | 2π/3 | 2π/3 |
| Q | 14000 | 12500 |
| Filling time | 740 ns | 690 ns |
| Number of cells | 156 | 89 |

The two main types of S-band accelerating structure that are readily available are the DESY type II and SLAC 3 m ones; these structures are compared in Table 2.

Performance of the structures is similar, and the 3 GeV NLS requirements can be met by either design with an accelerating gradient of around 20 MV/m.

The power delivered by the klystron can be compressed with a SLED cavity. Figure 1 shows the increase in acceleration through a DESY structure achievable with a SLED cavity with $Q_0=10^5$ and β=6.7, together with power dissipation in a single pulse.

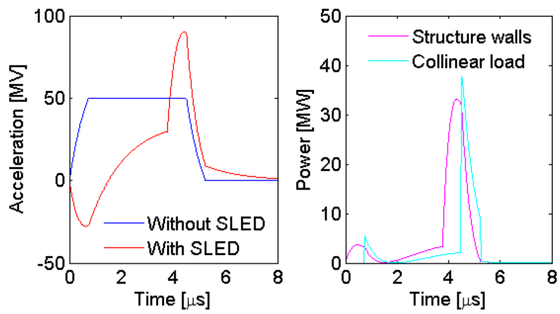

Figure 1: Acceleration through a DESY structure with and without SLED (left) and powers dissipated in structure and collinear load in a single pulse with SLED (right).

400 Hz repetition rate at 20 MV/m is much higher than operating rates of 120 Hz at SLAC and 50 Hz at DESY for similar gradients. At this rate, average klystron power is 70 kW. Average power dissipation limits have not been explored for either structure or for SLED cavities, and further work is required to determine what repetition rate is achievable. As a first estimate of the capability of an S-band structure to withstand such power levels, a thermal model has been developed. SUPERFISH was used to solve for the two accelerating modes in a 3 GHz structure, based on an adaptation of the SLAC 2856 MHz design, and shown in Figure 2 (dimensions in inches). Power transfer at the walls for these two modes was then taken as an input for a thermal model shown in Figure 3, demonstrating that with suitable water cooling on the outer surface of the structure, the temperature of a normal cell can be kept at an average of 30°C to 35°C.

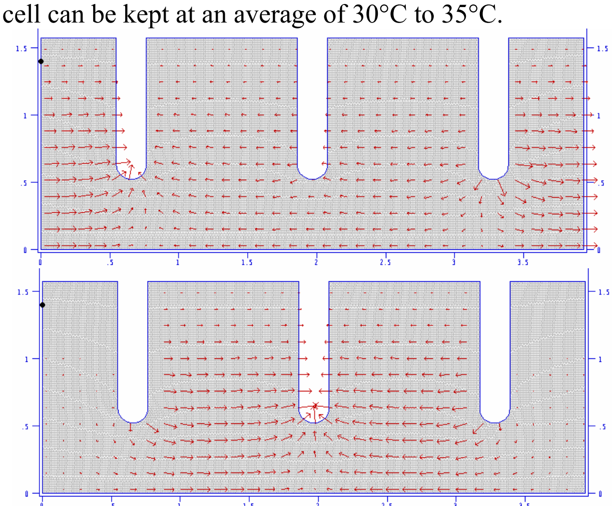

Figure 2: Accelerating modes in an S-band structure.

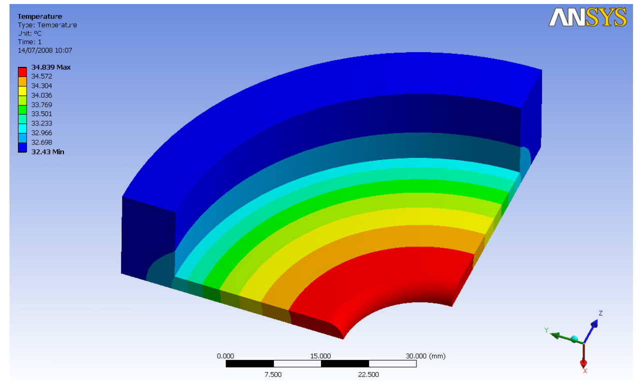

Figure 3: Equilibrium temperatures in an S-band structure operating at 400 Hz: blue is 32.4°C, red is 34.8°C.

The main design difference between the DESY and SLAC structures is the use of a collinear load in the DESY structure and an external load in the SLAC structures. While the DESY approach preserves the symmetry of the structure, it may prove to be more difficult to adapt the cooling to cope with the high power dissipated in the collinear load, as 38% of the total power must be dissipated in the final 8 cells of the structure. A full thermal model of the whole structure is needed before the impact of the intense heating can be fully assessed, but problems may arise in the matching of the load to the main part of the structure because of the existence of a longitudinal temperature gradient. Rapid thermal cycling of the load cells may also be problematic, as the SLED cavity delivers a very high power pulse to the load, as shown in Figure 1 and the cyclic stress may lead to metal fatigue. For fully annealed OFE copper the temperature rise required to initiate fatigue stress has been measured to be between 40 K [8] and 110 K [9]. Heat dissipation in the resistive coating in the load cells is a particular point of concern. We have therefore provisionally selected the SLAC structure for beam dynamics simulations and layout considerations.

## LINAC BEAM DYNAMICS

A suitable NLS 3 GeV design consists of 12 RF stations operating at 2998 MHz, each driving up to 4 SLAC structures, plus one X-band linearising structure, two bunch compressors (at 460 MeV and 1.2 GeV) and one dog-leg immediately before the undulator section The beam dynamics in the linac have been calculated with ELEGANT, taking CSR and wakefields into account [10]. Input is from an ASTRA model of a new S-band gun [11]. Initial simulations have been carried out with a charge of 0.2 nC, showing that the linac can deliver a 3 GeV beam with of peak current 7 kA, 0.7 mm mrad normalised emittance and 0.2% energy spread [12].

The sensitivity of the linac to jitter in RF phase and accelerating gradient of the structures has been studied in order to generate a baseline specification for modulator stability and low-level RF. This first stage analysis considers beam at the exit of the linac.

Figure 4 shows the change of peak linac current for a one percent change in gradient at all RF stations along the linac including the X-band structure. The first S-band plant is considered part of the injector and so is not studied here. Sensitivity is highest for RF stations S2 and S3 before BC1, smaller for S4 to S6 between the bunch compressors and smaller again after BC2.

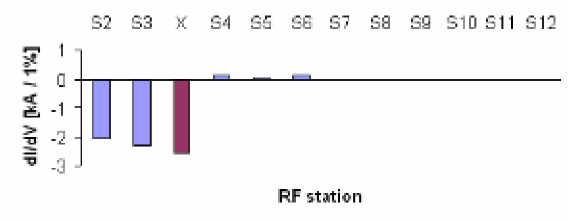

Figure 4: Sensitivity of peak beam current to accelerating gradient for all RF stations.

More detailed study of station S2 shown in Figure 5 shows the effect of changes in gradient, or accelerating voltage, on emittance. Large phase changes affect the bunch compression such that the peak beam current increases rapidly to tens of kA and horizontal emittance blows up through CSR effects. The figure shows perturbation of ±5% and ±5° about the working point.

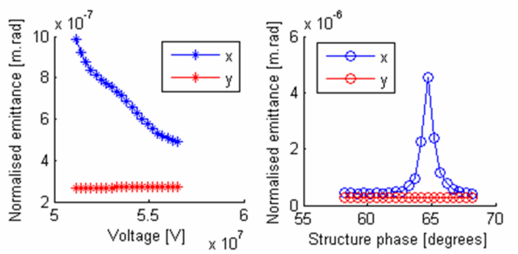

Figure 5: Output pulse emittance as a function of voltage and phase in the first accelerating structure.

The sensitivity of the different RF stations to small changes in RF voltage and phase are summarised in Table 3. In general, effects are greatest on the X-band structure and before the first bunch compressor.

Table 3: Sensitivity of Individual RF Stations to RF Errors

| | Before BC1 | BC1-BC2 | After BC2 | X-band | Units |
|---|---|---|---|---|---|
| dE/dV | 1.64 | 2.44 | 3.03 | -0.30 | MeV/1% |
| dE/dφ | -0.43 | 1.81 | 0.038 | 1.245 | MeV/1° |
| $d\varepsilon_{nx}/dV$ | -0.076 | 0.01 | 4e-4 | -0.04 | mm.mrad/1% |
| $d\varepsilon_{nx}/d\varphi$ | 0.87 | 0.08 | 2e-4 | -0.61 | mm.mrad/1° |
| dI/dV | -2.18 | 0.11 | -7e-3 | -2.56 | kA/1% |
| dI/dφ | 19.7 | 1.77 | 0.055 | -12.3 | kA/1° |

Summaries of the distributions of 10000-particle runs through the ELEGANT model with up to 500 runs at each point are shown in Figure 6. This demonstrates how the beam jitter grows with RF jitter. For comparison, the rms energy of a single 100000 particle distribution with no jitter is 7.0 MeV and the rms in arrival time is 28 fs. Jitter of 0.5° in S-band phase and 0.4% in accelerating structure gradient leads to a 0.1% jitter in beam energy.

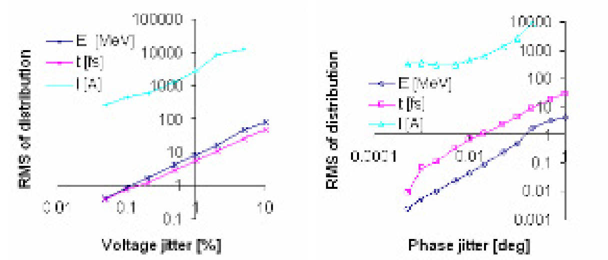

Figure 6: RMS values of mean energy, arrival time and peak current with voltage and phase jitter as displayed.

Similarly, the effect of small physical displacements on the RF structures can be calculated by inserting a lateral displacement or by introducing a kick into the lattice in ELEGANT. Results are summarised in Table 4.

Table 4: Sensitivity of RF Structures to Positioning Errors

| | Before BC1 | BC1-BC2 | After BC2 | X-band | Units |
|---|---|---|---|---|---|
| dE/dx | 9e-3 | -0.01 | 4e-4 | 0.29 | MeV/mm |
| $d\varepsilon_{nx}/dx$ | -8e-3 | 7e-3 | 2e-3 | -.13 | mm.mrad/mm |
| dI/dx | 0.46 | 1.36 | 1.76 | -1.5 | kA/mm |
| $dE/d\alpha_x$ | -2.39 | 0.47 | 2e-3 | 0.48 | MeV/mrad |
| $d\varepsilon_{nx}/d\alpha_x$ | 1.63 | -0.64 | 0.44 | 0.27 | mm.mrad/mrad |
| $dI/d\alpha_x$ | 6.53 | -8.66 | 1.10 | 3.42 | kA/mrad |

Positioning errors of the X-band structure have a large effect on the beam. For this reason, the X-band structures in the NLC design were designed to be mounted on moveable supports to align with the beam; this approach is recommended for the NLS.

## SUMMARY

Recent advances in solid state modulators, together with the adoption of well proven S-band linac technology offer the prospect of a reliable, cost effective normal conducting linac FEL for the UK New Light Source project operating at repetition rates previously impossible for such an approach. A 3 GeV linac design has been developed and the issues of power dissipation and RF stability have been considered.

# SIMULATIONS ON IMPACT OF THE 3.9 GHZ RF SECTION ON THE MULTI BUNCH EMITTANCE AT FLASH

Y. Kot, DESY, Hamburg, Germany.

*Abstract*

In order to compensate nonlinear distortions of the longitudinal phase space a RF section operated at three times the 1.3 GHz frequency of the existing TTF cavities is foreseen in the next phase of FLASH. Four modules of a nine cell 3.9 GHz cavities will be installed right after the first accelerating module ACC1. These cavities could cause additional long-range wake fields which would affect the multi bunch (MB) beam dynamics leading to increase of the MB emittance. The MB emittance at the end of the linac is determined by the strength of the transverse wake fields in the RF system. These so called higher order modes appear after any off-axis moving bunch, which could happen either due to the cavities misalignment, or by transverse position fluctuations of the injected bunches. It is intended to damp them by means of the HOM couplers, which can reduce the damping time by factor of $10^5$. The misalignment of the cavities offsets is expected to be limited by 0.5 mm rms. The paper describes the results of the simulations on the dependence of the MB emittance on cavities misalignment offsets and damping strength of the HOM couplers in the planned 3.9 GHz RF section.

## INTRODUCTION

In the next phase of FLASH it is planned to install four modules of a nine cell 3,9GHz cavities right after the ACC1 at 14-19meter. These cavities would cause additional long-range wake fields which could affect the multi bunch beam dynamics leading to the increase of the multi bunch emittance.

It is transverse long-range wake fields which determine the multi bunch emittance at the end of the LINAC. They appear after any off-axis moving bunch which could happen either due to the cavities offset misalignment, or by transverse position fluctuations of the injected bunches. According to the design of the cavities setup the precision of 0.5mm rms could be achieved, whereas the fluctuations of the transverse positions of the injected bunches could be kept well below this value.

In order to damp the wake fields HOM couplers will be installed which will reduce the damping time by the factor of $10^{-5}$. The MB emittance blow up is also mitigated due to the RF focussing since each cavity acts as a focussing quadrupole in both vertical and horizontal planes simultaneously. This effect could play an important role if the change of the energy per cavity is not negligible compared to the bunch energy.
